Neonatal porcine hearts were obtained from one day old piglets from a local farm. Each ventricle was visually inspected to avoid any anomalies prior to dissection and decellularization. The neonatal heart ventricles were dissected as longitudinally-oriented strips and marked by placing a suture on the upper left corner (Fig. 1A). Four groups were compared: left anterior ventricle (LAV), left posterior ventricle (LPV), right anterior ventricle (RAV), and right posterior ventricle (RPV). After dissection samples were placed in a 50 ml tube filled with 1% SDS solution. The tubes were placed in a rotational shaker continuously until the heart tissue appeared completely white color (Fig. 1B). Acellular ventricle scaffold samples were then subjected to uniaxial mechanical testing (TestResources universal machine). Tensile test and stress relaxation were performed. Histology was assessed with H&E staining and imaged with a bright field microscope (Nikon EC600).

RESULTS

Thorough decellularization was achieved and confirmed by histology (Fig. 1C, D). Preliminary testing results showed that (i) the acellular LAV was stiffer than the acellular RAV; (ii) the failure stress and strain of the acellular LAV were significantly higher than the acellular RAV (Fig. 1E). Both acellular LAV and RAV were much stiffer and the stress-strain showed a linear trend when compared with the native neonatal porcine ventricle, which showed a typical nonlinear behavior2. This difference was likely due to the removal of cardiomyocytes, and the left acellular scaffolds consisted of collagen fibers that experienced cardiomyocyte lacunae collapse. We also noticed that stress relaxation in the acellular LAV took place faster with a greater amount when compared with the acellular RAV (Fig. 1F).

DISCUSSION

A series of mechanical tests have been performed to characterize the biomechanical behavior of acellular neonatal porcine ventricles. The obtained knowledge will help better understanding cardiac biomechanics and multiscale tissue behavior of the newborn hearts.

INTRODUCTION

Loss of limb is accompanied by loss of independence, financial burden, and other traumatic effects [1]. The most common form of treatment is a prosthetic device. However, prosthetic limbs are not able to restore the entire function to the individual. Additionally, use of a prosthetic may provide residual problems such as long adjustment periods and increased skin irritation on the contact surface [2].

Up to 56% of individuals with upper limb loss use some sort of prosthetic [3]. Many upper extremity prosthetics, especially distal to the elbow, are passive prosthetics- they are aesthetically similar to the hand, but provide little hand function, other than stabilizing abilities [4]. Prosthetics that do focus on function are typically able to provide only part of the lost function.

In nerve driven prosthetics, neurons' action potentials are responsible for controlling the assigned movement in the prosthetic. This can lead to complications such as the misreading or crossing of neurological signals into the prosthetic. This is because a movement is usually thought of as a process of the brain sending signals to the body- but there is a need for prosthetics to be more intuitive. There is one animal that is able to act before it thinks- the octopus.

The octopus is a boneless, muscular hydrostat which allows for infinite degrees of freedom of the arms. The octopus is also equipped with an axial nerve in each of the arms that allows each arm to act without the brain's input. Studying this 'disconnect' between the limbs and brain could be crucial to the development of new, smarter robotics.

Therefore, the goals of this work were twofold 1) to determine the operational finger space for specific every-day tasks and 2) to initiate a study of octopus reach and grasp movements. Together, these unique studies have the potential to aid in the design of future smart prosthetics that parallel some natural components found in the octopus.

METHODS

Human: Five male participants (average age 20.2 years standard deviation 1.3 years) were tested using a motion capture system. Participants wore reflective markers (two individual markers and 16 pods) to track the movements of their dominant hand (Figure 1). Participants completed four experiments related to daily living: *typing, mousing, swiping on a phone, and moving a game controller*.

Motion data were analyzed and plotted on planes to accent differences in motion for both the task and specific finger. Ranges of motion were mapped for the thumb and the index finger.

Octopus: Preliminary work occurred with the octopus; species *Octopus bimaculoides.* The first step of this research was to evaluate the feasibility of obtaining movement of an octopus leg using a motion capture system (i.e. marker size, marker placement, adherence of markers, capturing movement type and speed of movements). Four marker pods and one singular marker were glued, using a human skin glue, along the length of the arm. Stereotypical arm movements were simulated out of water. Position profiles and curvature patterns were obtained.

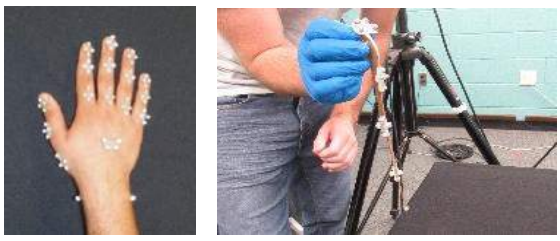

Figure 1: Hand marker setup for tasks of daily living experiment (left). Octopus marker setup (right)

RESULTS

Human Data: Figure 2 provides the visual results from the index finger space and the thumb space for the four tasks.

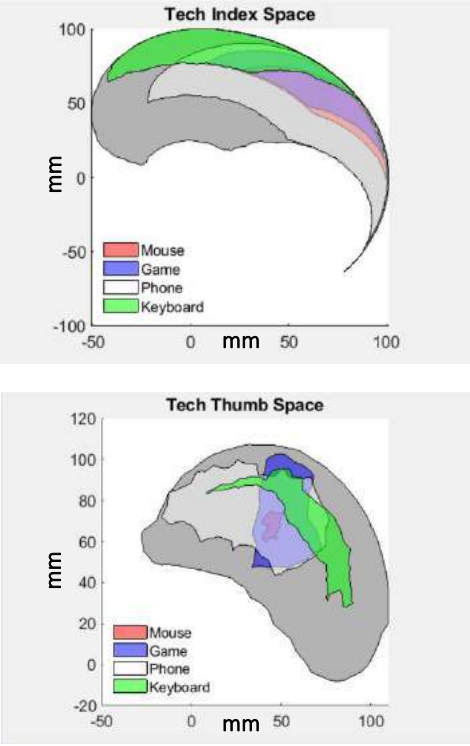

Figure 2: Range of motion for tasks of daily living involved in grasping for the index finger (top) and the thumb (bottom). Mousing can be seen in red, gaming in blue, phone swiping in white, and typing in green. The dark gray area describes the maximum range of motion of the index finger.

The index finger motion largely focused on the combined flexion of the interphalangeal joints whereas the thumb range of motion is reflected on the plane perpendicular to the proximal part of the hand.

The second piece of this experiment revolves around the position data associated with the octopus leg. Figure 3 (left) shows the unstretched length of the octopus' leg. The leg was whipped, being held at the most proximal part of the leg (peach-colored markers, top right) and a wave was produced, similar to that of a real octopus reaching motion in dry conditions.

DISCUSSION

In this experiment, human grasping tasks along with approaches to gathering data from an octopus leg were investigated. The end goal of this work is to link the two to the development of new, smart prosthetics.

For index finger data, the phone task used the greatest percentage of the maximum range of motion area, whereas the mousing task used the least. During both mousing and gaming, simple flexion actions dominated the movement strategies. The keyboard task involved greater extension of the fingers, especially to move to the letters higher on the keyboard (when the wrist is in a fixed location).

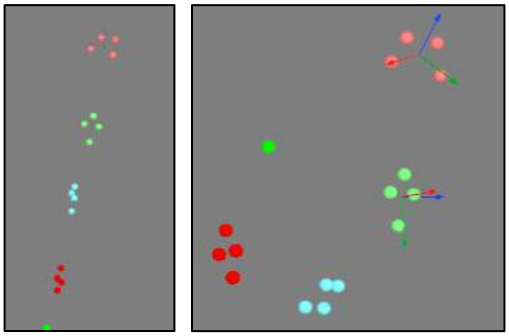

Figure 3: Motion capture visualization for a fully extended octopus' arm (left) and an octopus arm during the whip-like motion (right). Four marker pods and one single marker (at the tip) were glued onto the octopus' arm. Together, the 17 markers on the arm produced numerical data which define velocity profiles, curvature, and torsion.

The thumb data demonstrated a different story. Although one would think that the thumb always operated in the center of maximum boundaries, our data indicated that the tasks utilize different spaces. This may be because the thumb is in charge of stability and the space in which the thumb operates must accommodate both the movement and maintain stability.

The differences in the thumb and finger ranges of motion provide insight on how grasping and actions around activities occur. Clearly, based on the different movement spaces, different activities vary the postures of the index and thumb. Understanding these working spaces and the relative movements between the index finger and thumb are crucial to functional prosthetic hand designs.

The pilot octopus data also showed success with the initial steps. We were able to successfully adhere marker sets to an octopus' arms and gather movement data of a simulated motion. The whip-like motion of the octopus' arm successfully replicated a wave that moved distally along the arm. There is one parameter that was not included during this above water testing which is the torsional ability of the octopus' arm. Other than this, it is expected that similar data will be collected underwater, first with a detached leg, and then on a leg of a live octopus. We expect that further octopus reach and grasp data paired with the human hand data will indicate ways that the octopus' arm can be a better model for a prosthetic.

INTRODUCTION

Neuronal cells interacts with extracellular matrix (ECM) to detect the microenvironment to influence the cell functions such as differentiation, migration, and proliferation [1]. The two important transmembrane proteins that transmit signals between ECM and cell are integrin and neural cellular adhesion molecules (NCAM). They play an important role in sensing the ECM properties [2]. Neuronal cell differentiation is sensitive to the properties of natural or synthetic ECMs, which include biochemical composition, biomechanical properties, and structural/ topographical features [3]. *In vitro* study of neuronal cell differentiation uses mostly synthetic ECM; since it can be tuned for the desired mechanical properties such as stiffness and topography [4]. Biocompatible synthetic materials such as polyelectrolyte multilayers (PEMs), polyacrylamide hydrogels, Matrigel®, and peptoids are utilized to achieve the desired ECM stiffness and topography. Peptoids have gained importance due to its self-assembling structure as microsphere [5] and nanosheets [6]. Peptoids are biopolymers that have a backbone similar to that of peptides with the side chains attached to the amide group rather than the α-carbons [7]. The number of monomers addition to peptoid by solid-phase synthesis enables to control the chain length and the desired size of secondary structure [8]. Peptoids have the ability to form a microsphere when it is exposed to organic solvents [5]. The number of monomer addition to peptoid by solid-phase synthesis enables to control the chain length and the desired size of secondary structure [5]. Peptoids exhibit self-assembling and increased cellular permeability as compared to the corresponding peptide, thus enhancing the potential as an ECM [5]. Besides, peptoids have better biocompatibility compared to other synthetic ECM material while retaining the ability to interact with neuronal cell receptors [9]. Together, these characteristics render peptoids an attractive, novel ECM material for *in vitro* neuronal cell differentiation. Peptoids as an ECM ligands form a bond with the receptors; this physical linkage transfers the forces from receptors to the cell nucleus. Several experiments have proved the number of receptors binding with ligands and their strength determines the fate of cell growth [10]. However, in literature, there is a lack of understanding about the interaction mechanisms between the peptoids and neuronal cell receptors such as integrin and NCAM [5]. In this study, we specifically examine the peptoids 3 chemical structure extracted from the Bakovic et al., 2019 [11]. Since they have observed that peptoids 3 has the ability to form a uniform microsphere in solvent (water) concentration by varying the number of monomers (chain length). Hence, we plan to perform molecular dynamics study to investigate the peptoid as an ECM, and their interaction with neuronal cell receptors (integrin and NCAM). In addition, we plan to study the peptoid sphere size and number of monomer influence on the interaction energy between self-assembling peptoids and neuronal cell receptors.

METHODS

Peptoid 3 chemical structure extracted from the Bakovic et al., 2019 [5] is composed of nonstandard amino acid sequence $(NSPE_4 - NLYS_1 – NSPE_1)_n$, where n is the number of monomers in the chain. Modeling this non-standard amino acid is a challenging task. However, a recent study using density functional theory have proved that substituting the equivalent standard amino acid parameters (PHE and LYS) have yielded comparable results with the experiments[12].

The diameters of the peptoids sphere is chosen based on the normal distribution of microsphere observed in experimental results [11]. Due to the challenge in modeling microns range in MD, we model the peptoids sphere at the nanometers scale. Also, our focus in this study is to understand the number of monomers and sphere size influence on the interaction energy between peptoids and receptors. We build the peptoids sphere using a packmol open-source software [13] with n equal to 12 and 24 (refer Figure 1), and with different sphere diameter ≈ 25Å and 35Å respectively (refer Figure 2). These peptoid spheres will be equilibrated with integrin α1β1 and NCAM, to study the interaction energy between the peptoids sphere and neuronal cell receptors.

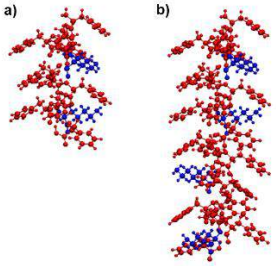

Figure 1: Shows the α-helix secondary structure of peptoid with the different number of monomers a) 12 mer and b) 24 mer.

The protein structure of receptors such as integrin α1β1 (1CK4 pdb) and NCAM Ig 1-2-3 (1QZ1 pdb) of Rattus norvegicus are extracted from the protein database [14]. CHARMM 22 [15] and MFTOID [16] force fields are used to analyze the peptoid and receptor interactions. First step of energy minimization is performed on the peptoid sphere-receptor mixture to reduce instabilities in the initial conformation. Next, the minimized mixture is equilibrated using NPT ensemble at a temperature of 300 K for 2ns. For all MD simulations, a time step of Δt= 2 fs is used. Constant temperature and pressure were maintained with the Berendsen algorithm using a barostatic time

constant of τ_p = 5.0 ps atm^{-1} and a thermostatic time constant of τ_t = 1.0 ps. To find the position and velocity of atoms at each time step, we use the Nose-Hoover method. The equilibration of proteins are carried out until the root mean square deviation is less than 1 Å. We used LAMMPS [17] (Large-scale Atomic/Molecular Massively Parallel Simulator) for all our MD simulations, which is an open-source code.

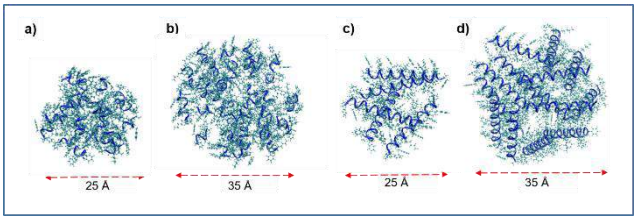

Figure 2: Molecular structure of the peptoid sphere with 25 Å (a,c) and 35 Å(b,d) diameters created from the random distribution of 12mer and 24 mer respectively.

RESULTS

After equilibration, we analyze the peptoid-integrin α1β1 structure to evaluate the pair interaction energy (*epair* = van der Waals (*evwdl*) + Coulombic energy (ecoul)). Preliminary results of peptoid-integrin α1β1structure show that increasing the peptoid sphere size the interaction energy increases; refer Figure 3a. This may be due to the increase in the number of peptoid molecules at the interface between peptoid-integrin. However, varying the number of monomers from 12 to 24 shows that interaction energy is higher for 12 mer when compared to 24 mer even though the number of molecules are equal in both cases; refer Figure 3b. To examine the reason for higher interaction energy in 12 mer peptoid sphere, we perform contact surface analysis on the peptoid-integrin structure using the solvent-accessible surface area (SASA) technique[18]. A previous study on collagen-integrin and laminin-integrin has shown that receptors are more attracted to hydrophilic surface molecules [19]. Hence, we evaluate the hydrophilic contact surface area between integrin and peptoid sphere with 25Å diameter; refer Figure 4. It shows that 12 mer peptoid sphere has a higher hydrophilic contact surface area, which explains the reason for higher interaction energy in 12 mer peptoid sphere.

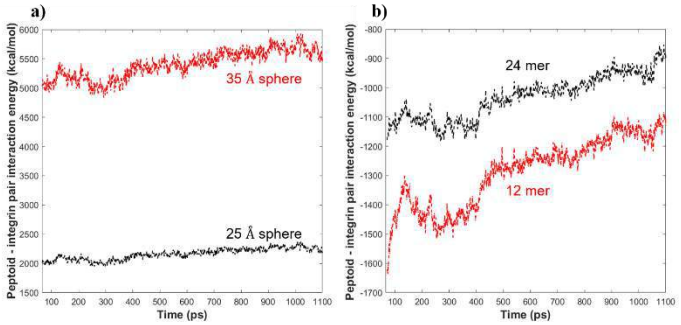

Figure 3: a) Shows the effect of varying sphere size (25 and 35Å) on pair interaction energy of peptoid – integrin for n=12 mer. b) Shows the effect of a varying number of monomers (n = 12 and 24) on pair interaction energy of peptoid – integrin.

DISCUSSION

We performed molecular dynamics studies to investigate the peptoid sphere size and chain length (number of monomers) influence on the interaction energies between peptoid and neuronal cell receptors. Preliminary results suggest that the peptoid sphere with 12 mer have better adhesion with integrin α1β1; since the number of hydrophilic contact surface area is higher in 12 mer when compared to 24 mer. This effect could be due to the flexibility of a smaller chain (12 mer) to accommodate a larger surface area at the peptoid –integrin interface. These findings will enhance the understanding of the interaction mechanism of peptoid- neuronal cell receptors and also aid *in vitro* studies to select the optimal peptoid sphere size and the number of monomers.

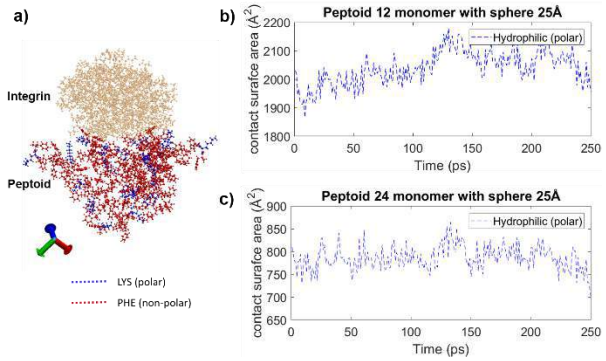

Figure 4: a) Shows the snapshot of integrin α1β1 - peptoids equilibrated structure along with the distribution of polar and non-polar molecules in the peptoid chain. Calculated hydrophilic surface area for different numbers of monomers 12 mer and 24 mer is plotted in b) and c), respectively.

INTRODUCTION

Acute coronary syndromes (ACS), characterized by reduced blood flow to the heart, remain the highest cause of mortalities worldwide with ~9 million deaths annually [1]. An ACS event is caused by the rupture of an atherosclerotic plaque and is the primary origin of major adverse cardiac events (MACE). Prior work has shown that rapid transition from stable to unstable plaque phenotypes precedes ACS [2], so there is great interest in establishing prognostication strategies to identify rapidly progressing coronary atherosclerosis. Indeed, virtual-histology intravascular ultrasound (VH-IVUS) has emerged as a clinical imaging tool to identify tissue composition, plaque phenotype, and disease progression; however, current image-based methods for predicting future MACE remain insufficient.

As mechanical loads have been postulated to play a central role in coronary atherosclerosis and plaque rupture, efforts have been directed at developing computational techniques to predict the *in vivo* biomechanical environment towards advancing prognostic capabilities. Recent investigations have shown that increased plaque structural stress is observed in vulnerable and ruptured coronary plaques when compared to stable and non-ruptures lesions [3,4]. It is important to note, however, that these image-based studies assumed plane strain (i.e., models were 2D). A primary challenge in the development of 3D patient-specific computational models is the application of boundary conditions to keep the curved vessel fixed in space while still permitting deformation under the application of a lumen pressure.

Therefore, this study aimed to optimize a perivascular (PV) support structure, including structure geometry and material properties, that prevents coronary tissue rigid body motions and prohibits impact upon tissue deformation under loading.

METHODS

Model Geometries Two computational geometries were created – idealized and patient-specific coronary geometry – and each included models with or without PV support (Fig. 1). The idealized geometry, created in the FEBio software suite [5], consisted of a quarter-cylinder with a 2-layer coronary artery model whose dimensions were derived from the literature (inner radius = 1.5 mm, medial thickness = 0.43 mm, adventitial thickness = 0.48 mm) (Fig. 1A) [6]. A PV support was added with a thickness of 5 or 10 mm. The patient-specific coronary geometry was created from VH-IVUS image data [7]. Briefly, ECG-gated (end-diastolic) VH-IVUS images acquired from a 71-year-old Caucasian female were segmented, boundaries were stacked along the VH-IVUS catheter centerline, and volume surfaces were generated and smoothed (Geomagic, 3D Systems, Rock Hill, SC). To aid study goals and modeling efforts, the centerline was straightened and the model only included data from 50% of the geometry circumference (Fig. 1B). Adventitial and PV support layers with thickness values of 0.48 and 10

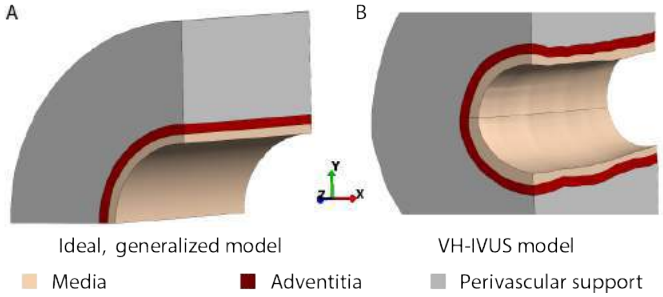

Figure 1: Coronary artery geometries with PV support for (A) an ideal, generalized quarter-symmetry model and (B) a VH-IVUS model.

mm, respectively, were added in ANSA (Beta CAE Systems, Thessaloniki, GD).

Computational Modeling Geometries were imported into ANSA and discretized with hexahedral elements. Each coronary geometry had an identical mesh regardless of whether the PV was present or not, and the arterial layers were meshed at 20× the density of the PV support.

Across both computational geometries, the medial and adventitial layers were defined as fiber-reinforced materials (i.e., an isotropic ground matrix with fiber reinforcements). Material coefficients for each layer were extracted from prior experiments [6]. Bulk moduli for the medial and adventitial layers were 50 and 90 MPa, respectively, to enforce incompressibility. The sensitivity of tissue deformation to PV support parameters in the idealized geometry was evaluated using combinations of Young's modulus (E) and thickness (h) (Table 1).

Across all computational models, the ends of the vessel and PV support structure, if present, were fixed in the z-direction. Furthermore, symmetry planes (i.e., θ-faces) were only allowed to deform in the radial direction. In the patient-specific model, the nodes lying at half the vessel circumference were not allowed to deform in the θ-direction. When the PV support structure was present, nodes on the outer PV surface were fixed in all directions. A pressure of 40 mmHg was applied to the vessel lumen. All computational simulations were performed in the FEBio software suite [5].

Data Analysis Following model convergence, element kinematic data and principal stresses were evaluated. An element-by-element comparison of total displacement was performed to evaluate the impact of the PV support structure on artery deformations and the sensitivity of deformations to PV support geometry and material properties. In addition, differences in transmural stress distributions in the presence or absence of the PV support structure were examined.

RESULTS

Table 1: Effects of varying PV parameters upon vessel displacement and 1st principal stress.

PV Parameters		Total Displacement [mm]		
h [mm]	E [kPa]	Min	Max	Avg.
no PV	-	0.781	0.930	0.854
5	1.0	0.779	0.928	0.852
5	0.1	0.781	0.930	0.854
5	0.01	0.781	0.930	0.854
10	1.0	0.779	0.928	0.852
10	0.01	0.781	0.930	0.854

Examination of tissue displacements in the idealized geometry demonstrated that deformations were not sensitive to variations in the thickness (h) or Young's modulus (E) of the PV support structure. Without the PV support, the minimum and maximum total displacements were 0.781 and 0.930 mm, respectively (Table 1). The addition of PV support with h and E values of 5 mm and 1.0 kPa, respectively, resulted in minimum and maximum tissue displacements of 0.779 and 0.928 mm, respectively. Furthermore, an element-by-element comparison revealed an average difference in total displacement of 2.25e-3 mm and ~96% of elements had a change of <2.4e-3 mm. Similar minute changes in total displacement were observed across other variations in h and E. Notably, h and E values of 10 mm and 0.01 kPa had nearly identical values of total displacement compared to the model with no PV support as 100% of elements had a total displacement change of <1.9e-5 mm.

The inclusion of a PV region with a thickness and Young's modulus of 10 mm and 0.01 kPa had a minimal effect upon arterial deformation in the VH-IVUS-derived model. Compared to the model without a PV region, the average and maximum differences in total displacement were 4.1e-5 and 1.52e-4 mm, respectively. Also, ~99% of elements had a displacement change of <1.3e-4 mm. Evaluation of the transmural distribution of 1st principal Cauchy stress further highlights the minimal impact that the PV structure had on the artery mechanical environment (Fig. 2A). At a location near the central region of the vessel, a nearly identical decrease of stress from the medial to the adventitial surface was observed in models with the presence or absence of the PV region (Fig. 2B). An element-by-element comparison revealed an average stress difference of 0.2% between the models, and ~97% of elements had a difference in stress of <0.04%.

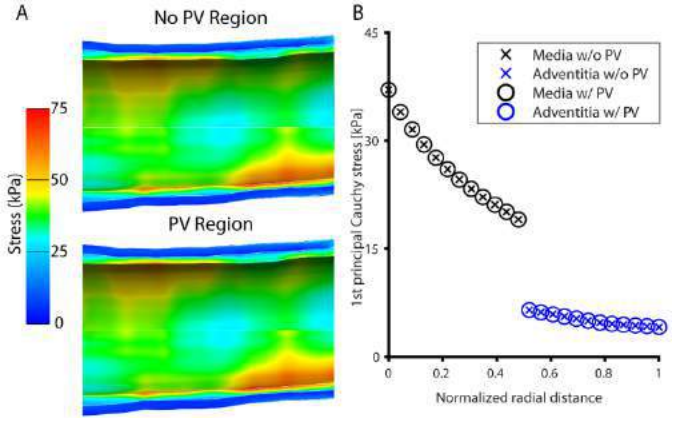

Figure 2: Impact of a PV region upon VH-IVUS model stresses (A) over the whole model and (B) at a central region of the vessel.

DISCUSSION

These results illustrate the minimal impact that an optimized PV support structure can have on the coronary artery mechanical environment during lumen pressurization. Data demonstrated that the identified PV geometry and material properties have minimal impact upon vessel distensibility in an ideal, generalized model (Table 1) and prevented rigid body motions in a straightened, patient-specific 3D coronary artery model (Fig. 2). Importantly, inclusion of a PV region allows application of boundary conditions in future 3D patient-specific coronary models with complex geometries, including multi-planar curvature and branching vessels. We acknowledge the limitation of using a straightened model cut in half. However, such a model was necessary to enable application of boundary conditions to an asymmetric coronary model without a PV region for comparative purposes. We anticipate the addition of a PV region will enable the establishment of 3D patient-specific coronary artery computational frameworks to more accurately predict the *in vivo* mechanical environment and enhance prognostic capabilities for plaque progression and ACS events.

INTRODUCTION

Articular cartilage is a connective tissue found at the joints of long bones in the body, where it serves to reduce friction while sustaining contact forces under intense mechanical stresses. Over time cartilage may degrade, leading to the formation of defects and lesions, and resulting in a painful, debilitating condition called osteoarthritis (OA). Despite being the leading cause of disability among older Americans and affecting 27 million people in the US alone [1], few early-stage treatment options are available for OA, in part because the disease is largely asymptomatic until degradation has become severe enough to cause pain and immobility. OA frequently progresses, until the only viable treatment option is total joint replacement.

Articular cartilage has a hydrated extracellular matrix (ECM) sparsely populated by chondrocytes. The ECM structure consists of negatively charged proteoglycans that produce an osmotic pressure, which contribute to its compressive stiffness, and an interwoven collagen network, which counteracts this swelling and provides tensile strength. A key pathogenic pathway of OA is the disruption or unraveling of this collagen network, which results in instability of the ECM and swelling of the tissue [2]. Therefore, methods of repairing this damaged collagen network have been studied as treatment strategies for combating the progression of OA.

Crosslinking by femtosecond laser treatment has been shown to strengthen cartilage tissue that has begun to wear in the superficial zone, by reconnecting the fragmented collagen pieces [3]. For large cartilage defects where an implant is used for repair, it has been shown that promoting collagen crosslinking at the interface can promote the integration of this implant with the native tissue [4]. Fibrin glues are also used clinically to aid in the repair of musculoskeletal tissue tears, like in the meniscus, by acting as an adhesive [5]. In this study, we examine the feasibility of repairing tears in cartilage and other collagenous tissues, by crosslinking collagen fibers across the interface to 'glue' and strengthen the bond. A collagen hydrogel can also be used to coat the surface of the interface, to increase the proximity of collagen fibrils and fibers at this junction and provide more sites for the broken collagen fragments to bind with. To address these aims, we measured the interface strength of cartilage explants bonded with and without a collagen gel and crosslinked with glutaraldehyde (GTA), a common crosslinking agent for cartilage tissue research [6].

METHODS

Cylindrical cartilage explants were harvested from the femoropatellar grooves of four immature bovine knee joints (∅10 mm). The superficial and middle zones were removed by sledge microtome resulting in a uniform thickness of 3.79 ± 0.1 mm. A ∅4 mm plug was cored out from the center of the explant. For six samples (Gel/GTA group), the hole of the annulus was filled with collagen type I liquid hydrogel (ThermoFisher Scientific A1064401), prepared at 4 mg/mL with 10X phosphate buffer saline (PBS) and 1N NaCl. The plug was then placed back into the hole. These samples were placed in a 37 °C incubator for 1 hour to allow the hydrogel to coagulate, then removed, wrapped in parafilm, and allowed to set for 12 hours at 25 °C. For six additional samples (GTA group), the plug was placed back into the hole without hydrogel. Six other samples (CTRL group) were separated so that the center plug was left outside of the annulus as a negative control, to isolate the effect of GTA on the interface strength. All samples were then exposed to 0.6% GTA, prepared in PBS, 6 mL per sample at 8 °C for 24 hours [7].

A standard push-out test was performed [8], conducted on mechanical testing devices with a modified platen. Each sample was stained with India ink to locate the top of the inner plug, placed on an aluminum support plate with a ∅6 mm hole to allow the inner plug to

be pushed out, and submerged in 1X PBS. A ∅3 mm rigid flat indenter parallel to the cartilage surface was pressed against the inner plug, concentric with the stained circle, and displacement was prescribed in the form of a linear ramp at a rate of 0.5 μm-s^{1}, until failure (Fig. 1, left). A 45 N load cell and LVDT recorded force and displacement data throughout the test.

The interface strength was reported as the failure stress, evaluated as the maximum load normalized by the lateral area of the interface, and energy to failure, evaluated as the area under the force-displacement curve from onset to maximum force. A one-way ANOVA with post hoc testing of the means was performed to analyze statistical significance.

RESULTS

For each sample, force-displacement curves were obtained, and converted to stress-displacement curves using the interface area of each sample, equal to the lateral area of the inner plug (Fig. 1, right). One outlier was removed from the GTA group, due to its very low failure stress of 8.3 kPa, when compared to other samples in that group (Fig. 2, left).

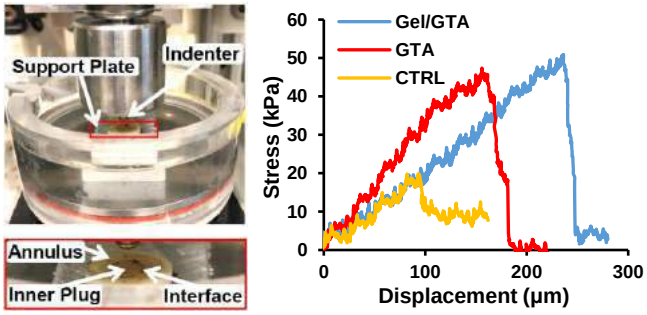

Figure 1: (Left) An image of the push-out test, cylindrical inner plugs were dislodged from an annulus via an indenter descending at a constant rate. (Right) Representative stress-displacement curves for push-out tests.

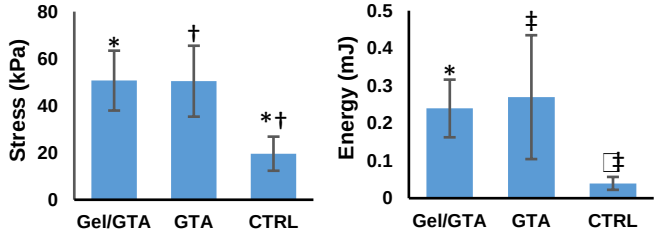

Figure 2: (Left) Average failure stress across each group (Right) Average energy to failure across each group. * p<0.0005, † p<0.005, ‡ p<0.05: statistical difference between mean value of two groups.

The failure stress for each sample was averaged across each group (Fig. 2, left). The Gel/GTA group had an average failure stress of 50.7 ± 12.7 kPa. The GTA group had a failure stress of 50.4 ± 15.1 kPa, which was not statistically different from the Gel/GTA group (p=0.98). The failure stress of the CTRL group, at 19.6 ± 7.2 kPa, was statistically lower than the Gel/GTA (p<0.0005) and GTA (p<0.005) groups.

The energy to failure for each sample was evaluated using units of mJ (Fig 2, right). This quantity was also similar between the treated groups, 0.24 ± 08 mJ for the Gel/GTA, and 0.27 ± 0.17 mJ for the GTA group. In contrast, the energy to failure in the CTRL group, 0.40 ± 0.02 mJ, was significantly lower than Gel/GRA (p<0.0005) and GTA (p<0.05) groups.

DISCUSSION

The results of this study indicate that collagen crosslinking can occur by simply fitting a cartilage plug within a cartilage annular ring and exposing it to a crosslinker (GTA in this study). Evidence in support of crosslinking was presented as an improvement in the mechanical strength of the interface. The higher failure stress in the treated groups compared to the control group suggests that collagen crosslinks did form at the interface, and contributed to increasing the interface strength. The lower failure stress of the control group provides support for the hypothesis that this increased mechanical strength was due to crosslinking, and not due to the presence of GTA-induced differential swelling of the plug and annulus, which might increase the frictional forces at the interface and consequently increase the failure stress. To further verify this finding, we have initiated additional tests where we place back the inner plug of the GTA group in its annulus and test the sample a second time, to see if the failure stress and energy to failure reproduce those of the CTRL group. Preliminary findings (not shown here) suggest that the crosslinks were indeed ruptured during the primary test, and were no longer contributing to mechanical strength.

The addition of collagen I gel to the interface (Gel/GTA group) did not significantly affect the failure stress or energy to failure of the samples when compared to the GTA group. This result indicates that solubilized collagen I fragments, when exposed to a crosslinker, may not form a matrix with significant mechanical integrity to enhance the interface strength. Nevertheless, since defects in OA joints may not present with a sufficiently smooth interface to crosslink with an allograft, we may continue exploring alternative collagenous gels to enhance the interfacial strength between allograft and native tissue. In particular, the primary collagen type found in articular cartilage is type II, not type I, which could affect the ability of these fragments to bind with the fragments native to the tissue. Collagen gel also has the advantage of being able to conform to the shape of irregular defects, and could be beneficial in bonding other geometries, where the two pieces of tissue do not fit together perfectly.

This study represents a proof of concept that crosslinking is a suitable repair strategy for collagenous tissue repair. In modifying this technique for the clinical setting, the use of glutaraldehyde would not be suitable, as it is toxic and can lead to cell apoptosis [9]. Therefore, other crosslinking methods should be investigated. UV light paired with a riboflavin photosensitizer has been successful in crosslinking corneal tissue, and could be an appropriate alternative if properly adapted to cartilage [10]. Another promising technique is femtosecond laser crosslinking, which has been successful in cornea and cartilage tissue [3]. This would be an advantageous technique, as unlike most other methods, it doesn't require use of any additional chemicals.

INTRODUCTION

One of the principal impediments to the broad success of conventional chemotherapy is poor delivery to and transport within the tumor microenvironment (TME), caused by irregular and leaky vasculature, the lack of functional lymphatics, and underscored by the overproduction of extracellular matrix (ECM) proteins such as collagen. Co-administration of proteases that degrade the ECM with chemotherapeutics has been shown to significantly enhance their transport in murine tumor models [1]. However, systemic administration of proteases causes collateral damage to normal tissue and has been suggested to increase the risk of tumor metastasis, necessitating targeted delivery. An innovative approach is to use engineered bacteria-based cancer therapy (BBCT), wherein microbes such as *Salmonella* Typhimurium, which preferentially replicate in the TME, are programmed to locally degrade the ECM. Not only would this target ECM degradation to tumors, but such an approach would augment the intrinsic benefits of BBCT over passive modalities such as active translocation and the ability to transport drug-loaded cargo. In this work, we engineered attenuated tumor-targeting *S.* Typhimurium VNP20009 [2] to express and secrete a recombinant collagenase to locally degrade the ECM. We then developed innovative microfluidic assays to systematically and quantitatively characterize the engineered bacteria transport in tissue-mimicking reductionist collagen models with and without interstitial flow. Our results demonstrate significant improvement of bacterial interstitial transport when advection dominates. To investigate the mechanism behind the observed enhanced transport, we tuned the collagenase expression rate and conducted swim plate assays in collagen. We show that besides collagenase secretion, bacterial fitness plays a strong role in self-actuation scenarios. Altogether, we show the vast potential of this approach for augmenting BBCT while highlighting the critical importance of balancing the overall metabolic load.

METHODS

Cloning of a Heterologous Collagenase – A bacterial matrix metalloproteinase gene, *mmpG*, was cloned into a plasmid vector and expressed constitutively along with mRFP1 to enable fluorescence imaging of the bacteria. Collagen degradation was quantified using a dye-quenched (DQ) collagen type I assay.

Microfluidic Assay – A microfluidic device with 7 parallel channels separated by pillars was designed to study interstitial transport of non-motile strains (Fig. 1a). The central channel was filled with 5 mg/mL collagen type I, while phosphate buffered saline (PBS) filled the adjacent channels. Polyethylene glycol diacrylate (PED-DA; 700 Da) was used between the outermost channels to create permeable barriers separating media flow from adjacent channels.

Microfluidic Experiments and Data Collection – Non-motile *S.* Typhimurium VNP20009Δ*fliF* expressing *mmpG*, at 5×10^7 CFU/mL,

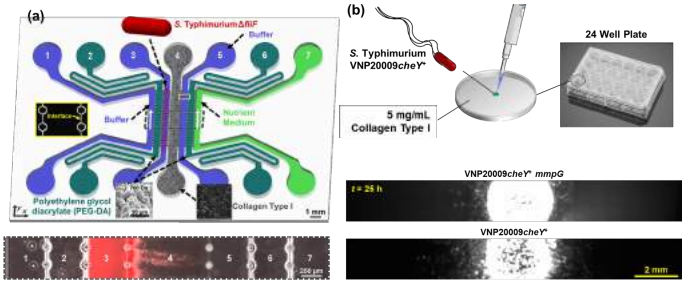

Figure 1: (a) Microfluidic assay and composite bright-field and fluorescent micrograph after 26 hr, and (b) collagen swim plate assay and fluorescent micrographs after 25 hr

were introduced into channel 3 (Fig. 1a). Nutrient medium and PBS were flowed through the outermost channels (1 and 7).

Swim Plate Assays – The chemotactic strain *S.* Typhimurium VNP20009*cheY*$^{+}$ [3] was used for swim plate experiments. Nutrient collagen was polymerized in the wells of a 24-well plate at 5 mg/mL, and 1 µL of bacterial suspension at 10^6 CFU/mL was introduced onto the center of the gel surface in each well (Fig. 1b). High and low frame rate movies were recorded for single-bacterium scale and population-scale transport characterization, respectively. From the single-cell tracking, we calculated the average squared displacement,

$$\mathrm{ASD}(t_{n_0}) = \frac{1}{\Delta t(N_t - 1)} \sum_{i=n_0-N_t}^{n_0} \|\vec{r}_i - \vec{r}_{i-1}\|^2 , \qquad (1)$$

where Δt is the time step, N_t is the number time steps used to define bin size (4), and $\vec{r}$ is bacterium position between each frame during 0.2 s bins. *Sticking* periods were defined as ASD < 20 µm^2/s, while a bacterium was *running* if ASD ≥ 20 µm^2/s.

RESULTS

We first performed microfluidic assays using the non-flagellated VNP20009Δ*fliF* to decouple the effects of motility and collagenase expression on transport in collagen hydrogel. Analogous to the aberrant nature of the TME, low rates of stochastic interstitial flow were present. Penetration of the *mmpG* strain was significantly greater than control, reaching an average of 171% greater depth between the 11th and 20th hour (Fig. 2a). We developed a mathematical model of transport:

$$\frac{\partial B}{\partial t} = D\frac{\partial^2 B}{\partial x^2} - v\frac{\partial B}{\partial x} + k_g B(1 - B), \qquad (2)$$

where B is bacterial concentration, D is bacterial diffusivity, v is the effective advection coefficient, and k_g is growth rate [4]. Fitting the model using time-lapse fluorescence data suggests that diffusion was negligible; advection was the primary driver of bacterial transport. The effective advection coefficient was significantly higher for the *mmpG* strain between 7 and 14 hr after bacterial introduction (Fig. 2b).

To further investigate the mechanisms behind enhanced *mmpG* transport, we developed a swim plate assay devoid of interstitial flow and engineered a ribosomal binding site (RBS) library to modulate the rate of collagenase secretion in motile, chemotactic VNP20009*cheY*$^{+}$ strains. Our original RBS design (RBS O) had the highest collagenase production rates, and we achieved good gradation amongst the other designs (Fig. 2c). Experiments with RBS O, RBS 1, RBS 2, and control strains revealed better colonization (*i.e.* greater radial penetration) of the swim plates by the RBS O strain on average (Fig. 2d,e).

We characterized each strain's growth rate and motility to elucidate differences at the single-cell scale. Bacterial fitness was

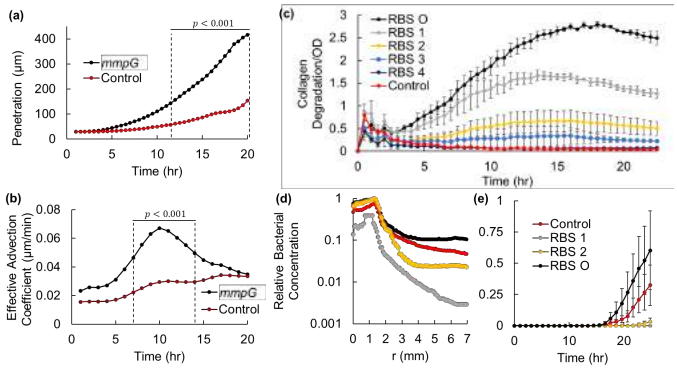

Figure 2: Average penetration (a) and effective advection coefficient (b) of bacteria in microfluidic collagen assay, (c) bulk collagen degradation normalized to bacterial optical density vs. time, and average relative bacterial concentrations in collagen swim plates vs. radial location (d) and vs. time at *r* = 6 mm (e)

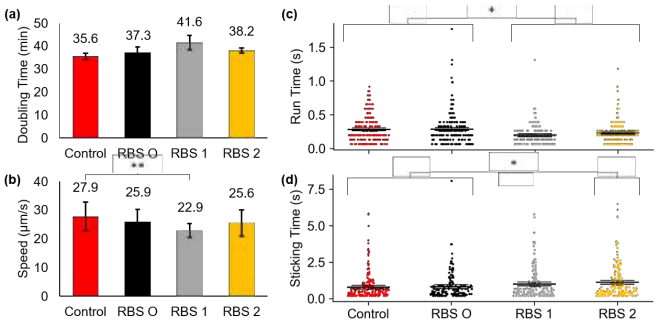

Figure 3: (a) doubling time of motile strains, (b) speed during run periods, (c) run duration, and (d) stick duration. Error bars show standard deviation (a,b) or 95% confidence intervals (c,d).

affected by collagenase expression, with the RBS 1 strain having the longest doubling time (Fig. 3a) and lowest swimming speed (Fig. 3b). Each of the other strains had similar swimming speeds, but the control strain had the highest growth rate. Bacterial swimming in collagen consisted of a series of "run" (smooth translation in space) and "stick" periods (collision with collagen, remaining fixed in space for at least 0.2 s). On average, the durations of runs were similar between RBS O and control, each being significantly higher than those of RBS 1 and 2 (Fig. 3c). Conversely, sticking periods were found to be lowest for the RBS O and control strains, while they were highest for RBS 2 (Fig. 3d).

DISCUSSION

Our work illustrates that bacterial collagenase secretion can improve the efficacy of transport by advection or by self-propulsion. In presence of advective flow, collagenase is particularly effective because bacteria may "clog" their local porous environment if daughter cells are not effectively transported away after proliferation. Our findings with motile strains in no-flow environments suggest that rates of "sticking" to collagen play a role in transport, but interpretation is complex due to differences in bacterial fitness. The RBS 1 strain harbored the greatest metabolic load, as its growth rate was lowest and swimming speed was significantly lower than that of the control strain. Stark differences existed between RBS O and RBS 2, which had nearly identical growth rates and swimming speeds, but the latter had a lower rate of collagenase expression, suggesting a clear role for collagenase in reducing bacteria sticking time. Moreover, RBS O also outperformed the control strain on average, despite the control bacteria having the best overall fitness.

Taken together, our findings suggest that collagenase secretion can enhance transport, but fitness plays a major role and must be balanced when engineering such strains, especially for applications where swimming motility is possible. Our results demonstrate strong overall potential for *in vivo* BBCT applications. The small pore size of the TME will likely preclude motility, and transport will be driven by coupled growth and advection. In the future, the collagenase-secreting strains will be further engineered for tumor-specific expression and will be evaluated using *in vitro* and *in vivo* tumor models.

INTRODUCTION

Osteoarthritis is the leading global cause of disability, and the most common form of arthritis in adults, impacting 27 million Americans age 25 and older [1]. Osteoarthritis is characterized by the degradation of articular cartilage in diarthrodial joints. This damage impacts the ability of cartilage to evenly cushion the joint and protect the underlying bone during normal daily activities. Approximately 10% of all cases of osteoarthritis in the knee are post-traumatic osteoarthritis (PTOA), initiated by a traumatic injury to the joint such as intraarticular fractures, acute ligament sprain, damage to subchondral bone, joint dislocation, meniscal tears, or any combination of these injuries [2]. Currently, the relatively limited lifespan of artificial joint replacement technologies is a major obstacle for treatment of younger patients with PTOA who are expected to outlive any orthopedic implants.

Osteochondral allografts provide a promising avenue for treatment of PTOA. Advancements in the capabilities of tissue banks to maintain tissue samples for longer periods of time have paved the way for the use of osteochondral allografts in replacing regions of damaged articular cartilage. Tissue banks can harvest fresh human donor tissue and preserve live articular cartilage and underlying subchondral bone prior to the transplantation process. Though osteochondral allografts have demonstrated positive clinical results in the knee, the technique is limited in surgical settings due to the difficulty of ensuring that joint congruence is not reduced in the patient. This is an important consideration, as a reduction in joint contact area causes increased localized contract stresses that can instigate degenerative changes in the transplanted allograft.

One of the primary limitations to osteochondral allografts in surgical settings is the difficulty of matching donor allograft size and curvature to the recipient's joint anatomy. Fresh donor allografts have a limited shelf life in the tissue bank, so the ability to alter the articular curvature of available donor tissue to match that of the recipient considerably expands the use of fresh allografts.

In our prior report, in silico models demonstrated that grooving the underlying bone in donor osteochondral patellar allografts increases their ability to conform to recipient femoral grooves [3]. Following up on these computational results, the objective of this study was to develop a robust experimental method for creating bendable osteochondral allografts (BOCAs) from canine patellae, and to demonstrate the ability to modify the surface curvature of these BOCAs in vitro, in advance of anticipated animal studies.

METHODS

Four canine patellae harvested from non-arthritic stifles were sourced from the Thompson Laboratory for Regenerative Orthopedics (University of Missouri, MO). Samples were shipped frozen to the Musculoskeletal Biomechanics Lab (Columbia University, NY) where they were thawed and dissected free of adherent soft tissue. The canine patellae were secured in a custom-built fixation rig for μCT scanning and machining. The rig was designed to allow complete processing of the patellae under sterile conditions, to enable future processing of live allografts. The articular surface of each patella was covered with hydrated gauze and submerged in a phosphate buffered saline bath, while the apical surface of the patella was fixed using soft fit clamps cast in Adafruit low temperature fixation thermoplastic (Adafruit Industries, New York, NY). Once fully suspended in the rig, the patella was scanned in a vivaCT 80 (ScanCo, Wangen-Brüttisellen, Switzerland) scanner to generate corresponding DICOM models with a voxel size of 78 μm. The DICOM was processed using the opensource imaging software 3D Slicer (Harvard, Boston MA) to create a volume scan of the subject-specific bony structure of the patella in relation to fiducial markers embedded in the scanning rig. The generated model and corresponding spatial data were used to create tailored CNC cutting

paths using the HSM Works application in SOLIDWORKS (Dassault Systèmes, Waltham, MA)

Prior finite element analyses on human knee models determined that enhancing congruence along the medial-lateral direction offered the best strategy for increasing surface conformity between patellar BOCAs and recipient femoral grooves. This has been achieved by milling grooves in the underlying bone of the patella. Each patella was first milled to plane the anterior surface before two 2.5 mm wide grooves were machined in the proximal-distal direction through the full depth of the subchondral bone (Fig. 1). Each groove in the patella was separated by a 6 mm wide bone strut. All machining was done in a custom-built sterile field cabinet using a Sherline 5400 CNC milling machine (Sherline, Vista, CA) using Flashcut CNC software (Flashcut, Deerfield, IL). The cuts were made using a 1/16" ball end mill and speeds and feeds were optimized for surface smoothness [4]. All four patellae were successfully grooved without visible damage to the articular surface.

Fig. 1: Canine patella following groove milling

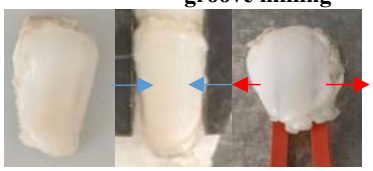

Fig. 2: Scanning configurations; arrows indicate direction of force applied to bone struts

After machining the osteochondral allografts, scans of the articular surface were acquired with a laser scanner, with the grooved bony struts placed in relaxed, compressed, and expanded states (Fig. 2). The relaxed, or reference, state representing the natural curvature of the patella, was obtained by scanning the surface of the grooved patellae without modification. Scanning of the compressed state was accomplished by clamping the bone struts of the sample together prior to scanning in order to minimize the radius of curvature to simulate conformity to a narrow femoral groove. The expanded state was created by expanding the space between bone with strips of 3.2 mm thick rubber to flatten the articular surface to simulate conformity to a wide femoral groove. The scanned point cloud data were reconstructed to form 3D models of the articular surface using custom C++ code and the SOLIDWORKS CAD software.

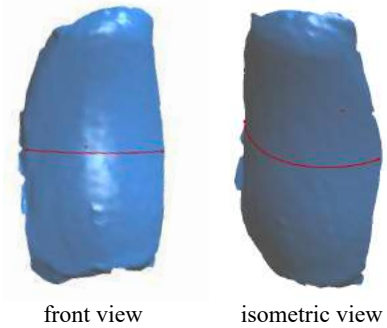

Fig. 3: Measuring surface curvature with 3 point curve fitting

Curvature was measured using CAD surface models fitted to the laser scan data by fitting a circular arc using a three-point circle fit method at the median antero-posterior surface of the patellae (Fig. 3). This result was further validated by fitting 4th degree B-spline surfaces to the scanned point cloud [5] and evaluating the surface-wide average of the maximum curvature (Fig. 4). These curvature results are displayed in Fig. 5.

RESULTS

Using the 3-point curve fitting method, the compression produced an average reduction of the radius of curvature by 70% ± 5.4% ($p = 1.59 \times 10^{-3}$), while extension produced 150% ± 19.9% ($p = 1.47 \times 10^{-2}$) increase of the radius of curvature. With the 4th degree B-spline surfaces method, the compression produced an average reduction of the radius of curvature by 71% ± 3.2% ($p = 3.71 \times 10^{-4}$), while extension produced 142% ± 9.8% ($p = 3.41 \times 10^{-3}$) increase of the radius of curvature.

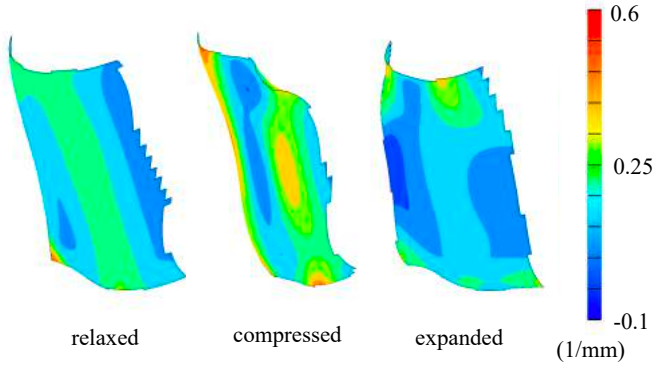

Fig. 4: Representative maps of maximum curvature from B-spline fits of the compressed, relaxed and expanded patellae

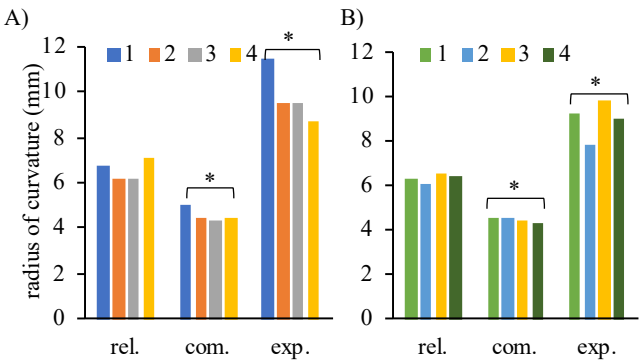

Fig. 5: Curve fit results from (4A) 3-point, (4B) B-Spline methods; * indicates difference compared to relaxed group (p<0.05)

While the 4th order B spline fitting method for measuring average radius is a more comprehensive measurement of curvature over the whole patella surface, both methods produced consistent results and no statistically significant differences for the results in compression ($p = 0.664$) or extension ($p = 0.347$).

DISCUSSION

The fabrication method for developing grooved patellar osteochondral allografts in this study provides a reliable method for altering surface curvature in osteochondral allografts through grooving of the subchondral bone. Follow-up studies are planned to ensure that this method of creating BOCAs does not negatively impact chondrocyte viability in live osteochondral allografts preceding a canine clinical trial.

ACKNOWLEDGEMENTS

We thank X. Edward Guo and the Bone Bioengineering Laboratory (Columbia) for use of their µCT scanner. We also thank Chantelle Boyzinski and Mary Romesburg (Missouri) for providing canine patella samples. This project is funded by U.S Department of Defense (W81XWH-18-1-0361/PR171360).

INTRODUCTION

In women, the vagina undergoes remarkable structural changes before (puberty and menstruation), during, and following (menopause) the reproductive lifespan[1]. As events linked with reproductive capacity occur at relatively predictable ages, shape changes in the vagina associated with these events should be identifiable within specific age ranges[2].

For example, prior to puberty, the pelvis is not fully developed and likely does not fully mature until the completion of the teenage years. Thus, we should anticipate that the vaginal shape of children (aged 0-19 years) would differ from that of mature, reproductive-aged women over age 20 years. During the prime reproductive years, age 20 to 34 years, the vagina and its supportive tissues likely remain consistent (unless pregnancy and delivery occurs) with only small changes occurring as a result of the menstrual cycle.[3] In the late reproductive and peri-menopausal years, the vagina likely undergoes additional shape changes as evidenced by increased maternal birth injury in women >34 years. Finally, post-reproduction (menopause) the vagina and its supportive tissues thin relative to younger women likely resulting in additional changes in shape.

This study aimed to quantify the average vaginal shape and shape variation across women of varying ages; children (0-19), young adults (20-34), adults (35-49), and seniors (50+). We hypothesized that there would be significant differences consistent with the known effects of aging on the vagina[1,2]. These data are intended to provide a baseline of the variations in shape with aging within the population to build towards better diagnostic tools for the identification of injury and disease.

METHODS

MR images were collected from the University of Pittsburgh Medical Center and Northshore University HealthSystem between 2005 and 2018. Patients underwent MRIs under instruction of their physician for medical indications. This retrospective study consisted of 106 women sorted into 4 groups based on their age. The groups were 0-19 (N=15), 20-34 (N=47; 11 imaged in pregnancy), 35-49 (N=24; 6 imaged in pregnancy), and 50+ (N=20) years old. These groups were chosen to show a range of the physiological changes throughout the life cycle. The young group's age range was chosen based on the majority of secondary ossification occurring by the age of 20, indicating skeletal maturation[4].

The vagina was segmented as one solid object. To decrease computational cost, the vaginal canal was not segmented. Additionally, the apical portion of the vagina (that may include both the vagina and cervix) was segmented as one continuous object.

In order to smooth the vaginal shapes and apply corresponding points, an ellipsoid template was generated. Previous 3D statistical shape models (SSMs) conducted in our lab showed that an ellipsoid model would allow for accurate representation of the structure while also smoothing the aliasing from the MRI scans which could incorrectly influence the SSM. After the corresponding points were determined, the shapes were imported into a Mathematica™ notebook that was previously established in our lab to conduct the rest of the SSM[5]. This process included a Procrustes analysis to scale and align the shapes. Followed by a principal component (PC) analysis to determine modes of variation in each shape and a parallel analysis to determine the variance due to noise. This analysis returns PC scores for each patient for every mode. These scores were then used for statistical analysis.

In order to isolate the effect of age on vaginal shape from that which occurs within pregnancy, pregnant women were excluded from the statistical analyses. To control for the impact of parity, a MANCOVA analysis was performed with total parity of the subject as the covariate followed by univariate ANOVAs with multiple comparisons followed by a Benjamini-Hochberg correction post-hoc[6]

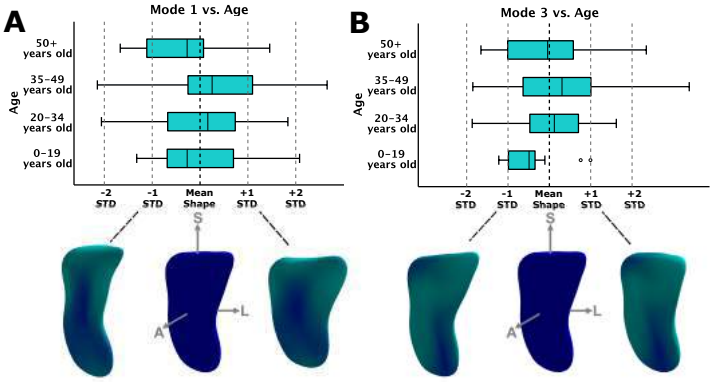

Figure 1: A) Mode 1, B) Mode 3. Top: Mode 1 Age vs. Standard deviations from the mean shape, Bottom: standard deviations of shape, lighter colors show more variation from the mean.

RESULTS

Twelve modes of variation explained 24, 18, 11, 9.2, 8.8 5.9, 2.9, 2.7, 2.2, 1.7, 1.5, and 1.3 percent of the total variance respectively, and were greater than that attributed to noise. For every mode, the average PC scores of all of the age groups fell within one standard deviation from the mean shape.

After the MANCOVA analysis (parity as covariate), we found that age differed significantly across four modes: 1, 3, 6, and 12 ($p=0.012$, $p=0.029$, $p=0.011$, $p=0.021$ respectively). Mode 1 also differed with parity ($p=0.001$). Following the ANOVA, modes 6 and 12 were significantly different between the 0-19 age group and the 20-34 age group ($p=0.006$, and $p=0.013$ respectively).

The top half of Figure 1 shows the standard deviations of modes 1 and 3, significant p-values shown by brackets. The bottom half of Figure 1 shows the average vaginal shape for each mode with ±1 standard deviation from the mean. Figure 2 shows the same for modes 6 and 12. All group averages are within this range.

DISCUSSION

The results showed that there are significant shape differences in the vagina that are due to age. Overall, we saw that there were two different types of variation that may be caused by aging, one that could be tied to maturity, and the other that could be tied to menopause/aging. Modes 3, 6, and 12 represent the changes due to maturation while mode 1 represents changes are suspected to be due to menopause.

In modes 6 and 12, the 0-19 group differs from the 20-34 group, while Mode 3 differs only at the univariate level but not significantly between any individual age groups. The outliers (denoted by empty circles in Figure 1) were infants, suggesting that there might be changes in early development that this study was not powered to detect. In each of these modes, the vaginas in the 0-19 group appear to be straighter and more vertically aligned relative to the older groups. The left shapes of Figure 1B, and Figure 2B, and C more closely represent the shape of the 0-19 group while the middle or right shapes represent the older groups. In all three of these modes, the left shape is more aligned with the frontal plane (plane created by the superior and left arrows in Figure 2) when compared to the average shape which is slightly angled posteriorly. The posterior angle that is observed in the older patients is consistent with literature demonstrating the support of the pelvic floor muscles for the upper portion of the vagina[7]. This support is hypothesized to limit the mobility of the vagina during increases in intrabdominal pressure. Our results seem to indicate that this angulation of the vagina may be related to skeletal maturity.

We hypothesize that the reason for the increased angulation is due the expansion of the pelvis in the anterior-posterior direction. The more posterior movement of the sacrum relative to the vagina has the effect of pulling the uterosacral ligaments and apex of the vagina posteriorly over the iliococcygeus. It could also be a consequence of muscle development within the pelvic floor. However, further analysis is required to test these hypotheses.

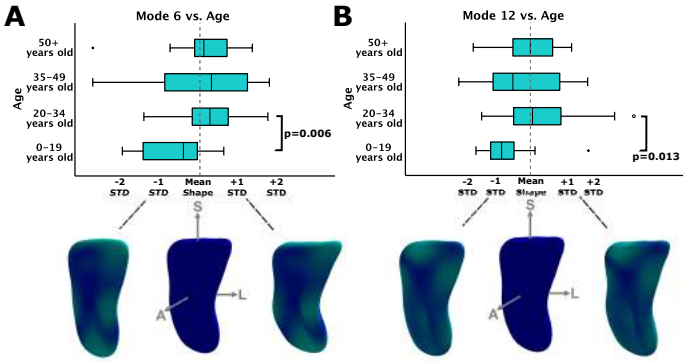

Figure 2: A) Mode 1, B) Mode 3. Top: Mode 1 Age vs. Standard deviations from the mean shape, Bottom: standard deviations of shape standard deviations of shape, lighter colors show more variation from the mean. Significant p-values shown.

Shape variation that may be related to menopause and/or aging is shown in mode 1 (Figure 1A). While only different at the univariate level, older women (50+) had a thinner and longer vaginal shape. This is consistent with prior literature that showed atrophy of many of the structures that support the vagina[1]. Prior research has shown that post-menopausal women (50+ years old) have a significant decrease in the physiologic cross-sectional area of the pelvic floor muscles and the rate at which this occurs substantially outpaces the natural loss of muscle mass in the rest of the body[8]. This loss of pelvic floor musculature allows the distal vagina to fall and become more suspended by the apex; thus, possibly explaining this shape variation.

This study was limited by the shape that was used as the template for the smoothing and corresponding point application did not include a vaginal lumen. Future studies should include a lumen so that resulting shapes can be more aptly used in computational simulations and the addition of a lumen could show shape variation of the interior vagina that would have been excluded by this study. Additionally, the retrospective nature of the study made it so that we only had one scan of each women. A future prospective study could collect scans of women at multiple timepoints throughout their lifespan and shed light on potential mechanisms of vaginal shape changes due to aging.

INTRODUCTION

The stress/strain curve of a biological soft tissue helps characterize its mechanical behavior. The yield point on this curve is when a specimen breaches its elastic range due to irreversible microstructural damage. This can easily be found in traditional engineering materials using the offset yield method, where a line is drawn parallel to the modulus and offset by a specified amount until the line and curve intersect at a yield point [1]. However, correctly identifying the yield point in soft tissues can be subjective due to its nonlinear material behavior. The typical method for yield point identification is visual inspection, which is investigator-dependent and doesn't lend itself to automation of the analysis pipeline [2]. Machine learning has been a growing field of study in data analytics. Bhandari et al. implements RF regression, a decision tree-based machine learning method, to predict yield strength in metals [3]. This method leverages computer algorithms to iteratively improve and converge to an answer that can be difficult to attain using conventional mathematical techniques. The goal of this study was to analyze data from uniaxial extension testing on biological soft tissue specimens and create a machine learning model to objectively determine a tissue sample's yield point. Developing an automated algorithm to identify the yield point can give researchers an objective assessment of the biomechanical properties of soft tissues, as well as progressing our understanding of elastic tissue behavior in general.

METHODS

Uniaxial extension testing was performed on 280 human soft tissue samples from a previous study [2]. These specimens were harvested from human cadavers and patients ranging in age from 30 to 70 years old. Samples were cut in rectangular strips approximately 4 mm wide and 20 mm long. Stress/strain curves were calculated from force-displacement data for each tissue sample, and ground truth yield point picks were adjudicated and determined by biomechanics experts. A 2% window was created surrounding the pre-determined yield point to indicate relative closeness to improve the model's learning process.

Tissue sample data was stored in individual files and compiled through MATLAB (R2020b, Natick, MA) before training the machine learning model. Extension and force measurements were recorded from extension tests and used to calculate stress and strain values. The datasets were then prepared using features derived from the stress and strain values including localized elastic moduli, strain failure ratio and others for a total of 22 unique parameters. These features were selected to analyze distinct properties of a tissue. Specifically, the elastic modulus analyzes the linear portion of a stress/strain curve and reveals elastic resistance to tension. Another feature, strain failure ratio, calculates the current strain over overall failure strain for each data point in a test case. This can be indicative of how much a specimen can be elongated to failure. A sample with a higher strain failure ratio value indicates higher ductility and lower tensile strength. These features were calculated prior to model training to maximize the model's learning capability and options.

The bulk data was input into MATLAB's Classification Learner toolbox. The machine learning model was trained using multiple algorithms within the toolbox, utilizing a fine tree algorithm with Principal Component Analysis disabled. The model's predictions were pre- and post-processed. Model output gave a small region of interest along the strain axis, and a mean clustering method was implemented to iteratively sweep across strain values using a 3% window to determine a singular point as the model's final pick. The resulting picks were compared to pre-determined, ground truth yield points.

The final model was evaluated using a separate set of test cases. Uniaxial extension testing was performed on 44 different human soft tissue samples, and yield points were again adjudicated and determined

by experts. The 2% window and 20 unique parameters were calculated as input features for evaluating the model. The model's test set results were compared to two rule-based algorithms used in a previous study. The first rule-based pick, the peak yield point (Y_p), designated the yield point as the point where the stress/strain ratio, or the current stress over current strain value, reaches its peak. The second pick, the elastic yield point (Y_e), designated the yield point as the first instance where the stress/strain ratio drops by 3% or more. In cases where this was invalid, the first rule-based pick, Y_p, was chosen. Notably, the rule-based picks Y_e and Y_p were included as features for model training. Evaluation consisted of case-by-case analysis followed by a final statistical assessment. Percent error in strain was calculated from each pick to the ground truth previously determined by experts.

RESULTS

Training consisted of 280 cases. The model was trained, and the cross-validation score had an internal accuracy of 93.9%. A separate dataset of 44 cases reserved for validation (and not used in training) was input into the trained classifier yielding a test accuracy of 97.7%.

Evaluation was done by calculating percent error in strain from the ground truth pick. The machine learning model determined yield point picks with an average percent error in strain of 5.04%. The rule-based picks had average percent errors in strain of 20.6% for Y_e and 5.06% for Y_p. Notably, several successful machine learning picks demonstrated a near-perfect prediction. **Figure 1** shows one of the test cases, where the model's prediction lies close to the actual yield point.

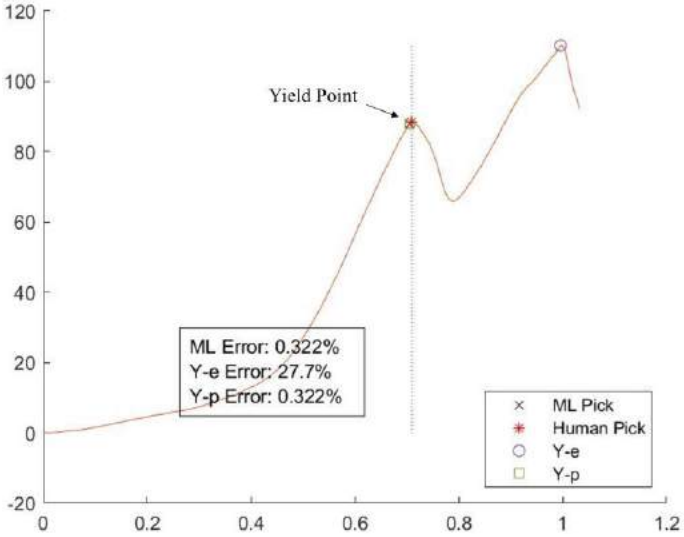

Figure 1. Illustration of yield point picks by rule-based and ML-based algorithm compared against expert-adjudicated picks.

Comparison with each rule-based method indicates the same pick as Y_p and a significantly closer pick than Y_e.

DISCUSSION

The percent error in strain was compared among the three yield points. The elastic yield point (Y_e) method gave several picks far from the ground truth resulting in 20.6% average percent error. The peak yield point (Y_p) method gave significantly lower average percent error with only 5.06%. The machine learning model returned a similar average percent error of 5.04%. A Wilcoxon signed rank test was performed to compare the machine learning model with each rule-based method. The ML-based approach had lower percent error than the Y_e-based approach with statistical significance (5.04% ± 15.8% s.d. versus 20.6% ± 21.4% s.d.; $p < 0.0005$). The ML-based approach had slightly lower percent error than the Y_p-based approach without statistical significance (5.04% ± 15.8% s.d. versus 5.06% ± 6.7% s.d.; $p > 0.5$).

The stress/strain curve obtained from tensile testing is widely used to quantitatively characterize soft tissue behavior. The yield point is often overlooked due to concerns about subjectivity and consistency in its determination. Overcoming this limitation may help to reveal it as a key aspect in biomaterial failure. We evaluated two rule-based approaches to picking yield point on uniaxial extension curve and one ML-based approach by comparing them against adjudicated expert-picked yield point as gold standard. We found that while the ML-based method was significantly improved over one of the rule-based approaches (Y_e), it offered insignificant improvement over the second rule-based approach (Y_p).

ACKNOWLEDGEMENTS

BLOOD FLOW IN A RETINA CAPILLARY VASCULAR NETWORK WITH EXPLICIT BLOOD CELLS

Kacper Ostalowski, Jifu Tan

Department of Mechanical Engineering
Northern Illinois University
DeKalb, IL, 60115, USA

INTRODUCTION

According to the Center for Disease Control and Prevention, cardiovascular diseases is the leading causes of death in the United States [1]. Cardiovascular diseases, including heart attacks and strokes, occur when a clot blocks a blood vessel and leads to a reduction of oxygen supply into downstream tissues. In this work, we study the flow of blood cell suspensions on the local circulation of a capillary network in a realistic retina vascular network.

Blood flow in a vascular network has been studied previously using various methods. The effects of vascular occlusion on local flow rates were studied in Ref. [2]. Similarly, changes to flow characteristics were studied under vascular dilation and occlusion [3]. Simulations of hematocrit distributions throughout a microvascular network were performed [4].A hybrid multiscale model for simulations of large scale networks was introduced and applied to a large realistic vascular configuration [5]. A full pulmonary vascular tree has been reconstructed [6] and the geometry and temporal flow characteristics were studied. A reconstructed model of a rat brain microvascular network [7] was analyzed using the finite volume method, where the flow rates, velocities, and pressures were solved using hematocrit and shear-dependent fluid properties. A set of generalized microvascular networks [8] have been simulated using the finite volume method, with explicitly modeled red blood cells in the suspending fluid. Flow in a tree-like capillary network was simulated [9] using a network model, tracking the hematocrit levels through the capillary network.

In this work, we quantified the flow rate without red blood cells (RBCs) and with RBCs suspended in the fluid to investigate the effect of complex geometry and blood cell suspension on the flow in the complex retina vascular network. The effect of red blood cells on the flow properties in the vascular network was observed and quantified. In the upcoming part of the study, various blood vessels will be blocked off to simulate a microstroke and its effect on flow redistribution in the network. The same analysis will be performed comparing pure fluid flow to the flow of red blood cell suspensions for each microstroke location.

METHODS

The RBCs were modeled as a coarse grained molecular dynamics cell membrane model implemented in LAMMPS (large-scale atomic/molecular massively parallel simulator) [10]. The membrane nodal forces are calculated from potential functions, and the positions are updated based on the Newton's law of motion. Bonds, angles, and dihedrals are defined for the cell membrane. In our implementation, the red blood cell has energy potentials which resist stretching and bending and maintain the red blood cell's equilibrium surface area and volume. The red blood cell coarse grained membrane model (Fig. 1) can react to external forces and restore its equilibrium shape after deformation.

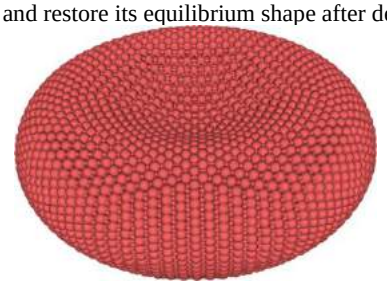

Figure 1: Red blood cell membrane model with particles connected with bonds.

The fluid flow was solved by the Lattice Boltzmann method using PALABOS [11]. The immersed boundary method (IBM) [12] was used to model fluid-cell interactions. The geometry of the retina network was

generated from a stl file obtained from NIH 3D print database (https://3dprint.nih.gov/discover/3dpx-005107). Off-lattice boundary conditions were used in between fluid nodes using linear interpolation for a smooth flow profile. Red blood cells were placed inside the network. Solid wall particles (Fig. 2) were placed at the vertices of the mesh to create a solid boundary for the red blood cells to interact with. The fluid velocity was defined at the inlet and the outlet of the retina network and the flow was developed until steady state was reached.

RESULTS

To analyze the flow in the retina vascular network, a few critical vessels were selected from the network, as labeled in Fig. 2. The diameter was calculated for each vessel of interest. The flow velocities were solved, and the volumetric flow rates were computed once the flow was at steady state. The flow rates of pure fluid and RBC suspensions were compared and are shown in Table 1. The largest difference in flow rates between pure fluid and RBC suspension occur in the main high-flow pathway between inlet and outlet through vessels C, D, and E. Vessels A and B are the only ones that did not see a change in flowrates between pure fluid and RBC suspension flow.

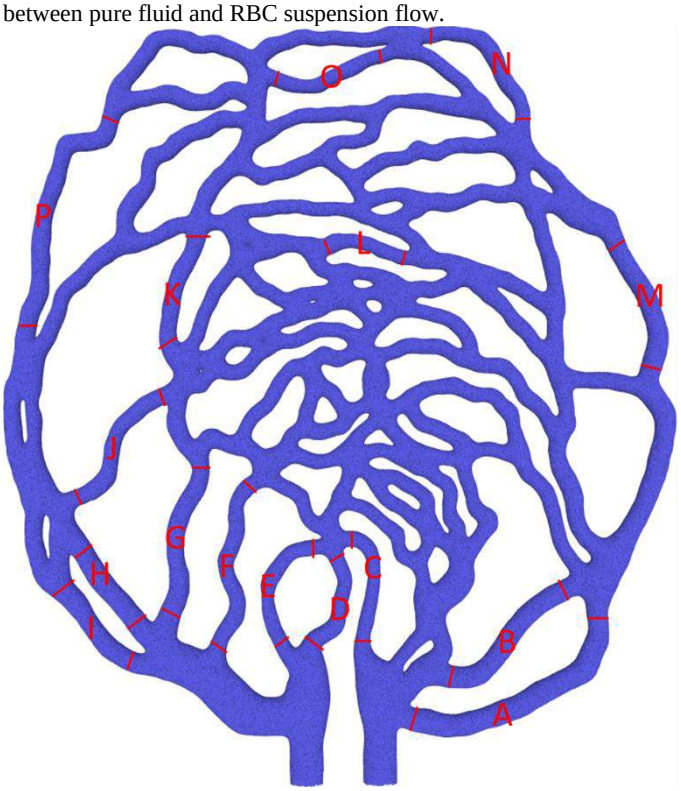

Figure 2: Retina capillary vascular network wall particles. Vessels of interest labeled A-P.

DISCUSSION

The pure fluid simulation shows the main pathways of fluid flow through the network. Vessel C acts as the main inlet into the short loop CDE, with D and E as outlets. Vessel G has the second highest flow rate in the network where it acts as the main outlet from the central region of the retina capillary network. Lowest flow rates were found in vessels K, L, N, and O, which are far from the inlet region. The four vessels also have other parallel vessels nearby which offer alternate fluid flow pathways.

The inclusion of red blood cells resulted in an overall decrease of flow rate through the vessels that were analyzed. The reduction of flow rate may be beneficial to allow for better exchange of oxygen between the red blood cells and the surrounding tissues. Further detailed analysis of the effects of hematocrit levels and microstrokes in the vascular networks will be presented at the conference.

EFFICACY OF COMBINATIONAL THERAPY ON BONE RESTORATION AND COMPENSATION AFTER CONTUSION SPINAL CORD INJURY

Valerie Lallo (1), Michael Feeley (1), Anita Singh (1)

(1) Biomedical Engineering
Widener University
Chester, PA, USA

INTRODUCTION

Spinal cord injury (SCI) can be detrimental to the patient's quality of life, and often leads to the loss of sensory and motor function below the injury site. As of 2020, SCI is seen in about 54 people per million residents of the US with approximately 17,810 new cases seen each year (1). Treatment is available in the form of active training rehabilitation techniques, but the effectiveness of combinational treatment, incorporating transplantation therapies along with rehabilitation, needs to be further investigated (2). This study evaluates the microstructural changes in the forelimb and hindlimb bones of adult rats that underwent incomplete SCI followed by combinational treatment, including scaffolds loaded with neurotrophins and body weight supported treadmill training (BWSTT).

METHODS

The Institutional Animal Care & Use Committee approved all procedures. Sprague Dawley rats (n=75) were split into five groups: a control group, a group that received no therapy after SCI, a group that received only active training (BWSTT) after SCI, a group that received only transplantation of neurotrophins after SCI, and a group that received both a transplantation of neurotrophins and active training (BWSTT) after SCI. As can be seen in Table 1, four of the five groups underwent SCI and eight weeks post their last surgery, the forelimb and hindlimb bones from all five groups were harvested. The harvested bones were then scanned using a SkyScan 1172 Micro-CT; these images were reconstructed and the regions of interest were drawn for the diaphyseal areas (Figure 1) of the bones using NRecon and CTan software, respectively. CTan was also used to a perform binary analysis on the reconstructed scans to acquire data.

Table 1: Details of experimental groups.

	Week 0	Week 1	Week 2	...	Week 8	Week 9	Week 10
Group 1	Normal	→			Harvest		
Group 2	Contusion	→			Harvest		
Group 3		BWSTT	→			Harvest	
Group 4		Transplant	→			Harvest	
Group 5		Transplant	BWSTT		→		Harvest

Figure 1: Regions of Tibial, Ulna and Humerus bone studied.

RESULTS

Changes in cortical parameters suggest that a combination of BWSTT and transplantation of a neurotrophin-releasing scaffold shows greater improvement than BWSTT by itself (Figure 2 and 3). This can be seen with Tibial decrease in cortical

BV/TV, when comparing Group 3 and Group 5 (Figure 3). In contrast to the hindlimb, the forelimbs' BV/TV of the cortical bone increased after injury due to compensation as observed commonly after SCI. Additionally in the forelimbs, animals in BWSTT (Group 3) and the combinational group (Group 5) had lower BV/TV when compared to injury (Group 2) and transplant (Group 4) animals, showing a decrease in overcompensation, and an increase in effectiveness of the therapy (Figure 3).

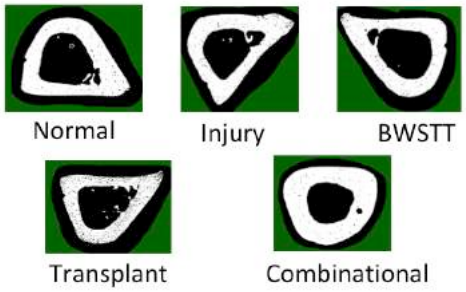

Figure 2: Diaphyseal scans of Tibial bone from all groups.

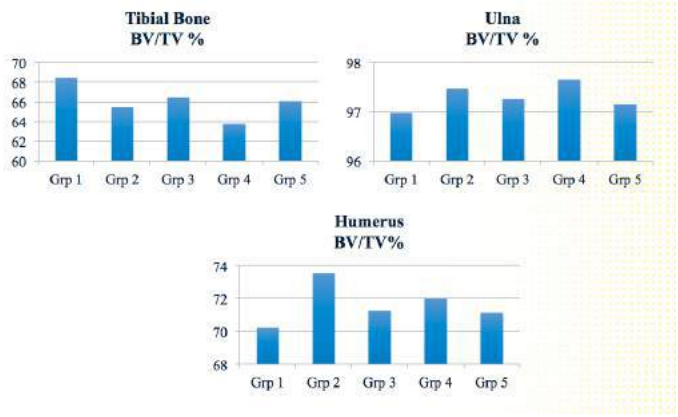

Figure 3: Structural parameters obtained from CT scans in Tibial, Ulnar and Humerus diaphyseal regions. Abbreviations and their respective meanings are as follows: BV/TV – bone volume over total volume.

DISCUSSION

SCI affects both the forelimb and hindlimb bones of rats, and BWSTT greatly helps restore some of the loss. While BWSTT leads to bone structural properties similar to normal rats, combinational treatment using a neurotrophin-releasing scaffold reports further improvement.

EFFECT OF SURGERY ON CORONARY FLOW HEMODYNAMICS IN CHILDREN WITH ANOMALOUS AORTIC ORIGIN OF A CORONARY ARTERY (AAOCA): A PATIENT-SPECIFIC COMPUTATIONAL STUDY

INTRODUCTION

AAOCA is a congenital defect where one coronary artery arises from the opposite sinus of Valsalva. Cross-sectional imaging often shows ostial stenosis, and an intramural course within the aortic wall of the anomalous coronary, which carry an increased risk of myocardial ischemia. AAOCA is the 2nd leading cause of sudden cardiac death (SCD) in children and may require life-long restriction from exercise [1] or surgery. There is controversy over the need for surgery, type of surgery, and residual risk of ischemia after surgery in AAOCA. The intramural course can be addressed by surgical procedures like unroofing of the intramural course or coronary artery reimplantation. While some groups favor unroofing as the primary option, with reimplantation restricted to specific conditions such as with a short intramural course [1], other groups advocate reimplantation as the primary approach [2]. The appropriate indication for each procedure, their effect on coronary morphology and blood flow patterns, and their short-term and long-term risk of residual or recurrent ischemia have not been systematically investigated. Recently it has been suggested that factional flow reserve (FFR) measurements (approximated as the ratio of pressure distal to the stenotic lesion to the pressure measured proximal to the lesion) can be used to identify hemodynamic significance in anomalous coronary arteries with FFR <0.8 as a threshold for ischemia [3]. There is an urgent need to develop physical and computational hemodynamic models of AAOCA in the pre-operative and post-operative period to explore mechanistic questions since hemodynamic assessment is not routinely performed in children with AAOCA. The objective of this work is to create patient-specific computational models of AAOCA, characterize local hemodynamics related to morphological variations in AAOCA pre-/post- operatively and assess hemodynamic effects of surgery using biomechanical flow modeling as well as virtually derived FFR (vFFR). Findings from this study may provide mechanistic insight into the cause of ischemia and eventually lead to improved surgical decision making, and assessment of residual risk after surgery.

METHODS

After Institutional Review Board approval, patient-specific geometries were reconstructed from computed tomography angiography (CTA) in a patient with anomalous left coronary artery (AAOCA-L), with a short 3.5 mm intramural course, who presented with SCD. He was treated with unroofing of the intramural segment and developed recurrent SCD. Repeat surgery demonstrated the intercoronary pillar as the cause of ischemia requiring coronary reimplantation. For computational model development, validity of the image segmentation and reconstruction method has been previously assessed by our group. A set of boundary conditions were assigned at the models' inlet and outlets to solve for the governing blood flow equations. At the inlet, aortic flow waveform was used from the in-vitro set-up of the current work with cardiac output of 5 L/min and heart rate 72 beats/min We used a coupled multi-domain method previously developed [4] in which 0D lumped parameter network (LPN) models are assigned at coronary outlets. Parameters of the LPN model were determined based on a robust protocol to capture physiologic flow and prescribed blood pressures (BP) [5]. Systolic and diastolic aortic BP were set as120mmHg/80mmHg. Geometries were then meshed using tetrahedral elements. Since our geometries include multi-scale dimensions (i.e., the size of the aorta is about one order of magnitude larger than the size of the coronary artery), mesh elements sizes were assigned proportional to the size of the arteries using the "local mesh" option. Regional mesh refinement was also performed to generate more elements for locations with high velocity gradients and expected flow disruptions. A mesh size of (600-800) K elements were used for the simulations. Blood was modeled as an incompressible Newtonian fluid

with a density of 1.06 g/cm^3 and viscosity of 4 cP. The artery walls were modeled as rigid. Solutions were run for (6-8) cardiac cycles until BP and flow at the inlet and outlets did not change more than 1%. Data including flow, pressure and velocity from the last cycle of each simulation were used for visualization and analysis using SimVascular (simtk.org), Paraview (Kitware, Clifton Park, NY), and Tecplot (Tecplot, Inc., Bellevue, WA) software packages and compared pre- vs post-unroofing and reimplantation.

RESULTS

Axial CTA of the aorta and the left coronary artery is depicted in Figure 1(A) for the patient preoperatively (PRE), post-unroofing (POST-1) and post reimplantation (POST-2). The reconstructed 3D model includes aorta, normal right coronary, and anomalous left main coronary artery. Results for the representative flow waveform show that physiologic phasic coronary behavior has been captured by the imposed BCs. Figure 1(B) shows that for the left coronary artery, minimum flow occurs during systole and the peak flow occurs during diastole. Contours of pressure distribution within the reconstructed models are indicated for the peak coronary flow in Figure 1(C). Pressure drop was highest (≅12 mmHg) for PRE in the anomalous artery during maximum coronary flow. This pressure drop was decreased POST-1 (≅8 mmHg) and POST-2 (≅6 mmHg). The pressure recovery was higher POST-2 compared to the POST-1. Therese pressure drops corresponds to vFFR values of 0.9, 0.93 and 0.95 for PRE, POST-1, and POST-2, respectively.

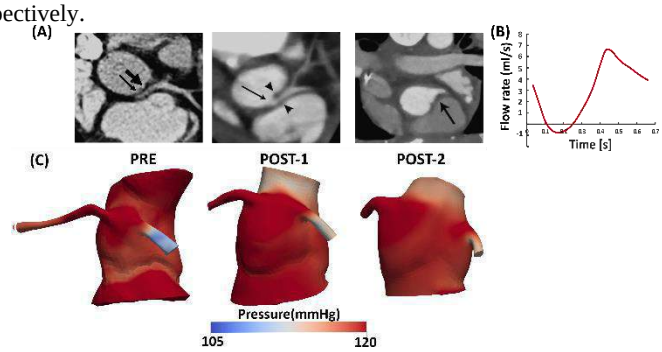

Figure 1: (A) Axial CTA of the aorta and the anomalous left coronary pre-operatively (PRE), post-unroofing (POST-1), and post coronary reimplantation (POST-2), (B) flow waveform at the left coronary outlet, (C) contour distribution of pressure in the patient PRE, POST-1, and POST-2

Contours of the velocity distribution as well as the streamlines are shown at a plane through the length of the anomalous artery for the peak coronary flow. For PRE, a complex flow pattern is observed distal to the coronary ostium. There is local accelerated flow region which forms a neck in the distal intramural segment. Flow recirculation zones are also observed in the anomalous coronary artery as highlighted by the streamlines. For POST-1, the complex flow behavior seen in PRE has been resolved. However, there is a spiral flow observed which is deviated towards the outer wall. For POST-2, streamlines are aligned with the anatomy and there is almost no localized flow acceleration compared to the other two models.

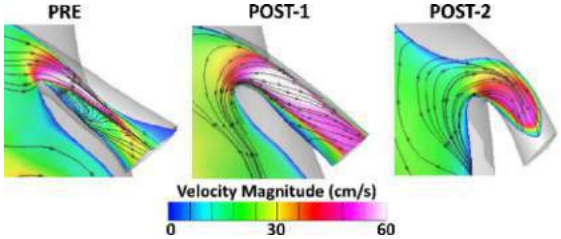

Figure 2: Contour distribution of velocity and streamlines in the patient pre-operatively (PRE), post-unroofing (POST-1), and post coronary reimplantation (POST-2)

DISCUSSION

This computational study is the first one which assesses coronary flow and pressure in an AAOCA patient who had both coronary unroofing (POST-1) and reimplantation (POST-2). We observed that the coronary flow was altered by the surgery and affected by the type of surgery. The jet flow with localized acceleration was observed pre-operatively due to the presence of the intramural segment (Figure 1 (A), PRE) which resulted in recirculation regions with increased energy dissipation. The energy dissipated in the intramural segment caused the pressure to drop and FFR to decrease. The complex flow pattern and wash-out was improved POST-1 but there was a helical flow leaning towards the outer wall that can be attributed to the intercoronary pillar which acted like ostial stenosis (Figure 1 (A), POST-1). The flow behavior was almost fully resolved POST-2 in which there was no residual intramural segment and localized flow acceleration (Figure 1 (A), POST-2). The ostium located in the correct sinus also provided a more streamlined flow similar to the flow patterns observed in normal coronary arteries. The energy dissipation was recovered and FFR increased consequently. Our results are in agreement with [6] where similar flow behavior was observed in the anomalous artery of a representative AAOCA-L model. Our vFFR data showed values >0.8 for the PRE and POST states. However, it should be noted that these calculations were performed for the nominal blood pressures 120 mmHg/80 mmHg which are below the blood pressures under maximum hyperemic conditions for which FFR is commonly calculated [7, 8].

The first limitation of the study is that the aortic valve was not included in the simulations. Nonetheless, the realistic BCs implemented will lead to temporal physiologic pressure gradients within the model, despite absence of the physical valve. We also assumed the walls to be rigid. Although we are aiming at including deformable walls for the future analyses, it is of note that material properties of the coronary arteries will not be patient specific due to limited data regarding coronary artery material properties of the adult or pediatric population in either healthy or diseased conditions. Furthermore, movement of the coronary arteries was not considered in this study since the effect of coronary artery motion has been shown to be secondary as compared to the geometry and BCs [9, 10].

We conclude that the type of surgery influences the local flow hemodynamics and FFR. Finding from the current study, once validated against the ongoing in-vitro experiments in our group, will allow us to design virtual surgical procedures for ultimate use in predicting the need for and type of surgery and residual risk of SCD after surgery.

INTRODUCTION

Smooth muscle cells (SMCs) form a connected layer that lines tubular organs in the cardiovascular, respiratory, digestive, and reproductive systems, and are responsible for constricting the lumen and regulating flow. Theoretical and experimental studies have treated smooth muscle as a homogenous ensemble of identically behaved cells, contributing equally to total force generated[1–3]. However, recent studies have shown that not only do SMCs respond to contractile agonist differently when they are isolated cells or part of a connected multicellular ensemble[4], but also that this connectivity between cells can change depending on underlying extracellular matrix (ECM) stiffness. ECM stiffness can cause cells to preferentially connect to each other directly via cell-cell adherens junctions (AJs), or indirectly via cell-matrix focal adhesions (FAs)[5] (**Fig 1**). Therefore, is it impossible to infer the force dynamics of a smooth muscle layer by scaling up the contractile response of a single cell by the number of SMCs present.

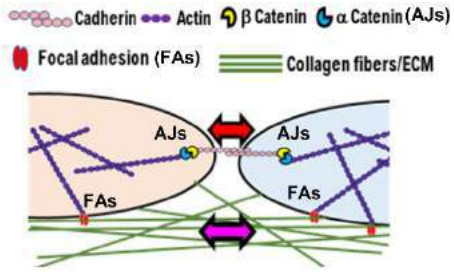

Figure 1: A schematic depicting mechanical connectivity between cells. Cells can connect directly to neighbor cells via cell-cell adherens junctions (AJs) or indirectly through the extracellular matrix (ECM) via focal adhesions (FAs).

In this study, we investigated dynamic intercellular coupling of SMCs undergoing agonist-induced constriction. By measuring traction forces and monolayer stresses within a multicellular ensemble over time, we were able to quantify the contractile moment of each cell as well as the pathway of force transmission between cells. Using this new method will help shed light on the mechanisms regulating the force transfer among a multicellular SMC ensemble, and improve our understanding of how SMCs regulate flow through airways, vasculature, and other organs, *in vivo*.

METHODS

Primary bronchial smooth muscle cells from healthy human donors (passage 3-7) were grown to confluence on collagen-coated silicone substrates with Young's modulus (E) of 13 kPa. The surface of the substrates was coated with fluorescent microspheres for displacement tracking prior to cell culture.

After serum starvation, the cells and microspheres were continuously imaged with a 20x objective at 1Hz for 1 minute at baseline followed by exposure to 10^{-5}M histamine, a contractile agonist, for 5 more minutes. A final phase contrast image of the cells was captured before removing the cells with lysis buffer to record the zero-displacement image of the microspheres.

In order to calculate intercellular coupling between cells, we first tracked microsphere displacements due to cell constriction over the course of the experiment using a particle velocimetry tracking algorithm adapted from Janke et al[6]. The resultant displacements were input into a Fourier transform traction force microscopy method using Bayesian regularization for noise filtering, modified from Huang et al[7]. The resulting traction vectors quantifying the cell stress exerted on the matrix were taken into a monolayer stress microscopy (MSM) code, adopted from our collaborator Dr. Dhananjay Tambe's work[8–10]. The

MSM algorithm uses the TFM inputs in a 2D force-balance equation to solve for mechanical forces within the layer of cells, which are then converted into stresses. Stresses at cell-cell borders were calculated using MSM stresses at points along cell borders demarcated by the phase contract image. Cell-matrix traction forces were calculated using the TFM forces over the area of the cells demarcated by the phase contrast image.

To evaluate the path of force transmission among cells undergoing constriction, we calculated each cell's net contractile moment, μ as well as a dimensionless ratio, Ψ, that varies from 0 to 1, and is defined as the fraction of the total contractile moment that a SMC exerts on its neighboring cells through AJs. As Ψ → 1, the cell's force is transmitted to its neighbors entirely through AJs. As Ψ → 0, the cell's force is transmitted entirely through FAs. This value is calculated for each cell over the course of the experiment.

RESULTS

Upon exposure to contractile agonist, the average net contractile moment of the SMCs increased over a period of approximately 60 seconds, but then held steady for the remaining 4 minutes of agonist exposure (**Fig 2A**). This indicates that there was an increase in SMC force. However, corresponding Ψ measurements show that intercellular coupling was continuously changing. When normalized to baseline, the mean Ψ value across cells decreased significantly over time (N=17, $p<0.05$, One-way ANOVA over time) (**Fig 2B**). This indicates that the cells were losing their direct coupling with neighboring SMCs via AJs, and dynamically switching to transmit force via FAs.

DISCUSSION

Smooth muscle is responsible for regulating flow through tubes in our body by constricting and controlling luminal area. In order to constrict these tubes, the SMC force must be transmitted through a percolating path around the circumference. Cells can communicate mechanically with other cells in two ways; by sending force directly to adjacent cells via adherens junctions, and by sending force to cells nearby and farther away through cell-matrix connections called focal adhesions. A recent study by Polio et al.[5] found that this path of preferred force transfer between cells can switch depending on underlying matrix stiffness. However, these studies were done at baseline, static conditions without addition of contractile agonist. Therefore, we asked if this force transfer pathway can change over time, and how it may change as cells undergo constriction.

To investigate dynamic force transmission, we recorded displacements of surface-adhered microspheres as cells constricted in response to agonist and used these displacements to calculate traction forces that cells exert on the matrix as well as stresses within the confluent monolayer that cells exert on each other. For each cell, we found the moments due to cell force exerted on its border, and therefore directly onto neighboring cells through AJs, and also the moments due to cell force exerted directly on the underlying substrate through FAs. Together, these moments gave the net contractile moment of each cell, μ. We also used a dimensionless metric, Ψ, comparing the moments due to cell-cell and cell-matrix forces, to quantify changes in force transfer pathway over time.

Upon agonist exposure, we found that the SMCs increase force over about 60 seconds, which matches published data on force development in this cell type[11]. The mean net contractile moment remained steady after this period. On the other hand, the psi value changed throughout the course of agonist exposure. While being exposed to histamine, the mean normalized Ψ value decreased significantly, indicating that the force transfer pathway was dynamically changing. Decreasing Ψ values shows that the force transfer pathway is

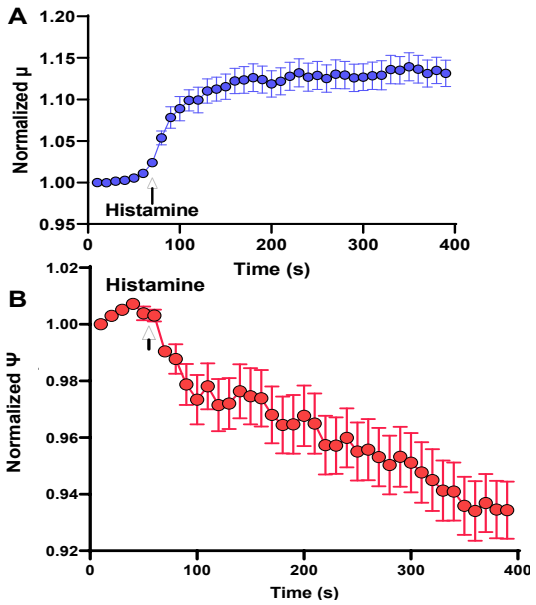

Figure 2: **We measured variations in the (A) contractile moment (μ) and (B) intercellular coupling (Ψ) for N=17 human bronchial SMCs. Symbols indicate mean and error bars indicate standard deviation. As the SMCs start to constrict, their direct cell-cell coupling (AJs) weakens in favor of focal adhesions, and more force is transmitted through the matrix.**

transitioning from cell-cell to cell-matrix as time goes on. These results indicate that cells change their connectivity from one moment to the next, and so we cannot infer dynamics of force transmission among smooth muscle by simply counting number of cells from static histology slices of airways, vasculature, and other organs.

This is the first time a technique has been able to decipher how force flows through a multicellular ensemble while also being able to quantify the contribution of each cell to the total force generated by the ensemble. Further investigation of the mechanisms regulating how cells actively modulate the path of force transmission has implications for understanding basic physiology as well as how constriction goes awry in disease conditions like asthma and hypertension.

THE ROLE OF GLYCOSAMINOGLYCANS IN ANTERIOR AND POSTERIOR SCLERAL SWELLING AND TENSILE BEHAVIOR

Mohammad Pachenari, Hamed Hatami-Marbini

INTRODUCTION

Many investigations have observed that scleral stiffness had the most dominance on ONH biomechanics [1,2]. The sclera is a hydrated tissue comprised of collagen fibers, elastin, proteoglycans, glycosaminoglycans (GAGs), and water molecules [3]. The assessment of scleral biomechanical properties is essential for better understanding the progression of a number of ocular diseases. For example, alteration in scleral biomechanical properties has been associated with the onset and further progression of pathological conditions such as myopia and glaucoma. It has also been shown that the content of scleral GAGs changes during normal growth, contributing to the regional alterations in scleral biomechanical properties [4]. Previous reports mainly examined the changes in the mechanical response and/or hydration-of the posterior sclera [5,6], and possible regional dependent structural roles of GAGs on sclera mechanics were not well characterized. In the present study, we investigated how GAG removal affects the tensile and swelling behavior of anterior and posterior porcine sclera. To this end, we meticulously tracked the hydration changes over time for anterior and posterior porcine sclera specimens before and after GAG removal treatment. The biochemical assay was also used to confirm the GAGs digestion method and measure the anterior- and posterior-GAG content of porcine samples. Followed by the hydration study, we performed uniaxial tensile stress-relaxation tests to characterize the mechanical behavior of the scleral strips after and before GAG removal. The findings characterized the regional differences in the scleral swelling and tensile properties in addition to clarifying the role of GAGs in hydration and mechanical response of sclera.

METHODS

The strip of size 4×12 mm^2 were dissected from anterior and posterior porcine sclera (Figure 1). The anterior/posterior samples were divided into two groups: buffer group and enzyme group. Following the protocol described in our recent studies [7,8], the samples in the enzyme group were treated enzymatically in 0.125 U/ml Chondroitinase ABC (ChABC) to remove the GAGs. We used the biochemical assay to measure the GAG content in the anterior and posterior by using scleral disks and confirm the GAG removal procedure was successful.

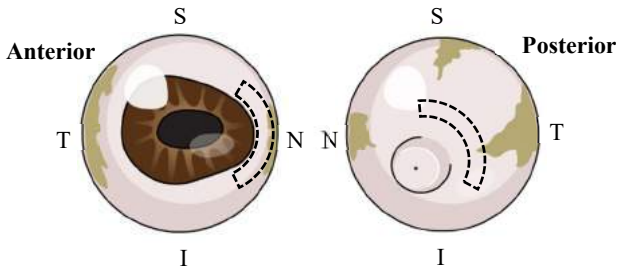

Figure 1: The dissection site of the anterior and posterior strip. S: Superior, I: Inferior, T: Temporal and N: Nasal.

We first let all samples after dissection to be dried in a desiccator for 24 hours in order to obtain their dry weight. The dry weight of samples is required to determine their hydration knowing their wet weight. Then, we soaked all samples in the buffer solution (containing no enzyme) for 24 hours and allowed them to rehydrate. During the rehydration period, we measured the wet weight of samples at certain time intervals in order to determine the hydration as a function of time. Then, the samples in the buffer group were allowed to stay in buffer for another 18 hours while the samples in the enzyme groups were immersed in the enzyme solution to deplete the GAGs from these samples. After measuring the weight of samples in both groups, they

were immersed in buffer solution (containing no enzyme) for four hours and their hydration was found as a function of time by measuring their wet weight. Then, all samples were dried again for 24 hours in a desiccator and later soaked in the buffer solution for 24 hours to measure the changes in the sclera hydration because of GAG removal. Finally, the strips were mechanically tested using a stress relaxation uniaxial experiment to determine the possible effects of GAGs removal on the sclera mechanical properties. Here, the strips were pulled with a displacement rate of 2 mm/min until an engineering strain of 5% was reached and were then allowed to relax for 20 minutes. The tensile stress was found from dividing the force by the initial cross-section of the samples. The stress at the end of the ramp period was denoted as the peak stress and the stress at the end of the relaxation time was called equilibrium stress.

RESULTS

The scleral GAGs content was obtained for the buffer-enzyme comparison in the anterior and posterior sclera (Table 1). Regional GAG content was significantly different, as the posterior specimens have, on average, 101.5% higher content of GAGs than anterior. The GAGs content was significantly different between buffer- and enzyme-treated groups in both anterior and posterior. The scleral hydration was obtained for buffer-enzyme comparisons in the anterior and posterior sclera (Figure 2). Hydration was the same for the buffer and enzyme groups before treatments. In the anterior and posterior specimens, enzyme digestion decreased the hydration immediately after the treatment. We compared the peak and equilibrium stress from the stress relaxation experiment between buffer and enzyme-treated, the results showed a significantly stiffer peak and equilibrium stress for anterior and posterior (Table 2).

	Buffer group	Enzyme group
Anterior	3.21 ± 0.34	0.1 ± 0.02
Posterior	6.46 ± 0.24	0.69 ± 0.2

Table 1: GAG content in µg/mg dry tissue weight, comparing the buffer-treated to the enzyme-treated specimens.

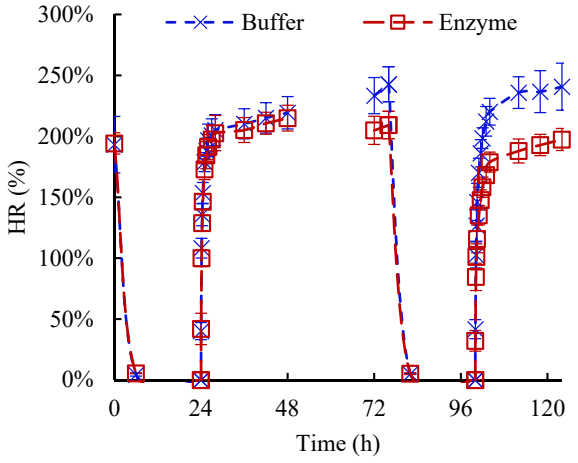

Figure 2: The average results of the hydration study on anterior strips; the plot shows the sample's water content in percentage during the experiment. The bars represent the standard deviations.

	Anterior		Posterior	
	Buffer	Enzyme	Buffer	Enzyme
Peak stress	54.2 ± 28.5	143.5 ± 51.6	85.3 ± 13.5	121.1 ± 13
Equilibrium stress	7.2 ± 3.2	21.6 ± 9.4	28 ± 8.4	45 ± 7.7

Table 2: Comparison of the peak and equilibrium stress (KPa) between the buffer- and enzyme-treated groups.

DISCUSSION

In the present study, anterior-posterior GAGs content and hydration, in addition to tensile properties, were characterized to explore how GAGs contribute to the sclera microstructural and biomechanical integrity. In our study, the posterior porcine specimens have a higher content of GAGs compared to anterior ones. These GAGs contents agree with in the human sclera, which showed a relatively same difference, comparing anterior to posterior. The results of this study suggest that GAGs are responsible for the hydration and swelling properties of sclera. Although a few studies in the past have suggested contradictory results for GAGs depletion in the sclera, this study is novel because it measured hydration changes and viscoelastic behavior simultaneously in order to identify the effects of GAGs in sclera properties. The present study also characterized the sclera swelling and mechanical properties in the posterior and anterior region. Despite its important findings, we should note that uniaxial tensile experiments do not measure the mechanical response of sclera in physiological conditions and experimental methods such as inflation tests can be used in future studies to see if they also give similar results.

INTRODUCTION

Upon laser stimulation plasmonic gold nanoparticles (AuNPs) can absorb light and convert that energy into heat [1], allowing AuNPs to serve as effective nanoheaters for applications such as hyperthermia-based cancer treatments [2] and selective inactivation of proteins via Molecular Hyperthermia [3,4]. However, pulsed laser induced heating of AuNPs can result in elevated lattice temperatures which promote particle degradation via melting and fragmentation [5]. Understanding how key thermal transport properties relate to AuNP structure and particle size, may allow for better rational tuning of nanoparticle properties in order to reduce or avoid unwanted particle degradation during laser stimulation.

Under laser stimulation AuNPs dissipate heat with a finite thermal interface conductance into the surrounding solvent [5]. This thermal interface conductance (or its inverse the Kapitza resistance) is a key parameter affecting the kinetics of heat dissipation from the nanoparticle [1], and it is a principal regulator of nanoparticle temperature during laser heating. We hypothesized that smaller AuNPs with larger particle-solvent interface curvature would have more efficient heat dissipation as measured by their thermal interface conductance. The objective of this work was therefore to use atomistic Molecular Dynamics simulation to investigate the effects of curvature on the heat transfer through the nanoscale gold-water interface. Our key finding thus far was that nanoscale gold-water interfaces with higher curvature had higher thermal interface conductance. In the case of spherical AuNPs, this meant that smaller particles had higher thermal interface conductance, corresponding to more efficient heat dissipation and thus lower AuNP temperatures for comparative heating power densities during steady-state heating.

METHODS

We constructed four atomistic models of nanoscale gold immersed in water. The first system was composed with a planar gold slab which was periodic in the x and y dimensions. The other three systems were composed with spherical AuNPs with diameters 3 nm, 5 nm, and 10 nm (Figure 1). Spherical AuNPs were cut from a block of Au(111).

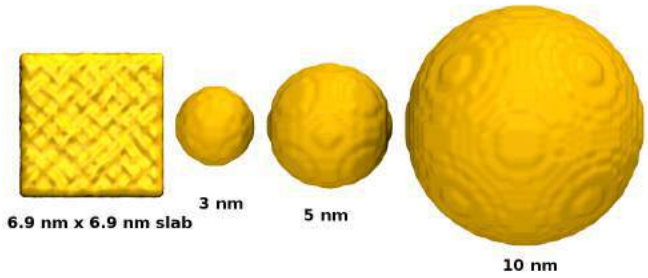

Figure 1: Nanoscale gold structures used in the simulated gold-water systems.

Gold-gold interactions were modeled using the Embedded Atom Model [6]. Water was modeled using the flexible SPCE-

F potential [7]. Gold-water interactions were modeled using 12-6 Lennard-Jones potential with parameters from Chen et al. [8]. All simulations were carried out with the LAMMPS software [9] using periodic boundary conditions. Nanoscale gold-water systems were first equilibrated for 1 nanosecond at 300 K under NVT conditions and then further equilibrated for 1 nanosecond at 300 K and 1 atm under NPT conditions. Laser stimulation was modeled using nonequilibrium molecular dynamics simulation at 1 atm under NPH conditions with continuous uniform heating of gold while a surrounding water pool (heat sink) was maintained at 300 K. Laser heating simulations were run for a total of 4 nanoseconds – the first 1 nanosecond was used to establish a steady-state and was not included in subsequent analysis. Analysis was carried out using custom Python code.

RESULTS

Our key finding thus far was that the thermal interface conductance of the nanoscale gold-water interface scaled linearly with interface curvature, so smaller AuNPs (curvature = 1/R) had higher thermal interface conductance (Figure 2 A).

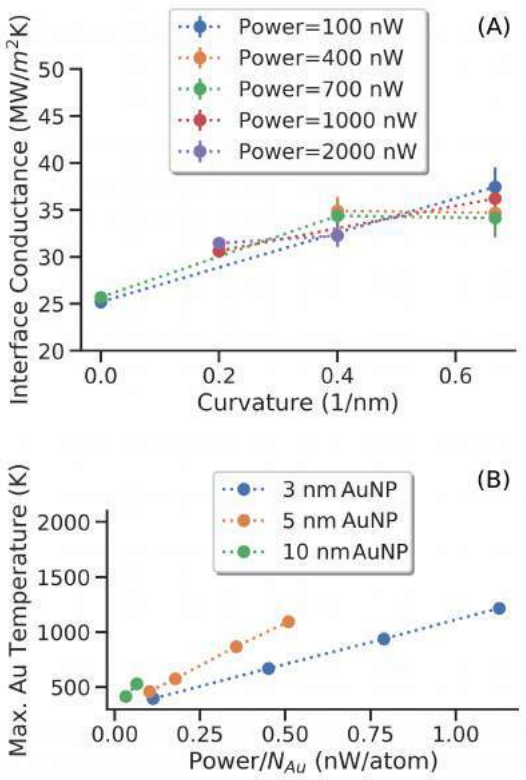

Figure 2: (A) Interface conductance versus nanoscale gold surface curvature at various total heating powers. (B) Maximum gold temperature versus heating power density for the three spherical AuNPs.

As a result, under similar heating power densities (power per gold atom) the smaller AuNPs with fewer gold atoms experienced lower gold lattice temperatures (Figure 2 B) which was consistent with more efficient heat dissipation.

DISCUSSION

We have constructed four atomistic models of nanoscale gold in water which were subjected to steady-state heating in order to estimate the effects of curvature on the gold-water heat transfer. Our results thus far have indicated that the thermal interface conductance between nanoscale gold and water increases with interface curvature. This trend is consistent with that reported by Tascini et al. [10] for nanospheres in liquid. However, it is in contrast to the results reported for molecular dynamics simulations of AuNPs in hexane [11] in which the thermal interface conductance between nanoscale gold and hexane decreased with interface curvature. Overall, previous molecular dynamics simulations [8, 10-12] suggest that the thermal interface conductance of nanoparticles is largely governed by two interrelated factors: i) overlap between the vibrational density of states of the nanoparticle lattice and solvent, and ii) adsorption of the solvent onto the surface of the nanoparticle. As such, we are currently investigating the role of these two factors in the curvature dependence of thermal interface conductance between nanoscale gold and water.

INTRODUCTION

Neurite polarization and arborization give rise to the distinct morphology of neurons and development of functional networks. Dotti et al. were among the first to characterize the morphology as the neurites develop into axons and dendrites [1]. The growth of these processes was qualitatively described into distinct stages for different neurons (e.g., hippocampal [1] and cerebellar granule [2]) [3]. With only qualitative characteristics, it is challenging for non-experts to identify the growth stage of an individual cell and determine when it has fully transitioned to a subsequent stage. Quantitative representations defining each growth phase are needed to accurately describe the neurite development process and for validation of neuron growth simulations in the future. In addition, neurite growth directions are influenced by various extracellular and intracellular factors to form functional networks. Thus, when observing the morphological development, it is crucial to identify locations at which the neurite redirected the direction of growth.

To identify locations of redirection in meandering paths, the change-point test (CPT) was previously developed to study animal travel [4]. This is analogous to identifying points along a neurite trajectory to determine when the path changed direction due to potential extracellular and intracellular sensory cues. However, to our knowledge, this approach has not yet been assessed for applicability in quantifying and comparing neuron growth stages. By identifying these points, further studies on neurite development can quantifiably determine whether a potential cue directed the change in neurite growth.

Additionally, morphological features, such as tortuosity and number of neurites, have been compared to distinguish different neuron types [5]. However, quantitative metrics have not been identified for defining neurite developmental stages. Therefore, this work compares CPT and morphological feature metrics from primary rat hippocampal neurons to characterize neurite morphogenesis.

METHODS

To assess neurite development, rat hippocampal neurons (A36513, Gibco, USA) were cultured (Figure 1A) per the manufacturer's protocol [6] at 10,000 and 20,000 cells/cm^2 on cell-culture-treated 48-well plates (150687, Nunc, USA). Prior to plating, the wells were incubated for 1 hour at room temperature with a poly-D-lysine (A3890401, Gibco, USA) solution, diluted to 50 µg/mL with 0.5 M borate buffer (PI28341, ThermoScientific, USA). Subsequently, the solution was aspirated, and the plate was rinsed with Dulbecco's phosphate buffered saline (14190144, Gibco, USA). Plated cells were imaged with phase contrast and brightfield microscopy (Echo Revolve 4, inverted) under 20X and 40X magnification at 0.5, 1, and 2 days *in vitro* (DIV) (Figure 1B-C), which correspond with Stages 2-3 in neurite growth.

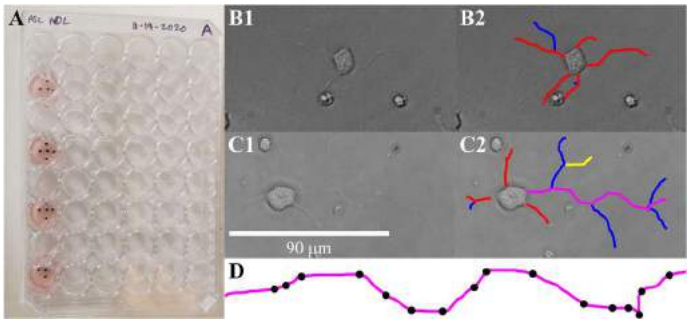

Figure 1: (A) Neurons were cultured per manufacturer protocols. Dots were drawn on the bottom of the plate prior to culture to facilitate neuron location. (B-C) Cells were imaged and traced at 0.5 (not shown), 1 (B1-2), and 2 (C1-2) DIV. (D) The CPT identified change points. The trace in D is the fuchsia trace in C2.

Neurites were semi-automatically traced with NeuronJ [7] in the Fiji [8] distribution of ImageJ [9] (Figure 1B-C). Length, tortuosity, number of neurite end points (degree) per cell, and number of neurites per cell were measured from the traces. Additionally, locations of significant direction changes in each trace were identified using the CPT (Figure 1D) [4]. The CPT decomposes tortuosity into growth length before a direction change (segment length) and the neurite growth direction (turning angle) for each segment. The CPT was applied 10 times to each trace with a significance level (α) of 0.5, while varying the number (q) of vectors prior to a change point from 1 to 10. The smallest q with the most points was selected to measure the segment length between direction changes. Relative turning angles were also measured for each neurite segment.

For all morphological features, the distributions were assessed for normality using the Anderson-Darling test. The distributions were found to be not normal; thus, the nonparametric Mann-Whitney test was used to determine whether there were statistically important differences between the medians of each feature between different culture ages.

RESULTS

The distributions of the morphological features were overall skewed to the left (Figure 2 for segment length as a characteristic example). The features were significantly different between 1 and 2 DIV, except for the relative turning angle at a density of 20,000 cells/cm^2 and for the number of neurites at a density of 10,000 cells/cm^2 (Table 1). Trace length at 20,000 cells/cm^2, segment length, degree, and number of neurites were significantly different between 0.5 and 2 DIV (Table 1). Only degree and number of neurites, both at a density of 10,000 cells/cm^2, were significantly different between 0.5 and 1 DIV.

DISCUSSION

For the time frame monitored for this study, the morphological features quantified were expected to have less change from 0.5 to 1 DIV and to change significantly by 2 DIV. Hippocampal neurons are expected to reach Stage 2 at around 0.5 DIV, with about half of them reaching Stage 3 by 1 DIV [1,10]. By 2 DIV, over 80% of the neurons should have transitioned from Stage 2 to 3 [1,10]. Several features investigated exhibited significant changes between 1 and 2 DIV. However, turning angle and tortuosity were not able to distinguish between 0.5 and 2 DIV, but still captured a significant difference between 1 and 2 DIV. This could indicate these features do not strongly correspond with the developmental stages.

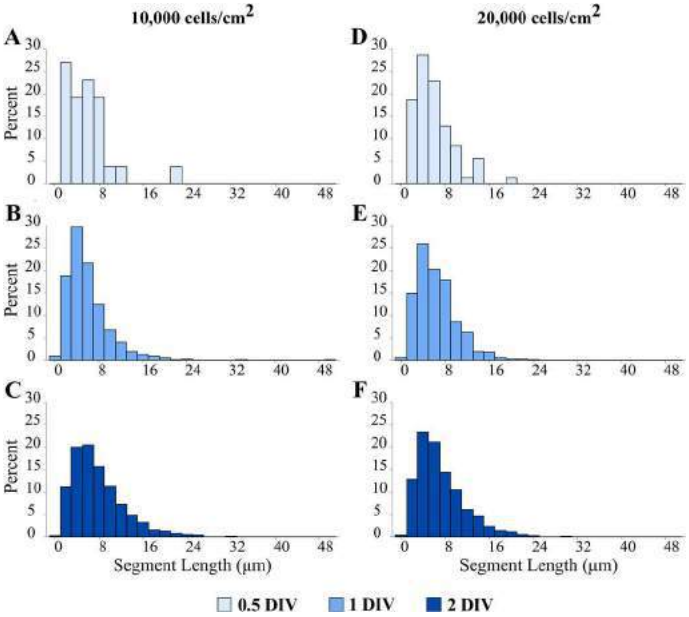

Figure 2: Distribution of segment length measured for neurites at a density of (A-C) 10,000 cells/cm^2 and (D-F) 20,000 cells/cm^2 at a culture age of (A, D) 0.5 DIV, (B, E) 1 DIV, and (C, F) 2 DIV.

In addition to standard morphological features investigated, potential new characteristics to quantify the neurite development process were identified using the CPT [4]. Additional studies manipulating neurite direction should be implemented to determine if the CPT can capture intentional directional changes. Overall, the CPT has potential use for identifying directional changes, but only segment length could distinguish neurons at 2 DIV from those at 0.5 and 1 DIV.

Complementing the qualitative descriptions of neurite growth stages with the CPT and quantitative metrics, particularly segment length, degree, and number of neurites can more clearly describe neurite morphogenesis. However, more studies at additional developmental stages are needed to fully characterize the process. Identifying relevant metrics simplifies tracking of neurite development and exhibits potential for direct comparison of experiments with mathematical neuron growth models, thereby supporting model validation.

INTRODUCTION

Current research has begun to investigate combining the techniques of tissue scaffolds and ultrasound stimulation to enhance bone growth [1-4]. However, these studies have mainly focused on how ultrasound interacts with the tissue and a lack of understanding remains in how the ultrasound wave energy distribution occurs within the scaffold, which will also affect the response of tissue to mechanical stimulation. This study hypothesizes that different pore shapes can cause higher or lower wave transmission at constant porosity. It is also hypothesized that the bioinspired scaffold from Gu et al., which is shown to be more resistant to deformation compared to scaffolds with uniform square or hexagonal pores [5], can maintain a high ultrasound transmission to enhance cell growth compared to pore geometries of uniform shape. This would be useful for addressing the issue of designing a scaffold structure with a high structural integrity that also does not impede tissue growth.

METHODS

In this study, we use finite element method (FEM) simulations and experiments with 3D-printed scaffolds composed of Acrylonitrile butadiene styrene (ABS) as a proof of concept to predict the effect of pore shape and wave signal frequency on acoustic wave scattering and transmission in porous scaffolds at constant porosity. The pore shapes studied are solid, square, hexagon, and a bioinspired geometry as shown in Figure 1.

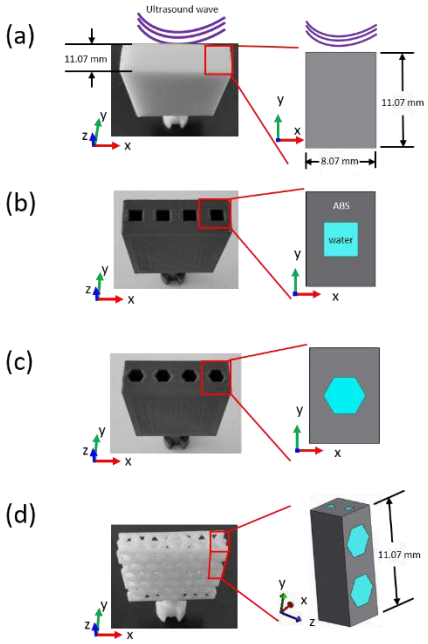

Figure 1: The scaffold structures studied are shown in the center of the figure. On the left side of the figure are the experimental scaffolds made from the unit cell, and on the right side of the figure are the finite element models made from the scaffold unit cell. The scaffold pore structures are (a) solid, (b) square, (c) hexagonal, (d) and bioinspired.

We predict the ultrasonic transmission and visualize solid displacements as the wave propagates, with the simulations performed using FEBio [6]. The ultrasound signal is a single sinusoidal pulse at frequencies of 1, 2.25, 5, 7, and 10 MHz with an amplitude of 1 μm. The transmission T is calculated as the amplitude of the transmitted wave divided by the amplitude of the input wave. An exponential curve is fitted to the transmission data points using Equation 1, which experiments has shown to be the relationship between transmission and frequency [7]. In Equation 1, α_o and η are fitting coefficients, f is the wave frequency, and d is the distance the wave travels and is 11.07 mm.

$$T = e^{-[\alpha_o d(2\pi)^{\eta}]f^{\eta}} \quad (1)$$

For the experiments the ABS scaffold fabrication is carried out using the 3D printing capabilities of the University of Arkansas Mechanical Engineering Department while the ultrasonic testing is conducted using Olympus Immersion ultrasonic transducers connected to a JSR DPR500 DUALPulser/Receiver and a Tektronix TBS 1000B oscilloscope.

The bone cell growth algorithm used is from Byrne et al. [8] and is written in MATLAB. For the growth simulations, the pores of the scaffold are filled with granulation tissue and the structure undergoes compression at 2 MPa. The simulations are also performed on the scaffold structures while also receiving compression and ultrasound stimulation at a frequency of 1 MHz. The scaffold is modeled as an isotropic solid while the granulation tissue is modeled as a biphasic material of an isotropic solid and Newtonian fluid. Initially, the granulation tissue is randomly seeded at 1% with mesenchymal stem cells (MSCs). These stem cells can then proliferate or differentiate into fibroblasts (fibrous tissue), chondrocytes (cartilage), or osteoblasts (bone) based on the mechanical stimulus.

RESULTS

First we performed FEM simulations of ultrasound waves propagating in the scaffolds to choose an appropriate scaffold structure, which was then confirmed by experiments. From Figure 2 (a), we find in both simulations (solid lines) and experiment (dashed lines) the hexagonal pore and bioinspired scaffolds show a significantly larger wave transmission compared to the square pore shapes. Figure 2 (b) shows the color plots of the normalized solid displacements as a wave propagates through the scaffolds and shows that the angle of the pore surfaces allows a higher transmission of the ultrasound wave and produces a more nonuniform wavefront in the hexagonal and bioinspired scaffolds compared to the square scaffolds.

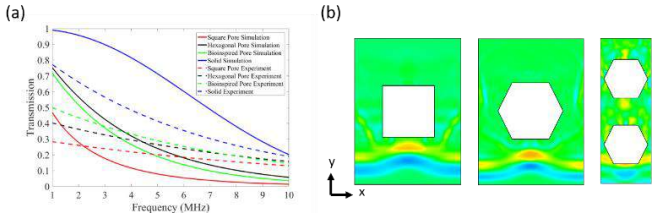

Figure 2: (a) Transmission versus frequency in different porous samples in simulations and experiments. (b) Normalized solid displacements in the pore shapes studied at a time of 6 μs. The wave signal frequency is 1 MHz.

Next we performed the cell growth simulations on the porous scaffolds. From Figure 3 we find the square scaffolds show the fastest bone growth while the bioinspired scaffolds show the slowest. Ultrasound waves have a negligible effect (less than 1%) on the bone growth in the hexagonal and bioinspired scaffolds since their higher wave transmission means that less wave energy is transferred to the cells to stimulate differentiation. In contrast, the lower wave transmission in the square scaffolds means more wave energy is transferred to the stem cells to produce approximately 2% more bone tissue after 60 days as seen in Figure 4. Some shortcomings of the cell growth model are that it does not account for variables such as nutrient transfer, scaffold degradation, or cell apoptosis.

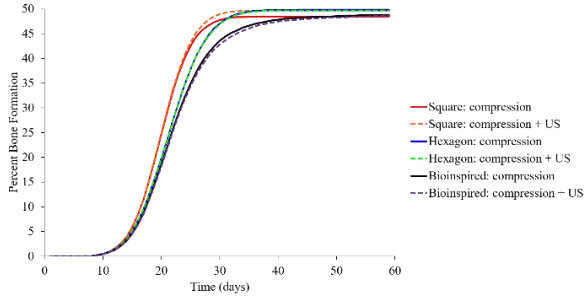

Figure 3: Percent bone formation over time for different scaffold geometries with and without ultrasound (US) stimulation.

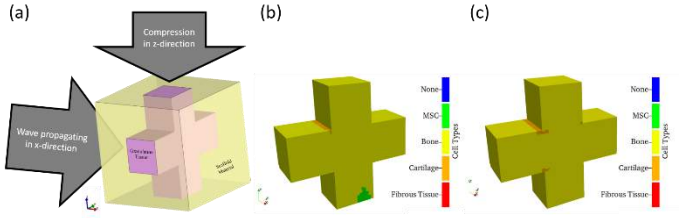

Figure 4: (a) Square pore scaffold with mechanical stimulation. Also shown is the cell distribution in the granulation tissue at day 60 while: (b) under compression, (c) under compression and ultrasound stimulation.

DISCUSSION

The results of this study show that the pore shape of the scaffold affects the ultrasound transmission even when porosity is constant, and that the bioinspired scaffolds can allow as much as 67% greater ultrasound wave transmission at 1 MHz wave frequency when compared to scaffolds with square pores. Additionally, finite element simulations give insight into how pore shape affects the ultrasonic transmission. The cell growth simulations in this study further show that while the bone tissue growth in the bioinspired scaffolds is slow, it can produce amounts of bone tissue comparable to the square and hexagonal scaffolds. The results of this study are important for designing bioinspired tissue scaffold geometries to maximize ultrasound wave penetration to enhance mechanical stimulation for tissue growth.

DO GLYCOSAMINOGLYCANS ACT AS A STRUCTURAL CONSTITUENT OF THE SCLERAL TISSUE?

Hamed Hatami-Marbini, Mohammad Pachenari

INTRODUCTION

The sclera delivers stable support to keep the optical process unaffected during intraocular pressure (IOP) variations and eye movements [1]. The microstructural components in the extracellular matrix (ECM) are accountable for scleral macroscopic behavior [2]. Fibrillar collagen is a significant load-bearing constituent of the extracellular matrix (ECM) of the sclera. Several studies of the structural components and mechanics of scleral ECM have explored collagen fiber effects, however, there have been fewer studies about the role of glycosaminoglycans (GAGs) [3]. GAGs are of pivotal importance because of their multiple biological functions and pathological processes [4]. The changes in the posterior sclera ultrastructure, arrangement, and biomechanical properties increase vulnerability to vision diseases, especially in elderlies [5].

The goal of this study was to perform a set of the experiments, including the effects of preconditioning, displacement rate, and stress relaxation, to thoroughly examine how GAGs contribute to sclera viscoelasticity. We treated scleral specimens by chondroitinase ABC enzyme and removed chondroitin/dermatan sulfate GAGs. Then, we studied whether the tensile mechanical behavior of the strips was affected because of GAG depletion. The sclera strips were divided into four control/no-GAG comparison group based upon applying two displacement rates and the presence or absence of the preconditioning step in the experimental protocol. Four-step stress-relaxation testing with 5% strain increments was used to characterize the posterior porcine sclera mechanical response. The experimental results indicated that a significant alteration in the sclera tensile stress-relaxation characteristics after the enzymatic modification, i.e. the GAGs play a significant role in the mechanical response of the sclera.

METHODS

The strip specimens (5 mm × 20 mm) were dissected from the posterior region (nasal-temporal direction) of fresh porcine eyeballs, obtained daily from a slaughterhouse. To remove all the sulfated GAGs, specimens in no-GAG groups were treated enzymatically in 0.125 U ml-1 Chondroitinase ABC [6]. The buffer solution contains 50 mM Trizma base, pH 8.0, with 60 mM sodium acetate and 0.02% BSA. The treatment process lasted for 18 hours and the samples were gently agitated during this period. Another group of specimens, represented as the control group, treated in the buffer solution but without the enzyme. Alcian Blue staining with a pH of 1.0 was employed to validate the successful removal of the sulfated GAGs.

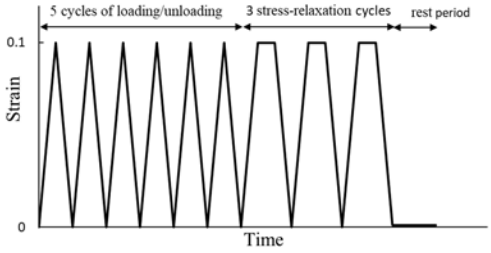

Figure 1: Precondition scheme before running final stress relaxation for 1 mm/min displacement rate.

We used two different displacement rates (0.2 mm/min and 1 mm/min) and performed the mechanical experiments with and without preconditioning of the samples. Thus, four sets of No GAG and control groups were considered, i.e. 1) displacement rate of 0.2 mm/min without preconditioning, 2) displacement rate of 1 mm/min without preconditioning, 3) displacement rate of 0.2 mm/min with

preconditioning and 4) displacement rate of 1 mm/min without preconditioning. The specimens in the preconditioned groups were initially preconditioned with five cycles of loading/unloading followed by three one-minute long relaxation cycles as shown in Figure 1. For the stepwise stress-relaxation tests, strains were applied to the scleral samples in 5% strain increments and were held for 30 minutes after each increment. The process was repeated four times and until the total applied strain as 20%. The stress was calculated by dividing the measured force by the initial cross-sectional area and the strain was defined as the ratio of the length change in each loading step and the reference length. The equilibrium modulus was defined as the variation in two successive relaxed stress to the strain increment.

RESULTS

The histochemical staining images, Figure 2, confirmed that GAGs were successfully removed from the samples. In the displacement rate effect comparisons, the higher rates exhibited higher stresses, especially at higher strains. In comparing the preconditioning load on the scleral biomechanical properties at two different displacement rates, the preconditioning caused a significant increase in the elastic modulus of the sclera in the control and No GAG groups.

Figure 3 shows the effect of GAG removal on the tensile response of porcine sclera. This figure also shows the effects of the loading displacement rate effect on the experimental results. It is seen that without preconditioning and independent of displacement rates and strain levels, scleral strips in the control group had significantly lower elastic modulus than samples in the No GAG group. The GAG removal did not have any significant effect on the elastic modulus of preconditioned specimens.

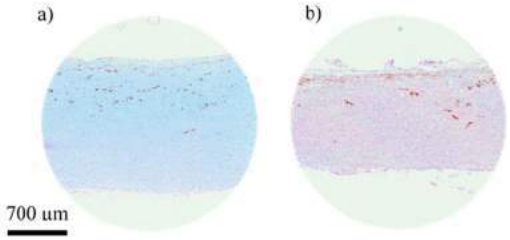

Figure 2: Alcian blue stain representing sulfated GAGs, indicating the successful removal of the GAG after enzyme treatment; a) a scleral sample immersed in buffer solution; b) a scleral sample digested in Chondroitinase ABC solution.

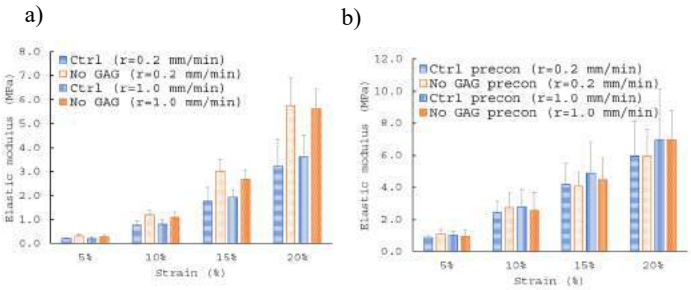

Figure 3: The variation of equilibrium elastic modulus following GAG removal for a) not preconditioned and b) preconditioned scleral samples. The bars represent the standard deviations.

DISCUSSION

The posterior sclera is an important load-bearing tissue around the optic nerve head (ONH). It is known that the majority of the lamina cribrosa (LC) displacement occurs in the ONH peripheral region, which may affect the signal transmission to the brain and subsequently the vision [7]. Therefore, it is essential to explore if there is a significant alteration to the scleral stiffness if there is a change in the GAG content of the tissue. In the present work, we characterized the scleral mechanical behavior after GAG depletion and investigated the displacement loading rate and the sample preconditioning effects by performing the uniaxial tensile experiments.

The difference in the stepwise relaxation behavior between control and no-GAG groups (set 1 and 2) was a function of the applied displacement rate and appeared to reduce as the displacement rate increased. Removing GAGs caused stronger tensile properties in experiments that did not initially preconditioned the samples. This is because the absence of GAGs from the tissue increases the friction between collagen fibers and allows them to fuse together forming bigger collagen fibers. In contrast, when the preconditioning step was used, the tensile stress values did not significantly change because of GAG removal. This is because an earlier stiffening of samples would occur during the precondition step because of significant fiber recruitment and reorientation. Considering the in-vivo loading condition of the sclera, using uniaxial tensile tests was a limitation of this study since we did not characterize scleral material properties under a physiological condition. We also note that, although our results showed that the majority of GAGs were removed, some residual GAGs still existed in the samples; these remaining GAGs might have affected the experimental results. Despite these limitations, our results showed that GAGs as a non-collagenous component of the tissue significantly contribute to the mechanical response of the sclera in tension. Improving the current knowledge about the complex GAG-collagen interaction in the sclera ECM may further help researchers recognize the underlying mechanisms causing significant damage to the ONH.

INTRODUCTION

Single nucleotide polymorphisms (SNPs) within the 9p21 locus have the strongest correlation with coronary artery disease (CAD) [1]. However, the 9p21 locus is a non-coding region, making its connection to CAD enigmatic. 9p21 SNPs affect vascular smooth muscle cells (VSMCs) contractility [2], which during CAD switch from a contractile phenotype, responsible for regulating vascular tone, to one more synthetic, which is more proliferative and migratory. Using induced pluripotent stem cells (iPSCs) derived from patients homozygous for risk (R/R) or non-risk (N/N) variants along with knock out cells (R/R KO), iPSCs are differentiated into VSMCs **(Figure 1A)** to study how variants alter phenotype. We have designed a microfluidic device with the aim of separating VSMCs into synthetic and contractile phenotypes to study the mechanism through which 9p21 variants alter phenotype. We hypothesize variable expression of lncRNA within a patient population drives heterogeneous gene expression resulting in variable penetrance of a synthetic phenotype that can be identified by adhesion strength.

METHODS

RNA Sequencing was performed on iPSC derived VSMCs from R/R and N/N patients as well as R/R KO and N/N KO and hierarchical clustering was performed to group cell lines based on similarity in integrin expression **(Figure 1B).** Microfluidic channels were designed **(Figure 1C)** to expose cells to an acute shear stress varied by adjusting the volumetric flow rate, following Equation 1. VSMCs were seeded in the device, allowed to adhere, and then exposed to acute shear stress, with the population that detach collected at the outlet (weakly adherent population, WA) and the cells that did not detach (strongly adherent population, SA) collected after disassociation with TrypLE. The percentage of cells that detached were subsequently analyzed. Post sorting, WA and SA populations were seeded onto gelatin for morphological analysis or onto gelatin coated polyacrylamide gels for traction force microscopy (TFM).

Equation 1: Shear Stress in Microfluidic Device

$$\tau = \frac{6\mu Q}{wh^2} \qquad (1)$$

$\tau = shear\ stress$
$\mu = viscocity$
$Q = volumetric\ flow\ rate$
$w = channel\ width$
$h = channel\ height$

RESULTS

All differentiated VSMCs stained positive for smooth muscle cell markers, calponin and SM22α **(Figure 1A),** but there were significant differences in size and morphology between R/R and non-risk patients as well as within a R/R population. RNA sequencing analysis revealed R/R VSMCs had reduced collagen binding integrin expression compared to other genotypes **(Figure 1B).** Fluid flow in the device is laminar and shear stress across the surface of the device is uniform, as confirmed by COMSOL simulations **(Figure 1D).** When cells are exposed to uniform shear stress, a greater percentage detached for both R/R patients compared to R/R KO and N/N **(Figure 1E)** which correlated with genotypic differences in size, specifically R/R cells are smaller than both R/R KO and N/N **(Figure 1F)**. When VSMCs are sorted using the microfluidic device, we found the WA are smaller and more circular than SA, for all genotypes, and there were fewer cells populating the WA fraction for the R/R Patient 1 KO line compared to the R/R Patient 1 **(Figure 2A).** TFM revealed differences in contractility between the WA and SA populations, with SA exerting greater tangential strain energy **(Figure 2B).** RNA Sequencing of WA and SA

populations will reveal differential gene expression and potential mechanisms through which these phenotypic differences arise.

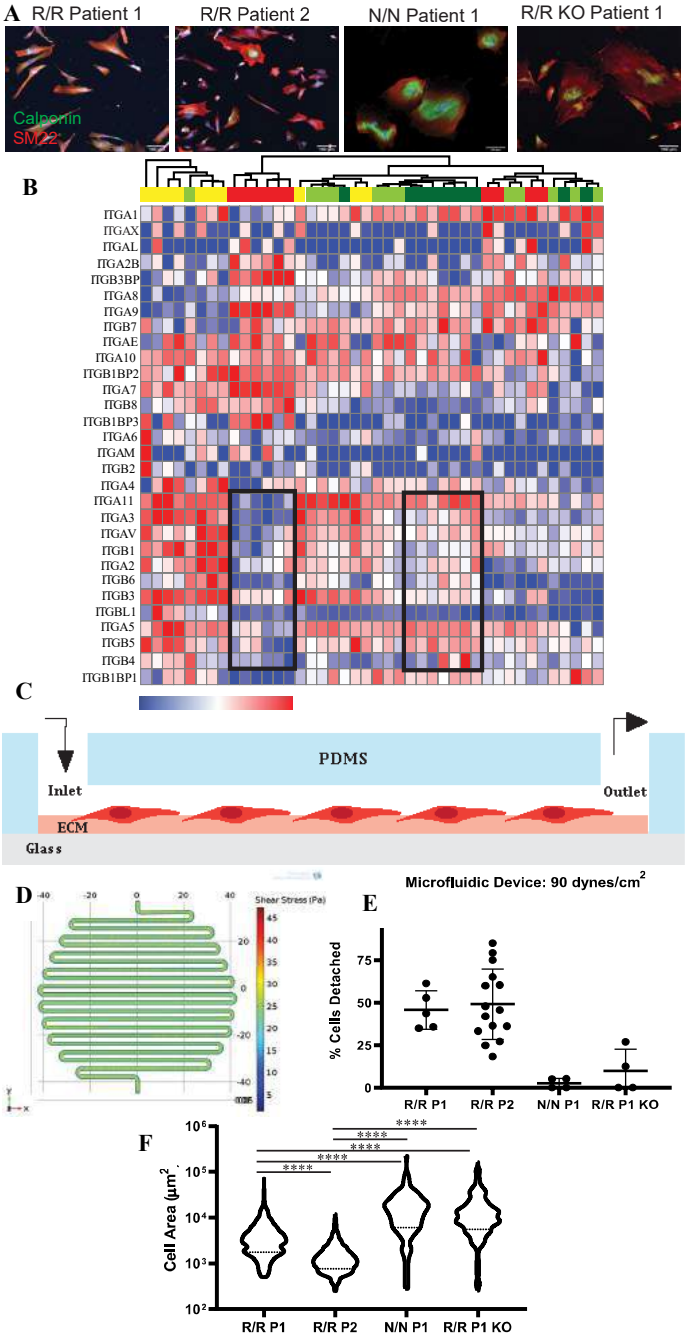

Figure 1: (A) Immunofluorescent staining for VSMC markers of cells differentiated from R/R, N/N and R/R KO iPSCs. **(B)** RNA sequencing of VSMCs clustered by similarity in integrin gene expression. **(C)** Schematic of the microfluidic device used to sort cells into WA and SA populations using shear stress. **(D)** Heatmap of shear stress across the channel's surface generated using a COMSOL simulation. **(E)** Percentage of cells that detach when exposed to a shear stress of 90 dynes/cm^2. **(F)** Cell area measurements of VMSCs for all cell lines.

In preliminary qPCR data, the WA also express more ANRIL, an associated lncRNA, compared to SA, suggesting that it plays a role in regulating VSMC adhesion and promotes a synthetic phenotype.

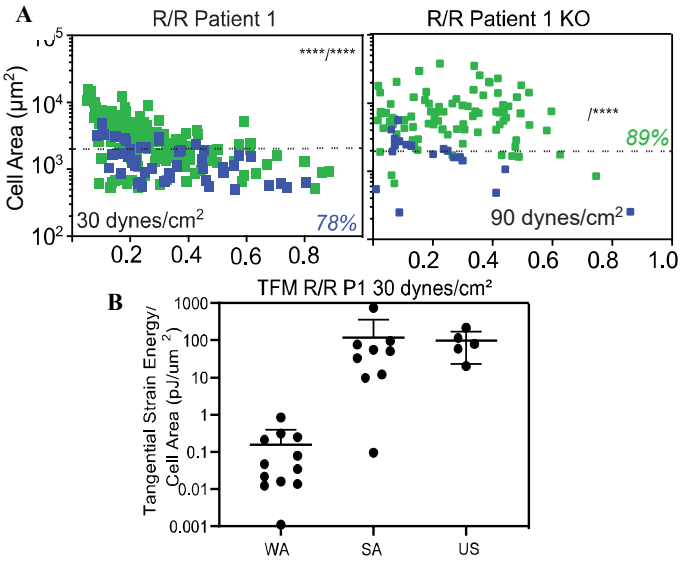

Figure 2: (A) Cell area and circularity of WA and SA populations for R/R Patient 1 sorted at 30 dynes/cm^2 and R/R Patient 1 KO sorted at 90 dynes/cm^2. **(B)** TFM contractility measurements for WA, SA, and unsorted R/R cells.

DISCUSSION

While VSMCs differentiated from every genotype expressed SMC markers **(Figure 1A)**, the differences in size and morphology between patients **(Figure 1A, F)** as well within a risk population suggested the presence of synthetic and contractile phenotypes. The differences in collagen binding integrin gene expression between genotypes **(Figure 1B)** were accompanied by functional differences in adhesion strength, with a greater percentage of cells detaching for R/R patient derived VSMCs **(Figure 1E)**. Such differences in adhesion suggest the R/R patients possess a less prevalent contractile phenotype population and more prominent synthetic population. The microfluidic device was able to sort patient iPSC derived VSMCs into distinct subpopulations, with WA cells being smaller and more circular, morphology indicative of synthetic phenotype, while SA are larger and more spread, indicative of a contractile phenotype **(Figure 2A).** TFM also revealed the SA are more contractile than WA **(Figure 2B)**. With contractile and synthetic phenotypes sorted from a single patient population, the mechanism through which VSMC phenotype is regulated can be more precisely studied using RNA sequencing and biochemical assays such as PCR. This work provides new perspectives on VSMC phenotype heterogeneity regulated by non-coding loci that contribute to CAD.

INTRODUCTION

Fibroblasts get activated into myofibroblasts during acute wound healing and this is accompanied with the inward deformation of collagenous rich extracellular matrix (ECM) by application of contractile forces. This myofibroblastic activation process is pivotal to physiological instances such as developmental process, wound healing. However, this process is also key to pathological instances such as chronic inflammation and fibrosis-related diseases such as the solid epithelial cancer[1,2]. The contractile tumor like microenvironment observed in such cases, known as desmoplasia, are characterized by aligned ECM fibers which are shown to be detrimental for patient outcomes. Cancer associated fibroblasts (CAFs) are activated fibroblasts and are responsible for the remodeling of the ECM fibers into aligned configuration. This expansion of desmoplasia can further activate the naïve fibroblastic cells into CAFs thereby perpetuating a cyclic process of desmoplastic expansion. However, it is still unclear as to how cells polarized along anisotropic fibers can exert these contractile forces as the commonly understood notion suggests restricted probing in lateral direction[3]. In this study[4], we thus use anisotropic fibers generated through STEP technique (Spinneret based Tunable Engineered Parameters) to identify the formation of a new structure we termed perpendicular lateral protrusions (PLPs) and also report the forces exerted by them. We demonstrate that cell spreading across multiple fiber configuration is facilitated by these contractile structures that deflect the fibrous ECM inwards.

METHODS

Human mesenchymal stem cells (hMSCs i.e. fibroblastic naïve) derived from human bone marrow (Lonza) were used in this study and cultured at 37˚C and 5% CO_2. Polystyrene nanofiber scaffolds (~250nm) were generated using the previously established STEP technique[5]. Immunostaining was performed using rhodamine phalloidin for actin and primary antibodies mouse total paxillin and rabbit anti-phospho FAK. Cell forces were computed using Nanonet Force Microscopy (NFM). Graphpad PRISM was used for ANOVA statistical tests.

RESULTS

As cells are suspended on anisotropic fibers, they stretch onto multiple fibers by extension of lateral protrusions. We observed this structure initiate from thin filamentous filopodia resembling structure which we termed as twine and is it matures, it becomes a force exerting structure as can be seen (Fig 1i). We also observed that these PLPs form not only in the planar geometry but also are capable of forming in 3D, which we captured by creating a 3D scaffold stack (Fig 1ii).

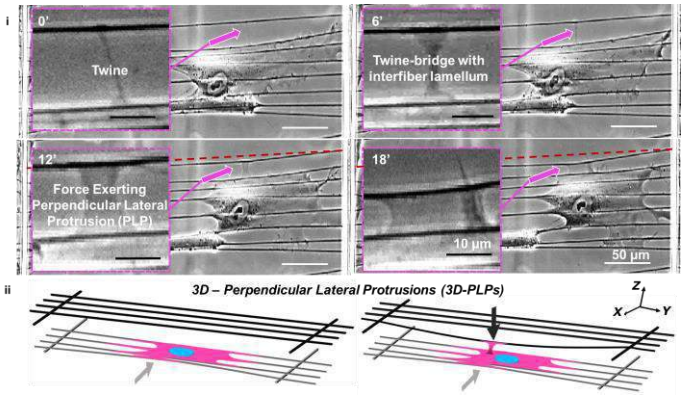

Figure 1: (i) Example case of cell forming PLP through the initiation of twine on anisotropic fibers (ii) Cartoon exhibiting the 3D nature of the PLPs. Adapted from Ref [4].

Our observations suggest 7 distinct steps involved in the formation of a force exerting perpendicular lateral protrusion (PLPs) (Fig 2i). As cells are suspended on anisotropic fibers, actin ruffles along the side of cell body give rise to filamentous twines that swing freely in 3D (i) to attach to neighboring fibers. After engagement to adjacent fiber in a matter of seconds (ii), a lamellum grows from the base of twines (iii). This gives rise to secondary twines (iv) one of which attaches to the neighboring fiber establishing a twine bridge (v). Interfiber lamellum grows along the railings of this bridge (vi) and the majority of these structures that attach perpendicularly initially, develop into force exerting PLPs that deflect the neighboring fiber inwards (vii). Interestingly, the force exerting PLPs are mostly perpendicular while the twines that do not form PLPs have a wider angle of attachment to neighboring fiber. Two example cases using phase contrast images of PLP formation are shown (Fig 2ii).

To investigate the role of fiber architecture in perpetuating the formation of these force exerting PLPs, we constructed fiber scaffolds of different architectures: anisotropic, hexagonal, angled and crosshatch. While higher aspect ratio of cells resulted in greater number of twines formed per cells, it was seen that only the anisotropic fiber arrangement was the most conducive to PLP formation, thereby suggesting the importance of fiber architecture.

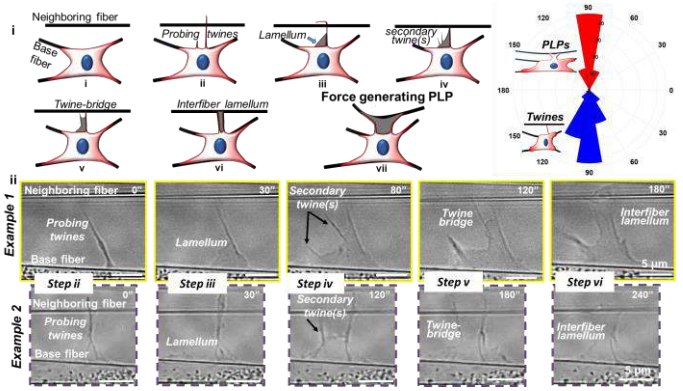

Figure 2: (i) Discreet steps in formation of force exerting perpendicular lateral protrusions shown by cartoons. Polar histogram shows that lateral protrusions are majorly perpendicular as opposed to twines with a wider distribution of angle of attachment (ii) Two example cases of the various steps involved in PLP formation. Adapted from Ref [4].

We next quantified the forces exerted by twines and PLPs using NFM. We observed that twines exert low forces and the mature PLPs exert high forces with sharp increase observed at 10µm width of the PLPs. The forces are computed by assuming the force vectors along the curvature of the PLPs as shown (Fig 3) and by modeling the fibers as beams with fixed-fixed boundary condition. The difference between a finite element model prediction and the experimentally observed fiber deflection is minimized to compute the forces.

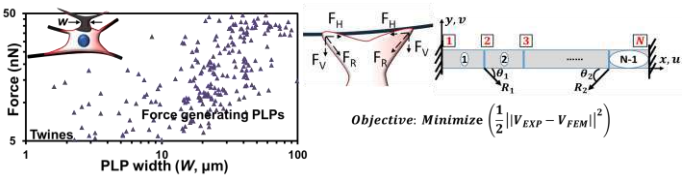

Figure 3: Forces exerted by twines and PLPs measured using NFM. Forces increase with increase in PLP width with a sharp increase observed around 10 µm width. Schematic representation of the mechanics model of NFM. Adapted from Ref [4].

Similarly, we utilize NFM to study the forces exerted by cells attached to different number of fibers. Through fixed staining, we observed the cytoskeletal arrangement of actin stress fibers and compute the average angles subtended. From paxillin staining, it is observed that the focal adhesion clusters are located at either ends of cell, so NFM uses forces originating at the ends of cells along the stress fibers (Fig 4i-iii). With increase in number of fibers a cell is attached to, the total forces exerted increases (Fig 4iv) while the migration velocity decreases (Fig 4v).

DISCUSSION

We demonstrate for the first time, fibroblastic cells form contractile force-generating 3D-PLPs originating all along the cell body. Our experimental observations suggest a new role of anisotropic environments in activating naïve fibroblasts into contractile activated myofibroblastic cells through 3D-PLP formation. We achieve this by generation of different fiber architectures and show that cellular polarity is not the governing factor in such activation. Further, these activated cells can remodel the microenvironment through extending the 3D PLP structures thereby providing the necessary contractile forces necessary for desmoplastic expansion.

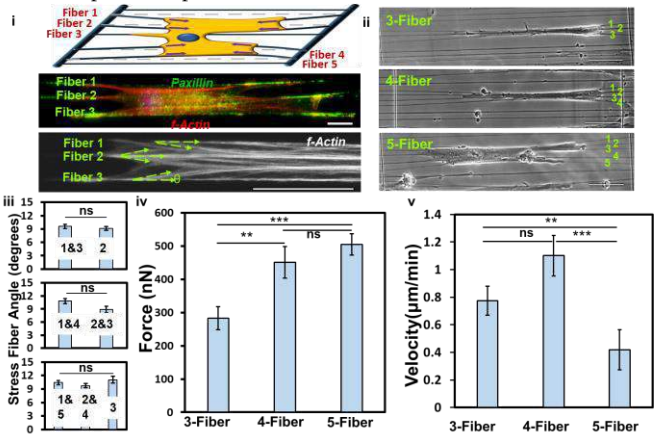

Figure 4: (i) Cell suspended on multiple fibers. Actin (red) and paxillin (green) is observed through immunostaining (ii) Example phase images of cells suspended on 3 fibers, 4 fibers and 5 fibers (iii) Actin stress fiber angles formed by cells on different fiber categories. Force vectors are along these stress fibers (iv) Magnitude of forces exerted by cells increase with the number of fibers, as computed using NFM (v) Increase in number of fiber attachments lead to decrease in migration velocity of cells. INTRODUCTION

Cancer is the second leading cause of mortality globally[1,2]. Various nanoparticles have been developed to improve the efficacy and safety of chemotherapy, photothermal therapy, and their combination for treating cancer. However, most of the existing nanoparticles are low in both subcellular precision and drug loading content (< ~5%), and the effect of targeted heating of subcellular organelles on the enhancement of chemotherapy has not been well explored. Here, we report a hybrid Py@Si-TH nanoparticle to first target cancer cells overexpressed with the variant CD44 via its natural ligand HA on the outermost surface of the nanoparticle before cellular uptake, and then target mitochondria after they are taken up inside cells. In addition, the nanoparticle is ultra-efficient for encapsulating doxorubicin hydrochloride (DOX) to form Py@Si-TH-DOX nanoparticle. The encapsulation efficiency is ~100% at the commonly used low feeding ratio of 1:20 (DOX:empty nanoparticle), and >80% at an ultrahigh feeding ratio of 1:1. In combination with near infrared (NIR, 808 nm) laser irradiation, the tumor weight in the Py@Si-TH-DOX treatment group is 8.5 times less than that in the Py@Si-H-DOX (i.e., DOX-laden nanoparticles without mitochondrial targeting) group, suggesting targeted heating of mitochondria is a valuable strategy for enhancing chemotherapy to combat cancer.

METHODS

Synthesis of Nanoparticles. Polypyrrole (Py) conductive polymer was encapsulated inside silica nanoparticles by a modified reverse microemulsion method. First, Triton X-100 (2 mL), hexanol (10 mL), and cyclohexane (2.4 mL) were mixed together for 30 min. A total of 600 μL of Py in DI water (5 mg/mL) was then added into the mixture and stirred at room temperature for 1 hour. Afterward, 120 μL of ammonium hydroxide (28 wt%) and 200 μL of TEOS were added consecutively and the sample was stirred at room temperature for 24 h to form the Py-embedded silica (Py@Si) nanoparticles. Then, 40 μL of APTMS and 10 μL of TEOS were added and stirred overnight. Lastly, the sample was added into 30 mL of ethanol to terminate the reaction. The resultant Py@Si-NH_2 nanoparticles were cleaned and collected by centrifuging at 13,000g for 10 min and washing with ethanol and DI water for 3 times, respectively. To further modify the nanoparticles, the mitochondria-targeting ligand TPP-COOH ((3-carboxyethyl)triphenylphosphonium bromide was prepared according to previously reported procedure [3]. Then, 167 mg of the TPP-COOH was treated with EDC·HCl (120 mg) and sulfo-NHS (120 mg) in 5 mL of DMSO and stirred at room temperature for 1 h before being added to the solution of Py@Si-NH_2 (150 mg) in 15 mL of DI water and 30 μL of triethylamine (TEA). The mixture was stirred at room temperature for 24 h and the resultant Py@Si-T nanoparticles were cleaned and collected by centrifuging at 13,000g for 10 min and washed with ethanol and DI water 3 times, respectively. Finally, the Py@Si-TH nanoparticle was synthesized by mixing the Py@Si-T nanoparticles (5 mg/mL) with HA (1 mg/mL) and stirring at room temperature for 3 h, and collected by centrifuging at 13,000g for 10 min. DOX-laden nanoparticles were made by mixing DOX and empty nanoparticles at various ratios in weight. The ratio of 1:10 (DOX:empty nanoparticles) was used for cell and animal studies.

All data was reported as mean ± standard deviation (s.d.) from at least three independent experiments. Student's t-test (unpaired and two-tailed) was used to compare two groups of independent samples. One-way analysis of variance (ANOVA) with Dunnett's post hoc analysis was used for multiple comparison (when more than two groups compared). In all cases, a p value less than 0.05 was considered to be statistically significant. All statistical analyses were carried out with Graphpad Prism 7.0.

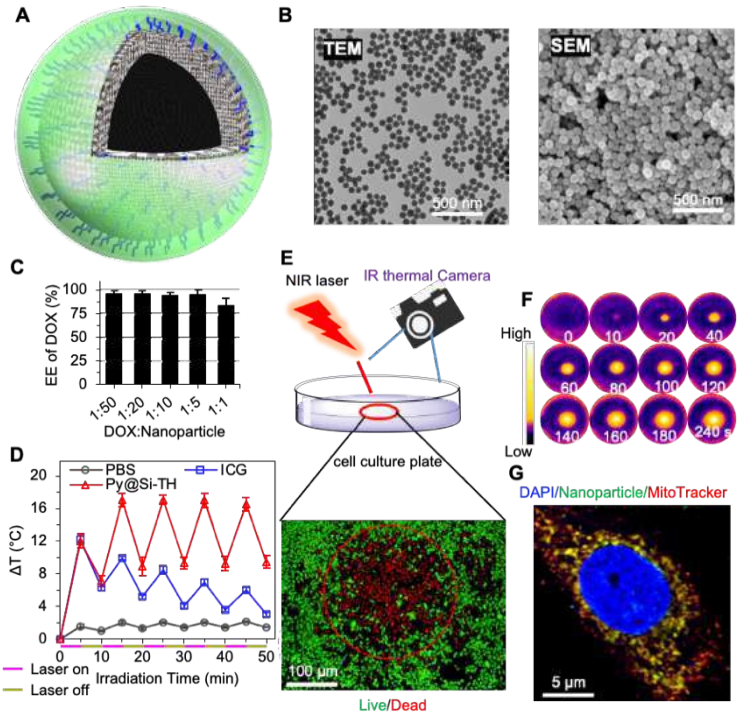

Fig. 1. Nanoparticles enabled ultra-efficient drug encapsulation and targeted heating of mitochondria.

RESULTS

The multi-functional nanoparticle is synthesized using polypyrrole (Py) conductive polymer and mesoporous silica, and further modified with triphenylphosphonium (TPP) and hyaluronic acid (HA) sequentially on the surface (**Fig. 1A**), exhibiting spherical morphology with ~70 nm in diameter (**Fig. 1B**). The nanoparticles can be used to encapsulate DOX in an ultra-efficient manner with simply mixing, ~100% of the DOX could be encapsulated in the nanoparticle when the feeding ratio is from 1:50 to 1:5 (DOX:nanoparticle) (**Fig. 1C**). **Fig. 1D** shows the photothermal effect of nanoparticles. The nanoparticle is highly stable compared with that of indocyanine green (ICG) within 5 cycles of NIR laser irradiation. The cells attached on Petri dish were first treated with nanoparticles for 4 h and washed with pure medium, then irradiated with NIR laser. The temperature of the cells was monitored by infrared thermal camera (**Fig. 1E,F**) and followed with live/dead staining (**Fig. 1E**), demonstrating the photothermal effect of the nanoparticle after taking up inside cells. The subcellular co-localization study, shown in **Fig. 1G,** indicate the targeted accumulation of the nanoparticles in mitochondria. The ivis imaging (**Fig. 2A,B**) and the NIR-mediated thermal imaging (**Fig. 2C**) studies demonstrate the tumor targeting capability and photothermal effect of nanoparticles *in vivo*. Interestingly, the combination of Py@Si-H-DOX nanoparticles (with no mitochondria targeting capability) and NIR laser irradiation (*i.e.*, the Py@Si-H-DOX+L treatment) is not as effective as the Py@Si-TH-DOX+L treatment; tumors from the Py@Si-H-DOX+L group is ~8.5 times more than that from the Py@Si-TH-DOX+L group on average (**Fig. 2D,E**). These data indicate that targeted heating of mitochondria significantly enhances the *in vivo* antitumor efficacy of the nanoparticle-mediated chemotherapy.

DISCUSSION

In summary, we demonstrate the ability to augment the effectiveness of chemotherapy using non-toxic, triple (tumor, cell, and mitochondria) targeting Py@Si-TH-DOX nanoparticles in combination with NIR laser irradiation. By embedding polypyrrole (Py) inside silica and decorating on the surface sequentially with triphenylphosphonium (TPP) and hyaluronic acid (HA), we fabricated a nanostructure with superb anticancer effect through precisely targeted heating of the mitochondria of cancer cells upon NIR laser irradiation. In addition, the nanoparticle is ultra-efficient for encapsulating doxorubicin hydrochloride (DOX) because of the π-π stacking interaction between Py and DOX. The encapsulation efficiency is ~100% at the commonly used low feeding ratio (in weight) of 1:20 (DOX:nanoparticle), and >80% at an ultrahigh feeding ratio of 1:1. Upon NIR laser irradiation, the temperature of both *in vitro* cancer cells and *in vivo* tumors loaded with Py@Si-TH nanoparticles can be elevated by ~10 °C within 1 min for mild hyperthermia. When combined with NIR laser irradiation, our Py@Si-TH-DOX nanoplatform can reduce tumor weight by 8.5 times compared to the Py@Si-H-DOX nanoplatform that is devoid of TPP, indicating the crucial role of the mitochondria-targeted heating for enhancing nanoparticle-mediated chemotherapy. This study suggests that targeted heating of subcellular organelles (*e.g.*, mitochondria) is a valuable strategy to enhance cancer chemotherapy.

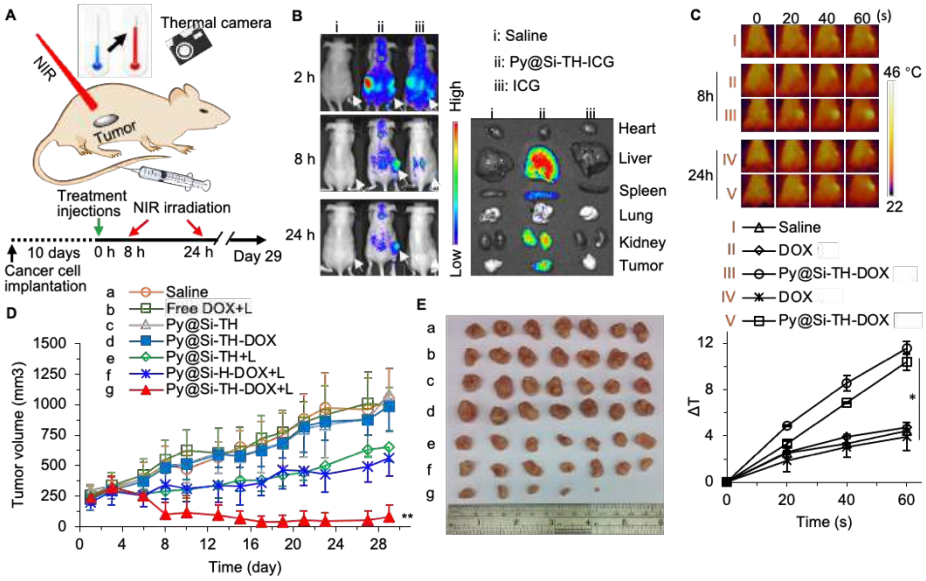

Fig. 2. Nanoparticle-mediated targeted heating of mitochondria is a valuable strategy to enhance chemotherapy *in vivo*.

INTRODUCTION

Intracranial aneurysms (IAs) are present in over 3% of the human population [1,2], and those with IAs have approximately a 30% lifetime risk of rupture [3]. While some general risk factors are established, such as aneurysm size and family history [3], there is a need for more specific rupture risk predictors based on the actual mechanics of rupture [4][5].

IAs are known to produce sound [6] at frequencies in the range of 150-800 Hz [6,7] which is thought to be caused by vibration of the aneurysm wall [7]. Aneurysm wall vibration could be a harbinger of deleterious wall remodeling, leading eventually to rupture [7,8]. However, such vibration has not been examined with modern fluid structure interaction (FSI) simulations, possibly because previous FSI software was unable to simulate high-frequency vibration, or previous thinking that blood flow in aneurysms is laminar. Recently, high-fidelity CFD has made it clear that high-frequency flow instabilities can exist in brain aneurysms [9,10]. In addition, new FSI tools are emerging which are capable of modelling aneurysm wall vibration [11].

It is uncertain what type of flow instability may cause aneurysm wall vibration. It is possible that vibration is driven by increasing turbulent kinetic energy, or by vortex-shedding at Reynolds numbers (Re) close to the onset of instability [12]. Previous studies have measured wall vibration in IAs at discrete flow rates [5]; however, it is possible that resonant frequency peaks could be missed by considering discrete flow rates. It is thought that a slowly increasing flow rate in an aneurysm CFD model may show all types of flow instability possible in a specific aneurysm geometry, and that the wall may vibrate most, not necessarily at the highest flow rates, but at the flow rates which induce more spectral power at frequencies close to a certain mechanical resonance frequency of the wall. Therefore, the objective of this preliminary study was to subject three aneurysm geometries to a slowly increasing flow rate to generate all possible types of flow instability, as a precursor to FSI simulation of the aneurysm wall vibration.

METHODS

We considered three aneurysm geometries in the current study, which have previously been shown to exhibit stable flow (Case 8), mildly unstable flow (Case 9) and highly unstable flow (Case 16) [10]. The computational fluid dynamics (CFD) meshes were generated using the Vascular Modelling Toolkit, with roughly 70,000 tetrahedral elements in each case (Figure 1a). Blood kinematic viscosity and density were 0.035 mPa-s and 1 g/cm^3 respectively. The simulations were run using a high-fidelity, finite-element CFD solver [13]. A medium temporal resolution of 5600 steps per cardiac cycle (~5888 steps per second), which has been shown in previous studies to be adequate to capture the main features of the flow [10].

A parabolic velocity profile was specified at the inlet, and zero pressure at the outlets. A linearly increasing flow rate (i.e., a "ramp") was applied to the inlet for a total physical simulation time of 6.7s, with a maximum spatial average inlet velocity of 0.8 m/s for all cases (Figure 1b), or a maximum flow rate of 2.21ml/s, 3.96 ml/s and 4.24 ml/s for Case 8, 9 and 16 respectively, representing twice the cycle-averaged flow rates reported in a previous study [10]. The slope of the ramp, and therefore the length of the simulation, was chosen to result in a maximum variation of 25% in flow rate for the 0.95s interval (the length of a cardiac cycle) required to calculate the spectrograms, at the onset of flow instability. Simulations at steady flow rates of 0.4, 0.5, 0.6, 0.7 m/s with a total simulation time of 1.9s (twice the length of a cardiac cycle) were compared to the ramp simulations.

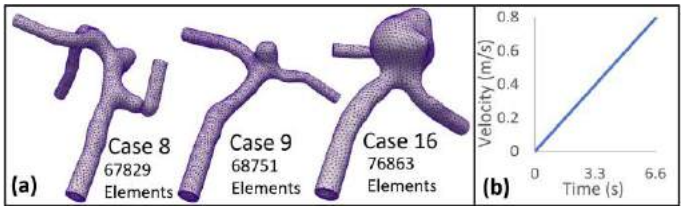

Figure 1: Model inputs: (a) mesh for Case 8, Case 9, Case 16, (b) spatial average inlet velocity as a function of time, for all cases.

Spectrograms of the fluid velocity magnitude were generated to demonstrate the onset and nature of flow instability in the three aneurysm cases, following methods presented previously [9]. Every fourth timestep was used to generate the spectrograms, resulting in a maximum frequency of ~750 Hz (the Nyquist limit). For steady flow, the last 0.95s of the simulation were analyzed, to eliminate the initial transient response.

RESULTS

The spectrograms for Case 9 and Case 16 both exhibited flow instability (Figure 2), while the spectrograms for Case 8 did not display any flow instability during the simulation. In Case 9, stable flow (no frequency content) was observed until Re = 310, with a rapid onset of flow instability after this time and frequencies exceeding 750 Hz observed at Re = 350 (Figure 2a). Prominent bands of power were present at 25-35 and 100-150 Hz, respectively, which rose in frequency with increasing Re. At ~5.25s, the prominent frequency band at 150 Hz widened and remained prominent for the remainder of the simulation. In Case 16, a slightly later onset of flow instability was observed at Re = 340, where very distinct bands appeared until Re = 400 (Figure 2b). Subsequently, the bands became broader and eventually blended, suggesting, as expected, a transition from periodic or near periodic flow (similar to laminar vortex shedding) to more disordered or turbulent-like flow. The ramp spectrograms captured similar spectral qualities to the steady flow spectrograms (Figure 3), however, the ramp slightly delayed the onset of instability due to the positive pressure gradient.

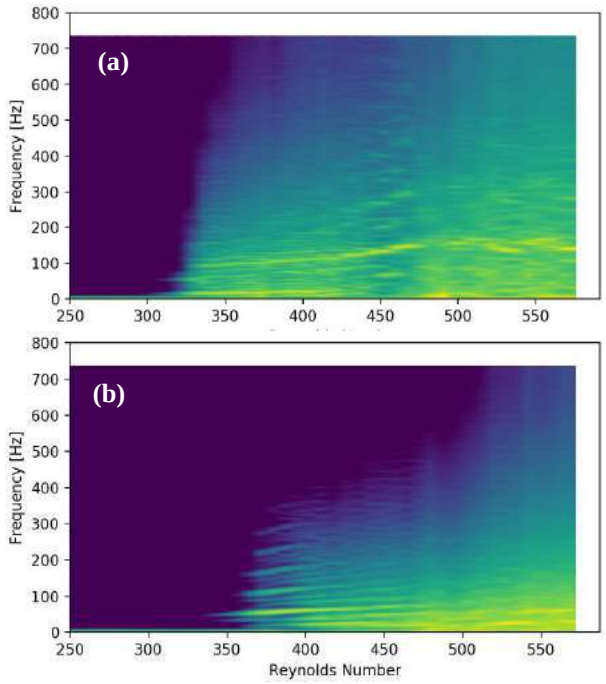

Figure 2: Spectrograms for (a) Case 9 and (b) Case 16, plotted against inlet Reynolds Number, which increased linearly in time.

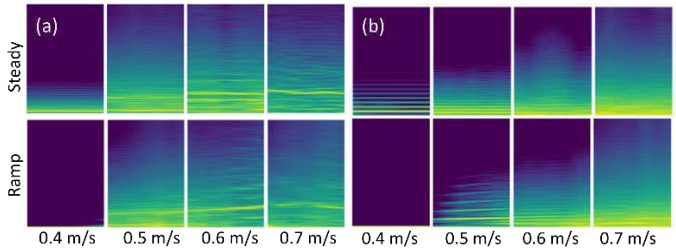

Figure 3: Steady Flow (top row) and Ramp (bottom row) Spectrograms for (a) Case 9 and (b) Case 16, with average velocity indicated. Spectrograms are the length of a cardiac cycle (0.95s).

DISCUSSION

In both Case 9 and 16, the ramped flow rate was found to induce the three major flow phenotypes commonly observed in high-fidelity CFD of aneurysm models: (1) stable flow with no high frequency content, (2) mildly unstable flow with periodic behavior and (3) highly unstable (turbulent-like) flow. While no flow instability was observed in Case 8, instability could of course be induced by prescribing higher, albeit non-physiological, flow rates.

Prominent frequency bands observed in both Case 9 and 16 were both within the range of frequencies of sounds recorded in aneurysm patients (150-800 Hz) [6,7]. Of course, not all aneurysms produce sound, consistent with Case 8 in the current study, which had stable flow. Balasso et al. used an experimental reconstruction of an IA to measure wall vibration and found that flow rate had little influence on the frequency content of the wall response. It was found that the wall vibrated at frequencies of 40-60Hz and 255–265Hz [5]. Intermediate flow rates (1.4 ml/s) were found to have high frequency vibration (260 Hz) at higher amplitudes than higher or lower flow rates [5].

The mechanism of vibration in aneurysm sounds is not clear. Additionally, the exact type of flow which causes aneurysm sounds is also not clear. The results of Balasso et al. suggest that higher flow rate does not necessarily cause higher amplitude of high-frequency wall vibration, suggesting that wall vibration is increased by flow with increased frequency content close to the high-frequency mode of the wall. Therefore, Case 16 in the current study could experience a higher amplitude of vibration at flow velocities immediately after the onset of flow instability, if the wall has a resonant frequency close to one of the prominent frequency bands and those bands have higher power than the more broadband turbulent-like flow near the end of the simulation. In Case 9, it is possible that strong vibration could occur if one of the wall resonant frequencies is close to the single prominent band at 100-150 Hz. However, if one of the main wall resonant frequencies is higher in either case (400 – 800 Hz), wall vibration may simply increase with flow rate, due to the increase in broad-band high frequency content in both cases.

To help characterize the influence of flow rate on wall vibration amplitude, we are currently repeating these Ramp simulations using a monolithic fluid structure interaction (FSI) solver, which was previously shown to predict the presence of wall vibration under steady flow conditions [11].

BIOINSPIRED 3D CULTURE IN NANOLITER CORE-SHELL HYDROGEL MICROCAPSULES ISOLATES HIGHLY PLURIPOTENT HUMAN IPSCS

Jiangsheng Xu, James G Shamul, Xiaoming He*

Fischell Department of Bioengineering,
University of Maryland
College Park, MD, USA

INTRODUCTION

Human induced pluripotent stem cells (iPSCs) are ideal for developing personalized medicine[1]. However, the spontaneous differentiation of human iPSCs under conventional 2D and 3D cultures for expansion, may compromise their quality for further use. Therefore, strategies to isolate and expand high-quality human iPSCs is critically needed. Here, we developed a biomimetic microencapsulation method to isolate and culture high-quality human iPSCs. This is inspired by the natural proliferation and development of blastomeres into early blastocyst where the pluripotent embryonic stem cells-containing inner cell mass (ICM) are enclosed in a semipermeable hydrogel shell known as the zona pellucida (Zona) during early embryonic development. Blastomere cluster-like human iPSC clusters were encapsulated in the core of microcapsules with a semipermeable Zona-like hydrogel shell and subsequently cultured to form the pluripotent ICM-like cell spheroids. This microencapsulation provides a biomimetic, miniaturized, and proliferation-only microenvironment for expanding iPSCs, which significantly improves their quality as indicated by the high expression of pluripotent markers Nanog, OCT4, SOX2, and SSEA-4. The ICM-like iPSC spheroids are capable of maintaining high pluripotency even after transferred into 2D culture. Collectively, our bioinspired approach has great potential for generating high-quality human iPSCs, which are essential for human iPSC-based personalized disease modeling and regenerative medicine.

METHODS

Human iPSC culture. Human iPSCs (DF19-9-11T.H) from WiCell (Madison, WI, USA) were used in this work. For 2D culture, the iPSCs were maintained in StemFlex medium (ThermoFisher Scientific, Waltham, MA, USA) in Matrigel (Corning, Corning, NY, USA)-coated 6-well plates (1×10^6 cells in 1.5 mL of medium per well) with medium being changed daily. For 3D suspension culture, uncoated petri dish and StemFlex medium with 10 μM Rock inhibitor (RI, Selleck Chemicals, Houston, TX, USA) were used.

Microfluidic devices. The non-planar PDMS-based microfluidic device was fabricated as described previously[2]. The 2% alginate and 1% HA solutions were made by dissolving the purified alginate and HA in 0.9% saline, respectively, followed by filtering through a 0.22 μm filter (Merck Millipore, Cork, IRL). The 2% alginate solution was used as the shell fluid. The fluid in the core (1% alginate + 0.5% HA) was made by mixing an equal volume of 2% alginate and 1% HA solutions. A mixture of mineral oil (15 mL), aqueous $CaCl_2$ solution (1.0 g/mL, 1.5 mL), and SPAN80 (93.3 μL) was sonicated for 1 min using a Branson 450 sonifier (22% power) to make the oil emulsion.

Microencapsulation of iPSC clusters. The 2D cultured iPSC colonies were treated with Versene, gathered with gentle washing of the well bottom, and centrifuged for 45 s at 300g. Then, the cells were gently pipetted 5 times into clusters and resuspended in the core solution at 3×10^5 clusters mL^{-1}. All the solutions were injected into the microfluidic device using syringe pumps (Harvard Apparatus, Holliston, MA, USA) to generate microcapsules. Flow rates for core, shell, and oil emulsion fluids were 250 μL h^{-1}, 500 μL h^{-1}, and 5 mL h^{-1}, respectively. The device outlet was submerged in a 50 mL tube containing 30 mL DMEM/F12 medium (ThermoFisher Scientific) to collect the microcapsules on ice. After collecting for 1 h, the microcapsules naturally sunk down to the bottom of the tube. After aspirating the supernatant including oil and 25 mL of medium, the remaining 5 mL of medium with microcapsules was transferred to a new 50 mL tube by pipetting. Thereafter, an equal volume (5 mL) of $CaCl_2$ (200 mM) was added to the tube to further gel alginate in the microcapsule for 45 s. The microcapsules were then rinsed using 25 mL

of DMED/F12 three times and further transferred into a 6-well plate for culture as aforementioned.

Statistical analysis. Each experiment was independently repeated at least three times. All data are presented as mean ± standard deviation (s.d.). One-way analysis of variance (ANOVA) with Turkey's post hoc analysis was used to compare between different groups. All statistical analyses were carried out with the Prism GraphPad Software. A p value less than 0.05 was considered statistically significant.

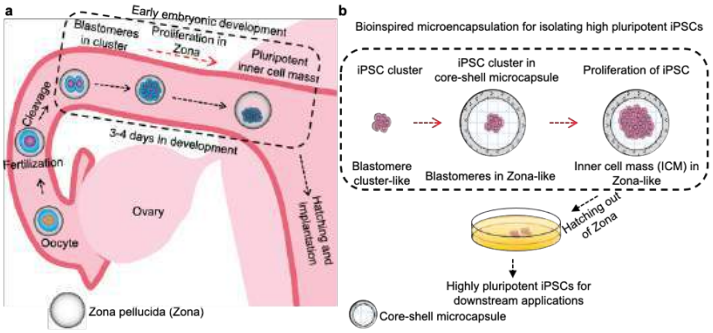

Fig. 1. A bioinspired microencapsulation approach for isolation and culture of high-quality human iPSCs.

RESULTS AND DISCUSSION

As schematically illustrated in **Fig. 1a**, in nature, the ESCs contained in the ICM are developed from blastomeres (e.g., at the 2- to 16-cell stages) via growth/proliferation without aggregation/fusion with blastomeres in any other early embryos[3]. This procedure includes the following key features: 1) encapsulation of a cluster of multiple blastomeres in a nanoliter core that is enclosed in a semipermeable Zona shell, and 2) proliferation of the blastomeres in the miniaturized core for 3-4 days to produce the ESC-containing ICM before hatching out of the Zona shell for implantation. Thus, we hypothesize that a strategy that shares some similarities with the basic steps of the aforementioned procedure in ICM development can be used to isolate/culture the highly pluripotent iPSCs among the conventionally cultured heterogeneous iPSCs (**Fig. 1b**). To test this hypothesis, we generated "blastomere cluster-like" human iPSC clusters and fabricated "Zona-like" core-shell microcapsules with a nanoliter-scale hydrogel core enclosed in a semipermeable alginate hydrogel shell. The non-planar microfluidic device for the bioinspired microencapsulation of human iPSC clusters, together with a schematic illustration of the formation of an iPSC cluster-laden core-shell microcapsule at the flow focusing junction, is shown in **Fig. 2a**. The iPSC clusters are suspended in aqueous core solution containing 0.5% (in weight, by default) hyaluronic acid (HA) and 1% alginate in saline, and the suspension is introduced into the device through Inlet 1 (In1). The microencapsulation of the iPSC clusters in the core enclosed in the semipermeable alginate shell is illustrated in **Fig. 2b**. The "Blastomere cluster-like" iPSC clusters with mostly 3-13 cells per cluster (**Fig. 2c**) were generated by detaching 2D cultured iPSCs and gently pipetting into iPSC clusters. These iPSC clusters were then encapsulated in the "Zona-like" core-shell microcapsules (Figure 2c) using the aforementioned microfluidic device. The microchannel dimensions and flow rates used in this study are given in **Fig. 2d**, which were chosen to achieve a high throughput of the microencapsulation (~150 microcapsules per minute) with

	W×D	Flow rate
Core	100×100	250
Shell	150×150	500
Oil	300×400	5000
gelling	400×400	5000

Fig. 2. Microencapsulation of human iPSC cluster in a Zona-like core-shell microcapsule.

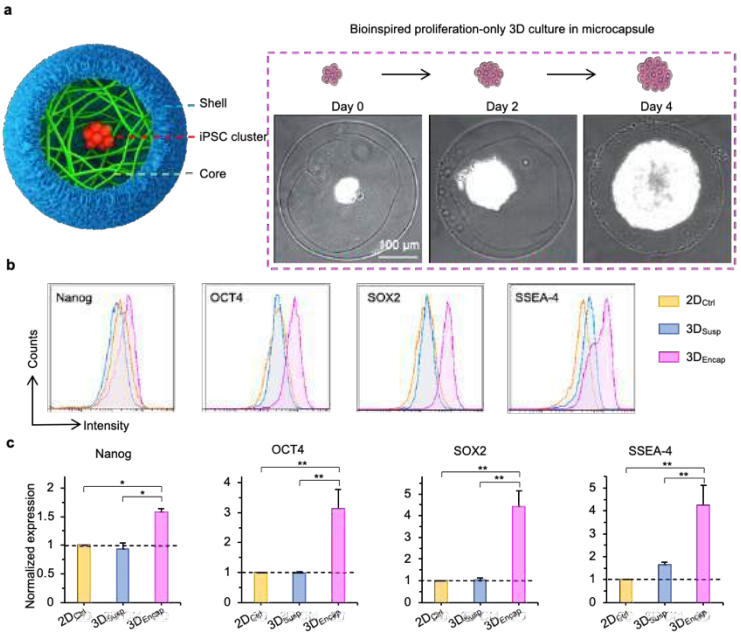

Fig. 3. Bioinspired culture isolates and produces highly pluripotent human iPSC spheroids.

microcapsules less than 400 μm in outer diameter. The microencapsulation approach creates a miniaturized 3D microenvironment for the iPSC clusters to proliferate into "ICM-like" iPSC spheroids. After 4 days of culture, only highly pluripotent iPSCs (20%) can proliferate into spheroids (**Fig. 3a**). The high pluripotency of the iPSCs is further confirmed using flow cytometry analyses (**Fig. 3b**), iPSCs from our bioinspired microencapsulation culture ($3D_{Encap}$) have significantly higher expression of Nanog, OCT4, SOX2, and SSEA-4 than the cells from both conventional 2D and 3D suspension culture methods ($2D_{Ctrl}$ and $3D_{Susp}$). Quantitative analyses showing that expression of in our microencapsulation iPSCs are 1.6-fold, 3.1-fold, 4.4-fold, and 4.2-fold higher than that in 2D iPSCs (**Fig. 3c**).

INTRODUCTION

Gluteraldehyde-treated pericardium has been the most common material for prosthetic heart valves for the past decade. However, it faces several problems, including durability and inconsistent material properties due to biological origins, just to name a few. To address these issues, we are developing a synthetic material for heart valves, consisting of electrospun polycarbonate urethane (ES-PCU) coated with a poly(ethylene glycol) diacrylate (PEGDA) hydrogel. The ES-PCU provides the mechanical structure and function, while the hydrogel helps with biocompatibility. In order to assist with future developmental efforts, we are developing a material modeling approach to predict the mechanical behavior of these materials. Here, we present material models for the fiber mesh, the gel and the composites. Our goal is to identify if there are any interactions between the fiber and the gel.

METHODS

The composite biomaterial was fabricated in two distinct groups: a) aligned fiber meshes, which had a strongly aligned preferred direction, and b) randomly oriented. A comprehensive set of strain-controlled experiments consisting of 9 deformation protocols (Table 1) were conducted using a novel biaxial testing device [1] capable of independent control of all components of the in-plane deformation gradient tensor, including in-plane shear. A maximum extensional deformation of 20% was used for aligned specimens and 37.5% for random specimens. To assist with modeling efforts, similar tests were also performed on the uncoated fiber meshes. Hydrogel isotropic properties were quantified using uniaxial tests. To model the composite biomaterial, we assumed a hyperelastic material model. The total strain energy of the composite was assumed to be given by algebraic sum of the strain energies of its constituents:

$$\Psi = \phi^{g}\Psi^{g} + \phi^{m}\Psi^{m} \quad (1)$$

where, Ψ, Ψ^{g} and Ψ^{m} are the strain energies of the composite, gel and fiber respectively, and Φ^{g} and ϕ^{m} are the volume fractions of the gel and the mesh. Any stress contributions from fiber-gel interactions were ignored at this stage.

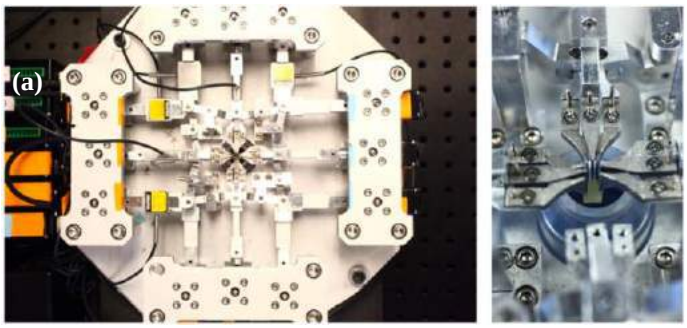

Figure 1 (a): Top view of the testing device showing specimen test area. (b) Close-up view of the mounted specimen.

Table 1: List of experimental protocols and corresponding deformation gradients for aligned specimens.

Extensional Protocols	$\begin{bmatrix}1.2 & 0\\ 0 & 1.2\end{bmatrix}$	$\begin{bmatrix}1.067 & 0\\ 0 & 1.2\end{bmatrix}$	$\begin{bmatrix}1.04 & 0\\ 0 & 1.2\end{bmatrix}$
		$\begin{bmatrix}1.2 & 0\\ 0 & 1.067\end{bmatrix}$	$\begin{bmatrix}1.2 & 0\\ 0 & 1.04\end{bmatrix}$
Shear Protocols	$\begin{bmatrix}1 & 0.3\\ 0 & 1\end{bmatrix}$	$\begin{bmatrix}1 & 0\\ 0.3 & 1\end{bmatrix}$	$\begin{bmatrix}1 & 0.3\\ 0.3 & 1\end{bmatrix}$
Extension and Shear	$F = \begin{bmatrix}1.2 & 0.3\\ 0.3 & 1.2\end{bmatrix}$		

Gel Model: The gel was assumed incompressible and was modeled with a neo-Hookean material model:

$$\Psi^{g} = C_1(I_1 - 3)$$
$$\mathbf{S}^{g} = 2C_1(I_1 - C_{33}\mathbf{C}^{-1}) \quad (2)$$

where, C_1 is a material constant and I_1 is the first invariant of right Cauchy-Green deformation tensor, **C**.

Mesh Model: The mesh model was developed by first modeling the response of a single fiber. We assumed the mesh to be hyperelastic and modeled the uniaxial response of a fiber with an Ogden model:

$$\Psi^f = G\left(\lambda_f{}^a + 2\lambda_f{}^{-\frac{a}{2}} - 3\right) \quad (3)$$

where Ψ^f is the strain energy function, λ_f is the fiber stretch, and G and a are model parameters. Next, the orientation of fibers spread throughout the scaffold was modeled with an orientation distribution function (ODF). The ODF was assumed to be a linear combination of beta distribution and uniform distribution, so that

$$\Gamma(\theta;\ \mu,\sigma,d) = (1-d) * \beta(\theta;\ \mu,\sigma) + \frac{d}{\pi} \quad (4)$$

$$\beta(\theta;\ \mu,\sigma) = \frac{[\omega^{\alpha-1}(1-\omega)^{\alpha-1}]}{\pi B(\alpha,\alpha)},\ \omega = \frac{\theta-\mu+\pi/2}{\pi},\ \sigma = \frac{\pi^2}{4(2\alpha+1)}$$

where, μ,σ are mean and standard deviation of the beta distribution and d is the random distribution parameter, and $B(a,b) = \int_0^1 t^{a-1}(1-t)^{b-1}\,dt$. Finally, the bulk level mesh response was obtained by integrating the fiber response with the ODF for all fiber orientations:

$$\mathbf{S^m} = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \Gamma(\theta) S^f \mathbf{n}\otimes\mathbf{n}\,d\theta \quad (5)$$

where, $\mathbf{S^m}$ is the second Piola-Kirchhoff stress tensor of the mesh, S^f is the fiber stress, $\mathbf{n} = \mathbf{n}(\boldsymbol{\theta})$ denotes the fiber direction and $\lambda_n = \sqrt{\mathbf{n}(\mathbf{Cn})}$, is the stretch along $\mathbf{n}$. This equation has 5 parameters, $G, a, \mu, \sigma,$ and d. These parameters were determined by fitting the model to data from 3 specimens for 5 extensional protocols with varying ratios of maximum stretch along the preferred (PD) and cross-preferred (XD) directions.

Composite Model: The composite model response was obtained by combining Eq. 1 with Eq. 2 and Eq. 4:

$$\mathbf{S} = \phi^g \mathbf{S}^g + \phi^m \mathbf{S}^m \quad (6)$$

$$= 2\phi^g C_1(I_1 - C_{33}\mathbf{C}^{-1}) + \phi^m \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \Gamma(\theta) G\left(\lambda_f{}^{a-2} - \lambda_f{}^{-\frac{a}{2}-2}\right)\mathbf{n}\otimes\mathbf{n}\,d\theta$$

We evaluated the validity of Eq. 6 by comparing the model prediction against experimental data for composites for extension and shear protocols. In the absence of interactions, it is expected that the model predictions should match experimental data, whereas if interactions are present, the model is expected to underpredict the data.

RESULTS

The gel response was captured very well by the neo-Hookean model with r^2=0.9809 (Fig. 2).

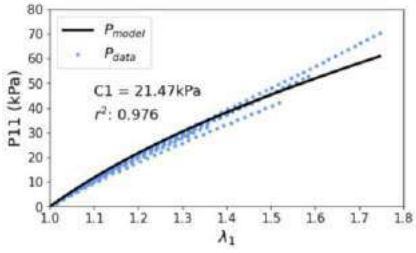

Figure 2: Gel model fit to uniaxial tension data

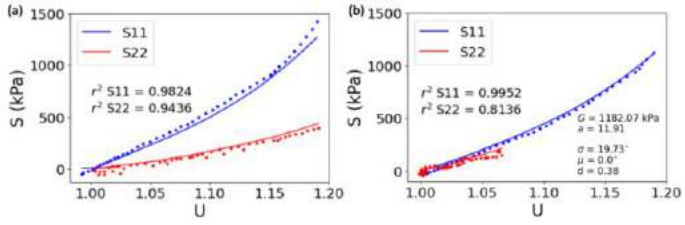

Figure 3: Mesh model fit to extensional protocols for (a) $\lambda_1{:}\lambda_2 = 1{:}1$, (b) $\lambda_1{:}\lambda_2 = 3{:}1$. Dotted line denotes the data, solid line denotes the model fit.

The mesh model was able to accurately capture the response of all mesh specimens for all the extensional protocols (Fig. 3), and yielded the following values for model parameters, $G = 1182.07$ kPa, $a = 11.91$, $\sigma = 19.73°$, $d = 0.38$, and μ was fixed to 0°.

The composite model was able to predict the results for all the extensional protocols with remarkable accuracy (Fig. 4). We also utilized the composite model to predict the results for shear protocols (Fig. 5). The model prediction seemed to slightly underestimate the experimental data implying strong evidence of fiber-gel interactions under these modes.

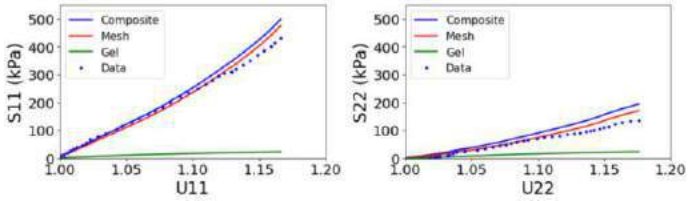

Figure 4: Model prediction for aligned composites for equibiaxial extension. Predicted stress closely matches experimental data, implying that there are no interactions between fiber and gel under extension. The gel contribution is to the total stress is very low.

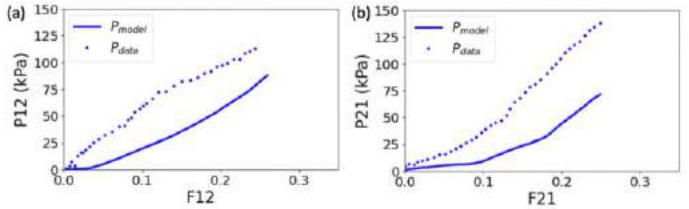

Figure 5: Model prediction for aligned composites for shear protocols (a) F12=0.3, F21=0, (b) F12=0, F21=0.3. The model underpredicts shear stresses, implying strong evidence of fiber-gel interactions under shear modes.

DISCUSSION

The primary goal of this project was to develop a material model that can predict the mechanical behavior of the ES fiber-gel composites under varying loading conditions and to determine if there is any evidence of interactions between the fiber and the gel. Our modeling results suggested that the properties of the mesh can be captured accurately. Furthermore, the composite model predictions under extensional stretches suggested that there is no evidence of interactions under pure extension. However, for shear protocols, the stresses were underpredicted by the model (Fig. 5). This suggested that there are stress contributions from interactions between the mesh and the gel under shear modes. Our assumption is that these interactions are primarily due to fiber rotation and coupling, since we do not see any conclusive evidence of interactions under biaxial extension. Thus, the pseudo-invariant $I_8 = (\mathbf{n}_\alpha.\mathbf{n}_\beta)\mathbf{n}_\alpha.\mathbf{C}\mathbf{n}_\beta$, appears to be a good candidate to capture the coupling phenomenon between fibers oriented at angles α and β. We are currently working on a model with a modified form of I_8 to capture these interactions, based on the model presented in [2].

INTRODUCTION

Cytoplasmic fragments or cellular fragments are independent bodies devoid of nucleus capable of exerting forces and sustaining migration long after separation from the parent cell body. Often understood as waste disposal mechanisms, their vital role in intercellular communication based on the cargo enclosed within their membranes such as proteins and RNA transcripts have been recently realized[1]. Their spontaneous emergence as cells migrate through the complex extracellular matrix (ECM) which is fibrous in nature, have also been implicated to be vital in pathological conditions such as in cancer biology[2]. Their potential as important diagnostic and therapeutic tool have been recognized, as for instance, their uptake in murine fibroblasts have led to loss of tumorigenic phenotype[2]. Biophysically, they have also been used as model systems to deduce the role of nucleus in guiding cellular polarity, migration as well as contractility. However, current understanding on fragment mechanobiology is derived from studies on flat, featureless substrates while the native ECM is fibrous. To quantitatively describe fragment biophysics in a more physiologically relevant ECM, we used non-electrospinning Spinneret-based Tunable Engineered Parameters (STEP) technique to generate various fiber architectures: crosshatch, hexagonal and parallel, with each fibrous geometry representing a subset of the in vivo ECM observed under different conditions. Using Nanonet Force Microscopy (NFM)[3,4], we estimate single fragment forces of varying shapes and sizes. On all fiber networks, we document a peculiar oscillatory migration mode, not readily observed on flat. Interestingly, these fragments remain contractile for several hours. Pharmacological ROCK inhibition drastically reduces the oscillatory behavior as well as the contractility. Overall, contextual fiber networks reveal new fragment behaviors, not observed on flat 2D.

METHODS

Suspended fiber networks were generated using our previously established STEP technique[5]. Parallel, crosshatch and hexagonal fiber networks were generated out of 220nm polystyrene fibers. Human mesenchymal stem cells (hMSCs) used were cultured in growth medium at 37˚C and 5% CO_2. Imaging was done in a Zeiss AxioObserver Z1 microscope equipped with incubation. 20x and 63x objectives were used for phase contrast imaging and fluorescent imaging respectively. Immunostaining was performed to stain actin, paxillin and microtubules. Fragment forces were evaluated using customized MATLAB code that minimizes error between computed and experimental fiber deflections. ROCK inhibition was performed by using the drug Y27632.

RESULTS

We observe spontaneous formation of fragments on fibers. Cells suspended on parallel fibers assume a polarized shape and as they stretch along the fibers, the lamellipodial extension pinches off to form a fragment (Fig 1A). Similar mechanism is demonstrated by cells on hexagonal as well as crosshatch fibers to generate fragments (Fig 1B,C). Fragments formed are of different shapes and sizes. We classified them into three main shapes: circular, blob-like and rectangular. Circular fragments are near spherical bodies (AR~1) while blob-like fragments are marked by characteristic blebbing (AR~4). Rectangular fragments are elongated fragments with high aspect ratio (AR~12).

The fragments formed mostly remained stationary. However, the motile fragments demonstrate majorly two main migratory modes: oscillatory and persistent (Fig 2A). In general, fragments move faster on fibers than on flat (Fig 2B). The fragments that moved back and forth about a mean position for at least one cycle were termed as oscillatory

fragments. This oscillatory behavior was conserved across the fiber categories but was not observed on flat. On quantification of time periods of their oscillations, we found them to be independent of fiber architecture (Fig 2C). This behavior is sometimes observed for hours and one example case is shown (Fig 2D). Interestingly, these fragments also extend lateral protrusions that helps them to transition across fibers (Fig 2E). Over time, these fragments rupture reminiscent of cells undergoing apoptosis (Fig 2F).

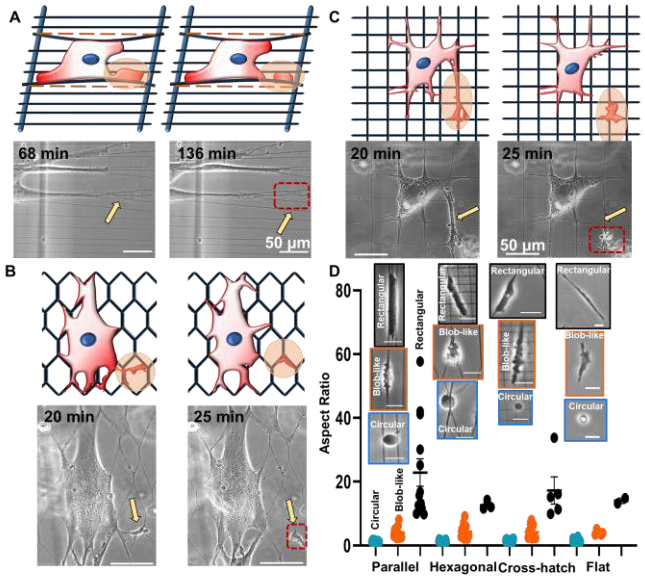

Figure 1: (A-C) Fragment formation by pinching on parallel, crosshatch, and hexagonal scaffolds (D) Aspect ratio of the different shapes (circular, blob-like and rectangular) of fragments formed on all fiber networks as well as flat. Adapted from Ref [6]

On inspection of the cytoskeletal and adhesion components, we found stark differences between fragments and intact cells. The f-actin distribution was diffusive without any dominant stress fibers. Further, the paxillin signal was found distributed across the entire length of fragment as opposed to concentration at the poles of intact cells (Fig 3A). Based on these observations, we modified our previously established NFM technique to measure the forces of contractile fragments (Fig 3B). We introduced distributed loading represented by 10 force vectors. It was found that fragment forces were not correlated with fragment sizes. Furthermore, the maximum force a fragment exerts does not necessarily occur immediately after its separation from the main cell body (Fig 3B inset). On inhibiting the contractility by introducing Y27632, a ROCK inhibitor, we observed reduction in number of small size fragments (Fig 3Ci). It was confirmed with shape analysis that circular fragments were reduced in number whereas the large rectangular fragments were higher in percentage of fragments formed (Fig 3D). Surprisingly, we observed that the oscillatory behavior is completely inhibited in presence of the drug which suggests that the origin of this peculiar motion is driven by the contractility driven changes in polarity.

DISCUSSION

In conclusion, for the first time to the best of our knowledge, we report precise force measurements as well as the migratory behavior of individual fragments of varying sizes and shapes on fiber architectures. The fragments undergo an oscillatory motion exclusive to fibrous environments, which we find to be driven by ROCK based contractility.

DEVELOPMENT OF A NOVEL TESTING SYSTEM TO EVALUATE MICROSCALE MECHANICS AT THE VITREORETINAL INTERFACE

Joseph D. Phillips (1), Brittany Coats (1)

(1) Mechanical Engineering
University of Utah
Salt Lake City, Utah, USA

INTRODUCTION

Posterior vitreous detachment (PVD) is a natural process that occurs in 87% of people by 80-89 years of age [1]. PVD results from vitreous liquefaction concurrent with interfacial weakening between the gel-like vitreous and the thin, delicate retina [2]. Complete PVD is typically harmless; however, partial PVD can lead to strong, localized adhesions at the vitreoretinal interface. These lingering adhesions exert traction forces that can cause retinal disruption and vision loss. Despite the critical role of vitreoretinal mechanics in PVD, the mechanical nature of PVD remains unclear. To date, few mechanical studies have been performed at the vitreoretinal interface, and no micromechanical studies exist. In this study, we aim to elucidate mechanisms of PVD by developing a novel magnetic-based micromechanical testing system and protocol that can be used to measure adhesion variability across localized regions of the retina.

METHODS

Whole vitreous with intact retina was dissected from fresh porcine eyes (n=2). Following dissection, a 17.5 mm wide specimen of vitreous and retina was cut from the equatorial region and fixed to a plastic tab using a thin layer of cyanoacrylate adhesive. The tab and specimen were then placed into a 3D-printed fixture with a #0 coverslip glued to the bottom (Figure 1).

Following specimen preparation, 25 µL of 5 mg/mL magnetic microbeads (BM551, Bangs Laboratories, Fishers, Indiana) were injected into the vitreous near the vitreoretinal interface. The microbeads are coated in streptavidin, a protein with an Arg-Tyr-Asp amino acid sequence that mimics the Arg-Gly-Asp receptor domain of fibronectin [3], a common adhesive protein to collagen. Therefore, the surface-modified streptavidin-coated beads can form covalent bonds with vitreous collagen, resulting in tight binding between beads and fibers. Specimens were incubated for 10 minutes following injection to facilitate bead-fiber binding.

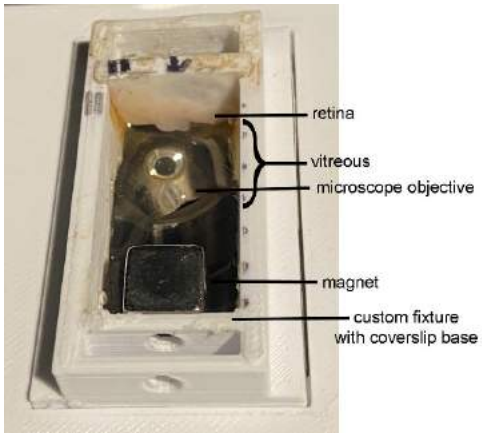

Figure 1: Image of testing system. Retina is fixed to a removable tab and placed inside a custom fixture for imaging.

Vitreous collagen fibers and beads were observed by confocal reflectance microscopy (Olympus FV1000, Olympus Corporation, Tokyo, Japan). Time-series images were captured prior to placement of a 9.51 mm cuboid magnet and every 10 seconds for two minutes after magnet placement. Bead and fiber displacement were tracked using a custom segmentation code in MATLAB (Figure 2). Prior to applying the magnet, a constant linear drift was observed. This linear drift was quantified and subtracted from displacement (Figure 3). The number of bound beads in each image was quantified and defined as beads with <10% relative displacement to adjacent collagen fibers.

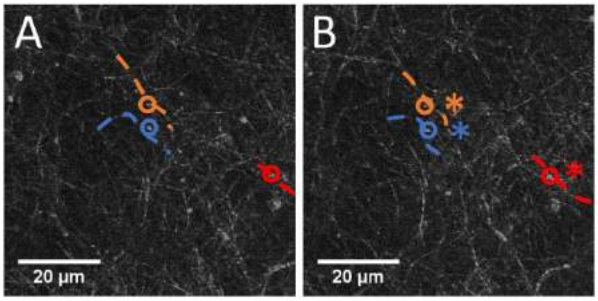

Figure 2: Confocal reflectance microscopy image of beads (circles) and collagen II (dashed lines) displaced 5.49 µm before (A) and after (B) magnet placement (*original bead location). 180X magnification.

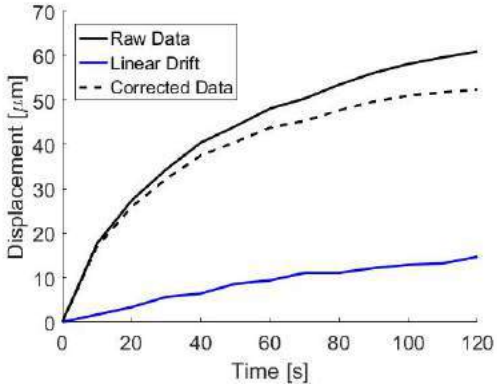

Figure 3: Magnetic displacement data were corrected for linear drift occurring without magnet placement.

The magnetic force exerted on one bead is given by [4]

$$F = \nabla(m_{Sat} \cdot B) \quad (1)$$

where m_{Sat} is the magnetic moment and B is the magnetic field at the bead. The magnetic field for a cuboid permanent magnet is given by

$$B(x) = \frac{B_r}{\pi}\left[\tan^{-1}\left(\frac{ab}{2x\sqrt{4x^2+\phi}}\right) - \tan^{-1}\left(\frac{ab}{2\varphi\sqrt{4\varphi^2+\phi}}\right)\right] \quad (2)$$

where $\phi = a^2 + b^2$, $\varphi = c + x$, and a, b, and c are the height, width, and thickness of the magnet, respectively. B_r, the residual magnetic field of the magnet, is 1.32 T (or 13,200 G) based on manufacturer data. The magnet was placed at an average distance of 26.00 mm from the center of the specimen, giving an approximate magnetic field of 62 G at the center of the specimen and a range of 23-131 G across the specimen. Using the field at the center of the specimen results in a magnetic moment of 8.975 emu/g. The estimated force on a bead at the center of the specimen is 1.03 pN and the potential bead force range is 0.38-2.18 pN, depending on bead location.

RESULTS

Approximately 34.9±8.0% of the beads successfully bound to collagen fibers and were displaced up to 70 µm during application of the magnetic field. The displacement was nonlinear and started to reach equilibrium at two minutes with a percent change of 0.87±0.41% from the previous time point (Figure 4). Within each image, bead displacement variation was small (2.52±1.05 µm), but displacement across image locations varied greatly (47.48±25.57 µm). Variation between specimens was 6.81-25.98 µm, depending on location.

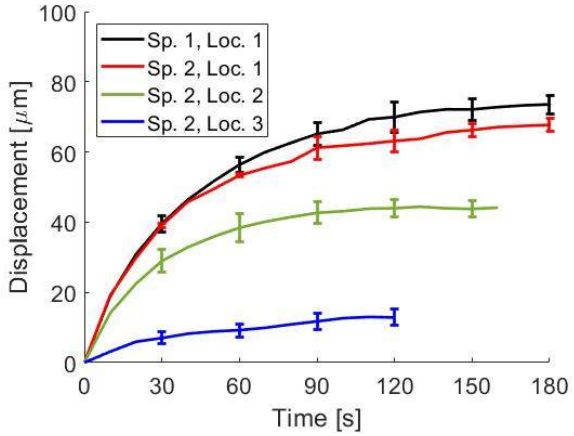

Figure 4: Displacement curves for four locations from two specimens. Error bars represent ±1 standard deviation.

DISCUSSION

In this study, we developed a testing system and procedure to perform micromechanical tests at the vitreoretinal interface. By binding magnetic microbeads to collagen fibers, the localized mechanics of the vitreous and vitreoretinal interface can be elucidated. The system and procedures were successful in binding 35% of the beads to collagen, resulting in approximately 9.21-28.9 pN of force in the imaging window and 0.889 µN of force in the volume of vitreous for beads injected at the center of the specimen. Parameters for confocal reflectance microscopy were carefully optimized to illuminate the highly reflective beads simultaneously with low autofluorescence collagen fibers. Natural linear drift was present in specimens, but this was overcome with application of a sufficiently strong magnet and linear correction of the data.

Bead displacement within an image was minimal, but displacement across imaging locations varied greatly. We observed distinct difference in displacement with visually different densities of collagen. This relationship will be quantified in future experiments. Timing of imaging may also contribute to the differences in displacement. All image locations were captured within 30 minutes of dissection, but as time passes, fluid may disperse across the coverslip, reducing the ease of collagen displacement. To evaluate this, we plan to implement an electromagnet to carefully control the application and magnitude of the magnetic field, and evaluate hysteresis curves over time within single location. While still in the preliminary stages, this novel test system has the potential to provide micromechanical data critical to closing gaps in our knowledge of the mechanisms of PVD. These data will aid in the development of pre-surgical methods to correct imbalances in vitreous liquefaction and interfacial weakening leading to partial PVD and vision loss.

INTRODUCTION

Neuropeptides are the most diverse class of signaling molecules in nervous system and play important roles in regulating neuronal activity and a wide range of physiological processes. In contrast to fast amino acid synaptic transmission, neuropeptides may diffuse from the release sites and exert their actions through G-protein coupled receptors (GPCRs) at relatively long distances. This diffusion-driven distribution is referred to as volume transmission, a nonsynaptic dispersion in the extracellular space (ECS).[1-2] Where a particular neuropeptide acts relative to its release site is a fundamental and critical question to elucidating its functional role in neural circuits, but less understood. While some neuropeptides travel long distances from a few micrometers to millimeters, several factors affect their diffusion, including the degradation by extracellular proteases and the narrow and diverse ECS in the brain.[3] Furthermore, neuropeptides can typically activate GPCRs at low endogenous concentrations, up to 1000-fold or lower than classical neurotransmitters.[2] These make it challenging to characterize neuropeptide and quantitatively measure the neuropeptide diffusion in the local brain environment by using traditional methods such as mass spectrometry or bioassays. To date, there are limited tools available to study the properties of neuropeptide released *in vivo*.

In this study, we developed an all-optical approach to probe neuropeptide diffusion *in vivo* by integrating two new neuropeptide release and sensing techniques. Photosensitive nanovesicles can be packaged with biomolecules (e.g., dyes, peptides) and provide a way to use near-infrared light to photorelease under tight temporal and spatial control *in vivo*. For detection, we developed a new cell-based neurotransmitter fluorescent engineered reporter (CNiFER) that is sensitive to nM concentrations of somatostatin (SST). By stimulating nanovesicle release and imaging under two-photon microscopy, we demonstrate, for the first time, *in vivo* measurement of neuropeptide local diffusion that contributes to volume transmission and determine the maximal diffusion distance. We further demonstrate that, the diffusion of fluorescent molecules and neuropeptide is altered in hyaluronan-deficient mouse, a disease condition indicated in various neurodegenerative diseases including Parkinson's disease.

METHODS

Nanovesicles preparation: Gold-coated calcein or somatostatin-14 (SST)-loaded liposomes were prepared by the thin-film rehydration method reported before.[4]

SST2 CNiFERs: We created a new SST2 CNiFER based on the design of previous CNiFERs,[5] but with the following changes: we increased the brightness and sensitivity by replacing the TN-XXL with Twitch 2B;[6] we coexpressed a chimeric G Protein Gqi5 that redirects Gi/o receptors to the Gq signaling pathway; we performed CRISPR to knockout the endogenous human muscarinic M4 receptor. We then expressed the hSSTR2 receptor in this modified HEK293 cell (clone #128C3) and isolated a single clone #5F3, which is referred to as SST2 CNiFER.

Diffusion measurement in mouse cortex: Gold-coated calcein-loaded nanovesicles (Au-nV-Cal) were stereotaxically injected to the somatosensory neocortex of C57BL/6 mice at depth of 400-500 μm through the open-skull cranial window. Nanovesicles were imaged at 920 nm and stimulated at 720 nm to trigger calcein release by a multi-photon laser scanning microscope (FVMPE-RS, Olympus). To measure SST diffusion, gold-coated SST-loaded nanovesicles (Au-nV-SST) were mixed with SST2 CNiFERs (core implant) and injected into mouse neocortex. Photo-stimulations at 720 nm were performed on the core implant. Several clusters of SST2 CNiFERs without nanovesicles were implanted into adjacent sites to detect the release of SST from the core implant. Fluorescence of CNiFERs was collected in cyan (460-500 nm) and yellow (520-560 nm) fluorescence channels when excited at 900 nm, and the ration change (ΔR/R) was calculated for each ROI. For calcein diffusion, the following equation was derived from the point source diffusion model:[7]

$$t = \left(\frac{1}{6D^*}\right) r^2 \quad (1)$$

where r represents the diffusion distance, and t is the time that the diffusion takes to reach the maximum concentration for a given r.

To develop a hyaluronan-deficient brain model, approximately 4 µL of 20 mg/mL hyaluronidase from bovine testes in PBS was injected intraventricularly at a depth of 2 mm two days before the diffusion measurement.

RESULTS AND DISCUSSION

As a proof of concept, we first demonstrate the feasibility of the all-optical approach by measuring the diffusion of a fluorescent dye in mouse cortex. As shown in Fig. 1a, near-infrared (720 nm) femtosecond laser scans on Au-nV-Cal implanted in the cortical layer II/III triggered the instantaneous release of calcein from the nanovesicles. In the nanovesicles, calcien fluorescence is quenched but upon photostimulation, a large increase in F is observed, which decreases as the dye diffuses through the ECS. Thus, the stimulated nanovesicles could be considered as the point source for calcein diffusion. The distribution of calcein was analyzed by a ring-analysis method (Fig. 1b). In addition to a decrease in F with distance, the time to reach the maximal intensity is longer. We considered the interval between these peak times to reflect the diffusion time at the corresponding distance. The relationship is fit well by a mathematical model for diffusion (Fig. 1c). Based on the equation (1), we calculated the calcein diffusion coefficient (D^*) *in vivo* (Fig. 1d). We predicted that this coefficient would increase if we increased the ECS. To test this, we treated brains with hyaluronidase (hyase) and found that D^* is 1.8-fold higher than that in normal brain, consistent with faster diffusion in this condition. The tortuosity (λ) was calculated as 73% lower after comparing D^* with free diffusion coefficient (D) in 0.2% agarose gel (Fig. 1e).

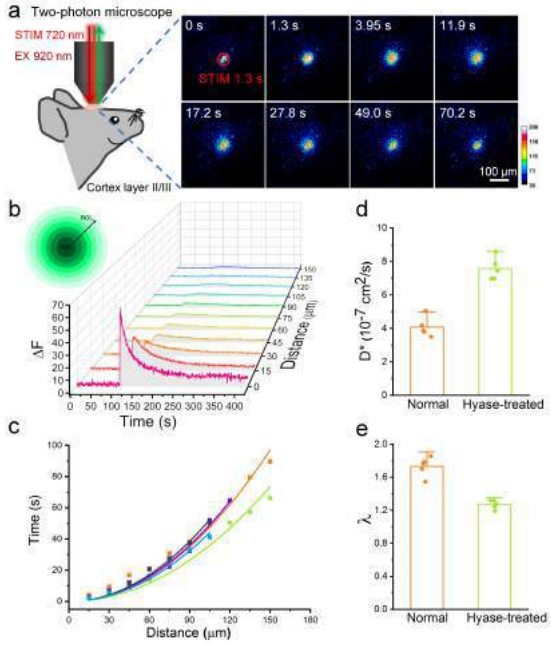

Fig. 1. Diffusion measurement of fluorescent dye in mouse cortex. (a) Calcein fluorescent images over time in mouse cortex measured by a two-photon microscope. Scale bar: 100 µm. (b) Calcein fluorescent intensity changes in different ring-ROIs. (c) The time intervals between the peaks in (b) and the corresponding distance were fitted by the equation (1). (d) Calcein effective diffusion coefficient D* and (e) the tortuosity (λ) in normal and hyase-treated mouse brains. Data were expressed as Mean ± SD (n = 5 independent implants in c, d, e).

To measure neuropeptide release *in vivo*, we developed a new CNiFER for detecting SST. SST2 CNiFERs have an EC_{50} of ~ 4 nM for SST, and little or no response to other peptides and neurotransmitters. Integrating the CNiFER technology with the ultrafast photorelease method provided us with the tools to measure neuropeptide diffusion and volume transmission *in vivo*. SST2 CNiFERs were mixed with Au-nV-SST and implanted in the cortical layer II/III (Fig. 2). In addition, two other CNiFER clusters without nanovesicles were implanted (ROI-2, ROI-3). Photo-stimulation of Au-nV-SST in the core implant (ROI-1) triggered the release of SST, which was detected first by SST2 CNiFERs in ROI-1 and then by SST2 CNiFERs in ROI-2 and ROI-3 (Fig. 2b). As with calcein, the peak was smaller and occurred after a delay in the SST2 CNiFERs in ROI-2 and ROI-3, reflecting the diffusion time for the peptide. We carried out several experiments varying the distances between core and satellite SST2 CNiFER implants to quantatively determine the diffusion time over these distances (within 250 µm). In the hyase-treated brain, the diffustion time is faster than that in normal brain, which is consistent with the results of calcien diffusion.

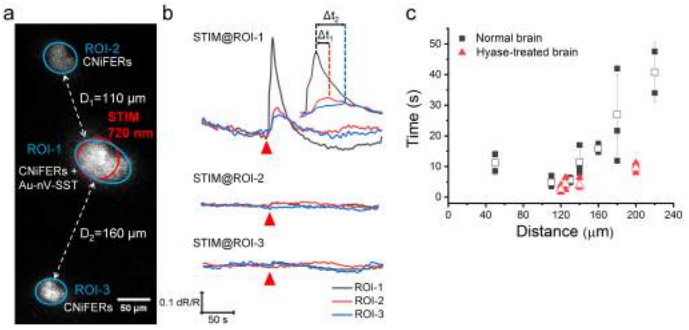

Fig. 2. Diffusion measurement of neuropeptide in mouse cortex. (a) Fluorescent image of SST2 CNiFERs implanted in the layer II/III of mouse cortex. The implant in the center (ROI-1) was mixed with Au-nV-SST, while the other two implants (ROI-2, ROI-3) were just SST2 CNiFERs alone. (b) The response curves of CNiFERs when stimulating at different regions (720 nm, 100 mW, 2.6 s). The enlarged curve shows the time intervals between the peaks of response. (c) Summary of SST diffusion distance and corresponding time measured in normal mice and hyase-treated mice. The blank squares and triangles indicate the mean values.

CONCLUSION

We developed a new all-optical approach to monitor the hindered diffusion of fluorescent dyes to neuropeptides in mouse cortex. We quantitatively determined the neuropeptide diffusion time over a certain distance for the first time. We also demonstrate that change of ECS matrix would affect the molecular diffusion. The mapping of neuropeptide spatial signaling provides more opportunity to elucidate the function of neuropeptides in regulating neural circuits.

THE EFFECT OF AGE-RELATED ADVANCED GLYCATION END-PRODUCTS ON TISSUE MECHANICS DEPENDS ON UNDERLYING COLLAGEN ORGANIZATION

INTRODUCTION

In musculoskeletal menisci, tendons, and ligaments there is a clear link between increasing age and injuries. Many mechanisms have been suggested to contribute; however due to the high reliance on collagen fibers in these tissues, the most prominent mechanism is believed to be advanced glycation end-products (AGEs).[1-2] AGEs accumulate in collagen with age, producing non-enzymatic crosslinks that alter tissue mechanics, leading to more injuries. Specifically, AGEs are thought to stiffen tissues making them more prone to injury. However, *in vivo* studies have shown inconsistent results, with AGE crosslinks increasing, decreasing, or not effecting mechanical properties in tendons and ligaments throughout the body.[1,3-4] Despite correlative evidence linking collagen glycation to age-related injury, little is known about how AGEs impact matrix mechanics and cell-matrix interactions, resulting in limited therapeutic options.[1-2] We hypothesize that these inconsistences in mechanics are primarily due to differences in collagen organization, with musculoskeletal tissues having varying degrees and sizes of collagen fibrils, fibers, and fascicles throughout the body. Recently, we developed a novel cell-seeded culture device that guides cells using mechanical restraints to produce native-sized hierarchically organized collagen fibers over 6 weeks of culture (Fig 1A).[5] Further, we recently developed a method for inducing physiological AGEs, which match AGE levels of 21-23 month old mice tail tendons and human 60-70 year old menisci,[2] without effecting cell viability or metabolism.[6] The objective of this study is to combine these two systems and induce AGEs temporally, as cells align fibrils and develop them into fibers and fascicles. We will evaluate the effect of AGEs on mechanics at each hierarchical level to better predict the impact of AGEs on different tissues throughout the body. We hypothesis AGEs will increase stiffness in fibrils but decrease viscoelasticity in fibers and fascicles.

METHODS

Rat type I collagen was extracted and reconstituted as previously described.[5,6] Isolated bovine meniscal fibrochondrocytes were mixed with collagen, injected between glass sheets, and gelled at 37°C for 1 hour to obtain 20 mg/ml collagen gels at $5x10^6$ cells/ml. Rectangles (8x30mm) were cut from sheet gels and cultured in our clamping device for up to 6 weeks in basic DMEM to drive the formation of fibrils, fibers and fascicles (Fig 1A).[5] Meniscal fibrochondrocytes were used since previously they produced the largest range.[5] At 0, 2, 4, or 6 weeks AGEs were induced with the addition of 100 mM ribose to the media for 3 days to induce AGE levels that match human 60-70 year old menisci (Fig 1B),[2,6] while control constructs remain in DMEM. Time points were collected after 3 days of induction at day 3, 17, 31, and 45 (labeled 0, 2, 4 and 6 weeks for simplicity) to evaluate the effect of AGEs in unorganized collagen, and at the fibril, fiber, and fascicle length scale, respectively. Samples were imaged with confocal reflectance to evaluate collagen organization, with auto-fluorescence of cells and AGEs captured together at 400-470 nm. DNA, collagen, total AGEs, and AGE specific crosslink pentosidine, were determined via PicoGreen, hydroxyproline (hypro), AGE fluorescence (360/460 nm, quinine standards), and pentosidine fluorescence (328/378 nm) assays, respectively.[6] Mechanical properties were determined by ramping to 5% strain at 5% strain/sec and holding for 180 seconds to measure stress relaxation.[5,7] Constructs were then returned to 0% strain for 60 seconds and ramped to failure at 0.5% strain/sec.[5] All data are expressed as mean±SD. Significance determined by 1- and 2-way ANOVA with Tukey post-hoc ($p<0.05$).

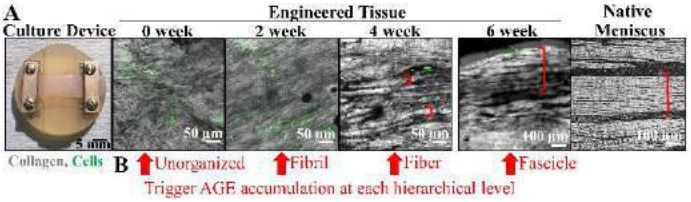

Figure 1: A) Culture device that guides cells to form aligned collagen fibrils, fibers, & fascicles at 2, 4 and 6 weeks, respectively. Brackets denote fibers and fascicles. B) AGEs induced at 0, 2, 4 or 6 weeks to evaluate how AGEs effect each level of organization

RESULTS

Constructs developed aligned fibrils by 2 weeks, native size fibers

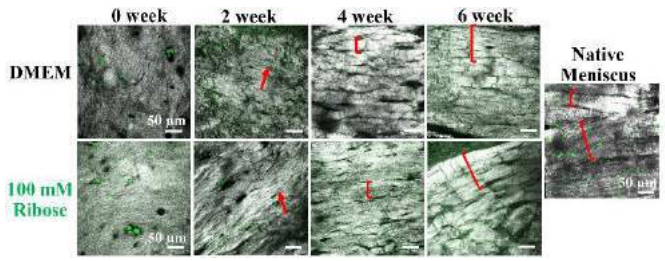

Figure 2: Confocal reflectance. Grey = collagen, Green = auto-fluorescent cells and fluorescent AGE crosslinks. Arrows denote fibrils and brackets denote fibers and fascicles.

by 4 weeks, and larger fascicles by 6 weeks (Fig 2), matching previous studies.[5] Induction of AGEs for 3 days with 100 mM ribose did not disrupt collagen organization and resulted in increased AGE fluorescence (Fig 2). As expected, DNA (not shown), and collagen content (Fig 3A) did not significantly change throughout culture. As cells form aligned fibrils in the first 2 weeks, there was a significant decrease in weight for all constructs (Fig 3B). However, interestingly, AGEs induced at 2 weeks resulted in a significantly higher percent weight then the controls at 2 weeks, while all other time points maintained similar weight to controls (Fig 3B). Three days of ribose induced a significant amount of total AGEs and AGE specific crosslink, pentosidine, at 0, 2, and 4 weeks of culture, with unorganized collagen accumulating the most amount of pentosidine crosslinks (Fig 3C-D). However, once fascicles formed at 6 weeks, 3 days of ribose did not induce a significant increase in AGE crosslinks (Fig 3C-D).

Generally, AGE induction resulted in reduced stress relaxation, with a trending decrease at 2 weeks, and a significant decrease at 6 weeks (Fig 4A). AGE induction also significantly increased the tensile and toe modulus compared to controls when induced at the fascicle level (6 weeks), but had no significant change in modulus when induced in unorganized (0 week) or fibril level organizations (2 weeks, Fig 4B-C). AGE induction at the fiber level (4 weeks), increased the tensile modulus over 0 week samples, but was not significantly different to controls at 4 weeks (Fig 4B). AGE induction had little effect on ultimate tensile strength, strain at failure, or strain at toe region transition (Fig 4D-F), expect for when AGEs were induced at the fiber level (4 weeks), which resulted in a significant decrease in strain at failure and transition (Fig 4E-F). Overall, the results show that the degree of collagen organization will alter AGE's effect on the mechanics of the tissue.

DISCUSSION

In this study we demonstrated that the degree of collagen organization has a significant effect on the amount of AGEs

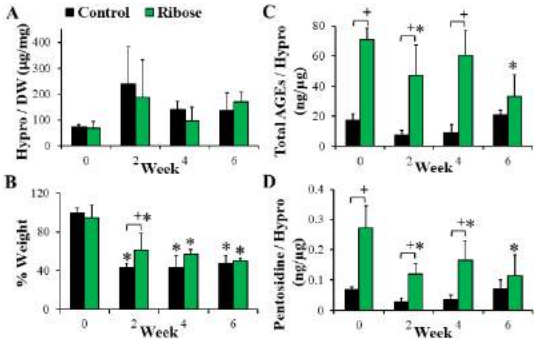

Figure 3: A) Hydroxyproline (hypro) normalized to dry weight, B) % weight compared to 0 week control, C) Total AGEs / hypro and D) AGE specific crosslink pentosidine / hypro. Significance compared to *0 week and +brackets (p<0.05), N = 4.

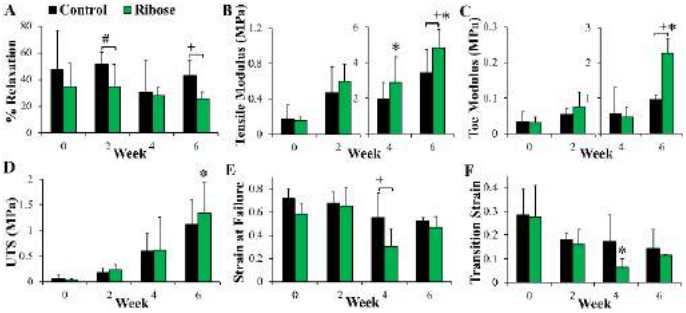

Figure 4: A) % relaxation, B) tensile and C) toe modulus, D) ultimate tensile strength (UTS), E) strain at failure, and F) strain at transition from toe to linear region. Significance compared to *0 week and +brackets (p<0.05). #trending (p<0.1). N = 3-4.

accumulated and the effect those AGEs have on tissue mechanics. At 0 weeks, with no collagen organization, the most AGEs were induced, however this had no effect on tissue mechanics. Once fascicles formed at 6 weeks, 3 days of ribose no longer induced a significant amount of AGEs, however this reduced amount of AGEs still showed a significant increase in both the tensile and toe modulus. At 2 weeks, once aligned fibrils had formed, AGEs did not affect tissue strength or strain properties, however it did decrease viscoelastic stress relaxation. Additionally, at 2 weeks ribose treated constructs had a significantly higher weight (Fig 3B), most likely due to AGE crosslinks having a great affinity for water;[8] however interestingly this was not observed at any other levels of organization. Overall, our work is in contrast to the general belief that crosslinking, both enzymatic and non-enzymatic, increases stiffness and modulus at the fibril level.[1,9] However, our findings support recent work which reported AGEs restrict fibril sliding, resulting in reduced viscoelasticity, but no change in fibril stiffness of rat tail tendons.[3,10] Together these results suggest AGEs occur primarily on the outside of fibrils, unlike enzymatic crosslinks which occur within fibrils and result in increased stiffness. Additionally, AGEs have been shown to effect fiber-fiber sliding at the fiber level,[3] which our work also supports with limited changes in stiffness at the fiber level, but significant changes in strain properties at 4 weeks.

Overall, we found AGEs induced at the fibril level effect viscoelastic properties but not stiffness, while AGEs at the fascicle level effecting both stiffness and viscoelasticity, demonstrating a complex relationship between collagen organization and AGE crosslinking. Our inducible glycation and culture system provides a means to investigate the mechanism of AGEs and their effect on tissue mechanics and cellular function at multiple levels of organization. This system will provide a better understanding of the effects of AGEs at each hierarchical level of collagen, helping to predict the impact of AGEs in tissues throughout the body, in an effort to produce new therapeutic options to reduce age-related injuries.

FIBRIL STRAIN PROMOTES ADDITION OF TYPE I COLLAGEN MOLECULES TO SINGLE, NATIVE COLLAGEN FIBRILS *IN VITRO*

INTRODUCTION

How organized collagenous fibrils can arise and grow from a cluster of cells remains one of the most important basic science questions associated with connective tissue research. The assembly of collagen network is concomitant with integrin expression to transmit compulsory biomechanical information from intracellular space to ECM [1]. Cultures of human dermal fibroblasts and tenocytes under static strain generate tendon-like structures where mechanical loading is required for formation of parallel collagen fibers, tissue maturation, and growth of fibrils' diameter [2]. While tension is part of the collagenous tissue niche and plays a critical role in formation and maintenance of collagen fibrils [3], the manner in which mechanical forces affect the addition of molecules or fibril segments to the growing fibril is not fully understood.

Fibril diameter may be limited by other extracellular matrix residence such as proteoglycans [4], hyaluronate [5], collagen propeptides [6], and minor types of collagen [7]. Nonetheless, failure to maintain tissue homeostasis and fibril diameter after a period of tissue unloading, points to the critical role of mechanics. Whether the association and dissociation rates of collagen monomers with fibrils are directly guided by mechanical load on fibrils or cells indirectly control fibril growth by sensing and processing mechanical information from the ECM is not clear. We hypothesize that local mechanical signals not only control fibril formation and alignment [8], they also directly govern the mechanism of fibril growth and remodeling. It has been suggested that collagen monomers and enzymes are in a dynamic equilibrium with existing fibrils [9]. Tensile forces on fibrils can shift this equilibrium and change the balance between molecular association and dissociation. Here, we sought to answer the question: Does fibril strain promote the molecular assembly of collagen?

METHODS

Bovine sclera fibrils Extraction. Collagen fibrils were extracted from 1-10-day old bovine scleras. Shallow cuts were made on each scleral piece and then placed into 20 mL of pH 7.5-8.0 extraction medium containing: >1000 BAEE unit/mL trypsin, 4 mM ethylenediaminetraacetic acid, 0.1 M tris-HCl, and 0.05% sodium azide. Samples were shaken for ~5 minutes until the sclera pieces swelled and fibrils could be removed.

Fluorescent Labeling of Collagen Molecules. Type I bovine collagen solution was mixed 1:1 with 0.2 M sodium carbonate–bicarbonate buffer containing 1 M sodium chloride. Alexa Fluor 488 TFP ester was added to collagen solution in 1:1 molar ratio. The reaction mixture was stirred for 3 hours at room temperature.

Fibril Stretching and Incubation with Labeled Monomers. Fibrils were attached between microneedles using two Eppendorf Transferman NK2 micromanipulators. Fibrils were kept under 0%, 4%, or 6% static strain at 35°C in a temperature controlled open dish. Labeled monomers were added to the dish at a final concentration of 0.5 µg/mL. DIC and fluorescent images were captured every 1 minute.

Image Analysis of Fluorescent Fibrils. The association rate was calculated based on the fibril fluorescent intensity and photobleaching of labeled monomers.

RESULTS

Monomer/Fibril Association is Fibril Strain-Dependent. For all tested fibrils, the fibril intensity increased rapidly and reached a plateau during the first 30 minutes. Figure 1 shows a representative fibril before and 30 minutes after adding labeled monomers.

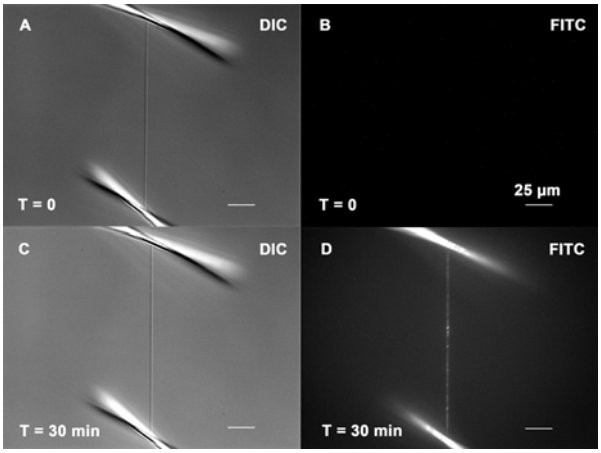

Figure 1: DIC and fluorescent images of a representative fibril stretched to 6% strain between needles. Panel A (DIC) and B (fluorescent) show the fibril at time 0, right before adding the labeled monomers. Panel C (DIC) and D (fluorescent) show the fibril at 30 minutes after adding the labeled monomers.

Normalizing each fibril's intensity by its maximum intensity at the plateau (Figure 2) showed that fibrils which were under 4% or 6% strain reached their plateau faster than the 0% strain fibrils. The plateau times (time to reach 90% of the maximum intensity) were 15.6 ± 5.3, 7.0 ± 1.7, and 6.0 ± 2.4 for fibrils under 0%, 4%, and 6% strain, respectively. Data are presented as mean ± standard deviation (n=3 replicates per group). Post-hoc Tukey HSD test showed a significant difference between 0% and 4% groups (p-value = 0.0234099; * $p<0.05$) and 0% and 6% groups (p-value = 0.0086839; ** $p<0.01$).

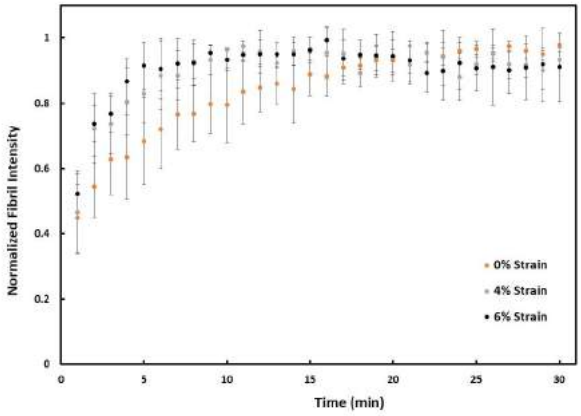

Figure 2: Normalized fibril intensity. The fibrils' intensity rapidly increased and reached a plateau during the first 30 minutes.

Monomers Associate with 6% Strained Fibrils with a Significantly Higher Rate compared with 0% and 4% Strained Fibrils. For all tested fibrils, the highest monomer association rate was immediately after addition of labeled monomers (Figure 3). Association rate rapidly decreased during the first 10 minutes, and remained rather constant afterward until 30 minutes. Remarkably, the fibrils under 6% strain maintained a higher association rate. Normalized association remained fairly constant after 10 minutes at 0.26 ± 0.03, 0.25 ± 0.04, and 0.49 ± 0.15 for fibrils under 0%, 4%, and 6% strain, respectively. Data are presented as mean ± standard deviation (n=3 replicates per group). Post-hoc Tukey HSD test showed a significant difference between 0% and 6% groups (p-value = 0.0122180; * $p<0.05$) and 4% and 6% groups (p-value = 0.0143004; ** $p<0.05$).

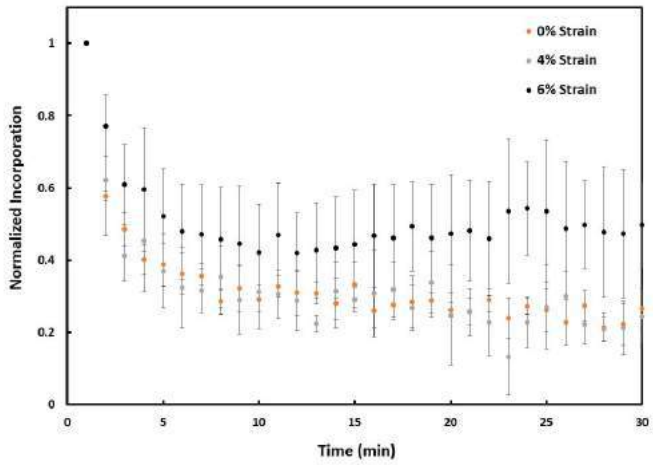

Figure 3: Labeled monomers incorporation onto fibrils.

DISCUSSION

A simple method was developed to mechanically stretch single native fibrils using microneedles and micromanipulators. Analysis of fibrils' fluorescent intensity showed that labeled monomers rapidly associated with fibrils with no lag time and that mechanical stretching of fibrils promoted monomer association with fibrils. Specifically, monomer association rate was significantly higher with fibrils under 6% strain compared with fibrils under 0% and 4% strain.

The higher association rate of fibrils under 6% strain supports a structural limited growth model, where mechanical strain stimulates monomers association and fibrils growth. It has been shown that 1) tension can directly drive initial fibrillogenesis and structures into the path of force [10], 2) applied mechanical strain preferentially preserves type I collagen against enzymatic degradation [11], and 3) in the absence of cells, unloading of collagen fibers can increase fiber disassociation [10]. Here we showed that stresses and strains on collagen fibrils can promote the molecular assembly and fibril growth. The results elucidate the role that mechanics could play in the collagen fibril growth mechanism and provide new opportunities to develop treatments for variety of pathological conditions by promoting growth or degradation when/where needed.

Microfluidics Layout Design for Improved Circulating Tumor Cell Capture Efficiency

Michael C. Hood (1), Jifu Tan (2)

(1,2) Department of Mechanical Engineering
Northern Illinois University
Dekalb, IL, USA

INTRODUCTION

Microfluidics is a promising technique in isolation of circulating tumor cells (CTCs) from patient derived blood samples in early cancer diagnostics, and exhibit several advantages over traditional tissue biopsies [1]–[3]. One challenge for early cancer diagnostics is that CTCs are exceedingly rare in samples [4]. Thus, devices should be able to capture CTCs at very low concentrations. Various capture mechanisms and device designs for CTC isolation can be found in the literature [4], [5]. However, study of device design on the performance of the immunoaffinity-based positive enrichment technique is limited. In this application, CTCs are intended to adhere to microposts coated with desired antibodies and placed throughout the device. Adhesion is accomplished through binding of ligand-receptor antibody pairs. Device performance can be characterized by capture efficiency, which quantifies how many cells out of the total available are captured. Because of the capture mechanism, device performance is highly influenced by the exposure of cells to microposts, as adhesion cannot occur without exposure.

Previous studies [6] found that cells follow streamlines throughout the device closely for low cell concentrations, and showed some deviation at higher cell concentrations. Streamlines in the device are determined by the device configuration, which can be characterized by micropost shape, size, and distribution. The distribution of the microposts defines what fraction of the domain they occupy, as well as how they are placed. The placement of microposts can take many styles, such as a grid, lattice, or algorithmic placement style. It is not well known how these layouts will affect the device performance. It is suspected that devices with a regular post layout would be outperformed by those with irregular post layouts due to greater likelihood of cells being exposed to microposts caused by transport along irregular and non-repeating streamlines. Of particular interest are disordered hyperuniform post layouts, due to their structural similarity with packed beds which are used in filtration processes [7], [8]. Disordered hyperuniform layouts suppress density fluctuations in the placement of posts on large length scales, similar to regular post placements, but allow for irregular flow patterns to arise. An example of prelimary cell trajectories obtained in a disordered hyperuniform device can be seen in Fig.(1). Additionally, cell trajectories obtained from a regular layout device can be seen in Fig.(2).

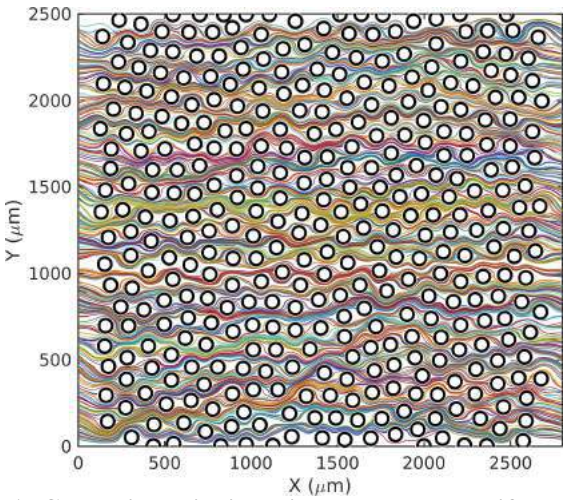

Figure 1: Cell trajectories in a disordered hyperuniform layout device. Microposts are indicated by circles.

METHODS

Because microfluidic devices typically have many thousands of microposts in these applications, it was decided to use a 2D simulation domain for computational efficiency. The fluid flow is solved by the lattice Boltzmann method through the Palabos [9] software library. The cells in the system are modeled using coarse-grained molecular dynamics through the LAMMPS [10] software library. Coupling of the fluid and solid is handled by the immersed boundary method. To model ligand-antibody binding, a probabilistic bond creation and breaking model was implemented based on the work of [11] for the purpose of analysing when adhesion occurs in the ongoing studies. The advantage of the use of a discrete bond

model is that it mimics the physical phenomenon of bond formation to impart forces on cells within the flow. This is in contrast to a pairwise interaction potential, where any particles within the cutoff distance from one another impart a force.

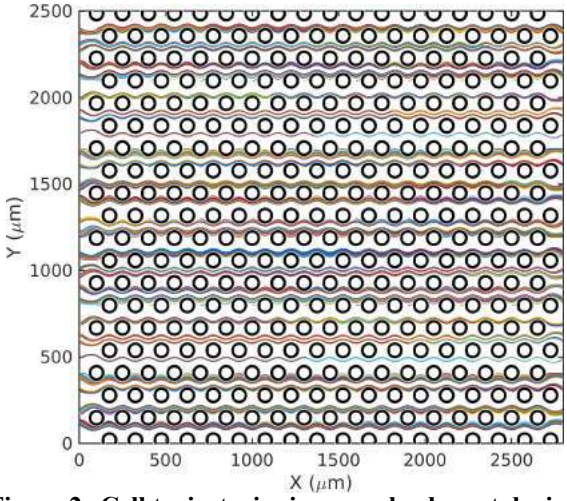

Figure 2: Cell trajectories in a regular layout device.

Device performance is measured by finding probabilities for cell exposure and capture with respect to different device configurations (e.g., micropost size, shape, layout) and operating conditions (e.g., shear rate, cell stiffness, and cell concentrations). An important metric for this application is the amount of time that CTCs spend near posts with reference to total time in the device. We call this the *normalized exposure time* of the CTCs, and it is calculated as:

$$\epsilon = \frac{T_{near}}{T_{total}} \tag{1}$$

The normalized exposure times for each cell are found via post-processing of the simulation data. T_{near} is calculated by summing the total time where the given cell is within a desired distance of a micropost.

RESULTS

Preliminary results show some evidence that disordered hyper-uniform layouts are superior to regular layouts. One can clearly see the qualitative differences in the trajectories between Fig.(1) and Fig.(2). Cases with different flow velocities were also conducted, which showed some indication that higher flow velocities introduced more exposure time to microposts for cells, however this result may not lead to better capture efficiency due to higher shear rates around microposts. Examples of the normalized exposure time can be seen in the distributions in Fig.(3). It is important to note that the regular layout creates a population of exposure times that are concentrated around a time fraction of 0 to 0.05, indicating that the design would not be ideal. It is intended to conduct these same analyses on a larger population of layouts to gain more comprehensive results. Of particular interest are the use of triangular posts, and providing more examples of these different layout classes for their comparison.

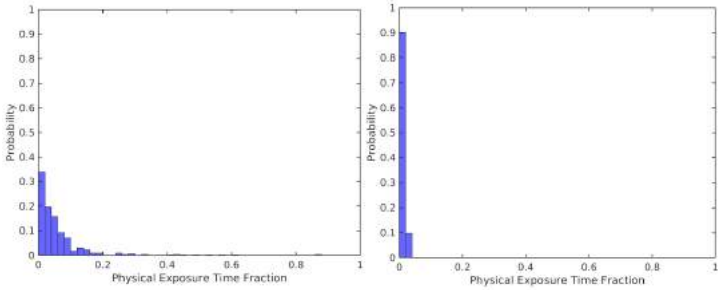

Figure 3: Normalized exposure times for the given device layouts using the same driving pressure, with the disordered layout on the left, and the regular layout on the right.

DISCUSSION

Results collected indicate very different behavior of a regular and disordered type device, as the regular device obtains very little exposure time and the disordered device obtains a much larger number of cells exposed to microposts for a significant amount of time. This shows some indication that disordered designs will generally outperform regular ones. Further studies are being conducted to develop a more in depth understanding of design principles for microfluidics in this application. To study the relationship of flow velocities and shear rates on the performance of these device, tests to find a range of when adhesion can occur are also underway. If a superior class of device designs can be found, it could lead to more efficient and smaller devices, as well as faster processing times. Informing design decisions for microfluidic devices is indispensable in creating more effective solutions for clinical and research settings.

DIRECTIONAL CELL MIGRATION GUIDED BY A STRAIN GRADIENT

Feiyu. Yang (1), Yubing. Sun (1)

Department of Mechanical and Industrial Engineering
University of Massachusetts Amherst
Amherst, MA 01003, USA

INTRODUCTION

Directional cell migration is critically involved in various physiological and pathological processes, including embryonic development, wound healing, and immune responses [1-3]. It is well-known that directional cell migration can be guided by a chemical gradient (chemotaxis) or a stiffness gradient (durotaxis). In this study, we prove directional cell migration by a strain gradient on the extracellular matrix using rat embryonic fibroblast (REF). We designed a low-cost, easily modified, programmable biaxial cell stretching device and corresponding cell culture samples. By adjusting the design, various strain fields on the extracellular matrix were generated. We proved by tracking the single-cell migration that about 60% to 70% of cells would prefer to migrate towards the lower strain direction in both static and 0.1Hz cyclic stretch experiments. The control experiment was conducted to exclude the potential effect of durotaxis and haptotaxis in directing cell migrations. Live-cell focal adhesion dynamic was quantified to investigate the mechanism. We found that focal adhesion size was relatively increased, coupled with more protrusion formations in the lower strain direction.

METHODS

We developed a low-cost, flexible cell stretching device using the Arduino interface. It had the unique feature of generating a strain gradient field on the cell culture area with biaxial stretching. The sample was fabricated by bonding a PDMS membrane to a silicon rubber base with specific geometries design generated by laser cutting (Fig.1a). A well-controlled 4% per mm strain gradient was established on the cell culture area. The sample strain fields were quantified experimentally with micro-contact printing techniques（ Fig.1b ）. During the experiment, rat embryonic fibroblast (REF) cells were cultured on top of the PDMS membrane with a density lower than 80 cells/mm^2. After cells were fully attached 15 hrs later, we started the cell stretching and image the cells for the next 6 hours. The sample was stretched once and kept at the stretched status for 6 hours for live-cell imaging for the static experiment group. For the cyclic experiment group, the sample was cyclic stretched at 0.1 Hz for 3 hrs. The cells were imaged at the same time for 6 hours. Durotaxis, a directional cell migration signal caused by the stiffness gradient, could coexist with the strain gradient on the extracellular matrix. To solve this problem, we design a control experiment, where REF cells were seeded after the cell culture sample was held at the stretched status. Therefore, cells were not exposed to the strain gradient without being stretched. As a result, only the potential durotaxis signals exist in the environment, and the condition of the cell culture substrate was not changed. However, unlike the gradient groups, the pre-stretched control group had no directional cell migration preferences.

To investigate the mechanisms, we analyzed the focal adhesion dynamics, the size of protrusion, and retraction. Two images were taken for each cell before and after stretching was applied, respectively (Fig 2.a). The cell was divided in half by the line passing the nucleus's center and perpendicular to the maximum gradient direction. One half was in the direction of the lower strain, and the other half was in the direction of the higher strain. Focal adhesion total size and the protrusion percentage at the lower and higher strain directions were compared.

RESULTS

When experiencing a strain gradient of 4% per mm, for the static group, approximately 60% of cells migrated towards the direction with the lower strain (Fig.1c). For the cyclic group, 65% of cells migrated towards the direction of lower strain (Fig.1d). No directional migration preferences have been observed for the pre-stretched control group (Fig.1. e). Rayleigh tests were applied to determine whether a single directional preference exists for all three groups. We further evaluate the efficacy of the strain gradient signaling in the migration preferences

using the Forward Migration Index (FMI) (Fig1.f). Both static and cyclic gradient groups were significantly different from the pre-stretched control group. Such preference of migration directionality is also correlated with the magnitude of the strain, albeit with the same strain gradient. It was found that a higher percentage of cells migrated along the decreasing strain direction in the regions with larger strain magnitude (data not shown).

We quantified the focal adhesion dynamics and the protrusion at the lower and higher strain direction to investigate the mechanism. Sixteen cells were analyzed from three experiment batches. The size of focal adhesion and protrusion were relatively increased at the lower strain direction after stretching (Fig 2).

DISCUSSION

In this work, we uncover that REF cells can sense a subtle change in local strain gradient and migrate towards the direction of lower strains. We excluded the potential effect of durotaxis with a pre-stretching control group. Without sensing a strain gradient, no directional cell migration was observed. This highlights the possibility that during embryo development and wound healing processes, a local strain gradient generated due to tissue-generated forces may facilitate the directed cell migration. The strain gradient generation device can be broadly applied for further studies of cellular strain sensing.

MEAN AND TRANSVERSE WALL SHEAR STRESS CORRELATE WITH ENOS EXPRESSION IN ENDOTHELIAL CELLS UNDER ORBITAL FLOW

Jaideep Sahni, Glenn T. Richardson, Ryan M. Pedrigi

Department of Mechanical and Materials Engineering
University of Nebraska-Lincoln
Lincoln, NE, USA

INTRODUCTION

Atherosclerosis is the primary pathology of coronary heart disease and ischemic stroke, and, thus, is the leading cause of death in the world [1]. Despite the systemic risk factors, such as age, obesity, and high LDL, atherosclerotic plaques localize to curvatures and branches of the arterial vasculature. These regions are dominated by disturbed flow, typically characterized by using metrics that quantify the magnitude or directionality of wall shear stress (WSS) over the cardiac cycle. WSS acts on the endothelium, which is a key regulator in the initiation and progression of the atherosclerotic pathology [2]. WSS metrics of disturbed flow have been strongly correlated to markers of endothelial cell dysfunction, primarily using microfluidics, orbital shakers, and step flow chambers *in vitro*, wherein high values of these metrics have been associated with an atherogenic phenotype and low values (indicating normal laminar flow) with an atheroprotective phenotype. To our knowledge, none of these studies have evaluated how markers of endothelial cell function change over a continuous degree of disturbed flow.

In this study, we used an orbital shaker, a machine with a platform moving in a circular motion that causes circumferential motion of the media contained within cell culture well plates placed atop the shaker platform. At the center of each well, media flow is highly multidirectional, mimicking an atherogenic flow condition, which transitions incrementally to unidirectional laminar (atheroprotective) flow with increasing radial position to the outer portion of the well [3]. We used the potential theory (PT)-Stokes method to compute WSS in the well and then computed two WSS metrics of disturbed flow as a function of radial position. We then evaluated the correlation between these WSS metrics and an established marker of endothelial cell function, endothelial nitric oxide synthase (eNOS).

METHODS

Computation of shear stress. We used a previously reported analytical approach called PT-Stokes to compute the instantaneous WSS vectors for a given point in the well of a 6-well plate over an orbital shaker cycle [4,5]. The input parameters were as follows: 2.5 mm fluid height at rest; 17.5 mm cylinder radius; 5 mm orbital radius; 200 rpm angular velocity; 0.76 mm^2/s fluid kinematic viscosity; 1000 kg/m^3 fluid density; and a 9.81 m/s^2 gravitational acceleration constant [6]. We then computed two WSS metrics, including magnitude of the mean wall shear stress over one orbital cycle (MagMeanWSS) and transverse wall shear stress (transWSS), which is the magnitude of the components of the instantaneous WSS vectors perpendicular to the mean WSS direction averaged over one orbital cycle that characterizes the multidirectionality of WSS [6]. The formulations of these two metrics are

$$MagMeanWSS = |\tau_{mean}|, \text{ where } \tau_{mean} = \frac{1}{T}\int_0^T \tau_w \, dt \quad \textbf{(1)}$$

$$transWSS = \frac{1}{T}\int_0^T \left| \overrightarrow{\tau_w} \cdot \left(\vec{n} \times \frac{\int_0^T \overrightarrow{\tau_w} \, dt}{\left| \int_0^T \overrightarrow{\tau_w} \, dt \right|} \right) \right| dt \quad \textbf{(2)}$$

where τ_w is the instantaneous WSS, T is the period of the cycle, and $\vec{n}$ is the unit normal vector to the flow. Bars represent magnitude.

Cell Culture. Primary human umbilical vein endothelial cells (HUVECs) pooled from 10 donors (ATCC), were used for all experiments at passages 4 to 7. HUVECs were maintained with vascular cell basal medium, supplemented with endothelial cell growth kit-BBE (ATCC) and 0.1% Penicillin-Streptomycin-Amphotericin B solution (ATCC) within a humidified incubator at 37°C and 5% CO_2, as per the supplier's protocol. Cells were sub-cultured and seeded into the wells

of 6-well plates at a density of 15,000 cells/cm^2. Prior to cell seeding, wells were coated with rat tail type I collagen (Corning) in 1% 17.5 mM of acetic acid and distilled water overnight in a humidified incubator at 37°C and 5% CO_2. After, collagen-coated wells were carefully washed three times with PBS and then seeded immediately.

Experiment Setup. Experiments were run two days after seeding with 2.41ml of media in each well to give a resting media height of 2.5 mm. PBS was put in the spaces between the wells to minimize the effects of media evaporation. One covered well plate was placed on an orbital shaker (Grant Instruments) and run for 24 hrs at 200 RPM within a humidified incubator at 37°C and 5% CO_2. As a control, a second cell-seeded well plate was placed in the same incubator as the orbital shaker.

Staining and Imaging. After 24 hrs of flow, cells were incubated in 4% paraformaldehyde in PBS for 10 mins and then stained for eNOS. Briefly, cells were permeabilized with 0.1% Triton X100 in PBS for 15 mins and incubated with blocking buffer (1% W/V bovine serum albumin, 22.52 mg/ml glycine, in PBST) for 30 mins to prevent nonspecific binding. Cell layers were then incubated with mouse-eNOS primary antibody at 1:100 (ab76198, Abcam) and Alexa Fluor secondary antibody (ab150117, Abcam) at 1:750, both of which were diluted in blocking buffer and incubated for 1 hr. All incubation steps were conducted on a rocker at room temperature.

Imaging and Analysis. Cells were imaged with Zeiss LSM 800 confocal microscope at 10x magnification. All confocal settings were kept constant over all cell layers. A tile scan of 30-by-2 was taken to capture the cells from the center to the periphery of the well with 16 focus points. The center of each well was identified by finding the left and upper most tangent of the well. Images were analyzed using a custom MATLAB script that computed the average pixel intensity for each image.

Outputs and Statistics. Fluorescence intensity of eNOS as a function of radial position in the well was quantified and a linear regression was performed for each cell layer. The slopes of these lines from experimental versus control cell layers were compared using a one-tailed, two-sample *t*-test. A Pearson's correlation coefficient was computed for eNOS intensity versus the WSS metrics.

RESULTS

Fluorescence intensity of cell layers under flow at the center of the well was 32.9% higher than the same location in cell layers under static culture. This ratio continually increased moving towards the periphery to 141% at 12.7 mm radially. Regressions showed a mean slope of 1.02 ±0.12 (eNOS intensity/mm) for the orbital shaker layers, which was significantly different from controls, 0.10±0.11, $p < 0.009$ (Figure 1).

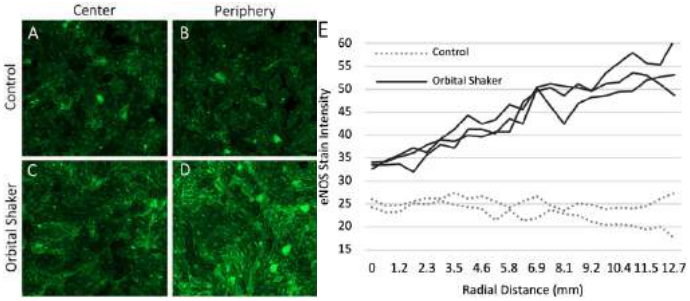

Figure 1: Representative eNOS fluorescence images at the center and periphery (12.7 mm from center) for the control (A and B) and orbital flow cell layers (C and D). (E) Plot shows comparison of average fluorescence intensity where all flow values are greater than control.

The fluorescence intensity of eNOS exhibited a statistically significant correlation with the two computed WSS metrics, wherein the relationship with MagMeanWSS had a Pearson's rho coefficient of 0.94 ($p < 0.001$) and that for transWSS had a coefficient of -0.93 ($p < 0.001$).

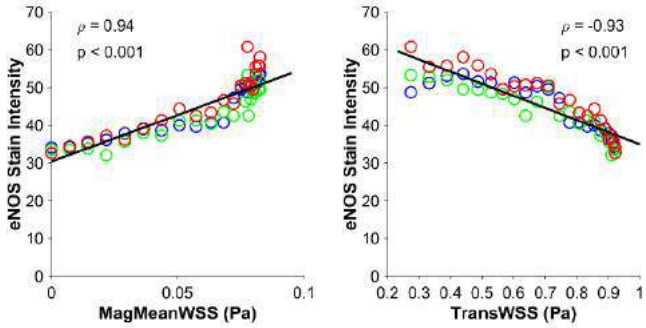

Figure 2: eNOS fluorescence intensity of endothelial cell layers under orbital flow (n=3, each given by red, blue, and green circles, respectively) as a function of two WSS metrics, magnitude of the mean WSS vector (left) and transverse WSS (right). Linear regression lines are in black.

DISCUSSION

Shear stress due to blood flow is an important determinant of endothelial cell function/dysfunction and the development of atherosclerosis. Numerous studies have characterized relationships between WSS metrics of disturbed flow and (patho-)biological readouts, but typically without consideration of the biological response over a continuous range of WSS [3]. The orbital shaker is a convenient tool that can address this deficiency because WSS in a well plate continuously varies from the center to the periphery. Using this approach herein, we found a nearly constant increase in eNOS expression over the well radius from the center to the periphery. In addition, eNOS was higher in cells at the center of the wells exposed to orbital flow compared to cells in static media, which suggests that some flow, even if disturbed, is better than none. These increases in eNOS expression as a function of well radius were highly significantly correlated with the computed WSS metrics, wherein a positive correlation was seen versus magmeanWSS (atheroprotective flow) and a negative correlation was seen with transWSS (atherogenic flow). Defining such relationships over a continuous range of WSS may improve our understanding of endothelial cell function and ability to predict atherosclerosis development.

ROLE OF MUSCLE ACTIVATION ON LUMBAR SPINE FORCE IN FRONTAL IMPACT LOADING

Sagar Umale, John Humm, Narayan Yoganandan

Medical College of Wisconsin
Milwaukee, WI, USA

INTRODUCTION

Anthropomorphic test devices (Hybrid III) are used for crashworthiness studies in automotive, military, aviation, and athletic environments [1-3]. These infrangible physical devices have been used for frontal and rear impacts, i.e., $G_{\pm X}$ accelerative loading, to protect civilian motor vehicle and mounted military occupants. The recorded data from load cells (e.g., femur and upper neck) and accelerometers (chest) are used in the injury criteria (femur force, upper neck axial force and sagittal moment, and head injury criterion) in Federal standards [2], whereas, loads on the lumbar spine are not a part of the assessment. While such studies are underway, human body models have been developed to understand the response of the various body regions with a better representation of the human anatomy, especially from a musculoskeletal perspective. Examples are the Global Human Body Models Consortium (GHBMC) and Toyota Model for Human Safety (THUMS), and others [4-6]. The GHBMC model has been widely used for analyzing loads on the spine and neck and kinematics under different load vectors ($G_{\pm X}$, $G_{\pm y}$, and $G_{\pm z}$) [7, 8]. The model currently does not include the effects of muscles on spinal loads. As muscles contribute to spine stability, posture, internal spinal load paths and load sharing, a better representation of the human musculature is necessary to obtain realistic estimates of the forces. As studies suggest bracing to be a contributor to kinematic variation and injury outcome [9], it is important to investigate the effect of muscle activation on spinal loads using a model that better represents the human muscular anatomy and material properties. The objective of the study, therefore, was to incorporate the thoracic musculature to the GHBMCv5 model and determine the segmental forces on the lumbar spine from frontal impact in a vehicle environment.

METHODS

The anatomy and the origin-insertion locations of muscle were identified [10]. Eleven muscle groups, consisting of 210 one-dimensional elements were incorporated (Figure 1 - left): erector spinae iliocostalis lumborum pars thoracis; erector spinae iliocostalis lumborum pars lumborum; erector spinae longissimus thoracis pars lumborum; erector spinae-longissimus thoracis pars thoracis; multifidus lumborum; multifidus thoracis, quadratus lumborum muscles; rectus abdominus; external oblique muscles, internal oblique muscles, and psoas major. The material properties (cross-sectional areas, density, stress-strain relationship, strain rate) [10-13] were used from the literature to define the Hill-type model for the muscles. The effect of the musculature on occupant kinematic response was verified using human volunteer (three males) sled test experimental data [14]. The setup included a volunteer placed on a rigid seat attached to a sled which was accelerated at 1g and decelerated by collision with a damper setup. The muscle activities were measured using EMG electrodes attached to the skin. The synchronized volunteer kinematics was measured using a motion capturing system. The model was simulated under same experimental boundary conditions (Figure 1 - center). It was positioned on a rigid seat and restrained using a two-point seatbelt to constrain the lower limbs. Three simulations were performed: model without muscles, model with no muscle activation, and muscle activation. The normalized (with respect to peak muscle activation) EMG curves reported in the tests were used for muscle activation.

The models were simulated for 500 ms, and each simulation took approximately 90 hours to solve on a high-performance computing cluster. The head and thoracic excursions from the simulations were compared with the experimental excursions.

Figure 1: Left – the thoracic musculature incorporated into the model, Center – the setup to reconstruct experiments, Right – the setup to simulate frontal impact.

To investigate the effect of bracing during frontal impacts, a Toyota Yaris vehicle environment was used (Figure 1 - right). The occupant was positioned in the seat and restrained with a 3-point seatbelt with pretensioner and retractor. The seatbelt pretensioner was activated as the impact started, the retractor was activated at 12 ms, and the steering wheel-mounted airbag was deployed at 20 ms [15]. Occupant contact with the vehicle environment was modeled using automatic surface-to-surface contact. The entire setup was given an initial velocity of 15.6 m/s, and the vehicle environment was decelerated using a 50 g pulse. Muscles activation was varied: no activation, 50% activation and 100% activation. Cross-section planes were defined at L1, L3 and L5 levels to obtain the lumbar spine forces. The models were simulated for 150 ms, and each simulation took approximately 27 hours to solve on a high-performance computing cluster.

RESULTS

The peak frontal head excursion from the volunteer tests was compared with the excursions from the three simulations. The simulation without muscles and with no activation of muscles showed larger head excursion compared to the volunteers. Whereas, the head excursion in the simulation with muscle activation, was within the range of volunteer excursions reported in the tests (Figure 2 - left). The thoracic excursions at T1 and T10 vertebrae were also within the experimental excursion range for muscle activation case.

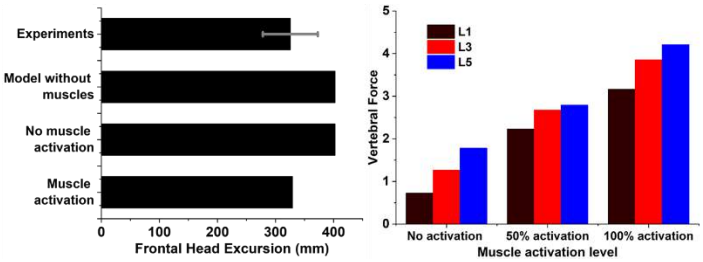

Figure 2: Left – comparison of model head excrusion with the volunteer head excursions, Right – the lumbar spine forces for different thoracic muscle activation levels.

The lumbar spine forces at the L1, L3 and L5 levels extracted using cross-sectional planes were, 0.7, 1.3 and 1.8 kN for no muscle activation, 2.2, 2.7 and 2.8 kN for 50% muscle activation, and 3.2, 3.8 and 4.2 kN for 100% muscle activation. They increased for the higher muscle activation levels and were greater at the inferior level for all activation levels. The timing of the peak forces for all three activation levels was between 80 and 90 ms.

DISCUSSION

The incorporation of the musculature improved the kinematic response of the occupant model for the low speed human volunteer impact tests. The EMG data in the tests was reported for superficial muscles and the same activation curves were used for the deep musculature activation. These results show that the occupant response in finite element human body models can be improved with muscle activation data from volunteer experiments.

The increase in the peak compressive force was more pronounced at the proximal levels of the spine with increased levels of activation. The upper lumbar spine injuries reported in literature [16, 17] under the $G_{\pm X}$ accelerative vector may be attributed to the muscle activation process, although the exact profile of activation for each muscle is not known. It should be noted that European studies have also reported the upper lumbar level bias in the injury, while the environment (belt restraints, seat and vehicle stiffness) is different [18, 19]. In the present study, muscle anatomical-geometrical data was used from literature in supine and upright postures. It is known that the morphologies of the human lumbar and cervical spine muscles are dependent on posture [20, 21]. From this perspective, it is important to obtain sitting posture muscle geometry data from radiographic or MRI scans, and develop volunteer-specific models to study the loading pattern of lumbar spine. The updated models can be used to determine the segmental or vertebral level loads due to the added personal protective equipment (PPE) for soldiers. These future studies will be helpful to delineate the role of muscles for civilian and military populations.

INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is one of the most-deadly cancers with a dismal 10% five-year survival rate [1]. Current treatment is primarily limited to chemotherapy but is largely ineffective due to chemoresistance and poor drug delivery to the cancer cells. A dense desmoplastic stroma is a hallmark of PDAC, including cancer-associated fibroblasts (CAFs) and substantial extracellular matrix (ECM) [2]. In order to enhance the treatment outcomes, it is essential to devise strategies for improving drug delivery through the PDAC tumor microenvironment (TME).

Therapeutic strategies targeting the tumor stroma have been proposed to address the poor drug delivery. Since the PDAC stroma matrix is abundant in type I collagen and hyaluronan (HA), depletion of HA is being pursued to improve drug delivery [3,4]. Despite recent advances, it is still extremely challenging to achieve effective drug delivery to PDAC due to the complex stromal microenvironment. Recently, it was reported that fibrin is another major component of the PDAC ECM [5]. Fibrin is the primary matrix component found in a blood clot, but it is also found to be abundant in the PDAC stroma because of leaky vasculature leading to coagulation in the PDAC TME. The coagulation cascade is amplified through conversion of prothrombin to active protease thrombin by Tissue Factor (TF), which is highly expressed by pancreatic cancer cells [5]. In turn, thrombin converts fibrinogen into fibrin in the ECM as illustrated in Figure 1.

The objective of this study is to investigate the effects of fibrin matrix on the drug delivery in PDAC. It is hypothesized that (i) blood coagulation and fibrin formation within the PDAC TME restricts drugs from reaching the tumor cells, and (ii) drug delivery to PDAC cells can be improved by reducing fibrin in the stromal matrix. To test this hypothesis, transport properties of FITC-labeled dextran was measured in a collagen-fibrin matrix using the integrated optical imaging (IOI) method. Moreover, doxorubicin accumulation and penetration in collagen-fibrin matrix was measured in the microfluidic model tumor-microenvironment-on-chip (T-MOC) which mimics *in vivo* transport dynamics.

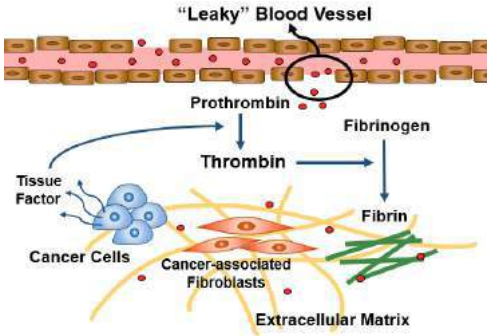

Figure 1. Thrombin mediated PDAC coagulation pathway and fibrin deposition in the extracellular matrix.

METHODS

Preparation of collagen-fibrin matrix

6 mg/ml type I collagen matrix was prepared with 10x PBS, NaOH, HEPES solution, FBS, Glu, P/S, and cell-culture grade distilled water. 6 mg/ml fibrinogen from bovine plasma (Sigma-Aldrich, St. Louis, MO) was dissolved in 0.9% NaCl at 37°C for 3 hours and sterile filtered with 0.2 μm polyethersulfone (PES) filter. Collagen and fibrinogen solutions were mixed in 1:1 ratio to reach a final concentration of 3mg/ml:3mg/ml collagen:fibrinogen. 500 μl of solution was suspended in PDMS mold with 12mm diameter and allowed to polymerize at 37°C for 1 hour 15 minutes. Subsequently, 1 U/ml thrombin was suspended above the gel and incubated for additional 1 hour for fibrin polymerization. The gel was thoroughly washed with distilled water before microinjection experiment.

Integrative optical imaging (IOI)

The diffusivity of the collagen-fibrin(ogen) matrix was measured using an integrative optical imaging (IOI) method [6]. A small volume (25-50 pL) of fluorescent probes with known sizes were injected into the tissue constructs using a microinjection system (MINJ-D-BDCI, Tritech). In this study, FITC-labeled dextran with molecular weight of 4 kDa (hydrodynamic radius = 1.3 nm) and 40 kDa (5.1nm) were used. After the injection, fluorescent images were taken at a 2-second interval for 120 seconds. The fluorescence intensity of the images was quantified using image processing software (MATLAB, Mathworks). The intensity profiles were curve-fit to the analytic solution of diffusion from a point source to obtain an estimated value of diffusivity.

Drug Delivery Assay using T-MOC

The T-MOC device was prepared with murine pancreatic cancer line, eKIC, as reported previously [7]. Briefly, cells mixed in 3 mg/mL collagen-fibrinogen solution at 1×10^7 cells/mL concentration was loaded through the interstitial channel and incubated at 37ºC for 1 hour 15 minutes. Afterward, 1 U/mL thrombin diluted in RPMI 1640 with 2.05 mM L-glutamine and 100 µg ml–1 penicillin/streptomycin was perfused through the lymphatic channels and incubated for 1 hour. 2 µM doxorubicin diluted in supplemented culture medium was perfused through the capillary channel and fluorescent images were taken at a 30-minute interval for 24 hours. Drug accumulation and penetration by cellular uptake were analyzed as developed previously [8].

RESULTS AND DISCUSSION

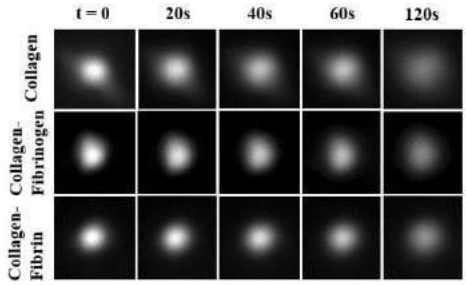

Figure 2. Fluorescent images of 4 kDa dextran diffusion in collagen and collagen-fibrin(ogen) matrices.

Sequential fluorescent images of 4 kDa dextran particle diffusion in different tissue constructs are shown in Figure 2. Even at early time point (20s), the radial diffusion of dextran in collagen-fibrin(ogen) matrices is notably reduced compared with collagen matrix. This difference is further intensified at the end of the experiment at 120s. The measured fluorescent intensity from above images is proportional to the spatiotemporal dextran concentration. The resulting relative decrease in the intensity at t = 120s normalized to t = 0s are 0.48, 0.5, and 0.51 for collagen, collagen-fibrinogen, and collagen-fibrin, respectively. The slowest decay of intensity in collagen-fibrin matrix reflects the reduced matrix transport properties due to the presence of fibrin.

The results from fluorescent images also correlate with the calculated diffusivity in Figure 3. For both 4 kDa and 40 kDa dextran, a significant decrease in diffusivity was observed with the introduction of fibrin(ogen) matrix compared with collagen matrix ($P < 0.05$). This phenomenon is likely due to the more clustered and finer mean fiber diameter when collagen is formed with fibrin [9]. Moreover, fibrin matrix has a reported smaller pore size and fiber radius compared with collagen [10]. Taken together, these findings suggest that mechanical properties of fibrin imposes physical hindrances for particle diffusion. The decrease in diffusivity with fibrin(ogen) is more evident with 40 kDa dextran compared with 4 kDa dextran. However, the saturation of matrix pores with 40 kDa dextran resulting from greater particle size likely contributes to the no meaningful difference between diffusion in fibrinogen and fibrin.

To more accurately model what may be happening the *in vivo*, pancreatic cancer cells were cultured in collagen-fibrin matrix in microfluidic device, known as tumor-microenvironment-on-chip (T-MOC).

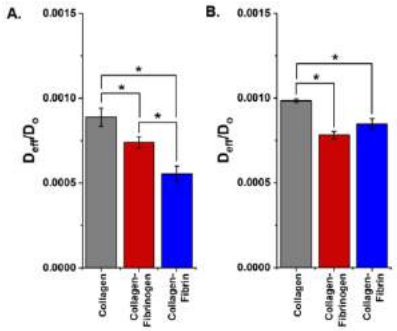

Figure 3. A. 4 kDa and B. 40 kDa dextran diffusivities normalized to free diffusivity, D_o, at 37ºC.

Doxorubicin transport was measured from capillary into the interstitial channel (Figure 4). Pancreatic cancer cells demonstrated a notable decrease in accumulation and penetration of doxorubicin in collagen-fibrin compared with collagen matrix alone. The concentration of collagen-fibrin was 3 mg/ml and that of collagen control was 6 mg/ml. Even at lower concentrations, collagen-fibrin significantly deterred doxorubicin transport.

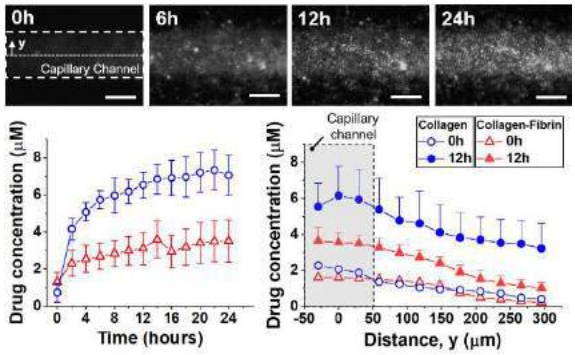

Figure 4. Doxorubicin accumulation by cellular uptake and penetration are hindered with fibrin deposition with collagen.

The results from this study demonstrated significantly reduced matrix transport properties within a fibrin matrix by measuring the diffusivity of varying sizes of dextran and doxorubicin transport in T-MOC. These results further provide convincing evidence for fibrin as a novel target for enhancing drug delivery to PDAC tissue. Additional studies are necessary to demonstrate the improved drug transport after fibrin degradation.

MODULATING EPITHELIAL FLUID SECRETION AND TRANSMURAL FLUID PRESSURE TO REGULATE PROLIFERATION AND BRANCHING MORPHOGENESIS IN THE EMBRYONIC LUNG

Shelby R. Mohr-Allen (1), Victor D. Varner (1)

INTRODUCTION

The development of several organs in the body, including the lung, kidney, and salivary gland, involves a series of recursive branching events that are referred to collectively as branching morphogenesis. In the embryonic lung, this process builds the bronchial tree, which facilitates the transport of air to the distal alveoli where gas exchange occurs [1]. Normal airway branching depends crucially on cell proliferation, as well as on reciprocal interactions between the branching airway epithelium and the adjacent pulmonary mesenchyme. Several signaling pathways, including those downstream of sonic hedgehog (Shh), Wnt, as well as various fibroblast growth factors (FGFs), have been shown to regulate airway branching, but recent work has shown that mechanical forces can also influence this process. The embryonic airways are fluid-filled, and changes in luminal fluid pressure can modulate rates of branching morphogenesis in cultured embryonic lung explants [2]. It is unclear, however, how these changes in pressure impact the patterns of proliferation that sculpt the bronchial tree.

Here, we used different pharmacological activators and inhibitors of epithelial fluid secretion to modulate the transmural fluid pressure in cultured embryonic chicken lungs. These experiments were then combined with quantitative fluorescence microscopy to determine how changes in fluid secretion impact the patterns of proliferation in the developing lung. We also microinjected a small volume of biologically-inert oil into the lumen of other embryonic lungs to locally dilate the embryonic airway. These explants were then cultured and quantified for changes in proliferation in the neighborhood of the distended airway.

METHODS

Fertilized White Leghorn chicken eggs were incubated at 37°C in a forced-draft incubator to Hamburger and Hamilton stage 26. Embryonic lungs were dissected in phosphate-buffered saline (PBS) using fine forceps and cultured for 24 hr on Nucleopore membranes at the air/liquid interface in DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS) and antibiotics. The culture medium was supplemented with either an agonist (1-10 μM forskolin, or 100 μM CPT-cAMP) or antagonist (100 μM CFTR inhibitor-172 or 100 μM bumetanide) of epithelial fluid secretion. In order to directly dilate the airway epithelium in some experiments, a pulled glass micropipette was filled with mineral oil and inserted it into the lumen of the embryonic airway. A small amount of mineral oil was then injected into the lumen with the use of a pneumatic pump.

Bright-field images of cultured explants were captured at 0 and 24 hr. We used the Click-iT EdU Imaging Kit to quantify rates of epithelial proliferation. Samples were pulsed with EdU 20 min prior to fixation. Fixed explants were then co-stained with LCAM (E-Cadherin) immunofluorescence and DAPI, to label the airway epithelium and nuclei, respectively, and then optically cleared. Confocal fluorescence images of whole-mount explants were then captured using a laser scanning confocal microscope. Quantitative image analysis was performed using ImageJ. Briefly, individual nuclei were counted on high resolution confocal images of both EdU and DAPI fluorescence and used to compute the fraction of proliferating cells along both bud-forming and non-bud-forming regions of the airway epithelium.

RESULTS

We used pharmacological modulators of epithelial fluid secretion to modulate the transmural fluid pressure in cultured embryonic chicken lungs. Treatment with forskolin, an activator of cAMP and agonist of fluid secretion, caused the embryonic airways to dilate dramatically and produced a significant decrease in the formation of new branches after 24 hrs of culture (Fig. 1). (Similar results were also obtained using

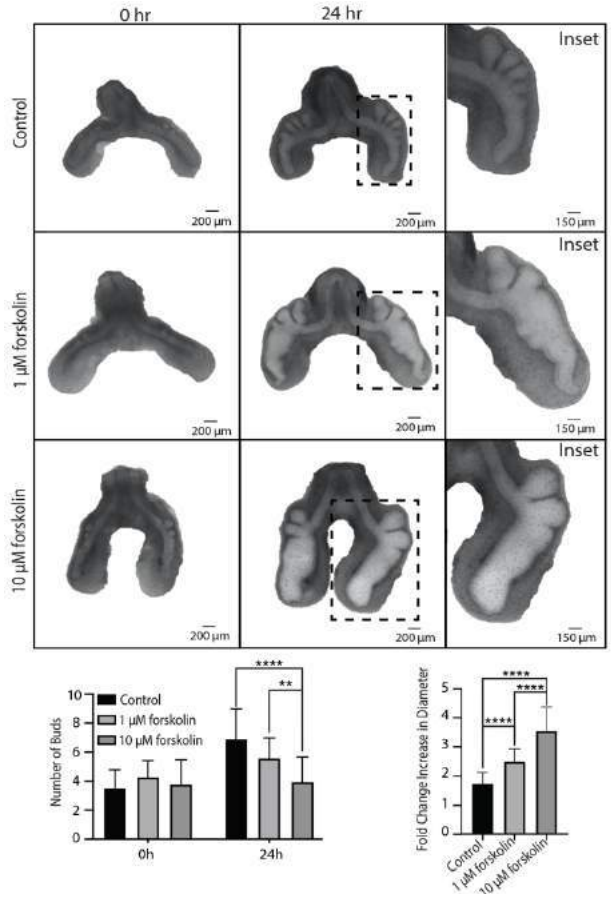

Figure 1: Embryonic chick lungs treated with forskolin, an agonist of fluid secretion, show decreased branching morphogenesis.

explants treated with 100 µM CPT-cAMP, another activator of cAMP and agonist of fluid secretion.) To determine if the observed decreases in branching were associated with a concomitant change in epithelial proliferation, we quantified rates of EdU incorporation in explants cultured in the presence of forskolin. Increased levels of fluid secretion modified the patterns of proliferation observed along the embryonic airway epithelium (Fig. 2). In control explants, we detected elevated

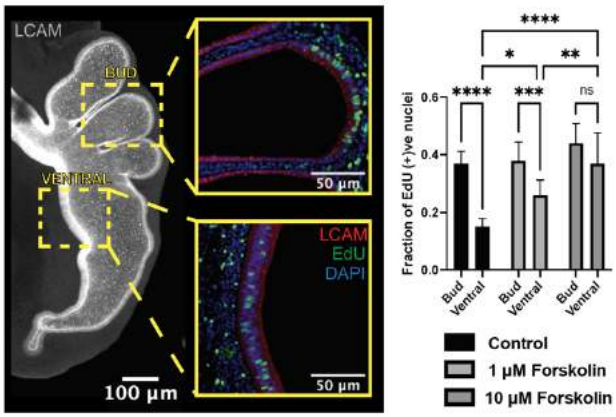

Figure 2: Increased luminal pressure promotes proliferation in a non-bud forming region of the embryonic chick airway epithelium

levels of proliferation in new epithelial buds, but low levels along non-branching regions of the ventral airway epithelium. Treatment with forskolin, however, increased proliferation in this non-bud-forming region of the airway to levels on par with those observed in epithelial buds (Fig. 2).

To perturb the transmural pressure in other embryonic lungs, we microinjected a small volume of mineral oil into the lumen to locally distend the embryonic airway (Fig. 3). This purely physical perturbation eliminates the possibility of off-target molecular effects due to pharmacological modulators of fluid secretion, allowing us to attribute any changes in branching and proliferation to localized changes in transmural pressure. Preliminary experiments have suggested that each localized distension of the airway inhibits the formation of nearby epithelial buds (Fig. 3) and leads to a localized increase in proliferation, as revealed by EdU incorporation.

Lastly, we also cultured some explants in the presence of either 100 µM CFTR inhibitor-172 or 100 µM bumetanide, which inhibit epithelial fluid secretion via the inactivation of either the CFTR or NKCC1/2 ion channels, respectively, to determine if decreases in transmural pressure elicit a branching phenotype. Indeed, explants treated with either of these inhibitors developed collapsed airways and increased numbers of new epithelial buds. Taken together, these data suggest that changes in transmural pressure can modulate the branching and proliferation of cultured embryonic lung explants.

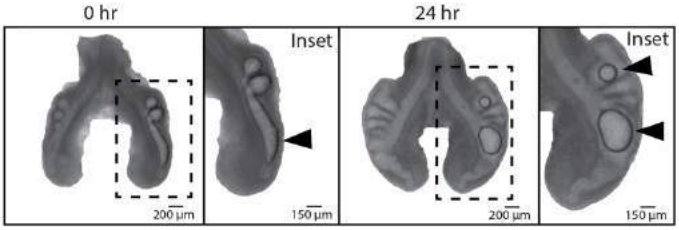

Figure 3: Microinjection with mineral oil produces local dilation of airway epithelium leading to disrupted branching morphogenesis.

DISCUSSION

Many congenital lung conditions, including pulmonary hypoplasia and congenital diaphragmatic hernia, can be attributed to defects in the mechanical environment surrounding the lung [3]. It is unclear, however, if the changes in transmural fluid pressure associated with these conditions can regulate the patterns of proliferation that underlie airway branching morphogenesis. Our experiments suggest that increases in epithelial fluid secretion, and thus transmural pressure, can inhibit branching and alter the spatial distribution of proliferating cells in cultured avian lungs. These results were somewhat suprising, since previous work has suggested that increases in pressure promote branching morphogenesis in the embryonic mouse lung. The reason for these species-specific differences remains unclear. Future work will use similar experimental approaches to modulate transmural pressure in cultured mammalian lung explants to resolve this apparent contradiction.

INTRODUCTION

As an alternative option to the highly invasive surgical aortic valve replacement (SAVR), transcatheter aortic valve replacement (TAVR) has become more popular in recent years [1, 2], even among low-risk patients [3]. Unlike SAVR, whose size and implantation location can be precisely determined during surgery, TAVR relies on more thorough pre-surgery evaluations to determine the valve type, size, and deployment strategies with the help of advanced medical imaging techniques [4]. A sub-optimal valve deployment has been associated with various adverse effects including elevated transvalvular pressure gradient, paravalvular leakage, aortic root rupture during implantation [5], coronary obstructions [6], etc. To minimize these adverse effects, pre-TAVR evaluations may involve accurately reconstructing the patient's anatomy, generating a computational mesh, and using it for Finite Element Analysis (FEA) or/and Computational Fluid Dynamics (CFD) simulations. These state-of-the-art approaches based on patient-specific geometries have proven to have high predictive capabilities for TAVR outcomes and to prevent severe adverse events from happening in high-risk patients. However, conducting such evaluations requires reconstructing a patient's anatomy from CT or MRI data, which is a tedious and time-consuming manual process (3-6 hours per case). To address this problem, we have developed an automatic method to build patient-specific geometries based on a parametric leaflet model and generate meshes for *in-silico* studies with just a few manual inputs (about 5-10 minutes per case).

METHODS and RESULTS

To start the automatic mesh generation from imaging data, one needs to pick several landmark points related to the aortic valve. A parametric leaflet model is used to fit the valve geometry, followed by an automatic aortic root reconstruction algorithm that extracts the shape of the aorta. Later, the coronary arteries and calcium deposits are obtained automatically using a region-growing algorithm. Finally, a mesh for computational studies is generated by combining all the components. A visual inspection and possible manual clean-up are performed to ensure the accuracy and quality of the mesh. A detailed illustration of the process is shown in Fig.1.

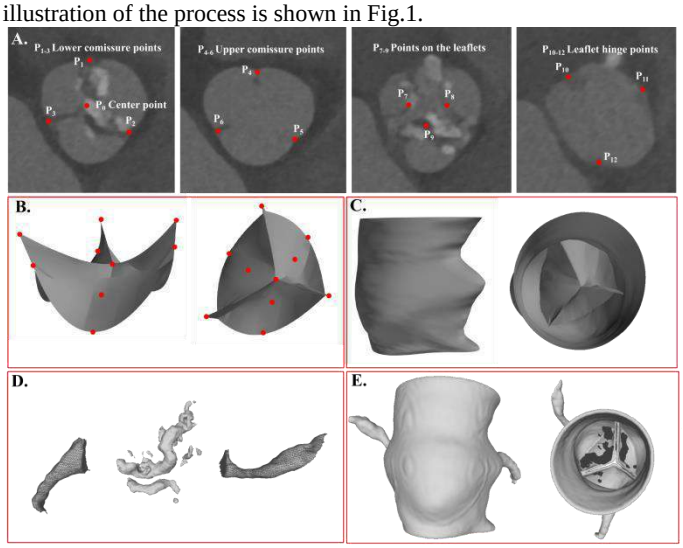

Figure 1: A detailed illustration of the auto segmentation process. (A) The locations of the thirteen landmark points; (B) The parametric leaflet model with landmarks shown; (C) Aortic root with parametric leaflets; (D) Coronary arteries and calcium deposits; (E) The final mesh output.

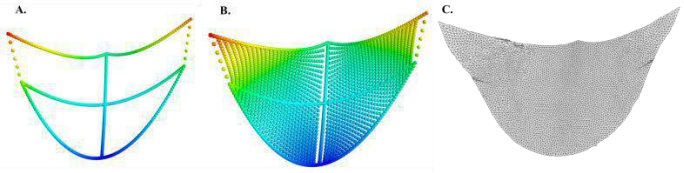

Figure 2: The parametric leaflet generation process. (A) A skeleton connecting the landmarks using second-order polynomials; (B) Multiple second-order polynomials are used to fit the leaflet surface; (C) The final triangular mesh.

Parametric leaflet model:

The parametric leaflet model is constructed based on thirteen landmark points (shown in Figs.1A&B: P_0 at the center coaptation point of the three leaflets; P_{1-3} and P_{4-6} are the six commissural points. P_{7-9} are three surface points on the leaflets, and P_{10-12} are the three leaflet hinges). First, a leaflet skeleton is generated using second-order polynomials connecting these landmarks (Fig.2A). Then, multiple second-order polynomials are fitted to the skeleton to create a surface (Fig.2B). Finally, triangular meshes are used to represent the leaflet (Fig.3C). This parametric leaflet model can handle complex surface geometries and capture individual leaflet's irregular shape. A parametric aortic valve sample is shown in Figs.1B &D.

Aortic root/aorta extraction algorithm:

The extraction of the aortic root/aorta geometry is based on an intensity-based, slice-by-slice, multi-point ray-casting edge detection algorithm (Fig.3). Slices parallel to the aortic annulus are extracted from the original 3D data. Starting with one point in the blood domain and casting rays in all directions, one can extract the intensity variations along the rays. A sudden jump of the intensity value from high (blood) to low (tissue) indicates the location of the aortic wall (Fig.3A). The boundary of the aorta is defined by connecting all the detected edge points. However, errors may occur in this process due to noise or poor image quality (Fig.3A). A modified method that casts rays from a series of origins is introduced to address this issue. Since most rays from different origins should converge at specific points on the actual aortic wall, and if there is a detection error for one ray, it is unlikely for rays from other origins to repeat the same error. Thus by comparing the detected edges from all origins, one can filter out the ambiguous points if they are too far away from the mean location. The mean value of the remaining points should accurately determine the aorta wall (Fig. 3B). Figures 3A&B have shown clearly that this multi-point approach can accurately capture the aortic root's shape. Finally, a cubic spline is fitted to all the detected points. This algorithm works from the left ventricular outflow graft to the ascending aorta. A reconstructed root geometry is shown in Fig.1C.

Coronary artery and calcium deposit segmentation:

Both coronary artery and calcium deposit geometries are segmented by an intensity-based region-growing algorithm. The coordinates of the two coronary ostia need to be specified (human input) as starting points for the algorithm. A global threshold of 850 Hounsfield Units (HU) is applied for the calcium as suggested in the literature [7], followed by a cleaning process that discards blobs smaller than 20 voxels or located outside the aorta.

Final mesh generation:

The final mesh assembling process is based on Boolean operations in the intensity space. First, the surface meshes of the aorta and the leaflets are thickened based on physiological values and voxelized. Later the coronary arteries and calcium deposits are added to the domain using Boolean operations. Finally, a marching cubes algorithm converts the voxel data into an STL mesh. The final mesh will be visually inspected and corrected for any problems before using it in computational simulation.

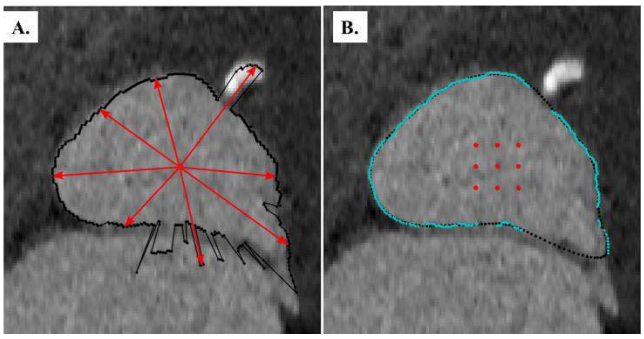

Figure 3: Aorta reconstruction process. (A) Detected aortic wall using a single-point ray-casting algorithm. (B) Detected aortic wall using the multi-point ray-casting algorithm.

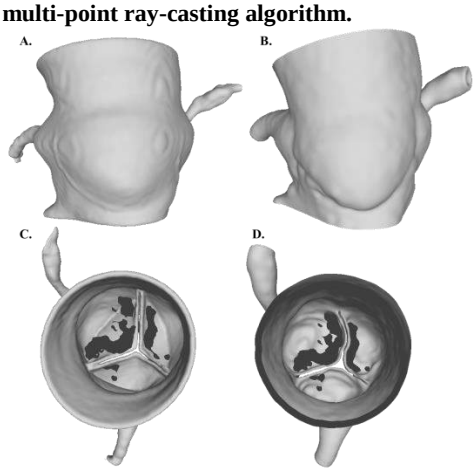

Figure 4: Comparisons between the automatic (left) and manual (right) segmentation results.

DISCUSSION

Comparisons with the manual segmentation results were carried out (Fig.4) to ensure the accuracy of this method. For the aorta, the auto-generated geometry (Fig.4A) was very similar to that from the manual segmentation process (Fig.4B). However, the manual result had more fine details due to less smoothing. In the en face views between the models (Figs.4C&D), they showed similar aortic leaflet geometries and calcium distributions. However, the current parametric leaflet model could not resolve the curved coaptation line between the leaflets, since only three landmark points were used for this line. If an extra landmark point along the coaptation line was added or a local deformation algorithm was applied, the edge of the leaflet would be captured more accurately. This improvement will be implemented and tested in our future work.

INTRODUCTION

Mitral regurgitation is a prevalent disease which occurs when the two leaflets of the mitral valve (MV) do not close properly during systole. For treatment of symptomatic moderate-to-severe or severe MR in patients deemed high-risk for surgical treatment, Abbott's MitraClip may be used. MitraClip is the only FDA approved transcatheter device and one of two transcatheter devices with CE mark. The device clips the two leaflets together to reduce MR, creating a double orifice. The clipping scheme, i.e., placement of the device, depends on MR characteristics of the individual patient.

Analyzing mitral valve (MV) pressure gradient (MVPG) during the MitraClip procedure is important, as gradients of 5 mmHg or more are undesirable and can lead to iatrogenic mitral stenosis, worsening patient prognosis [1-2]. However, MVPG through the MV and the vena contracta can differ based on the clipping scheme. The objective of the study is to assess the pressure drop through a single and symmetric and asymmetric double orifice mitral valve analog.

METHODS

A rigid MV model was created for the unclipped single orifice (Figure 1a), symmetrically clipped (Figure 1b), and asymmetrically clipped (Figure 1c) cases, where the clipped cases mimic the MitraClip NT MV repair. The models were created using ABAQUS, where the MV was approximated as a tube, and opposing areas of 5 mm x 9 mm (the MitraClip footprint) were brought together while transvalvular pressure (30 mmHg) was imposed for the clipped cases. The inlet and total outlet areas were approximately 6.47 cm^2 and 1.82 cm^2, respectively.

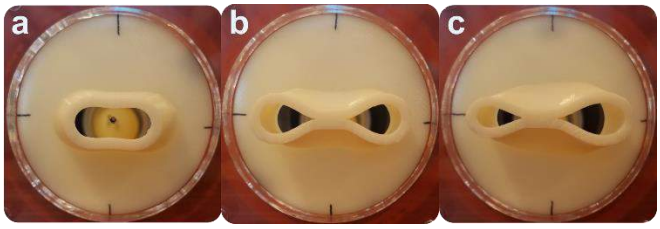

Figure 1: a) Single Orifice, and b) Symmetric and c) Asymmetric Double Orifice Models

Each model was placed upstream a bioprosthetic mitral valve in an *in vitro* left heart simulator, shown in Figure 2, that allows for high fidelity pressure and flow measurements. Hemodynamic conditions imposed include: 60 bpm heart rate; 3 and 5 L/min cardiac output (CO); 120 mmHg peak ventricular pressure. A 60-40 water-glycerin mixture was used to mimic the density (1060 kg/m^3) and kinematic viscosity (3.88 cSt) of blood. A Millar catheter was dragged through the orifice for pressure measurements, and data was collected at 100 Hz for 200 cycles at 19 positions, starting 4 mm upstream the annulus and ending 3 cm downstream the leaflet tip; volumetric flow rate was recorded simultaneously. MVPG was calculated.

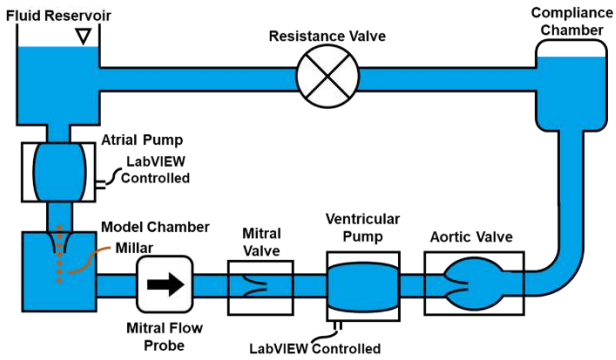

Figure 2: Mitral Flow Loop Schematic

RESULTS

MVPG for each model and CO is shown in Figures 3 and 4 for the peak of the E and A waves of mitral flow, respectively.

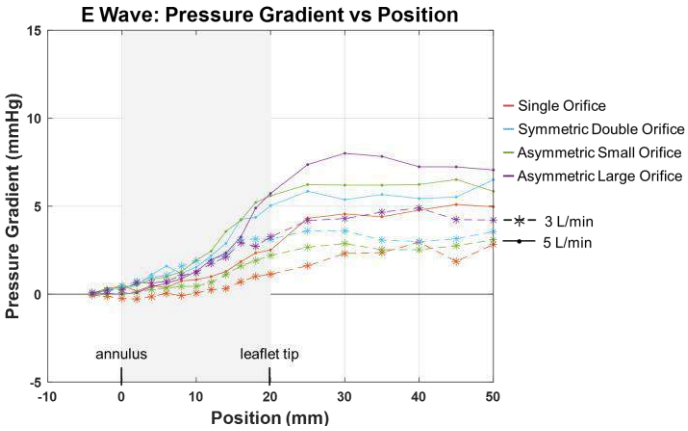

Figure 3: Pressure Gradient vs Position at the E Wave

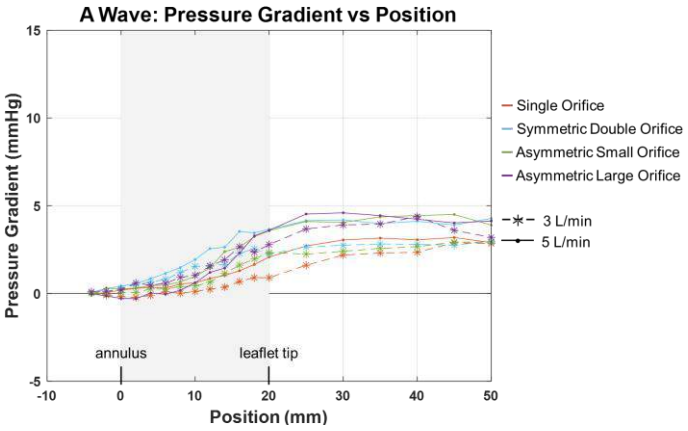

Figure 4: Pressure Gradient vs Position at the A Wave

For each orifice, the MVPG curve followed the same trend of increasing rapidly through the model followed by a slight further increase through the vena contracta before remaining approximately constant further downstream the model.

Overall, MVPG did not exceed 5 mmHg, except for the double orifice cases at a CO of 5 L/min. The E-wave had higher MVPG than A-wave, and 5 L/min had higher MVPG than 3 L/min.

Focusing on the vena contracta, which is just downstream the leaflet tip, MVPG was higher for the clipped cases compared to the unclipped case. The large orifice of the asymmetric model had higher MVPG than the small orifice, and both were higher than the symmetric case.

DISCUSSION

Focusing on the vena contracta, MVPG was higher for the clipped cases compared to the unclipped case. This shows that a single orifice is most efficient.

Comparing the large and small orifices of the asymmetric case, the MVPG of the large orifice is higher than the small orifice. This may be due to flow diverting to the large orifice as a result of increased flow resistance through the small orifice. This can be further explained by applying mass conservation and the inviscid flow theory to the orifice. Equation 1 shows the total fluid velocity, V_T, as a function of the large and small orifice velocities, V_L and V_S, respectively, and β, which is the ratio of the small orifice area to the total area and is less than 0.50 for the asymmetric case.

$$V_T = V_L(1-\beta) + V_S\beta \tag{1}$$

Applying the inviscid flow theory to each orifice, the relation between V_S and V_L can be obtained, as shown in Equation 2.

$$\frac{V_S}{V_L} = \sqrt{\frac{2\beta-\beta^2}{1-\beta^2}} \tag{2}$$

By solving the system of equations, the normalized velocities for the large and small orifices can be obtained, as shown in Equations 3 and 4, respectively.

$$\frac{V_L}{V_T} = \left[1-\beta+\beta\sqrt{\frac{2\beta-\beta^2}{1-\beta^2}}\right]^{-1} \tag{3}$$

$$\frac{V_S}{V_T} = \left[\beta+(1-\beta)\sqrt{\frac{1-\beta^2}{2\beta-\beta^2}}\right]^{-1} \tag{4}$$

With $\beta < 0.50$, the V_L is higher than V_S. This accounts for the higher pressure gradient across the large orifice due to turbulent losses past the vena contracta.

Among the clipped orifices, focusing on the 5 L/min CO cases, the symmetric model had lowest MVPG, indicating that the symmetric clipping scheme is more efficient than the asymmetric clip placement chosen in this study.

In conclusion, analysis of MVPG through the MV can be used to characterize efficiency of transcatheter edge-to-edge repair, which varies based clipping scheme. Overall, a double orifice has higher MVPG. Since the asymmetric clipping scheme had higher MVPG, a central clipping scheme is more efficient.

Future work includes improvement of models to better match MV leaflet geometry, further exploration of the effect of device location on MVPG, and exploration of different device generations.

CHANGE IN KNEE JOINT MECHANICS AFTER ACL TRANSECTION DURING SIMULATED GAIT: A HUMAN CADAVERIC MODEL

INTRODUCTION

Anterior cruciate ligament (ACL) rupture predisposes patients to developing post-traumatic osteoarthritis (PTOA) [1]. While many causative factors have been suggested, for example the magnitude of the impact and continued unresolved inflammation, a central concept has been that after ACL rupture the distribution of forces across the joint change, and cartilage cannot respond quickly to those changes.

Our objective was to quantify changes in joint kinematics and tibiofemoral contact mechanics after ACL rupture during simulated gait. We hypothesized that the location of peak contact stress would change, and that those changes would concur with kinematic changes including increased anterior translation.

METHODS

Following IRB approval, six intact, freshly frozen human cadaveric knees were stripped of bulk soft tissue and patella, leaving the remaining joint capsule, ligaments and menisci intact. A Kirshner wire was drilled through the femur flexion axis, using fluoroscopic guidance to determine the epicondylar axis. Knees were then potted in custom fixtures, such that the knee was in full extension with the flexion axis aligned with the six degree of freedom VIVO joint simulator (AMTI, Watertown, MA), Fig 1. Once mounted on the simulator, each knee was subjected to 200N axial load in full extension, with other off-axes loads left floating for 30 seconds. The position of the joint after this loading was set as the zero position for that knee.

Simulated gait testing consisted of 12 cycles of ISO standard gait input waveforms, normalized to specimen specific bodyweight, at 0.2 Hz. The simulator's iterative learning control adjusted all axes control parameters every 3rd cycle, to correct measured differences between applied load and the ISO standard. All data presented is from the 11th tested gait cycle for each specimen.

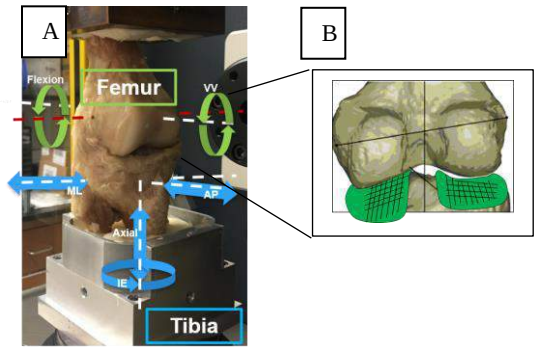

Figure 1: (A) A cadaveric knee fixed in the VIVO knee simulator (AMTI) with six degrees of control. (B) A schematic of the positioning of the sensor, which was prepared with tabs for easier insertion.

Knee joint kinematics were quantified by encoded sensors on each axis of control. Kinematics are reported in the Grood and Suntay [3] coordinate system. Contact mechanics were measured using a Tekscan 4011 pressure sensor (Tekscan, Boston, MA) placed along the tibial plateaus, under the meniscus and secured to the ACL and posterior capsule.

Kinematics and contact mechanics were compared between intact and ACL deficient knees at specific instances: 0%, 4%, 8%, 14%, 20%, 45%, and 60% of the gait cycle. Contact mechanics measures included in the analysis were maximum force, total force, and contact area for the entire tibial plateau, and individually for the medial and lateral plateaus. Additionally, the position of the weighted center of contact for the

medial and lateral plateaus were analyzed. One-way repeated measures ANOVA with Holm-Sidak method for multiple comparisons was conducted ($p<0.05$ considered significant).

RESULTS

We successfully quantified kinematics and contact mechanics throughout simulated gait for all knees, see **Fig 1,** for representative contact mechanics.

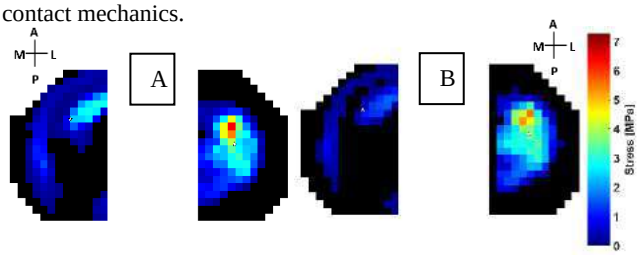

Figure 1: Sample contact maps of a representative specimen (A) intact and (B) after ACL transection, both at 4% gait. Maps are oriented with anterior at the top and the medial plateau on the right of each map.

The total force across the tibial plateau decreased after ACL transection at 4%, 14%, and 45% gait ($p=0.007$, $p=0.020$, $p=0.002$, respectively) (**Fig 2**). The decrease in total force after ACL transection was also observed when considering each plateau individually, with the medial plateau showing differences at 4% and 45% gait ($p=0.008$, $p=0.046$), and the lateral plateau at 8%, 14%, 20%, and 45% gait ($p=0.031$, $p<0.001$, $p=0.035$, $p=0.001$).

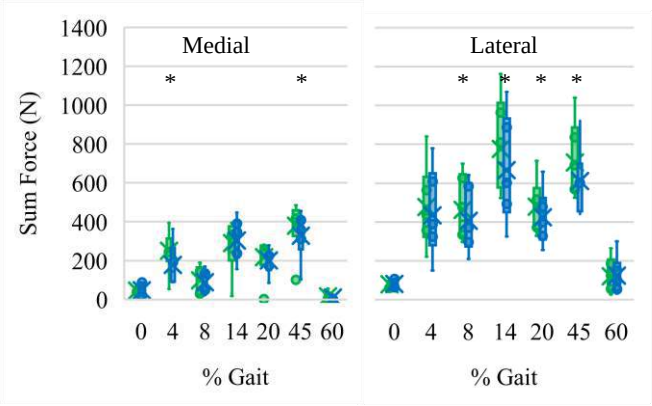

Figure 2: Intact (green) and ACL-transected (blue) medial and lateral plateau sum force.

Total contact area decreased after ACL transection at 4%, 8%, 14%, 20%, and 45% gait ($p<0.001$, $p=0.032$, $p=0.035$, $p=0.036$, $p=0.020$). Similarly, lateral plateau contact area decreased at 4%, 8%, 14%, 20%, and 45% gait ($p=0.003$, $p=0.003$, $p=0.007$, $p=0.020$, $p=0.003$). The medial plateau showed a decrease in contact area at 4% gait ($p=0.004$).

The weighted center of contact on the medial plateau moved posteriorly after ACL transection at 0%, 20%, and 45% gait ($p<0.001$, $p=0.045$, $p=0.034$) and peripherally, at 60% gait ($p<0.001$). The weighted center of contact on the lateral plateau also moved posteriorly at 0% gait ($p<0.001$). No differences in maximum force were determined across the total tibial plateau, medial plateau, or lateral plateau after ACL transection.

Kinematic differences between intact and ACL transected knees were minimal. At 0% and 45% gait, ACL transected knees showed increased anterior transection ($p<0.001$ at 0%; $p=0.03$ at 45%) and lateral translation ($p<0.001$ at 0%; $p=0.03$ at 45%), **Figure 3**.

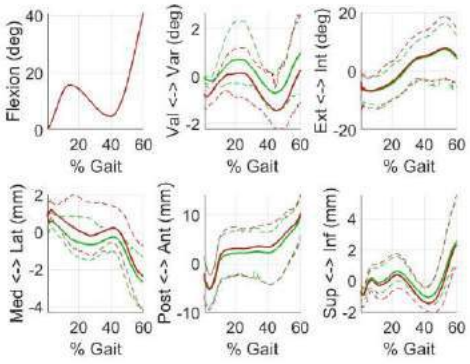

Figure 3: Intact (green) and ACL-transected (red) average gait anterior-posterior (A) and medial-lateral (B) translations with 95% confidence intervals included (dashed).

DISCUSSION

We successfully developed a protocol to simulate gait in cadaveric knees before and after ACL transection. As seen clinically [2, 4], anterior translation increased after ACL injury, with significant differences observed at heel strike (0% gait) and in late stance (45% gait). These kinematic changes corresponded to movement of the weighted center of contact on each plateau – which moved posteriorly at heel strike - and which moved posteriorly on the medial plateau at 45% gait.

Total force and contact area decreased after ACL transection. These changes in contact could indicate altered loading of the meniscus as it behaves as a secondary stabilizer after ACL injury [5]. These results warrant further investigation, particularly in changes of loads distributed along tibial cartilage directly or through the meniscus.

We accepted our hypothesis that there exists a relationship between the change in tibial kinematics during simulated gait and the posterior shift in contact forces after ACL rupture. The alteration in force location will require that cartilage can respond adequately, to avoid degeneration. We plan to input the quantified contact mechanics data generated in this study into bioreactors, so that we can explore the effect of changes in force on the response of chondrocytes, thereby allowing us to investigate at least one hypothesized mechanism of the development of PTOA.

INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF) is a major public health problem in the United States and its prevalence is increasing [1]. Left ventricular diastolic dysfunction (LVDD) remains to be the predominant characteristic of impaired cardiac function in HFpEF [2] which indicates a need for better understanding and characterizing diastolic abnormalities. Indeed, strong pathophysiological heterogeneity of LVDD remains a key impeding factor for developing effective treatments for HFpEF patients [3]. Typical organ-level manifestations of LVDD includes slow and incomplete relaxation and/or a stiff end-diastolic pressure–volume relationship (EDPVR) [4]. In particular, myocardial stiffening is a major tissue-level mechanism contributing to LVDD, here, referred to as *passive remodeling*. Imaging-based methods that can non-invasively identify the presence and severity of myocardial passive remodeling and its contribution to LVDD is essential for treatment planning for HFpEF patients.

The estimation of *intrinsic* changes in mechanical properties of myocardium through medical imaging serves as an important step to quantify the contribution of passive remodeling. The current technique to estimate LV passive remodeling is limited to the measurement of LV-EDPVR through left heart catheterization. However, the LV-EDPVR provides a confounded picture of myocardial *tissue-level* stiffening as it is influenced by chamber anatomy and loading. Therefore, an integrated in-silico-imaging method that allows us to estimate myocardial stiffening independent of LV anatomy and loading will be of high significance. Our objective in this work is to use four-dimensional ultrasound (4DUS) imaging in mice models of HFpEF and estimate myocardial stiffness from a collection of hemodynamic and image-based data including chamber volume and pressure and myocardial wall strain. 4DUS is an advanced imaging modality that can be used to fully capture cardiac motion (in space and time) in small animals as well as in humans. The estimation of intrinsic myocardial stiffening promotes the development of personalized treatment for HFpEF.

METHODS

Animal model. We have established a transgenic murine model of HFpEF based on the studies of the phosphorylation of cardiac myosin binding protein (cMyBP)-C and its important role in actin-myosin cross-bridge mechanism [5,6]. Briefly, the model expresses deficient phosphorylation of cMyBP-C causing diastolic dysfunction and phenotypes resembling HFpEF.

Our study includes a total of 21 male mice which will be divided into three groups labeled as: t3SA, t3SD, and tWT described below [5,6]:

t3SA: cMyBP-C is readily phosphorylated by protein kinase A (PKA). Three PKA phosphorylation sites in mouse cMyBP-C are Ser273, Ser282, and Ser 302 in the M-domain. In this model, all 3 residues were mutated to alanine by expressing non–PKA-phosphorylatable cMyBP-C in the FVB/N mouse strain. FVB/N mice expressing this transgene were then bred with the cMyBP-C knockout mouse to produce t3SA mouse.

t3SD: This model restores phosphorylation at PKA sites and is generated by expressing phosphorylation-mimetic transgene on the cMyBP-C knockout mouse.

tWT: This model serves as the control and is generated by expressing wild-type transgene on the cMyBP-C knockout mouse.

In-vivo imaging and hemodynamic measurements. The gated 4DUS imaging is performed for all the mice at the terminal point using FUJIFILM/Visualsonics Vevo3100 rodent ultrasound system. These images provide a 4D representation of cardiac motion enabling the reconstruction of full left ventricle at multiple time points within a cardiac cycle. The imaging will be followed by the catheter-based intraventricular pressure measurement in the LV. After sacrifice, the hearts will be harvested and the ex-vivo studies are followed.

Ex-vivo studies. After organ-level in-vivo measurements, hearts will be used to characterize biomechanical adaptations of LVFW (Fig. 1):

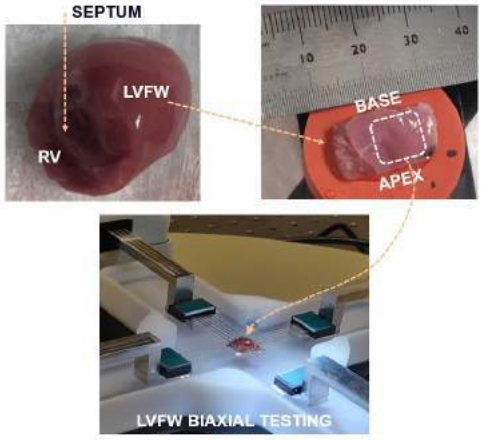

Figure 1: Tissue-level biomechanical testing of LVFW specimens.

Biaxial tests. LVFW excised tissues are placed in BDM-enriched cardioplegic solution and tested under multiple strain ratios to quantify the passive response.

Histology. A total of 10 sections is taken of each LVFW specimen after biaxial tests and stained using Gomori Trichrome. Structural analysis is performed to reconstruct transmural fiber architecture for myo- and collagen fibers.

Inverse modeling to estimate myocardial stiffness and its contribution to LVDD. The inverse model consists of four majors steps:

(i) Extracting myocardial strains. Regional radial, circumferential, and longitudinal strains is estimated and contrasted using speckle tracking (Fig. 2).

(ii) FE model development. A FE model of the LV at the beginning of filling will be created using 3D Dicom images generated from 4DUS. Helical fiber distribution and structural stress-strain model will be incorporated into the FE model for each mouse.

(iii) Matching the strains. The regional strains calculated from the FE model and the strains calculated directly from 4DUS in (i) will be used in an objective function.

(iv) Estimate tissue-level properties. The minimization of the objective function will lead to the estimation of myocardium mechanical properties.

Estimate the contributions of remodeling mechanisms resulting in LVFW stiffening. We will integrate the data from tissue mechanical tests, together with fiber-specific stress-strain model, within an inverse model framework, to estimate unknown myofiber and collagen mechanical properties.

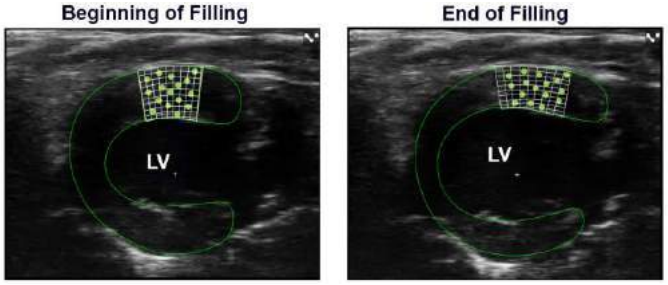

Figure 2: Speckle tracking technique to estimate 3-D strains during diastole.

RESULTS

Our central hypothesis is that 4DUS, integrated with computational modeling of cardiac motion, can provide a load-independent biomarker that reflects intrinsic stiffness of myocardium.

We are currently conducting 4DUS imaging, ex-vivo experiments, and modeling. We expect that the multiscale tissue-level measurements will provide us with a unique set of data to quantify the relations between LV stiffening and the alterations in myofiber and collagen characteristics.

Further, we expect that the 4DUS-based animal-specific computational inverse model provides similar estimates for overall LVFW stiffness. These findings will serve as an important step towards facilitating the clinical use of the integrated 4DUS-computational modeling approach in the patient-specific diagnosis and treatment of HFpEF patients.

DISCUSSION

In this work, we are taking an essential step towards multiscale modeling of the LVDD in HFpEF. The final product of this research offers an impactful and highly translational toolset for a feasible determination of LVDD phenotype in HFpEF that serves as an essential step towards individualizing therapeutic strategies for HFpEF.

INTRODUCTION

Congenital heart defects such as aortic valve stenosis and ventricular outflow tract dysfunctions often require heart valve replacements in pediatric patients [1]. Optimal valve substitutes would constitute a valve that is the right patient size, has potential to grow, has minimal susceptibility to thrombosis and demonstrates excellent prosthesis longevity. Currently the standard of care for pediatric valve replacement is mechanical prosthesis or a smaller sized adult tissue prosthesis which requires lifelong anticoagulation or risks limited longevity due to increasing patient-prosthesis mismatch [2]. The only expandable valve prostheses for accommodating growth are off-label products that were not designed for pediatric patients, and therefore, they are not available in sizes less than 19mm [3]. Common complications involving off-label pediatric valves include valve dislodgement, stent fracturing, recurrent stenosis, and regurgitation. Assuming the pediatric patient survives after a successful heart valve replacement, the medical procedure is still expensive due to their elaborate manufacturing, quality control and storage requirements. The additional surgical intervention caused by the above complications only exacerbates the medical cost. Therefore, a critical need exists for a safe, durable, and cost-effective pediatric valve.

The objective of this study is to develop a pediatric polymeric heart valve (PPHV), based on our hyaluronan (HA) enhanced and biomechanically designed polymeric transcatheter heart valve (HAPTAV) technology [4], and furthermore develop a testing paradigm to investigate the function of the valve. The material has the a unique features such as (1) flexible leaflets made from an interpenetrating polymer network (IPN) between linear low density polyethylene (LLDPE) and hyaluronan (HA) and (2) advanced valve design with unique three-dimensional leaflets and stent frame configuration to provide optimal hemodynamic performance while minimizing the stresses and strains in the leaflet to maximize durability.

The hypothesis is that the HA enhanced pediatric valve will not need anticoagulant therapy, will have comparable hemodynamic and durability compared to commercially available valves, and will be capable of expanding to accommodate growth and development of the pediatric patients' hearts. This advanced valve design with unique three-dimensional leaflets and stent frame configuration provide optimal hemodynamic performance while minimizing the stresses and strains in the leaflet to maximize durability.

METHODS

In order to test the efficacy of our design, we created valve models in Solidworks (Dassault Systèmes, Concord, Massachusetts, USA) and then meshed these geometries using Altair Hypermesh (Altair Engineering, Troy, Michigan, USA). We then conducted simulations using ABAQUS (ABAQUS Inc., Johnston, Rhode Island, USA) to determine areas of high stresses on the stents and leaflets, to identify candidate designs that we can implement in the experimental growth model.

To identify stresses on the stent, we crimped our adult HATAV model to a pediatric size. We conducted additional simulations to identify stresses on leaflets. Since this is a self-expandable valve that is expected to grow with the patient, we wanted to identify loading condition on the leaflets in the initial and fully deployed conditions. As such, we simulated one in the completely deployed position (16mm sized valve) and one in the initial underexpanded condition as shown in Figure 1. The leaflets consisted of approximately 19,000 meshed elements. They were modelled to be of LLDPE material and a diastolic load of 60mmHg was applied to the leaflets. A displacement type boundary condition was used to compress the leaflets radially and a loading type boundary condition was used to apply uniform pressure on the leaflets.

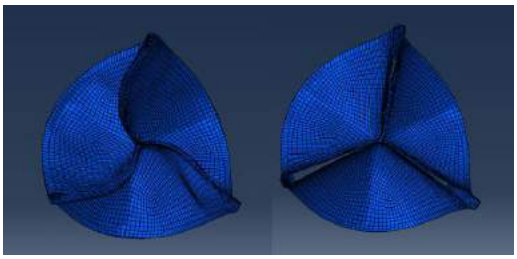

Figure 1: Simulated leaflets shown in the initial crimped and final fully deployed conditions

In order to simulate a benchtop growth scenario, we developed a compliant 'growth' model made of silicone (Silicones Inc., High Point, North Carolina) to test a valve in a left heart simulator, for demonstration purposes. The valve was sutured inside the model and it was used with an in-house designed crimper to allow manipulation of 'growth' in vitro. The crimper was designed especially for the manufactured mold with dimensions that allow valve size adjustment from a pediatric to an adult size. The buttons around the crimper were used to manually reduce the orifice area and crimp or expand the valve. It was fit on the outside allowing for control during the experiment. The pulse duplicator was run at varied flow rates (3.5 to 5 L/min) and pressure (90/60mmHg) to test the silicone prototype.

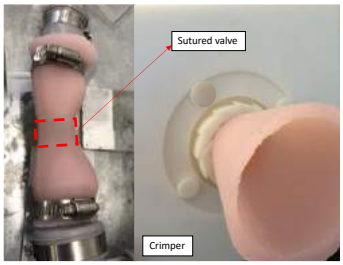

Figure 2: Silicone 'growth' model with implanted valve and crimper shown here during preliminary tests

RESULTS

Upon simulation of the experiment, the compliant model expanded and contracted, successfully withstanding the pressure in the setup and mimicking pulsatile motion.

From our stent simulation it was observed that finite element modeling demonstrated that the valve can be crimped to the pediatric size of 15 mm diameter while maintaining symmetry and the structural integrity of the stent, as shown in Figure 3.

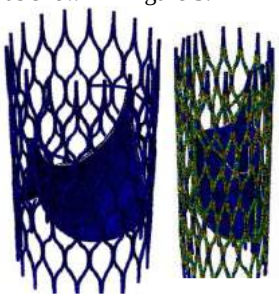

Figure 3: Our HATAV from previous work was be used as the basis for our pediatric valve design.

Preliminary results for the crimped valve prototype from ABAQUS simulations are shown in Figure 3. The maximum loads were seen at the commissures and at the center of the coaptation zone of the leaflets and as they were compressed progressively, the principal stresses got larger. As shown in Figure 4 for example, between two time steps, the maximum principal stresses increased from 2.18 to 2.44 MPa. The stent was not simulated for computational time optimization and due to the fact that the main goal was to observe loading conditions on the leaflets.

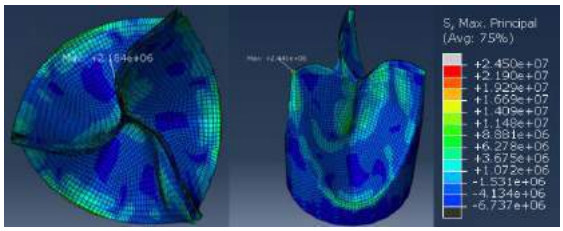

Figure 4: Our in house 3D leaflet design evaluated at the crimped or initial state of pediatric loading conditions. Highest loads are observed at the commissures and leaflet free edges

In the fully expanded state, the maximum principal loads were observed on the commissural regions in the order of 1.67MPa.

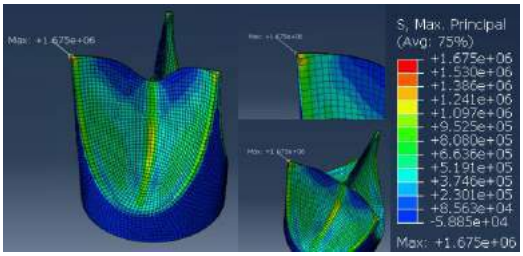

Figure 5: Our in house 3D leaflet design evaluated in its final fully expanded form. Highest loads are observed at the commissures

DISCUSSION

We have seen excellent hemodynamic performance in our preliminary work for adult polymeric heart valves [4] and expect similar conclusions. The loads we currently see in our simulations are comparable to those described in literature [5-6]. In the crimped state, the leaflets tend to pinwheel possibly due to the overall taller profile of the valve. As the valve starts to expand with growth, the leaflets will automatically assume their natural 3D shape. Optimizing the leaflet design will reduce the free edge length and reduce effects of pinwheeling. In the fully expanded state, the loads on the leaflets are lower. However, these commissural stresses are expected as the leaflets are anchored to the stent in that region.

Our results are expected to have positive impact because it lays the foundation for potentially solving the long-standing problems that plague all pediatric heart valves – patient-prosthesis mismatch, need for lifelong anticoagulation and long term durability.

INTRODUCTION

Abdominal aortic aneurysm (AAA) is an irreversible localized dilatation of the aorta and if left untreated may lead to rupture, the 15th leading cause of death in the United States[1]. Upon diagnosis of AAA a clinician will intervene using the maximum diameter criteria of 5.5 cm, when the risk of intervention is thought to be lower than the risk of rupture. However, it has been reported that up to 23.4% of smaller sized aneurysms between 4.1 and 5.5 cm rupture adding complexity to the clinical management of AAA[2,3] and highlighting the deficiencies of a one-size-fits-all maximum diameter criterion.

The biomechanics of AAA has been extensively studied to experimentally measure the material properties of the degenerated wall and intraluminal thrombus towards the development of representative patient-specific computational finite element models[4–7]. In addition to stress analysis of AAA, morphological indices have yielded multi-dimensional (one, two, and three-dimensional) measurements to provide rigorous interrogation of reconstructed patient-specific aneurysm geometries[3,8]. In addition, the rupture potential index was introduced as a mathematical model to provide a ratio of wall stress to wall strength based on experimental uniaxial extension tests and clinical indices[9,10]. However, the major limitation of these studies include a low number of aneurysms studies for clinical relevance (n = 348 Khosla et al.), variations in the finite element model and the fact that nearly all of the aneurysms analyzed were clinical size or greater than 5.0 cm in diameter[11].

Machine learning (ML) algorithms have improved over time and has been implemented in clinical datasets to aid in diagnosis and predict patient prognosis[12,13]. In this study we present a novel aneurysm prognosis classifier that trains a ML classification model using clinical, biomechanical and morphological indices to predict patient outcomes with the aim of highly informed clinical decision support.

METHODS

An anonymized dataset of clinical and imaging data was delivered via Globus cloud services (Argonne National Laboratory, Chicago, IL) by the Health Record Research Request in collaboration with the University of Pittsburgh Medical Center and the Department of Biomedical Informatics at the University of Pittsburgh. A total of 778 patients that were diagnosed with AAA were identified to extract clinical and imaging data at each follow up visit. Clinical data included demographics, pharmaceutical use, and co-morbidities (diabetes, peripheral vascular disease, coronary artery disease, renal failure and other conditions). A total of 32,067 images were collected that included both 2D and 3D images but were filtered to include only CT images that totaled 11,040 for the cohort. For the preliminary proof-of-concept study, 385 unique patients were chosen at a single time point. There was a total of 356 stable aneurysms, 16 clinical interventions and 13 rupture events in the cohort.

Image segmentation was performed using two primary approaches: A U-NET convolutional neural network was trained using Amazon Web Services (Amazon, Seattle, WA) Elastic Compute Cloud and local machines using multiple graphics processing units for automated segmentation and semi-automated segmentation using in-house code in MATLAB (Mathworks, Natwick, MA). The segmented CT images were then imported into an automated pipeline that converted the 3D point cloud to a surface reconstruction, converted the surface reconstruction of the wall/lumen/ILT into a computational mesh with ANSYS (ANSYS, Canonsburg, PA), and assembled of a final Abaqus (Dassault Systemés, Johnston, Rhode Island) input file. The computational model consisted of shell elements (S3R) for the wall that were defined with a uniform thickness of 1.3 mm and anisotropic material properties[6] and tetrahedral elements (C3D4H) for the ILT defined as an isotropic hyperelastic material under compression[7]. Biomechanical indices were extracted that included mean wall stress, peak wall stress, tension, and additional stress values (25th, 50th, 75th percentile). Further geometric quantification was performed using in-house code to measure one, two, and three-dimensional indices that included maximum diameter, surface area, tortuosity, vessel asymmetry, non-sphericity index, ILT volume, and other morphological indices[3,8,14,15].

A tabulated dataset was created using a finalized list of clinical, biomechanical, and morphological indices that included a final column for patient outcome (0 for stable, 1 for clinical intervention and 2 for

rupture). There were three levels of training performed, the first level was performed using each category and patient outcomes, the second level paired clinical/biomechanical, clinical/morphological, and biomechanical/morphological categories, and the third level included all three categories for training. The ML classification algorithms were trained using Tree-based optimization pipeline (TPOT) and the MATLAB Classification libraries.

RESULTS

Confusion matrices (CM) and receiver operator characteristic (ROC) curves were generated for each training level and the area under the curve (AUC) was calculated to inform the classifiers ability to discriminate patient outcomes. The AUC for the first level when predicting clinical intervention or repair was 0.57 for clinical data training, 0.78 for biomechanical data training and 0.80 for morphological data training. The AUC for the second level when predicting clinical intervention or repair was 0.87 for clinical and biomechanical data training, 0.89 for clinical and morphological data training and 0.87 for biomechanical and morphological data training. Finally, the AUC when predicting clinical intervention was 0.87 when trained with all categories, 0.88 for predicting stable aneurysms and 0.79 when predicting for rupture (**Fig. 1**). The confusion matrix

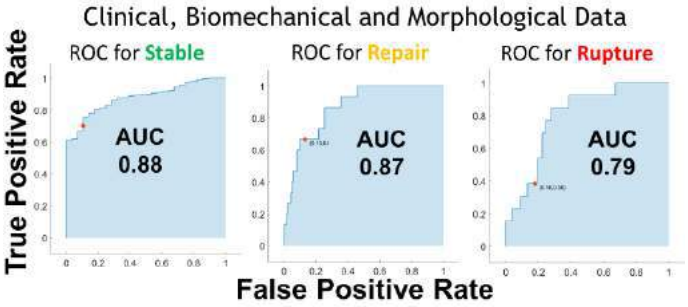

Fig. 1: Output from the APC trained with clinical, biomechanical, and morphological data. These are the ROC curves for each patient outcome (stable, repaired, and ruptured).

displayed in **Fig. 2** reports the predictions of APC and their true outcomes.

DISCUSSION

The trained ML classifiers based on individual categories, paired categories and all categories resulted in varying degrees of accuracy and discriminability of patient outcomes. When training a classifier with clinical data alone, it was found that the discriminability of patient outcomes remained poor (0.57 for clinical intervention). When incorporating image-based studies (biomechanics and morphological indices) there was a significant improvement, an indication that aneurysm progression towards intervention and rupture is driven by shape and biomechanical wall stresses. Although not shown, the CMs for the first level and second level failed to predict clinical intervention/repair and rupture events. However, the third level of training that incorporated all categorical indices was able to accurately predict clinical intervention/repair and rupture events. It is important to note that the CM (**Fig. 2**) predicted 0.78% of AAA as stable when in fact they ruptured, but this is a considerable improvement over the maximum diameter criterion (where up to 23.4% smaller sized aneurysm were found to rupture). There are several limitations to the study including the reliance on internal cross-validation and using a single data point rather than incorporating longitudinal forecasting models. In future studies, external cross validation will be performed with additional clinical and imaging datasets. This body of work demonstrates that rigorous biomechanical and morphological assessment along with clinical data may better inform clinical decision making and, to our knowledge, represents the single largest study to predict patient outcome.

INTRODUCTION

The Transcatheter Aortic Valve Replacement (TAVR) procedure is a common surgery performed in adults, and the amount of procedures is increasing [1]. The TAVR procedure does have complications, and underlying mechanisms of the complications have not been well studied [1]. It is unknown if the complications due to the procedure are from wear and tear of the heart tissue or due to changes in mechanical forces due to the implant. To study the underlying mechanisms, a small sensor that can detect changes in localized stresses and pressures before and after implant is required. One possible material that is promising is Polyvinylidene Fluoride (PVDF).

PVDF is a piezoelectric material that has applications as a nanogenerator of electricity [2]. PVDF has also been used as a biosensor in other applications. For example, McLaughlin used PVDF to study arterial pulse wave velocity of peripheral arterial blood vessels, to detect pressure changes associated with pulse of the blood vessels and to calculate the flow of blood through the arteries [3]. Although PVDF is a piezoelectric material and it can produce electrical signals in pure bulk strips, it was found that porous strips produce a larger signal likely due to larger deformations to the material due to the porous structure [2].

While many piezoelectric sensors have been characterized under a tensile load, there are few studies that have measured piezoelectric properties under compression, which is necessary for our application. For example, Bernard et al determined the d_{31} value of PVDF, which is the piezoelectric coefficient under strain [4]. Bernard reported the d_{31} to be 3.98 $pC.N^{-1}$, when used as a sensor and actuator[4]. However, d_{31} is determine by stress applied as tension on the piezoelectric material, not from compressive loads or pressures. Hence the overall goal of this study is to investigate the effect of porosity on the d_{33} piezoelectric coefficient of PVDF membranes.

METHODS

PVDF Synthesis:

PVDF powder (Sigma Aldrich, St. Louis MO) was dissolved in 2-butanone solvent at 75° C, then mixed with Zinc Oxide (ZnO) nanoparticles (35-45 nm, US Research Nanomaterials INC, Houston TX.). The mass ratio between ZnO nanoparticles and PVDF were adjusted to 10%, 20%, 30% and 40% wt ZnO to create differences in porosity. The mixture was treated in ultrasonic bath for 30 minutes to create a uniformly mixed PVDF and ZnO nanoparticle suspension. The suspension was cast into films in petri dishes and dried at 75° C. The dried strips then were placed in an acid bath of 10molar HCl for three hours to remove the ZnO nanoparticles from the structure. The films were then washed in deionized (DI) water before testing.

Compression tests:

A Test Resources Newton 100 series Tensile Tester was used to apply loads of 30, 60 and 100lb_f at a rate of 3in/min to the PVDF samples. Copper tape was placed on both sides of the PVDF membrane as electrodes to detect any voltage produced by the samples.

The PVDF membranes with copper tape electrodes was connected to a modified Sawyer-Tower Circuit in parallel to the capacitor (Figure 1). The voltage generated from the PVDF samples were collected over the 0.01 μF capacitor using a National Instruments cDAQ-917 and 9215 Voltage Input Modules at a rate of 1,000Hz for 10 seconds.

Theory:

To measure the piezoelectric output of the PVDF, the d_{33} coefficient was calculated. d_{33} is calculated by

$$d_{33} = \frac{D}{\sigma} \quad (1)$$

In which D is the electric displacement given by equation 2.

$$D = \frac{CV}{A} \quad (2)$$

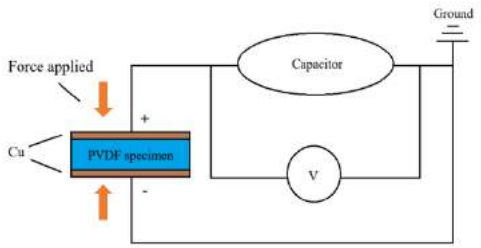

Figure 1: Modified Sawyer-Tower Circuit. The porous PVDF membrane with Copper tape electrodes was connected to a 0.01 µ F capacitor. The voltage acquired was measured across the capacitor.

C is defined as the capacitance of the capacitor, V is the voltage generated from the PVDF membranes, A is the area of the electrode. The applied compressive stress is $\sigma = \frac{F}{A}$, where F is the force applied to the membranes and A is the area of the PVDF under stress. Since the area of the electrode is the same as the area of PVDF under stress, and equation 1 becomes

$$d_{33} = \frac{CV}{F} \qquad (3)$$

This means that the slope of the voltage (V) versus load (F) graph for each membrane can be used to calculate the d_{33} coefficient.

RESULTS

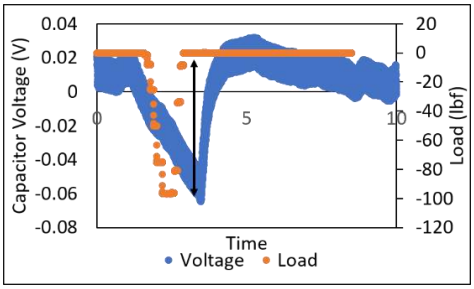

Figure 2: Sample Voltage and Load Data of 40% Wt ZnO at 100lbf. This figure shows the filtered voltage from the PVDF membrane, using a 5point Savitzy Golay fit, and the load applied to the membrane. The black arrow shows where the peak voltage is collected.

Figure 2 shows that there is a change in voltage occurring while the compressive load is applied. The voltage peak of each trial was calculated by finding the voltage values at the peak and valley during the compressed load application.

Once the voltage values were determined, the relationship between voltage and force was plotted. An example for the 40% wt ZnO sample is shown in figure 3.

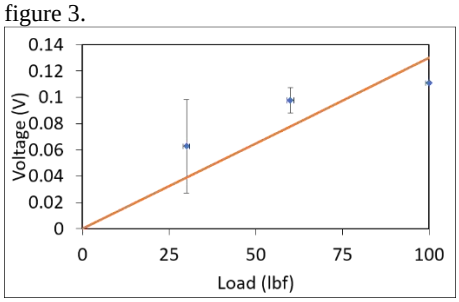

Figure 3: Linear Regression of 40% Wt ZnO Membranes The figure shows the average voltage values from 5 replicates compared to the line of best fit.

Figure 3 shows that as the compressive force increased, the voltage generated increased. The slope from the linear regression was used to calculate the d_{33} values according to equation (3).

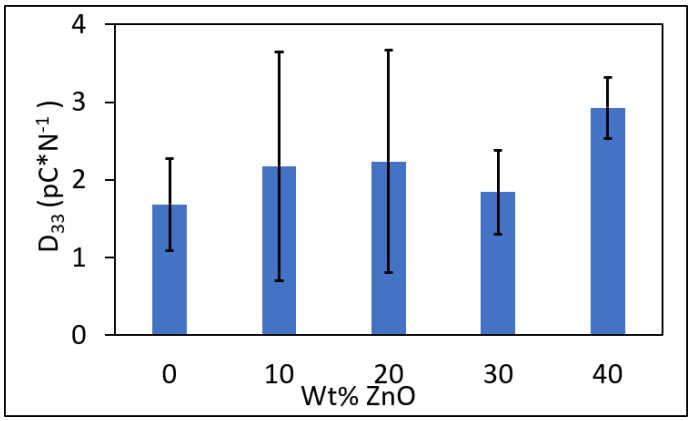

Figure 4: d_{33} values for Porous PVDF Membranes. The graph above shows the d_{33} values as the porosity changes. Error bars represent the standard error of the slope obtained from linear regression.

Figure 4 shoes the d_{33} values for the different PVDF samples tested. The pure, or 0% wt ZnO, 10%, 20% and 30% wt ZnO samples all have similar d_{33} values. The 40% wt ZnO membrane shows larger average d_{33} values, however, this larger value is not statistically significant due to the large deviations in d_{33} values.

DISCUSSION

The d_{33} values for 0% through 30% porosity vary and do not seem to follow a trend, but once the porosity is increased up to 40% wt ZnO, the d_{33} value increases. This suggests that porosity can affect the d_{33} values of PVDF. Mao reported a linear increase in voltage generated from increasing porosity of PVDF membranes up to 50% wt ZnO, but those experiments involved looking at the voltage generated under surface oscillations, where these d_{33} experiments look at how PVDF reacts under single compressive forces [2].

Even though the d_{33} values do not increase with increasing loads as expected, these results are still promising. Mao suggested that the increase in voltage was a result from the pores which allowed great deformation of the PVDF polymer chain [2]. This is likely the reason the d_{33} value for the 40% wt ZnO increased compared to the other porous membranes.

Although the d_{33} values calculated are not significantly different due to large deviations, there is potential that increasing the porosity of the membranes could result in larger piezoelectric coefficients. This means further studies on the porous PVDF membranes are warranted, including increasing the porosity past 40% Wt ZnO to values of 50%, 60% or even 70% wt ZnO.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has become a viable alternative to tackle severe aortic stenosis, especially for high surgical risk patients that are unable to undergo traditional surgical procedures. Computational modeling is a critical tool that can be used to visualize and predict deployment behavior for patient-specific TAVR procedures, and identify potential complications including coronary obstruction, paravalvular leakage, and thrombosis. Within this modeling pipeline, the key component is simulating the structural dynamics of the valve frame, native valve leaflets, and aortic root. However, due to the intrinsic complexity of the geometrical and mechanical aspects of the problem, the computational simulations of TAVR deployment becomes extremely expensive.

For systems that are heavily structured, reduced order models (ROMs) can be used to decrease the computational costs of the full order model (FOM) by orders of magnitude [1]. ROMs are low dimensional versions of the FOM that are created using available data; typically, there are two stages in the development of the ROM. In the *offline* stage, the FOM is run for a specific set of parameters from which a low-dimensional basis is formed. In the *online* stage, the ROM is then used for parameters different from the original parameters to rapidly obtain new solutions [2]. ROMs have been employed in various biomedical engineering applications, including fluid-structure interaction problems and computational electrocardiology [3]. However, the application of ROMs in TAVR deployment has not yet been studied.

The primary objective of this study is to develop a model reduction methodology for the structural deformation of a 29 mm Medtronic Evolut R valve. Specifically, a series of linear elastic simulations were performed with an idealized Evolut stent to obtain a databank of deformed states, which are called *snapshots*. From this, a singular value decomposition (SVD) procedure was performed to identify the principle components of the mechanical problem. A Proper Orthogonal Decomposition (POD) approach can then be taken to create the ROM. The ultimate goal of this work is to use this model reduction approach to significantly reduce the computational costs associated with simulating TAVR deployment procedures.

METHODS

An idealized geometry of the Evolut stent frame was created in *SolidWorks*. The geometry was meshed and refined using a combination of *Netgen* and *Mmg Platform*, resulting in a final mesh size of 257,000 tetrahedral elements. Snapshots were obtained by defining five nodes across three planes of the stent geometry (top, middle, and bottom planes), for a total of fifteen nodes, all of which are shown in Fig. 1.

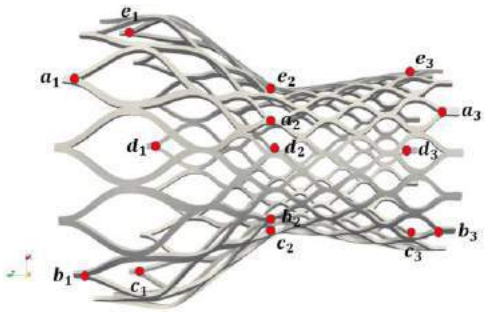

Figure 1. Evolut valve stent frame with all defined nodes.

Coordinates for each node were extracted from the mesh using *Autodesk Netfabb™*. Each snapshot consisted of defining an equal and opposite displacement (with a magnitude of 2.0 mm) between two nodes and simulating a linear elastic problem over the entire stent geometry. Each

of these displacement pair simulations represents the different effects of the forces from the aorta and aortic valve onto the Evolut stent. Material parameters defined include the Young's modulus (50,000 MPa) and the Poisson ratio (0.33). Simulations were performed in *FEniCS*, an open source Finite Elements library. In total, 105 node pairs were simulated. Displacement fields at all fifteen nodes were extracted from each simulation and placed into a 45 by 105 matrix. The rows of the matrix are the *x*, *y*, and *z* components of the displacement for each node, while the columns show all possible combinations with the fifteen nodes.

The SVD analysis was performed using *MATLAB*. Singular values of the individual *x*, *y*, and *z* components of displacement are plotted to determine if there is a significant exponential decay. A sharp and fast decay in the singular values suggests that the data can be well approximated by a linear combination of a small number of vectors, given by the eigenvectors associated with the largest singular values. Using the POD approach, the solution $\underline{x}$ to the differential problem is

$$\underline{x} = W\underline{c} \quad (1)$$

where, W is the rectangular matrix of the chosen eigenvectors, and $\underline{c}$ is a vector of unknown coefficients. Generally, $\underline{c}$ is a much lower dimensional vector than $\underline{x}$ (tens vs hundreds of thousands), yielding the model reduction. Plugging (1) into the original elasticity problem to solve in a least-squares sense, one obtains the ROM. Having to solve tens or hundreds of unknowns, as opposed to hundreds of thousands in the FOM is anticipated to reduce the computational costs significantly. More precisely, let

$$A\underline{x} = f \quad (2)$$

be the FOM represented by a linear system obtained after a finite element discretization of the elasticity problem in the stent. Here, f is the applied force. The square matrix A depends on the finite element mesh and is generally hundreds of thousands of rows. The ROM model on the other hand reads as follows, where W^TAW is a matrix that generally features a size in the range of tens or hundreds of rows [4].

$$W^TAW\underline{c} = W^Tf \quad (3)$$

RESULTS

All 105 node pair simulations were analyzed in terms of the resulting displacement field along the stent geometry. Displacement field vectors for one specific node pair simulation (nodes $a_1 - d_3$) are shown in Fig. 2. Maximum displacement of approximately 7.6 mm is seen near the top left edge nodes of the stent, while the remaining portions of the stent deformed within a range of 0.6 to 5.0 mm. At the nodes themselves, a displacement of 2.0 mm is seen, which matches the prescribed boundary conditions.

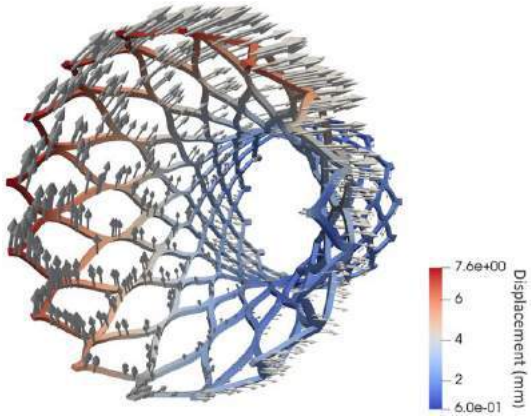

Figure 2. Resultant displacement field (mm) for simulating the $a_1 - d_3$ node pair.

Displacement data is extracted for each of the fifteen nodes over all 105 simulations. From this data set, the individual *x*, *y*, and *z* displacement vectors are separated, and the SVD analysis is performed. The resulting singular values are plotted and shown in Fig. 3. The *x*-axis here represents the total number of nodes (fifteen), and the *y*-axis represents the singular values. A sharp and rapid decline in the singular values is seen at approximately five nodes.

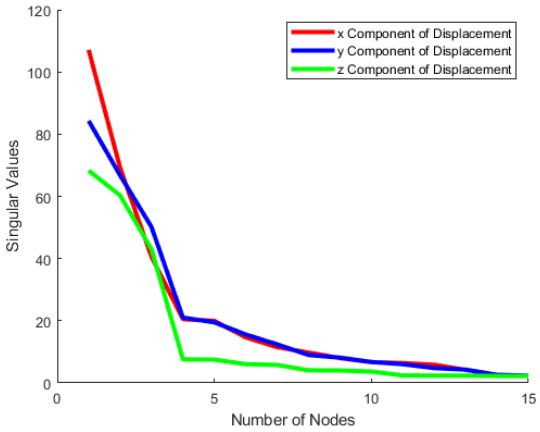

Figure 3. Singular values of the displacement snapshots.

DISCUSSION

In this study, a model reduction approach is introduced to reduce the computational costs associated with simulating TAVR deployment. Specifically, the aim was to determine if the snapshot data obtained from the linear elastic simulations with the Evolut stent was reduceable. To this end, an SVD analysis was performed as the initial steps towards creating the ROM. From the SVD analysis (Fig. 3), a significant decay in the singular values is apparent. This suggests that a combination of only five displacements is enough to represent the entire FOM and reduce the problem. This conclusion will be tested on several linearly elastic test cases. However, in reality the self-expanding nitinol frame of the Evolut valve would be more accurately modeled as a superelastic alloy. Thus, a constitutive model for superelasticity is needed to capture all material properties of the nitinol stent and provide more reliable results from which the ROM can be constructed. The basic POD approach, however, also requires linear differential operators. To extend the approach to more practical superelastic cases, the Empirical Interpolation Method (EIM) will be applied. In addition, these findings will be further corroborated with a mesh independence study, showing the importance of ROMs for reliable and efficient solutions.

In conclusion, this study shows that POD is a viable method for reducing the computational costs for predicting the structural deformation of the Evolut stent. The rapid decay of the singular values suggests room for a significant reduction of the computational costs that may, in turn, enable the use of computational mechanics in optimization problems or real-time settings.

INTRODUCTION

Borderline left ventricle (BLV) patients are neonates born with an undersized left ventricle, possibly concomitant with aortic valve stenosis, hypoplastic aortic arch, hypoplastic left heart complex, and right ventricular pressure overload. [1] A critical dilemma facing pediatric heart surgeons is to choose between a biventricular repair (BiVR) or a single ventricle palliation procedure (SVPP) for BLV patients. While BiVR is aimed at creating two functioning ventricles in a single surgery, SVPP involves multiple staged open-heart surgeries resulting in a single functional ventricle. Typically, SVPP has high inter-stage mortality, especially after the first stage (Norwood procedure) performed as neonates, and has poor long-term outcomes with only 70% reaching adulthood. [2] On the other hand, patients undergoing BiVR may exhibit reduced heart function post-surgery and may have to be subsequently switched to SVPP. [3] There is a need to better stratify BLV patients based on functional data and predicted outcomes for different surgical pathways.

While tremendous progress has been made in applying computational modeling for SVPP, modeling the circulation of BLV patients has not received much attention to date. We present a computational model of the preoperative BLV circulation using lumped parameter network (LPN) and modify the layout to simulate BiVR and Norwood surgical procedures. The LPN models have been independently verified with previously published data, although we aim to personalize the model by tuning the preoperative LPN to match actual patient data. Model predictions will be correlated with patient outcomes retrospectively using available clinical data at the New York-Presbyterian (NYP) Morgan-Stanley Children's hospital and the database at the Society of Thoracic Surgeons (STS), to assess the viability of using simulations to guide surgical decision-making.

METHODS

We have developed an LPN-based computational model of preoperative BLV circulation for neonates (Figure 1). Our model is derived from Corsini et al. [4], originally developed for Norwood procedure, with the following modifications: (a) we reintroduce the undersized left heart into the network and model atrial and ventricular septal defects using resistances; (b) we model the aortic arch hypoplasia by including an additional resistive element in the ascending aorta; (c) we employ a versatile valve model for all four cardiac valves, which accounts for stenosis and regurgitation effects [5]; (d) we also retain the patent ductus arteriosus (PDA) between the pulmonary artery (PA) and ascending aorta supporting neonatal systemic circulation.

We further modified the preoperative LPN layout to simulate BiVR and Norwood procedures. For BiVR, we close all the septal defects, lower the resistance and compliance of the aortic arch mimicking its reconstruction with a homograft patch, and lower the degree of valvular stenoses. For the Norwood procedure, the LPN layout is the same as that of Corsini et al. [4] with a 3.5mm Blalock-Taussig shunt between the aorta and PA. The PDA is assumed to be closed post-surgery in both procedures. The LPN parameters are extracted from Corsini et al. [4] tuned for a Norwood patient with BSA = $0.34\ m^2$ and PVR = $6\ WU \cdot m^2$. [6, 7] For the preoperative BLV model, we have reduced the unloaded volume of the ventricle to 50% of its nominal value and assumed that the mitral and aortic orifices are 70% stenosed.

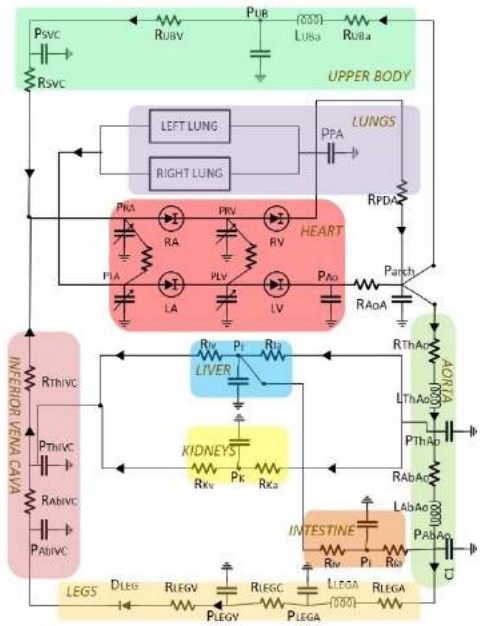

Figure 1: Layout of the preoperative LPN-based circulation model of a borderline left ventricle (BLV).

Our LPN model provides functional hemodynamic variables including atrial and ventricular pressure-volume (PV) loops, cardiac stroke work (SW), cardiac index (CI), the ratio of pulmonary (Qp) to systemic (Qs) flow rates, and other key pressures and flow rates of the circulation system. We also perform O_2 calculations including O_2 saturations of the systemic arteries (S_{ART}) and veins (S_{VEN}), and oxygen delivery (OD). [8]

RESULTS

In Figure 2, we compare the LPN results between BiVR and Norwood procedures for a BLV patient, including PV loops for both left and right ventricles, aortic and pulmonary flow rates and pressures, and flow through upper (UB) and lower body (LB) during the cardiac cycle. A quantitative comparison of the hemodynamic indices is shown in Table 1.

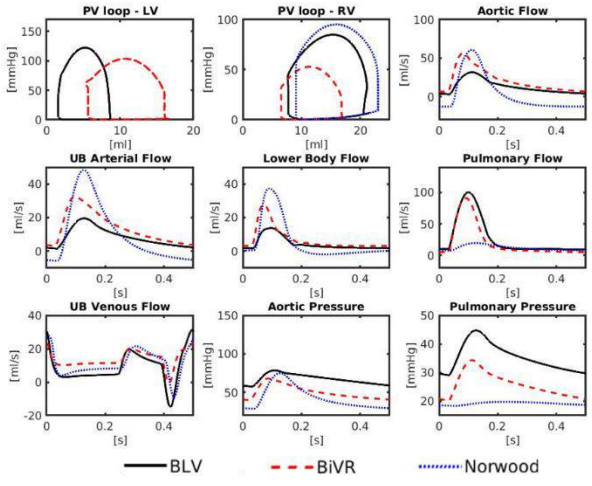

Figure 2: Model predicted hemodynamic quantities during the cardiac cycle for a BLV patient before and after surgery.

Table 1: Comparison of hemodynamic indices before and after surgical procedures. (Qp/Qs: ratio of pulmonary to systemic flows; SW: stroke work; LV: left ventricle; RV: right ventricle; CI: cardiac index; S_{ART}, S_{VEN}: arterial and venous saturations; OD: O_2 delivery)

	Qp/Qs	SW (LV)	SW (RV)	CI	S_{ART}	S_{VEN}	OD
BLV	2.05	646	807	2.28	82.0	51.1	407
BiVR	1.00	835	404	3.65	98.0	77.5	749
Norwood	0.74	-	1023	4.34	64.7	39.9	416

Units: SW [mmHg·ml], CI [l/min/m^2], S_{art}, S_{ven} [%], OD [ml/min/m^2]

Our results indicate that performing a BiVR on the current BLV patient leads to an equal distribution of pulmonary and systemic flows (Qp/Qs=1), reduction in RV SW (~50%), and an increase in CI (~60%). On the contrary, performing a Norwood would increase RV SW (~27%) although CI increases by 90%. A BiVR leads to higher S_{ART} and S_{VEN} while performing Norwood would lead to a substantial reduction in both the saturations. OD is substantially elevated (80%) after a BiVR compared to only a marginal increase from Norwood.

DISCUSSION

We have demonstrated a proof-of-concept application of computational modeling to predict the post-operative outcomes of a BLV patient. Typically, these patients undergo a binary evaluation between BiVR and SVPP, primarily based on anatomical markers. Computational modeling provides functional data that could be of critical importance to surgical decision-making. In this study, our preoperative BLV model with an undersized LV and valvular stenosis, correctly predicts insufficient OD and higher RV SW. Functional data from post-operative models indicate that BiVR is the optimal choice of surgery for this patient that restores bi-ventricular circulation with a substantial increase in OD and reduced RV SW.

There are several limitations in the current study that we plan to overcome in the future. While the current study involves only one patient, whose LPN parameters have been tuned for Norwood circulation, we plan to perform patient-specific modeling by tuning the preoperative LPN to match BLV patient data. We also plan to demonstrate statistical significance by recruiting more patients (20+) from NYP and STS databases and perform validation of the preop and postop LPN models. Our novel framework will also allow us to investigate outliers such as those BLV patients who had to be switched from one surgical procedure to another. We hope that our pilot study will pave way for the development of personalized multiscale finite element models of BLV circulation to address the important clinical question, `how small is too small?'

THE EFFECT OF AORTA SHAPE ON TYPE A DISSECTION RISK

INTRODUCTION

In patients with ascending thoracic aortic aneurysm, an enlarged maximum aortic diameter is correlated with increased risk of clinical events (ATAA)[1], and maximum diameter is often used as a predictor of potential tearing of the inner layer of the aorta, or thoracic ascending aortic dissection (TAAD). However, assessment of maximum diameter alone fails to capture the multifaceted geometric structure of the aorta, and in fact, it has been shown that maximum diameter serves as an imperfect indicator of dissection risk[2]. Instead, the three-dimensional structure of the aorta serves as a better predictor of functional aortic characteristics (flow, stiffness, remodelling) and could hence be superior in dissection risk stratification. Statistical shape analysis (SSA) enables identification of key modes of shape variation, or particular shape changes that capture the majority of geometric dissimilarities among a cohort of individual geometric structures. Application of SSA to the aorta has revealed differences between principal modes of aortic variability among asymptomatic patients[3], but has not previously been used to identify shape features associated with risk of TAAD.

METHODS

SSA reduces a complex geometric structure to single, discrete shape scores, describing the structure's associations with particular shape features extracted from a larger population. Our retrospective study explores the correlations between SSA-derived shape feature and TAAD occurrence on a dataset of 31 patients with ATAA, 12 of which dissected and 19 of which did not dissect. Using clinical thoracic computed tomography (CT) images, we extracted aortic geometries for all patients using standard image segmentation techniques, truncating the carotid arteries and smoothening the resulting geometries using VMTK[4]. We utilized open-source software, Deformetrica[5], to perform SSA on the cohort of aorta shapes and performed principal component analysis (PCA) to extract principal shape features. Furthermore, we utilized partial least-squares (PLS) regression to identify the shape mode most correlated with dissection outcome.

RESULTS

In Figure 1, a visual representation of the first three PCA modes of the full dataset is provided. Figure 1 (a)-(c) displays PCA 1 (corresponding visually with aortic size), (d)-(e) shows PCA 2 (corresponding visually to cubic[6] – rectangular arch with reduced inner curvature in comparison to outer curvature – or gothic arch shape[6] – acute angulation between the ascending and descending portions of the aorta), and (f)-(g) demonstrates PCA 3 (corresponding visually to aortic arch angle). The middle column shows the mean (template) shape, which corresponds to a shape score of zero along any mode, and the left and right columns display the shapes corresponding to shape scores -2σ and $+2\sigma$, respectively, where σ is the standard deviation of shape scores along each particular mode. The aortas are colored corresponding to the distance from the template shape. Quantifying the percent shape variation captured by each mode, PCA 1 represents 26.4% of the total shape variation, PCA 2 14.7%, and PCA 13.2%, respectively.

The results of the PLS analysis are provided in Figure 2, where aortas which dissect are more associated with negative scores and those which do not dissect associated with positive scores. This shape mode explains

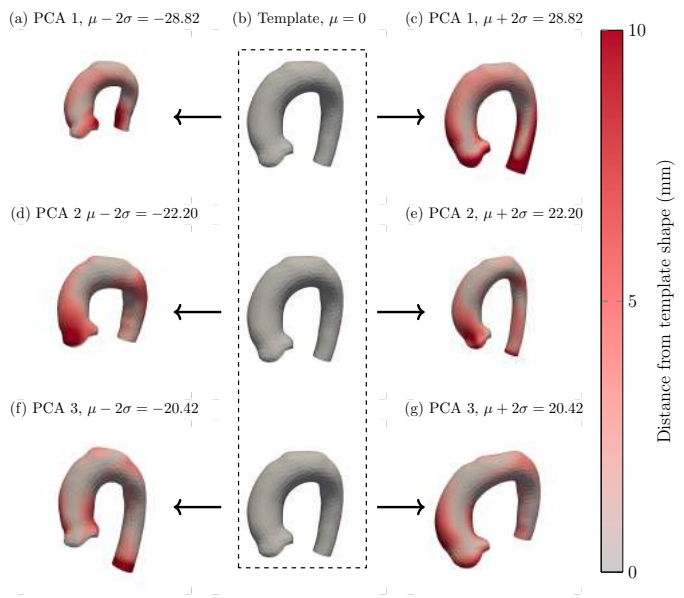

Figure 1: The first three shape modes: (a)-(c) PCA 1, (d)-(e) PCA 2, and (f)-(g) PCA 3. The mean shape (middle column) corresponds with a shape score of zero, left column shows each mode at -2σ, where σ is the standard deviation of shape scores along the mode, and right column at $+2\sigma$. The aorta surfaces are colored according to distance between each point and the corresponding point on the template surface.

10.6% of the total shape variation in the entire cohort. The shape scores for all four modes are summarized in Figure 3, with boxplots splitting the cohort into aortas which dissect (red) and don't dissect (blue). Comparing the dissection and no dissection populations with a Wilcoxon rank-sum test, there is a strong statistically significant difference between shape scores for the two groups along the PLS mode ($p = 1e-3$), a slight difference along PCA 2 ($p = 9e-2$), and no significant difference ($p > 0.1$) between shape scores for the two groups along PCA 1 or 3.

DISCUSSION

We have explored shape variation amongst a cohort of 31 aneurysmal aortas, using SSA techniques, and compared the shape scores for extracted shape modes with dissection outcome. We have found that the first three shape modes correlate visually with aortic size, arch shape (cubic vs. gothic), and aortic arch angle, and that these three together account for almost half of the total shape variations within the evaluated cohort. Furthermore, out of these three, PCA 2 showed weak, but

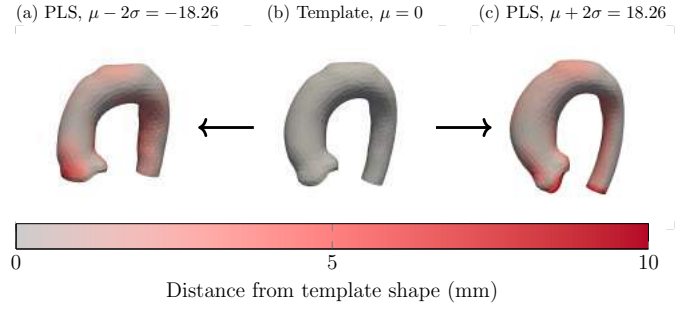

Figure 2: The shape mode resulting from a PLS analysis of the dataset with dissection outcome. Negative scores are more associated with dissection and positive scores with no dissection.

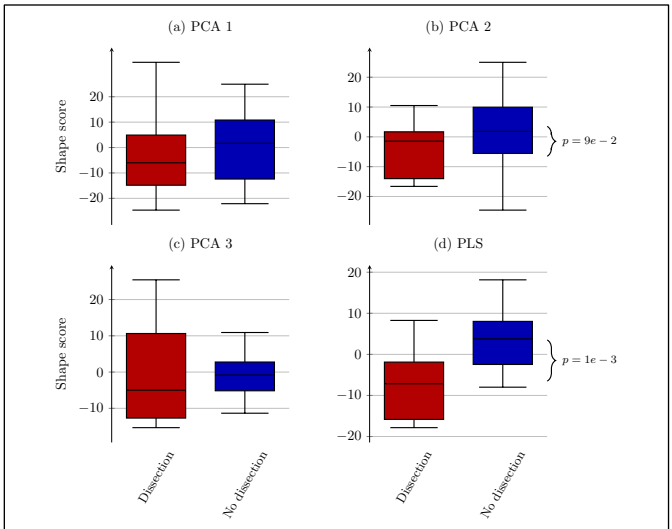

Figure 3: Shape scores for all 31 aortas along (a) PCA 1, (b) PCA 2, (c) PCA 3, and (d) the PLS mode correlated with dissection outcome. The red boxplots are for aortas which dissect and the blue boxplots for aortas which do not dissect. The p-values are shown next to (b) and (d) as the results hold statistical significance.

significant, correlation with dissection outcome. We used PLS regression to identify a shape mode most correlated with dissection outcome, and found that shape scores along this mode do separate statistically significantly with dissection outcome. The work presented here demonstrates the capacity for SSA techniques to quantify three-dimensional shape features for use in dissection risk assessment. Further work in fluid and structural analysis of blood flow through shapes correlated with dissection occurrence is required to mechanistically understand why particular aorta shape features may contribute to dissection risk.

INTRODUCTION

Glioblastoma (GBM) preclinical cancer models with primarily cultured GBM cells such as in vivo xenografts could recapitulate parental tumor invasiveness, proliferation index, microvessel density, genomic alterations, and patient GBM subtypes [1]. With consensus clustering of RNA-seq data of freshly isolated GBM patient cells, GBM cells were classified into three subtypes, Mesenchymal (MES), Proneural (PN), and Classical (CL), and MES and PN became dominant for recurrent tumor [2]. Since GBM cell invasion and migration is the key factor for GBM recurrence and poor survival [3], it is critical to understand the migratory phenotypes of GBMS cells with different subtypes using GBM preclinical models.

In a typical cell migration cycle, the first step is the protrusion of the leading edge driven by actin polymerization into self-assembled actin filaments (F-actin). F-actin undergoes retrograde flow driven by myosin II (motor)-mediated contraction, while binding and stretching actin-adhesion linkage proteins (clutch). These adhesion proteins form focal adhesions and allow the cell to transmit traction forces onto compliant substrates. This system is referred to as a motor-clutch mechanism [4], and was implemented and simulated by the motor-clutch model [5]. In addition, the cell nucleates multiple protrusions via F-actin polymerization, each of which can be modeled as a motor-clutch system, with traction forces balancing across the different protrusions. Stochastic perturbations to the force balance due to adhesion bond rupture enable larger scale cell movements and can define the front and the rear of the cell. This force-driven cell motion was described and simulated in the cell migration simulation (CMS) developed by [6] (Figure 1a).

In this study, the cell migratory mechanics was measured for GBM patient cells derived from in vivo xenografts in adherent culture. Migratory mechanisms were studied by fitting the CMS predictions to patient cell migration data in order to parameterize patient cells. Highly correlated genes to CMS parameters were investigated using patient cell RNA-seq data derived from mRNA sequencing.

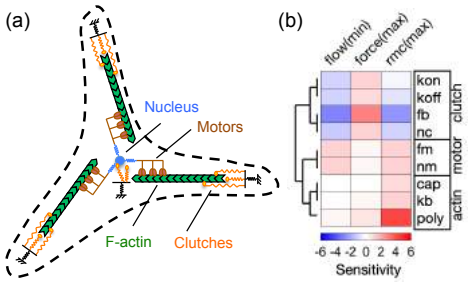

Figure 1: (a) The cell migration simulator (CMS). (b) Sensitivity analysis of CMS.

METHODS

6 GBM patient cell lines (3 MES, 3PN subtype) were derived from Mayo PDX lines developed in Mayo Clinic Sarkaria Lab with adherent culture [7] (Figure 2a). Cells were cryopreserved and cultured adherently with Neural Stem Cell (NSC) media before experiments. GBM cells were then plated on polyacrylamide (PA) gels coated with laminin. Cell migration speed, traction force, and F-actin flow speed were measured following previous protocols [6] (Figure 2b,c).

The C++ version of the CMS was compiled and simulated using High Performance Computing system at the Minnesota Supercomputing Institute. Based the base parameter values described in [6], the parameter sensitivity analysis was studied on the minimum

F-actin flow, maximum traction force, and maximum migration speed for different substrate stiffness (Figure 1b). Three parameter groups were classified using unsupervised hierarchical clustering (Figure 1b).

We found three principal parameters, one from each parameter group, can be variable to different cells and can predict their migratory mechanics. The three principal parameters include motor number (nm), clutch number (nc), and F-actin polymerization rate (poly), which represent cell myosin motor level, adhesion protein level, and actin polymerization activity, respectively. The specific CMS parameter values for each patient cell line were further determined by fitting CMS predictions with adjustable principal parameters (nc,nm,poly) to patient cell migration data (Figure 3).

Mayo cell RNA-seq data was derived from www.cbioportal.org, and verified using NovaSeq at UMN Genomics Center. Cell migration gene list was derived from Gene Ontology (http://geneontology.org).

RESULTS

Based on GBM cells derived by Mayo PDX lines, we found that GBM MES cells had significantly faster migration speed and higher F-actin flow rate compared to PN cells, while traction forces were similar to both subtypes (Figure 2c).

The CMS parameter values for each patient cell lines were derived by fitting CMS predictions with adjustable principal parameters (nc,nm,poly) to patient cell migration data (Figure 3). We found that GBM MES cells generally have higher nm and poly compared to PN cells, indicating higher myosin II level and enhanced actin polymerization activity. The CMS predicted that higher nm and poly result in faster migration and higher F-actin flow [6], which is consistent with the patient cell migration data (Figure 2c).

Based on the RNA-seq data of GBM patient cells, and using the migration gene list derived from Gene Ontology, we found the most correlated migration genes to CMS principal parameters (nm, nc, poly) for GBM patient cells ($R > 0.6$, $p < 0.05$, Figure 4a). We recognized that, for example, the motor-correlated genes, RHOG and RRAS, and the poly-correlated genes, CD2AP, have higher expressions in MES cells than in PN cells (Figure 4b). RHOG belongs to Rho family, which regulates myosin activity by affecting myosin light chain via ROCKs [8]. RRAS regulates Rac and Rho activity, and further effects myosin activity [9]. CD2AP directly associates with actin filament formation [10].

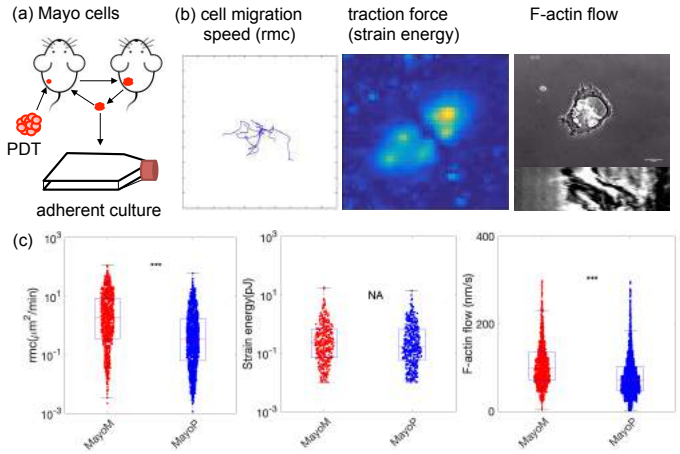

Figure 2: Cells derived from Mayo PDX lines (a). Cell migration speed, traction force, and F-actin flow rate were measured for MES(red) and PN(blue) cells (c), using previous protocols (b) [6].

ACKNOWLEDGEMENTS NIH U54 CA210190

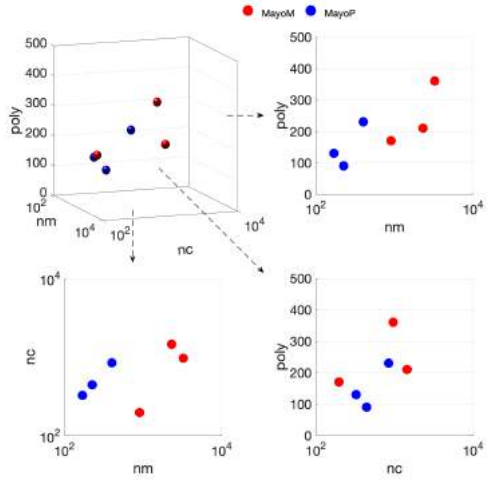

Figure 3: The CMS parameter values for GBM patient cells.

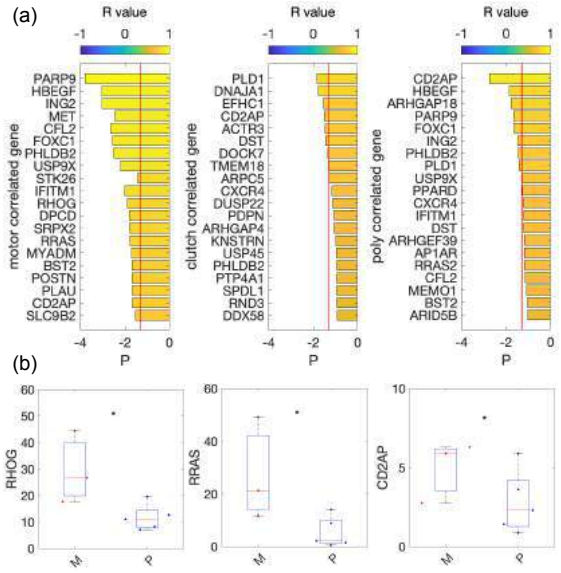

Figure 4: (a) Most correlated genes within migration gene list (geneontology.org) to CMS principal parameters based on patient cell RNA-seq data. (b) Three example correlated genes.

DISCUSSION

In this study, we used the CMS framework to understand the biophysical mechanisms of the heterogeneity of GBM patient cell migration with MES and PN subtypes (Figure 3), and to link migratory mechanics to cell transcriptomic information (Figure 4).

In order to have better statistical significance, more patient cell lines could be studied, including in vitro freshly isolated GBM cells from patient tumors, which can also retain tumorigenic and infiltration potentials in vivo, and similar gene profiles as to parental tumors [11].

INTRODUCTION

Coronary heart disease (CHD) accounts for the majority of all cardiovascular disease related mortality in the United States. CHD is often characterized by persistent narrowing of the coronary vasculature which leads to the formation of cardiac ischemic events. Patients with severe CHD often undergo percutaneous coronary intervention (PCI) to deploy intravascular stents intended to restore coronary blood flow. However, the process of stenting can lead to injury of the vascular wall which promotes cellular ingrowth and in-stent restenosis. Therefore, patients often present with common comorbidities of myocardial infarction (MI) and neointimal hyperplasia (NH) formation. Though drug-eluting stents have shown efficacy at mitigating NH formation, the overall impact of novel therapeutic strategies targeting cardiac fibrosis after MI should also be investigated in the context of vascular injury.

Toward this end, cadherin-11 (CDH11) is a cell-cell adhesion protein known to regulate inflammation and fibrosis in multiple conditions ranging from rheumatoid arthritis to pulmonary fibrosis and calcific aortic valve disease [1]. Recently, we have shown that inhibition of CDH11 following MI preserves cardiac function and reduces scar burden in the left ventricle [2] due to a reduction in immune cell recruitment immediately following injury that attenuates myofibroblast activation and collagen deposition at later times.

Though CDH11 blockade has shown a beneficial effect in the heart, this treatment strategy has yet to be evaluated in the context of vascular injury. Preliminary data shows that CDH11-deficiency promotes neointima formation, though the cellular source responsible for these changes is not currently known. Thus, the objective of this study was to investigate the role of CDH11-deficient T cells in the remodeling response of the murine femoral artery following mechanical wire injury. Our findings reveal that T cells from CDH11-deficient animals promote NH formation in immune-compromised recipients.

METHODS

Animal Models. CDH11 transgenic mice (*Cdh11*$^{+/+}$, *Cdh11*$^{+/-}$, and *Cdh11*$^{-/-}$) were used in all vascular injury studies. Additionally, to investigate the specific role of CDH11-deficient T cells, immuno-compromised *Rag1*$^{-/-}$ mice lacking mature T and B lymphocytes were reconstituted with purified *Cdh11* transgenic splenic T cells by adoptive transfer. For all cell transplantation studies, a total of $3x10^6$ donor cells were delivered to each recipient mouse retro-orbitally.

Femoral Artery Wire Injury. Mice were anesthetized by isoflurane and the femoral artery was exposed and gently dissected away from the femoral vein. Proximal blood flow was temporarily ligated and a small transverse arteriotomy was introduced in the muscular branch of the femoral artery. A straight spring wire (0.38 mm in diameter) was then inserted into the arteriotomy and advanced toward the iliac artery. The wire was left in place for 1 minute prior to removal, closure of the arteriotomy by cautery, and restoration of blood flow [3]. Injured animals were maintained for 28 days after surgery.

Histology and Immunohistochemistry. Injured animals were perfusion fixed with cold formalin to maintain tissue architecture, and femoral arteries and spleens were gently dissected and placed in formalin overnight. Fixed samples were then embedded, frozen, and sectioned at a thickness of 8 μm. Slides were stained with either Elastica van Gieson to visualize the elastic lamellae of the femoral artery or fluorescent antibodies to visualize specific markers of interest. Custom image processing algorithms were developed to quantify neointima area (defined by tissue inside of the continuous internal elastic lamina) and media area of femoral artery sections, as well as immunofluorescent staining from all tissues.

Migration Assay. Spleens from *Cdh11*$^{+/+}$ and *Cdh11*$^{-/-}$ mice were excised and digested into a single cell suspension. T lymphocytes were isolated from all splenocytes by negative selection magnetic assisted

cell sorting (MACS). Following isolation, cells were plated into a 5 μm pore 96-well plate and allowed to migrate toward gradients of potent T cell chemokines CCL21, CXCL10, 11 and 12 [4]. Cells were allowed to migrate at 37°C and 5% CO_2 for 3 hours prior to staining with calcein; the number of migrated cells was calculated based on the formation of a calcein standard curve.

Bulk RNA-sequencing. Injured femoral arteries with isolated and frozen prior to homogenization and RNA isolation. The Vanderbilt Technologies for Advanced Genomics (VANTAGE) center performed library preparation, sequencing, and read alignment. Differential gene expression analysis was performed using the R package DEseq2 using Cook's outliers to filter low gene counts and $\alpha = 0.05$. Gene sets were considered over-represented if $p_{adj} < 0.05$.

Statistical Analysis. Comparisons between groups were assessed by one-way ANOVA followed by a post-hoc Tukey HSD test for multiple comparisons. Nonparametric statistics were used where appropriate based on normality and equal variance tests.

RESULTS

Following wire injury, the extent of vascular remodeling – as defined by the ratio of neointima to media area – increased with loss of CDH11. Indeed, *Cdh11*$^{-/-}$ mice were found to have a roughly 2-fold increase in the intima/media ratio, relative to *Cdh11*$^{+/+}$ (Fig. 1).

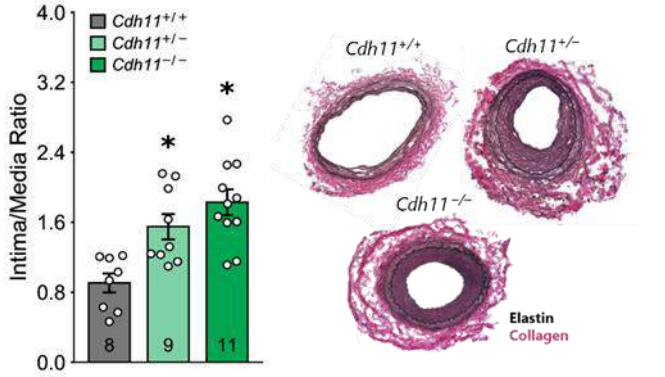

Figure 1: NH formation is increased in *Cdh11*$^{-/-}$ mice after injury

To examine the transcriptional differences between the injury response of *Cdh11*$^{+/+}$ and *Cdh11*$^{-/-}$ mice, bulk RNA-sequencing was performed. Following RNA isolation, library preparation, sequencing, and read alignment, differential gene expression analysis identified a total of 95 differentially expressed genes (Fig. 2A). Of these, 43 genes were downregulated and 52 genes were upregulated in *Cdh11*$^{-/-}$ mice, relative to *Cdh11*$^{+/+}$. Gene set enrichment analysis (GSEA) revealed multiple enriched gene sets. Notably, we observed a positive enrichment in genes associated with mesenchymal cell proliferation and a negative enrichment in genes associated with leukocyte proliferation (Fig. 2B). The former is consistent with our observation of increased NH formation and the latter would suggest an altered immune response to vascular injury. Further analysis revealed a downregulation of genes set related to T cell activation, proliferation, and migration. This would suggest an altered T cell phenotype in *Cdh11*$^{-/-}$ mice, relative to *Cdh11*$^{+/+}$. To investigate this further, we performed adoptive transfer of T cells from *Cdh11* mutant donors into *Rag1*$^{-/-}$ mice lacking mature lymphocytes. Indeed, we observed a similar level of injury in *Rag1*$^{-/-}$ mice with *Cdh11*$^{-/-}$ T cells and global *Cdh11*$^{-/-}$ mice as well as in *Rag1*$^{-/-}$ mice with *Cdh11*$^{+/+}$ T cells and global *Cdh11*$^{+/+}$ mice (Fig. 3A). Further, analysis of immunofluorescence images revealed a decrease in CD3+ T cell expression in the neointimal layer of injured femoral arteries from *Cdh11*$^{-/-}$ mice, relative to *Cdh11*$^{+/+}$ (Fig. 3B).

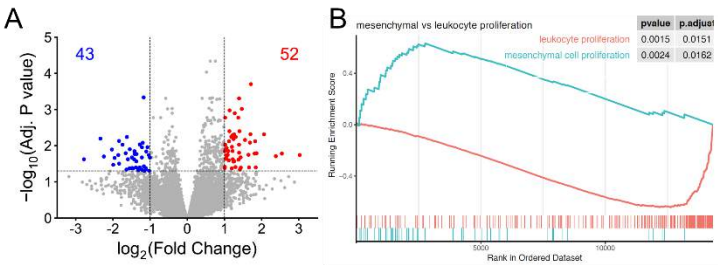

Figure 2: (A) Volcano plot showing differentially expressed genes and (B) GSEA plot of positively and negatively enriched gene sets

Given the observation of reduced T cell expression, we hypothesized this may be due to altered migratory potential of *Cdh11*$^{-/-}$ T cells. Using a transwell migration assay, we confirmed that *Cdh11*$^{-/-}$ T cells were less migratory than *Cdh11*$^{+/+}$ T cells to multiple potent chemoattractants (Fig. 3C). In particular, the chemotaxis in responses to CXCL10 and CXCL12 stimulation are likely the most relevant in this disease context. Altogether, this may provide insight into a potential mechanism and suggests that altered T cell recruitment is contributing to the excessive NH observed with CDH11 deletion.

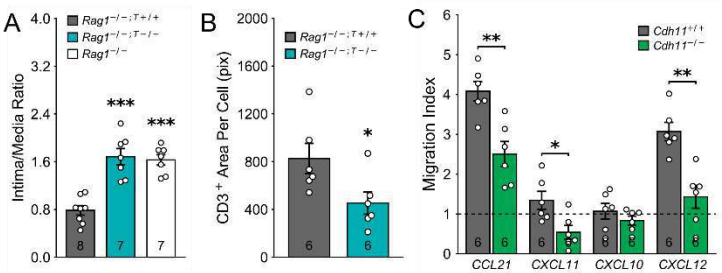

Figure 3: (A) *Cdh11*$^{-/-}$ T cells promote NH in *Rag1*$^{-/-}$ mice. (B) *Cdh11*$^{-/-}$ T cells are less expressed in the neointima after injury and are (C) less migratory to chemokine stimuli than *Cdh11*$^{+/+}$ T cells

DISCUSSION

Using transgenic animals, RNA-sequencing, and adoptive transfer, we show that the exacerbated NH response observed in *Cdh11-/-* mice is due to an altered T cell. While the specific effect of CDH11 in T cells is yet unknown, findings from this work suggest it may be involved in either T cell recruitment or may modulate another secreted factor to promote excessive cell proliferation. For example, altered levels of T cell cytokines – such as IFN-γ and IL-17a, among others – are known to contribute to altered vascular smooth muscle cells responses in conditions such as atherosclerotic plaque formation [5]. Altogether, the findings from this work highlights the role of the immune system in regulating cardiovascular disease progression and importance of evaluating the effect of novel treatment strategies for CHD in both cardiac and vascular disease models.

INTRODUCTION

In the U.S., cancer is the second leading cause of death, responsible for over 600,000 deaths per year. Nanomedicine has immense potential in cancer treatment due to unique properties such as preserving therapeutics' bioavailability and reduced systemic toxicity via improved targeting. However, only ~0.7% of the systemically administered dose of nanomedicine accumulates in solid tumors[1]. Furthermore, the transport of nanoparticles (NPs) from blood to tumor cells is impeded due to the irregular tumor vasculature structure as well as increased interstitial pressure, dense stroma, and compressive tissue stress within the tumor microenvironment. The tumor microenvironment consists of stromal cells, including cancer-associated fibroblasts (CAFs) and the extracellular matrix (ECM). CAFs play a crucial role in tumor growth, progression, and metastasis in part by producing the physical scaffold of the tumor microenvironment - the ECM[2]. Collagen, a primary component of ECM, promotes the elevation of tumor interstitial pressure, collapse of blood vessels, and increase of hypoxia, which all limit the delivery of anticancer drugs.

Microbe-based drug delivery systems are a potential strategy to overcome the intratumoral transport challenge and significantly enhance drug delivery efficacy in cancer through improved targeted transport. Attenuated bacteria are promising candidates with advantages of self-propulsion and targeted accumulation, which enable deep penetration to overcome the transport limitation of nanomedicine. However, the effect of ECM content on the distribution of bacteria-based drug delivery agents remains largely unexplored. Here, we use a breast cancer organoid model comprising mammary CAFs (mCAFs) and epithelial breast cancer cells to assess the role of ECM production by mCAFs in the penetration of bacteria and bacteria-nanoparticle assemblies, known as NanoBEADS[3,4]. We introduce a new generation of our Nanoscale Bacteria-Enabled Autonomous Drug Delivery System (NanoBEADS) constructed by linking maleimide-activated gold nanoparticles to the thiol groups on the outer membrane of the tumor-targeting *S.* Typhimurium VNP20009 *cheY*$^+$ bacteria. First, we evaluated the nanoparticle loading capacity of the NanoBEADS. Then, we investigated the impact matrix production by mCAFs on the penetration of bacteria and NanoBEADS into breast cancer organoid models *in vitro*. We found that high ECM content significantly hinders the intratumoral transport of bacteria and NanoBEADS in tumor organoids and limits the tumor killing potential of bacteria. This model could be used to evaluate the tumor colonization and delivery efficacy of microbial-based drug delivery agents with different bacterial strains.

METHODS

Salmonella Typhimurium VNP20009 *cheY*$^+$ RFP were cultured in MSB medium[5] supplemented with 35 μg/mL of chloramphenicol at 37 °C and 100 rpm. Bacterial culture at OD_{600} = 1.0 was washed with motility media (MM)[5] twice and concentrated to OD_{600} = 2.0. The bacterial suspension was mixed with 40 nm maleimide-activated gold nanoparticles at 1:100 bacteria/NP ratio and incubated for 60 mins at 15 rpm on an end-over-end shaker at room temperature to facilitate NanoBEADS formation. Subsequently, the NanoBEADS were incubated with mPEG-thiol (Mw: 5000 g/mol) at 0.8 μg/mL for 30 min to quench the remaining maleimide binding sites.

Tumor organoids were formed with 4T1 murine mammary carcinoma cells and mCAFs murine cancer-associated fibroblasts[6]. 4T1 cells or 4T1 cells with mCAFs (1:5 ratio) were seeded in ultra-low adhesion 96 well plates. Once tumor diameters reached 600 μm, up to 6 tumor spheroids were transferred into Eppendorf tubes and incubated with bacteria or NanoBEADS at OD_{600} = 1.0 in L15 media supplemented with 10% calf serum on an end-over-end shaker at 37 ºC. After an hour, tumor spheroids were washed twice with fresh culture

media and put back on the shaker. After 12 h, 18 h, and 24 h incubation period, the tumor spheroids were assayed for viability and also were frozen to evaluate the spatial distribution of bacteria. A minimum of 3 independent experiments and 3 tumors for each experiment category were used.

RESULTS

We developed a new class of NanoBEADS by conjugating 40 nm maleimide-activated gold nanoparticles to the thiol groups on the surfaces of bacteria (**Fig 1a**). This nanoparticle size was selected due to its well-known performance for drug delivery applications[7] and its lack of adverse influence on bacteria growth and motility[8]. First, we investigated the role of the bacteria/NP ratio on conjugation outcome. The attachment number was quantified using scanning electron microscopy (SEM) images (**Fig 1b**). At 1:50 bacteria/NP assembly ratio, an average of 46 ± 17 nanoparticles per bacteria was achieved, whereas the 1:100 bacteria/NP assembly ratio resulted an average of 26 ± 15 attached (**Fig 1c**). The distribution of NP loading, shown in **Fig 1d**, demonstrates that the 1:50 bacteria/NP ratio produced NanoBEADS with not only high average NP load but also small variation across the samples. Thus, this preparation of NanoBEADS was used for the tumor studies.

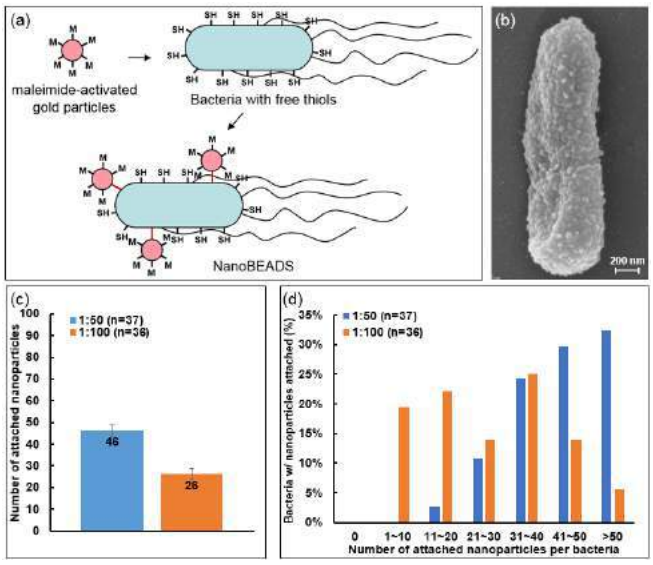

Figure 1: a) Schematic of the conjugation chemistry and b) representative SEM images of a NanoBEADS agent. c) The average nanoparticle loading of NanoBEADS agents constructed at different bacteria/NP assembly ratios. d) The distribution of number of nanoparticles on NanoBEADS agents as a function of assembly ratio.

Before tumor experiments, NanoBEADS were incubated with mPEG-thiol to quench residual maleimide groups on the nanoparticles. The 4T1 and co-culture tumor organoids were incubated with bacteria or PEGylated NanoBEADS for the specified durations. Bacteria were used as a control to determine the effect of nanoparticle conjugation on intratumoral transport. The 4T1 tumor organoids and the 4T1-mCAF organoids were used to investigate the influence of mCAFs on bacteria and NanoBEADS colonization and penetration. Using immunofluorescence staining, it is shown that the collagen content of co-culture tumor organoids is significantly higher than the 4T1 tumor organoids (**Fig 2a**). After 12 h, bacteria self-propelled into the tumor, in some cases reaching the tumor center. Over time, the number of accumulated bacteria increased, primarily due to growth (**Fig 2b**). At 24 h, 4T1 tumor organoids completely disintegrated, and only 9% of the cells were alive (**Fig. 2c**). In contrast, the co-culture tumors contained very few bacteria at 12 h, which were all limited to 20% of the radial distance from the tumor's surface (**Fig 2d**). Even after 18 h, bacteria were primarily limited to 30% of the radial distance, although their number increased due to growth. At 24 h, the bacteria finally reached the core of the co-culture tumors; however, the tumors remained intact and viable (**Fig 2c-d**).

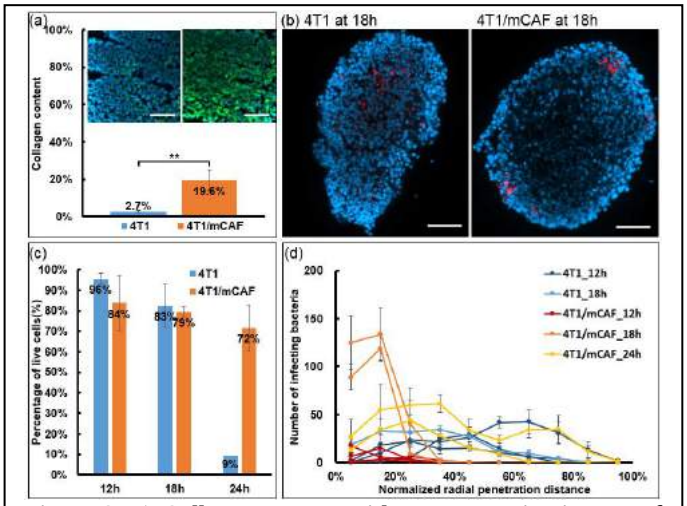

Figure 2: a) Collagen content with representative images of collagen type I immunofluorescence staining in co-culture and 4T1 tumor slices. **p value < 0.01. All scale bars are 50 µm. b) Intratumoral distribution of bacteria in 4T1 and co-culture tumor slices at 18 h. Blue, DAPI; red, bacteria; green, collagen I. All scale bars are 50 µm. c) Viability of tumor cells after tumor incubation with bacteria. d) Radial distribution of bacteria in 4T1 and co-culture tumor organoids.

DISCUSSION

A new class of NanoBEADS, which uses thiol-maleimide linkage to achieve high nanoparticle loading on the bacterial cell, is reported. This one-step conjugation method does not require the use of an antibody, precluding immune stimulation. Furthermore, the attachment chemistry is specific to the membrane and will not interfere with bacterial flagellar motility.

In the breast cancer organoid model with mCAFs, the higher collagen content inhibits bacteria's intratumoral transport and limits bacteria tumor-cell killing effects. We expect that the NanoBEADS will have similar trends to bacteria and is currently being investigated. In the future, we will develop a nano-bio-based approach to overcome the ECM barrier to drug delivery in high-collagen content solid tumors.

COMPARISON OF ANABOLIC OSTEOPOROSIS TREATMENTS: PTH *VS*. PTHRP ON THE ACTIVATION OF NEW BONE FORMATION AND IMPROVEMENTS IN BONE MICROARCHITECTURE

INTRODUCTION

Postmenopausal osteoporosis is a chronic condition that leads to deterioration of trabecular microarchitecture and reduced bone mass. Current osteoporosis treatments are categorized as either anticatabolic, which reduce bone resorption, or anabolic, which increase new bone formation. Intermittent parathyroid hormone (PTH, teriparatide) was the first and only FDA-approved anabolic treatment for postmenopausal osteoporosis since 2002 and until 2017, when PTH-related peptide analogue (PTHrP, abaloparatide) was approved by the FDA. Like PTH, PTHrP exerts its anabolic effects by activating the PTH 1 receptor (PTH1R), which subsequently activates multiple downstream pathways. However, the effects of PTHrP on bone microarchitecture, activation of new bone formation, and how these effects compare to those of PTH remain unclear.

It has been widely known that remodeling-based bone formation (RBF – bone formation coupled with resorption by osteoclasts) plays an important role in maintaining healthy skeletal homeostasis. Recently, modeling-based bone formation (MBF – *de novo* bone formation on quiescent surfaces without prior bone resorption) has been identified as an important mechanism by which anabolic agents improve bone mass. MBF is an intrinsically rare cellular mechanism that only naturally occurs during growth, healing, and with external mechanical loading in the adult skeleton [1]. However, recent studies demonstrated that both MBF and RBF can be activated by PTH/PTHrP and are critical to their anabolic effects [2, 3]. Therefore, the objective of this study was to compare the efficacy of PTH and PTHrP by assessing their effects on trabecular bone microarchitecture and their ability to induce MBF and RBF. We hypothesized that different levels of MBF and RBF induced by PTHrP *vs.* PTH may lead to different degrees of improvement in trabecular bone microarchitecture.

METHODS

Animal protocol and treatment: All animal experiments were IACUC approved. Female Sprague-Dawley (SD) rats received bilateral ovariectomy (OVX) surgery at 4 months of age to simulate post-menopause estrogen deficiency and they developed osteopenia after 4 weeks. All animals received treatment 5x/wk for 3 wks (40 μg/kg/day for μCT and 20 μg/kg/day for histomorphometry). Animals were assigned to μCT or histomorphometry. Within each set of animals, there were three groups: (1) Vehicle: saline treated (n=15 for μCT, n=6 for histomorphometry), (2) PTH (n=36 for μCT, n=6 for histomorphometry), and (3) PTHrP (n=17 for μCT, n=6 for histomorphometry). *In vivo* μCT imaging: At wks 0 and 3, μCT scans of the metaphysis of the right proximal tibia were performed (Fig. 1A) using the VivaCT40 (Scanco Medical AG, 10.5 μm voxel size). Trabecular bone microarchitectural parameters were obtained. Mineral label injections, cryohistomorphometry, and imaging: Calcein (green, G), alizarin complexone (red, R), and tetracycline (yellow, Y) fluorochrome labels were injected in a G-R-Y-G sequence on days -2, 5, 12, and 19 (treatment initiated on day 0) with euthanasia on day 21. Cryosections (8μm thick) of the proximal tibia underwent imaging using darkfield and fluorescent microscopy to obtain the trabecular structure and visualize multi-fluorochrome labels (Fig. 2A-C). These same sections were then decalcified and viewed under a polarizing microscope to visualize the cement line and surrounding collagen fibers. Identification of MBF and RBF sites: MBF sites were identified as having a smooth cement line and uniform surrounding collagen fibers (Fig. 2D). RBF sites were identified as having a scalloped cement line with interrupted collagen fibers (Fig. 2E). Dynamic histomorphometry: Mineral labels were used to calculate dynamic histomorphometry parameters. Statistics: Data from μCT are reported as percent change from wk 0, except for structural model index (SMI -

ranging from -3 to 3, reported as absolute change). A one-way ANOVA with Bonferroni post-hoc tests was used to compare responses between treatments. For all analyses, $p \leq 0.05$ was considered to indicate statistical significance.

RESULTS

In vivo μCT (Fig. 1B-G): Without anabolic treatment, OVX led to a deteriorated trabecular bone microarchitecture. This is indicated by a reduction in bone volume fraction (BV/TV), trabecular number (Tb.N), trabecular thickness (Tb.Th), connectivity density (Conn.D), and plate-like trabeculae (indicated by SMI), and an increase in trabecular separation (Tb.Sp) in the VEH group. However, with both PTH and PTHrP treatment, there were improvements in trabecular bone microarchitecture compared to VEH. This is indicated by improvements in BV/TV, Tb.Th, and more plate like trabeculae. PTH and PTHrP lessened the reduction in Tb.N and Conn.D and attenuated the increase in Tb.Sp. Interestingly, we found greater improvements in trabecular bone microarchitecture with PTHrP than with PTH, including BV/TV (68% *vs*. 44%), Tb.Th (54% *vs*. 45%), plate-like trabeculae (-0.9 *vs*. -0.6 in SMI), and greater connectivity (-12% *vs*. -14% in Conn.D). However, no difference was detected between the percent change of Tb.N between PTHrP (-14%) and PTH (-9%).

Histomorphometry (Fig. 2F-H): PTH and PTHrP resulted in greater MBF- and RBF-induced mineralizing surface (MS/BS), mineral apposition rate (MAR), and bone formation rate (BFR/BS) compared to VEH. No difference was found in MAR between PTH and PTHrP groups in both MBF and RBF. However, PTHrP led to a greater MS/BS and BFR/BS compared to PTH at MBF sites (0.33 *vs*. 0.22 for MS/BS, 0.53 *vs*. 0.35 for BFR/BS), but not RBF sites.

DISCUSSION

This was the first study to compare PTH and PTHrP in a rat model. It also provided valuable longitudinal tracking of trabecular bone microarchitecture using *in vivo* imaging. Lastly, using a novel cryohistology imaging platform coupled with sequential mineral labels, we were able to distinguish the effects of MBF *vs*. RBF.

PTH and PTHrP enhanced trabecular bone microarchitecture through the induction of a higher MAR and greater MBF and RBF surfaces compared to VEH treatment. PTHrP was more efficient at improving trabecular bone volume and microarchitecture than PTH due to the formation of more MBF surfaces that may improve trabecular bone microarchitecture.

Here, we studied both PTH and PTHrP at the same dose to compare the efficacy of the drugs. In a clinical trial that tested the efficacy of abaloparatide (PTHrP), abaloparatide was administered at a clinically relevant dose, which is four times (4x) that of teriparatide (PTH) [4]. In human trans-iliac bone biopsies from that trial, compared to teriparatide, the 4x dose of abaloparatide resulted in a greater MS/BS at the periosteal envelope [5]. MAR did not differ between the two treatments. Arlt *et al*. compared equal doses, like in our study, and clinically relevant doses of PTHrP *vs*. PTH in 8-week-old female B6 mice [6]. PTHrP at both doses resulted in a higher osteoblast surface at the proximal tibia than PTH and VEH. These studies and our results suggest that the greater benefit observed with PTHrP *vs*. PTH exists between both equal and clinically relevant doses. PTHrP incurred greater benefits to bone than PTH, although MAR did not contribute to this improvement. Furthermore, the benefits of PTHrP that we see here may be further amplified if this drug were administered at a higher dose.

In summary, our study suggests that MBF and RBF are important contributing factors to the improved trabecular bone microarchitecture by anabolic agents and that PTHrP may be a more efficient anabolic agent than PTH, although more work is needed to confirm this result.

INTRODUCTION

A prominent symptom of hemiparesis is an imbalance of muscular strength between the left and right leg, resulting in gait abnormalities. The individual develops compensatory motor patterns, causing overuse and pain. Secondary symptoms associated with sedentary lifestyle emerge, including heart disease and obesity. While the simple answer to such problems is "exercise", it is consistently more difficult for individuals with mobility impairments to access the proper equipment due to physical, social, psychological, and/or financial reasons. A home-based exercise system would bypass transportation limitations by default while providing privacy for the user, and a more affordable device would ameliorate financial concerns, increasing the potential to reach more users.

Significance. Every 40 seconds someone has a stroke, and every year in the United States alone, nearly 800,000 people will have a stroke [1]. Depression, anxiety, and reduced gait stability conspire to keep survivors of stroke off their feet, thus increasing the rate of health decline [2, 3]. Meanwhile, faster gait velocity and better appearance of gait are regarded as ultimate goals of rehabilitation in the post stroke population [4, 5].

Role of Resistance Training and Aerobic Exercise. The accomplishment of rehabilitation goals often entails the use of technologies such as specialized treadmills and ellipticals. There exists an array of commercial gait trainers for users with hemiparesis. Unfortunately, either high cost or sub-optimal functionality seem to be yet unavoidable compromises. There are more basic, less expensive models without motor assistance and more expensive models such as the Innowalk-Pro and Lokomat. Ellipticals have been investigated as rehabilitation devices for more than a decade, producing devices such as the iCARE, a device which is marketed as affordable yet costs approximately $30,000.

Specific Aims. Elliptical exercise machines provide a low impact alternative for users with limited aerobic capacity or injury in fitness improvement. A motorized elliptical device (the Motogaitor) was created for a child with level IV cerebral palsy by a team of students under the guidance of the senior author. User testing produced an enthusiastic reception, and feedback indicated a number of new design constraints, including:

1. The need for freewheeling capability such that a user could bypass motor assistance and encounter resistance;
2. The ability for device access while using a walker;
3. Price tag less than $3000.

It has been demonstrated that the application of horizontal resistance to the user while walking on a treadmill at self-selected velocity can be scaled to produce strength adaptations in post stroke individuals [6, 7, 8]. Critically, Brown et al. found that increasing posteriorly directed forces while post-stroke users walked on a split belt treadmill resulted in the paretic limb producing more propulsive force [9]. This finding has been a primary impetus for development of an elliptical with differential resistance capability that targets adults post stroke.

Therefore, the goal of this master's thesis was to design, construct, and test an elliptical exercise machine with adjustable differential resistance, a freewheeling motor drive mechanism, and compatibility with a Rifton walker, all with a budget of less than $2000 so that the resultant device could be sold commercially for $3000.

METHODS

In order to verify compatibility with a Rifton walker, it was necessary to create a CAD model of the walker. A front-drive elliptical configuration was chosen to allow ease of access from rear. Interferences were eliminated throughout the range of motion.

Figure 1: Clearances were verified using CAD model.

Freewheeling allows the user to rely on motor assistance for startup of the device. This removes the contribution of static friction, preventing the need to overcome these greater force values. Once the device is moving at a baseline velocity chosen by the user via the control panel, they are free to "out-pedal" the motor.

This function was achieved by attaching a freewheeling sprocket to the main axle about which the flywheel and crank arms rotate. An ANSI 41 chain couples this rotating assembly to the motor output. Due to the unidirectional engagement of the freewheeling sprocket, the motor only applies assistive force when the user's RPM falls below that of the motor. Conversely, when the user's RPM is greater than the motor RPM, the motor only experiences the load of the chain itself. This relationship is functionally identical to a ratcheting socket wrench.

Figure 2: Differential resistance was implemented.

Differential resistance will be achieved by adjusting the length of the moment arm for each leg independently. The crank arm was drilled at 0.5" increments to allow consistency between uses and ease of adjustment.

To save cost, the final device was constructed using mild steel, a relatively inexpensive material. Parts were ordered when necessary and fabricated when possible.

RESULTS

The resultant device, dubbed the Motogaitor Elite, is fully compatible with the Rifton walker, features a freewheeling mechanism that incorporates a motor with variable speed control, implements differential resistance at the crank arm with adjustable friction resistance at the flywheel, and was produced at a final cost of $1748.67. Additionally, it has been estimated that larger scale production could reduce this production cost to $1200-$1400.

The prototype occupies a floor space of 60"x25" which means it would likely fit comfortably in most living spaces. Height adjustable handles, full-sized flywheel for smooth operation, and readily accessible controls are also prominent features of this design.

Figure 3: The Motogaitor Elite is pictured here.

DISCUSSION

Ongoing work includes safety testing, which will utilize motion analysis and collection of pedal force data for inverse dynamics calculations to compare joint torques experienced during use of the device with those seen in overground walking. Future work will ultimately prove whether this model produces a differential training effect, but regardless of the outcome, its creation will provide further insight into ways exercise can combat the secondary effects of stroke.

INTRODUCTION

There are numerous benefits associated with running; however, the tibia is subjected to repeating forces and can develop bone stress injuries (BSIs) [1]. BSIs begin with a mild pain that can progress with continued exercise [2]. Studies have suggested that, each year, more than 20% of runners develop BSIs and 40-60% of those BSIs occur in the tibia [3, 4, 5]. In order to develop and propose interventions for BSIs, a better understanding of the mechanisms for BSIs is needed. To obtain a better understanding of BSIs, computational methods like 3D finite element (FE) analysis are used. The objective of this study was to develop a workflow to create 3D tibia FE models using personalized running force data from the stance phase and magnetic resonance (MR)-derived subject-specific tibia geometries in both male and female runners.

METHODS

Data were previously collected from 40 volunteers, who were aged 18-35, healthy, non-injured, and frequently ran more than 16 kilometers weekly. As producing personalized 3D models is a very time-intensive process, four females and four males were used in this study. All the participants warmed up on an instrumented force treadmill (Bertec, Columbia, Ohio, USA). 3D kinetic and kinematic data (100 and 200 Hz respectively) was collected using a real-time motion capture acquisition and processing software (TheMotionMonitor, Innovative Sports Training, Chicago, Illinois, USA) and a 10-camera 3D motion capture system was used to track reflective markers (Qualysis Corporation™, Gothenburg, Sweden). Ground reaction forces were filtered, and kinetic and kinematic data of the stance phase were isolated and input to a musculoskeletal model to estimate muscle forces of the muscles that span the tibial region of interest [6, 7]. Static optimization and vector summation of the muscle forces with distal tibia reaction forces were further used to approximate the forces acting at the distal tibia.

Each subject's right tibia was imaged using a 1.5-T scanner with a torso coil. Sagittal and Coronal T1 weighted turbo spin echoes (4mm thick/1mm gap, 480 FOV) and axial T1-weighted turbo spin echoes (7mm thick/2mm gap, 220 FOV) were acquired. Vitamin E capsules were placed on anatomical landmarks to aid in coordinate system alignment. Each MR image was imported into Mimics (Materialise, Belgium) where semi-automatic thresholding was used to segment the entire bone (cortical and inner bone), and the inner bone (trabecular bone, bone marrow, etc.).

The entire tibia was rotated about the longitudinal axis to align the MRI and force coordinate systems. Due to low trabecular bone resolution, the distal and proximal ends were cropped resulting in a tibial model comprised of the middle 70% of the tibia shaft. The distal and proximal centroid locations were identified and imported into 3-Matic (Materialise, Belgium). The longitudinal axis of the tibial model, defined as a line from the distal to proximal centroid locations, was aligned with the 3-Matic coordinate system. Volumetric meshes were created from the 3D models using tetrahedral (10-node) elements.

A preliminary mesh sensitivity analysis was performed. For this initial analysis, 1.2 mm was selected to ensure a uniform edge length across all subjects. The volumetric meshes were exported into ANSYS (ANSYS, Canonsburg PA). A Young's Modulus of 17.19 GPa and a Poisson's ratio of 0.3 was defined for the cortical bone [8]. Previously determined distal tibial forces for the 10 increments of the stance phase were used for FE analysis and the distal end was fixed. For each subject the maximum equivalent stresses and equivalent elastic strains were extracted at each 10% interval of stance phase and analyzed descriptively.

RESULTS

Subject demographics and maximum equivalent stress and strain are reported in Table 1. The maximum equivalent stress and equivalent elastic strain occurred at 50-60% of the stance phase and are visualized in Figure 1. The maximum stress across the entire stance phase is shown in Figure 2.

Table 1: Subject Information and FE Outputs.

Parameter	All	Males	Females
Age	23.75 ± 3.53	24.0 ± 4.42	23.50 ± 2.29
Mass (kg)	70.56 ± 13.3	82.79 ± 6.72	58.34 ± 2.96
Preferred Run Speed (m/s)	2.94 ± 0.13	3.00 ± 0.07	2.87 ± 0.14
Max. Equivalent stress (MPa)	149.6 ± 39.6	143.5 ± 29.5	155.8 ± 46.8
Max. Principal Strain (με)	7616 ± 2032	7478 ± 1423	7752 ± 2489

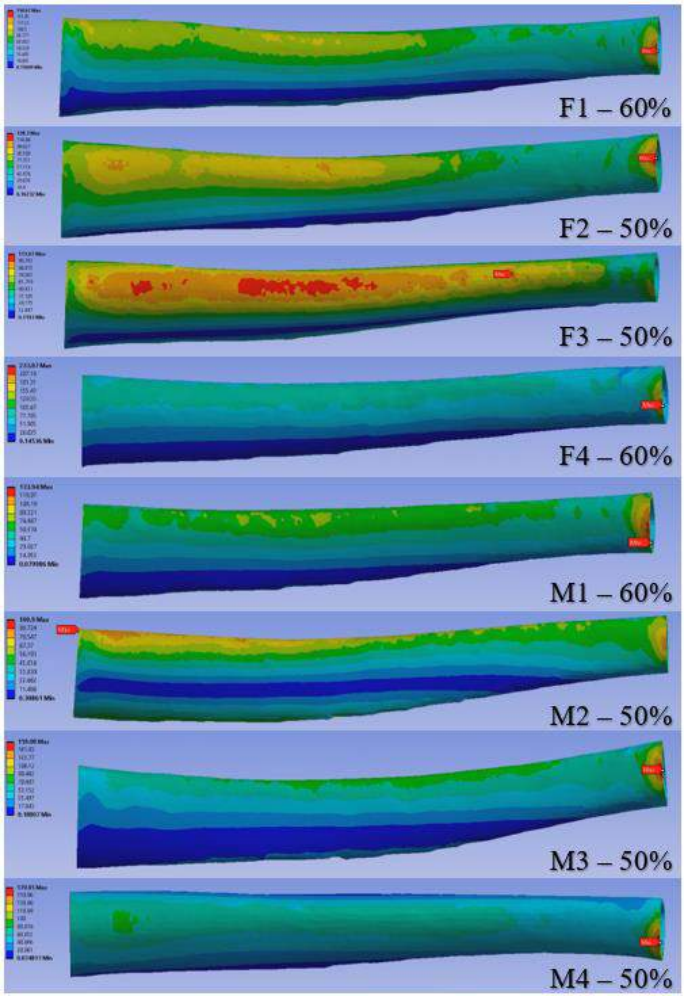

Figure 1: Equivalent Stress at the time point corresponding to maximum equivalent stress and strain for each subject. (Note the scales vary across subjects; M-male and F-female)

DISCUSSION

This study demonstrates a workflow for MR-reconstruction of the tibia to FEM utilizing subject specific running forces across the stance phase in young healthy female and male runners. Past studies have utilized CT scans to acquire tibia geometry and estimate mechanical properties [9]; however, subjects are exposed to radiation. Furthermore, we have combined subject specific geometry with subject specific forces; whereas other studies have used generalize geometries [8, 10] or estimated forces [9].

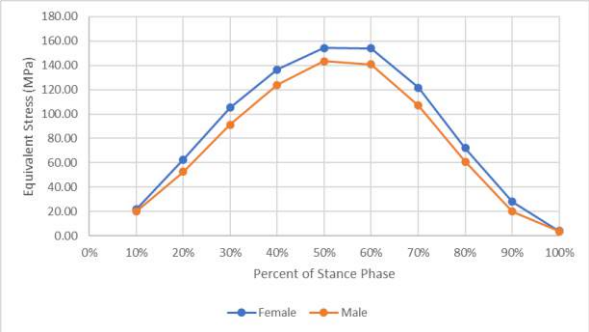

Figure 2: Subject averaged maximum equivalent stress across 10% intervals of the stance phase.

The values for Maximum Equivalent von Mises stresses found in this study (149.6 ± 39.6 MPa) are similar to those from [9]: 102.1MPa and 120.24 MPa for one male and one female respectively. The minor difference may be explained by the inclusion of both trabecular and cortical bone versus just cortical bone as in this study. Trabecular bone is not captured well with MRI. Furthermore, the subjects were older, and the applied forces were estimated based on the subject's body weight. The location of maximum stress and strain, as seen here in the posterior middle of the tibia, is similar to other studies [8-10].

In this study the maximum equivalent strain was 7616 ± 2032 με. Other studies have reported similar values during running such as 7939.79 ± 1588.74 με for rear foot-strike [8]. Edwards et al, reported maximum compressive strains between 2800 and 4800 με during running conditions [10]. Here, the maximum normal strains were 5782 ± 1895 με. However, the subjects from Edwards et al. were all male and the inclusion of female runners may increase the subject-averaged maximum strain.

There were limitations of this study such as a small population size, cortical bone-only hollow models, not accounting for the contribution of the fibula, and use of a generalized Young's modulus instead of personalized values. However, this work demonstrates a successful workflow to build personalized FEMs from MR images and running data. As 3D modeling is time intensive, future work will compare these results to that of simpler 2D cross-sectional analyses. Ultimately, these data can improve understanding of BSI and risk-mitigating strategies.

INTRODUCTION

Studies have reported a high prevalence of back pain (lumbar spine) and neck pain in the military population [1-4]. Low back pain has been attributed to mechanical loading (vibrations), constrained posture, or simultaneous exposures to both these factors in civilian and military populations [5-7]. Similar variables are attributed to neck pain. Painful conditions can have consequences in the work environment. They may lead to compromised mission efficiency, and or early termination from the original mission or occupation (e.g., truck driving population) [8]. A study on F-16 pilots found that flight duration and sitting posture were the main causes of back pain [9]. From a physiological perspective, muscles undergo morphological alterations including alignment or curvature to accommodate loading and or age-related changes in both neck and spine structures. From a bioengineering perspective, such changes can be accommodated in finite element models to determine the internal loads in the various joints of the spine.

Supine magnetic resonance imaging (MRI) is routinely performed for diagnostic purposes; however, they are not effective to quantify the potential geometrical changes in the spine musculature for the in vivo situation as the axial loading is not included in this posture [10]. For example, in the upright sitting posture, increased extension of the upper lumbar spine is not captured in the supine imaging mode [11]. There is a lack of human morphological studies for spinal musculature in the upright position as it is not the most common mode for patient screening. The present study was conducted determine the changes the lumbar musculature in the upright position for females with the following two purposes. The first purpose was to obtain the morphology of lumbar muscles in the upright position, and the second purpose was to develop cross-sectional area scaling factors from the supine to upright posture.

METHODS

Ten healthy female civilian volunteers participated in the study according to the approved protocols from the Institutional Review Board and sponsor. The inclusion criteria for the subject selection were: Females under the age of 40 years, asymptomatic individuals, no history of low back pain or injuries or congenital spinal abnormalities or spinal surgeries. The demographics of the volunteers were age 31±4.8 years, stature 163.6±7.1 cm, and BMI 25.6±4.2 kg/m^2.

An upright MRI scanner (Fonar Corporation, Melville, NY, USA) was used to image the volunteers in a seated posture. A custom seat was used. Image data were stored in Digital Imaging and Communication in Medicine (DICOM) format for analysis. All scans were obtained in the neutral position defined as the horizontal Frankfort plane with volunteer facing forward. T1 and T2 weighted MRIs were used in the analysis. The morphology of the psoas, multifidus and erector spinae muscles were measured using a commercial software (OSIRIX, Bernex, Switzerland). The cross-sectional area of each muscle was measured at the cranial surface of each vertebra from L1 to L5 levels by a practicing and board-certified neurosurgeon and a trained biomedical engineer. The reliability of the observations by the observers were measured using inter-class correlation coefficient (3,1), and coefficients of < 0.40 were categorized as poor, 0.40 to 0.60, as fair, 0.60 to 0.75 as good, and >0.75 as excellent [12].

A systematic review was performed to obtain the muscle cross-sectional areas of asymptomatic and symptomatic subjects in supine and upright positions. Literature data were normalized to the upright position to

compare the differences in morphology. The weighted average technique was used to obtain the aggregated mean effect size for muscle morphology of asymptomatic and symptomatic subjects [13]. The effect size was calculated by dividing the mean by standard deviation. The mean of the effect size from an individual study was used to obtain the aggregated effect size in the present analysis.

RESULTS

The muscle cross-sectional areas were measured from the MRI images (Figure 1). The psoas muscle and multifidus muscles cross-sectional areas increased from the cephalad to caudal levels. The erector spinae cross-sectional area was the greatest in the middle region and reduced towards both cephalad and caudal ends. The range for the psoas muscles cross-sectional was from 1.9 cm^2 to 12.1 cm^2. For the erector spinae, it ranged from 8.8 cm^2 to 13.9 cm^2, and for the multifidus it ranged from 1.8 to 5.7 cm^2. (Table 1).

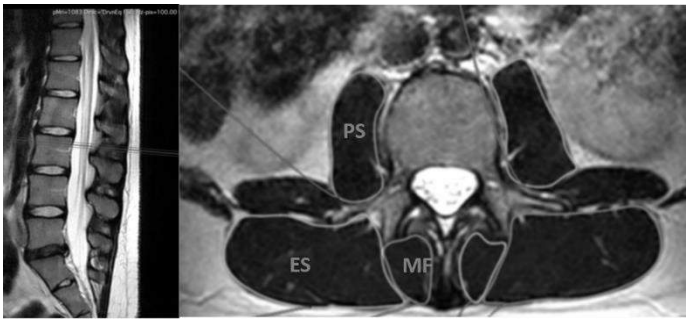

Figure 1: Lumbar muscle cross-sectional area measured at the L3 level. The areas of psoas (PS), erector spinae (ES) and multifidus (MF) are marked in the MRI image.

Table 1: Area (cm^2) data

Level	Psoas		Erector spinae		Multifidus	
	Mean	SD	Mean	SD	Mean	SD
L1	1.9	1.1	8.8	3.4	1.8	0.3
L2	4.3	1.9	12.9	2.6	2.4	0.5
L3	7.2	2.0	13.9	2.2	3.1	0.6
L4	11.1	2.3	13.0	2.4	4.2	0.9
L5	12.1	2.5	11.4	2.9	5.7	1.4

The inter-class correlation analysis showed that all coefficients in excellent category except for the multifidus muscles (inter-class: good at L2 and L3, intra class: L1 and L5 good and fair at L3). Female volunteer psoas muscle cross-sectional areas at the L3-L5 levels ranged from 12.08 to 11.9 cm^2, and the cross-sectional areas of the combined multifidus and erector spinae ranged from 19.5 to 20.7 cm^2 [14]. The scaling factor from the supine to upright data was obtained as the ratio of upright to the supine cross-sectional areas at each level. The scaling factors for the psoas muscles were: L3-L4: 1.34, L4-L5: 1.10, and L5-S1:0.93 and multifidus-erector spinae muscles were: L3-L4: 0.94, L4-L5: 0.88, and L5-S1:0.87. These scaling factors were used to convert the literature data of muscle cross-sectional areas in the supine to upright position. Similar muscle cross-section areas were obtained from other studies [15], [14], [16]. The effect size of the psoas muscle cross-sectional area for the asymptomatic subjects at L3 and L4 was 5.05 and 5.13, whereas for symptomatic back pain patients, they were 3.58 and 3.97. There was a 25% reduction at the L3 level, and 24% reduction at L4 level.

DISCUSSION

The upright muscle cross-sectional areas from the current study are comparable with those in the literature [14]. The scaling factors showed an increase in cross-sectional area for flexors (psoas muscle, except at L5-S1), and a decrease in the cross-sectional area for the extensors, i.e., combined multifidus and erector spinae muscles. This can be attributed to the shortening of the psoas muscles with flexion in the sitting posture. Lengthening may occur for the extensor muscles in the siting posture. The scaled literature data showed a decrease in psoas muscle cross-sectional area in patients with low back pain. Additional data such as muscle centroid location (radius and angle) are needed to better quantify the muscle geometry due to posture and pain. As muscles locate closer to the spine in back pain patients, muscle radii and angle decreases. These changes alter the internal load paths and load (re)distributions within the osteoligamentous lumbar column. It should be possible to determine segmental loads by inputting the data from present study into isolated thoracolumbar column or total human body models [17]. The present results may have application in biomedical, automotive, and military scenarios. The limitation of the current study is the small sample size although the comparison of effect size with similar studies in literature shows comparable results. Additional studies are needed to determine these parameters for the male spine.

INTRODUCTION

Ice hockey is an increasingly popular sport, with nearly 1 million registered athletes under the age of 20 worldwide [1]. Boys' and men's hockey is considered a collision sport, as athletes use body checking (intentionally colliding with an opponent) to control the flow of gameplay. Ice hockey has a high rate of concussions. Additionally, athletes are frequently exposed to subconcussive impacts which do result in overt signs and symptoms of concussion, but are of rising concern due to their association with neurocognitive and microstructural brain changes [2-4]. Prior research has demonstrated that apparent player anticipation of contact affects head kinematics, while player position does not [5,6]. However, positioning in hockey is dynamic during play, as such, zone location on the ice during an impact may be an additional exposure measure of interest. Additionally, athlete awareness during impacts does not differentiate between different roles athletes may play during a checking scenario and their impact on head kinematics. As greater understanding of sport-specific determinants of head impact exposure is necessary to inform safety measures in the sport, the objective of this study was to evaluate the effect of ice zone and athlete intent on peak head kinematics in youth boys' ice hockey.

METHODS

This study enrolled male athletes (n=18, ages 12-14) participating in a local 14U hockey team over two seasons of play. Athletes were fit with a custom instrumented mouthpiece to wear during all games and practices. Mouthpieces featured a tri-axial accelerometer and gyroscope embedded within a rigid retainer material bonded to a soft elastomer overlay and have been previously validated for sport-related impacts [7,8].

On-ice impact data were collected during 127 sessions. Data acquisition was triggered when the linear acceleration exceeded 5 g for at least 3 ms; when triggered, mouthpieces collected 60 ms of linear acceleration and rotational velocity data. Kinematic data from the mouthpiece were paired with time-synchronized video of each corresponding session to identify characteristics of contact scenarios experienced on-ice using a custom MATLAB graphical user interface (MathWorks, Natick, MA).

Contact scenarios were coded by type, including board checks, mid-ice collisions, falls, fights, unintentional collisions with the boards, and other head impacts. For this study, board checks and mid-ice collisions (i.e., body checks) were further categorized by ice zone (location on the ice the contact occurred): offensive, neutral, and defensive zones on the ice. Intent of the instrumented athlete (i.e., athlete intent) was coded as target (i.e., the instrumented athlete is intentionally contacted by an opponent), initiator (i.e., the instrumented athlete intentionally contacts the opponent), and incidental contact (the instrumented athlete and opponent collide unintentionally) based on criteria in table 1.

Table 1: Criteria to evaluate athlete intent during body checking.

1.	Does instrumented athlete approach opponent?
2.	Does the instrumented athlete keep knees bent?
3.	Does the instrumented athlete lead into the collision with their shoulders?
4.	Does the instrumented athlete keep their head up?
5.	Does the instrumented athlete have control of the puck?
6.	Is the instrumented athlete pinned between the boards and their opponent during a board check?

Post-processing of the mouthpiece data follows the methodology detailed by Rich et al. (2019) [8]. Following data transformation, resultant time histories and summary statistics associated with peak

resultant kinematics were calculated and compared by ice zone and athlete intent.

RESULTS

A total of 892 visually verified contact scenarios were recorded by the mouthpiece; of which, 235 were board checks and 350 were mid-ice collisions, resulting in 585 body checks for the present analysis. Most body checks occurred in games (n=533, 91%) compared to practices (n=52, 8.9%). The median (95th percentile) peak linear acceleration, rotational velocity, and rotational acceleration for all body checking impacts was 7.30 (27.8) g, 8.62 (19.2) rad/s, and 610 (2147) rad/s^2 respectively.

Among the body checks, 213 (36.4%) occurred in the offensive zone, 220 (37.6%) in the defensive zone, and 103 (17.6%) in the neutral zone; 49 (8.3%) impacts were not coded for zone, as they occurred during practice drills in which zone type could not be defined. Additionally, 197 (33.6%) body checks involved the instrumented athlete as the initiator, 350 (59.8%) involved the instrumented athlete as the target, and 38 (6.5%) were deemed incidental contact. There was little variation in medial and 95th percentile peak kinematics between ice zones; however, intentional body checks (initiator and target type contacts) had greater peak kinematics than incidental contact, with the exception of 95th percentile accelerations.

Table 2: Median (95th percentile) peak head kinematics by ice zone and athlete intent.

		N	*Linear Accel.(g)*	*Rotational Vel. (rad/s)*	*Rotational Accel.(rad/s^2)*
Ice Zone	Offensive	213	7.26 (28.57)	8.77 (18.95)	616 (2585)
	Neutral	103	6.91 (23.15)	8.43 (22.76)	585 (1980)
	Defensive	220	7.68 (32.96)	8.93 (19.50)	629 (2337)
Athlete Intent	Initiator	197	7.31 (27.28)	8.33 (17.67)	597 (2092)
	Target	350	7.40 (27.93)	9.08 (19.89)	635 (2404)
	Incidental	38	5.58 (38.19)	4.61 (12.44)	419 (3245)

DISCUSSION

This study evaluated head kinematics during body checking by two novel determinants of exposure: ice zone and athlete intent. We found that athletes experienced more impacts in defensive and offensive zones compared to the neutral zone, and that intentional contact types (target, initiator) had greater median and 95th percentile peak kinematics than incidental contact, with the exception of 95th percentile accelerations.

Previous studies revealed no significant differences in kinematics experienced by player position [6]; positioning is relatively fluid in ice hockey compared to sports such as football, and with the exception of goaltenders, athletes will spend time in each of the three ice zones. This study found that there was little variation in median and 95th percentile peak head kinematics experienced across ice zones. However, we observed that among mouthpiece-recorded impacts, impacts occurred in the offensive and defensive zones 2.06 to 2.13 times as in the neutral zone. This is could be influenced by the relative size of the zone, as the offensive and defensive zones are larger compared to the neutral zone. Additionally, due to the competitive nature of the sport, more gameplay occurs in defensive and offensive zones, where athletes are likely to attempt to disrupt plays than in the neutral zone, where athletes primarily carry the puck to set up a play.

We observed that intentional body checks (target and initiator contact types) had higher median and 95th percentile peak kinematics than incidental contact, except for 95th percentile linear and rotational acceleration. Higher magnitude incidental contacts were observed to occur when athletes were unintentionally involved in an impact between other players, or when athletes appeared less aware of their surroundings on the ice (e.g., skating backwards or with their head down). This is consistent with findings from Mihalik et al., who reported athletes with poor anticipation of collisions experienced more severe impacts compared to well-anticipated collisions, particularly for impacts in the 50th-75th percentile severity range [5]. Among our sample, the instrument athlete was most often involved in contact in which they were the target during the impact. Among body checks resulting in a mouthpiece recording, the instrumented athlete was the target 1.77 times more often than the initiator. However, it is possible that not all contact scenarios experienced on-ice were recorded by the mouthpiece. For example, if an instrumented athlete delivered a check without contacting his head, the mouthpiece linear acceleration may not have crossed the 5 g threshold to trigger recording. Additional video review of all contact scenarios, not just mouthpiece-recorded events may provide insight on differences in intent and the frequencies at which different types of impacts occur.

This study was limited by several factors. Firstly, the sample size for this study was small, with 18 athletes over 2 seasons of play. Future studies within this population aim to include a larger sample size. Similarly, to judging athlete anticipation of an impact, objective characterization of athlete intent from video is challenging [5]. Other objective measurements of factors affecting head impact exposure, such as player speed and angle of approach should be explored to better understand how characteristics of contact influence head kinematics and head impact exposure in ice hockey [9].

The goal of this study was to compare head kinematics to ice zone and athlete intent. This adds to a limited, but growing body of knowledge on determinants of head impact exposure in the sport. Results of this study and of future studies of head impact exposure may be used to drive sport-specific interventions and regulations, reducing athlete head impact exposure and improving sport safety.

ACKNOWLEDGEMENTS

The authors extend their gratitude to the Childress Institute for Pediatric Trauma for funding this study and thank the Triad Alliance Hockey Association for participation in this study. Special thanks Konstantina Strates for her efforts in project management and study coordination, as well as Autumn Knight, Jordan Rahm, Nicole Rogers, and Richard Metzler Jr. for their assistance in data collection and video review. The mouthpiece technology presented herein is patent pending.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has quickly evolved into the preferred mode of aortic valve replacement in patients diagnosed with aortic valve stenosis. However, as TAVR is still a developing method of treatment, there are some complications associated with it that could affect success of the valve replacement namely coronary obstruction, root rupture, paravalvular leak etc. emphasizing the need for procedural planning. Many computational studies on the design, implantation, and post-procedural complications have been published since the beginning of TAVR [1-3]. Recently, patients who received TAVR have presented to the hospital with degenerated prostheses needing another intervention to help with the elevated transvalvular gradients. In such cases, a second TAV is deployed inside of the degenerated transcatheter valve, called redo-TAVR, to treat the aortic stenosis. Computational modeling and 3-dimensional (3D) printing allows us to predict and plan for post-TAVR complications including root rupture, coronary obstruction, paravalvular leak etc. The objective of this study is to develop a computational framework to model redo-TAVR accurately and predict the risk of coronary obstruction to help with optimization of placement of TAV in redo-TAVR for best outcomes.

METHODS

Pre-procedural computed tomography (CT) images of a 63-year-old patient with a pre-existing Evolut 26mm TAV (Medtronic, Dublin, Ireland) were obtained through an IRB approved protocol. Aortic root, TAV stent and calcification of the patient were segmented from CT images and lofted using Mimics 22.0 (Materialise, Leuven, Belgium). Segmenting the Evolut stent geometry and accurately reconstructing the valve geometry without artifacts from pre-procedural cardiac CT scans has always been a challenge due to artifacts caused by the metal stents and the leaflets' poor visibly [4,5]. As illustrated in Figure 1, we have developed a registration-based valve geometry reconstruction method to address this issue. First, a high-quality valve geometry file (29mm Evolut R) was obtained from high-resolution micro CT scans (Figure 1A). Contrast agent was sprayed onto the leaflets to increase their signal strength during scanning. The stent segmented from the patient's pre-procedural CT images (Figure 1B) showed a significant increase in stent thickness due to blooming artifacts. The deviation from the original stent geometry would cause problems in evaluating the effectiveness of the treatment. The registration started with manually picking several corresponding points between the two geometries. After an initial pass of 3D rigid transformation, a spline-based non-rigid transform [6] accurately aligned the high-quality stent to match the patient's CT scan results. As shown in Figure 1C, good agreement between the two geometries was achieved. The last step was to apply the same transformations to the leaflets and combine them with the deformed stent to generate the final valve model for 3D printing (Figure 1D).

Aorta vessel anatomy with an embedded stent structure was 3D printed using a Stratasys Digital Anatomy (DAP) J750 polyjet printer (https://www.stratasys.com/3d-printers/j750-digital-anatomy). The .STL file created from the patient CT scan was loaded into GrabCAD (https://grabcad.com/print) and assigned specific anatomical presets to appropriate structures within the assembly. The aortic wall was assigned the “blood vessel wall” preset with a compliance preset of “moderately compliant”, the stent was assigned a rigid Vero material and the leaflets were assigned the “valve leaflet” preset with a stiffness preset of “stiffened.” The J750 Polyjet printer jets small liquid resin droplets that are cured by a UV lamp layer by layer. It is able to achieve a variety of textures, colors, and compliances due to a six-material capacity allowing for multi-material prototypes. After printing is completed, the prototypes were Post processed using the Forti by Post Process which

includes a support-removal submersion bath that dissolves support material.

The 3D geometry of the aortic wall and TAV stent and leaflets were then discretized in ABAQUS (Dassault Systèmes, Johnston, RI, US) using explicit 4-node linear tetrahedron elements. Neo-Hookean hyper-elastic constitutive equation was used to represent the aortic material properties with shear modulus, μ=1 MPa, bulk modulus, κ=10 MPa, and density, ρ=1000 kg/m^3 [7]. Stent model of a SAPIEN 3 23mm valve was employed after meshing with quadratic tetrahedral elements in ABAQUS. The SAPIEN stent was modeled using an elasto-plastic model with Young's modulus, E=193 GPa, σ_y (0.2%) =340 MPa, σ_u (48%) =670 MPa, Poisson's ratio, ν = 0.29 and, density, ρ =7760 kg/m^3[8]. The balloon was modeled with shell elements as a linear elastic material with E=600 MPa, ν =0.45 and ρ=1100 kg/m^3 [8]. The crimped balloon and stent were positioned coaxially inside the aortic root (Z-axis). Fluid-cavity based approach was employed to inflate the balloon and deploy the stent. The ends of the aortic root were constrained in translational and rotational degrees of freedom about Z-axis. Scaled penalty contact was employed for the stent-balloon and stent-AV interactions. Results were visualized and analyzed in ABAQUS.

RESULTS

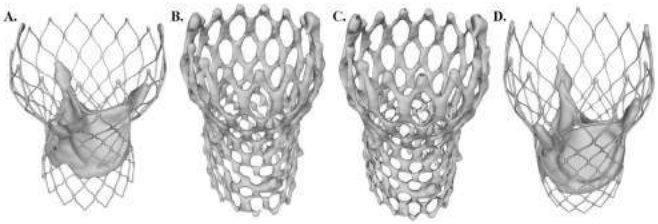

Figure 1. (A) Stent and leaflet geometry reconstructed from high-resolution micro CT scans. (B) Manually segmented stent from the patient's pre-procedural cardiac CT scan. (C) Comparison between the registered high-resolution stent (shown in a darker color) and the patient's stent. (D) The final valve geometry with deformed leaflets

As seen in Fig. 1, the use of image registration algorithm resulted in a precise transcatheter valve geometry free of artifacts and captured the deformed state of the valve inside the patient anatomy accurately. The segmented aortic root geometry was combined with the TAV model to 3-D print the geometry of the patient (Fig. 2) for subsequent inspection by clinicians to decide the optimal deployment position that gave minimal risk of coronary obstruction. The deployment in the nominal showed very high risk of coronary occlusion whereas deployment of the SAPIEN stent below the leaflets of the Evolut resulted in no obstruction (Fig. 4). Comparison of the simulation result with post-procedural CT

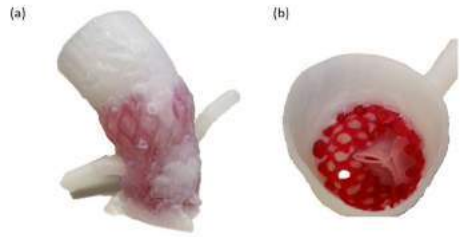

Figure 2. Pictures of the 3D-printed geometry provided to clinicians for decision making in (a) lateral and (b) axial views.

imaging showed very good agreement (Fig. 4).

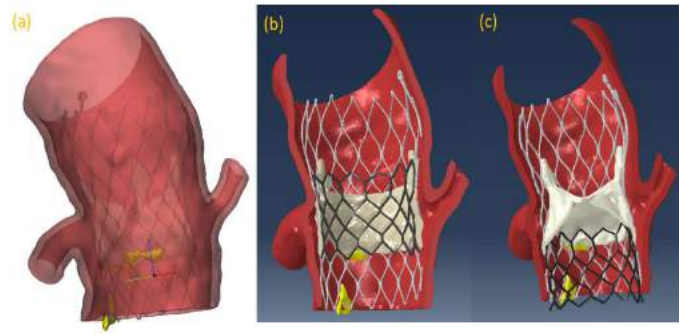

Figure 3. (a) Geometry of the aortic root, TAV and calcification after segmentation and image registration (b) Result of simulation of SAPIEN 23mm valve deployment in nominal position and (c) below the leaflets of the Evolut THV

DISCUSSION

In this case study, clinicians at Piedmont Hospital were provided with 3-D printed models of the patient anatomy to plan the redo-TAVR procedure. In conjunction, simulations were run with two deployment configurations to assess obstruction risk. The patient underwent TAVR similar to Fig. 3(b). Redo-TAVR is expected to increase in volume as TAVs currently being implanted in patients have limited durability. Computational modeling and 3-D printing can play a major role in improving the understanding of redo TAVR and ensuring successful outcomes. Further computational fluid dynamic studies and experiments with 3-D printed geometry are planned for this case.

INTRODUCTION

Intervertebral disc degeneration (DD), a debilitating condition that is a leading cause of low back and neck pain, is estimated to affect 403 million individuals worldwide and costs at least $100 billion annually in healthcare[1–3]. Common occupations that are associated with higher prevalence of DD include large vehicle operators, flying aircraft personnel, and those working on vibrating surfaces[4]. Pro-inflammatory cytokines, such as TNFα and nitric oxide (NO), have been shown to be catabolic mediators of DD, promoting matrix degradation and fibrosis [6–10]. It is well established that loading profiles regulate the biological responses of IVD cells in a magnitude and frequency dependent manner. While prolonged static loading or dynamic loading above 0.5 Hz promote matrix degradation, changes in inflammatory cytokine profiles in response to loading are less well understood[11–13]. The goal of this study was to characterize the inflammatory signaling changes in response to static and dynamic loading. Recent studies of human DD suggest that the innate immune receptor toll-like receptor-4 (TLR4) regulates inflammatory signaling in the IVD[10]. Therefore, this study also investigated the contributions of TLR4 to inflammatory signaling induced by mechanical loading. We hypothesize that inflammatory responses of the IVD will depend on loading frequency and amplitude, and that blocking TLR4 signaling reduces pro-inflammatory signaling in loaded discs.

METHODS

Caudal (Co) motion segments from 14 mature male Sprague-Dawley rats ranging from 300-500g were dissected from the Co9 to Co13 vertebral levels. Samples were loaded for 3 hours using a custom-made displacement control mechanical loader to mimic static, low frequency dynamic, high frequency dynamic, and physiologic loading conditions. A static tare displacement of 1.75 mm (~20% of segment height) was applied to the static, low dynamic and high dynamic groups, followed by an additional 0.35 mm displacement at 0.5 Hz for low dynamic, or a 0.7 mm displacement at 3 Hz for high dynamic, or a 0.1 mm displacement at 0.125 Hz for the physiologic loading groups. Unloaded motion segments were also cultured as a control group. Change in IVD height was measured from pre- to post loading using fluoroscopy images, serving as an estimate of effective compressive strain magnitude in each loading group. Three discs were loaded at a time in the bioreactor with ~25 mL of chemically modified phenol-free media. At the end of 3 hours of loading, the culture media was collected, and volume was recorded. Motion segments were then cultured in fresh phenol-free chemically defined media for 9 hours to allow a period for biological responses to loading to play out (**Figure 1**). In some groups, TAK-242, a drug known to block TLR4 signaling, was added to the organ culture model at a dose of 1.0 µM to examine the potential downstream effects during the 3-hour loading period as well as 9 hours post-loading. Outcome measures: Media was analyzed for NO release. Motion segments were snap-frozen and prepared for qPCR. Gene expression of TLR4 and TNFα in motion segments post loading was

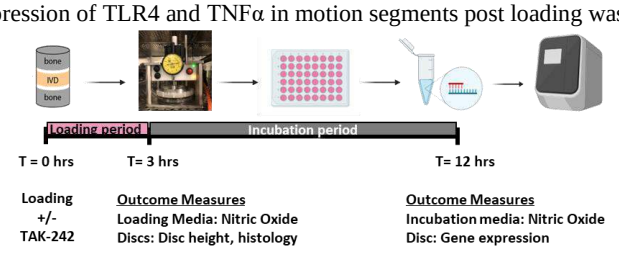

Figure 1: Experimental Setup

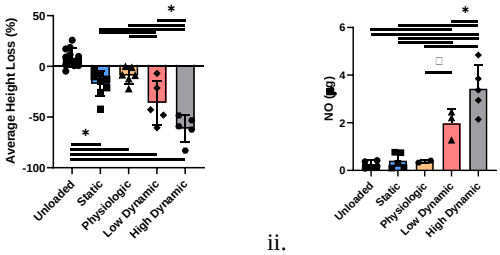
also measured, with GAPDH as the housekeeping gene. Gene expression results were normalized to the unloaded controls without the

TAK-242 drug using the $2^{-\Delta\Delta Ct}$ method. Statistics: One-way ANOVA followed by Holm-Sidak post hoc tests were conducted for NO release into loading media. Individual student t-tests were conducted to compare loading groups ± TAK-242. Kruskal-Wallis and Mann-Whitney tests were used for non-normal data distributions. Statistical significance was set at $p < 0.05$.

RESULTS

Loading profile had a significant effect on average disc height change (unloaded: 8.5±9.3%, static: -17.3±12.3%, physiologic: -8.9± 8.0%, low dynamic: -36.0±21.5%, and high dynamic: -61.3±13.3%). Static, physiologic, low dynamic, and high dynamic loading profiles were all significantly different compared to unloaded discs resulting in greater height changes ($p<0.032$ for all comparisons). Static, physiologic, and low dynamic loading profiles were also statistically significant compared to the high dynamic loading profile ($p\leq0.014$). Disc height change in static loading was also significantly lower than low dynamic loading (p=0.032) but not physiologic loading (p=0.23). In addition, low dynamic loading was statistically significant compared to physiologic loading ($p=6.8\times10^{-3}$) (**Figure 2i**). Nitric oxide (NO) release into the loading media of low dynamic (p=0.019) and high dynamic ($p<1.0\times10^{-4}$) loading was statistically greater compared to media of unloaded discs. NO release in loading media of unloaded, static (p=0.98) and physiologic loading (p=0.98) groups were comparable. NO in low (p=0.022) and high dynamic ($p<1.0\times10^{-4}$) loading groups was significantly greater than static, physiologic, and unloaded groups. NO in high dynamic loading was significantly greater compared to low dynamic loading (p=0.030). NO release of low dynamic loading was also trending upwards compared to the media of physiologic loading (p=0.052) (**Figure 2ii**).



i. ii.

Figure 2: i. Average height loss experienced under each loading profile ii. Nitric oxide release into loading media

There was no difference in NO release from individual discs during the 9 hrs post loading incubation period (p=0.67). When incubated for 9 hrs with TAK-242, the discs had a significant decrease in NO release into the media (**Figure 3**).

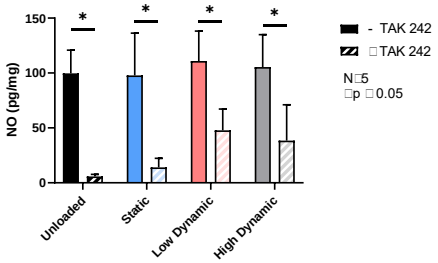


Figure 3: Nitric oxide release from individual motion segments 9 hours post loading ± TAK-242.

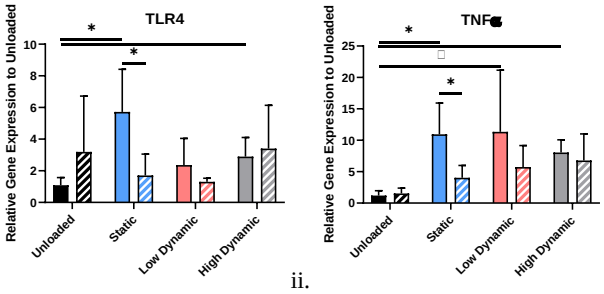
Among loading groups, TLR4 gene expression in the disc was significantly greater in static (p=0.012) and high dynamic conditions (p=0.028) compared to unloaded discs. Co-culture with TAK-242 significantly decreased the gene expression of TLR4 in static loading (p=0.018) but not high dynamic loading groups (**Figure 4i**). In addition, when examining the expression of the proinflammatory cytokine TNFα, expression was significantly higher in static ($p=2.6\times10^{-3}$) and high dynamic ($p<1.0\times10^{-4}$) discs compared to unloaded discs. TNFα expression in low dynamic discs exhibited a moderate increase compared to unloaded discs (p=0.051). Co-culture with TAK-242 mitigated the expression of TNFα in the static (p=0.020) but not high dynamic loading group (**Figure 4ii**).



i. ii.

Figure 4: i. TLR4 and ii. TNFα gene expression of loaded motion segments cultured for 9 hours in ± TAK-242 media.

DISCUSSION

The loading organ culture system used in this study produced varying degrees of disc height loss and inflammatory responses that depended on loading magnitude and frequency. Magnitudes of disc height loss in low and high dynamic loading were clearly hyper physiologic, and NO release was also elevated under these conditions. Expression of TNFα was moderately elevated in low dynamic loading and significantly elevated in high dynamic loading. In addition, only the high dynamic group exhibited a significant increase in TLR4 expression. On the other hand, static loading, which had a lower disc height change magnitude, exhibited upregulation of both TNFα and TLR4, but not NO release. Addition of the TLR4 inhibitor, TAK-242, reduced TLR4 and TNFα expression only under static loading. These results suggest that dynamic and injurious static loading both promote pro-inflammatory signaling though through distinct pathways and temporal profiles. Dynamic loading led to more pro-inflammatory activation by NO signaling during loading, whereas static loading led to pro-inflammatory activation of TNFα. TLR4 appears to play a greater role on static loading response, compared to dynamic loading, as indicated by the greater protective effects of the TAK-242 drug on static loaded groups. Future studies will evaluate the temporal response of inflammation and therapeutic strategies to mitigate inflammatory responses to loading via cell based anti-inflammatory strategies.

MODELLING COLLOGEN FIBER RECRUITMENT IN AORTIC TISSUE USING KINEMATIC AVERAGE

Xuehuan He, Jia Lu

Department of Mechanical Engineering
The University of Iowa
Iowa City, Iowa, United States

INTRODUCTION

The gradual recruitment of wavy collagen fibers is an important feature of the aortic tissue. In this work, we introduce a framework for incorporating the fiber recruitment in hyperelastic modeling of aortic tissues by means of kinematic average approach. An effective stretch, which is a response variable representing the true stretch at the tissue-scale, is introduced. The waviness distribution of collagen fibers is quantified using a beta distribution function [1], which enables the effective stretch to be expressed in a closed form. Incorporating fiber recruitment amounts to replacing the strain values in a structurally motivated strain energy function with modified invariants. This construction is investigated in conjunction with the Holzapfel-Gasser-Ogden (HGO) strain energy function (SEF) and its variants [2].
In this talk, we present the theoretical framework of the proposed method, and investigate the predictive capability of the constitutive construction using experimental data.

METHODS

Consider a single fiber whose curved length is L_f and the end-to-end length is L, the straightness parameter p (defined as the ratio of L to L_f) is assumed to distribute in the tissue level following a beta distribution as

$$\psi(p;\alpha,\beta) = \frac{p^{\alpha-1}(1-p)^{\beta-1}}{B(\alpha,\beta)}, \quad p \in [0,1], \tag{1}$$

where (α,β) are shape parameters, both positive and $B(\alpha,\beta)$ is the beta function. For a single wavy fiber with straightness p, the recruitment stretch spent to uncrimp the fiber is $\frac{L_f}{L} = \frac{1}{p}$. The following piecewise response holds for the true stretch λ_t (a portion of stretch responsible for stress generation)

$$\begin{aligned} \lambda_t &= \lambda \cdot p; \qquad if\ \lambda > p^{-1}\left(p \geq \frac{1}{\lambda}\right) \\ \lambda_t &= 1; \qquad if\ \lambda \leq p^{-1}\left(p < \frac{1}{\lambda}\right) \end{aligned} \tag{3}$$

Consider now an ensemble of fibers or fiber bundles on the tissue-level, taking into account the straightness distribution, the effective stretch $\bar{\lambda}$ is

$$\bar{\lambda} = \int_0^{\frac{1}{\lambda}} \psi(p)\ dp + \int_{\frac{1}{\lambda}}^1 \lambda p\, \psi(p)\, dp \tag{4}$$

Upon using the beta distribution $\psi(p,\alpha,\beta)$, the effective stretch reduces to a closed-form expression of λ as.

$$\bar{\lambda} = F(\lambda^{-1},\alpha,\beta) + \frac{\alpha}{\alpha+\beta}\lambda F(\lambda^{-1},\alpha+1,\beta,\text{upper}) \tag{5}$$

where $F(x;\alpha,\beta) = \frac{\int_0^x p^{\alpha-1}(1-p)^{\beta-1}\,dp}{B(\alpha,\beta)}$ is the cumulative distribution function and $F(x;\alpha,\beta,upper) = 1 - F(x;\alpha,\beta)$ is its tail.

The Gasser-Ogden-Holzapfel (GOH) model (Equation 6) has been broadly adopted to describe the vascular tissue response [3]. The first term accounts for the isotropic response of ground substance and the second term represents the contribution of the collagen fiber network.

$$W = \frac{\mu_1}{2}(\mathrm{I}_1 - 3) + \sum_{i=1}^{2}\frac{\mu_2}{4\gamma}\left(e^{\gamma(\mathrm{I}_{ki}-1)^2} - 1\right) \tag{6}$$

Without considering the recruitment, the 2nd Piola-Kirchhoff stress is

$$\begin{aligned} S = \mu_1(I - I_2^{-1}C^{-1}) + \\ \mu_2 e^{\gamma(I_{ki}-1)^2}(I_{ki}-1)(\kappa I + (1-2\kappa)\boldsymbol{M_i}\otimes\boldsymbol{M_i}) \end{aligned} \tag{7}$$

Here invariant I_{ki} is a weighted average of squared stretches in the *i-th* family considering the orientation density. $\boldsymbol{M_i}$ is the preferred direction of the *i-th* family. The parameter *ki* represents the dispersion. Considering fiber recruitment, we define

$$\bar{\mathrm{I}}_{ki} = \frac{1}{4\pi}\int_{S^2}\rho(\phi,\theta)\overline{\lambda^2}\ da \quad \text{with} \quad \frac{1}{4\pi}\int_{S^2}\rho(\phi,\theta)\ da = 1 \tag{8}$$

Where ρ is the orientation density function. The integral is approximated using the six-point Lebedev quadrature. To this end we choose a local basis $\{\boldsymbol{E}_I'\}_{I=1}^3$ (called the fiber basis hereafter) such that

$\boldsymbol{E_3'}$ aligns with the fiber direction $\boldsymbol{M}_i$ and other two basis vectors are in the transverse plane. The integration points are taken to be the vertices of the local basis vectors $\{\pm\boldsymbol{E_1'}, \pm\boldsymbol{E_2'}, \pm\boldsymbol{M}_i\}$. The weights are uniform and equal to $4\pi/6$. This gives

$$\bar{\mathrm{I}}_{\kappa i} = \frac{1}{3}\left(\rho(\boldsymbol{E_1'})\bar{\lambda^2}(\boldsymbol{E_1'}) + \rho(\boldsymbol{E_2'})\bar{\lambda^2}(\boldsymbol{E_2'}) + \rho(\boldsymbol{M}_i)\bar{\lambda^2}(\boldsymbol{M}_i)\right) \quad (9)$$

Under the same normalization scheme as shown in Equation 6. We have $\frac{1}{3}\left(\rho(\boldsymbol{E_1'}) + \rho(\boldsymbol{E_2'}) + \rho(\boldsymbol{M}_i)\right) = 1$. Let $\frac{\rho(\boldsymbol{E_1'})}{3} = \kappa$. We obtain

$$\bar{\mathrm{I}}_{\kappa i} = \kappa\left(\bar{\lambda^2}(\boldsymbol{E_1'}) + \bar{\lambda^2}(\boldsymbol{E_2'})\right) + (1-2\kappa)\bar{\lambda^2}(\boldsymbol{M}_i) \quad (10)$$

With the new invariant (Equation 9), the energy function becomes

$$W = \frac{\mu_1}{2}(I_1 - 3) + \sum_{i=1}^{2}\frac{\mu_2}{4\gamma}\left(e^{\gamma(\bar{\mathrm{I}}_{\kappa i}-1)^2} - 1\right) \quad (11)$$

The fiber stress $\boldsymbol{S_f} = 2\frac{dW_f}{d\,\boldsymbol{C}}$ is

$$\boldsymbol{S_f} = \sum_{i=1}^{2}\mu_2 e^{\gamma(\bar{\mathrm{I}}_{\kappa i}-1)^2}(\bar{\mathrm{I}}_{\kappa i} - 1) * \left(\kappa_i\left(\sum_{I=1}^{2}\frac{d\left(\bar{\lambda^2}(\boldsymbol{E_I'})\right)}{d\left(\lambda^2(\boldsymbol{E_I'})\right)}\boldsymbol{E_I'}\otimes\boldsymbol{E_I'}\right) + (1-2\kappa_i)\frac{d\bar{J_i}}{dJ_i}\boldsymbol{M_i}\otimes\boldsymbol{M_i}\right) \quad (12)$$

To investigate the descriptive capability of the proposed recruitment models, they are fitted to two groups of experimental data. The first group consists of 157 uniaxial stress-stretch data from human ascending thoracic aortic aneurysm (ATAA) tissues collected at Dr. Auricchio's laboratory [4]. We elect to describe the uniaxial response of ATAA tissue using a 1D HGO SEF, which is a special case of GOH model .

$$W = \frac{\mu_1}{2}\left(\lambda^2 + \frac{2}{\lambda} - 3\right) + \frac{\mu_2}{4\gamma}\left\{e^{\gamma(\lambda^2-1)^2} - 1\right) \quad (13)$$

$$\sigma = \mu_1(\lambda^2 - \lambda^{-1}) + \mu_2 e^{\gamma(\lambda^2-1)^2}(\lambda^4 - \lambda^2) \quad (14)$$

Considering the fiber recruitment, we replace λ the second term in SEF (Equation 13) with $\bar{\lambda}$ to arrive at

$$\sigma = \mu_1(\lambda^2 - \lambda^{-1}) + \mu_2 e^{\gamma(\bar{\lambda}^2-1)^2}\left(\bar{\lambda^3} - \bar{\lambda}\right)\lambda\bar{\lambda}'(\lambda) \quad (15)$$

The performance of 2D model with (Equation 12) and without fiber recruitment (Equation 7) are examined using bi-axial response data of ATAA tissues collected from bulge inflation test [5]. There are 2304 data points for each specimen.

Optimized material parameters were determined by minimizing the sum of square difference between the experimental stress values and the model predictions. For the recruitment model, the parameters include the elastic properties and the straightness parameters. The latter are absent in the original model. In our work, elastic parameters were constrained such that $(u_1, u_2, \gamma) > 0$ for 1D model and $(u_1, u_2, \gamma) > 0, 0 \le \theta \le \pi, 0 \le \kappa \le 0.5$ for 2D model. As for the straightness parameters (α, β), the density function is unbounded when p approaches 0 or 1 if α <1 or β <1. Therefore, the straightness parameters are constrained as α >1 and β >1.

RESULTS

Figure 1 illustrates the fitting result for the uniaxial response data. Figure 1 (left) presents the fitted curve with and without recruitment for one sample. It is a good representation of the majority of cases. The improvement is garnered in the toe region. This is the region where the graduate fiber recruitment takes place. The original model categorically over-predicts the stress, resulting a curve that lies above the experimental data points. The over-stress is rectified by using the effective stretch, with R^2 increasing from 0.932 to 0.99. The R^2 values of all 157 samples are compared in Figure 1 (right). The percentage of points (PP) which show improvement in the R^2 value reaches 99%. Clearly, the fitting quality are universally improved when the recruitment is considered.

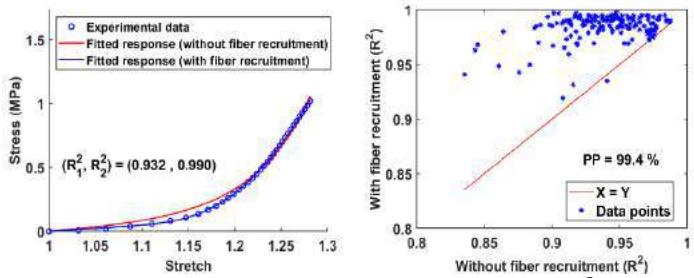

Figure 1: Fitted response curves (left). Comparison of R^2 values with and without fiber recruitment in all 157 samples (right). (R_1^2, R_2^2): R^2 values without and with considering the fiber recruitment, respectively.

Figure 2 depicts the pointwise fitting behavior with and without considering the fiber recruitment in specimens 1 and 2. Each subfigure represents a specimen. The mean R^2 values (R_2^2 with fiber recruitment , R_1^2: without) and the PP values are also presented. Overall the fitting quality are improved when taking into account the fiber recruitment, with PP values greater than 90% for both specimens.

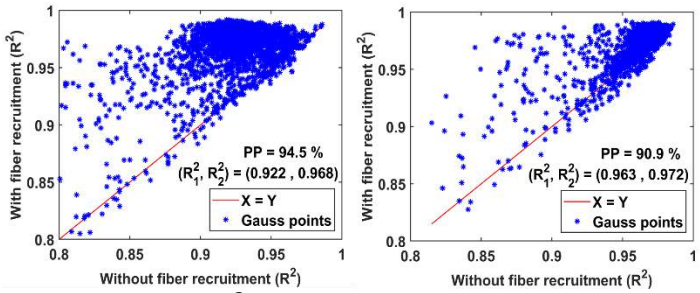

Figure 2: Pointwise R^2 values with and without considering the fiber recruitment. (R_1^2, R_2^2): R^2 values without and with considering the fiber recruitment, respectively.

DISCUSSION

In this study, we presented a framework for considering the graduate recruitment of collagen fibers in hypereslastic modeling of aortic tissues. We have examined the descriptive capability of this constitutive construction against experiments. Models incorporated the fiber recruitment significantly improve the fitting quality. Although not reported here, we also assessed the predictive capability using finite element simulation. The model incorporated fiber recruitment overwhelmingly outperformed the model without recruitment in reproducing the experimental results.

INTRODUCTION

The COVID-19 pandemic has created a great deal of fear and uncertainty around whether aerosols from singers and musical instruments can transmit the virus. The World Health Organization has recognized that SARS-COV-2 is transmissible through aerosols[1]. Additionally, outbreaks from singing have resulted in superspreader events leading to many infections and deaths[2]. Hence, aerosol generation in performance (playing brass and woodwind instruments, singing, and theatre speech delivery) should be quantified, monitored, and mitigated. Notable work in this area includes Becher et al.[3] who used the Background Oriented Schlieren (BOS) technique to determine the extent of jets generated while playing musical instruments and singing[4]. Abkarian and Stone made particle counts using visible light images and documented the stretching and breakup of saliva filaments during speech delivery[5].The present work incorporates imaging, aerosol measurements and CFD to address the following research questions: (i) What is the aerosol generation rate? (ii) How does air flow from the performer's mouth/instrument and how does it disseminate into the environment? and (iii) What control methods can be employed to mitigate risk?

METHODS

This study consisted of 3 methods: (i) flow visualization and characterization, (ii) aerosol measurements, and (iii) computational fluid dynamics modeling. We first characterized the flow visually using schlieren imaging (Figure 1) and laser sheet imaging (Figure 2).

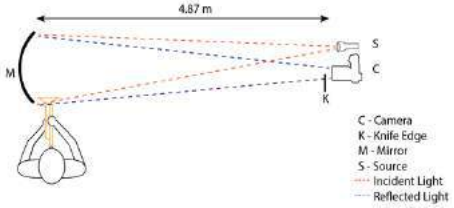

Figure 1: The Schlieren Method

The mentioned techniques provided a general sense of the extent and velocities of the plumes/ jets of air emanating from the instrument/performer, and provided sampling location data for aerosol measurements. Hot wire anemometry was also used to measure maximum velocities in the near field. Aerosol and CO_2 measurements were then made using a LICOR 7000 and UHSAS Aerosol Spectrometer to measure aerosols with sizes ranging from 60-1000 nm. The chosen sampling time was 1 second.

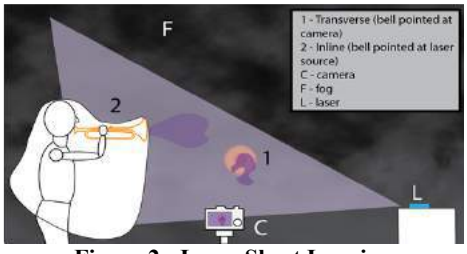

Figure 2: Laser Sheet Imaging

An Aerodynamic Particle Sizer (APS) was also used to measure aerosols with sizes ranging from 0.5-20 um, with a sampling time of 50 seconds and 10 seconds between each sample. The study included singers, actors and a variety of woodwind and brass instrument performances, with and without surgical masks. Results from imaging and aerosol measurements are presented here.

RESULTS

Bell velocity data obtained from schlieren, laser sheet imaging, and anemometry are provided below (see Figure 3).

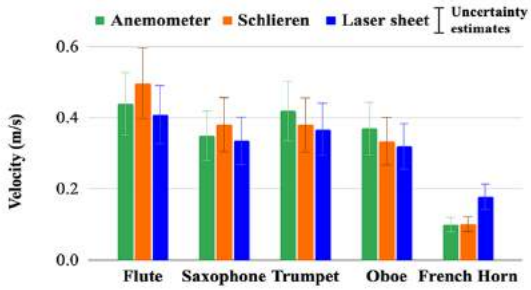

Figure 3: Maximum bell velocities

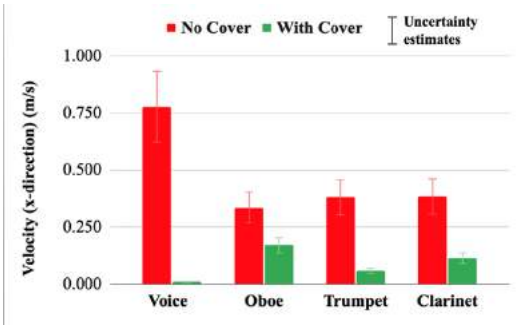

Figure 4: Horizontal velocity comparison with and without cover

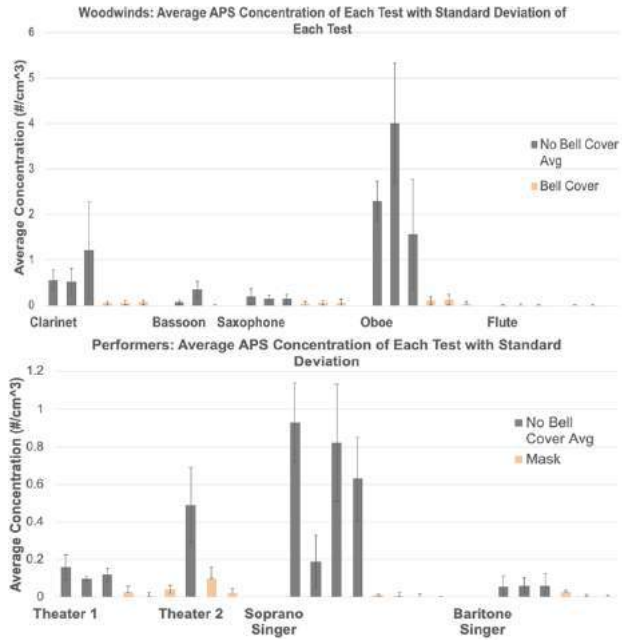

Figure 5: APS total aerosol concentration for woodwinds (above) and voice (below)

Velocity measurements were also made with and without bell covers/ masks (Figure 4). Uncertainty was estimated at 20%, or 0.10 m/s. For both instrument and voice performers, aerosol concentrations near the bell of the instrument or in front of the mouth were lower when a mitigation strategy was used compared to when it was not used. Surgical masks were used as bell covers and masks for voice performers with the exception of the flute, which instead utilized a piece of high density woven cotton fabric. The error bars in figure 5 show the standard deviation of each test.

DISCUSSION

Preliminary flow visualization results suggest that musicians and performers produce prominent jets, particularly when specific notes throughout the range are played. The jets are complex, unsteady, and highly three-dimensional. For example, the clarinet produces higher velocity jets from its bell compared to most notes in the lower register, which have higher velocities out of the keyholes. The direction of jets produced by a singer varies dramatically depending on the consonant or vowel sounds.

The preliminary velocity measurements clearly indicate that covers are effective in significantly diffusing the jet velocities, by more than half in most cases (Figure 4). Leakage flows (for singing, theatre performances, and from keyholes) can still occur when covers are used, depending on the fit. The anemometry data agrees with the flow visualization analyses.

These aerosol results show that playing musical instruments generate micron-sized aerosols similar in number concentration and size to singing, over 100x increase in aerosols compared to breathing (from previous studies[6]). Aerosols measured from keyholes were minimal, and hence negligible. Wearing masks when singing reduces aerosol emissions. Although aerosol emissions from these activities are generally low and must be measured in a controlled environment, disease transmission may occur at low concentrations as well especially if allowed to build up in low ventilation settings.

Tests to determine volume flow rates for different instruments, and estimation of generation rates for CFD modeling applications are currently underway. Our conclusions to date include: (i) activities including singing and playing brass and woodwinds produce 100x more aerosols compared to a quiet, inactive human, (ii) proper masking with quality materials and minimized leaks reduce these higher emissions to normal conversation levels. Our recommendations to minimize the risk of SARS-COV-2 transmission are to play instruments/perform outside or in well-ventilated spaces, use HEPA filter air cleaners, reduce occupancy, limit rehearsal time to 30 minutes, socially distance, maintain hand hygiene, and use masks and bell covers.

INTRODUCTION

Aortic valve stenosis (AS) is caused by valve degeneration and affects 3% of all adults over 65 years of age. Based on the severity, the aortic valve is replaced by an artificial bioprosthetic valve device. Currently, transcatheter based approaches to valve replacement are being widely adopted, especially in patients with comorbidities. However, there are many risks associated with transcatheter aortic valve replacement (TAVR), such as coronary obstruction, that are associated with high mortality rates. Bioprosthetic valve degeneration is a commonly known issue with aortic valve replacement, with patients receiving a TAV inside a degenerated surgical aortic valve, known as valve-in-valve (ViV) TAVR. Occurrence of coronary obstruction in ViV TAVR is specifically of concern as the coronary arteries are positioned low with respect to the bioprosthetic aortic valve (BAV) whose leaflets possess a high risk of obstruction after TAVR. Bioprosthetic Aortic Scallop Intentional Laceration to prevent Iatrogenic Coronary Artery obstruction (BASILICA) is a technique that is adopted in ViV TAVR cases to mitigate the risk of coronary obstruction. Due to the limitations of current imaging techniques in visualizing the risk of complications post-TAVR, computational patient specific modeling has proven to be extremely valuable in the procedural planning for TAVR [1-3]. The objective of this study is to utilize patient specific computational modeling of TAVR to simulate the risk of coronary obstruction in ViV TAVR with and without BASILICA and assess the obstruction risk with change in laceration location to aid in pre-procedural planning.

METHODS

Pre-procedural computed tomography (CT) images of a 78-year-old female patient who had a degenerated surgical bioprosthetic aortic valve and diagnosed with aortic stenosis were obtained through an IRB approved protocol. After discussion with the clinical team at Piedmont Atlanta Hospital, the patient was modeled for valve-in-valve TAVR for planning the procedure. Aortic root, bioprosthetic valve stent and leaflets of the patient were segmented from CT images using Mimics 22.0 (Materialise, Leuven, Belgium) (Fig. 1 a-b). Lacerations were made in the leaflet geometry (Fig. 1c-d) in both aligned and misaligned configurations with respect to the coronaries to simulate the effectiveness of the BASILICA procedure. The 3D geometry of the aortic wall and BAV stent and leaflets were then discretized in ABAQUS (Dassault Systèmes, Johnston, RI, US) using explicit 4-node linear tetrahedron elements. Neo-Hookean hyper-elastic constitutive equation was used to represent the aortic material properties with shear modulus, μ=1 MPa, bulk modulus, κ=10 MPa, and density, ρ=1000 kg/m^3 [4]. Stent model of SAPIEN 3 23mm was employed after meshing with quadratic tetrahedral elements in ABAQUS. The SAPIEN stent was modeled using an elasto-plastic model with Young's modulus, E=193 GPa, σ_y (0.2%) =340 MPa, σ_u (48%) =670 MPa, Poisson's ratio, ν = 0.29 and, density, ρ =7760 kg/m^3[5]. The balloon was modeled with quadrilateral shell elements as a linear elastic material with E=600 MPa, ν =0.45

and ρ=1100 kg/m^3 [5]. The CoreValve stent was modeled using superelastic nitinol properties and employed as beam elements in ABAQUS using VUMAT subroutine. The crimped balloon and stent were positioned coaxially inside the aortic root (Z-axis). The CoreValve was crimped and released inside the BAV as it is modeled as a self-expandable stent. Fluid-cavity based approach was employed to inflate the balloon and deploy the stent. The ends of the aortic root were constrained in translational and rotational degrees of freedom about Z-axis. Scaled penalty contact was employed for the stent-balloon and stent-AV interactions. Results were visualized and analyzed in ABAQUS.

RESULTS

Geometries of the aortic root and bioprosthetic valve are shown in Fig. 1 along with lacerations tested for mitigating coronary obstruction. Simulation of an idealized TAV expanded to 20mm inside the BAV showed a high risk of obstruction for both coronary arteries (Fig. 2). Deployment of the SAPIEN 20mm stent inside the bioprosthetic valve with aligned and misaligned lacerations on the leaflets is shown in Fig. 3. Deployment of the CoreValve 23mm TAV inside BAV with aligned lacerations is shown in Fig. 4.

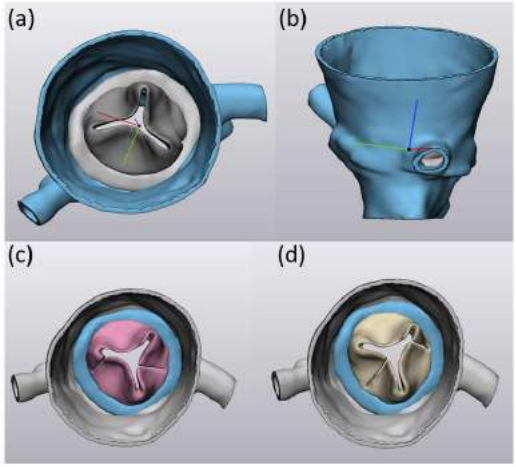

Figure 1. Geometry of the aortic root and bioprosthetic stent and leaflets in axial (a) and lateral (b) views. En-face view of aligned (c) and misaligned (d) lacerations of the bioprosthetic leaflets.

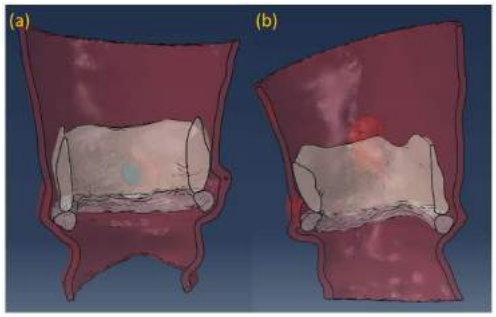

Figure 2. Cross sectional views of the left (a) and right (b) coronary arteries after idealized TAV deployment without BASILICA show high degree of obstruction.

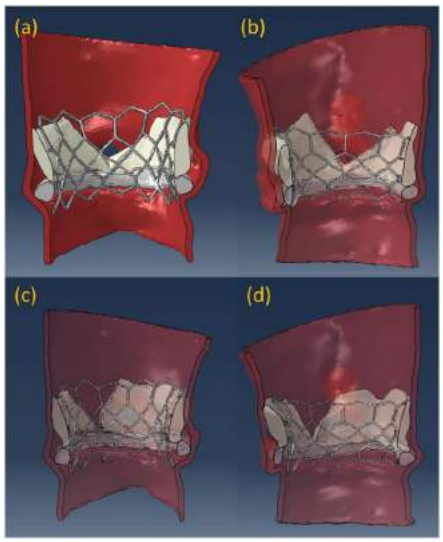

Figure 3. Cross-sectional views of the left (a) and right (b) coronary arteries after SAPIEN deployment with aligned (top) and misaligned (bottom) lacerations

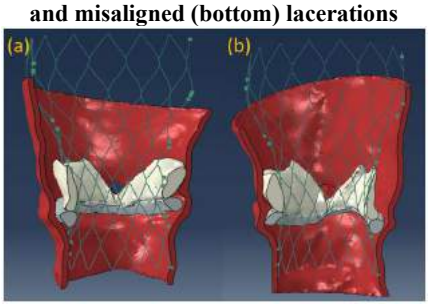

Figure 4. Cross-sectional views of the left (a) and right (b) coronary arteries after CoreValve deployment with aligned lacerations

DISCUSSION

Coronary obstruction is a rare but deadly procedural complication of TAVR that plays an important role in decision making during procedural planning. As shown in Fig. 2, ViV TAVR elevates the risk of obstruction due to relatively low heights of coronaries from the bioprosthetic valve stent. Lacerations made to mitigate obstruction may or may not be effective depending on the location of laceration relative to the coronary ostium as seen in Fig. 3. Precise computational modeling of ViV TAVR allows for optimization of outcomes ensuring the success of the procedure. In conclusion, computational modeling plays a very important role in TAVR planning specifically in the mitigation of coronary obstruction. Further computational fluid dynamic studies could provide a better insight into the degree of obstruction of flow as pressure gradients.

INTRODUCTION

Shoulder pain is the second most common musculoskeletal condition [1], accounting for nearly 4.5 million annual visits to physicians in the United States [2]. Rotator cuff (RC) pathology has been recognized as the predominant factor underlying shoulder pain. RC pathology has been linked with chronic, repetitive deformation and compression of the RC tendons, particularly within the supraspinatus tendon (SST). Current standard clinical care mainly focuses on a static magnetic resonance (MR) scan to diagnose RC pathology. While an MRI would allow identification of soft tissue damage, it only provides a static view of the joint, typically in a supine position, and does not consider combinatory effects of individual-specific anatomical and movement-based abnormalities causing excessive RC deformation. Therefore, using computational techniques to simulate and analyze in vivo mechanical environment of the SST during functional activities and across the range of motion would provide a deeper insight about the underlying factors of SST pain and injury. The purpose of this study was to develop a finite element model with individual-specific anatomy and in vivo joint kinematics to computationally simulate functional reach task and study the consequent stress/strain measures.

METHODS

A 3T MRI scan of a right shoulder (48-year-old female) was used for 3D reconstruction of the shoulder joint model. Humerus, scapula and supraspinatus muscle and tendon were manually segmented using Mimics software (Materialise, Leuven, Belgium). The 3D models were meshed using HyperMesh software (Altair, Troy, MI) and imported into FEBio software [3]. Four-noded tetrahedral elements (TET4) were used for all bony and soft tissue structures. Figure 1 demonstrates the components of the developed finite element model.

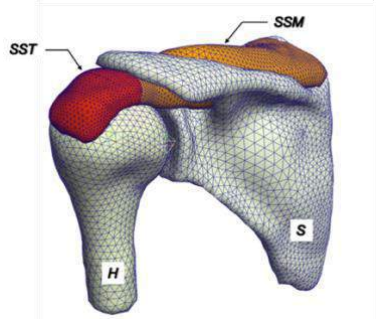

Figure 1: Depiction of the developed finite element model of the shoulder joint with scapula (S), humerus (H), supraspinatus muscle (SSM) and tendon (SST).

Scapula and humerus were modeled as rigid bodies, with supraspinatus muscle (SSM) defined as incompressible, hyper-elastic material with Mooney-Rivlin constitutive model. SST was defined with the same base material reinforced by fibers aligned with a semi-circular von Mises distribution. The main fiber orientation was defined along the medial-lateral axis of the SST, with fibers distributed up to 90° posterior and anterior to this orientation. A fiber concentration factor of k_f = 4 was used to represent highly aligned fibers along the main orientation, based on previous literature [4,5]. The constitutive model parameters used for the SST material properties are as follows: C_1 = 1 (MPa); C_2 = 1 (MPa); C_3 = 0.1 (MPa); C_4 = 25; C_5 = 98.7 (MPa); bulk modulus = 10,000; and *lam_max* = 1.06. It should be noted that bulk modulus is in fact a penalty parameter that, when set as a large number, enforces incompressibility of the represented material. Prior to simulating functional reach, these material parameters were evaluated

through a uniaxial tensile test simulation and comparison of the results with previous experimental and computational data [4,8].

The scapula was fixed to the global reference frame, and the glenohumeral joint was represented with a spherical joint about the center of the humeral head. The SST was attached to the humerus at the insertion via a "rigid" contact. Frictionless sliding contacts were defined between the bony structures and the soft tissues. Average joint kinematics of healthy participants during functional reach movement were acquired from our previous in vivo study [6] and were used to drive the simulation following International Society of Biomechanics (ISB) recommendation for the glenohumeral joint [7]. A 70N uniaxial force was simultaneously applied to the proximal end of the SSM throughout the simulated motion to represent muscle activation and contraction during the arm movement. Relative volume output was used to inspect the incompressibility of the soft tissue. Maximum principal Green-Lagrange strain was extracted throughout the simulated motion to investigate the strain distribution, as well as the magnitude and location of the peak strain values.

RESULTS

A maximum volume change of 3% was found within the SST, verifying acceptable incompressibility of the defined material properties. The results demonstrated a maximum principal strain of 13% with 180N of uniaxial tensile load (Fig.2), consistent with previous studies on the mechanical properties of the SST [8,9]. During simulated functional reach task, the maximum principal strain was found to be 0.99 occurring at the posterior joint surface of the SST at nearly 90° of glenohumeral abduction (Fig.3).

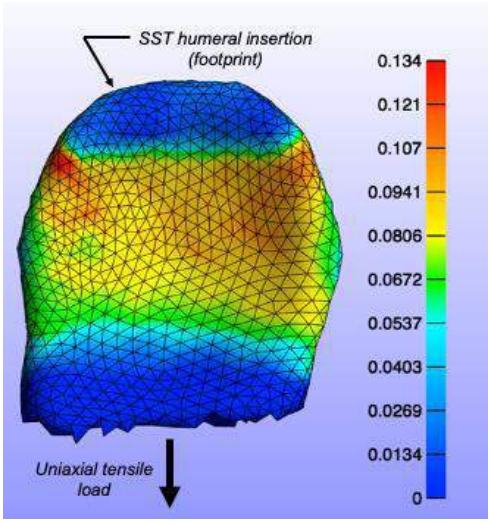

Figure 2: Demonstration of maximum principal strain on the joint surface of the SST under 180N uniaxial tensile load.

DISCUSSION

In this study, a finite element model was developed to investigate SST strains during a functional reach task. The results were in agreement with previous literature on the average magnitude and location of highest strains on the joint (articular) side of the SST under uniaxial tensile loading [8]. Multiple experimental and computational studies have previously studied in vitro mechanical properties of SST [5,8,9] under uniaxial loading conditions. However, the developed model provides the unique advantage of combining subject-specific anatomy and in vivo joint kinematics to study the mechanical environment of SST within the shoulder range of motion.

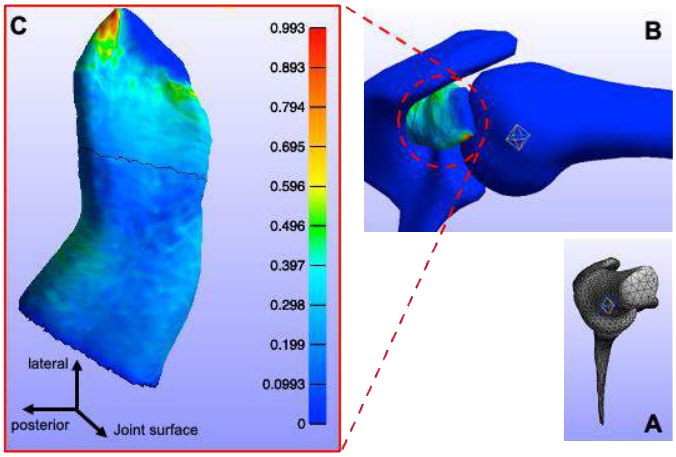

Figure 3: Depiction of end-range simulated glenohumeral abduction (A), colormap of 1st principal Lagrange strain within the SST (B), and a magnified view of strain distribution on SST joint surface

Future work will address certain limitations of the current model. First, we speculate that the excessively large strain magnitudes found in some areas might be due to stress concentration near the footprint rigid contact or material properties with inappropriate formulation for larger strains. Further computational and experimental work will be performed to ensure the validity of the results. Additionally, SST material properties will be varied along anterior/posterior and superior/inferior sections to reflect findings of previous literature [5]. Second, a mesh study will be performed to ensure the accuracy and reliability of the computational output measures irrespective of the mesh size. Third, SSM was simulated with the same material properties as SST (Mooney-Rivlin constitutive model) without fiber reinforcements. Future work will improve upon the material properties of the SSM to more realistically simulate in vivo functions. While the foregoing alterations may affect the magnitude of observed strain values within the SST, the overall strain distribution and location of critical spots are expected to remain generally the same. The developed model lays the groundwork for investigating the effect of various anatomical features as well as different athletic and daily activities on the mechanical behavior of SST and enables a more accurate prediction of risk and location of rotator cuff injuries.

INTRODUCTION

While the field of biomedical engineering is set to cultivate future breakthroughs in biology, medicine, and engineering, a clear strategy for empowering undergraduate students to develop skills in solving complex problems at the interface between engineering and biology has yet not been established [1]. Education in this area is supported by two main pillars: research and up-to-date learning strategies [2, 3]. Undergraduate research experiences commonly include course laboratories, however, laboratories that fail to connect the course content with hands-on application in a meaningful way result in poor conceptual learning outcomes [4,5]. Designing hands-on laboratories specifically to clarify challenging concepts and highlight connections between topics introduced in lectures (the "minds-on" approach) has been shown to be more effective [6]. Additionally, incorporating faculty members' own research into these laboratories can provide a more authentic and engaging research experience for students, effectively "science-ing them up". In this work, we linked faculty research expertise with concept-based teaching strategies to design and implement a novel laboratory experience for an undergraduate biomechanics of tissues course at the University of Calgary.

METHODS

In our designed laboratory activity, we related mathematically heavy nonlinear continuum mechanics to its practical applications in the experimental analysis of cardiovascular tissues, the area of research expertise of the faculty member instructing the course.

We designed and built a miniaturized version of a planar-biaxial tensile testing device typically used for soft anisotropic tissues and biomaterials (Fig. 1). Miniaturization was done to reduce equipment cost and overcome accessibility barriers that students often face to gaining hands-on experience with expensive and sophisticated laboratory equipment.

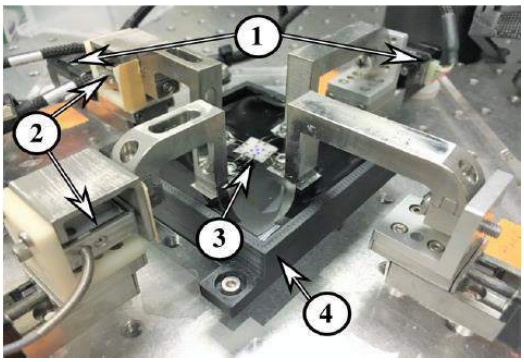

Figure 1: The mini-biaxial testing device: ① linear actuators, ② load cells, ③ specimen, ④ tissue bath

The laboratory itself was optimized into a "storyline" format by partially completing some steps of the experiment ahead of time to facilitate student engagement and conceptual learning without the stress of executing complex laboratory procedures correctly. Four stations were assembled. Stations 1 and 4 took place in a conference room and described the required pre- and post-lab information, respectively. Station 2 gave students hands on experience with a porcine aorta ring opening angle experiment and with hooking mini-biaxial specimens. Station 3 featured the mini-biaxial experiment with a pre-attached specimen. Following the laboratory session, students completed a lab report which required them to analyze data using a wide variety of the

techniques and concepts introduced during lectures, including using stress-strain curves to judge the tissue's behaviour.

Students were surveyed twice, once immediately following the laboratory activity and again following their completion of the laboratory report to gather data on their level of engagement and their overall experience. The survey was prepared and utilized in accordance with the regulations for human research at the University of Calgary, and this study was approved by the Conjoint Faculties Research Ethics Board. The survey included both Likert Scale-based and open-ended questions.

RESULTS

16 out of 18 students volunteered to take part in the survey. Overall, student feedback suggested that the students found the laboratory fun, easy, and worthy of their attention. Strong evidence was present in survey responses of students acknowledging the "storyline" format and wishing for it to be adopted more widely. A large portion of students expressed appreciation that their "hands-on" experiences with human tissues were intended for training purposes only and that the actual experimental samples for data collection had been prepared by lab instructors ahead of time. Students actively engaged in discussions of research with lab facilitators, demonstrating the "scienced-up" laboratory environment. Several students reported that this activity reinforced the concepts from the course by relating theory to application and helped them deepen their understanding. A few students were dissatisfied with either the report or the lab session timing.

Examining historical grade point average (GPA) and universal student rating of instruction (URSI) scores for students (University of Calgary scoring schemes) seemed to suggest small increases in student academic performance and course satisfaction the year of the laboratory. While the instructor was the same in the years examined, these gains may have resulted from other factors unrelated to the lab.

DISCUSSION

The positive attitude exhibited by the students involved in this laboratory can be attributed chiefly to the format of this experience. Our activity injected research into their undergraduate coursework by adding a relatively less demanding "scienced-up" activity to capture their attention while still holding true to the related course content. This matches other studies which have shown that the introduction of research activities promotes high levels of student engagement and can also be useful for accommodating different learning styles [7, 8].

Qualitative survey responses indicated that students found it easier to focus and openly communicate with instructors and facilitators while working in small groups during the "storyline" exercise. This setup may help better engage passive students – those who are resistant to active learning approaches – in a nonconfrontational way [7]. The format of our laboratory also empowered students to think critically, as evidenced by the questions they raised regarding the limitations of our testing machine.

Several students specifically mentioned that they appreciated the pre- and post-lab presentations at stations 1 and 4, which is congruent with previous findings that most students complete little or no preparation for laboratory sessions [9 – 11]. Effective pre-lab sessions are known to reduce students' stress-levels, increase their engagement and confidence, and decrease their resistance to active learning [7, 11]. Similar increases in levels of student comfort related to working with specimens purely for the sake of practice have also been reported elsewhere [6]. It is noted that this laboratory was not without its flaws, as evidenced by facilitators and feedback from some students.

A key limitation of this laboratory activity is its scale-up potential. The work presented took place in a course with small enrolment (15 – 25 senior undergraduates). In this study, two options were presented for scale-up to a 100-student class with the ability to host minimum 4 hour-long laboratory sessions. Both options required that for a larger and more junior audience, the content presented would have to be simplified (i.e. simplified linear elasticity) at the cost of its related accuracy in predicting tissue biomechanical behaviour.

Facilitator and instructor hours for activity preparation and execution would also scale appropriately. In the first option, three laboratory sessions would occur, group sizes would remain at three to four students each, and groups would circulate between four stations analogous to those presented. Each facilitator would need to spend approximately 15 hours running the lab. In the second option, the group sizes would be increased to 11 – 12 students, and experimental stations would be modified to accommodate larger space requirements. As a result, students would most likely experience less direct interaction with the instructors and facilitators. This second option would be more time efficient, and could be performed in a single laboratory session, requiring 5 hours from each facilitator. Other areas of concern for scale-up include access to sufficient amounts of tissue and monitoring safety.

In summary, we bridged faculty research expertise with concept-based learning pedagogy to design and implement a unique laboratory experience for biomedical engineering undergraduate students enrolled in a biomechanics of tissues course at the University of Calgary. By designing custom equipment and using a "storyline" format, students were able to focus on the conceptual understanding underlying the experiment. This approach resulted in an overall valuable and positive learning experience for students.

INTRODUCTION

Poor clinical outcomes following Achilles tendon (AT) rupture are largely attributed to the generation of disorganized, hypervascularized, hypercellular scar tissue lacking the architecture necessary to meet the mechanical demands of the tendon.[1,2] Regenerative tendon healing that restores its densely aligned architecture would dramatically improve outcomes and reduce the significant socioeconomic burden of these injuries. Tendon healing relies on the timed recruitment of cellular mediators of tissue repair.[2] Thus, therapies that can regulate the identity and number of repair cells entering the wound site are likely required for the regeneration of functional tendon in lieu of dysfunctional scar tissue. While injection and suture-based delivery of drugs and biologics have shown promise, these approaches lack the spatiotemporal control required for regenerating the tendon's native architecture.[3,4] To address this problem, efforts have shifted toward tissue constructs engineered to recapitulate the biochemical and mechanical properties of tendon.[5,6]

Synthetic hydrogels represent an exciting avenue in the field of regenerative biomaterials given their injectability, orthogonally tunable mechanical properties, and potential for modular inclusion of cellular cues. However, optimizing physical cues to permit cell infiltration while still maintaining sufficient mechanical properties required of a musculoskeletal implant remains challenging. Analogous to rebar-reinforced concrete, synthetic fibers can mechanically reinforce bulk hydrogels with the added benefit of providing topographical cues to guide cell migration and spreading in a 3D hydrogel network.[7] Separately, recent advances in soluble factor release technology have demonstrated microparticle-mediated, sustained release of growth factors.[8] A composite hydrogel incorporating both of these components could robustly mediate tendon healing with a single injection. Therefore, we sought to assess whether 3D migration of cells involved in tendon healing can be enhanced via combined mechanical, topographical, and microparticle-delivered soluble cues.

METHODS

Cell Isolation and Spheroid Formation: All cells used in this work were harvested from C57BL/6J mice. Tendon stem/progenitor cells (TSPCs) and mesenchymal stem cells (MSCs) were isolated using established methods.[9,10] Spheroids were formed using AggreWells™.

Chemokine Screening: A 3D migration assay that generates chemokine gradients across hydrogels was microfabricated as in previous work.[11]

Microgel Fabrication and Loading: To achieve the monodispersity required for precise control of soluble factor release,[12] a droplet-based microfluidic device was used to fabricate dextran vinyl sulfone (DexVS) microgels with either 1 or 10 wt/vol% heparin methacrylate (HepMA) (**Fig. 1**). Water-in-oil droplets 107±5 μm in diameter were formed and crosslinked (**Fig. 1C**). UV exposure and emulsion breaking yielded an aqueous suspension of DexVS/HepMA microgels, which absorbed PDGF-BB at 250 ng/mL overnight. Loaded microgels were washed twice with HEPES buffer before use in cell experiments.

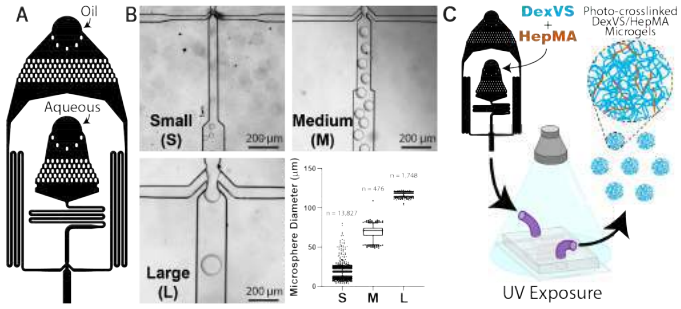

Fig. 1: A) Microfluidic device design for generating monodisperse water-in-oil droplets. B) Images and quantification of droplet radii as a function of channel geometry. C) DexVS/HepMA microgel fabrication scheme.

Composite Hydrogel Fabrication: Fiber segments were fabricated by crosslinking electrospun DexVS fibers with UV light through a photomask followed by functionalization with RGD in HEPES buffer.[7] Fibers, spheroids, and microgels were added to a mixture of DexVS, RGD, heparin binding peptide, and a cell degradable peptide crosslinker (VPMS) to encapsulate them together in a hydrogel bulk. Bulk stiffnesses of 0.5 and 2.0 kPa were respectively achieved by adding 12.5 mM and 20.0 mM VPMS.[7] Importantly, varying fiber density does not influence cell-scale bulk stiffness in this material system.[7]

Immunostaining and Microscopy: Samples were fixed, permeabilized, and stained with Hoechst dye and phalloidin. Z-stacks of microfluidic channels and spheroids were collected via confocal microscopy. Data

Analysis and Statistics: Custom MATLAB software either quantified migration distance for the chemokine screen or the increase in cell spreading area outside of the original boundary of a spheroid (presented as mean ± SD). Statistical significance was determined by one- or two-way ANOVA with Tukey's post-hoc analysis ($\alpha = 0.05$).

RESULTS

We used a 3D migration assay to screen a panel of chemokines for their ability to enhance TSPC migration into type I collagen matrices (**Fig. 2A**). For each chemokine, concentrations were screened over a range of 0 to 1 μg/mL to find an optimum with respect to cell migration. Then, comparison of these optima revealed that PDGF-BB and SDF-1α are relatively potent inducers of 3D TSPC migration (**Fig. 2B, C**).

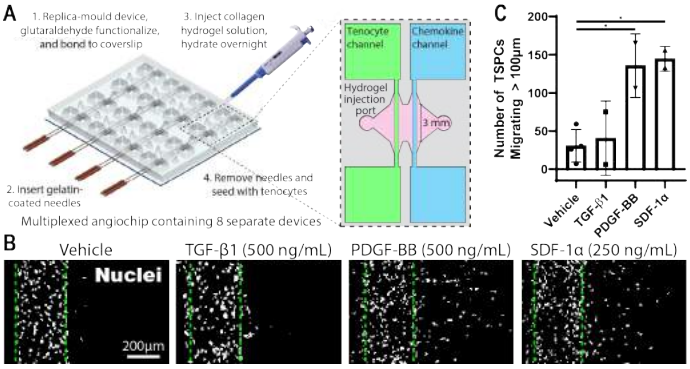

Fig. 2: A) Schematic of chemokine assay. B) Confocal fluorescent images of migrating tenocytes (channel in green). C) #cells invading >100μm. *p<0.05.

Synthetic hydrogels afford increased tunability of mechanical and topographical properties, which are known to impact cell spreading and migration in 3D microenvironments.[7,11] Therefore, we explored the combined effect of PDGF-BB and fiber density on outgrowth of tendon MSC spheroids in a composite DexVS hydrogel (**Fig. 3A**). This assay only required 10 ng/mL of chemokine in the media, as there is no need to establish a persistent gradient like in the case of the chemokine screen. Comparison of spheroid outgrowth areas confirmed that PDGF-BB enhances 3D MSC migration in DexVS and showed that fiber density can synergistically increase migration but can potentially hinder outgrowth above 2.5 vol% (**Fig. 3B**).

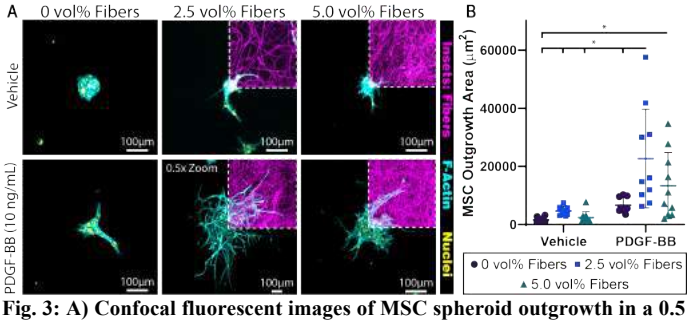

Fig. 3: A) Confocal fluorescent images of MSC spheroid outgrowth in a 0.5 kPa DexVS gel, varying fiber density and PDGF-BB concentration. B) Outgrowth area. *p<0.05.

Heparin affinity-based delivery vehicles can prolong the presence of soluble factors in cellular microenvironments through sustained release.[8,12] Therefore, we investigated the effect of sustained release of PDGF-BB from co-encapsulated DexVS/HepMA microgels on TSPC and MSC migration in fibrous DexVS matrices (**Fig. 4A**). Fibers were included at 2.5 vol% per the optimum determined previously, and HepMA wt/vol% was varied in the microgels to alter their loading capacity and release rate.[12] Given its dual implications for scaffold durability and cell spreading/migration, we also examined the effect of bulk matrix stiffness. Both TSPCs and tendon MSCs exhibited increased spheroid outgrowth in response to microgel-delivered PDGF-BB. Moreover, we found that these trends persist at a higher bulk matrix stiffness, albeit with an attenuated response (**Fig. 4B-D**).

DISCUSSION

In this work, we investigated the role of physical and soluble microenvironmental cues in regulating migration of tendon repair cells through fabrication of hydrogel composites with orthogonally tunable mechanical and biochemical properties. Our results show that multiple chemokines are capable of encouraging tenocyte infiltration into 3D hydrogel matrices, and that this effect exhibits synergy with fibrous topographical cues. Moreover, we demonstrate a method for high-throughput generation of monodisperse microgels capable of heparin affinity-based release of growth factors and chemokines,[8] and we apply this technology to elicit cell migration over a range of bulk matrix stiffnesses. These studies strongly suggest that modular, composite DexVS hydrogels meet fundamental criteria for an injectable musculoskeletal scaffold:[13] (1) mechanical durability via fiber reinforcement over a range of bulk moduli permissive to migration and (2) programmed regulation of the soluble milieu following a single administration. Thus, this biomaterial approach could likely be generalized to a range of connective tissue injuries, including skin, ligaments, and bone. Future studies will examine how cell recruitment impacts tenogenesis and tendon repair *in vitro* and in a murine tendon injury model.

INTRODUCTION

Blood vessels in the brain are surrounded by slender perivascular spaces (PVS) that are involved in the clearance of waste from brain tissue by enabling fluid exchange between interstitial fluid and cerebrospinal fluid (CSF) compartments [1]. The clearance function of PVS may be related to accumulation of harmful proteins in Alzheimer's and Parkinson's disease [2]. While a number of studies have demonstrated uptake of imaging tracers into PVS near the brain surface [1], few have examined deeper PVS and their connections to the ventricular CSF channels [3]. Histological sections following tracer uptake suggest an intricate and extensive network of PVS throughout the brain, but the resolution of whole brain imaging *in vivo* has limited analysis of the intact network to only the largest vessels [4]. There is a need for a 3D map of PVS to better understand their waste clearance function and create more accurate mechanical models of drug delivery in the brain. Magdoom et. al. [5] presents a set of *ex vivo* whole rodent brain images, at the highest resolution to date, following intraventricular contrast agent infusion, revealing numerous connections between the PVS network and the cerebral ventricles. In the present study, these images were newly processed to produce clearer visualizations of the PVS that facilitate identification of major blood vessel groups surrounded by functional PVS structures. A custom segmentation workflow was developed to create 3D maps of the PVS network containing contrast agent following intraventricular infusion. The resulting maps revealed continuous PVS segments several millimeters in length and the portions of the network directly connected to the ventricles by numerous PVS segments. Further analysis shows the PVS network greatly reduces the transport distance from the parenchyma to CSF, a condition which may be central to their waste clearance function.

METHODS

In a previous study from our group [5], high-resolution magnetic resonance images (40 μm isotropic voxels) were acquired from seven excised whole rat brains. In five of the animals, gadolinium-labeled human serum albumin (Gd-DTPA-albumin) was infused into the lateral ventricle for 40 min to allow distribution into the PVS. The remaining animals served as naïve controls. The animals were sacrificed via vascular perfusion with a 4% formaldehyde fixative solution to crosslink the contrast agent to the brain tissue. Each brain was subsequently excised and imaged at 17.6 T with a T1-weighted 3D gradient echo imaging sequence lasting approximately 24 hrs. This high-resolution scan was acquired with TR = 100 ms, TE = 0.2 ms, flip angle = 50°, an FOV of 20 x 16 x 12 mm^3, a matrix size of 500 x 400 x 300, and 7 averages.

The ventricles and PVS appear bright in the T1-weigted 3D images because of a reduction in T1 caused by Gd-DTPA-albumin [5]. Computing a maximum intensity projection of the data resulted in a set of projection images in which the brightest PVS and the ventricles were more apparent. However, smaller, dimmer PVS were not projected and many PVS were occluded by the bright ventricles in the center of the brain. To overcome these limitations, partial projections (pMIPs) through a subset of planar images spanning 30-voxels were produced.

Because the PVS surround blood vessels, they appeared like slender, tube-like, bright structures in many brain regions having a range of mean intensity values. To better distinguish the PVS, a measure of the tube-like nature, or *tubeness*, of the intensity field surrounding each voxel was computed. The tubeness metric for a given voxel is defined as the geometric mean of the two most negative eigenvalues of the Hessian matrix for that voxel [6]. The Hessian matrix elements are the second spatial derivatives of the intensity field, I:

$$H_{ij} = \frac{\partial^2 I}{\partial x_i \partial x_j} \qquad (1)$$

The PVS segmentation was generated by computing the tubeness of the 3D image and selecting voxels with tubeness values greater than 99 percent of the voxels in the naïve control brains. The ventricles were segmented separately. The connectivity between the PVS and ventricle networks was examined with a custom region grow algorithm that iteratively expanded the ventricle segmentation into the PVS segmentation. The extent to which the PVS network facilitates clearance from parenchyma was quantified by calculating the minimum distance, d, between parenchyma voxels and the nearest CSF voxel with and without the PVS network. Time scales for diffusion, t_D, and advection, t_a, were computed for bovine serum albumin (D^*= 1.63 × 10^{-7} cm^2/s [7]) as in Eq 2. The assumed parenchyma interstitial velocity, u, was 1 μm/s.

$$t_D = d^2/D^* \qquad (2a)$$
$$t_a = d/u \qquad (2b)$$

RESULTS

Extensive PVS uptake of Gd-DTPA-albumin throughout the brain was observed following intraventricular infusion. Long PVS segments, some over several millimeters in length, extended from the surface of the brain into the deep tissues surrounding the ventricular system (Fig 1 a-c). PVS surrounding subcortical penetrating arteries (scop) traversed the cortex and appeared to provide a pathway for tracer between the dorsal subarachnoid space and the lateral ventricles (Fig 1 a-c). Branches from large ventral surface vessels extended dorsally into the midbrain and include the anterior (astr), medial (mstr), and posterior striate arteries (pstr), as well as the anterior choroidal arteries (ach) (Fig 1 a-c). Image segmentation revealed a dense network of PVS throughout the brain (Fig 1 d-f). Isolating the portion of the PVS network that approaches the ventricles within 120 μm revealed connections between the lateral ventricles and major ventral and dorsal surface vessels via the scop, ach, and the striate arteries (Fig 1 g-i)

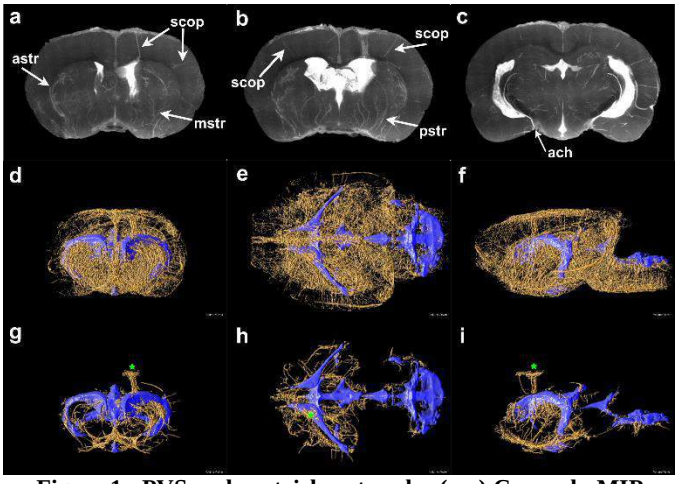

Figure 1: PVS and ventricle networks. (a-c) Coronal pMIPs proceeding caudally. See text for notable vessel group names. (d-f) Solid renderings of the PVS segmentation (gold) and ventricle segmentation (blue). (g-i) Solid rendering of the portion of the PVS network (gold) most closely connected to the ventricles (blue). The needle track is indicated by a green star.

To quantify the extent to which the PVS network may improve waste clearance from parenchyma to CSF spaces, the distance between each parenchyma voxel and the nearest CSF voxel was computed. In the absence of PVS, the parenchyma was on average 0.78 ± 0.52 mm away from the nearest CSF space with some parenchymal regions located over 2 mm away from the nearest CSF space (Fig 2 a-c, g and h). When PVS was considered part of the CSF spaces, the minimum distance between parenchyma and the CSF was reduced to 0.17 ± 0.10 mm and all parenchyma voxels were within approximately 1 mm of a CSF space (Fig 2 d-f, g and h). This reduction in minimum distance represents a nearly 22 fold reduction in the time scale for diffusive clearance from the parenchyma (Fig 2 h). Assuming an interstitial flow is present in parenchyma as posited by the glymphatic hypothesis [1], the presence of PVS affords a nearly 5 fold reduction in advective clearance time from the parenchyma (Fig 2 h).

	No PVS	With PVS	Transport Advantage
Mean nearest distance (mm)	0.78	0.17	--
SD nearest distance (mm)	0.52	0.10	--
Diffusion time scale (min)	10.48 (hr)	28.71	21.91
Advection time scale (min)	13.07	2.79	4.68

Figure 2: Minimum distance between parenchyma and CSF. The distances between parenchyma voxels and the nearest CSF fluid voxel without PVS (a-c) and including PVS (d-f) presented as coronal (a and d), horizontal (b and e), and sagittal (c and f) planar color images. (g) Minimum distance distributions with and without PVS. (h) Table of transport parameters with and without PVS. The transport advantage is the factor by which the transport time scales are reduced due to the presence of PVS.

DISCUSSION

Growing evidence suggests that PVS are central to the clearance of dissolved compounds from brain tissue [2]. However, little is known about the 3D arrangement of the PVS available for transport, especially their connections to the ventricles and cisterns. The PVS segmentation presented here includes continuous PVS segments several millimeters in length that traverse the parenchyma and link distant CSF spaces. Moreover, the PVS form a dense and extensive network, substantially reducing the distance between parenchyma and low resistance clearance pathways that exchange fluid with larger CSF spaces. Irrespective of the main transport mode within the parenchyma itself, our results suggest PVS substantially enhance parenchyma clearance rates.

SEGMENTAL LOADS IN MALE AND FEMALE NECKS UNDER HELMETED CONDITION IN FRONTAL (G-X) IMPACTS

Yuvaraj Purushothaman, Sagar Umale, John Humm, Narayan Yoganandan

Medical College of Wisconsin
Milwaukee, WI, USA

INTRODUCTION

The cervical spine is flexible and holds the head and bears the weight of the head [1]. Its motion is facilitated by the deformations of intervertebral discs and facets. The anatomical and structural characteristics of spine differ based on sex [2, 3]. Any head supported mass such as the helmet adds to the in-vivo head mass. This additional mass increases load on the cervical spine, in both civilian and military training and operational activities [4]. From a biomechanical perspective, it is important to understand the effect of the added head mass on the responses of the human cervical spine during these types of events. Therefore, the objectives of the present study were to investigate the forces and moments at each vertebral level using three-dimensional finite element models (FEM) of male and female models with and without the helmet, and determine the role of gender and head mass under G_X loading.

METHODS

A mid-size male head-neck finite element model was developed in house and validated using experimental data [5, 6]. The head model was integrated with a detailed cervical spine that consisted of the intervertebral discs, endplates, facets, ligaments, and musculature. The head, vertebral cortical bones, endplates and ligaments were modeled using shell elements. The cancellous bone, annulus, nucleus and facets were modeled using solid elements. The musculature was incorporated using anatomical origin-insertion locations as 1D beam elements. The material properties were based on the literature [7, 8]. The mid-size female model was developed by morphing the male model using anatomical ratios between male and females for the cervical spine and head mass [2]. The mapping block morphing approach was used for the development of female model [5]. The morphing process incorporated the variations in the shape and size of each vertebral body and overall spinal column length [2].

An advanced combat helmet model was developed inhouse by scanning the geometry of helmet using a coordinate measurement system. The inner part of the helmet was lined with seven foam pads. The helmet and inner foam were modeled as solid hexahedral elements and the material properties were assigned based on the literature [9, 10]. The mass of the helmet was 1.47 kg. The helmet was strapped to the male and female models using a chinstrap modeled using solid elements.

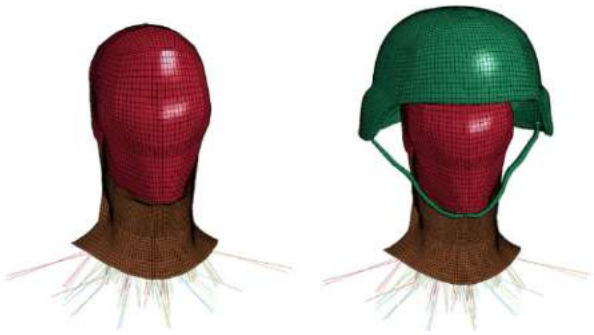

Figure 1: Left - the head neck model without helmet, and right the head neck model with helmeted condition.

The finite element models were exercised under a frontal impact scenario by inputting the acceleration pulse (velocity 6.5 m/s) to the T1 vertebra [11]. A total of 4 models were simulated for male and female anthropometry, with and without helmet. The results of male model without helmet were used to validate the model (kinematics of the head,

forces at the lower spine C7- T1, and time signal morphologies) with the experimental data. The forces and moments at the vertebral bodies were analyzed for male and female models with and without helmet, to delineate the effect of sex and the added helmet mass. The forces and moments at each disc level were determined along the local axis using cross-section planes in the model. The axial forces (along longitudinal axis), shear forces (along sagittal axis) and moments (along frontal axis) for male and female models were extracted.

RESULTS

The male model was validated using in-house PMHS sled test data. The input was acceleration pulse to the T1 vertebra in x, y, and z axes. The kinematic head response from the simulation was within the experimental corridors (average ± one standard deviation).

For the male model without helmet, the segmental axial forces at the C2-C3, C3-C4. C4-C5, C5-C6, C6-C7 and C7-T1 were 1.10, 0.89, 0.99, 0.97, 0.87 and 0.93 kN, respectively. The segmental shear forces were 0.5, 0.29, 0.37, 0.22, 0.45, and 0.53 kN, respectively. The moments at these intervertebral joints were 12.0, 21.1, 29.8, 43.8, 41.2, and 42.6 Nm, respectively. The axial forces with helmet at C2-C3, C3-C4. C4-C5, C5-C6, C6-C7 and C7-T1 were 1.21, 0.95, 1.12, 1.11, 0.97 and 0.99 kN, respectively. The segmental shear forces were 0.54, 0.31, 0.41, 0.24, 0.50, and 0.58 kN, respectively. The moments at these intervertebral joints were 12.7, 23.1, 32.8, 49.7, 45.5, and 45.4 Nm, respectively.

For the female model without helmet, the segmental axial forces at the C2-C3, C3-C4. C4-C5, C5-C6, C6-C7 and C7-T1 were 1.18, 0.93, 1.07, 1.09, 0.95 and 0.97 kN, respectively. The segmental shear forces were 0.55, 0.31, 0.40, 0.25, 0.49, and 0.57 kN, respectively. The moments at these intervertebral joints were 12.7, 23.0, 32.8, 49.7, 45.6, and 45.4 Nm, respectively. The axial forces with helmet at C2-C3, C3-C4. C4-C5, C5-C6, C6-C7 and C7-T1 were 1.31, 1.02, 1.23, 1.27, 1.10 and 1.04 kN, respectively. The segmental shear forces were 0.59, 0.35, 0.47, 0.28, 0.57, and 0.65 kN, respectively. The moments at these intervertebral joints were 14.3, 25.1, 37.4, 61.2, 54.6, and 51 Nm, respectively.

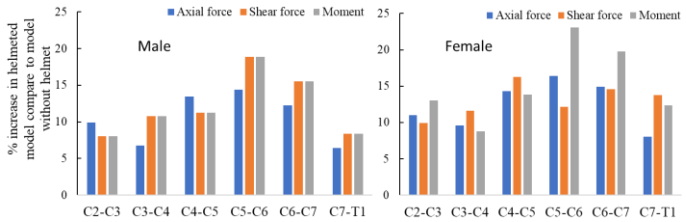

Figure 2: Percentage increase in force and moment responses for female model with respect of male model

The percentage increase in the peak force and moment responses in the male model with helmet, the axial forces, shear forces and moment increased by an average of 10.5%, 9.3% and 12.1%. In the female model with helmet, the axial forces, shear forces and moment increased by an average of 12.4%, 13% and 15.1%.

The force and moment responses were higher in female spine compared to male. The axial forces, shear forces and moments were higher by an average of 7.6%, 9.6%, and 9.2% (Figure 3), for model without helmet. In helmeted condition, the axial forces, shear forces and moments were higher by an average of 9.5%, 12.6%, and 12.3%, for helmeted condition.

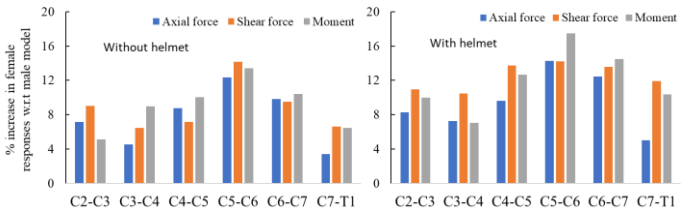

Figure 3: Percentage increase in force and moment responses for male and female model in helmeted condition

DISCUSSION

In the current study, head neck models of male and females were simulated in helmeted and without helmet condition. The helmet resulted in an increase in spinal loads (force and moments) for both males and females. The ratio of increase in shear force and moment was greater at the C5-C6 and C6-C7 discs in the male model. Whereas for females, the ratio of increase in axial force and moment was greater at C5-C6 and C6-C7 discs. Thus, the risk of injury may be higher at the lower cervical spine due to head supported mass.

The female model had greater load compared to the male model in both helmeted and without helmet condition. Thus, the females are at greater risk of neck injury compared to the males. The female cervical spine is also regarded weaker compared to males [2].

INTRODUCTION

Collagen fibers are the primary structural element of many soft-tissues [1], so that fiber morphology dictates macroscopic behavior in health and disease. Moreover, cross-linked soft-tissues are used in bioprosthetic heart valves (BHVs), and are intimately related to their limited durability [2]. Extant methods to quantify collagen structure are typically either restricted to thin tissues or histological sections, or requires optical clearing. Additionally, the local tissue deformation field is often required, and the ability to obtain both dynamic fiber structure and tissue deformation is thus highly desirable. Polarized Spatial Frequency Domain Imaging (pSFDI) is a recently developed non-contacting, wide-field, light scattering-based technique that can rapidly obtain fiber architecture without requiring sample preparation [1]. In addition to structural quantification, it is also possible to exploit pSFDI structural information, which is at the individual pixel level, as a texture source for digital image correlation (DIC) [3] to track local deformation. We present a method that combines pSFDI and DIC analyses in a single system that can rapidly collect soft tissue specimen structure, strain, and stress information. We also investigated the role of measurement length scale on strain measurements, with an aim to inform soft tissue material modeling.

METHODS

A detailed description of the pSFDI technique has been previously presented [1]. Briefly, a spatial frequency pattern is projected on to a soft-tissue specimen (Figure 1). There is an anisotropic scattering of the light by the fibrous microstructure and the measured scattering yield is dependent on the rotation of the polarization of the input beam relative the fiber orientation. Therefore, the output contains information about the fiber orientation. The signal is then captured by a CMOS camera after passing again through the linear polarizer and post-processing produces spatial 2D maps of fiber preferred direction, θ_p.

The pSFDI was integrated with our biaxial testing device (BTD) [4]. Native bovine pericardium (BP) samples were pre-sorted by their preferred direction (PD) and mounted on to the BTD and testing carried out by stretching the sample along perpendicular loading directions parallel to the plane of the tissue sample. Equibiaxial stress up to 225 kPa was applied to the specimens over several steps under the pSFDI device. The technique was confirmed via the agreement of the deformation gradient tensor **F** derived from physical markers and non-contacting pSFDI 'virtual' markers derived from the DIC analysis of the images.

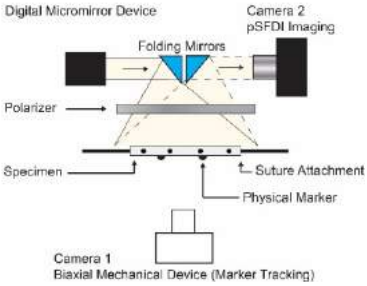

Figure 1: Schematic of the pSFDI device

This analysis was carried out using the μDIC package [3], a finite-element based software that utilizes bicubic spline interpolation. The software compares a 'reference' image (the unloaded, mounted specimen) with subsequent deformed images and by tracking the changing position of local surface texture, the software quantifies the local deformation.

The measured $I_{pSFDI}(\theta)$ signal is a convolution of the single fiber scattering function, $I_{fiber}(\theta)$ and the orientation distribution function $\Gamma(\theta)$.

$$I_{pSFDI}(\theta) = \int_{-\pi}^{\pi} \Gamma(\theta) I_{fiber}(\theta) \tag{1}$$

$\Gamma(\theta)$ was fitted to a wrapped normal distribution [5]

$$\Gamma(\theta; \mu, \sigma) = d\left\{\frac{1}{\sigma\sqrt{2\pi}} \sum_{k=1}^{1} exp\left[\frac{-(\theta-\mu+\pi k)^2}{2\sigma^2}\right]\right\} + \frac{1-d}{2\pi} \tag{2}$$

Where μ, σ, and d are the mean, standard deviation, and isotropic component fraction. μ was set to θ_p, so only σ and d were fit. The following transformation was used to determine Γ in the deformed state [5]

$$\Gamma(\beta) = \Gamma\left(\theta, \theta_p; \mu, \sigma\right) \frac{\boldsymbol{n}(\theta)(C_n(\theta))}{J_{2D}}$$
$$\beta = tan^{-1}\left[\frac{F_{21}\cos(\theta) + F_{22}\sin(\theta)}{F_{11}\cos(\theta) + F_{12}\sin(\theta)}\right] \tag{3}$$

Where $C=F^TF$, $J_{2D}=\|C\|$, and β is the θ fiber orientation in the deformed state.

RESULTS

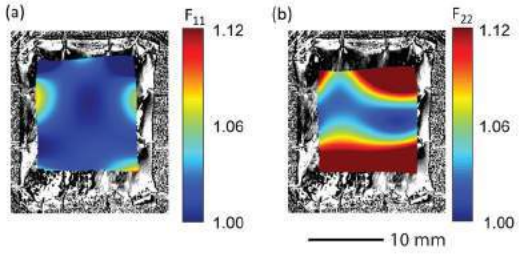

Figure 2: (a) F_{11} and (b) F_{22} fields calculated using pSFDI measurements as a texture source for DIC analysis.

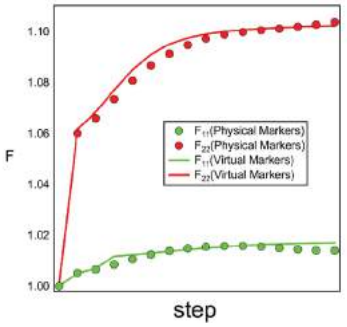

Figure 3: F_{11} (green) and (b) F_{22} (red) calculated from physical (circles) and virtual (solid lines) markers.

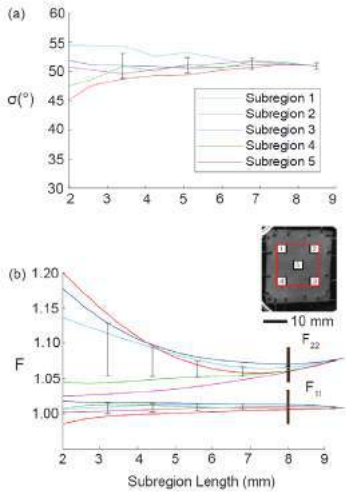

Figure 4: sub–regions selected within the ROI (inset: red box). (a) Associated fiber splay results. and (b) the F_{11} and F_{22} values determined by expanding each sub–region. The vertical black line indicates the approximate length scale where local variations become negligible.

The deformation field of the central ROI was tracked successfully using DIC analysis to an accuracy of a single pixel (~40μm). The resulting displacement field complex and heterogenous (Figure 2). The resulting spatial maps of **F**(**X**) were predictably complex. This can be best seen in the fully loaded state, where **F**(**X**) demonstrated complex, spatially varying behavior. We compared **F**(**X**) derived from physical markers (Figure 3) with the virtual **F**(**X**) from the tracked ROI region corners to confirm equivalence and an excellent agreement was established. Substantial regional

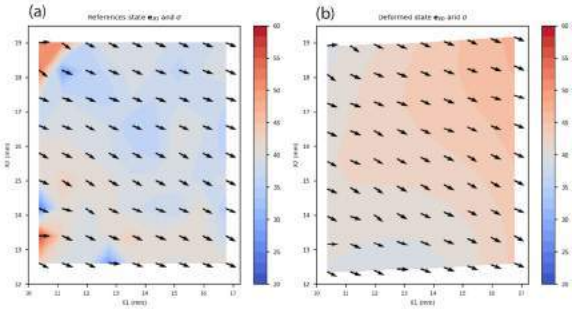

Figure 5: Mapped n(θp) (black vectors) and σ (color scale in degrees) for the ROI region of specimen 2 in the (a) referential and (b) peak equibiaxial stress state of 225 kPa.

variation was observed for the smallest size of ~2 mm for **F**, which converged to a common value as the distinct sub–regions were increased in size (Figure 4). Similar trends were observed in the σ, but with less overall initial variation (Figure 4). Collectively, these results indicate that there is a critical length (conservatively ~8 mm) at which the strain measurements become more representative of the bulk (i.e. homogenized) tissue.

Γ(β) was computed and mapped (Figure 5). Results for specimen 2 exhibited changes in both **n**(θp) and σ with deformation (Figure 5). Although the preferred directions **n**(θp) had small rotation, the σ values increased due to preferential stretch in the cross-preferred direction, which increases the Γ splay.

DISCUSSION

The aim of this study was to demonstrate that pSFDI texture (θ_p) can be utilized as a texture source for DIC in a manner equivalent to particle-based speckle patterns. This facilitated the simultaneous measurement of the tissue level deformation and collagen structure behavior. We demonstrated a step towards addressing this problem with a non-contact, non-destructive approach. The deformation behavior of distinct subregions within the ROI were examined and it was found that at the critical length of ~8 mm the data homogenizes. This has immediate potential in discerning what are local and global effects of soft-tissue behavior and structure. This is *vital* to correctly assigning the role of data in the overall picture. Moreover, it allows the role of suturing and structural defects (in both healthy and diseased specimens) on tissue-level behavior to be correctly characterized, improving the applicability of *in-vitro* measurements to *in-vivo* processes.

REMODELING OF THE THORACIC AORTA DUE TO AGEING IN MICE

Yasmeen M. Farra (1), Jacqueline Matz (1), Chiara Bellini (1)

(1) Bioengineering Department
Northeastern University
Boston, MA, USA

INTRODUCTION

Cardiovascular disease is the leading cause of death in older adults [1]. Age-related remodeling of the human vasculature features dilatation and thickening of central arteries [2-3], which contribute to the doubling of pulse wave velocity (a measure of structural stiffness) between 20 and 80 years of age [4]. Critically, aortic stiffening is a known, independent predictor of cardiovascular disease mortality [5].

Preclinical studies in mice are often used to elucidate underlying mechanisms of cardiovascular disease, yet whether mouse models can recapitulate aging processes observed in humans remains unclear. Moreover, longitudinal studies in mice necessitate a baseline understanding of the interactions between disease-inducing treatment and natural ageing. Allometric scaling laws, which correlate physiological parameters with body mass [6-7, 10], may further illuminate the effects of ageing on vascular morphology. To address these questions, we characterized here the age-related structural and functional remodeling of the thoracic aorta in female C57BL/6 mice.

METHODS

Natural ageing. Adult, female C57BL/6 mice (N=48) were randomly assigned to groups that were aged naturally to 26 ± 1 weeks (shown as "0.5 year", blue), 48 ± 2 weeks ("1 year", purple), 68 ± 1 weeks ("1.5 year", red), and 84 ± 4 weeks ("2 year", gold), respectively.

Aorta mechanics. Mice were euthanized and descending thoracic aortas (DTA) were dissected. Passive biaxial inflation-extension tests were conducted using a computer-controlled custom device that measured luminal pressure, outer diameter, axial force, and axial length. Aortic rings were imaged using a dissection microscope to obtain unloaded wall thickness. A microstructurally-motivated constitutive model was fit to experimental data using a nonlinear regression algorithm. Estimated material parameters were used to predict biaxial Cauchy stresses, linearized material stiffness, distensibility, and energy storage at physiological systolic pressure and axial length. A Pearson correlation was used to determine if there was a significant relationship between estimated parameters and age, with significance set to $p<0.005$.

Allometric scaling. Allometric scaling was used to describe how aortic geometry (luminal diameter, d) changes with body mass (M), according to the relationship $d = \alpha * M^{\beta}$, where constant α and scaling exponent β relating inner diameter to body mass were estimated via linear regression on the experimental data.

RESULTS

Biaxial data revealed changes in the material response of the thoracic aorta across age groups. In the circumferential direction, the tissue experienced a progressive decrease in distensibility, accompanied by a decline in stress (Fig. 1A, red arrow). A similar behavior was observed in the axial direction up to 1.5 years of age (Fig. 1B, green arrow), followed by a stark leftward shift of the stress / stretch curve at 2 years (Fig. 1B, black arrow).

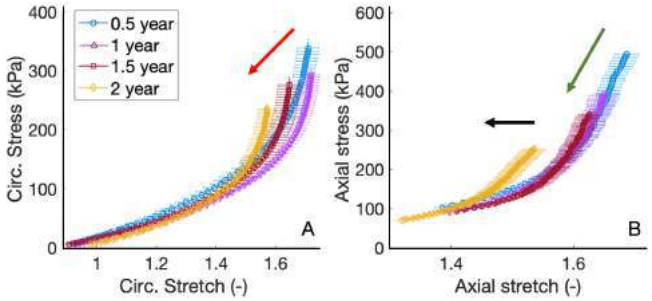

Figure 1: DTA biaxial stresses across four age groups. A) Circumferential and B) Axial stress / stretch curves.

The thickness of the DTA increased significantly and linearly with age, from 32 ± 1 μm at 0.5 years to 54 ± 2 μm at 2 years (Pearson's correlation coefficient r=0.748, p<0.001, Fig. 2A). Consistently, the stretch of the tissue declined linearly in the circumferential (r=-0.647, p<0.001, data not shown) and axial (r=-0.551, p<0.001, data not shown) directions, from 1.68 ± 0.02 to 1.54 ± 0.02 and from 1.57 ± 0.02 to 1.45 ± 0.02, respectively. The circumferential (r=-0.721, p<0.001, Fig. 2B) and axial (r=-0.769, p<0.001, data not shown) components of the Cauchy stress exhibited a similar behavior, decreasing linearly with age, from 294 ± 12 to 201 ± 7 kPa and from 268 ± 14 to 171 ± 7 kPa, respectively. While material stiffness was negatively correlated with age in the axial direction, declining from 2.94 ± 0.19 MPa at 0.5 years to 2.09 ± 0.09 MPa at 2 years of age (r=-0.579, p<0.001, data not shown), circumferential stiffness and age were not significantly correlated (r=-0.320, p=0.034, data not shown). Nonetheless, structural stiffness (distensibility) decreased steadily from 22 ± 1 $mmHg^{-1}$ at 0.5 years to 16 ± 1 $mmHg^{-1}$ at 2 years of age (r=-0.698, p<0.001, Fig. 2D). Finally, the stored elastic energy declined linearly with age, from 73 ± 4 to 40 ± 2 kPa (r=-0.834, p<0.001, Fig. 2C).

Allometric analysis estimated a scaling exponent β = 0.3835 and a constant α = 361.27 $m * g^{-0.3835}$ for the exponential relationship between the luminal diameter of the DTA and the mouse body mass (Fig. 3).

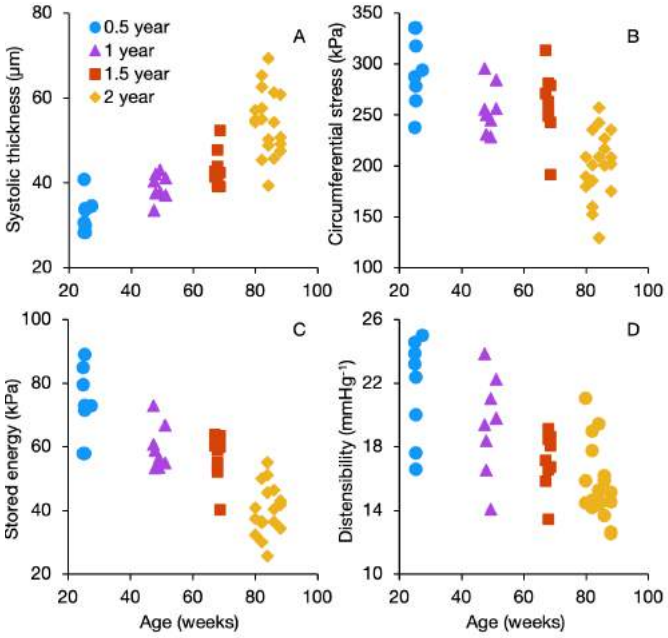

Figure 2: Mechanical parameters at systolic pressure in the DTA across four age groups. A) Wall thickness, B) Circumferential stress, C) Stored energy W, and D) Structural distensibility.

DISCUSSION

Motivated by the need to elucidate age-induced vascular remodeling, we monitored changes in the passive structure and function of the descending thoracic aorta at 4 equally spaced timepoints throughout the life of female wild-type mice.

The wall of the aorta became progressively thicker (Fig. 2A), leading to a decline in estimated biaxial Cauchy stresses (Fig. 2B). Aortic specimens exhibited a progressive loss of both circumferential and axial stretch with ageing, which caused the stored elastic energy to decline (Fig. 2C). Coupled with the increased structural stiffness (Fig. 2D), the loss of energy storage capability indicates that ageing may promote a gradual functional loss in the thoracic aorta, possibly rendering the vessel vulnerable to cardiovascular disease.

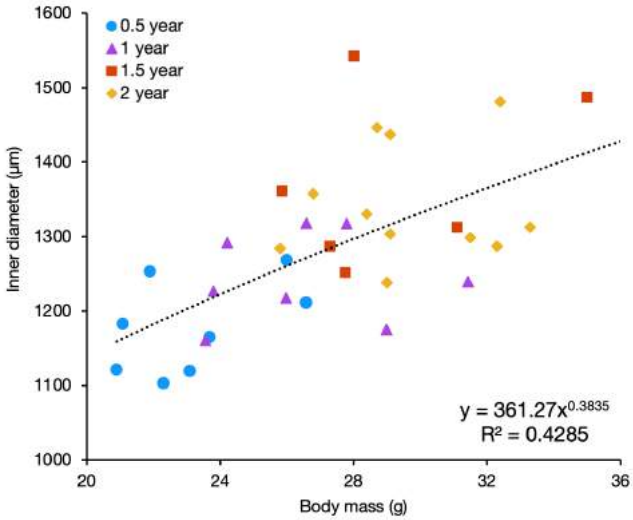

Figure 3: Allometric scaling using an exponential relationship to relate systolic inner diameter of the DTA to body mass.

In agreement with our findings (Fig. 2A), Ferruzzi *et al.* [8] and Wheeler *et al.* [9] also reported thickening of the thoracic aorta in aged (100 weeks and 21 months old, respectively) mice, driven by collagen deposition and increased medial interlamellar spacing, as shown by histological analysis [8-9]. Using stress relaxation tests, Wheeler *et al.* further observed structural stiffening of the thoracic aorta at 21 months of age when compared with 6-month-old mice [9], consistent with our results of decreased distensibility (Fig. 2D). Finally, past studies have established the need to use allometric scaling laws for the purpose of relating aortic geometry to body mass [6-7, 10]. The value of the allometric exponent (β = 0.3835) that we estimated from our experimental data falls within the range of previously reported allometric coefficients (β ≅ 0.375) between mammalian aortic diameter and body mass [7, 10].

In conclusion, our data suggest that the mouse thoracic aorta undergoes a natural process of age-related remodeling, which leads to dilatation, thickening, structural stiffening, and loss of energy storage capability. These features recapitulate salient aspects of human vascular ageing [2-4] and may provide insights on the interaction between the natural ageing process and the progression of cardiovascular disease.

ROLE OF MITRAL VALVE LEAFLET PRE-STRAIN IN AN INTEGRATED LEFT VENTRICLE-MITRAL VALVE MODEL

INTRODUCTION

The first integrated left ventricle-mitral valve (LV-MV) computational model was developed in 2010 which is based on MRI data from a sheep with moderate ischemic MR [1]. In the following study, living heart project model, as the first one modeling the whole heart with four chambers and four valves [2], was capable of capturing electrical potential, mechanical deformation, and strain in fiber from finite element model which had an agreement with clinical observation. In a recent study on LV-MV model with fluid-structure interaction had been investigated [3]. However, detailed LV-MV interactions, especially in the post-infarcted state, have yet to be achieved.

When strain is relieved when an organ is excised from the body, it is defined as a form of residual or pre-strain. It was firstly found to exit in living organ or tissue dating back to two decades ago by opening angle analysis of arteries [4][5]. Along these lines, we discovered mitral valve tissues also exhibited pre-strain in a novel in-vivo study [7]. We determined that a unit square of leaflet's area decreased by 17% when heart was excised from the body, and by 43% when MV leaflets were excised from the heart. More recently, we explored the micro-mechanical mechanisms in a nonlinear material model was used to investigate the effect of pre-strains on MV leaflets [8] . However, this effect has never been explored as part of LV function.

The goals of the present study were to 1) investigate the role of MV leaflet prestrain on model predictions and 2) study the role of regional myocardial infarction patterns on MV function and strain. We first developed a pipeline of creating an anatomically accurate LV-MV model. Then parametric studies were conducted to explore the role of pre-strain and infarct location and extent to MV function.

METHODS

A biventricular LV/MV ovine model was developed, with all data collected in a single living heart to facilitate model integration of the various model components. The geometry of biventricular model was obtained by MRI and local myofiber orientation obtained from diffusion tensor MRI after the animal is sacrificed. Dynamic heart cavity pressure and volume data were captured using in-vivo catherization and sonomicrometry, respectively. With respect to mitral valve, we processed real-time 3D echocardiographic (rt-3DE) images of another animal to obtain geometry of leaflets [Figure 1, top line] and the MV plane. These two annular traces were represented as 3D spline curves parameterized by arc length and point-wise mapping between the curves was optimized by minimization of total displacement [Figure 1 bottom left]. Finally, we used functionally equivalent chordal structure [9] to capture the native chordal behavior [Figure 1 bottom right].

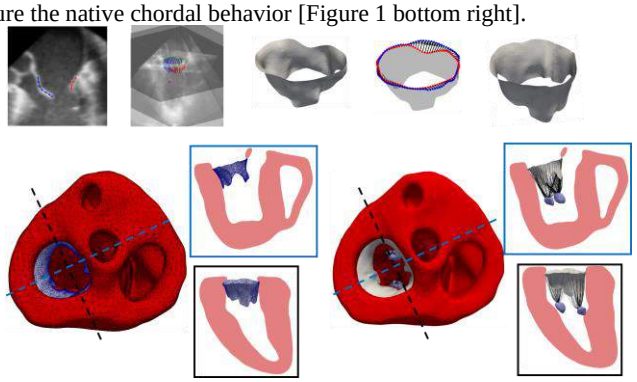

Figure 1: Pipeline of how we built the anatomically accurate LV-MV model: MV geometry segmented from rt-3d echo (top); insertion of mitral valve in left ventricle (bottom left); insertion of papillary muscle and chordae tendineae in left ventricle

MV closure was simulated under pressure. From previous findings of constitutive model of MV leaflets, accurate MV closure and strain

analysis could be obtained with an incompressible nonlinear isotropic material model [10]

$$S = \frac{1}{\pi}\int_{-\pi/2}^{\pi/2} S_{ens}[E_{ens}(\theta)]\hat{n}(\theta)\otimes\hat{n}(\theta)d\theta + \mu_m(\mathbf{I} - C_{33}\boldsymbol{C}^{-1}) \quad (1)$$

Where S is the second Piola-kirchhoff stress tensor with contribution of collagen fibers oriented along local coordinates and neo-Hookean ground matrix.

After the LV-MV computational model was established, we moved on to next step of looking into pre-strain of mitral valve leaflets. Adding prestrain into MV leaflets was performed by updating deformation matrix $F^{new} = F^{old}F^{pre-strain}$ where the amount of pre-strain applied in circumferential and radial direction were introduced. First trial has been made with uniform pre-strain applied on MV leaflets. Then, actual in-vivo pre-strain measured from sonocrystal study of MV was obtained and it was used as input for in-silico model.

RESULTS

Substantial pre-strain was first observed along loading path from unloaded state to end-diastolic state [Figure 2], with fiber stretch defined as $\lambda = \sqrt{N^T F^T F N}$ (F is deformation matrix and N means local direction). These results show the extensive effects of incorporating the MV in the ED deformation state.

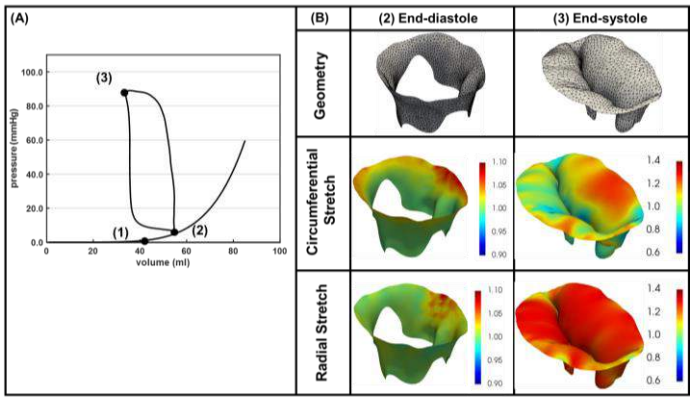

Figure 2: [A] The simulation was following pressure-volume loop with three critical states (1) unloaded state (2) end-diastolic state (3) end-systolic state; [B] Fiber strain mapping with respect to unload state as reference state

In our previous MV in-vivo strain mapping study [11], we developed a computational method to morph MV leaflets in constructed from in-vivo images of the open-state geometry to enforce MV close-state geometry, which resulted in accurate strain maps of the MV leaflets. The results of these strain maps for the ovine MV are shown in the last column of Figure 3. We then compared the open and close state of MV geometries from LV-MV in-silico model to this result, using various pre-strain values [First column of Figure 3]. When compared to the in-vivo strain maps, some differences have been observed including less compression ($\lambda < 1$) along free edge in circumferential direction and larger fiber extension ($\lambda > 1$) in radial direction. Uniform prestrain as $\lambda_1 = \lambda_2 = 0.9$ was prescribed in the MV leaflets which results in strain increase while uniform pre-strain of $\lambda_1 = \lambda_2 = 1.1$ leads to strain reduction due to material stiffening. Interestingly, when the actual observed in-vivo pre-strain was used, the strain maps agreed most closely [fourth column, Figure 3].

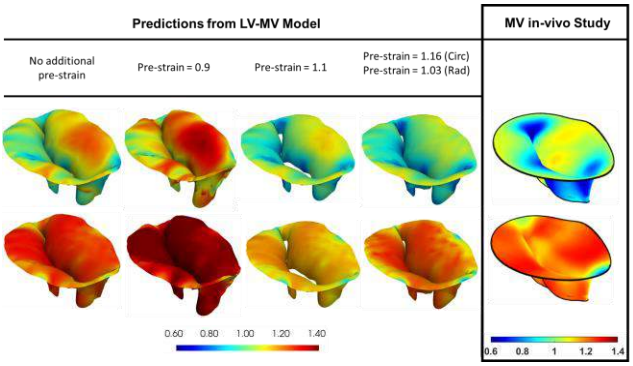

Figure 3: Role of prestrain in prediction of strain analysis from simulation with comparison of in-vivo MV strain analysis. Actual in-vivo MV strain mapping was shown in the last column

In a final step, we the explored various infarct locations and simulated them in the LV-MV model by shutting down local contraction. Simulation results indicated that the posterobasal infarction location induced the largest regurgitation orifice area, consistent with largest IMR grade reported from related animal studies [Table 1].

	ROA (In-silico Model)	IMR Grade Prediction	IMR Grade (Enomoto, et al. 2005)
Posterobasal	23.52 mm²	2.0	1.98 ± 0.20
Laterobasal	11.40 mm²	1.0	0.28 ± 0.22
Anterobasal	13.79 mm²	1.0	1.06 ± 0.25
Anteroapical	6.63 mm²	1.0	0.96 ± 0.25

Table 1: Predicted IMR grade from in-silico model of different infarct locations, with the value reported an in-vivo animal study. Our LV-MV model accurately predicted that the posterobasal infarct location induced the greatest IMR grade.

DISCUSSION

This study established a connection between MV in-vivo functional state and in-vitro reference state through applying pre-strain. The importance of this role has been emphasized by comparing with in-vivo stain mapping and it should be included in the future LV-MV modeling. However, uniform pre-strains in both circumferential and radial directions were introduced into the model which had spatial variation in reality. We then demonstrated the that this modeling approach was able to accurately predict the severity IMR grade in an initial study of myocardial infarction location and extent. We thus conclude that the incorporation of MV pre-strain of MV in FE model presented in this work contributes to a more accurate physiological picture of MV function in health and disease.

A SEMI-AUTOMATIC APPROACH FOR AORTIC WALL SEGMENTATION TO IMPROVE RAPID AND REPEATABLE ASSESSMENTS OF REGIONAL WALL STRAIN USING DENSE MRI

Patrick A. Jones (1), John S. Wilson (1,2)

INTRODUCTION

Aortic mechanics plays a significant role in a large number of aortopathies, including aneurysms, dissections, and hypertension; however, a reliable method for non-invasively assessing patient-specific regional mechanical data of the aortic wall has been lacking. Recently, a novel method for quantifying heterogeneous *in vivo* distributions of circumferential strain in the aortic wall using 2D Displacement Encoding with Stimulated Echoes (DENSE) MRI has shown promise [1-3]. However, a limitation of this approach has been reliance on manual segmentation of the cross-section of the aortic wall. Due to the thinness of the wall and limits on the resolution of aortic DENSE MRI for generating adequate signal, these masks are generally only two pixels thick. Thus, the inclusion or exclusion of only a few pixels in a mask can result in differences in calculated regional strain [3]. Additionally, this manual segmentation is time-intensive and subject to interuser variation, currently limiting the turnaround and reliability of this unique strain imaging modality for clinical analysis.

Similar to previous work to automate cardiac DENSE imaging segmentation [4], we aimed to develop an iterative semi-automated segmentation approach to improve repeatability and dramatically reduce processing time by utilizing the unique DENSE-derived displacement data for each voxel of the wall through time rather than relying solely on traditional image processing techniques for thresholding or edge detection.

METHODS

For this study, we re-analyzed previously acquired 2D spiral cine DENSE data (voxel size 1.3 x 1.3 x 8 mm, TE 1.21 ms, TR 16 ms, ω=0.17-0.25 cyc/mm, 4 signal averages) from a transverse cross-section of three *in vitro* cylindrical polymer phantoms connected to a pulsatile flow pump and from six healthy volunteers at either the infrarenal abdominal aorta (IAA, n=2), descending thoracic aorta (DTA, n=2), or distal aortic arch (DAA, n=2) [1]. Aortic wall masks were manually segmented from the *in vivo* DENSE images by two readers for the 'manual' strain calculations, and the results were averaged. Manual segmentation and analysis of the DENSE images from the *in vitro* phantoms was performed by one reader. The new semi-automatic method was conducted by a third reader to generate the 'automated' strain calculations for both the *in vivo* and *in vitro* images.

For the semiautomatic segmentation approach, MATLAB (Mathworks, Natick, MA) was utilized to manually select an initial rough region of interest that fully encompassed the aortic wall and surrounding periaortic and luminal regions in all timepoints for each scan. Note that with 2D DENSE imaging, each voxel in each serial image is phase-encoded to allow quantitative assessment of *x* and *y*-direction displacement since the encoding time. By 'back-projecting' these displacement vectors from each consecutive image to their common reference state (immediately before timepoint 1) tracked position vectors for each voxel in the mask at timepoint 1 can be interpolated for all subsequent timepoints [5]. Notably, the DENSE-derived displacements for luminal and some periaortic voxels are often random, unlike voxels from the aortic wall that tend to follow a stable path through each timepoint.

To establish the best reference mask at timepoint 1, the back-projected displacement vectors from the initial masks at each subsequent timepoint were used to create an originating point density map at the reference time. The point density map was divided into 16 sectors and used to calculate a centerline and standard deviation for the estimated position of the aortic wall at reference. Voxels outside of one standard deviation away from the centerline were then excluded from an updated mask. The voxels included in this new reference mask were

then tracked through each subsequent timepoint to generate updated masks for the full cine series. This process was repeated iteratively until termination criteria of three iterations or a minimum mask wall thickness of two voxels were met. Additional weighting was also applied as a function of path linearity and overall spatial variability for the tracked voxels to further filter out voxels representing areas that were stationary or moving erratically and therefore less likely to represent aortic wall (with the notable exception of limited displacements for points along the aorto-vertebral interface). The final automated aortic wall masks and manually segmented masks (**Figure 1**) were used in previously described custom post-processing algorithms to generate a 16-sector regional circumferential strain map [1-3].

Finally, quantitative comparisons of the processing time and the regional strain distributions (both in absolute values and normalized values relative to the mean circumferential strain of each cross-section) were performed between the original manual segmentation method and the new automated method. Strain results of the automated segmentation were considered reasonable in this pilot study if they were within 33% difference of normalized circumferential strain compared to the manual method.

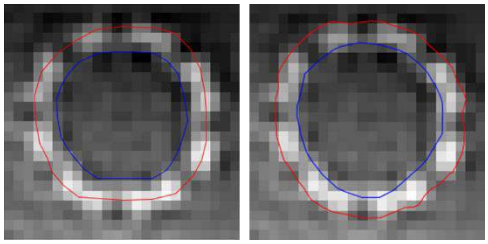

Figure 1: Comparison of a manually drawn (*left*) and automatically generated (*right*) aortic phantom wall mask.

RESULTS

Aortic DENSE strain analysis using the new semi-automatic segmentation approach took <10 minutes per phantom/volunteer, compared to ~2 hours for the standard manual method. Mean absolute differences in sector-wise circumferential wall strain between the manual and automated methods averaged ~2% for the phantoms, and 3-5% for the *in vivo* scans (**Table 1**).

Table 1: Mean circumferential strain, mean absolute difference in strain, and coefficient of variation (CoV) of the differences in strain calculated using manual vs. automated masks, and the percentage of total sectors with a normalized circumferential strain (NCS) difference between the methods below 33%.

	Phantom	IAA	DTA	DAA
Mean Strain (Manual)	0.08	0.15	0.10	0.10
Mean Abs. Diff.	0.023 ± 0.01	0.031 ± 0.01	0.047 ± 0.03	0.042 ± 0.01
CoV (Mean Diff.)	0.193 ± 0.07	0.182 ± 0.05	0.387 ± 0.07	0.376 ± 0.20
Sectors <33% NCS diff.	75%	81%	47%	56%

For the phantoms, 75% of total sectors differed by less than 33% normalized circumferential strain (i.e., 1/3 of the mean circumferential strain, ~3% strain) between the manual and automatic methods, with the most notable differences occurring in the left lateral wall region of Phantom 2 (**Figure 2**). For the *in vivo* scans, the automated method performed better in the IAA than the DTA and DAA (81% of sectors with a reasonable match compared to 47% and 56%). For the IAA & DTA, when the sectors bordering the aorta-vertebral interface were excluded from the analysis, the percent of sectors below the 33% normalized strain threshold increased to 88% and 50%, respectively.

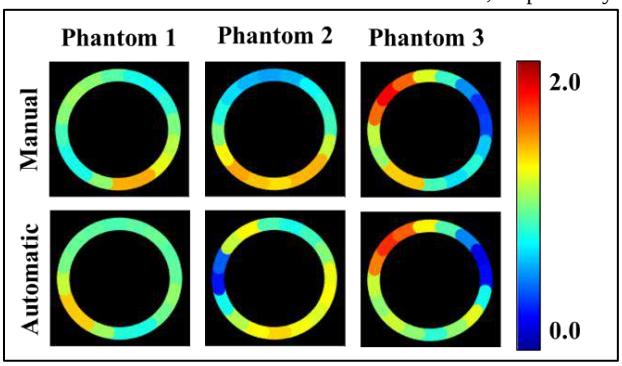

Figure 2: Normalized circumferential strain maps for three phantoms comparing strain results calculated using the manual and semi-automatic methods.

DISCUSSION

The new semi-automatic segmentation method reduced the time required to quantify patient-specific aortic circumferential wall strain using DENSE MRI by an order of magnitude (from ~120 minutes to <10 minutes); however, the reliability of the automated strain results suggests the need for further improvement to the semi-automatic segmentation. In comparison to the manual DENSE analysis, the new automated method performed reasonably in the majority of sectors in the *in vitro* phantoms and IAA, but only half of the sectors in the DTA and DAA. Notably, the motion of the thoracic aorta is more complex than the abdominal aorta due to the large motions of the heart that can displace and twist the aorta at these locations. In addition, wall segments along the aorto-vertebral interface in the IAA & DTA undergo little displacement (possibly due to local tethering), making them difficult to distinguish from non-moving periaortic structures like the vertebra and adjacent connective tissue. This may explain the slight improvement in results when excluding these regions.

Finally, the semi-automatic method currently uses initial voxel displacement data before phase unwrapping has been performed and is therefore sensitive to phase-wrap artifacts. Closer inspection revealed this was likely a major contributor to the elevated circumferential strain difference along the left lateral wall of Phantom 2, and may have also played a role in the *in vivo* data. Future efforts will be focused towards increasing the robustness of the elimination processes for outlying voxels on the adventitial surface of the masks (particularly along the aorto-vertebral interface) and incorporating phase unwrapping into the iterative processing. With these improvements, a rapid and reliable semi-automatic method for processing clinical aortic DENSE MRI may be attainable in the future.

INTRODUCTION

Bicuspid aortic valve (BAV) disease is considered the most common congenital heart disease, occurring in 0.5–2% of the population [1], where the aortic valve (AV) has only two rather than the normal three leaflets. Compared with patients with a tricuspid AV (TAV), BAV patients are more prone to develop ascending aortic dilation, or bicuspid aortopathy [2]. The exact cause of BAV aortopathy remains unclear, as both the genetic factors and biomechanical factors can play a role. Recent studies have found strong evidence that BAV aortopathy is different than Marfan patients which have proven genetic aortopathies [3]; on the other hand, there have been growing evidence that the abnormal hemodynamics in BAV could lead to altered regional wall shear stresses [4], the change in aortic wall histology [5], which could contribute to the disease progression.

Detailed investigation of biomechanical factors related with BAV aortopathy disease progression requires computational approaches. However, most of the previous computational models have been significantly limited by their inability to simultaneously solve the soft tissue mechanics and the fluid dynamics. Moreover, most studies were limited to idealized or simplified geometries of the leaflets, and did not considered the calcification in their analysis. Fully-coupled patient-specific fluid-structure interaction (FSI) models of BAV patients that solve the 3D time-dependent flow and large deformation of the valve tissue are not yet available.

With these challenges in mind, this study aimed to: 1) develop patient-specific BAV models, and validate the coupled function of the valve and hemodynamics with clinical imaging and echocardiography (echo) data, 2) investigate the relationship between the flow patterns in the ascending aorta and the BAV phenotypes, 3) compare the results between the rigid and flexible aorta, and evaluate the effect of the aortic wall elasticity on the hemodynamics in the ascending aorta.

METHODS

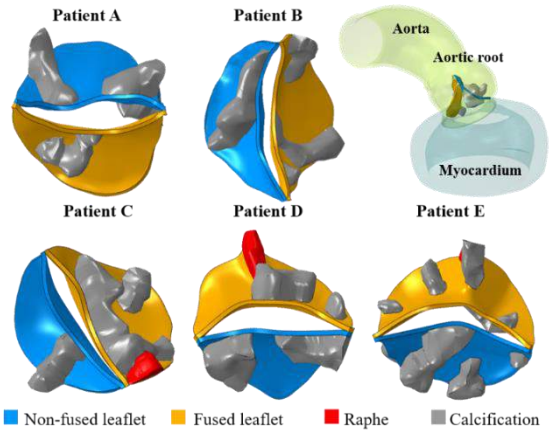

Figure 1: Patient-specific BAV models.

This retrospective study consisted of 5 BAV patients that underwent successful transcatheter aortic valve replacement (TAVR). BAV was classified using the Sievers system, based on the number of functional leaflets and presence of raphe: type 0, pure BAV with 2 leaflets and no raphe; and type 1, presence of one raphe [6]. The cardiac multislice computed tomography (MSCT) images, as well as the transthoracic echo examination were collected from Emory University Hospital (Atlanta, GA). The use of de-identified patient data for this study was approved by the Institutional Review Board. Patient-specific 3D models containing the BAV leaflets, raphe (if present), calcification, sinuses, ascending aorta, left ventricular outflow tract (LVOT) and proximal myocardium were constructed from the MSCT images using 3D solid elements (HyperMesh, Altair Engineering, Inc., MI), as seen

in Figure 1. Soft tissue mechanical behavior was characterized using the anisotropic hyperelastic modified Holzapfel-Gasser-Ogden model. Material properties were obtained in-house by fitting multiprotocol biaxial testing data of human cardiac tissues.

A previously validated FSI framework that combines smoothed particle hydrodynamics (SPH) for the blood flow, and nonlinear FE analysis for the tissue deformation [7, 8] was used to simulate the dynamics throughout the cardiac cycle. Time-dependent pressure boundary conditions were applied at the LV myocardium inlet and ascending aorta outlet. These waveforms were fitted to match the pressure values clinically measured for each patient. To evaluate the effect of aortic wall elasticity on the flow patterns, both fixed aorta and flexible aorta were used to developed the BAV model. For fixed aorta, the aortic root geometries were directly segmented from the MSCT images and were assumed static throughout the cardiac cycle. For flexible aorta, the unpressurized (stress-free) aortic root geometries were obtained using the generalized pre-stressing algorithm based on the MSCT images at mid-systole [9], and used as the initial geometries. Abaqus/Explicit (SIMULIA, Providence, RI) was used for all FSI simulations presented in this study.

RESULTS

Patients were between 57 and 82 years old. Sievers classification was type 0 in two patients and type 1 in three patients. The patient-specific FSI models were validated by comparing: 1) the deformed BAV leaflet geometries with the MSCT images (ground truth) at mid-diastole, and 2) the computed hemodynamic parameters with the clinical echo measurements. The average point-to-mesh error distance between the simulated and ground truth geometries was < 1.8 mm for all patients. Differences in the simulated and *in vivo* aortic peak velocity were < 10%.

For each BAV patient, systolic flow patterns were identified and analyzed using the 3D velocity field obtained from the FSI models. The streamlines at peak systole (Figure 2) showed two asymmetric recirculation rolls above the two BAV leaflets; in addition, helical flows were observed in the ascending aorta. The flow at the different cross-sections along the aortic root (Figure 3) showed eccentric jets at the level of sinotubular junction (STJ), and the counterclockwise secondary flow in the cross-sections which were associated with the right-handed helical flow structure. The flow patterns between the fixed aorta and the flexible aorta were qualitatively similar. The recirculation rolls within the fused sinuses were larger with the fixed aorta. In addition, the helical flow was stronger in the fixed aorta, which a higher peak velocity, and a more pronounced secondary flow.

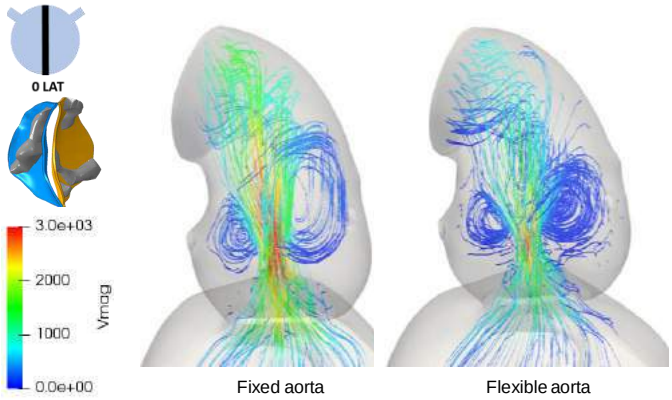

Figure 2: Representative BAV model (Patient B) showing streamlines at peak systole with a) fixed aorta, b) flexible aorta.

DISCUSSION

In this study, patient-specific FSI modeling in 5 BAV patients under various anatomic scenarios provided novel quantitative data about the 3D flow patterns in the aortic root. The accuracy and predictability of our FSI modeling framework were confirmed with pre-operative echo and imaging data. Additionally, this work provided mechanistic insights that led to better understanding of BAV aortopathy disease progression. While helical flow structures have been associated with ascending aortic aneurysms [11], it was found that even though all the five BAV patients in this study had normal size of aorta, abnormal eccentric jets and helical flows were still observed. This suggests that the abnormal flow patterns in BAV might not be secondary to dilated aorta, but could be the contributing factor to BAV aortopathy. In addition, the jet structures at peak systole were qualitatively similar between the fixed and flexible aorta, while the size and location of the recirculation flow above the sinuses, and the velocity magnitude showed some difference.

This study was small and retrospective, and would be enhanced through a larger, prospective evaluation of BAV patients, which is required to definitively establish the power of the computational simulations.

CONSTANT PRESSURE CED INFUSIONS WITH CONTROLLED CATHETER MOVEMENT IN AGAROSE GEL BRAIN TISSUE PHANTOMS

INTRODUCTION

Convection-enhanced delivery (CED) is a drug delivery technique that can be used to effectively bypass the blood-brain barrier and can be used in the treatment of brain tumors such as Glioblastoma. While this technique shows promise, the Phase III clinical trial (PRECISE) failed to show an advantage with CED treatment compared to the control arm [1]. A retrospective study found that the failure could be partially explained by an inability of catheters to distribute therapeutics in high enough quantities to treat the entire tumor and its margins [2]. To combat this we proposed the use of controlled catheter movement which was shown to increase the volume dispersed (V_d) of indigo carmine dye in an agarose gel brain tissue phantom by about 50% when catheters were continuously retracted [3]. This work along with most clinical trials relied on the use of syringe pumps that create a constant flow rate. But, one cause of the increase in V_d with controlled catheter retraction is a constantly growing surface area over which advection can occur. Since this surface area is growing, an increase in flow rate may be achievable throughout the infusion without causing reflux, a common occurrence with increased flow rate [4]. In the present work, we develop a controller to allow a syringe pump to be used as a constant pressure source and test the ability of constant pressure infusions coupled with controlled catheter movement to increase the V_d in agarose gel brain tissue phantoms.

METHODS

Controller: A PID controller was implemented to control infusion line pressure, measured at the needle inlet (P_N in Figure 1) by updating the flow rate of a programmable syringe pump. In the absence of a reliable plant model, the system was tuned experimentally using data obtained from the stationary, constant flow rate experimental group. The mean of 5 pressure response curves were used to determine a plant model using the system identification toolbox in Matlab (version R2018a, MathWorks Inc., Natick, MA). This model was then used to tune a PID controller with a design focus toward reference tracking. This focus was chosen in order to limit overshoot as excessive overshoot could result in the creation of reflux. The resulting controller was then implemented in a custom LabView program to control the flow rate of a programmable syringe pump. Pressure measurements were recorded once a second and flow rate was updated on the same interval.

Experimental Setup: A 23.5 cm catheter was fabricated by gluing a fused silica capillary tube (150 µm ID/ 350 µm OD) into a 20 G plastic dispensing needle. As shown in Figure 1, the catheter was then clamped to a deployment mechanism driven by a leadscrew attached to a stepper motor. Next, the catheter was connected to a t-connector, one end of which was attached to a pressure sensor, the other end was attached to

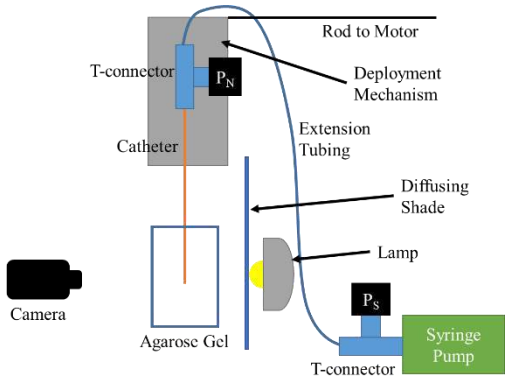

Figure 1: Schematic of experimental setup with P_N and P_S representing the locations of the pressure sensors.

a micro bore extension tubing which was connected to another t-connector with a second pressure sensor (P_s) on one arm and a 3 mL syringe on the third arm. Finally, the syringe was inserted into the syringe pump which was used to create the desired flow rate.

Infusions of 1% (wt./wt.) indigo carmine dye were performed in 0.6% (wt./wt.) agarose gel brain tissue phantoms for a total of 100 minutes per infusion. Optical images were acquired once per minute and were used to measure the V_d of each infusion in a similar fashion to previous work [3, 5]. In addition, infusion line pressure was sampled at 2 kHz and the mean pressure was recorded once per second. Four experimental groups with 5 replicates were evaluated: 1) stationary, constant flow rate (Sta. CF), 2) controlled retraction, constant flow rate (Ret CF), 3) stationary, constant pressure (Sta. CP), and 4) controlled retraction, constant pressure (Sta. CP). The constant flow rate was chosen to be 1 µL/min and the constant pressure was chosen to be the average pressure of the stationary, constant flow rate infusions, 977 Pa. Finally, the controlled retraction rate was 0.25 mm/min resulting in a total retraction distance of 25 mm.

RESULTS

As shown in **Table 1**, the controlled retraction catheter with a constant infusion line pressure of 977 Pa resulted in a nearly 130% increase in V_d compared to both the constant pressure and constant flow rate stationary catheters and an over 50% increase in V_d compared to the controlled retraction constant flow rate catheter. Further, the controlled retraction constant flow rate catheter had a 46% increase in V_d compared to the stationary constant flow rate catheter. Finally, the stationary constant pressure catheter resulted in nearly the same V_d as its constant flow rate counterpart, but was about 1.6% lower. Figure 2 shows the average pressure (**a**) and average flow rates (**b**) of all four groups, and reveals the decrease in pressure and subsequent increase in flow rate over time with the constant flow rate controlled retraction catheter.

Table 1: Results from infusions in agarose gel (n=5).

Group	V_d (mL)	V_i (mL)	V_d:V_i	Avg. Pressure (Pa)	Avg. Flow Rate (µL/min)
Sta. CF	1.0 ± 0.04	0.1	10.4 ± 0.4	976.7 ± 160.3	1
Ret. CF	1.5 ± 0.11	0.1	15.1 ± 1.1	309.7 ± 196.5	1
Sta. CP	1.0 ± 0.09	0.11 ± 0.01	9.3 ± 1.4	967.1 ± 93.1	1.1 ± 0.1
Ret. CP	2.4 ± 0.17	0.24 ± 0.01	9.8 ± 0.8	945.7 ± 89.4	2.4 ± 0.4

DISCUSSION

While the addition of controlled catheter retraction results in a significant increase in V_d of 46-50% [3] compared to a stationary catheter, the addition of constant pressure with the controlled retraction appears to more than double this advantage. What is more, the use of constant pressure infusions allows for time varying infusion flow rates which not only could increase the amount of drug infused (and likely the V_d) but it can also be used to minimize reflux of the infusate up the needle tract. Commonly, the magnitude of flow rate has been used as the metric to predict whether reflux would occur as flow rate is the usual controllable parameter for CED infusions [4]. However, it is most likely that a critical infusion pressure resulting in tissue deformation would result in reflux, as reflux is believed to be the result of the creation of an annular gap between the catheter and the tissue due to tissue deformation [6-8]. While infusion line pressure is not a perfect representation of actual infusion pressure, prescribing infusion line

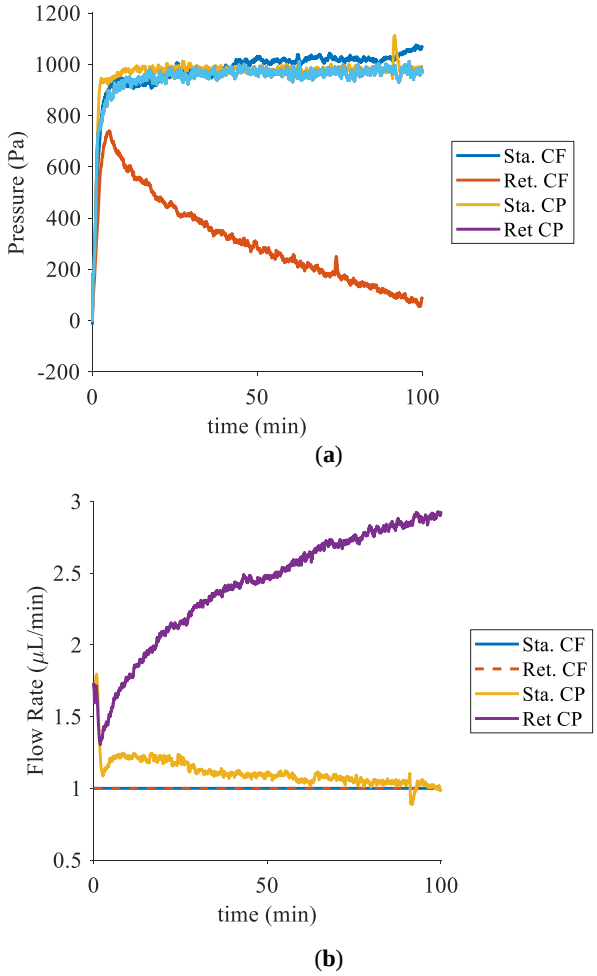

Figure 2: Plot of (a) average pressure over time and (b) average flow rate over time for Sta. CF, Ret. CF, Sta. CP, and Ret. CP (n=5 each).

pressure near but below a critical reflux inducing pressure may have significant benefits in increasing the overall V_d, especially when catheter movement or other catheter control is used. It should be noted however, that real time imaging will be an extremely important component in these systems as reflux could also result in a drop in measured pressure which would have negative consequences in a constant pressure system if intervention does not occur. Lastly, the limitations of agarose gel brain tissue phantoms should be acknowledged as it is a homogeneous material and does not fully replicate infusions in tissue.

INTRODUCTION

Mitral regurgitation (MR) is the most common valvular heart disease, with a prevalence of 9.3% in the US population aged 75 and above [1]. Although Doppler echocardiography (echo) is the primary clinical tool to evaluate MR severity, MR quantification remains challenging, and a true gold standard technique is still missing [2]. With the recent advent of 3D color Doppler imaging, vena contracta area or VCA method has drawn more attention in MR quantification [3,4], however, there still lacks an in-depth analysis based on the fundamental theoretical background of VCA. The clinical studies are often limited by the lack of a robust reference value (gold standard) for MR quantification. *Ex vivo* bench experimental studies are also challenging due to the complexity of experimental setups (e.g., beating heart conditions) and the difficulty to obtain the detailed interrogation of the MR flow field crossing the mitral valve (MV).

Recent advances in patient image-based computational modeling, on the other hand, have substantially enhanced the investigation of patient-specific cardiac dynamics. In particular, a patient specific fluid-structure interaction (FSI) computer framework has been applied to study valvular functions under a variety of physiologic, pathologic states, including the echo measurement for MR [5], where the FSI models were able to replicate the patient-specific flow field inside the left heart, and can be treated as a phantom model for systematical quantification of different sources of errors in echo measurements.

Therefore, in this study we will investigate the accuracy and reliability of VCA in functional MR (FMR) using FSI models, from which the reference values of mitral regurgitation flow rate and regurgitant volume can be directly obtained. The virtual VCA measurements were then performed on the same phantom models assuming optimal echo probe angulation and positioning. By comparing the results obtained using VCA methods with the reference values, the accuracy of different VCA methods will be evaluated, and the multiple sources of errors in VCA method will be analyzed and quantified.

METHODS

FSI models: Five FSI models for FMR patients were created, validated and treated as phantom models. The first model was a previously validated patient-specific left heart FMR computer model based on a 71-year-old male patient [6, 7] (data collected under the Institutional Review Broad approvals). The other four FMR models were computationally created from the first model by displacing the papillary muscles (PM) apically and laterally, replicating a type IIIb lesion with restricted leaflet motion [8].

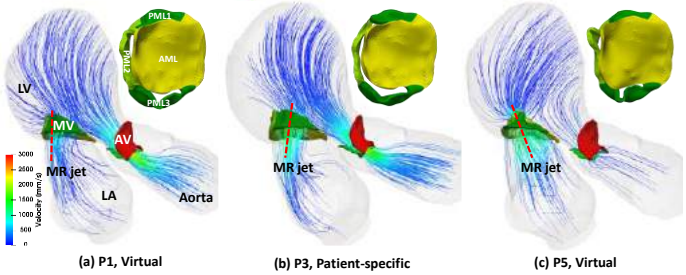

Figure 1. The velocity field of three representative FMR computer models (P1, P3, and P5) ranging from mild to severe MR.

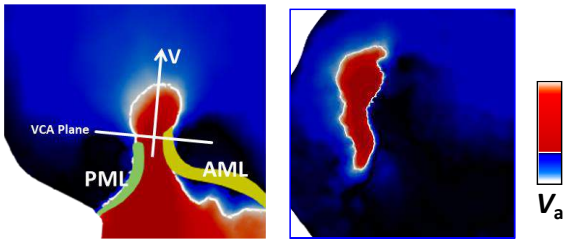
Reference values: The phantom models have fully resolved and detailed flow fields (Figure 1) in the left atrium (LA), left ventricle (LV) and cross the mitral valve, from which the reference values of mitral regurgitant flow rate and regurgitant volume can be obtained. Specifically, the reference MV regurgitant volume RV_{MV} was obtained by integrating the negative MV flow rate over systole. The regurgitant

fraction $RF_{MV} = RV_{MV}/SV_{LV}$ was used to grade MR severity, where $SV_{LV} = SV_{AV} + RV_{MV}$ is the total stroke volume (SV) of the LV.

Virtual echo acquisition and VCA measurement: The velocity field obtained directly from FSI models (Figure 1) is referred to as the "true velocity", while the velocity field used for virtual echocardiographic data acquisition is referred to as the "Doppler velocity". Due to the Doppler angle effect [2], the virtual echo only measures the velocity component aligned with the ultrasound beam. Therefore, the Doppler velocity field was obtained by projecting the true velocity field along the direction of the ultrasound beam. To emulate VCA method, we will identify the narrowest location of the regurgitant jet at peak systole on color Doppler with aliasing velocity V_a (Figure 2a), then rotate the third cropping plane normal to the jet orientation, and measure the effective regurgitant orifice area (S_{VCA}) directly on the cropping VCA plane (Figure 2b). The regurgitant volume RV_{MV} can then be calculated as $RV_{MV} = S_{VCA} \times VTI_{MR}$. The velocity time integral VTI_{MR} of the regurgitant jet were obtained by emulating continuous wave Doppler (CWD) measurements with the virtual ultrasonic probe parallel to the jet in an optimal position.



(a) (b)

Figure 2. Schematic showing (a) MR jet of velocity V across VCA plane; (b) measurement of VCA area (in red) on VCA plane. AML-anterior mitral leaflet, PML-posterior mitral leaflet

RESULTS

The reference values were obtained directly from FSI models. Patient 1 (P1) and P2 have mild-moderate MR, P3 has moderate-severe MR, while P4 and P5 have severe MR (Table 1). To evaluate the accuracy of the VCA method, the regurgitant volumes obtained with VCA measured at peak MR were compared with the reference values using Bland-Altman analysis (Table 2). For comparison, the same analysis was performed for the 3D PISA method on the same FSI models [9], which was found to be the most accurate PISA method. The VCA method showed a significantly smaller bias (-1.3 ± 3.3 ml) than that of the 3D PISA method (-12.7 ± 7.8 ml) for the quantification of regurgitant volume.

Table 1. Patient (FMR FSI model) information.

Patient	P1	P2	P3	P4	P5
SV_{AV} (ml)	55.65	51.02	46.28	33.71	21.52
SV_{MV} (ml)	74.59	75.58	74.64	77.26	75.61
RV_{MV} (ml)	27.68	32.61	37.59	51.62	62.69
RF_{MV} (%)	33.22	38.99	44.82	60.50	74.45
MR Severity (Based on RF_{MV})	Mild-moderate	Mild-moderate	Moderate-severe	Severe	Severe

Table 2. Results of Bland-Altman analysis for RV_{MV} quantification using both VCA method and 3D PISA method.

Method	Mean bias (ml)	Limits of agreement (ml)
VCA	-1.3	[-4.6, 2.0]
3D PISA [9]	-12.7	[-20.4,-4.9]

DISCUSSION

In this study, five FSI models of FMR were used to evaluate the accuracy of VCA method for MR quantification. Based on fundamental fluid mechanics principles, the instantaneous regurgitant flow rate through VCA is $Q_{MR} = \int_s V_n dS$, where V_n is the *normal* component of the true velocity V across VCA. The simplified expression $Q_{MR} = V_{MR} S_{VCA}$ used in VCA method will therefore only be accurate when $V_{MR} = V_n$ over the entire VCA plane, which is not always the case. Due to the Doppler angle effect, the velocity of the MR jet detected by echo $V_{MR} = V\cos\theta$ underestimates the true velocity V, where θ is the "Doppler angle" between the direction of flow and the ultrasound beam. On the other hand, only the normal component $V_n = V\cos\gamma$ will contribute to the flow rate across VCA, where γ is the angle between the flow direction across VCA and the normal direction of VCA plane. As $V_{MR} = V_n\left(\frac{\cos\theta}{\cos\gamma}\right)$, the underestimation due to the Doppler angle θ, and the overestimation due to the flow direction angle γ compensate each other. In addition, since the ultrasound beam is aligned with the MR jet, and the VCA plane is cropped normal to the MR jet, both θ and γ are close to zero. This is why VCA method tend to be more accurate than PISA method, as θ and γ could deviate significantly from zero in PISA method. However, the accuracy of VCA method is directly affected by the selection of the aliasing velocity V_a, as the VCA area will increase (or decreases) with a smaller (or larger) aliasing velocity. In this study, the aliasing velocity is selected as one third of the peak MR velocity.

For the quantification of regurgitant volume, an additional source of error is due to the dynamic feature of the regurgitant orifice, especially in FMR [10,11]. The calculation based on a single measurement at peak MR ignores the dynamic variation of the regurgitant orifice, therefore can lead to either over- or underestimation of MR.

This study focused on FMR of type IIIb lesion with restricted leaflet motion. Other types of FMR such as type I MR with normal leaflet motion have not been investigated. Additionally, the effect of the aliasing velocity settings on the VCA method was not investigated. These warrant a future study. Virtual echo represents an ideal measurement with optimal positioning and angle of the echo probe, hence certain sources of error for clinical echo such as reverberation artifacts and shadowing were not incorporated.

INTRODUCTION

Despite more than a century of research, one of the most fundamental questions in biology: "How is tissue built? [1]" remains unanswered. Understanding extracellular matrix (ECM) assembly is critical for connective tissue engineers who are trying to produce or induce load-bearing structures but cannot point to a viable mechanistic model of organized matrix morphogenesis. Collagen, the principal structural molecule in vertebrates, is generally produced and secreted by fibroblasts, and then assembles to form fibrils through a process known as fibrillogenesis [2]. Collagen fibrils are further processed into fibrillar structures and organized into macroscale tissues by mechanisms that are not well-understood.

Our current understanding of collagen assembly is derived primarily from electron microscopy images of ECM formation. Based on interpretations of these static images, it has been suggested that fibrillogenesis occurs within cell surface crypts or invaginations and that fibrils are then released from the cell into the ECM [2],[3],[4]. Recent revisions to this concept suggest that tensional forces are critical to formation of fibrils in these putative fibril depositors [4] and that, for the cornea in particular, fibrils form on the outside of cell extensions or keratopodia [5]. However, it is difficult to confirm or reject any hypothesis of matrix assembly using static images alone. Indeed, recent data suggests that fibrillogenesis is a highly dynamic process [6]. Even sophisticated, high-resolution serial block face SEM imaging tells us little of the dynamics of fibril formation. To access fibril assembly dynamics requires live cell dynamic imaging at high resolution and the ability to resolve the formation of nanometer scale fibrils, without affecting their formation kinetics. No study to date has combined all of these requirements to expose collagen fibrillogenesis in real-time. In this study we have examined a model of human corneal development during the critical period of matrix production to elucidate the dynamics of collagen fibril formation for the first time.

METHODS

Primary Human Corneal Fibroblast (PHCF) cultures were established from 74yr donor corneas as described in Bueno *et al*. [7]. Briefly, donor corneas were cut into 2x2 mm pieces, adhered to 6well dishes, and were cultured in Dulbecco's modified eagle medium containing 10% fetal bovine serum and 1% antibiotic/antimycotic until PHCF migrated off and were expanded. PHCF were seeded on temperature-controlled dishes at passage 3 at a concentration of 30,000 cells/cm^2. Once confluent on Day 3, 0.5mM L-Ascorbic Acid was added to permit the culture to construct a 3D matrix of orthogonal cell layers.

Acid soluble type I bovine collagen (TeloCol, #5225, Advanced BioMatrix) was labeled with Alexa Fluor 488 (AF488) to be added exogenously to the PHCF culture. Briefly, 2 mg/mL TeloCol was adjusted to pH 7.5 and mixed with AF488 in a 1:2 collagen:dye molar ratio. The degree of labeling (moles of AF488 per mole of collagen monomer) was measured as 0.9.

1.5 mL of CO_2 infused media containing 0.5 mM L-ascorbic acid and 1 µg/mL AF488-col was added to the cells at timepoints ranging from day 3 to day 8. The culture was imaged using 600x differential interference contrast microscopy by taking a photo every 5 seconds.

To analyze the live cell images, the following equations were used:

PHCF Velocity of Cellular Contraction Calculation:

$$v_{cellular\ contraction} = \frac{\Delta L}{\Delta t} \quad (1)$$

PHCF Filament Extensional Strain Rate Calculation:

$$\dot{\varepsilon} = \frac{\Delta L / L_o}{\Delta t} \quad (2)$$

Where *Lo* is the initial length of the filament and *ΔL* is the change in filament length. 42 filaments were measured, and were assumed to have cylindrical geometry, constant volume, and experience radial thinning.

RESULTS

Fibrillar Network Evolution: Within 5 minutes after the addition of AF488-col, AF488 was primarily concentrated in vesicles within the cell, trafficked through the cell in a parallel direction to ECM fibers, and also associated with the pre-existing fibril network (Figure 1). Vesicles containing AF488-col moved constantly within cell body and keratopodia, with the highest recorded vesicle velocity being 7.28 µm/min. Over a period of 48 hours, there was an evolution of the fibrillar network containing AF488-col (Figure 1). Overall, there appears to be a transfer of labeled collagen from cell vesicles to the extracellular fibrillar network.

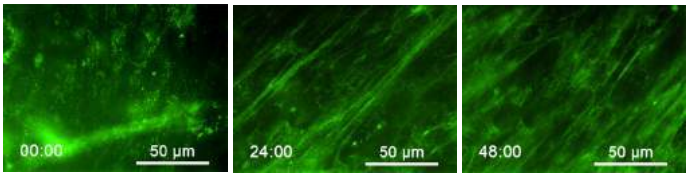

Figure 1: 74yr PHCF, 1.5µg AF488-col added D6 at T=0HRS

Rapid Cellular Contraction Events: Cells and cell processes were continually connecting between cells and rapidly contracting, often forming trailing and persistent filaments. These contraction events were categorized as bubbling keratopodia, non-bubbling keratopodia, parallel to cell axis, and perpendicular to cell axis (Figure 2).

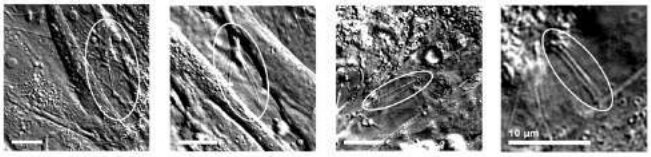

Figure 2: DIC Images of 74yr PHCF Cellular Contraction Events Left to Right: Bubbling Keratopodia, Non-Bubbling Keratopodia, Parallel to Cell Axis, Perpendicular to Cell Axis

Keratopodia, the sites of fibril formation in corneal development [5], were continually connecting one cell to another at multiple adjacent sites in a starburst configuration. Some keratopodia attachment sites also exhibited dynamic bubbling with high velocities and extensional strain rates. Figure 3 shows this event, where bubbling cell material contracts, forming a starburst of keratopodia that are rapidly stretched. The plot shows the corresponding velocity of this contraction, and the extensional strain rate on the thinning keratopodia.

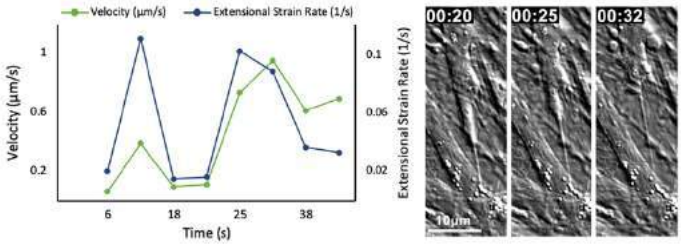

Figure 3: Plot of Cellular Contraction Velocity and Filament Extensional Strain Rate, and DIC Images of 74yr PHCF Bubbling Keratopodia Cellular Contraction

Smaller cell processes and lamellae were also formed between contracting cells in a parallel or perpendicular fashion. The maximum velocities for all pull types were significantly larger than the average cell nucleus velocity ($p<0.05$) (Figure 4). As the cells contracted, the persistent filaments stretched and thinned, with 7 out of 42 exhibiting extensional strain rates within the range of 0.1 and 0.3 s^{-1} (Figure 4), which may be sufficient for collagen fibrillogenesis given a concentrated collagen solution [8].

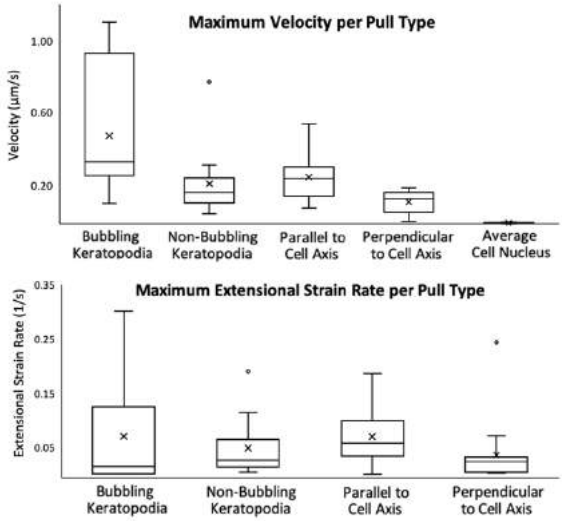

Figure 4: Plots of Velocities and Extensional Strain Rates for Four Types of Cellular Contractions

DISCUSSION

Our investigation has revealed a number of novel phenomena. The first is the near immediate internalization and trafficking of our AF488-col within the cell body and extensions. The second is the association of the label with the extant network, upon introduction and apparently after trafficking within the cell. The third discovery is the continuous application of forces from one cell to another through rapid contractions and the characterization of four distinct cellular contraction types. It is clear that tensile force, applied between cells, is an important part of the process of cell/matrix organization in this model system. Contraction velocities of the cell extensions were often more than 100 times faster than average cell nucleus velocities suggesting a critical function unrelated to locomotion. It is not yet clear if collagen is associated with these persistent filaments, however the contractions cause extensional strain rates sufficient to induce collagen fibrillogenesis [8], [9].

Taken together, our observations support a mechanochemical mechanism of matrix assembly whereby tensile forces produce extensional strains that initiate and sustain the growth of mechanosensitive filaments (perhaps fibronectin/collagen co-fibers [9]) directly in the path of the force that created them.

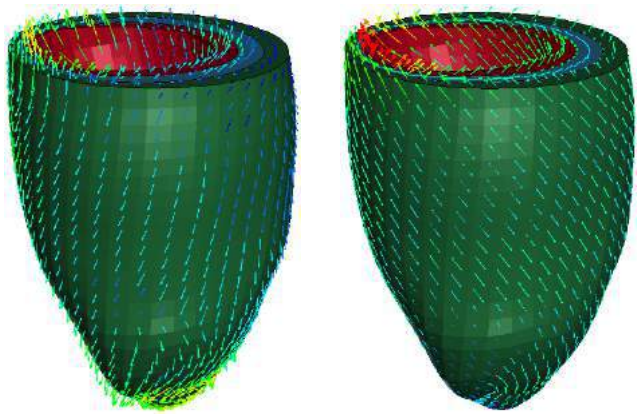
INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a genetic cardiac disease, characterized by the thickening of the left ventricular (LV) walls, fibrosis, and myofiber disarray. A study performed by Tseng et al. suggests that fiber disarray contributes to impaired passive and active cardiac function in HCM patients [1]. Current cardiac models are capable of simulating the mechanical and structural properties of the left ventricle, as well as volumetric growth and remodeling of the cardiac tissue. However, to the knowledge of the authors, none of the current cardiac models simulating HCM incorporate the remodeling of cardiac myofibers.

This omission is partly due to the fact that the mechanisms related to fiber orientation in the heart are yet still unclear, and few adaptative laws have been created to explore these mechanisms. Kroon et al. developed an adaptative orientation law based on stretch to accomplish reorientation [2]. This stretch-based law aimed to reduce circumferential-radial shear strain and achieved realignment in the principal strain directions. However, the strain-based approach is not sufficient to reproduce the fiber orientations found in the human heart. Based on observations of the principal stress and principal strain distributions in a previous LV model from our group, which did not include fiber remodeling, it was shown that the fibers throughout the cardiac cycle are very closely aligned with the direction of maximum principal stress (Figure 1). This is the motivation for implementing and investigating a stress-based remodeling law, which is then compared to the strain-based law from Kroon et al. The goal of this abstract is to present a novel stress-based fiber reorientation law and compare to the previous strain-based law.



(a) (b)

Figure 1: Finite element model of the left ventricle comparing (a) principal strains and (b) principal stresses at end-systole.

METHODS

Reorientation Laws The reorientation law presented by Kroon et al. [2] uses the right stretch tensor to evolve the fiber orientation:

$$\frac{de_{f,0}}{dt} = \frac{1}{\kappa}\left(e_f(U) - e_{f,0}\right) \quad (1)$$

where $e_{f,0}$ is the fiber orientation in the reference configuration and e_f is the fiber orientation in the current configuration after correction for rigid rotation. The term κ is a rate constant used to adjust the rate of evolution. We developed a stress-based reorientation law which uses the first eigenvector of the second Piola-Kirchhoff stress tensor, e_g, to evolve the fiber orientation:

$$\frac{de_{f,0}}{dt} = \frac{1}{\kappa}\left(e_g(S) - e_{f,0}\right) \qquad (2)$$

where S is the second Piola-Kirchhoff stress tensor.

Uniaxial Simulations The mesh and finite element (FE) analysis were performed using the FEniCS platform. A unit cube mesh consisting of 6 second-order Lagrangian tetrahedrons was generated using built-in functions. The left face normal to the x-axis was constrained to remain in the yz plane, and a displacement boundary condition was applied to the opposite face. One of the faces normal to the z-axis was constrained to remain in the xy plane, in order to avoid rigid body motion. For all cases presented in this abstract, the mesh was subjected to a uniaxial stretch along the x-axis. A local orthogonal coordinate system $\{\mathbf{f}_0, \mathbf{s}_0, \mathbf{n}_0\}$ is defined using the prevailing fiber, sheet, and sheet-normal directions, respectively.

For the initial period of time of the simulation, no deformation is applied, after which uniaxial stretch is incrementally applied over a given interval of time. Once the deformation phase is complete, the appropriate reorientation law is activated, and the simulation is run until the fiber reorientation is completed to steady state. The Guccione transversely isotropic constitutive law is used for material properties of the cube [3]. The weak form of the balance of linear momentum is solved using a built-in Newton solver withing FEniCS.

Two sets of simulations were run to compare the strain-based law and stress-based law. The first set of simulations compare the resulting fiber orientations when each reorientation law is applied to fibers initialized at 0 degrees. The second set of simulations differ from the first set only in regards to the initial fiber orientation being assigned to 70 degrees.

RESULTS

Neither reorientation law resulted in reorientation when the fiber orientation was initialized at 0 degrees, i.e. the fibers remain oriented along the x-axis over the duration of the simulation. The deformation was uniform and uniaxial for both the stress-based law and the strain-based law.

Differences in final reorientation were observed between the stress- and strain-based laws when the fiber orientation is initialized at 70 degrees (Figure 2). The strain-based law results in a final orientation which corresponds with the direction of applied stretch, i.e. along the x-axis. Again, the deformation pattern is uniform and uniaxial along the x-axis. The stress-based law, however, results in a final fiber orientation approximating 45 degrees. The deformation pattern resembles a simple shear deformation.

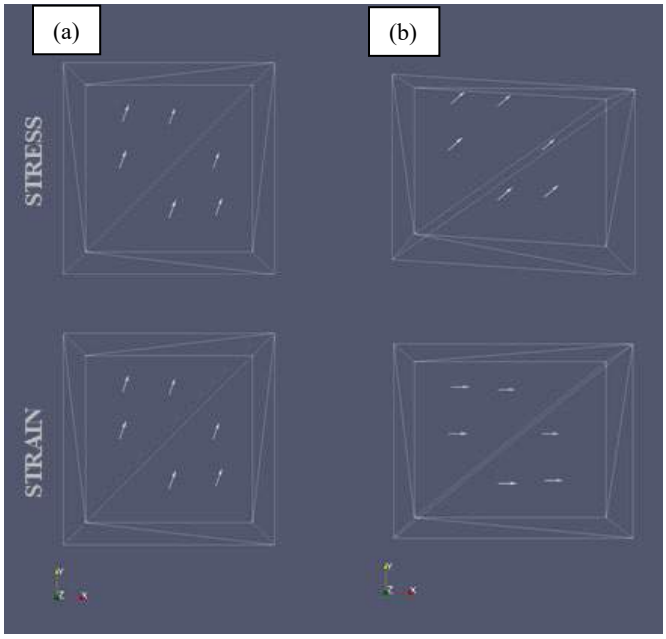


Figure 2: Simulations of uniaxial stretch cases with fibers initialized at 70 degrees (a) before and (b) after the application of the stress and the strain reorientation laws. The arrows represent the fiber orientation in each element.

DISCUSSION

To the best of the authors' knowledge, this preliminary work presents a novel stress-based fiber reorientation law. This work reveals a key difference in the two reorientation laws and demonstrates the potential for the use of stress as a primary signal for fiber remodeling. The difference in fiber reorientation seems to be due, in large part, to the transversely isotropic nature of the material. Since such a material has a direction of maximum stiffness, cases of loading and fiber orientation emerge in which the principal stretch direction and principal stress direction do not coincide. Future work will include a more complex range of loading and geometric cases, which will further elucidate the effect of a stress-based reorientation law. Ultimately, this work confirms the potential for the incorporation of a stress-based law into a LV model to more fully represent the structural state of the HCM heart, and to explore the mechanism behind the development of myofiber disarray.

INTRODUCTION

Advanced Heart Failure (HF) affects more than 6 million people over the age of 20 within the United States [1], where the patient's heart is unable to pump blood to support normal circulation. Left Ventricle Assist Device (LVAD) provides mechanical circulation support in HF patients by shunting blood from dysfunctional left ventricle using a pump directly into the aorta. LVADs have emerged as the primary treatment modality for HF - as a *bridge to transplant* when donor heart is not available and also as a *destination therapy* when a patient is ineligible for heart transplantation due to other medical conditions [2]. LVAD therapy is frequently associated with serious complications such as stroke and thrombo-embolic events, gastrointestinal bleeding, and aortic insufficiency. These complications are reckoned to be intimately related to the altered state of hemodynamics as the LVAD bypasses flow into the aorta. Several existing studies have looked into LVAD outflow graft anastomosis as a key determinant for hemodynamic status [3]. However, with continuous flow LVAD designs, the lack of flow pulsation, the physiological benefits of pulsation, and pulse-modulation of LVAD flow could be key hemodynamic drivers [4] which have received lesser attention [5]. Here, we study flow in the aortic arch and abdominal aorta as function of pulsatile LVAD flow modulation, with the aim of elucidating the role of pulsation in LVAD flows.

METHODS

Hemodynamics simulation: A patient-specific model of the aorta from the aortic valve outlet to the ilio-femoral branches was obtained from approved patient CT images [6, 7]. A model LVAD outflow graft (diameter: 1.0 cm) was virtually attached to the ascending aorta at an incident angle 45° towards the aortic valve. Blood was assumed to be a Newtonian fluid with density 1.06 g/cm^3 and dynamic viscosity 0.04 $g/(cm \cdot s^2)$. The incompressible Newtonian fluid mass and momentum balance equations were numerically solved using a stabilized finite element method implemented in SimVascular [7]. Baseline flow simulations without an implanted LVAD were driven by a pulsatile flow imposed at the aortic inlet with a Womersley-type profile. Corresponding LVAD flow simulations imposed a specified profile at the outflow graft inlet, keeping the aortic inlet sealed. All remaining outflow boundary conditions were specified as three-element Windkessel conditions, with resistance and capacitances held the same between baseline and LVAD flow computations. Three LVAD inflow profiles with successively increasing extent of pulse modulation were chosen for this study [8] (see Fig: 1). All flow profiles have a mean of 5.0 L/min equivalent to the normal cardiac output for the baseline model.

Flow descriptor quantification: Based on the resultant flow velocity field, the extent of helical flow was quantified using Local Normalized Helicity (LNH), described as a scaled version (ranging between -1 and $+1$) of the pointwise flow helicity value as follows:

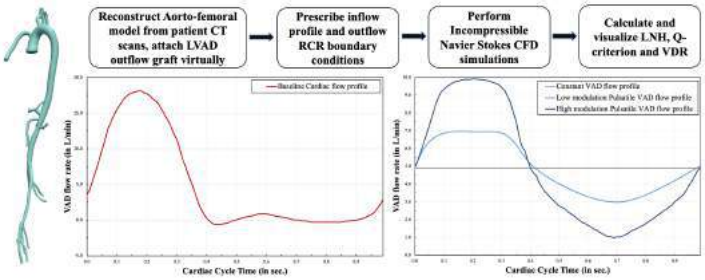

Figure 1: Hemodynamics modelling workflow (top); Baseline(natural) flow profile and LVAD flow profiles used in simulation (bottom); Virtual Aorto-femoral Model with LVAD outflow graft towards aortic valve (left corner).

$$LNH = \frac{\boldsymbol{u} \cdot (\nabla \times \boldsymbol{u})}{\| \boldsymbol{u} \| \| \nabla \times \boldsymbol{u} \|} \tag{1}$$

In addition, the extent of vortex generation in the flow was quantified using isosurfaces of the Q-criterion to identify vortical structures in the flow.

Estimation of viscous dissipation: Viscous dissipation rate is estimated using the localized fluid energy balance equation stated as follows:

$$\rho \frac{De}{Dt} = \underbrace{\boldsymbol{\tau} : \boldsymbol{\nabla u}}_{\text{Stress power}} + \underbrace{\boldsymbol{\nabla} \cdot \boldsymbol{q}}_{\text{Surface heat flux}} + \underbrace{\rho \phi_h}_{\text{Heat sources/sinks}} \tag{2}$$

The stress power term above incorporates contribution from all internal mechanical forces, and is the basis for estimating viscous dissipation. The stress power for a Newtonian constitutive relation can be written as a combination of volumetric deformation and viscous contributions - where the former is zero for incompressible flows, and the latter yields the viscous dissipation rate (VDR) as stated below:

$$\tau_{ij} \frac{\partial u_i}{\partial x_j} = \tau_{ij} \epsilon_{ij} = \underbrace{-p \boldsymbol{\nabla} \cdot \boldsymbol{u}}_{\text{volume deformation}} + \underbrace{2\mu \epsilon_{ij} \epsilon_{ij} - \frac{2}{3} \mu (\boldsymbol{\nabla} \cdot \boldsymbol{u})^2}_{\text{viscous effects}} \tag{3}$$

$$\boldsymbol{\nabla} \cdot \boldsymbol{u} = 0 \Rightarrow \tau_{ij} \epsilon_{ij} = VDR = 2\mu \epsilon_{ij} \epsilon_{ij} \tag{4}$$

where μ is the dynamic viscosity of blood, and ϵ_{ij} are the components of the rate of strain tensor: $\boldsymbol{\epsilon} = 0.5 \left(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T \right)$. For this study, we computed the pointwise VDR estimate, as well as computed a volume integrated VDR for the aortic arch and branching vessels; and the abdominal aorta and branching vessels.

RESULTS

Influence of pulsation on flow features: In Figure 2 panel a, isosurfaces at ± 0.20 of LNH values averaged over one cardiac cycle are shown for *constant*, *low-pulsation*, and *high-pulsation* cases. Panel b presents the instantaneous LNH isosurfaces at ± 0.80, taken at $t = 0.18\ sec$ (peak systole) respectively. These are compared against the corresponding baseline values, and we observed that pulse-modulation retains a helical flow in the aortic arch but the spatial variation of helical flow patterns show differences with increasing pulsation. This is a consequence of the impingement of the jet flow emanating from the LVAD outflow graft onto the aorta wall. This is further illustrated via the Q-criterion isosurfaces in the aortic arch at peak systole shown in Figure 2 panel c. The Q-criterion values are normalized by the peak Q-value for the baseline case. The illustration clearly shows a significant increase in the extent of vortical structures with pulse-modulation, as the increased pulsation with fixed mean flow leads to a faster LVAD jet impinging on the wall. Further, reduced vorticity near aortic inlet in constant and low-pulsation cases indicate presence of a region of flow stasis, which was observed to reduce with increase in pulsatility.

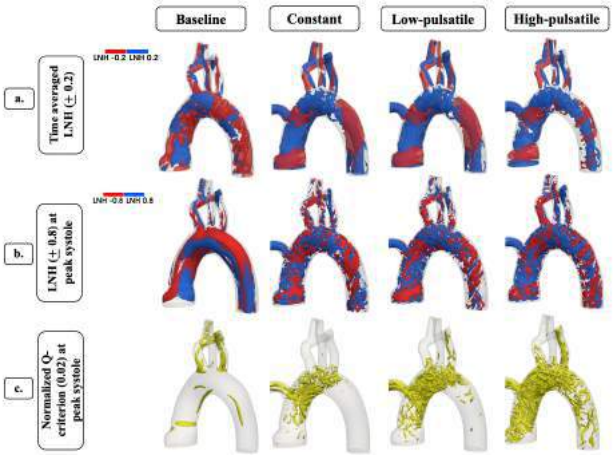

Figure 2: Time averaged LNH isosurfaces at ± 0.2(a); Peak systole LNH isosurfaces at ± 0.8(b); Normalized systole Q-criterion isosurfaces at 0.02(c).

Influence of pulsation on energy dissipation: Volumetric visualization of VDR iso-surfaces in the range 2×10^4 to 10^5 $g/(cm \cdot s^3)$ for varying extent of pulse-modulation are presented for the aortic arch in Figure 3, panel a. Panel b represents similar VDR iso-surfaces viewed for the abdominal aorta (until immediately after the renal arteries). For each of these vascular regions, the corresponding VDR isosurfaces for the baseline case are also provided for comparison. Volume integrated values of the time-averaged VDR for the entire aortic arch region, and the abdominal region (including the branching vessels) are provided in Figure 3 panel c. These results indicate that all LVAD induced flows have significantly higher dissipation in the aortic arch, and significantly lower dissipation in the abdominal aorta region, as compared to the baseline case. It is also observed that viscous dissipation increases with an increase in pulsation of LVAD flow, with the changes in dissipation in the aortic arch being more pronounced. This can be also attributed to the jet impingement from the LVAD outflow graft, where higher pulsation increases the extent of dissipative vortical structures in the aortic arch which contribute to the net viscous dissipation. This aspect is further illustrated in Figure 4, where time-averaged VDR values normalized with those for the baseline case, are plotted along the centerline of the aortic arch (panel a) and the abdominal aorta (panel b) for *constant*, *low-pulsation*, and *high-pulsation* cases. We observe that within the ascending aorta and aortic arch region, the VDR values peak in the LVAD jet impingement zone, with the maximum values being around 1000 times higher than corresponding baseline case. At locations away from the impingement zone, the VDR values become comparable to those of the baseline case - including in the abdominal aorta (deviating within a factor of $0.1 - 10.0$ of the baseline VDR values). Data in Figure 4 also support the observation that, generally, increased pulsation increases the extent of dissipation.

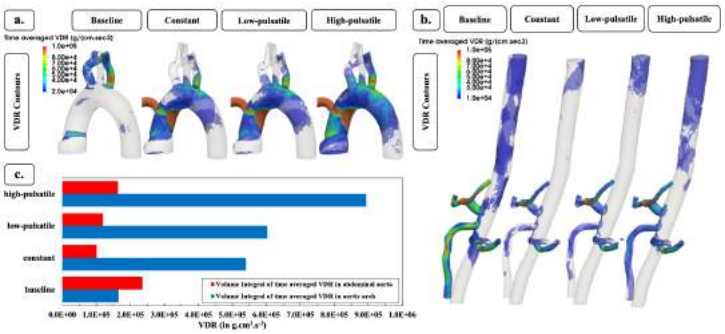

Figure 3: Isosurfaces of Viscous Dissipation Rate(VDR) in the Aortic arch(a) and Abdominal Aorta(b); Comparison of Volume integrated values of time averaged VDR for aortic arch and abdominal aorta(c).

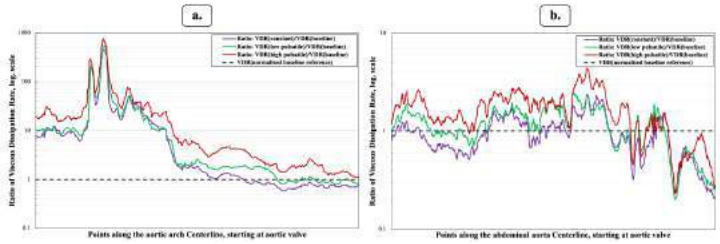

Figure 4: Plot of Time averaged Viscous Dissipation Rate(VDR) along the center-line of Aortic Arch(a); Abdominal Aorta(b).

DISCUSSION

Data obtained from our study indicate a multi-faceted role that pulse-modulation of LVAD flow can play. Hemodynamically, pulsation influences helical flow and vortex generation, which in turn are intimately connected to mixing, flow stasis, and thrombogenic potential. Simultaneously, pulsation influences energy dissipation, which can further influence LVAD pump operational efficiency, and associated complications in HF patients. Specifically, for each oscillatory frequency component of the pulse, it can be shown that in a cycle-averaged sense the energy expenditure to drive the flow is solely due to viscous dissipation [9]. Additionally, our observations highlight the flow physics significance of the impingement of LVAD jet flow onto the aorta wall. This unsteady jet impingement is the defining feature of the altered state of hemodynamics in LVAD patients, even in the presence of pulse-modulation. We note that, while the impingement and subsequent vortex generation can affect mixing (and thereby thrombogenicity) and energy dissipation (and thereby flow efficiency); arbitrarily raising the outflow graft angle towards the arch to negate the impingement is not advisable due to increased stroke risks as the flow gets directed towards the cervical vessels. This motivates our ongoing investigations on comprehensive characterization of hemodynamics and stroke risks in patients with LVAD, towards obtaining optimal guidelines for LVAD surgical therapy for HF - specifically with regards to optimizing the LVAD outflow graft surgical anastomosis.

SIGNIFICANCE OF GAGS IN UNCONFINED COMPRESSION RESPONSE OF POSTERIOR PORCINE SCLERA

Anshul Bhardwaj and Hamed Hatami-Marbini

Department of Mechanical and Industrial Engineering
University of Illinois at Chicago
Chicago, Illinois, USA Email. hatami@uic.edu

INTRODUCTION

The sclera is the enveloping soft tissue layer that forms the outer shell of the eyeball and is continuous with the cornea. The sclera resists against stresses caused by the intraocular pressure (IOP), maintains the shape of an eyeball, and protects the eye from the external trauma such as laceration and rupture. The alternation in the normal mechanical properties of the posterior sclera could lead to Glaucoma, the second leading cause of irreversible blindness worldwide affecting 60 million people [1,2]. Thus, it is important to fully understand the mechanical response of the posterior sclera and investigate how it is related to the microstructure and mechanical properties of its constituents.

The mechanical properties of the sclera originate from its extracellular matrix, which is primarily composed of collagen fibrils, proteoglycans (PGs), and elastin [3]. Various researchers have contributed and demystified the mechanical properties of sclera using uniaxial tensile, inflation, and biaxial tensile testing methods among others [1,3,4,5]. However, only a few researchers have conducted compression studies on the posterior porcine sclera. In the present work, we investigated the compressive mechanical response of scleral tissue and determined the possible structural roles of sulfated glycosaminoglycans (GAGs). GAGs are composed of repeating negatively charged disaccharide units. We have recently shown that they play an important role in tensile mechanical properties of the sclera [3]. In these studies, we compared the tensile response of sclera after and before digesting the GAGs using the chondroitinase ABC enzyme. This paper discusses our recent study on the mechanical response of posterior porcine sclera under unconfined compression (UCC) in order to determine the structural roles of GAGs in compressive response of posterior sclera.

METHODS

The porcine eyeballs were obtained and transported from the local butcher shop to the UIC CBRL laboratory within 4 to 6 hours of post-mortem at a regulated temperature of 4˚C. The specimens were carefully operated and dissected with the help of scalpels and micro-dissecting scissors from the surrounding extraocular muscles to obtain eyeballs. A trephine biopsy punch was used to dissect an 8mm disc from the superior temporal (ST) section of the sclera as shown in Figure 1.

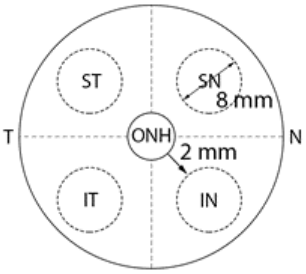

Figure 1. Sclera tissue's region-based nomenclature (right-eye). The samples were obtained from ST section.

Three groups were considered, Table 1. a) control group: here the samples were incubated in PBS solution Then samples were placed in the PBS bath for 3 hours prior to the mechanical experiments, b) buffer group: the samples were placed in the buffer solution composed of 50mM Trizma Base, 60 mM Sodium Acetate, and bovine serum albumin at pH 8 for 18 hours prior to mechanical tests, and c) enzyme group: the samples were placed in the buffer solution which includes the 0.125 U/ml ChondroitinaseABC for 18 hours. Alcian Blue staining

with a pH of 1.0 was employed to validate the successful removal of the sulfated GAGs. The thickness and weight of all sample were recorded after the incubation period, as shown in Table 1, and before subjecting to unconfined compression.

Table 1. different groups considered in the present work

Group name	Treatment	Incubation Period
Control	Phosphate Buffered Saline	3 hours
Buffer	Triz and Sodium Acetate Buffer	18 hours
Enzyme	ChABC in Buffer	18 hours

The mechanical tests were done by a RSA-G2 rheology equipment (TA instruments) using the protocol that we have previously used to test corneal samples [6,7]. After determining the initial thickness of the disks, the upper head of the machine was displaced such that the tissue was compressed by 5%. Then, the samples were allowed to relax until the compressive stress reached equilibrium. The above procedure was repeated five times until the total compressive strain reached 25%. The data acquisition was enabled for every half a second for compressive axial reaction force. The stress was found from dividing the compressive force by the initial cross-sectional area of the samples, and the stress-time behavior of the samples was plotted. The stress at the end of each ramp period was referred to as the peak stress and the stress at the end of each relaxation period was denoted by the equilibrium stress.

RESULTS

No significant difference was observed in the thickness of samples from the different control groups following their incubation in their respective solution and prior to the mechanical experiments. Figure 2 shows a typical mechanical response of samples in the present study. It is seen that the stress increased during the ramp period and then relaxed to an equilibrium stress during the relaxation period.

Figure 3 shows the variation of the peak stress as a function of applied compressive strain in different groups. It is seen that although the samples in the buffer and control groups had an almost similar response, there was a significant reduction in the peak compressive stress of the scleral samples from the enzyme group.

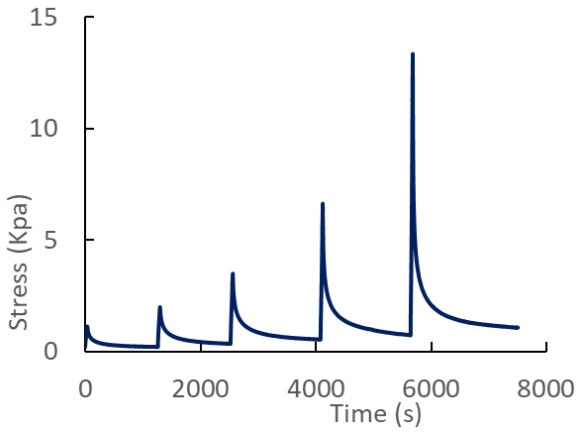

Figure 2. The compressive stress variation as a function of time during successive unconfined compression experiments on a typical sclera samples.

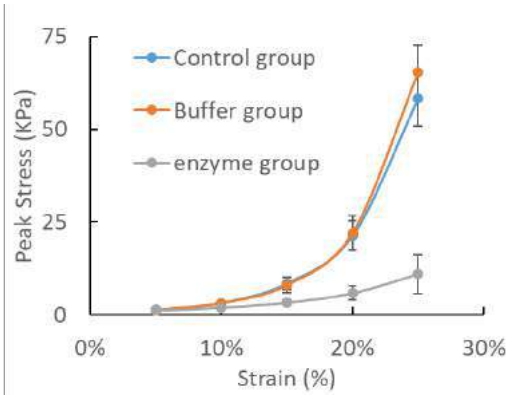

Figure 3. The effect of GAGs on the maximum compressive stress-strain behavior of the posterior sclera.

DISCUSSION

The objective of the study was to investigate the role of GAGs on the compressive mechanical response of posterior sclera. To this end, we removed GAGs from the scleral disks obtained from the posterior porcine sclera. We then conducted unconfined compression experiments to compare the mechanical response of samples with and without GAGs. It was found that GAGs had a significant effect on the compressive properties of the sclera. This is because GAGs are negatively charged and their presence in the soft tissues, including the sclera, induces a tendency for the tissue to absorb water when immersed in the tissue [6,7]. The presence of the water and its interaction with GAGs are important in defining the mechanical response in compression. With removal of the GAGs (a complete removal was not achievable, we observed a reduction of about 90%), water still will be absorbed inside the tissue (we saw an insignificant difference in the thickness of samples in all groups). However, this water was removed easily from these samples because the pore size inside the tissue was larger (because the GAG density was significantly reduced).

INTRODUCTION

Human skin is a complex tissue, consisting of multiple layers, vascular networks, and cell types to create a barrier against environmental factors. As the largest organ in the body, skin covers $2m^2$ for the average human and makes up about 15% of total adult body weight [1]. Therefore, many studies have been conducted to develop the most effective and representative model for human skin to study skin diseases and wound inflammation and develop regenerative therapies for skin wounds.

Existing skin models employ animal models, ex vivo models of human tissue, two-dimensional (2D) cell monolayers, or simple three-dimensional (3D) skin platforms lacking vasculature and immune components typically composed of only a single layer or without the addition of any 3D ECM. Without robust biomimetic in vitro testing platforms, a number of false-positive therapeutics are being studied in vivo. Although pig models provide the most complete and physiologic microenvironment for studying burn injury and testing therapeutics, the dynamics and spatial kinetics of burn injury cannot be easily studied without significant time and expense. We have created a first-of-its-kind vascularized human skin equivalent (VHSE) platform, consisting of an epidermis with differentiated keratinocytes cultured on top of collagen type I mixed with equal weight of dry keratin powder. This unique collagen/keratin (C/KTN) composition of our epidermis was used to better mimic the ECM of the native epidermis, which is made of approximately 80-90% keratin. Below the epidermis resides the vascularized dermis composed of normal human dermal fibroblasts (NHDFs) cultured in 100% collagen type I, the main type of ECM protein found in the native human dermis. The major innovation of the VHSE is the presence of an aligned, endothelialized fully functional vessel, enabling perfusion of media/blood, immune cells, therapeutics, and growth factors.

METHODS

To initially determine whether KTN itself increased keratinocyte differentiation, 100% collagen, 50/50 C/KTN (w%/w%), and 30/70 C/KTN hydrogels were prepared Ker-CT (TERT-immortalized keratinocytes) were seeded on to the hydrogels and cultured with calcium-free media and once 80% confluent, was cultured with the same media or switched to an increased calcium concentration differentiation media to increase differentiation (Figure 1A). Lysosomal activity, an indication of keratinocyte differentiation [2], was measured by the glucocerebrosidase (GBA) activity at 12, 24 and 48 hours post-media change. Samples were also fixed at day 4 and 10 post-media change and stained for caspase 14, a keratinocyte differentiation marker.

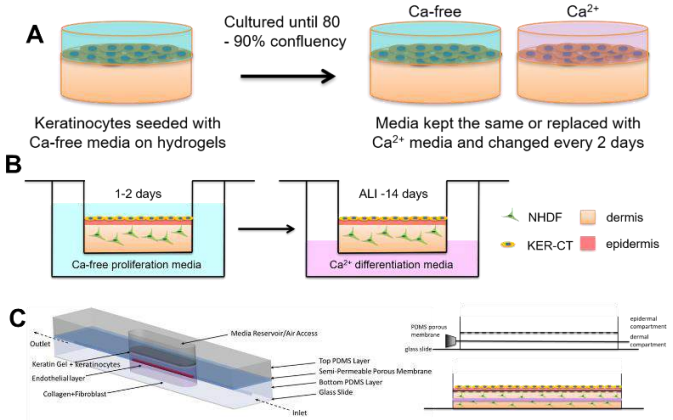

Figure 1: Schematics of 2D keratintocyte model (A), organotypic transwell skin model (B), and vascularized human skin equivalent model (C).

Organotypic skin platforms were prepared using a transwell system to further determine the effect of increased KTN on differentiation (B). The dermis was composed of fibroblast (NHDF)-seeded collagen and the epidermal layer was composed of either pure collagen or the C/KTN blend seeded on top if Ker-CT cells. Transwells were lifted to the air-liquid interface (ALI) and cultured in Ca^{2+} media for 14-21 days until they were fixed for staining of diffentiation markers, used for transepithelial electrical resistance (TEER) measurements, or for permeability assays employing 70 kDa dextran.

The VHSE housed within a PDMS was fabricated by inserting a 22 G needle through the dermal layer to create a 700 µm diameter microchannel vessel and removed after polymerization (Figure 1C). The platform was cultured in Ca^{2+} differentiation media on a rocker at the ALI to allow differentiation for 2 weeks. The vessel was injected with telomerase-immortalized microvascular endothelial (TIME) cells and cultured for 3 days on a rocker with endothelial media. The VHSE was stained for CD90 (NHDFs) and CK14 (keratinocytes).

RESULTS

As shown in Figure 2A, the increase in KTN increased the GBA/lysosomal activity of keratinocytes in both calcium-free and Ca^{2+} (differentiation) media when compared to pure 100% collagen hydrogels. This indicates that there is an increase in differentiation with increase in KTN concentration of the hydrogel. In addition, keratinocytes showed higher expression of caspase 14, both with and without the presence of calcium. (Figure 2B). Keratinocytes were able to differentiate on their own with calcium-free media, with even higher expression of caspase 14 when calcium+ media was used.

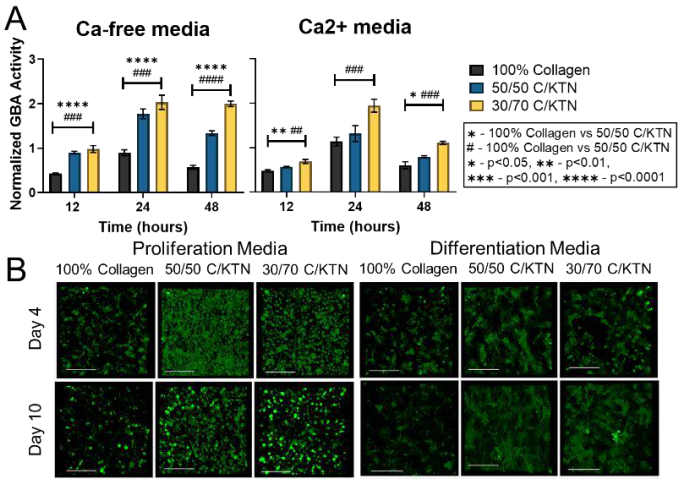

Figure 2: 2D hydrogel studies analyzing GBA activity (A) and caspase 14 expression (B) of keratinocytes. Scale bar = 200 µm.

Transwell studies were conducted to analyze the permeability of the stratum corneum layer of differentiated keratinocytes. As shown in Figure 3A, no significant differences in permeability between pure collagen and C/KTN hydrogels after 2 weeks of differentiation were observed. Significantly lower permeability was observed between NHDF-only hydrogels and 50/50 C/KTN hydrogels after 2 weeks of differentiation. Significant decrease in permeability between weeks 2 and 3 were only observed with 30/70 C/KTN hydrogels. TEER measurements demonstrated there was significant increase in resistance with 50/50 C/KTN hydrogels when compared to 100% collagen hydrogels (Figure 3B). CK14 (proliferation marker) and involucrin (differentiation marker) was also expressed in all samples with similar expression to 100% collagen (Figure 3C). H&E staining showed a well-stratified stratum corneum layer after 2 weeks of differentiation. C/KTN hydrogels showed similar stratification to 100% collagen (Figure 3C).

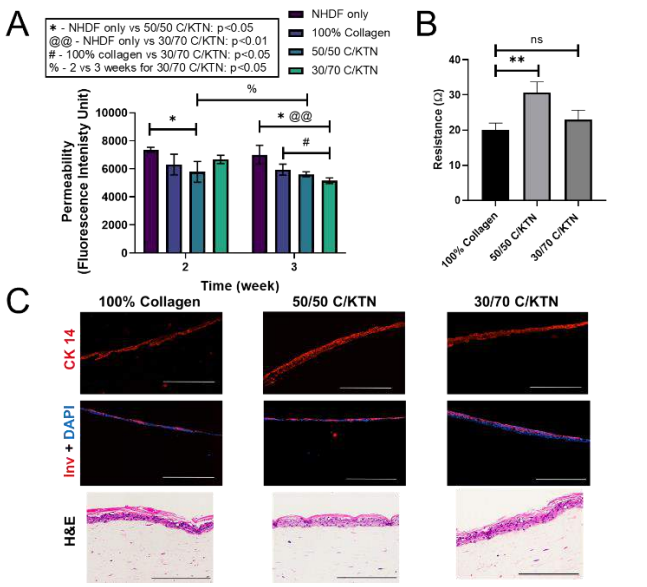

Figure 3: Skin barrier function was analyzed by measuring permeability of 70 kDa dextran perfused through the skin barrier (A) and resistance (B). Expression of CK14 and involucrin with a well-developed stratum corneum (C). Scale bar = 100 µm.

We were also able to develop a functional vessel within our skin platform. By placing the platform on a rocker, a confluent lumen of endothelial cells was created to form a functional vessel surrounded by dermal fibroblasts (Figure 4). 2 distinct layers of the dermis and epidermis was developed with the vessel in the dermal layer and keratinocytes in the epidermal layer.

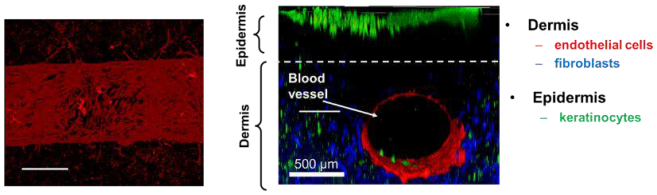

Figure 4: VHSE platform with a fully developed vessel (left) and distinct layers of the dermis and epidermis (right).

DISCUSSION

In this study, we demonstrated that keratin promoted the differentiation of keratinocytes with increased GBA activity and increased caspase 14 expression when seeded on top of C/KTN hydrogels. The addition of keratin serving as the epidermal layer led to a trend of decreasing permeability, indicating that keratin promotes increased barrier function with a stratified stratum corneum similar to that of 100% collagen. Creation of a vascularized skin model better recapitulates in vivo skin with a functional vessel.

By providing an affordable high-throughput VHSE system which can be used to down-select therapeutics before in vivo testing with the presence of a vessel, the use of the VHSE will reduce the time and cost of product development. Developing and testing therapeutic strategies in the VHSE will significantly decrease the product translation time of drugs and therapeutics for skin.

INTRODUCTION

The mechanical function of the myocardium is in part defined by a highly organized network of fibrous extracellular matrix (ECM) proteins that surround cardiomyocytes (CMs) and facilitate anisotropic contraction of the tissue [1]. The importance of this structure-function relationship is particularly evident in disease states such as fibrosis, where fibroblasts deposit excessive amounts of disorganized matrix in the perimysial space and impair tissue function [2]. Because of the critical role that microenvironmental cues play in driving proper tissue organization and function, a number of material platforms have been developed to recapitulate these cell-instructive cues to drive structural and functional maturation of engineered induced pluripotent stem cell (iPSC) derived cardiac tissue [3-5]. Despite the success of these and other culture platforms in improving iPSC-CM tissue function, each of these approaches only mimics certain aspects of the cardiac ECM. As such, a comprehensive, multiparameter understanding of the physical environmental cues necessary to form high-functioning CM tissues is currently lacking. Thus, new biomaterial approaches are needed that can accurately and orthogonally recapitulate fibrous, biochemical, and mechanical attributes of the cardiac ECM to promote cardiac tissue assembly. Previously, our lab developed a cell-adhesive, mechanically tunable synthetic fibrous ECM consisting of electrospun dextran vinyl sulfone (DVS) fiber matrices that support long term cell culture [6]. Here, we employ this platform to create a robust culture system for iPSC-CMs and examine how architectural and mechanical properties of the ECM impact cardiac tissue assembly and function [7].

METHODS

Substrate Fabrication: DVS dissolved at 0.7 g/ml in 1:1 milli-Q water and dimethylformamide with 0.6% w/v lithium phenyl-2,4,6-trimethylbenzoyl phosphinate (LAP), 2.5% v/v 25 mM methacrylated rhodamine, and 5.0% v/v glycidyl methacrylate was electrospun on coverslips affixed to a rotating mandrel, stabilized by UV crosslinking (20 s at 100 mW/cm^2), hydrated in LAP photoinitiator solution, and UV crosslinked again. Heparin methacrylate was covalently attached during photocrosslinking and fibronectin (FN) (100 µg/ml) was then adsorbed to fibers at RT for 1 h. CM Differentiation: Induced pluripotent stem cells containing a GFP-titin reporter or a connexin43 (Cxn43) reporter (Allen Institute) were expanded in mTeSR1 media and differentiated in RPMI 1640 with B27 lacking insulin. Differentiation was initiated on d0 with 12 µM CHIR99021 for 24 h and then 5 µM IWP4 on d3 for 48 h. On d9, insulin was introduced. CMs were purified by culturing in RPMI lacking glucose and glutamine supplemented with 4 mM DL-lactate on d11-15. CMs were seeded on substrates on d30. Staining and Microscopy: Calcium handling analysis was performed by incubating cells for 1 h with 5 uM Cal520, AM and imaging cells at 37 °C and 5% CO_2. For immunostaining, samples were fixed, permeabilized, blocked in 2% BSA, incubated for 1 h at RT with anti-vinculin antibody (1:1000; Sigma), and counterstained with Alex Fluor 647 (1:1000; Sigma) and DAPI. Sarcomeres were visualized by GFP-titin. All calcium imaging and staining was conducted on d7 after seeding. Data analysis: Sarcomere alignment, calcium tracings, and focal adhesion data were analyzed using custom MATLAB scripts. Statistics: Statistical significance was determined by one-way ANOVA with Tukey's post-hoc analysis or Student's t-test where appropriate, with significance indicated by $*p < 0.05$. All data presented as mean $\pm$ std.

RESULTS

We first modulated matrix alignment by altering the speed of the rotating collection mandrel (**Fig. 1a,b**). With alignment of matrix fibers, sarcomere alignment increased and calcium flux rise time and decay time decreased, suggesting more functional subcellular calcium

handling machinery (**Fig. 1c,d**). Next, we altered matrix stiffness by controlling LAP photoinitiator concentration during the crosslinking of aligned matrices (**Fig. 1e**). While sarcomeres remained highly aligned on matrices of all stiffness conditions, calcium flux decay time and peak-to-peak irregularity increased on stiffer matrices, suggesting decreased function at supraphysiologic stiffnesses (**Fig. 1f,g**).

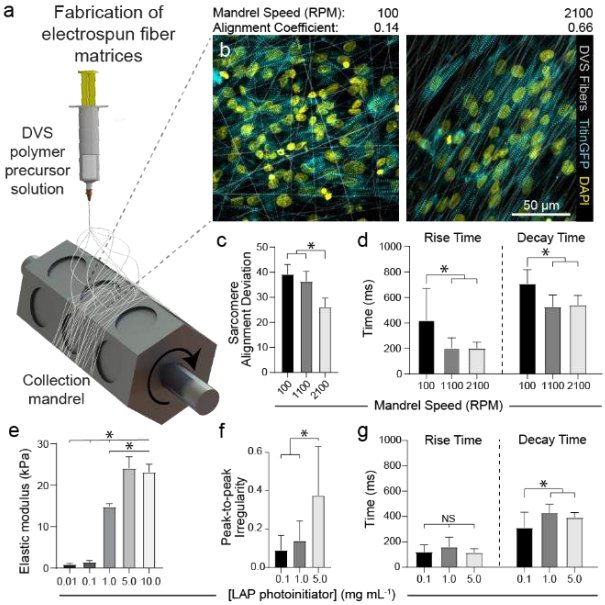

Fig. 1: a) Electrospinning setup for fabrication DVS matrices. b) CMs cultured on DVS aligned/non-aligned DVS matrices. c) Sarcomere alignment and d) calcium dynamics of CMs on matrices of varied alignment. e) Elastic modulus of DVS matrices. f-g) Calcium flux dynamics of CMs on matrices of varied stiffness. n ≥ 12 fields.

Because changes in matrix architecture and mechanics have been noted in numerous disease states, we next took advantage of the tunability of DVS matrices to examine how matrix alignment and mechanics affect CM tissue formation. Given the role of cell-matrix adhesions in CM mechanotransduction and function, we immunostained for the focal adhesion (FA) protein vinculin and found that both alignment and stiffness of matrix fibers influenced adhesion morphometrics (**Fig. 2a-d**). CMs on aligned/soft matrices had the most adhesions with higher aspect ratios, in contrast to cells on stiff/aligned matrices (**Fig. 2b**).

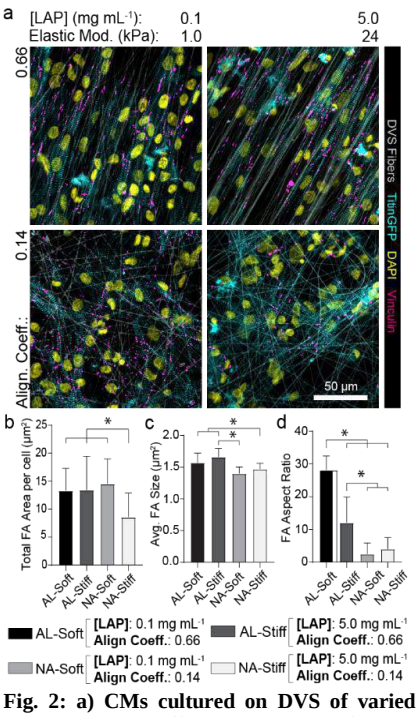

Fig. 2: a) CMs cultured on DVS of varied alignment and stiffness. b-d) Quantification of FA formation in CM tissues. n ≥ 18.

Lastly, we found that DVS matrices afford greater stability of iPSC-CM tissues over long-term culture as compared to other commonly used culture platforms including microcontact FN lines and FN coated glass, where CMs detach after ~10 days [7]. As it has previously been indicated that extended culture of non-confluent iPSC-CMs facilitates further structural organization [8], we examined Cxn43 expression of iPSC-CMs on aligned DVS matrices over time and observed a marked increase in expression after 7 days in culture as compared to FN-coated glass and non-aligned DVS (**Fig. 3a,b**). On day 14, Cxn43 expression increased further on both aligned and non-aligned matrices, with aligned matrices driving significantly more expression.

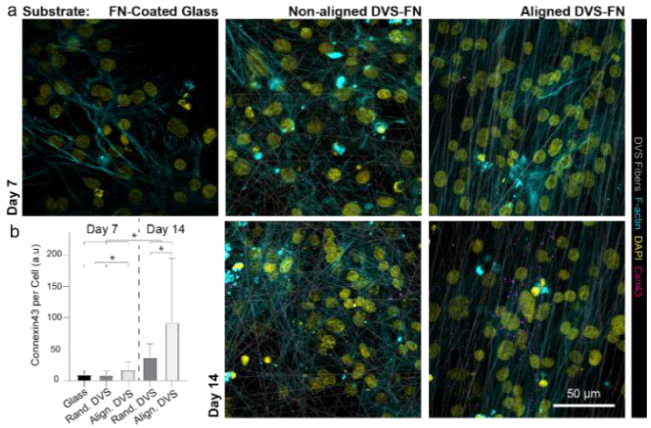

Fig. 3: a) CMs cultured on various substrates expressing Cxn43-GFP for 7 and 14 days. b) Quantification of Cxn43 expression. n ≥ 18.

DISCUSSION

In this work, we examined how matrix structural anisotropy and mechanics affect iPSC-CM tissue formation by generating CM tissue on tunable, synthetic fibrous DVS matrices. Our results indicate that iPSC-CMs sense and respond to architectural and nano-scale mechanical cues from the matrix as characterized by changes in sarcomere organization and calcium handling dynamics. By examining FAs, we found that matrix architecture and mechanics exert a synergistic effect on iPSC-CM tissue formation. It has been noted that cell-matrix adhesions drive myofibrillogenesis, further supporting the use of soft aligned matrices in creating functional CM tissues [9]. Additionally, iPSC-CMs cultured on soft, aligned DVS matrices for 14 days indicated higher levels of structural organization as evidenced by Cxn43 expression. As limitations in long-term culture on substrates that introduce physiologic anisotropic cues to drive significant maturation have been suggested [10], ongoing work is focused on taking advantage of the long-term stability of CMs on DVS to examine how metabolic factors can drive further tissue maturation. Additionally, this platform has great potential for studying how pathologic microenvironmental changes affect CM functionality.

A 3D MACROMOLECULAR MODELING FRAMEWORK FOR COLLAGEN FIBRIL MECHANICS AND PLASTICITY

Lauren M. Bersie-Larson (1), Paolo P. Provenzano (1), Victor H. Barocas (1)

(1) Department of Biomedical Engineering
University of Minnesota – Twin Cities
Minneapolis, MN, USA

INTRODUCTION

Collagen fibers are present in all tissues within the body and provide the main source of mechanical strength within the extracellular matrix [1]. Connected by chemical crosslinks and physical entanglements, collagen fibers form interconnected fibrous matrices that are in a constant state of flux, dynamically rearranging and remodeling in response to cellular forces [2].

The concept of plasticity has recently been invoked to describe collagen rearrangement (e.g., [3-5]). Although classically defined in terms of crystalline dislocations [SOURCE], plasticity in the collagen fiber network context refers to deformation that results in lasting changes_to network topology and/or inter-fibrillar connections upon unloading. Such plasticity in collagen networks has been widely observed in both developmental and pathological processes, but it remains poorly understood. Previous models of this behavior thus far have only been in 2D and simplify assumptions of these bonds.

To address the limitations of existing models, we used the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS), an open-source molecular dynamics software [6], to construct a collagen fiber network model that accounts for fiber-fiber bonding in 3D. LAMMPS has been used previously in studies of fiber network mechanics [7].

METHODS

Model Creation Networks were created in MATLAB as previously described [8]. Briefly, random seed points were generated in 3D, and a Voronoi diagram was constructed to create the fiber network with a volume fraction of approximately 2%. Fibers were discretized into segments 0.1 um long, and the resulting geometry was imported into LAMMPS; each fiber junction was modeled as an "atom," and each fiber was modeled as a "bond" (Figure 1).

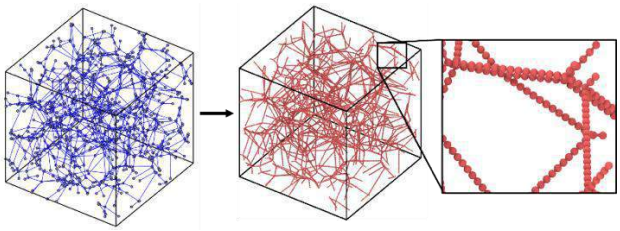

Figure 1. a) A Voronoi network created in MATLAB. b) The same network input into LAMMPS as bonds and atoms. c) A close-up of the atoms and bonds making up the fibers of the network.

Simulation Setup Atoms were modeled as point particles of unit mass, and harmonic bonds were used to model fibers as linear springs:

$$f = -K(r - r_0) \quad (1)$$

Where K is the spring stiffness (200 nN/μm), r is the current bond length, and r_0 is the equilibrium bond length (~ 0.1 μm). To model the new inter-fibrillar connections that drive plasticity, fibers were bonded together when within 0.1 to 0.25 microns of each other. New bonds were as in Eqn. (1), but with a spring stiffness of 400 nN.

Simulations were run using the *minimize* command in LAMMPS, utilizing a conjugate gradient solver with the *forcezero* style line search.

Uniaxial Tensile Loading To simulate uniaxial tensile loading of networks with and without plasticity, networks were stretched in the x-direction incrementally to a stretch of 150%, and then incrementally unloaded. Atoms on the x-faces were fixed in x but allowed to slide in-plane, while atoms on the transverse faces were left free. The resulting fiber orientation tensor in the direction of loading, Ω_{xx}, was measured for each load and unload step as follows:

$$\boldsymbol{\Omega}_{xx} = \frac{1}{l^{f,total}} \sum l^f n_x^f n_x^f \qquad (2)$$

where $l^{f,\,total}$ is total length of fibers, l^f is length of each fiber, and n_x^f is the x-component of a unit vector in the fiber direction. For a highly aligned network, Ω_{xx} goes to one; for an isotropic network, Ω_{xx} is 0.33.

Cell Contraction Cell contraction in a 3D collagen gel was simulated in both networks with and without plasticity. Two spherical particles representing cells were placed in the networks 1 micron apart, and contractile force was modeled using a cut-off Lennard-Jones potential:

$$f = -24\epsilon \left[\frac{2}{r}\left(\frac{\sigma}{r}\right)^{12} - \frac{1}{r}\left(\frac{\sigma}{r}\right)^{6}\right] \; for\; r < r_{cut} \qquad (3)$$

where f is the force exerted on an atom in a fiber, ϵ corresponds to the energy minimum of the pair potential ($1x10^{-1}$), σ the distance between two atoms where the energy minimum exists (2 μm), r is the distance between the cells and atoms in the fibers, and r_{cut} (3.5 μm) is the maximum distance over which two atoms can interact. Sigma was chosen to match the radius of the cells, such that the repulsive force term represented steric interactions of any fibers with the cell and prevented overlapping. After cell contraction, cell lysis was simulated by turning off the pair potential in Eqn. (3).

RESULTS

Uniaxial Tensile Loading Results from the uniaxial simulations are shown in Fig. 2. Network x-orientation, Ω_{xx}, is plotted against network stretch ratio for the loading and unloading portions of the test, for the same network without plasticity and with plasticity.

The network without plastic fiber interactions (Fig. 2a) reaches a maximum fiber orientation value of approximately 0.35, which is still close to isotropic, and follows the same path during unloading, resulting in no difference in fiber orientation once the test is complete.

When plastic fiber interactions are added (Fig. 2b), fiber orientation in the x-direction becomes more pronounced with stretch, and a slight hysteresis appears, with Ω_{xx} increased at the end of the simulation relative to the start.

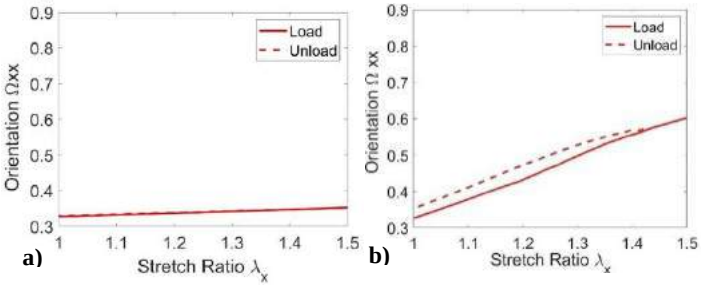

Figure 2: (a) Network orientation in the stretch direction (Ω_{xx}) for all load-unload steps of the uniaxial tensile test, without plasticity. (b) Network orientation in the stretch direction (Ω_{xx}) for all load-unload steps of the uniaxial tensile test, with plasticity.

Cell Contraction Figure 3 shows the results of the simulated cell contraction experiments. In Fig. 3a-c, the network (with no plastic fiber interactions) and cells are shown before and during contraction, and after simulated cell lysing. In this instance, no difference in the network architecture is observed before and after cell contraction.

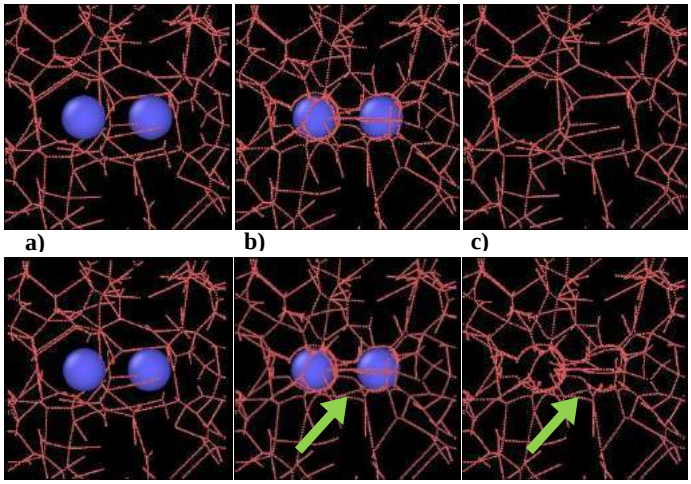

Figure 3: Cells in a network without plasticity a) before contraction, b) during contraction (middle), c) and after lysis; cells in a network with plasticity d) before contraction, e) during contraction, and f) after lysis. Densified fibers are marked by an arrow.

In contrast, in Fig. 3d-f, the fiber network does not return to its original state after cell contraction. After lysis, as shown in Fig. 3f panel, fibers have remained densified where the cells once were, and a cord of fibers has been created in between the two cells.

DISCUSSION

In this work, we present a modeling framework for simulating plasticity in 3D fiber networks. We simulated both uniaxial tensile testing and cellular contraction within a collagen gel and examined how modeling plastic fiber interactions in each case affected the resulting fiber architecture. For both the uniaxial and cell contractility cases, with plasticity, we found permanent fiber rearrangement, consistent with both our expectations and existing literature [3].

Although the fiber mesh in this study was fairly coarse, and the model of cell contraction was a considerable simplification of the actual interactions that occur between a cell and the surrounding fibrous matrix, the model nevertheless gave promising qualitative results and appears to be capable of describing at least some of the plastic-like effects observed experimentally. Other observations, such as network collapse during confined compression [8, 9], remain to be simulated and will provide additional tests for the new framework.

INTRODUCTION

The mechanical function of the myocardium is dictated by contractile cardiomyocytes (CMs) and the fibrous extracellular matrix (ECM) that surrounds, orients, and groups CM bundles [1]. Aberrations to the architectural or mechanical properties of the cardiac microenvironment common in numerous cardiomyopathies often result in cardiac dysfunction [2]. However, due to limitations in existing models of cardiac disease, how CMs and other cells in the myocardium sense and respond to these mechanical microenvironmental changes is largely unknown. *In vivo* models lack control over matrix architecture and mechanics, with confounding factors limiting the ability to parse the signaling and behavior of individual cell types within the tissue [3]. Current *in vitro* models leverage natural materials to generate 3D microtissues but lack the mechanical control required to accurately model fibrotic ECM changes and require the inclusion of stromal cells [4-6]. Therefore, improved *in vitro* models of the cardiac microenvironment are necessary to advance our understanding of how fibrosis initiated changes to the ECM alter tissue function and propagate disease progression.

Here, we establish a robust method for creating well-defined fibrous cardiac microtissues composed of photocrosslinkable dextran vinyl sulfone (DVS) suspended between two elastomeric cantilevers (termed fibroTUGs). Previous work from our lab has shown the ability to create organized and functional cardiac tissues on DVS matrices [7]. Expanding on these findings, we present a novel system to generate highly tunable pure CM tissues that enables tissue fractional shortening and real-time contractile force measurments. Additionally, we report on the effects of pathogenic microenvironmental cues on induced pluripotent stem cell derived-CM (iPSC-CMs) tissue function by tuning boundary stiffness, DVS matrix stiffness, and fiber alignment and analyzing tissue contractile output and cellular organization.

METHODS

Microfabrication: DVS was synthesized and electrospun as previously described [7]. Fibers were collected on poly(dimethylsiloxane) (PDMS) post arrays fabricated by soft lithography affixed to a rotating mandrel. Fibers were then crosslinked through a chrome mask such that only fibers suspended between two posts were exposed to UV light (**Fig. 1a**). Uncrosslinked fibers were dissolved upon hydration (**Fig. 1b**). Matrices were then crosslinked further to define matrix stiffness and functionalized with cRGD. Mechanical Testing: PDMS cantilever mechanics were characterized by deflecting individual cantilevers with a tungsten rod of known elastic modulus (**Fig. 2a**). Bending stiffness was calculated by measuring the cantilever deflection and the force applied by the tungsten rod using custom Matlab scripts. Matrix modulus was determined by pressing a microfabricated SU8 rectangle across the center of the fiber matrices to apply a tension on the matrix (**Fig. 2b**). Using custom Matlab scripts, matrix modulus was extrapolated from measured cantilever deflection. CM Differentiation: iPSCs were differentiated into cardiomyocytes as previously described via temporal modulation of the Wnt signaling pathway [7]. After differentiation, iPSC-CMs were seeded on substrates on after d25. Seeding: PDMS seeding masks were cast from 3D printed molds and aligned with suspended fibers (**Fig. 1a**). 125k pure CMs were then added through the mask and allowed to adhere for 18h. Immunostaining and Microscopy: Contractile stress analysis was conducted via brightfield, time lapse imaging (>30 Hz) at 37 °C and 5% CO_2. Fixed samples were then stained for anti-α-actinin and DAPI. All analysis was conducted on d10 after seeding and quantified using custom MATLAB scripts [7]. Statistics: Statistical significance was determined by one-way ANOVA or Student's t-test where appropriate, with significance indicated by $*p < 0.05$. All data presented as mean ± std.

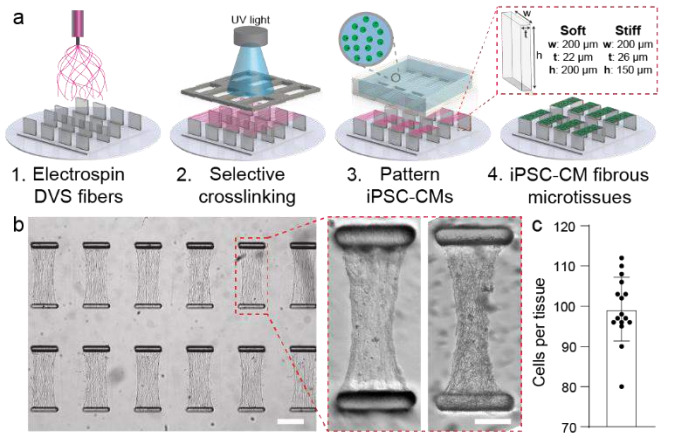

Fig. 1: a) fibroTUG fabrication scheme. b) Array of suspended matrices (scale bar: 200 µm) and example tissues on aligned and random suspended matrices (scale bar: 100 µm). c) Distribution of CM seeding densities.

RESULTS

Fibrous matrices were fabricated by electrospinning DVS on to an array of microfabricated PDMS posts affixed to a rotating mandrel [7] (**Fig. 1a**). Post arrays consisted of 98 pairs of posts spaced 500 µm apart. Fibers were then selectively crosslinked through a chrome mask and iPSC-CMs patterned on matrices through a microfabricated seeding mask (**Fig. 1a,b**). Reproducibility of fibroTUG fabrication and seeding protocol was quantified to confirm consistant tissue formation (**Fig. 1c**).

As this culture platform affords precise mechanical tunability, we preformed mechanical characterization of the PDMS cantilevers and suspended fiber matrices using custom analysis techniques (**Fig. 2a,b**). Alterations to post dimensions (**Fig 1a**) defined boundary stiffnesses with relevance to healthy and diseased cardiac tissue (**Fig. 2c**) [8,9]. DVS matrix modulus was determined via microindentation and increased with higher photoinitiator concentration (**Fig. 2d**).

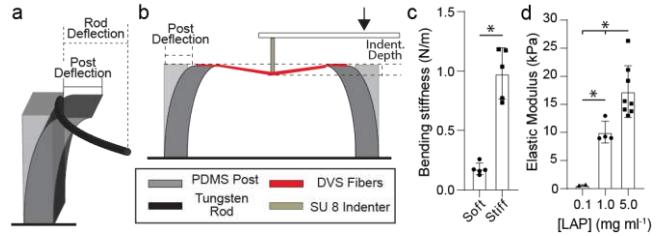

Fig.2: Schematics of PDMS cantilever (a) and DVS matrix (b) mechanical characterization methods. c) Bending stiffness of soft and stiff cantilever. d) Elastic modulus of DVS matrices.

Lastly, we examined how iPSC-CMs respond to alterations in boundary stiffness, matrix stiffness and alignment. When keeping matrix alignment and stiffness constant, we observed an increase in iPSC-CM tissue contractile stress on stiffer cantilevers (**Fig. 3a,b**). Additionally, we found that iPSC-CMs cultured on soft matrices (~1 kPa) contracted with a higher stress than iPSC-CMs cultured on stiff matrices (>20 kPa) (**Fig. 3c**). To our surprise, we observed no difference in tissue contractile stress between aligned and non-aligned soft matrices (**Fig 3f**). In line with this finding, sarcomere alignment was consistent regardless of the underlying matrix organization (**Fig. 3d,e**).

DISCUSSION

In this work, we developed a new microfabrication strategy to create fibrous cardiac microtissues of pure iPSC-CMs to examine how alterations in the mechanical cues affect cardiac tissue function. Mechanical characterization of this platform indicated an ability to orthogonally define boundary mechanics, matrix stiffness, and matrix architecture, enabling precise exploration of the role that the ECM plays in cardiac mechanosensing and contractile function. Additionally, this platform facilitates tissue fractional shortening, which has been shown to be critical for myofibrillar development and maintenance [4]. Previously established platforms used to study cardiac fibrosis have a variety of limitations including a lack of control over fibrous elements that induce iPSC-CM organization, limited mechanical control over the matrix, and the necessary inclusion of stromal cells for tissue formation which may confound studies focused on CM biology [5,6,8,9]. Using the fibroTUG platform, we highlight the importance of orthogonal mechanical and architectural control in creating *in vitro* models of cardiac tissue. Specifically, we find that altered boundary stiffness, matrix stiffness, and matrix architecture have distinct effects on iPSC-CM function, potentially due to the activation of distinct mechanosensing pathways. Intriguingly, we find that decreased matrix alignment does not result in decreased contractile stress in the platform. A possible explanation for this could be that only aligned fibers that span the entire distance between the two PDMS cantilevers remain in tension in contrast to those oriented perpendicularly. High myofibril alignment on both matrices suggests that CMs develop strong cell-matrix interaction only with tensed fibers, consistant with previous studies on focal adhesion formation of CMs in various mechanical environments 10,11]. Future experiments will assess how iPSC-CM tissues respond to pathologic alteration in their physical environment. Additionally, this platform could be useful in examining how physical cues and tissue forces affect iPSC-CM maturation.

INTRODUCTION

There is a lack of burn studies using *in vitro* and *in vivo* models that quantify both time-temperature history and tissue response for short-duration, high-temperature burns, both of which are needed to elucidate mechanisms of burn injury and to develop predictive models [1, 2]. The influence of vasculature embedded within skin on resulting burn injuries has not been adequately investigated. Engineered *in vitro* tissue platforms provide a great system for evaluating burn injury mechanisms [1, 3]. Some previous studies have created skin platforms with embedded vascular networks, however to the best of our knowledge none have been used as models for burn or wound healing research [4]. 3D bioprinting allows for the creation of complex skin platforms with more representative branching vascular networks to better understand the influence of blood vessel structure and perfusion on burn injury. This paper presents a multilayer vascularized *in vitro* human skin platform to conduct quantitative burn experiments for investigation into the influence of vasculature on burn injuries.

$$\Omega(\tau) = \ln\left(\frac{C(0)}{C(\tau)}\right) = \int_0^{\tau} A\, e^{\left(\frac{-Ea}{R\,T(t)}\right)} dt \quad (1)$$

The Arrhenius model (equation 1) has been widely used for modelling burn injuries to account for the temperature-dependence of damage rates, with the common form assuming irreversible first-order kinetics [cc]. Use of this model allows tissue damage and cell response to be predicted from time/temperature data, assisting heat-based therapies to achieve successful outcomes while minimizing complications due to damage to surrounding tissue [2]. $C(0)/C(\tau)$ is the ratio of the initial cell concentration or tissue strength over that at time τ, the logarithm of which gives the damage parameter Ω. Two process coefficients determine the behavior of the common form of the Arrhenius model (Equation 1), frequency factor A (Hz) and activation energy Ea (kJ/mol). Each type of tissue damage and cell response is modelled by its own set of coefficients, which must be determined for the temperature range of interest due to the domination of different mechanisms at different temperatures [5]. Results from quantitative burn experiments using *in vitro* skin models can be applied to the Arrhenius model to facilitate better understanding of the underlying mechanisms of burn injury and enable prediction of burns using time and temperature.

METHODS

In vitro skin tissue platforms were created by 3D printing collagen I hydrogels bearing human dermal keratinocytes and fibroblasts into a layered structure using a BioX bioprinter. Using a narrow-gauge needle, collagen solution was extruded into a gelatin microbead slurry serving as a support scaffold. The shear-thinning behavior of this microbead slurry allows for it to be readily displaced at the point of collagen extrusion and as the needle passes through the upper portion of the support scaffold. After completion of the bioprinting process, the support scaffold with its embedded skin platform was placed into an incubator at 37 ˚C to complete the polymerization of the collagen matrix and to melt the surrounding gelatin microbeads into a thin liquid that is readily washed off. This approach allows use of the same collagen I solution used in our previous skin burn studies, without modification to facilitate printing [6]. Larger skin platforms with more complex configurations can be created without loss of shape at larger heights, and without being restricted to a 2D printing surface.

In order to create vascular networks within printed skin platforms, a sacrificial Pluronic bioink was extruded into the shape of the desired

vasculature within the dermis layer and surrounded with collagen hydrogel. Removal of this sacrificial bioink by rinsing after polymerization of the collagen left behind channels in the shape of the extruded Pluronic filaments, forming the foundation for the vascular network. Holders for skin platforms were created by 3D printing bottomless wells out of PLA, which were then adhered to the top of glass slides using polydimethylsiloxame (PDMS). Inlet and outlet ports incorporated into the holder allowed connection to hoses and a pump for perfusion through the platforms. Vascular networks within skin platforms were gradually perfused with a suspension of microvascular endothelial cells in a ramping flow scheme. After creation, platforms were sustained by the perfusion of culture media through their vascular networks, with exposure to air on the top surface facilitating differentiation of keratinocytes.

Platforms were created with variable distances between parallel channels, and variable media perfusion rates. They were subjected to contact burn injury to characterize both extracellular matrix damage and the response of cells to thermal stress. A contact burn apparatus was made with a 3 mm diameter cylindrical copper burn tip and a motor with a microcontroller for consistent control of tip position and contact duration. Burn tests were performed with the burn tip heated to 50-100 ^{o}C for 3 seconds of contact with the platforms. Platforms were treated with a variety of fluorescent stains and imaged with z-stack confocal microscopy 24 hours after exposure. The resulting 3D images show the spatial distribution of this damage throughout the platforms and were used to measure the volumes of damaged regions.

Temperature distributions within platforms during contact burns were modeled computationally in Comsol Multiphysics (5.4a) to obtain a much higher temporal and spatial resolution than could be directly measured. Experimentally determined thermal characteristics of skin platforms and perfused media were used as inputs for this model. The resulting time/temperature histories were correlated with the experimentally determined distributions of tissue damage and cell response to determine which temperature conditions caused which level of damage. Arrhenius process coefficients A and E_a were determined for cell death and collagen ablation that closely predict the experimentally observed tissue damage using the computational temperature model.

RESULTS

Vascularized skin platforms were successfully created using a bioprinting methodology designed in our lab. Cells are stratified within their respective layers and retain their viability. Endothelial cells form monolayers adhered to the channel walls similar to *in vivo* vessels. Bioprinting methodology allowed for rapid creation of vascularized platforms without the need for specialized molds for each channel.

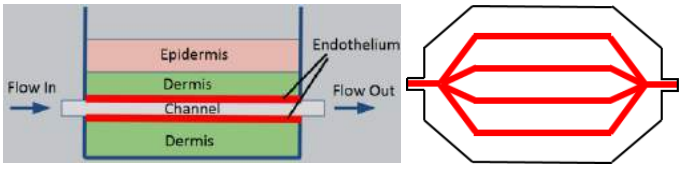

Figure 1 - Configuration of vascularized skin platforms. Left: cross-section of endothelialized channel within skin platforms. Right: Top-down layout of branching channels

Figure 2 – Demonstration of 3D printed networks

Contact burn injuries resulted in consistent injury to the skin platforms, which were quantified by the volume of damaged regions. Close to the contact point collagen was completely ablated, whereas further out the damage is progressively less severe as evaluated by different stains. The different measurements taken show a range of severities of cell response, and provide a potential means to study how cell fate is determined after burn exposure. Further work is in progress to collect burn injury data using variants of vascularized skin platforms.

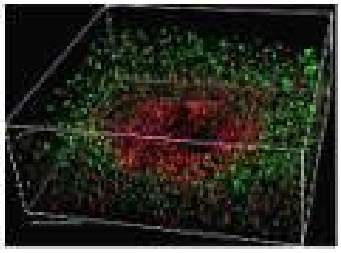

Figure 3 - Live/dead (green/red) staining of skin platform 24 hours after contact burning with a 75 ^{O}C copper cylinder.

DISCUSSION

The *in vitro* multilayer vascularized skin tissue platforms created in this project provide a means of quantitatively evaluating the as-of-yet unknown influence of vasculature on burn injury response. Platforms can be created in large quantities with minimal specialized equipment and maintained with minimal labor due to the perfusion of media – essential for the large sample sizes required to determine mechanisms of burn injury. Knowledge of these parameters is needed to elucidate mechanisms of burn injuries and to help drive the parameters of predictive therapeutic models.

EFFECTS OF IMPACT POSITION, MUSCLE ACTIVATION, AND POSTURE ON HEAD INJURY RISK

Jonathan Mortensen (1), Nikolaus Benko (1), Britany Coats (1), Andrew Merryweather (1)

INTRODUCTION

Musculoskeletal modeling has been proposed as an ethical tool for studying risk mitigation strategies in contact sports such as American football [1]. To date, these models have been used to study the effect of impact location, muscle strength, muscle activation, and posture on head accelerations caused by head-to-head collisions. These studies have quantified the risk of concussion using traditional kinematic-based injury metrics such as HIC, HIP, and BRIC. However, strain-based methods of injury prediction are thought to be more accurate at predicting concussion because they account for complex brain geometry and the directional dependency of injury. Strain-based injury metrics have not been adopted for use in conjunction with musculoskeletal models due to the large computational time required to compute brain strain. In this study, we incorporate a recently developed method for rapid brain strain estimation with a musculoskeletal model of head-to-head impact to quantify the effect of impact direction, muscle activation, and posture on brain strain.

METHODS

An OpenSim musculoskeletal model of the head and neck was previously used to investigate the effects of several parameters, including posture, impact location, and muscle activation on head accelerations [1]. This model is composed of rigid bodies connected by rotational joints which are constrained by realistic kinematic relationships. The model includes 72 Hill-Type muscle actuators and additional force elements which provide passive resistance.

To determine the effect of neck posture and impact location on brain strain, the kinematic outputs of 76 musculoskeletal simulations were analyzed. These simulations incorporated 5 impact directions (frontal, occipital, lateral, lateral off-center) and 5 postures (neutral, extended, flexed, toward and away from lateral impact, Figure 1).

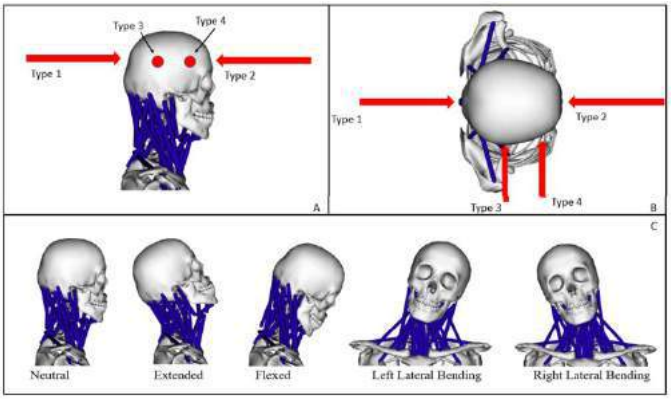

Figure 1. Impact directions (top) and postures (bottom) simulated with stiff or loose neck muscle activation at low (2914 N) and high (6800 N) head impacts.

'Stiff' neck muscle activation represented anticipation of the impact and a 'loose' response to represent unanticipated impact. The stiff response coactivates neck muscles and generates maximum muscle forces to resist impacts. The loose response involves no muscle activation. Each simulation was initiated with a low (2914 N) or high (6800 N) head impact force.

To estimate brain strain, we fit a second-order response surface concussion [2]. Briefly, a central composite design with circumscribed axial points was used to generate simplified acceleration inputs for the finite element model. Seven degrees of freedom were used to define the duration and 3D linear and angular accelerations for each finite element simulation. model to brain strain outputs from a finite element model of adult A total of 79 finite element simulations spanning a range of

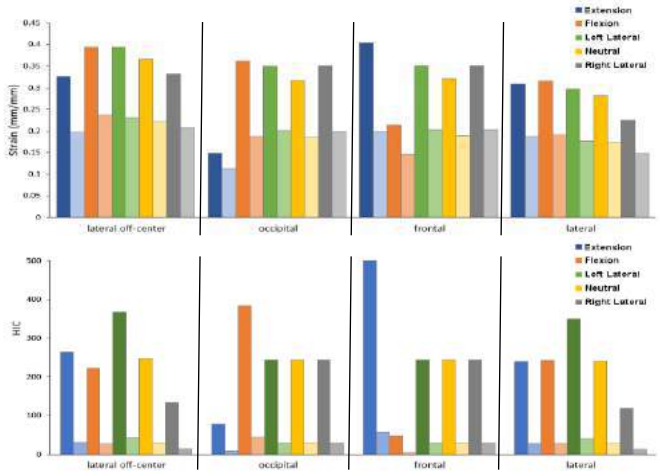

Figure 2. Strain (top) and HIC (bottom) calculated from head kinematic data following musculoskeletal simulation of head impact from multiple directions and postures. Darker shades indicate high impact and lighter shades indicate lower impact.

Table 1. Summary of kinematic parameters used to generate response surface model

Parameter	$A_x\,(g)$	A_y (g)	A_z (g)	$\alpha_x\left(\frac{rad}{s^2}\right)$	$\alpha_y\left(\frac{rad}{s^2}\right)$	$\alpha_z\left(\frac{rad}{s^2}\right)$	$\Delta t\,(ms)$
Minimum	5	5	2	800	200	300	6
Maximum	60	90	42	5000	3400	7300	24

kinematic parameters (Table 1) informed the model.

Using methods similar to the finite element model, a simplified triangular acceleration pulse was fit to the kinematic data from the musculoskeletal model simulations. These acceleration parameters were then input into the response surface model to estimate brain strain associated with each musculoskeletal simulation.

Two-way ANOVAs were performed to determine the effects of posture and impact direction on strain for each activation method and each impact force. A type I error of 0.5 was considered significant.

RESULTS

Stiff muscle activation had a minimal average reduction of 0.00237±0.00318 brain strain. Based on this finding, the remainder of the analysis combined data from both muscle activation configurations. Impact direction, posture, and the interaction between the two effects significantly affected brain strain ($p<0.001$). Lateral off-center impacts resulted in the largest average brain strains (0.290±0.077) and lateral impacts resulted in the lowest average brain strains (0.231±0.062). The effect of posture on brain strain was significantly related to the impact direction. Specifically, an extension posture associated with a frontal impact had the worst effect on brain strain (0.406), while an extension posture with occipital impacts resulted in the lowest brain strain (0.145). During lateral impacts, angling the head toward the impacts resulted in larger strains (0.073±0.005) than angling the head away from the impact. Low impacts (light colors in Figure 2) had similar trends to higher impacts (dark colors in Figure 2), but the distinctions between all the impact direction/posture combinations was more muted.

The strain-based trends were compared to calculations of HIC to compare the effect of strain-based metrics to kinematics-based head injury metrics. HIC lowest and highest values corresponded to those from strain, but values in between were not well correlated with strain.

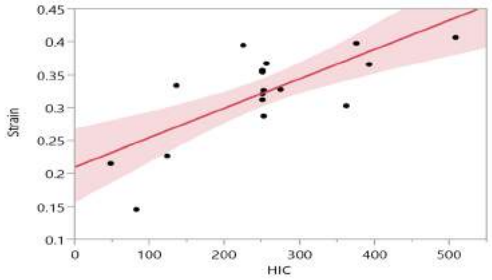

Figure 3. Correlation of HIC to brain strain for all high-impact simulations with loose neck muscle activation.

Specifically, HIC values were less sensitive to subtle changes in posture and direction with the majority of values near 245 (Figure 3).

DISCUSSION

Posture, impact direction, and the interaction between the two affects brain strain and can be explained by the change in moment arm of the applied force with either a change in impact direction or posture. Applying a force to the same location on the skull can result in a dramatically different applied moment about the base of the neck as posture changes. For example, applying a lateral force to the center of the head in a neutral posture will result in mostly lateral bending, but applying a lateral force to the center of the head in a flexed posture will result in both lateral bending and axial rotation of the neck. The increased moment arm allows the same magnitude of force to result in higher linear and rotational accelerations.

Overall, the brain strain followed the same trends as the HIC as posture, impact location/direction, and muscle activation were altered. Notably, frontal impacts and an extended posture both resulted in higher relative HIC than brain strain. This difference highlights the need for additional research on the potential insights of strain-based injury metrics. The results of HIC and brain strain in this study may lead to different conclusions. The results suggest that even while frontal impacts or extended postures result in higher linear accelerations than other directions or postures, the anatomy of the brain allows for lower strain than other directions or postures.

This study demonstrates how the limitations of both kinematic-based and strain-based methods can be addressed using musculoskeletal modeling and rapid brain strain estimation. The musculoskeletal modeling has allowed for estimation of head kinematics for a broad range of impact scenarios. These kinematics can directly be used to calculate kinematic-based injury metrics, such as the HIC. However, the results of this study indicate strain-based methods may lead to different conclusions. This is likely due to neglecting the effects of brain geometry and impact direction. Previously, strain-based methods required finite element simulations. The limitations of finite element models, including simulation time, prohibit simulating a broad range of impact scenarios. Using rapid strain estimation methods accounts for complex brain geometry and the directional dependency of injury, while using the musculoskeletal model allows for investigating a large range of impact parameters.

EFFECTS OF COVID-19 INFLAMMATION ON THE REGIONAL BEHAVIOR OF THE LUNG: A COMPUTATIONAL STUDY

INTRODUCTION

Lung biomechanics has gained significant attention in recent years, and particularly very recently due to the COVID-19 pandemic. The outbreak has indicated the need for a better understanding of the structure-function relationship in the lungs and its computational modeling. Acute respiratory distress syndrome (ARDS) is a frequent complication in COVID-19 and is manifested by mild to severe hypoxemia. Patient with ARDS often require to be mechanically ventilated and poor ventilation protocols can lead to further complications such as ventilator induced lung injury (VILI).

Existing physical models of lung parenchyma involve approximating the acinar structure into a cluster of spheres or dodecahedrons (1). These models may require simulating a large number of clusters to statistically represent the lungs containing over a million alveolar sacs. Alternatively, phenomenological models treating the lung parenchyma as a poroelastic isotropic material can be sought to reduce computational complexity for whole organ modeling. Berger et al. (2) is an example of such models that studies the effect of a spherical blockage on lung function.

In this study, we developed a patient-specific computational model of the lungs for a covid-19 patient. The model is based on thoracic CT scans indicating inflamed regions in the lungs. Our primary objective was to study the effect of inflammation on the regional kinematics and stress distribution in the lung. This study serves as an initial step to understand and predict the mechanical behavior of lung parenchyma with inflammation to improve mechanical ventilation protocols to reduce patients suffering from ARDS and VILI.

METHODS

The patient thoracic CT scans were obtained from St. Joseph Health Regional Hospital. Presence of inflamed regions (indicated by opaque regions in the CT scan) was clear in the scan and was identifiable for image segmentation and reconstruction. The lungs, airways, and the inflamed regions were segmented and reconstructed. The generated mesh was used in ABAQUS to simulate the ventilation of the left lung.

Image reconstruction

The lungs, airways and inflamed region were segmented using the CT scan images. The segmentation of the airways is sensitive to the resolution and number of images in a CT stack. In the current work, 7-8 generations of airways were segmented using the CT images. A representative image from the CT scans is shown in Fig. 1 with inflamed regions being shown with red arrows.

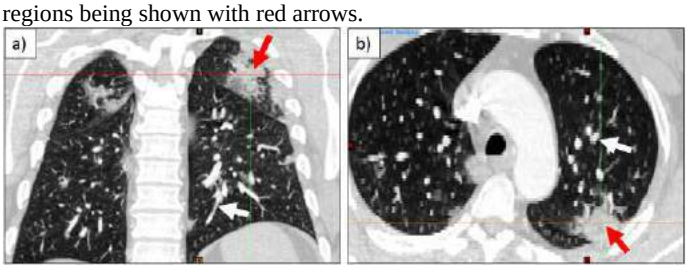

Figure 1: CT scan of patient lungs with inflammation. The inflamed region is marked by the red arrows and the airways are marked by the white arrow. (a) the coronal view, (b) the axial view.

Meshing

The airways were subtracted from the lobes and the resulting part was meshed, i.e., the solid domain is the whole lung with the airways removed. A volumetric mesh was generated for the lungs using quadratic tetrahedral elements. Representative surface/volumetric mesh have been shown in Fig. 2.

Material Model

We developed a poroelastic material model in ABAQUS that relates the alveolar pressure to volumetric deformation. The stress-strain relationship accounts for the changes in local porosity and permeability of the tissue with deformation which leading to a non-linear behavior between pressure and deformation.

Similar stress-strain relationships were used for healthy and inflamed regions. The permeability and compressibility values were altered in the inflamed region to represent the change in the biomechanical behavior of parenchymal tissue due to inflammation.

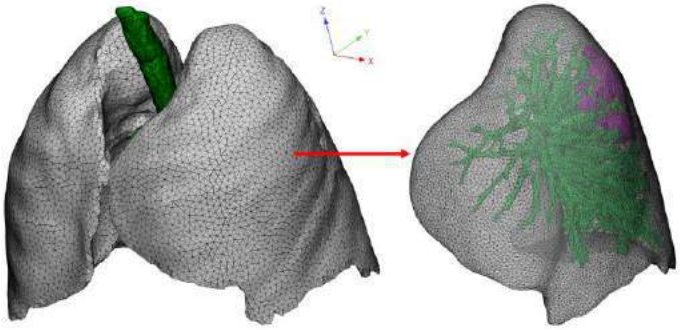

Figure 2: The surface mesh of the lungs. The left lung has been shown separately with transparency with the airways (in green) and inflamed regions (in purple).

Forward model

We conducted several forward simulations to study the effect of inflammation on the regional mechanical behavior. We used pore-pressure elements in ABAQUS for the simulations. The soils solver was used designated for boundary value problems for porous material with fluid pressure in the pores.

The primary bronchus was fixed, and the fluid pressure of 2 cmH_2O was applied in the airways. The initial pressure in the lungs was set to atmospheric pressure and initial porosity was set to 75%. The local stress and strain in the deformed configuration were investigated.

RESULTS

Representative Cauchy stress and logarithmic strain contours in the deformed configuration of the lung with inflammation are shown in fig. 3. Changes in the permeability and compressibility of the inflamed regions led to reductions in stress and strain in the region close to the inflammation.

The initial volume of the lung, 1.61 liters, increased by 250 ml when pressurized to 2cmH_2O. These volume and pressure values are consistent with those reported in Ben-Tal (3). In the healthy regions, strain values of around 5% were observed on the surface of the lungs along with stress values of around 160 Pa.

DISCUSSION

Our results suggest that the inflamed regions sustain a lower strain when compared to the healthy region due to a lower compressibility and permeability. Therefore, compared to a fully healthy lung, when the same volume of air is pumped into a patient with regions of inflammation, the remaining healthy tissue needs to expand further to compensate for reduced deformation in the inflamed regions. This larger strain may lead to damage in the alveoli of the healthy tissue leading to VILI.

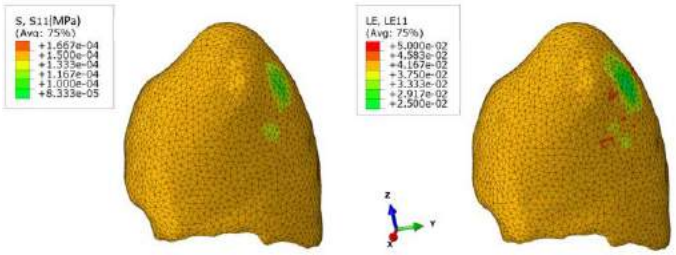

Figure 3: Strain and stress contour plots of the left lung with inflammation. The left figure shows the Cauchy stress where the x-axis is the normal to the sagittal plane.

Our poroelastic lung model serves as a proof-of-concept effort to study the biomechanics of the lungs affected under inflammation. Similar models can be developed for animal models of lung diseases where a variety of experimental measurements and imaging can be conducted. Animal models allow measuring relevant tissue properties in ex-vivo mechanical testing of excised parenchymal tissues. Such integrated models can be used to improve mechanical ventilation protocols.

One limitation of the current study is the absence of the effect of surface tension caused by the thin liquid film present on the inner surface of the alveoli. The surface tension is a function of surfactant concentration which are secreted by the epithelial cells and prevent the alveoli from collapse at low volumes (4, 5). Inclusion of the effect of surface tension will eliminate the need for artificial stresses to keep the lungs inflated in simulations.

Another limitation is the absence of forces acting on the lungs as a result of pleural pressure, the rib cage, diaphragm, and inspiratory muscles. While replicating such forces could be complex, they improve the model towards the representation of patient-specific in-vivo lung function and potential validations with plethysmography data. These limitations are currently being addressed.

MODELLING MECHANICAL FEEDBACK MECHANISMS IN MULTISCALE SLIDING FILAMENT MODEL OF LYMPHATIC MUSCLE PUMPING

Peter Y. Xie (1), Christopher J. Morris (1), James E. Moore (1)

(1) Department of Bioengineering
Imperial College London
London, United Kingdom

INTRODUCTION

The lymphatic system is responsible for returning interstitial fluid back into the venous circulation to maintain fluid homeostasis. Lymph flow can occur via extrinsic and intrinsic pumping mechanisms, although the relative contributions of these mechanisms to flow is poorly understood. The intrinsic pumping mechanisms are intricately regulated by mechanical forces acting on the lymphatic vessel [1]. The ability of the lymphatic vessel to respond to local mechanical forces allows it to respond to transient changes in interstitial fluid volume or local pressure/flow conditions [2]. Although multiple studies and experiments have explored the effects of varying pressure gradients and transmural pressures on lymphatic pumping [3,4], little is understood of the sub-cellular/molecular mechanisms underlying this behavior [5].

From existing research, we understand that the two most significant biomechanical signals that affects lymphatic contractile activity are flow-induced shear stress and pressure-induced stretch. Flow-induced shear stress induces the production of the chemical substance Nitric Oxide (NO), produced by eNOS in the lymphatic endothelial cells and diffuses rapidly into nearby lymphatic muscle cells. NO is a well-known vasodilator which inhibits Ca^{2+} entry from internal stores, resulting in negative inotropic and chronotropic effects [5]. Pressure-induced stretch results in clear elevations in both basal and peak calcium levels as pressure in the lymphatics is increased. This results in intrinsic positive inotropic and chronotropic effects [1]. The increase in phasic contractile force occurs up to a maximum level of stretch, when the amount of stroke work required to compress the lumen surpasses the increase in phasic contractile force [6]. It is speculated that stretch-activated ion channels undergo conformational changes in response to stretch, allowing more calcium entry from outside the cell [5].

The overarching aim of this research is to develop a more accurate and representative model of a single lymphangion at the sub-cellular level, to improve our understanding of lymphatic pumping on multiple scales and find ways to improve lymphedema treatments.

METHODS

An existing sub-cellular muscle model developed by our research group [7] was updated to incorporate biomechanical feedback mechanisms, modelled and trained to replicate experimental results exploring the effects of varying pressures on lymphatic pumping [3,4]. We used experimental results obtained from rat mesenteric vessels as a basis for parameter values in the model. The performance of the model with the incorporation of biomechanical feedback mechanisms is verified using afterload experiments [8].

In the implementation of biomechanical feedback mechanisms, wall shear stress imposed on the lymphatic vessel is calculated assuming Poiseuille flow:

$$\tau = \frac{32\mu Q}{\pi D^3} \quad (1)$$

and the magnitude of pressure-induced stretch of the lymphatic vessel is defined by the stretch_ratio (ratio of diastolic diameter to the diameter at 0cmH2O transmural pressure).

The average value of wall shear stress across the whole contractile cycle and the average stretch_ratio across the diastolic period of a contractile cycle are used as variables to modulate sub-cellular mechanisms in the next contractile cycle. These control signals are then processed to modify a) the systolic calcium amplitude concentration and b) frequency of action potentials.

The 3D representation of the functions modulating a) and b) (Fig 1,2.), represents the computational function, and the line plots represent experimental data from Gashev [3,4].

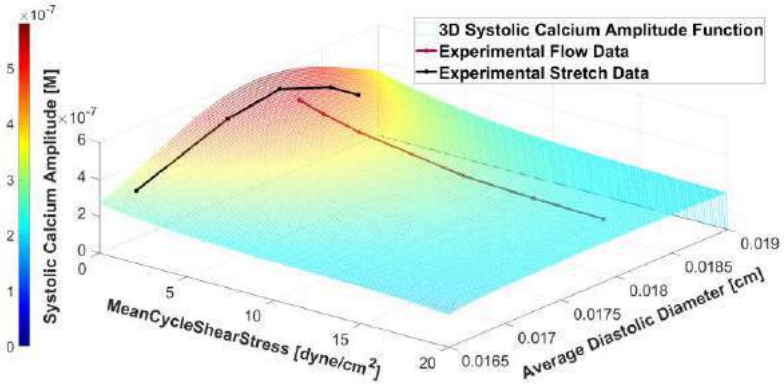

Figure 1. 3D Plot of Systolic Calcium Amplitude Modulation. Function postulated by considering experimental flow data (red) [3] and experimental stretch data (black) [4].

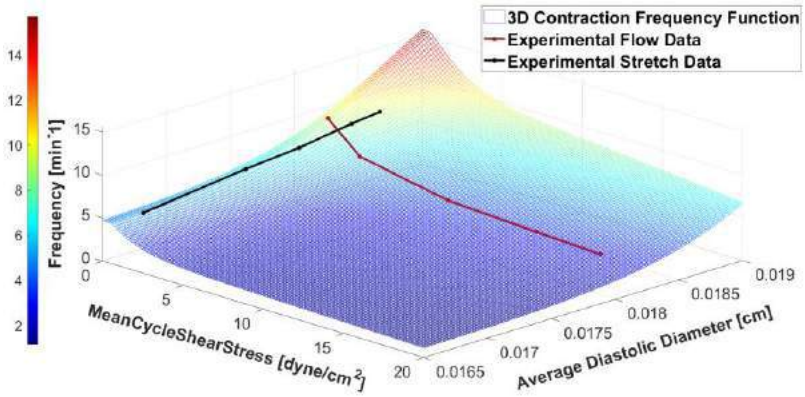

Figure 2. 3D Plot of Frequency Modulation Function. Function postulated by considering experimental flow data (red) [3] and experimental stretch data (black) [4].

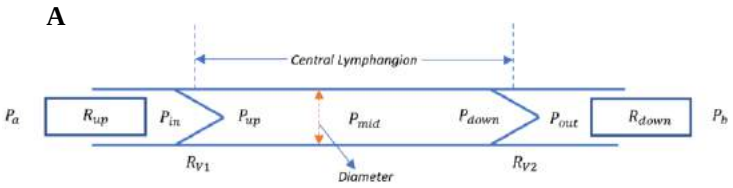
RESULTS

The performance of the model with the incorporation of biomechanical feedback mechanisms was tested by comparing to afterload experiments on isolated rat mesenteric lymphatics from the literature [8].

Elevation of outlet pressure tests the response of the lymphangion to increases in pressure that could result from a gravitational load, outflow obstruction, or tissue compression [8]. In the model, Diameter response to elevated outlet pressure shows a gradual increase in systolic diameter (Fig 3B), due to a combination of the increase mid-lymphangion pressure, as well as inhibition of the intracellular systolic calcium amplitude during the pressure ramp.



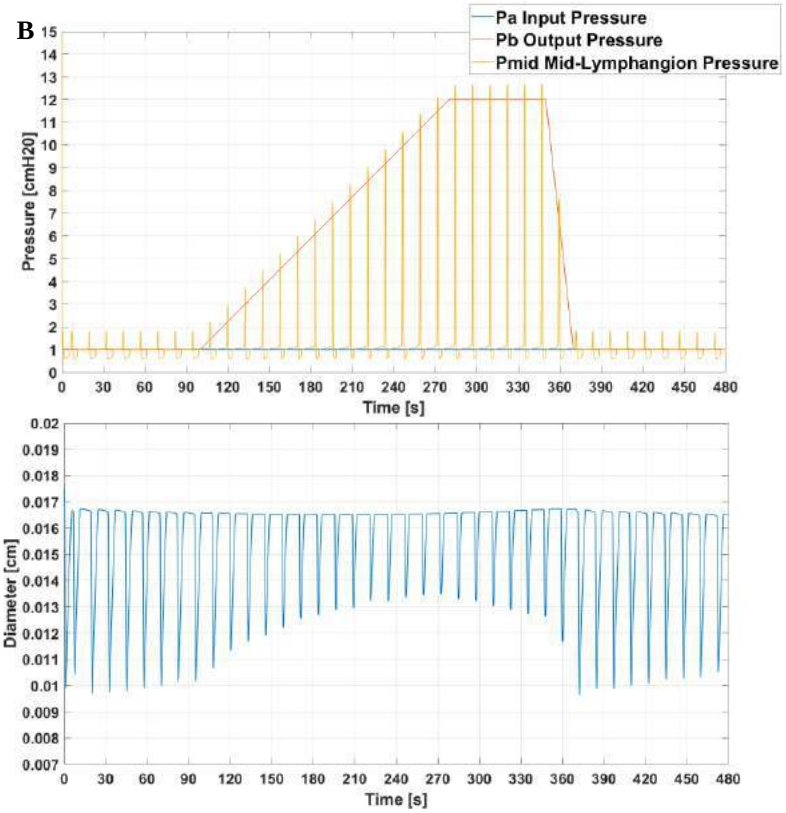


Figure 3. Response of single lymphangion to an output pressure ramp. A: Schematic of the single lymphangion with associated pressure values. B: Diameter response of Lymphangion to ramp-wise elevation in outlet pressure.

DISCUSSION

Stroke volume comparison show there is close replication between the response of the computational model and the experimental results from Davis [8]. The addition of biomechanical feedback mechanisms is a first step to quantitatively understand the relationship between mechanical signals acting in lymphatic vessels and its effect on the subcellular response of lymphatic muscle cells.

Further validation with experimental results, as well as extending this model to multiple lymphangions in series will further progress our understanding of lymphatic pumping to help find better treatments for lymphedema.

INTRODUCTION

Alzheimer's Disease (AD) is a progressive neurodegenerative disorder and the most prevalent form of dementia [1]. AD is known for extreme memory loss, cognitive decline, and ultimately death. The two primary biomarkers of AD are amyloid-beta (Aβ) peptides and neurofibrillary tangles (NFT) of tau. These proteins and their interactions lead to disruptions in neuronal activity and eventually neuronal death. Corresponding cerebral atrophy, which manifests as cortical thinning and ventricular enlargement, follows a spatiotemporal pattern that is incongruous with each biomarker's spreading pathways. This study aims to formalize the relationship between neurofibrillary tangles and Aβ plaques progression. To date, it has been shown that Aβ plaques, which precede tau, spread by proximity, while NFTs spread based on the structural network form by axons and are typically referred to as the connectome. Our proposed model incorporates these distinct differences and forms a unifying theory of atrophy progression in AD patients.

METHODS

We review the literature on experimental methods and medical imaging that investigate the initiation, progression, interaction, and neurodegenerative effect of the two misfolded proteins involved in AD: Aβ and NFT. We summarize our findings in schematic pathways and propose a tissue damage model that couples Aβ and NFTs and can be used to predict cerebral atrophy.

RESULTS

Aβ plaques. The Aβ monomer is formed when the amyloid precursor protein (APP) misfolds. This changes Aβ's conformation, which proceeds to form low (dimer/trimer) oligomers [2]. These oligomers accumulate in intraneuronal pathways and exhibit prion-like behavior [3]. As shown in Figure 1, these oligomers convert normal APP into Aβ oligomers. These oligomers are then released outside the cell via exocytosis, where they form Aβ fibrils that ultimately form Aβ plaques. In AD, these Aβ plaques are first found in the neocortex, from where they progress into subcortical regions, medulla oblongata, and finally, appear in the cerebellum [4].

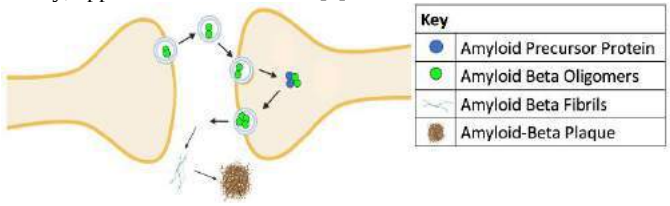

Figure 1: Schematic of Aβ pathway from precursor protein to plaque. Aβ infiltrates proximal neurons via trans-synaptic spread.

Neurofibrillary tangles. Tau protein appears primarily in axons and stabilizes microtubules. In AD, tau is hyperphosphorylated, which causes it to misfold and form fibrils. Fibrils then aggregate as neurofibrillary tangles that substantially disrupt normal axon function due to the destabilization of microtubules. As shown in Figure 2, tau travels intercellularly through tunneling nanotube structures (TNT's) or via the release of exosomes [5]. Tau pathology is first observed in the transentorhinal cortex from where it spreads into the hippocampus. The subsequent stages are well known and based on the work of Braak et al. [6]. Following the hippocampus, NFTS begin to appear in structurally connected regions in the neocortex via the axonal connections of the brain [6]. This spreading pattern is markedly different from Aβ and plays a critical role in formulating a model that couples Aβ and NFT concentrations to form a tissue damage model.

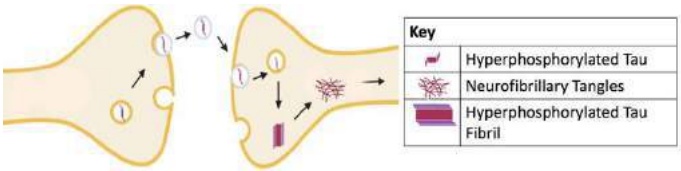

Figure 2: Schematic of intracellular spreading of NFTs.

Aβ and NFT coupling. Besides the independent pathways described above, we identified pathways in which Aβ oligomers directly contribute to tau's hyperphosphorylation in various pathways. As illustrated in Figure 3, there are three main interaction pathways: In the first pathway (black arrows), Aβ peptides bind to the NMDAR receptor. This leads to calcium ion dysregulation and drives calcium ion influx, which activates another kinase named calmodulin-dependent protein kinase (CAMKKB). CAMKKB, in turn, phosphorylates adenosine monophosphate protein kinase (AMPK), which is known to phosphorylate tau [7]. In the second pathway (red and green arrows), Aβ oligomers bind to insulin receptors and subsequently inhibit the Akt pathway (shown in red arrows) [8]. Akt is a serine/threonine kinase that inhibits GSK3beta through the activation of P13k. However, since the Akt pathway is inhibited, P13k cannot inactivate GSK3beta, leading to tau's hyperphosphorylation [8]. Finally, the third pathway (blue arrows) shows how Aβ oligomers inhibit Wnt signaling, leading to the overactivation of GSK3beta [8]. In this case, Aβ oligomers activate the kinase DKK1, which internalizes LRP6 receptors. This inhibits Wnt signaling and leads to GSK3beta overactivation [8]. This then leads to hyperphosphorylation of tau.

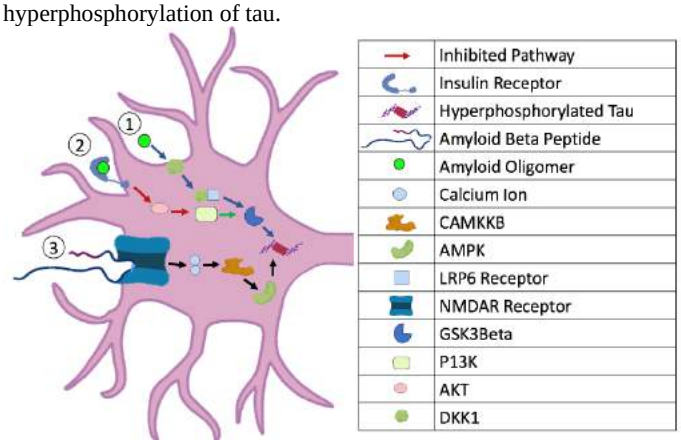

Figure 3: Schematic of Aβ-facilitated hyperphosphorylation of tau. We identified three relevant pathways (black/red/blue arrows).

Framework for a mathematical atrophy model. Aβ plaques damage neuronal synapses and induce neuron cell death based on the amyloid cascade hypothesis [2]. Hyperphosphorylated tau is implicated in disrupting microtubule dynamics, which can lead to apoptosis [5]. Additionally, Aβ is also known to precede and contribute to tau's hyperphosphorylation, such that there is an intricate coupling that leads to spatially heterogeneous neurodegeneration. We schematically show our Aβ-NFTS-apoptosis model in Figure 4. We pose that the production of Aβ leads to the creation of Aβ plaques that cause apoptosis. In a similar process, and not necessarily in the same place, tau protein is converted into neurotoxic NFTs. Coupling takes place in the form of Aβ plaques accelerating the production of neurotoxic NFTs. The result is a positive feedback loop that triggers progressive neurodegeneration that spreads through the brain by distinct spatial mechanisms.

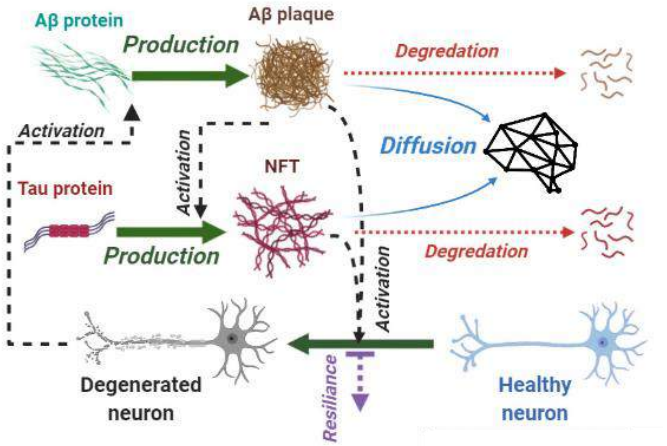

Figure 4: Schematic of our atrophy model that couples Aβ and tau to make predictions of spatiotemporal AD progression patterns.

DISCUSSION

Two biomarkers characterize AD: Aβ plaques and hyperphosphorylated tau. Tau spreads through neuronal connectivity, whereas Aβ spreads by proximity. There are structural changes in AD that can be correlated to Aβ and hyperphosphorylated tau progression. In AD patients, the earliest atrophy occurs within the hippocampus and the entorhinal cortex, where neurofibrillary tangles pathology is initially detected [9]. The atrophy spreads into the neocortical regions, where Aβ plaques are first detected, and neurofibrillary tangles are later found [8]. Aβ pathology is widespread in early disease stages, while tau pathology develops considerably later. This observation is in line with the amyloid cascade hypothesis, which predicts that changes in Aβ are the initial driving force behind tau pathology [10].

Symptoms of AD begin to appear when tau pathology spreads into the hippocampus, and the symptoms become more severe when tau pathology reaches the neocortex's primary and secondary areas [10]. This suggests that AD pathology is driven by a coupling between tau pathology and Aβ pathology [10]. The presence of Aβ plaques in non-demented brains is further evidence that AD is characterized by a distinct interaction between these two biomarkers [9]. Using the information provided in this study, we will be able to formulate the corresponding mathematical in order to simulate the spatiotemporal progression of cerebral atrophy. We will validate our simulations by comparing longitudinal structural and functional PET imaging data from the Alzheimer's Disease Neuroimaging Initiative.

ENGAGING BIOMEDICAL ENGINEERING STUDENTS WITH GAMIFICATION IN ONLINE LEARNING

N. Dorfner (1), R. Zakerzadeh (1)

Pittsburgh, PA, US

INTRODUCTION

In the past year, remote education has become much more prevalent due to the COVID-19 pandemic. Within online learning environments, students have fewer opportunities to engage with peers, which requires instructors to adjust their teaching approaches and strategies [1]. This study offers evaluation of gamification in remote teaching of a third-year level biomedical engineering core course. The course teaches introductory concepts of cardiovascular fluid mechanics and flow characteristics of biological systems.

While gamification in pedagogy is not new, procedures must be altered for a remote classroom in order to improve lecture engagement. In both in-person and remote environments, the same approach can be utilized to employ games, however, the benefits of increasing attentiveness and inducing motivation are more advantageous in an apathetic online setting [2]. In this work, we present a roadmap for creating a more engaged environment in BME classrooms by using academic games for teaching. The incorporation of BME concepts is in the "preparation" stage of gamification, regardless of the type of game. Various game ideas with BME integration are suggested, as well as a preliminary analysis of student engagement while playing Bingo with cardiovascular biofluid terminology.

METHODS

Several key steps must be followed in creating an academic game: definition of learning objectives, game design, preparation of tools, implementation, and assessment [3]. This process is illustrated in **Figure 1.** When following these stages to create a BME Bingo game, we first define the learning goal as practicing cardiovascular mechanics concepts. For game design and preparation, a list of keywords is composed and input into an online Bingo card generator. The preparation step is unique in its incorporation of the fluid mechanics course concepts. The selected keywords should reflect course material to fulfill the learning objective of practicing and reviewing the terminology. For example, the keyword list can include but is not limited to density, artery, viscosity, Bernoulli, stent, stenosis, blood flow, velocity profile, pressure gradient, laminar flow, diffusion, aneurysm, and cardiac cycle. Bingo cards are then distributed to students in an online link or downloadable PDF via email or a file sharing service, such as Blackboard or Canvas.

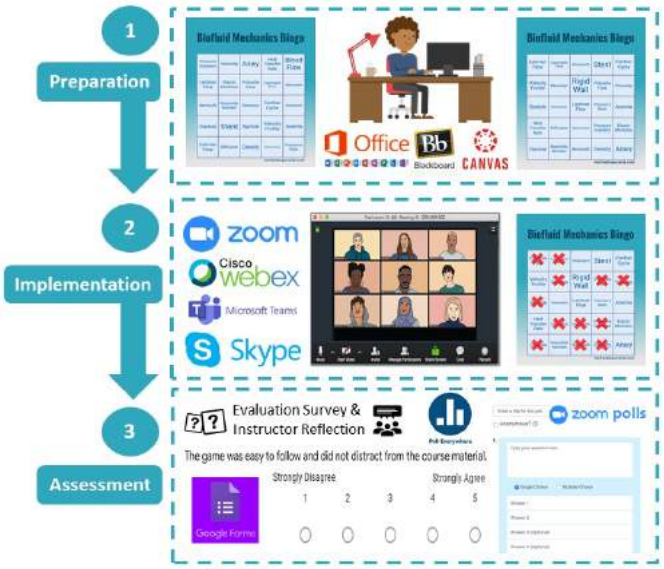

Figure 1: Steps to implement Bingo as an academic game.

In the virtual classroom on Zoom, instructors ask students to select a random Bingo card to play. The instructor solves problems and students mark keywords as they notice definitions, formulas, or concepts applied in the problem set. Students who mark 5 keywords in the same horizontal, vertical, or diagonal row send the word "Bingo" in the chat box. A reward or incentive can be offered to induce motivation and participation. However, this reward must be carefully selected [4]. All 38 students enrolled in the course were given the option to participate in the game activity. We played Bingo twice in the Fall 2020 semester as exam review. Participation was voluntary and no reward was offered to ensure authentic student motivation and engagement in the game. 35 students participated in Bingo and responded to a post-game questionnaire (92% of the course enrollment).

RESULTS

Through instructor observations and interpretation of the gameplay, students responded positively to the game and were motivated to play. Students asked more questions during the game and sent more In the post-game survey distributed after the second Bingo game, students were asked to rank their perception of engagement with the Likert Scale, where 1 represents "strongly disagree" and 5 represents "strongly agree." The statements on the survey and results are presented in **Figure 2.**

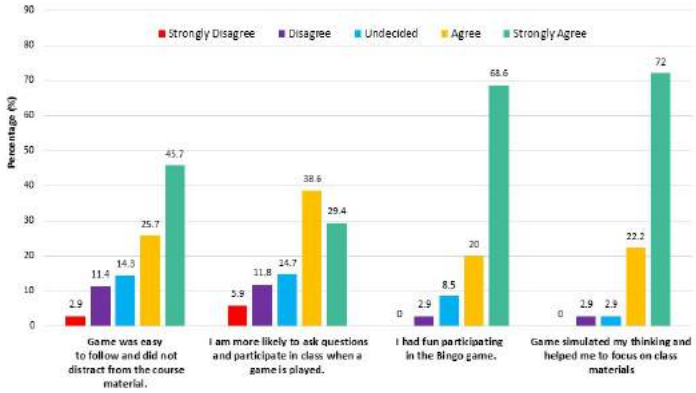

Figure 2: Results of the survey showing the percentage of students participating in the game and responding in each category to the statements.

Based on the survey results, students agreed that they were more engaged in class while playing Bingo. Students felt comfortable and relaxed while playing the game, as they enjoyed Bingo and were more likely to ask questions. The game also stimulated their thinking, and students said they were attentive to the problem solving. Due to ethical and logistical concerns, student marks were not used to evaluate comprehension or engagement in material. Only four survey statements were used to generate high student participation in the post-game questionnaire. The survey was not designed to be strenuous or time consuming for students, as that negates the simple, entertaining, and engaging intention of playing Bingo. We also employed the anonymous polling feature on Google Forms, so students could leave honest responses about the game without fear of bias or concern of their grades.

DISCUSSION

Our results demonstrate that this instance of gamification successfully engaged students during course review of biofluid mechanics concepts. However, the study is limited to the small sample size, time, and resources dedicated to preparation and implementation of Bingo. Games are recommended when instructors need to break their typical classroom routine and make teaching fun. Remote gamification proved to be more difficult than anticipated. One challenge experienced was the lack of emotional and social interaction during the game. Students absorb energy from the social aspect of education, and instructors respond accordingly with dynamic teaching. The absence of this exchange made game play engagement uninspiring and more demanding. Another challenge was finding game materials that can be easily distributed virtually.

Despite these inconveniences, the adaptation of Bingo to encompass biomedical engineering concepts was rather simple. Additional examples of biomedical engineering academic games are shown in **Figure 3**. In Pictionary, instructors present a picture, such as a diagram of laminar flow, and students explain the meaning and application of the picture. Similarly, in "the one-minute paper," students read a paper for homework and explain the significance and application of course concepts the next class period. Execution of a trivia game, like Jeopardy, involves instructors making questions relating to course material and vocabulary with teams of students answering for points. Students in an online environment may benefit from an interactive picture or experiment of the day, where the instructor performs a demonstration relating to a course concept. In biofluid mechanics, the definition of viscosity would be explained by showing that honey has a higher viscosity than water or blood.

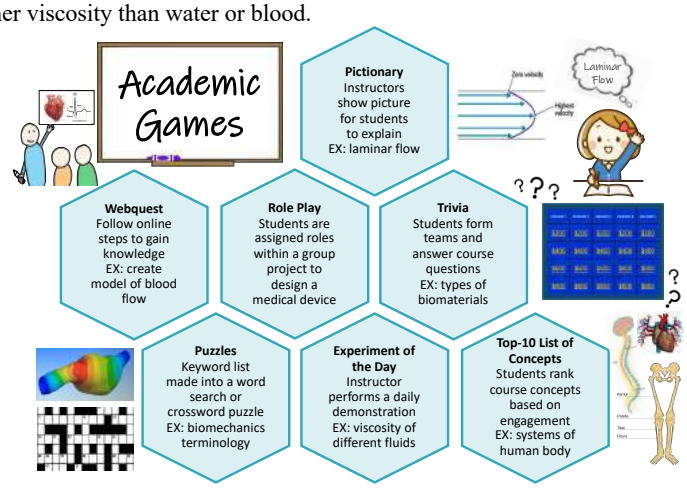

Figure 3: Examples of academic games for online biomedical engineering implementation.

In the future, we would like to investigate gamification using course marks, lecture attendance, and more detailed student feedback. This can be achieved using reflection assignments, blog posts, and activity evaluation rubrics to enhance our perception of students' thought process, suggestions, and improvements for games. Gamification is not appropriate in all educational setting or classes. Games can make concepts seem less serious to students, and the time-consuming nature of the gamification process may outweigh the potential benefits. Games cannot be used to replace pedagogy, but rather should be integrated into course delivery to enhance the overall learning experience.

SIMULATION OF OXYGEN MASS TRANSPORT IN A COMPLIANT ABDOMINAL AORTIC ANEURYSM MODEL

A. Throop (1), B. Carbino (1), A. Guy (1), N. Dorfner (1), R. Zakerzadeh (1)

(1) Department of Engineering, Rangos School of Health Sciences, Duquesne University, Pittsburgh, PA, USA

INTRODUCTION

Abdominal aortic aneurysm (AAA) is a cardiovascular disorder that affects more than 3 million Americans per year. Ruptured aneurysms of this type are up to 80% fatal in clinical cases [1], and detection of symptoms is particularly challenging. Little is understood about the mechanisms of AAA formation in the body and the progression towards AAA rupture. Consequently, a proper understanding of AAA behavior can lead to diagnostic tools that can simulate and assess patient-specific cases. The use of computational models has been employed on a number of AAA problems, but most lack interactions between arterial components and blood. This study will model and examine patient-specific AAA using a fluid-structure interaction approach with coupling of blood flow and wall deformation. Observations of total deformation, blood velocity, and maximum principal stress are made on a fully coupled, ANSYS Workbench model. In addition to analyzing hemodynamics and wall deformation, we will also present findings of the oxygen concentration in the vessel. Unlike existing literature, combining a coupled hemodynamic and wall deformation model with oxygen transport is addressed in this study.

METHODS

The patient specific geometry is provided by the NIH repository in an STL (STereoLithography) file format [2]. It is constructed from CT scans visualizing the lumen and arterial wall but lacks the ILT due to its complex nature [3]. This model includes one inlet, with diameter of 1.5 cm and wall thickness of 0.1 cm, and four outlets. The discretized model consists of 2367337 elements, while the fluidic domain is comprised of 843879 tetrahedral cells. To account for the dynamic fluid-structure interactions between blood and AAA wall, a fully-coupled multiphysics model was created in ANSYS 2020 R2. Blood dynamics are defined in ANSYS CFX, arterial wall mechanics are modeled in ANSYS Mechanical, and the fluid and solid components interact directly through a fully coupled Fluid-Structure Interaction (FSI) method.

With regard to hemodynamics, blood is modeled as a steady state, incompressible, Newtonian, laminar fluid with the Navier-Stokes equations. The blood flow is coupled with the oxygen transfer in the lumen and accounted for by the convection-diffusion equation. The diffusion-reaction equation is used to model the oxygen transport in the AAA wall. The inlet boundary condition is described as a uniform velocity profile of U_f^{in} = 0.3 m/s and an oxygen concentration of C_f^{in} = 5.2×10^{-3} kg/cm^3, while the outlet has a pressure of 0 Pa [4]. These equations and conditions are implemented in a fully coupled system with the arterial wall treated as an impermeable structure. The fluid and structure are solved simultaneously in a monolithic linear system (Figure 1).

Table 1: Physical material properties and values

Material Name	Parameter Description	Parameter Value
Blood	Density	1050 kg/m^3
	Dynamic Viscosity	0.0035 kg/m.s
Arterial Wall	Density	2000 kg/m^3
	Poisson Ratio	0.49
	Oxygen Diffusivity	1.08×10^{-9} m^2/s
	Young's Modulus	1.08 MPa

The arterial wall is assumed to be elastic, isotropic, incompressible and homogeneous. Concerning structural interactions, the material properties shown in Table 1 are input into the Engineering Data widget of Static Structural. The static AAA mesh is then assigned elastic fixed supports at the inlet and outlet boundaries, and a fluid-solid interface was defined on the inside of the lumen to act as the system coupling region.

The two models are joined along a single FSI boundary. The simulation is carried out using ANSYS' system coupling feature included with the ANSYS Workbench product. The System Coupling component solves fluid and solid domains separately to obtain the pressure loads from the blood flow in ANSYS CFX. These pressure loads are applied to the solid arterial wall through the fluid-solid interface and the wall displacement is solved in ANSYS Mechanical. This process of the System Coupling algorithm in ANSYS is illustrated in Figure 1.

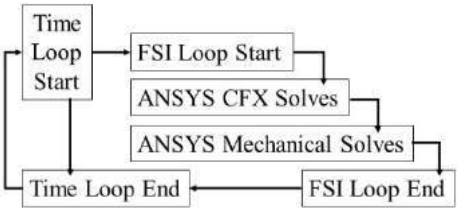

Figure 1: FSI algorithm in ANSYS.

RESULTS

Figure 2 demonstrates the results of the system coupling's CFX component. The plot on the left shows colored streamlines to demonstrate the velocity magnitude. The pattern shown expresses a three-dimensional helical shape at the bulge which uncoils further down the lumen. The blood velocity at different cross-sectional slices are also shown on the right plot of Figure 2. As expected, the blood velocity is observed to be the smallest at the bulge.

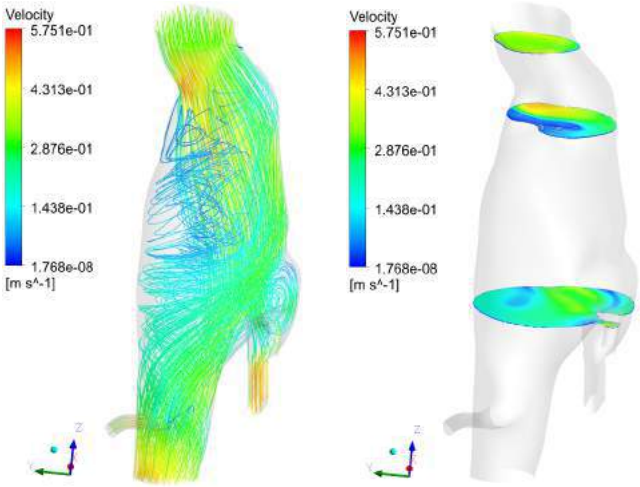

Figure 2: Stream traces colored by the velocity (left) and velocity contours of steady flow on cross-sectional slices (right).

The results of the structural component are shown in Figure 3. On the left of the figure, the plot shows the total wall deformation from the stress of the blood. The greatest point of deformation is found at the bulge. This correlates with the plot of the maximum principal stress on the right of Figure 3 which indicates the maximum stress to be at the bulge.

In Figure 4, the oxygen concentration is plotted on the top view of the cross-sectional slices from Figure 2. The smallest concentration is indicated to be on the outer portion of the wall and the largest on the interior. These results are expected due to the oxygen transport from the blood in the lumen.

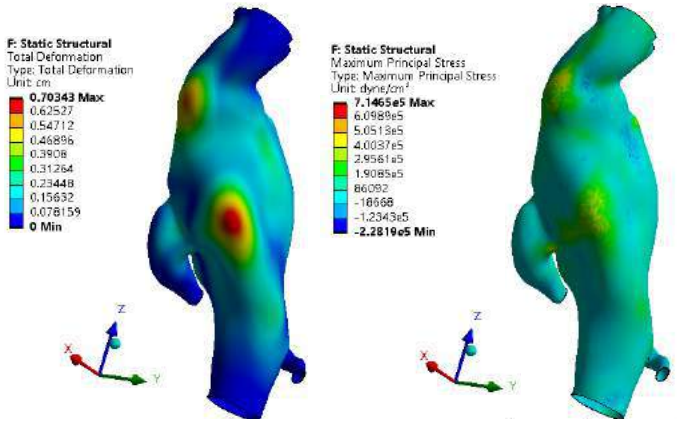

Figure 3: Total deformation (left) and maximum principal stress (right) on the arterial wall.

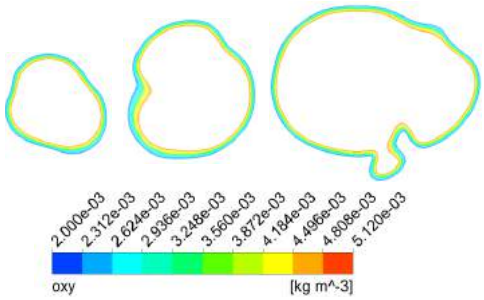

Figure 4: Oxygen concentration profiles of cross-sectional slices shown in Figure 2.

DISCUSSION

In this study, a patient-specific AAA case was modeled using the fluid-structure interaction (FSI) method on ANSYS. The finite element solver accounted for blood flow, oxygen concentration, and arterial wall deformation. The displacement of the wall was taken into consideration through the implementation of the static structural component. This allows for a better representation of the stress from the blood on the arterial wall. Our goal is to further investigate the effects of wall compliance of oxygen transport in the model.

Our approach, however, has some limitations: the geometry does not include the ILT. We have previously explored the effect of a porous arterial wall on oxygen transport [3] using a rigid wall model, and we plan to investigate how the wall deformation affects the flow-driven mass transport. Additionally, although we believe that the steady-state assumption is reasonable for the current stages of our study; we would like to analyze the effect of transient behavior and pulsatile simulation in our future studies. This consideration, combined with the shift towards accounting for ILT and arterial wall permeability could generate high computational costs, so alternative computing methods may be required.

THE EFFECT OF STENOSIS SEVERITY AND ARTERIAL WALL MECHANICS ON FUNCTIONAL DIAGNOSTIC PARAMETERS

A. Alday (1), T. Lone (1), R. Zakerzadeh (1)

(1) Department of Engineering, Rangos School of Health Sciences, Duquesne University, Pittsburgh, PA, USA

INTRODUCTION

Vascular stenosis is the hardening of arteries caused by a buildup of fat and cells. This can cause narrowing of vessels and ultimately cause difficulty in fluid flow, indicated by a pressure gradient that occurs across the stenosed region (**Figure 1**).

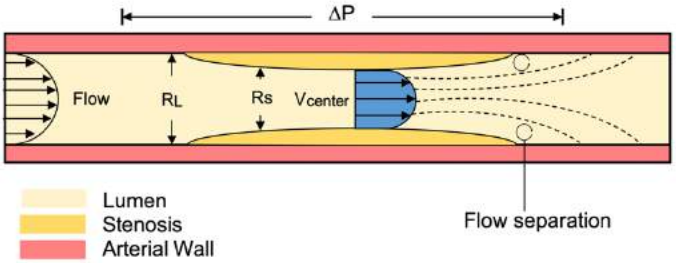

Figure 1. Schematic of a stenosed blood vessel.

This is indicative of the energy loss of the fluid flow which inhibits the distribution of nutrients throughout the body. Depending on the severity of the stenosis, it is possible for the condition to occur undiagnosed until a fatality occurs. The most common method to assess this condition is through routine clinical testing. Doppler echocardiography is a widely used, non-invasive method that often provides inaccurate information regarding pressure and blood flow [1]. This is due to the conversion of velocity to pressure drop by means of the Bernoulli equation, which can lead to premature surgical treatment. Another option frequently utilized is an invasive catheter operation that provides direct pressure values but can be hazardous to a patient's health [1]. In order to minimize clinical risk and ensure the safety of the patient, it is necessary to develop a reproducible, non-invasive, and comprehensive method. A computational model is more suitable than the Doppler measurement as it can simulate functional assessment factors, such as pressure gradient, more accurately by taking into account the viscous losses resulting from resistance of the fluid flow.

The purpose of this study is to assist with the assessment method of an arterial stenosis by analyzing the effect of stenosis severity and arterial wall stiffness on pressure gradient and diagnostic parameters across the stenosed region. We hypothesize that the computational model will sufficiently measure invasive parameters in a vascular stenosis without the risks of invasive clinical assessment methods.

METHODS

Our objective is to identify the relation between arterial wall motion and pressure drop in a model of a stenosed vessel. In order to approximate this problem, we use a partitioned, loosely coupled finite element solver developed in our previous work (see [2] for details). Our fluid-structure interaction (FSI) solver is based on the weak enforcement of interface conditions using Nitsche's method, allowing us to independently solve the equations in different regions. The computational method allows us to simulate propagation of pressure waves and the related arterial wall deformation into an arterial segment. Blood is modeled as an incompressible, viscous fluid and the arterial wall consists of a thick material, accounting for its multilayer structure.

We created finite element geometric models using FreeFem++, an open-source software package, for the FSI simulations. Our solver used Navier-Stokes equations to model blood flow and a hyperelastic material was employed to model a deformable arterial wall. An Arbitrary Lagrangian-Eulerian mesh was generated to perform the FSI simulations. To simulate the response to stenosis, we modified the geometry to exhibit a defined degree of narrowing. Wall mechanical properties in the geometrical models were tuned to account for the wide range of stenotic wall features reported in literature. Using this model, Fractional Flow Reserve (FFR), Pressure Drop Coefficient (CDP), and fluid pressure across the stenosed region are measured. FFR is a ratio of pressure values measured in dyne/cm^2 determined using equation (1):

$$FFR = \frac{Pressure_{distal}}{Pressure_{proximal}} . \quad (1)$$

FFR measures trans-stenotic pressure difference to assess severity of

arterial damage. CDP is a non-dimensional index that combines stenotic pressure, proximal velocity flow, and blood density. It is determined by the following equation (2), where ρ is the density of blood (1 g/cm^3) and $\mathcal{V}$ is the velocity proximal to the stenosis measured in cm/s:

$$CDP = \frac{\Delta P}{0.5\rho\mathcal{V}^2}\ . \quad (2)$$

This parameter can be utilized to further evaluate a stenosis because it takes into account the viscous energy lost to friction and the change in momentum across a stenosed region. These techniques are used in invasive catheterization, whereas non-invasive Doppler echo-cardiography assesses stenosis severity using a simplified Bernoulli principle. This equation (3) relates pressure difference to maximum velocity at the neck of the stenosis, represented by V_{max} in cm/s:

$$\Delta P_{Doppler} = 4V_{max}^2. \quad (3)$$

RESULTS

The computational model was executed at seven different stenosis severity percentages (10, 30, 50, 70, 80, 90, 95) and with four different arterial wall elasticity measurements in MPa (0.5, 1, 4 10). In order to confirm the functionality of the model, fluid pressure was analyzed. The peak fluid pressure gradient was found to occur prior to the completion of half of a cardiac cycle **(Figure 2**). Further, FFR nonlinearly decreased with increased stenosis severity in the cases with varying wall elasticity (**Figure 3**). We found at the greatest wall stiffness, the FFR value decreased the most among all stenosis severities. **Figure 4** showed a nonlinear increase in CDP with increased stenosis severity for all arterial wall elasticity values. We found the greatest increase in CDP occurred in the case of most extreme stenosis severity. Finally, in **Figure 5** a nonlinear increase in P-Doppler with an increase in stenosis severity for varing values of wall compliance is observed.

DISCUSSION

Our computational model is a sound approach because the trans-stenotic pressure over two cardiac cycles confirmed physiological hemodynamics, visualized by the increased pressure proximal to the stenosis and the slight decrease distal to the stenosis (**Figure 2**). Doppler echocardiography does not account for this pressure gradient, thus overestimating stenosis severity [3]. Therefore, surgical correction is often premature and unnecessarily risky. Furthermore, clinical literature states that FFR<0.75 requires surgical correction; this was determined to fall in the range of 78.7-82.7% stenosis severity [4]. Our data is in agreeance with this conclusion, as **Figure 3** demonstrated that stenosis cases greater than 80% severity, across all arterial wall stiffnesses, indicate FFR>0.75. Thus, the computational model successfully simulated parameters from invasive stenosis assessments as opposed to the non-invasive Doppler echocardiography approach.

Figure 3 and **Figure 4** demonstrated that FFR and CDP are inversely related. As stenosis severity increased, blood flow velocity increased across the stenosis which caused a decrease in distal pressure and increase in viscous energy loss. This can be attributed to frictional forces and change in momentum [4]. **Figure 3** also demonstrated that pressure drops proximal to the stenosis are minor in mild stenosis cases (<30% severity level). Therefore, we can conclude that mild stenoses maintain relatively consistent velocity across the stenosis for all arterial wall stiffness levels.

Although a standardized cut-off value for CDP has yet to be determined, we observed that the nonlinear increase in CDP values began to rapidly increase at stenosis severity levels greater than 80%. In the future, patient-specific geometries can be used to create a higher fidelity framework, as well as expand on parameteric knowledge like that of CDP. Also, using heterogenous material properties for the arterial wall may result in more realistic physics of the lesion.

INTRODUCTION

Benchtop design is a longstanding cornerstone of medical device design. One upside of benchtop design is its inherent reality. That is, because it is carried out in the physical world on the benchtop, numerous factors that affect use of a device in its intended environment (which of course is also in the physical world) are inherent. One downside of benchtop design in the context of medical devices, however, is lack of scalability. That is, only so many benchtop models of anatomical and physiological environments can be explored. This lack of scalability is particularly problematic when a single device is intended for use across a highly variable patient population.

Computational modeling and simulation on the other hand have historically played a very different role in medical device design. In fact, only over the past decades has it become more common for the FDA to consider (and now recommend) computational modeling and simulation in the design of certain devices. One downside of simulation is that that unlike benchtop work it is not rooted in reality. That is, the result of a simulation will only be as realistic as the underlying model that is employed and the assumptions that inform it. But there is also a massive upside to simulation – scalability. That is, simulations can be performed to explore countless scenarios bounded only by computing power and input data, both of which continue to grow.

One device that may benefit greatly from computational design practices is the flow diverter (FD). In fact, computational components are already common to applications to the FDA involving new FD designs. FDs are braided stents composed of many wires that can be deployed across the neck of a cerebral aneurysm (CA), which is a localized ballooning of a blood vessel in the brain. One objective of deploying an FD is to limit flow of blood into the aneurysm, thereby promoting clotting in the aneurysm and eventual exclusion of the lesion from circulation over time. Like most, if not all, medical devices, many design inputs affect FD performance, and performance can be quantified based on many different interventional outputs.

Although patient-specific FD design and manufacture may be on the horizon given the advent of 3D printing, we still live in a world of "one device for many patients." In this paper, we propose a preliminary framework for FD design at scale. Specifically, computational modeling and simulation are used to identify the optimal wire count design input across a population of five anatomies based on interventional outputs including apposition proximity and post-deployment pore density.

METHODS

DICOM format CT images of five sidewall CA anatomies with similar parent vessel diameters were segmented in Mimics (Materialise, Lueven, Belgium) to create STL models. The centerline of each CA geometry was computed, smoothed, and resampled using the Vascular Modeling Toolkit (VMTK) in Python. All further computation and processing was done in Python, using the Visualization Toolkit (VTK) for visualization. Unique planes were ascribed to each centerline point defined by the vector pointing to the subsequent centerline point as the normal. A coordinate system was created on each plane for raycasting and visualization of FD models. By raycasting vectors at increments of ¼ degree through every plane, the in-plane vessel wall contours were approximated and used to locate the aneurysm and its neck.

To model the aggregate behavior of the FD wires, circular stent contours were expanded along vectors every ¼ degree using active contour modeling. Contours were bounded spatially by the vessel wall. Curvature parameters constrained the ovalization of the stent contour to model FD compliance as informed by prior studies of physically deployed FDs [1]. The rate of change of the distance from a centerline point to a stent contour was constrained by adjacent stent contours to maintain gradual expansion of the FD mesh along the main vessel axis.

The landing zone of each deployment simulation spanned 4 mm proximally from the aneurysm neck to 4 mm distally from the aneurysm neck. Beginning from the distal end of the landing zone, a modified form of the Jedwab et al. [2] equations describing geometric stent properties was employed to determine wire position on the stent contours. The resulting deployments are shown in Figure 1.

Apposition proximity was defined as the inverse of the distance from a stent wire point to the blood vessel wall and only measured on the landing zone portions outside of the aneurysm neck. Pore density was defined as the number of pores per mm^2 and calculated by dividing the number of pores in one pitch of the FD by the surface area of one pitch of the FD. The number of pores (P) in one pitch is given by:

$$P = \frac{n^2}{2}, \quad (1)$$

where n is the number of wires in the FD. The surface area (SA) of one pitch of the FD is given by:

$$SA = 4\,R^2\,\pi^2 \tan\left(\arccos\left(\frac{2\,R\cos(\beta_0)}{D_0}\right)\right), \quad (2)$$

where R is the distance from the centerline point to the stent contour point, β_0 is the on-mandrel pitch angle, and D_0 is the on-mandrel diameter. Pore density (PD) is given by:

$$PD = \frac{P}{SA}. \quad (3)$$

FDs with wire counts of 40, 44, 48, 52, and 56 were deployed in each CA geometry. The percent metal coverage as defined by Jedwab et al. [2] was kept constant across all deployments at 30%. An FD of 4.5 mm fully-extended diameter was appropriate for all five geometries according to standard FD Instructions for Use. The landing zone was consistent for all five deployments.

To approximate pore density, the pore density values calculated at each stent contour point at the aneurysm neck were averaged across all five cases then normalized. Apposition proximity was calculated as the inverse of wire-to-vessel wall distance outside of the aneurysm neck. Values were again averaged across all five cases then normalized.

RESULTS

As wire count increased, the pore density increased approximately linearly while the apposition proximity decreased less linearly, as shown in Figure 2. High pore density is favorable because it reduces velocity of blood flow inside of aneurysms [3]. High apposition proximity is also favorable because it keeps the FD in position and has been found to indicate aneurysm occlusion [4, 5].

The optimal FD, based on the summative value of normalized pore density and apposition proximity, was the 48-wire FD, which exhibited the best overall performance given the assignment of equal importance weightings to the two output parameters. However, a recent study by Aquarius et al. [6] indicated that wall apposition is more important than pore density. The optimal FD could then be either the 40-wire or 44-wire version, both of which exhibited higher apposition proximity at the expense of lower pore density.

DISCUSSION

This paper demonstrated a preliminary framework for flow diverter design optimization at scale. While the framework considered only several aneurysm geometries, the goal is to extend application to several hundred geometries, then several thousand, etc. A few shortcomings of the specific approach presented here are noteworthy. First, there are more sophisticated methods of combining the deployment outputs than normalization and averaging to appropriately consider the impact of outliers on design efficacy. Second, the spatial regions over which deployment outputs are calculated can be further improved to focus where those outputs are most relevant. Lastly, the weightings of the outputs themselves in identifying optimal designs should be adjusted to reflect clinical importance as defined by expert physicians. Nevertheless, the results revealed a key design tradeoff between apposition and pore density with respect to wire count. Although a wire count of 48 appeared optimal in this case, weighting the outputs differently within the proposed framework could point to different optimal wire counts. The framework thus affords designers the opportunity to make informed decisions about design performance based on quantitative data that transcend the scale of the benchtop.

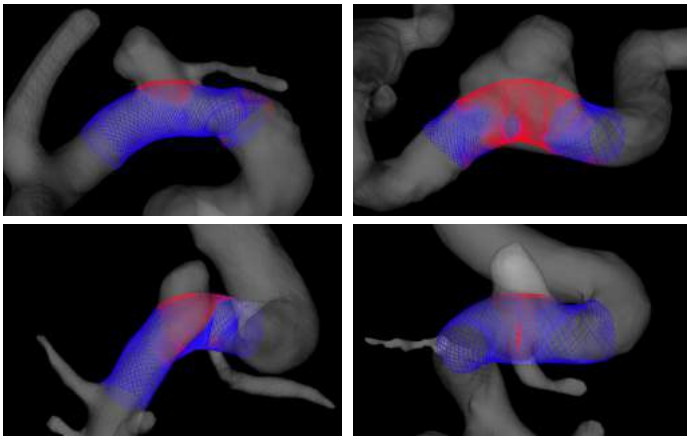

Figure 1: 48-wire FD deployments in four sidewall aneurysm models. Blue indicates regions of high apposition proximity. Red indicates regions of low apposition proximity. (Additional models and wire counts are omitted due to space constraints.)

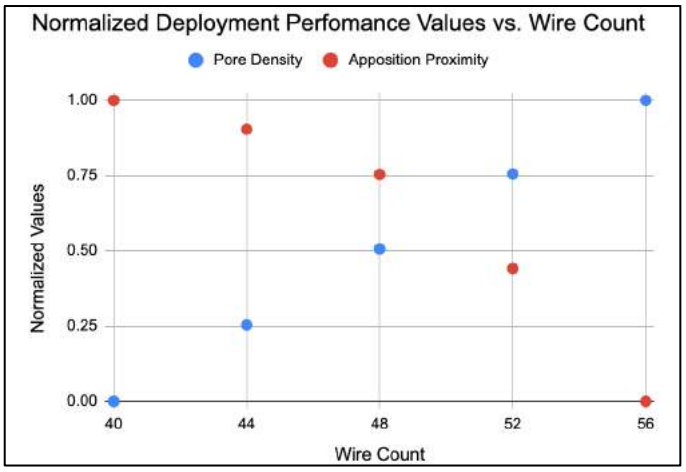

Figure 2: Normalized values of pore density (blue) and apposition proximity (red) plotted versus various wire counts.

WHITEWATER HELMET STAR: EVALUATING THE BIOMECHANICAL PERFORMANCE AND RISK OF HEAD INJURY FOR WHITEWATER HELMETS

Brock G. Duma, Mark T. Begonia, Stefan M. Duma

Institute for Critical Technology and Applied Science
Virginia Tech
Blacksburg, Virginia, USA

INTRODUCTION

There are more than 6 million people who participate in whitewater kayaking and rafting in the United States each year (Figure 1).[1] Of these 6 million participants, there are over 50 whitewater related deaths each year, which makes it have one of the highest fatality risks of all sports. As the popularity in whitewater activities grows, the number of injuries, including concussions, also increases. The objective of this study was to create a rating system for whitewater helmets by evaluating the biomechanical performance and risk of head injury of whitewater helmets using the STAR system.

Figure 1: Whitewater rafting is one of the most dangerous sports in the U.S with over 50 fatalities each year.

METHODS

All watersport helmets that passed the EN: 1385: 2012 standard and that were clearly marketed for whitewater use were selected for this study. A total of 21 helmets models were selected, and 2 samples of each model were tested. A custom pendulum impactor was used to test the helmets under conditions which are known to be associated with the highest risk of head injury and death. The struck head consisted of a NOCSAE head and Hybrid III 50th percentile neck, with the head instrumented with three linear accelerometers, and a triaxial angular rate sensor. For this study, 126 tests were performed at six different configurations. The helmets were tested at 3.1 m/s and 4.9 m/s with impacts to the front, side, and rear for each speed (Figures 2-4). The velocities were chosen given that the highest recorded flow rate in a whitewater river is 5 m/s, which implies that any underwater head impact is unlikely to occur at a speed greater than 5 m/s.[2] Each helmet's Summation of Tests for the Analysis of Risk (*STAR*) value was calculated using the combination of exposure and injury risk that was determined by the linear and rotational accelerations (Eq. 1).[3-7]

$$Whitewater\ STAR = \sum_{L=1}^{3}\sum_{V=1}^{2} E(L,V) * R(a,\alpha)$$

Equation 1: Whitewater *STAR* equation where *L* = location, *V* = Velocity, *E* = exposure, *R* = risk, *a* = linear acceleration, and *α* = rotational acceleration.

Figures 2-4: (left) Front impact location, (Center) side impact location, (right) rear impact location.

RESULTS

In the 3.1 m/s front impact condition the 21 helmeted tests resulted in a range of 30.2 – 131.2 (g), and 1601 - 5036 (rad/sec^2). In the 3.1 m/s side impact condition the 21 helmeted tests resulted in a range of 35.7 – 129.7 (g), and 2500 - 3678 (rad/sec^2). In the 3.1 m/s rear impact condition the 21 helmeted tests resulted in a range of 24.7 - 152.6 (g), and 1759 – 6889 (rad/sec^2). In the 4.9 m/s front impact condition the 21 helmeted tests resulted in a range of 82.0 – 282.5 (g), and 4024 - 13069 (rad/sec^2) (Figure 5 and 6). In the 4.9 m/s side impact condition the 21 helmeted tests resulted in a range of 88.1 – 316.4 (g), and 5609 - 24563 (rad/sec^2). In the 4.9 m/s rear impact condition the 21 helmeted tests resulted in a range of 82.9 – 332.0 (g), and 3336 - 14381 (rad/sec^2). The helmets' star values resulted in a range of 0.2518 - 4.8634 (Figure 7).

Higher linear acceleration values were observed for the front impact conditions, and higher rotational acceleration values were observed for the side impact conditions. The linear regression relating linear and rotational acceleration was strongly correlated (r^2=0.71). However, there was a low correlation between helmet price and STAR value (r^2=0.11), and there was also a low correlation between helmet mass and STAR value (r^2=0.03).

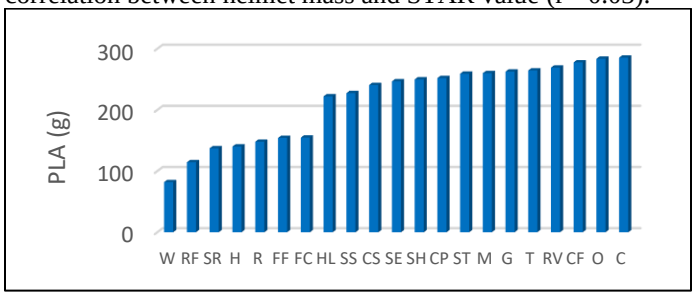

Figure 5: Peak resultant linear acceleration values (g) for the high speed of 4.9 m/s in the front impact direction.

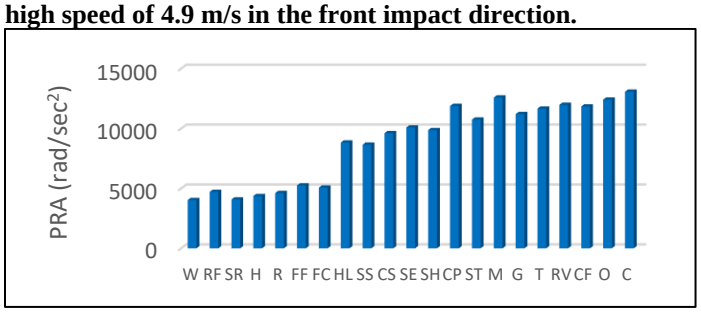

Figure 6: Peak resultant rotational acceleration values (rad/sec^2) for the high speed of 4.9 m/s, front impact direction.

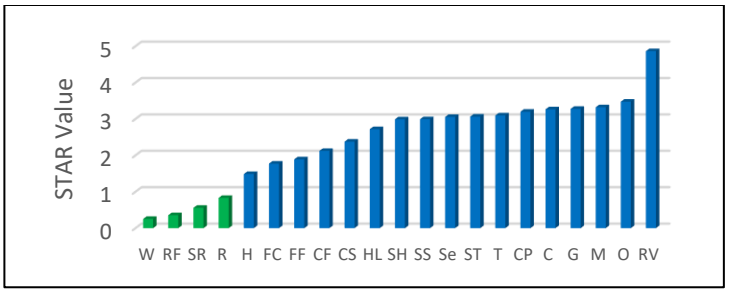

Figure 7: STAR values for each helmet, lower values indicating lower risk of concussion on the left.

DISCUSSION

The majority of the whitewater helmets are not recommended given that the STAR values observed for the helmets indicate an extremely high probability of concussion for each impact. The helmets should reduce head accelerations by a far greater margin for lower concussion risks. For example, the STAR values over three indicate that for the six impact conditions over three concussions would be predicted. In contrast, the best helmets can reduce this value below one. The whitewater helmets should be able to reduce the head impact accelerations much more across all helmets. One method to accomplish this would be to mirror some of the technologies utilized to design newer and more advanced football helmets.

Higher acceleration values for both linear and rotational acceleration were observed at higher impact speeds, with linear and rotational acceleration being strongly correlated (r^2 =0.72). Linear acceleration was observed to be higher in the front impact conditions, whereas rotational acceleration was observed to be higher in the side condition. A possible cause for this observation is the difference in centric and non-centric aspects for each impact location.

Helmet performance did not correlate well with other factors such as weight (r^2=0.03) and price (r^2=0.11). This highlights the necessity of a helmet rating system, because consumers cannot always use these factors as an indication of helmet performance. When comparing the 21 total helmet models tested by brand, the top four best performing helmets (W, RF, SR, and R) were all manufactured by "Sweet Protection."

INTRODUCTION

Globally, glaucoma is the leading cause of irreversible blindness, and disproportionally impacts people of African and Asian descent [1]. To investigate the effect of scleral stiffness on the susceptibility to glaucoma, Kimball treated mouse eyes with glyceraldehyde via subconjunctival injections but found no effect on the structure or function of the retina. However, in mice with experimentally-induced glaucoma, it was found that glyceraldehyde significantly increased intraocular pressure (IOP) and axon loss after 6 weeks [2]. It can therefore be hypothesized that de-stiffening of the sclera can halt glaucomatous damage, but we want to ensure that de-stiffening agents are delivered through the sclera. Therefore, we will enhance scleral permeability in porcine eyes via ultrasound and deliver Texas Red Dextran, a fluorophore with similar molecular weight to certain de-stiffening agents at 70 kDa.

METHODS

Twenty fresh porcine eyes and Texas Red Dextran (D1864, Thermo Fisher) were purchased commercially. Porcine whole globes were submerged in either 1X PBS or Texas Red Dextran solution. Half of the globes (n=5 eyes per group, see **Table 1**) from each solution were treated with or without 1 MHz ultrasound (0.250 MPa, spatial temporal peak intensity 2.0 W/cm^2, 40% duty cycle [40 ms on, 60 ms off, 10 Hz PRF] spatial peak temporal average intensity 0.8 W/cm^2, TI 1.2) via a flat disk transducer for 3 minutes, after which the eyes were fixed in 10% formalin (see **Figure 1** for transducer set up).

Table 1: Experimental Setup

	Without Ultrasound	With Ultrasound (1 MHz)
PBS	n = 5 pig eyes; Expected Outcome: no fluorescent signal	n = 5 pig eyes; Expected Outcome: no fluorescent signal
Texas Red Dextran	n = 5 pig eyes; Expected Outcome: fluorescent signal observed on the outer surface of the sclera	n = 5 pig eyes; Expected Outcome: fluorescent signal penetrated through the sclera

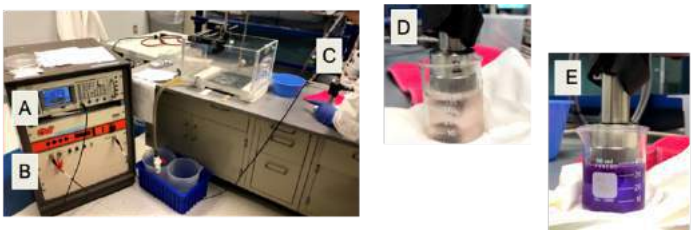

Figure 1: [A] Generator, [B] Amplifier, [C] Transducer, [D] Whole globe in PBS, and [E] Whole globe in Texas Red Dextran.

The porcine optic nerve heads (pONHs) were isolated, embedded in paraffin, and sectioned for imaging. A Cy3 filter and 4x objective on the fluorescent microscope were utilized to visualize the Texas Red Dextran signals

After obtaining the microscopy images, a MATLAB open-source code was used to calculate the porosity of the Texas Red Dextran-treated eyes. The images were also processed by MATLAB with a line

intensity program that demonstrates the fluorescent intensity of the Texas Red Dextran shown from the external side of the sclera into the thickness of the sclera.

RESULTS

All eyes were imaged under fluorescence microscopy and some representative samples of each group can be seen in **Figure 2**. All of the PBS-treated eyes showed no fluorescence in their images.

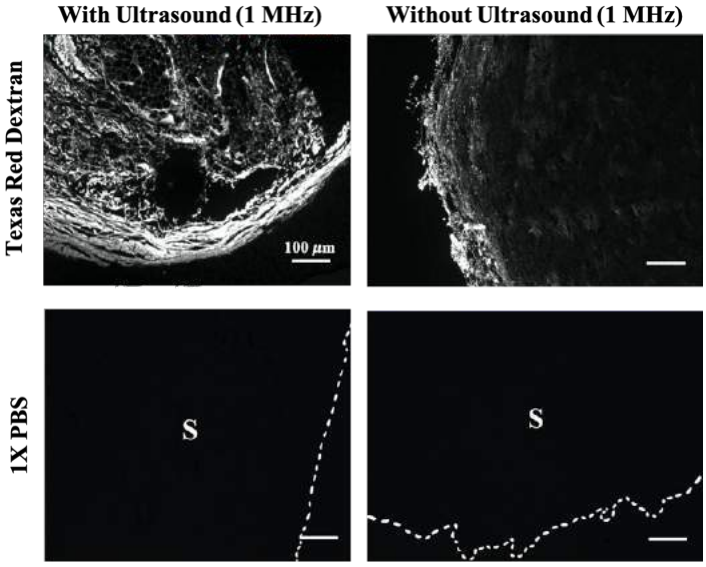

Figure 2: Fluorescent microscope images of pONH sclera (S depicting sclera not emitting fluorescence).

The results of the porosity calculation showed a 54.1% mean porosity for the ultrasound-treated eyes (SD = 15.5%) and a 60.3% mean porosity for the untreated eyes (SD = 17.2%) (see **Figure 3**).

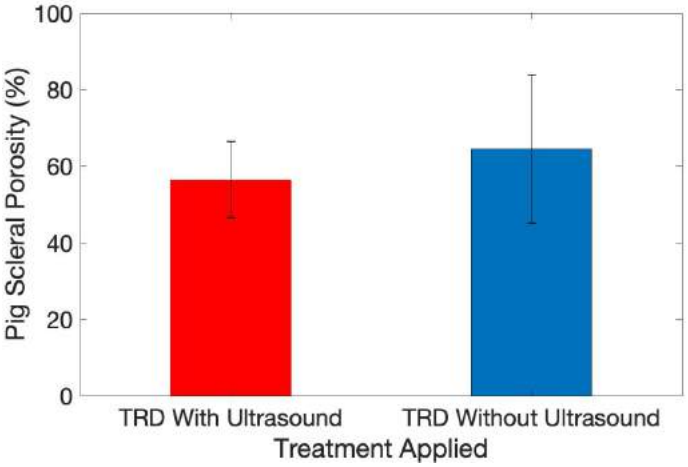

Figure 3: pONH head porosity between Texas Red Dextran (TRD) groups treated with or without ultrasound.

The graphs for the ultrasound-treated porcine eyes are shown to have a sustained intensity through the sclera, while the untreated eyes show an intensity localized to the external sclera lacking penetrance throughout (see **Figure 4**).

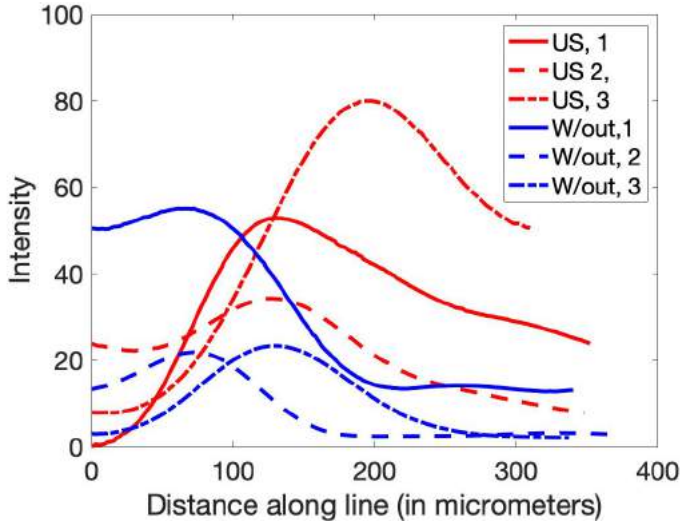

Figure 4: Graph depicting the intensity of fluorescent signal going from the outer sclera into the sclera of both ultrasound treated (US) and untreated (W/out) pONHs.

DISCUSSION

A two-sample t-test showed no statistical significance between the porosity of ultrasound-treated and untreated porcine eyes ($p = 0.15$). The results of the intensity study showed that the intensity of the Texas Red Dextran fluorescence in the untreated porcine eyes was limited to the outer surface of the sclera, while the ultrasound-treated eyes showed fluorescent permeance throughout the sclera, suggesting that diffusion of the fluorophore was enhanced by the application of ultrasound. The increased intensity does not appear to correspond with an increased porosity of the tissue, however this could relate to a change in porosity on a smaller scale that allowed for the diffusion of the Texas Red Dextran. This work leads us to believe that the application of ultrasound to eyes during treatment for glaucoma may help facilitate an increased responsivity of the sclera and therefore better outcomes, but we also must continue research to ensure this ultrasound is not causing any additional damage to the eyes.

ACKNOWLEDGEMENTS

INTRODUCTION

Obtaining and maintaining compression between bone surfaces is critical for successful healing in fixing fractures and fusing joints because bone remodeling is highly dependent on mechanical loading [1]. Bone, like other biologic tissues, is viscoelastic, meaning that stress on the bone dissipates over time [2]. An understanding of how and when compressive stress is lost is critical to the design of surgical devices and techniques created to maintain bone compression for optimized healing. While many sensors exist to study compressive forces, few are optimized to the demands of screw implantation, which is a key component to many orthopaedic surgical techniques, including joint arthrodesis [3]. Here we present a simple and cost-effective sensor and data acquisition system that quantifies bone compression over time and to demonstrate the viability of this model in cadaveric models for hindfoot and midfoot arthrodesis.

METHODS

The key component of this system is a Futek LTH 300 donut load cell, since the hole in the center of the sensor allows for screw placement through the device. This sensor was connected to a Futek IAA 100 amplifier and MEGA 2560 Arduino board. This amplifier is designed to work with the sensor's existing wiring, but custom gain and shunt settings were used to adjust for the voltage outputs of the Arduino board. The Arduino was connected to the computer via USB, and data collection and processing was done in a custom MATLAB app (Figure 1). Key features of this program include the real-time data visualization, embedded filtering, continuous autosaving (so raw and filtered data are not lost if there is an interruption in data collection), calibration and check calibration features, and flexibility to modify filter parameters or data collection frequency. The system was calibrated from 0 to 2000N using an MTS machine, and calibration was checked in the lab prior to each data collection using handheld weights. Data were collected at 10 Hz and filtered with a 6th order Butterworth lowpass filter with a 0.075 normalized frequency cutoff.

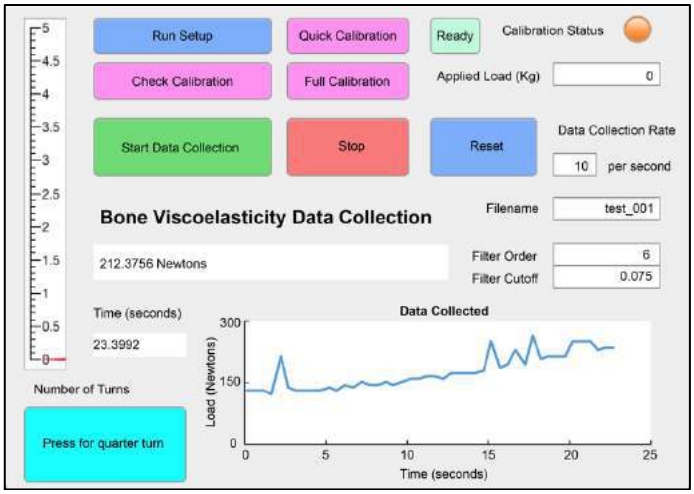

Figure 1: Graphic User Interface for custom MATLAB program

Hindfoot Arthrodesis Model: 25 mm diameter bone cylinders were cut from cadaveric talus and calcaneal pairs. The bone cylinders were prepared for simulated arthrodesis by removing the cartilage and flattening the subchondral bone surface. The sensor was placed between the two cylinders with a washer on each side to contact the loading surface, and additional washers were added as spacers when needed (Figure 2). A partially threaded cannulated lag screw was placed from the posterior-inferior aspect of the calcaneus cylinder to the anterior-superior aspect of the talus cylinder to simulate subtalar arthrodesis. The complex was left to rest for three minutes before screw retightening, then left untouched for 30 minutes with compression data collected throughout the trial.

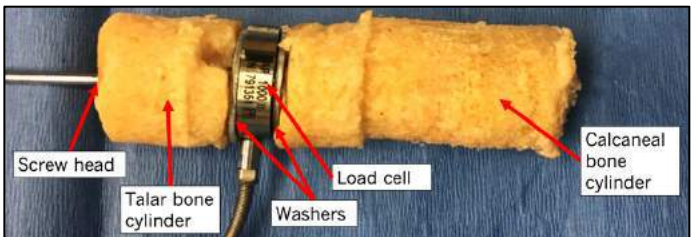

Figure 2: Hindfoot arthrodesis model

Midfoot Arthrodesis Model: A guide pin was placed along the optimal trajectory for medial column beaming from the center of the first metatarsal head along the first ray to the center of the dome of the talus. The middle 12 mm of the medial and intermediate cuneiforms was excised to create space for the compression sensor, leaving in place the articular surfaces of the naviculocuneiform and 1st tarso-metatarsal joints. Using the guide pin for alignment, the load cell was placed in this space with two or three washers on each side to contact the loading surfaces (Figure 3). A drill was used to prepare the screw track and a cannulated screw was inserted over the guide pin. Compression data was collected starting when the threads at the head of the screw entered the metatarsal head and recorded until the head of the screw was buried 10mm deep in the metatarsal head and then allowed to sit untouched for 150 seconds.

Figure 3: Midfoot arthrodesis model

RESULTS

This system was able to accurately collect data in both hindfoot and midfoot arthrodesis cadaveric models. An example of this data is shown in Figure 4, which gives data from the retightening lag screw trials in the hindfoot arthrodesis model. Data output includes raw, calibrated, and filtered values.

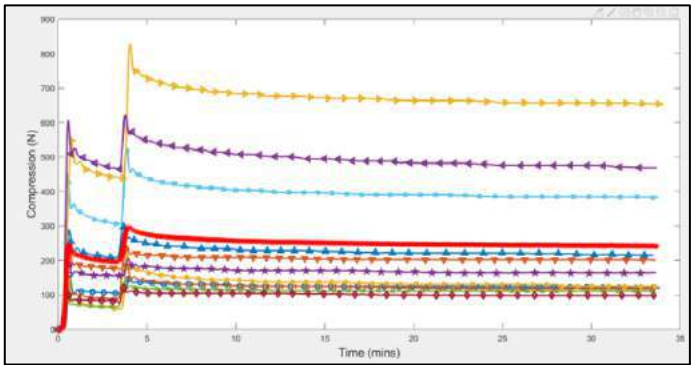

Figure 4: Example data from screw retightening trials for simulated hindfoot arthrodesis model

In addition to functioning satisfactorily, the sensor system is also cost-effective, in large part due to the use of an Arduino board and a custom MATLAB data acquisition program. Prices for all components of this system are given in Table 1. The MATLAB and Arduino based setup further allow adaptability for use of this system in a variety of applications and transferability to be used by different researchers and computers.

Table 1: Cost for components of the data acquisition system

Component	Cost
Futek LTH 300	$598.00
Futek IAA 100	$450.00
Elegoo MEGA 2560 Arduino	$17.99
MATLAB*	$0.00
Flat washers**	$0.74
Wiring**	$0.48

*MATLAB subscriptions are covered by many academic institutions, hence why $0 is listed. The annual student license is $49, the annual academic license is $250 and the annual standard license if $860.
**Price reflects components used, even if they are not purchasable in that small of a quantity.

DISCUSSION

This data acquisition system represents a cost-effective and easily adaptable strategy for studying longitudinal compressive stress response in bones with screw implantation. The Arduino and MATLAB base allow the system to be easily used by different operators and computers, and give flexibility for modifications to adapt this system to many applications. We demonstrated to applications, with cadaveric models of hindfoot and midfoot fusion, and further work with focus on using these models to answer clinical questions and adding additional sensor inputs to the system for more complex models.

LOCATION DEPENDENT MECHANICAL BEHAVIOR OF APONEUROSIS TISSUE UNDER UNIAXIAL TENSILE STRETCH

Emily E. Tully (1), Benjamin B. Wheatley (1)

(1) Department of Mechanical Engineering
Bucknell University
Lewisburg, PA, USA

INTRODUCTION

Aponeurosis is a connective tissue that attaches muscle fibers to tendon [1]. The aponeurosis covers the surface of a muscle in a sheath-like manner and fans out with decreasing thickness away from tendon [2]. Although aponeurosis is commonly found in muscle-tendon units throughout the body, there have been comparably few studies on the mechanical role of aponeurosis and fewer still on the material properties of aponeurosis. Specifically, there are no reported investigations on the interaction of aponeurosis thickness, distance from the tendon, and mechanical response to load. Previous studies measured material properties of aponeurosis samples assuming that there is a constant thickness throughout the tissue, when it is known to be variable [2-5].

This unknown relationship between aponeurosis regional structure and function makes aponeurosis tissue a poorly understood component of muscle-tendon units. For example, it remains unclear if aponeurosis acts as a material extension of tendon, or if it transitions from a higher or lower stiffness near the tendon to a different stiffness near the muscle midbelly. Computational models regularly neglect aponeurosis tissue or aponeurosis variability due to lack of information, rather than confidence in assumptions. The goal of this work is to perform uniaxial tensile testing and digital image correlation analysis to measure the mechanical response of aponeurosis tissue as a function of thickness and location from tendon to muscle. We hypothesize that aponeurosis tissue maintains consistent material properties, as measured by stress-strain curves, as it transitions from tendon to muscle.

METHODS

Triceps brachii tissue was extracted from porcine shoulder for testing (Figure 1A). The aponeurosis was separated from the muscle tissue using standard dissection tools such as scalpel and forceps. Ten (n=10) samples were then cut into rectangular strips measuring ~60 mm in length and ten mm in width with custom dissection equipment, with fibers oriented longitudinally. Five mm increments were marked on each sample with permanent marker. Each sample was placed under a dissection microscope with the marked edge facing up. Four evenly spaced thickness measurements were taken between each marking in the middle 40 mm, for a total of 32 total thickness measurements for each sample (Figure 1B).

Uniaxial tensile testing was completed on a custom planar biaxial material testing system (ADMET, Inc., Norwood, MA). Ten mm sections at both ends of the sample were clamped with serrated grips and the strain rate for the tensile test was set to 0.03 min^{-1} elongation to failure. A charcoal powder was lightly dusted onto the sample through a sifter for digital image correlation (DIC) (Figure 1C).

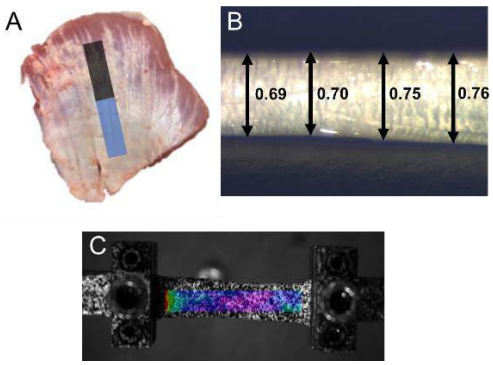

Figure 1. A) Triceps brachii muscle with attached aponeurosis and representative sample regions (black – transition region, blue – insertion region) [2] B) dissection light microscope image for

measuring thickness [mm] C) rectangular sample used for tensile testing, including charcoal speckle pattern and representative DIC analysis strain color contour plot.

Image capture rate was at an interval of 0.5 seconds. Using the uniaxial force data, inhomogeneous 2D DIC data, and thickness measurements, the average nominal (engineering) stress and Lagrange strain values were determined for two sections of each sample, one considered the 'transition region', where the aponeurosis tissue connects to muscle fibers and is thinner, and the other considered the 'insertion region', where the aponeurosis tissue connects to the tendon tissue and is thicker. Linearized moduli were determined at each time point by dividing nominal stress by Lagrange strain of both regions. Paired t-tests ($p<0.05$) were performed on the Lagrange strain and linearized modulus at each time point to determine any statistically significant differences in the material behavior of tissue of varying thickness and location.

RESULTS

The average nominal stress and Lagrange strain data for both regions showed a nonlinear response, with an initial toe-region, a linear region, and a softening region (Figure 2). The transition region had an average thickness of 0.703 ± 0.073 mm, and the insertion region had an average thickness of 0.952 ± 0.061 mm. The Lagrange strain t-tests remained above $p=0.05$ for each data point. At 131 seconds, indicated by a red asterisk in Figure 2, the p-value of the linearize modulus t-test drops below $p=0.05$ and remains below that threshold until the test is complete at 200 seconds (Figure 3).

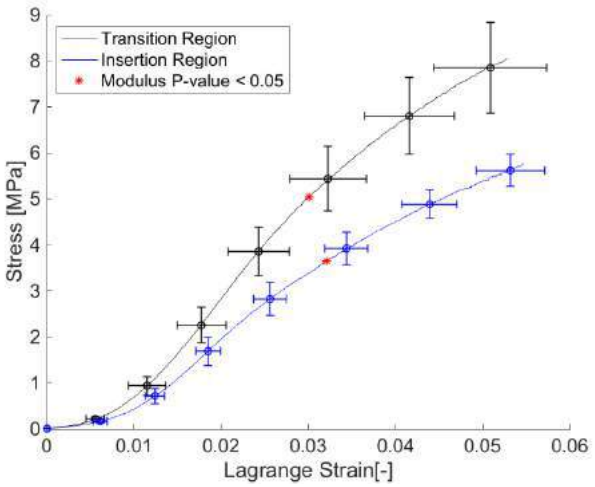

Figure 2. Average stress-strain curves for each quarter of aponeurosis tissue samples. Error bars in Figure 2 are shown at time points with intervals of 55 seconds.

DISCUSSION

Previous studies have investigated the material properties of aponeurosis tissue assuming an average thickness across samples, while this study investigated how variations in thickness may affect stress-strain behavior. Aponeurosis thickness measurements from this study showed a decrease in thickness from the tendon insertion region to the muscle transition region. This varying thickness may be a function of the inhomogeneous load the aponeurosis bears *in vivo*. A paired t-test of the strain of the two regions indicated that there is no significant difference in the strain of an aponeurosis sample at different thicknesses. However, a paired t-test of the linearized modulus shows that the moduli of the regions may diverge as the stress increases over time (Figure 3). Specifically, the transition (thinner) region exhibited a stiffer stress-strain response than the insertion (thicker) region, disproving our hypothesis. This suggests that under load, aponeurosis may exhibit higher moduli in thinner sections.

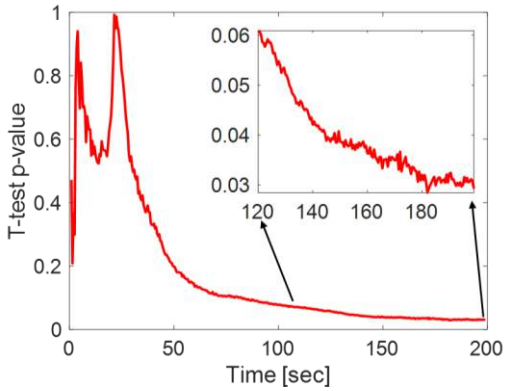

Figure 3. P-values of t-test comparing insertion and transition region linearized modulus (stress/strain) versus time.

When working with and analyzing the mechanical properties of many biological materials, including aponeurosis tissue, it is important to consider how natural variations in the material may affect the observed behavior. The collagen fibers in aponeurosis are likely to have some inhomogeneous alignment and/or crimping, which is shown in the existence of a toe region at the beginning of stress-strain curves (Figure 2). Additionally, individual collagen bundles are likely to have varying geometry, meaning they experience different stresses under the same force or uncrimp and fail at different loads and strains, and may naturally have different stiffness. This study assumed that there were consistent material properties and thicknesses across the width and thickness of the sample, with variations only occurring lengthwise, when the DIC imaging showed varying strain measurements in both directions (Figure 1C). Future work to better characterize the stress-strain response of the two regions, such as with tangent moduli or hyperelastic modeling would benefit this work.

CONCLUSIONS

Variations in aponeurosis tissue thickness and material properties are likely to affect muscle-tendon unit mechanics and subsequent modeling efforts [3]. This work suggests thinner aponeurosis regions near the muscle midbelly may exhibit a stiffer stress-strain response than regions closer to the tendon. The mechanical consequences of this are not known but could impact the function of muscle-tendon units. These data help to create a more complete understanding of the material properties of aponeurosis, with the goal of improving future computational studies of muscle-tendon unit mechanics.

INTRODUCTION

Left heart failure (LHF) burdens an estimated 6.2 million American adults and appeared on 379,800 death certificates in 2018 [1]. Pulmonary hypertension occurs in 60-80% of patients with LHF (PH-LHF) leading to a two-fold increase in mortality compared to isolated LHF [2,3]. Initial PH-LHF, termed isolated post-capillary PH (Ipc-PH), develops due to a passive one-to-one increase in pressure throughout the pulmonary vasculature. Classified by elevated mean pulmonary arterial pressure (mPAP) with normal pulmonary vascular resistance (PVR), the effects of Ipc-PH can be reversed [4]. However, Ipc-PH progresses to combined pre- and post – capillary PH (Cpc-PH) in 12-38% of the patient population [5]. Cpc-PH patients demonstrate increased vascular resistance and diastolic pressure gradient (DPG), both contributing to the irreversibility of this disease and the increased prevalence of right heart failure, a key predictor of decreased survival [6].

The mechanisms associated with Ipc-PH progressing to Cpc-PH remain unknown. We sought to investigate the contributions of mechanobiological pathways to disease progression. Worsening LHF leads to increased left atrial pressure (LAP) and decreased cardiac index (CI), which should decrease venous shear stress. Low shear stress has been observed in PH patients and is associated with pathologic changes including pulmonary remodeling [7,8]. Endothelial cells sense changes to mechanical stimuli, including decreased shear stress, and respond through mechanotransduction signaling. These pathways lead to decreased endothelial nitric oxide synthase (eNOS) phosphorylation and increased vasoconstrictor endothelin-1 (ET-1) release [9]. Clinical studies observed increased ET-1 levels in PH-LHF patients [10,11]. We hypothesized that LHF leads to decreased shear stress and increased ET-1, promoting increased total PVR (TPVR) and thus RV remodeling. To test this hypothesis, we generated myocardial infarction (MI) in control mice (Ctrl) and those with a mutation of ET-1 in pulmonary artery endothelial cells (Mut).

METHODS

Mice with disrupted ET-1 expression in pulmonary endothelial cells were bred using the flox allele of ET-1 and an inducible Cre-recombinase directed by the Tbx4 lung enhancer which is active in the pulmonary vascular endothelium [12,13]. Litter mate controls and Mut mice were randomly assigned into myocardial infarction (MI) and sham groups. Initial anaesthetization used 5% isoflurane followed by a maintained dosage of 1-2% during the procedure. We performed left anterior descending coronary artery ligation on a heated platform to produce an MI and thus, LHF. Operational complications resulted in an n=2 for each group with no animals in the mutant sham group.

At week 0, 4, 10, and 20, animals underwent echocardiography using previously established M-Mode, mitral valve, tricuspid valve, and pulmonary valve protocols. Values were averaged over three consecutive cardiac cycles.

Terminal studies at week 20 began with urethane anesthetization followed by intubation. To obtain *in vivo* hemodynamic measurements, the thoracic cavity was exposed, and a calibrated 1.2-Fr admittance catheter was inserted into the right ventricle (RV). We monitored heart rate and systemic pressure throughout the procedure. After baseline pressure-volume data was obtained, brief occlusions of the inferior vena cava allowed measurement of end-systolic and end-diastolic pressures to assess alterations in venous return. Commercial software (Notocord; Croissy Sur Seine, France) recorded pressure volume data for analysis. A minimum of three steady state timepoints and two occlusions were averaged for each hemodynamic metric.

After right heart catheterization, animals were euthanized, and the RV free wall was separated from the left ventricle and septum (LV+S)

for weights and preservation in liquid N_2 or formalin. All animal procedures were approved by the University of Wisconsin – Madison Institutional Animal Care and Use Committee.

All values presented as mean ± SD. With n=2 per group, statistical analysis could not be conducted. Evaluations of results were based on observable trends to inform future studies.

RESULTS

Echo, morphology, and RHC data demonstrate possible differences in PH-LHF progression in control mice compared to Mut mice. Echo data indicates the systolic LV volume normalized to bodyweight was greater for control MI group compared to Mut MI and control sham (Figure 1A). Additionally, LV ejection fraction (LVEF) was decreased in control MI animals compared to Mut MI animals with an increased difference at week 20 compared to week 10 (Figure 1B).

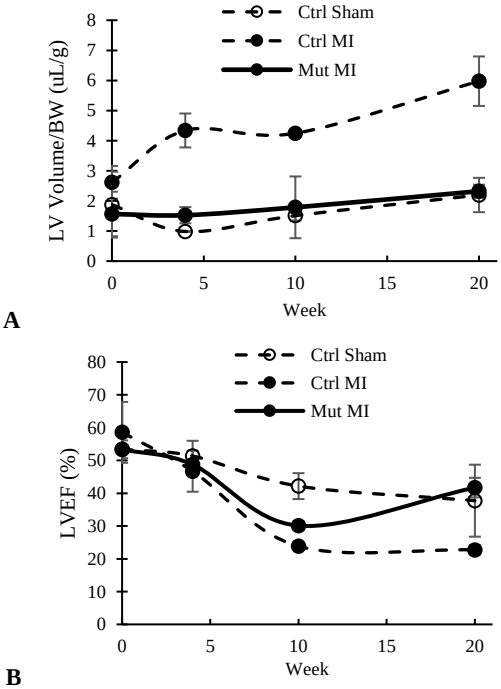

Figure 1 A: Systolic LV volume normalized to BW and B: LVEF throughout experimental time course.

Control MI mice developed greater ventricular remodeling compared to Mut MI mice and control sham animals as evident in LV+S and RV weights normalized to bodyweight (Figure 2 A&B).

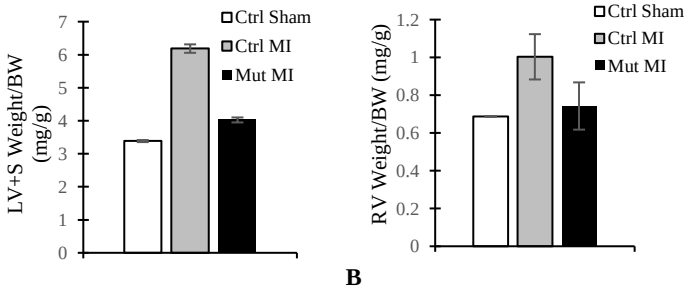

Figure 2 A: LV and septum weight normalized to bodyweight. B: RV weight normalized to bodyweight.

Cardiac index was lowest in the control MI animals followed by Mut MI animals and highest in the control sham (Figure 3A). TPVR, calculated by dividing RV end-diastolic pressure by cardiac output, was generally increased for control MI animals compared to control sham and Mut MI animals (Figure 3B).

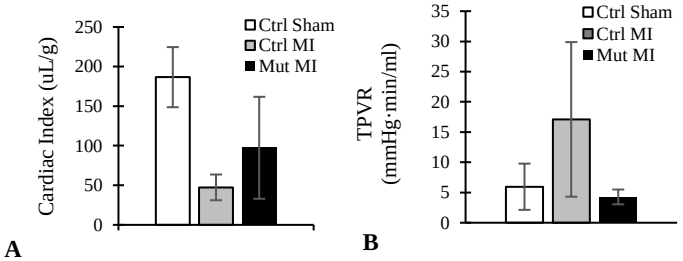

Figure 3 A: Cardiac index and B: TPVR values from RHC analysis 20 weeks after MI surgery.

DISCUSSION

As PH-LHF progresses from Ipc-PH to Cpc-PH, biventricular remodeling occurs (Figure 2) and cardiac function decreases (Figure 1B and 3A). ET-1 mutant mice appear to have less remodeling and dysfunction 20 weeks after MI surgery compared to control MI mice. The time course of LVEF suggest mice with ET-1 mutation recovered LV function after week 10 (Figure 1A). We propose the lack of pulmonary ET-1 prevents both the pulmonary arterial vasoconstriction and remodeling that leads to increased TPVR observed in control MI animals. This inhibition may prevent RV remodeling by maintaining a low RV afterload.

The current study has three main limitations. First, the sample size prevented statistical analysis and definitive conclusions. Second, the original study design included both male and female mice, but early mortality after MI surgeries generated a Mut MI group with only male mice and a control MI group with only female mice. Finally, there were no Mut sham animals.

The results from this initial study justify future experiments investigating the role of ET-1 in progression of Ipc-PH to Cpc-PH. Discerning the mechanism contributing to PH progression and RV failure secondary to LHF may provide a targetable pathway for pharmacological treatment in the future.

ACKNOWLEDGEMENTS

We would like to thank Dr. Tim Hacker for performing MI and RHC procedures and Allison Brodbeck for performing echocardiography. Funding from NIH 5R01HL147590-02 is gratefully acknowledged.

INTRODUCTION: Osteoarthritis (OA) is a degenerative joint disease characterized by articular cartilage degradation and inflammation of the synovium, the specialized connective tissue that envelops the diarthrodial joint.[1] The prevalence of type 2 diabetes (DM) is linked with OA progression.[2] DM is characterized by chronic hyperglycemia that results from insulin resistance or defects in insulin secretion.[3,4] The correlation between OA and DM are associated with shared risk factors, including age and joint loading from obesity.[2] Fluid-induced shear stress from joint articulation is a relevant stimulus for fibroblast-like synoviocytes (FLS).[5] It is known that insulin resistance contributes to decreased cellular response[6], but FLS respond to mechanical cues to support joint health and modulate inflammation.[7,8] We hypothesized that synoviocyte mechanotransduction is modulated by glycemic and cytokine exposure. To simulate OA and DM in the synovial joint, we subjected healthy fibroblast-like synoviocytes (FLS) to varying glycemic and cytokine culture treatments to induce the biological response of the diseased phenotype. By exposing healthy FLS to hyperglycemic conditions and interleukin-1 (IL), a pro-inflammatory cytokine elevated in OA, we could model diabetic insulin resistance and OA pathogenesis, in order to overcome challenges associated with age and/or disease state.[9] It is known that patients with DM can suffer compromised synovium function as the development of synovial insulin resistance leads to the production of inflammatory mediators linked with OA.[1,10] In OA, pro-inflammatory cytokines, including IL, are known to stimulate the synthesis and release of nitric oxide (NO), which contributes to joint pathology.[11] In DM, the AKT signaling pathway is involved in the regulation of insulin and glucose uptake in adipose tissue[3], where AKT phosphorylation stimulates translocation of glucose transporters to cell surface insulin receptors.[12] Study 1 characterized concurrent changes in AKT phosphorylation and NO release of synovial explants (healthy, OA±DM) in response to hyperglycemic, IL, and insulin culture conditions as an indicator of diabetic insulin resistance and OA inflammatory response, respectively. While the AKT pathway and NO secretion are separate downstream markers of DM and OA, both are regulated by upstream calcium influxes, an ubiquitous measure of cellular activity.[13,14,15,16] By investigating synovial explants under glycemic and cytokine treatments, we optimized preconditioning conditions to confer the diabetic and OA phenotype in healthy tissue, from which we derived cells to monitor the intracellular calcium response ($[Ca^{2+}]_i$) to shear. Study 2 characterized mechanotransduction of FLS cultured in glucose (low: euglycemic, high: hyperglycemic) ± IL by observing the $[Ca^{2+}]_i$ response to fluid-induced shear stress.

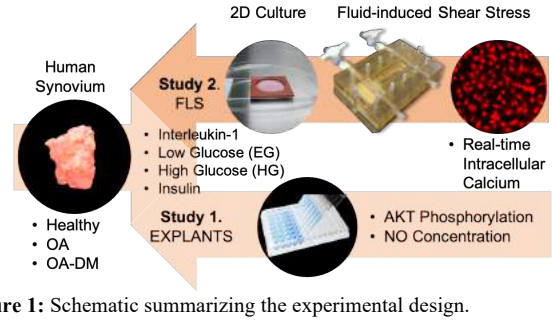

Figure 1: Schematic summarizing the experimental design.

METHODS: *Explant Preparation*. OA human synovia were harvested from diabetic and non-diabetic patients during total knee arthroplasty (IRB#AAAQ2703) and healthy synovium was obtained from the Musculoskeletal Transplant Foundation (Edison, NJ). Synovial explants were pre-conditioned in varying glucose and insulin levels for 5 days to detect levels of AKT (Ser 473) phosphorylation (n = 3 donors per group, 2 explants/donor). Synovial explants were treated in euglycemic (EG;

5.56 mM D-glucose) and hyperglycemic (HG; 12.5 mM D-glucose) culture conditions.[3] Physiologic levels of human recombinant insulin (6.25 µg/mL) were added to both EG and HG groups (EGI and HGI respectively).[3] *AKT Phosphorylation*. Synovial explants were lysed, homogenized, and quantified for relative levels of phospho- and pan-AKT using an ELISA (RayBiotech, Inc.). *Nitric Oxide*. NO released into the glucose and cytokine treated media was quantified using Griess Reagent for nitrite quantification (Life Technologies). *Cell Isolation and Culture*. FLS were isolated from healthy and OA±DM synovial explants using 1mg/mL of type II collagenase digestion. Cells were expanded in αMEM supplemented with 10% FBS, 1% PSAM and 5 ng/mL FGF (Life Technologies) for two passages.[13] *Calcium Imaging*. FLS were plated in silicone wells (Grace Bio-Labs) on 5 µg/cm^2 collagen type 1 coated glass slides at 5.3 x 10^4 cells/cm^2.[13] Cells were pre-conditioned in the same glucose groups with 10 ng/mL IL-1 for an additional 24 h prior to imaging, with parallel untreated controls (EG, HG, EG+IL, HG+IL). An osmotic control consisted of EG medium supplemented with sucrose (EGS). Changes in $[Ca^{2+}]_i$ were tracked via Fura Red-AM (Life Technologies).[13] Fluid flow using HBSS with 0.1% FBS was applied in a parallel plate flow chamber at 0.1 Pa shear stress (N=100 cells/slide,5 slides/group).[13,17] FLS were considered responders for $[Ca^{2+}]_i \geq 20\%$ above baseline level.[13] *Statistical Analysis*. Non-parametric data was analyzed via Fisher's Exact Test with Holms-Sidak correction for multiple comparisons ($\alpha = 0.05$). Healthy and OA±DM donor groups were analyzed using a three-way ANOVA with Tukey's post-hoc test ($\alpha<0.05$) to determine significant differences between disease states, glycemic conditions, and cytokine treatment **(Fig. 1)**.

RESULTS: *Study 1*. Phospho-AKT levels were significantly elevated in baseline EG compared to HG groups across explants (healthy, OA±DM; p<0.0001) **(Fig. 2A-C)**. OA+DM synovium exhibited greater decrease in AKT phosphorylation for the HG group, possibly indicative of a more insulin resistant environment **(Fig. 2C)**. For the healthy and non-diabetic phenotype, insulin treatment increased phospho-AKT levels compared to the respective non-insulin treated EG and HG groups (p<0.001) **(Fig. 2A, B)**. The EGI group in the OA+DM phenotype exhibited increased levels of phospho-AKT compared to control (p=0.004), but no significant changes were observed between the insulin and non-insulin treated HG groups (p=0.2182). Hyperglycemic treatment led to decreased release of nitric oxide in media compared to the control EG group in both the healthy and non-diabetic OA cells (p<0.0001) **(Fig. 2D, E)**. No significant differences in NO secretion were observed between the EG and HG treated groups in the diabetic OA group **(Fig. 2F)**. IL significantly increased NO release compared to the non-cytokine treated groups across all three phenotypes and both glycemic conditions. *Study 2*. The $[Ca^{2+}]_i$ response for healthy FLS was significantly elevated in the control EG group compared to HG treated cells, 73.3 ± 7.3% responders vs. 14.0 ± 6.7%, p<0.001 **(Fig. 2G)**. While the OA±DM FLS response to shear was elevated in the EG treated cells (p<0.001), the HG group for both diseased phenotypes had a greater response to shear compared to healthy FLS with 53.7 ± 2.1% and 34.0 ± 12.5% responders respectively **(Fig. 2H, I)**. The response of EGS and EG groups suggest no osmolarity effects. FLS response to IL treatment was significantly greater in the EG compared to the HG group for both the healthy and diseased cells. (p=0.0032 healthy, p=0.0813 OA-DM, p=0.0012 OA+DM) **(Fig. 2G-I)**. However, compared to non-cytokine treated FLS, IL exposure significantly increased the percentile response across all control groups. Specifically, the HG+IL group for the healthy FLS exhibited a significant increase in response that yielded similar behaviors to those of native OA cells, with 44.7 ± 12.7% responders for the heathy HG-IL group vs. 53.6 ± 4.1% and 34.0 ± 12.5% for the OA non-diabetic and diabetic hyperglycemic groups respectively.

DISCUSSION: Under conditions of the current study, healthy synoviocytes exhibited biological behavior consistent with a disease phenotype associated with OA and DM. Study 1 demonstrated that hyperglycemic treatment for both healthy and diseased synovial explants led to decreased phospho-AKT levels compared to the control EG groups, characteristic of the diabetic disease state. Lower levels of AKT phosphorylation are indicative of more insulin resistant environments.[18] The explants also exhibited elevated NO secretion in media supplemented with IL compared to groups without cytokine treatment, characteristic of OA.[19] As recognized downstream markers of DM and OA pathogenesis, both AKT and NO concentrations exhibited consistent changes in cell behavior between healthy and diseased tissue, suggesting a potential link between glycemic conditions, insulin resistance, and joint inflammation. Studies of shear-induced calcium signaling (Study 2) suggest that cells from healthy (young) synovium can be cultured to exhibit the biologic response of diseased (aged) synovium, providing a model system to support basic science and translational studies towards developing therapies to mitigate diabetic insulin resistance and OA pathogenesis.

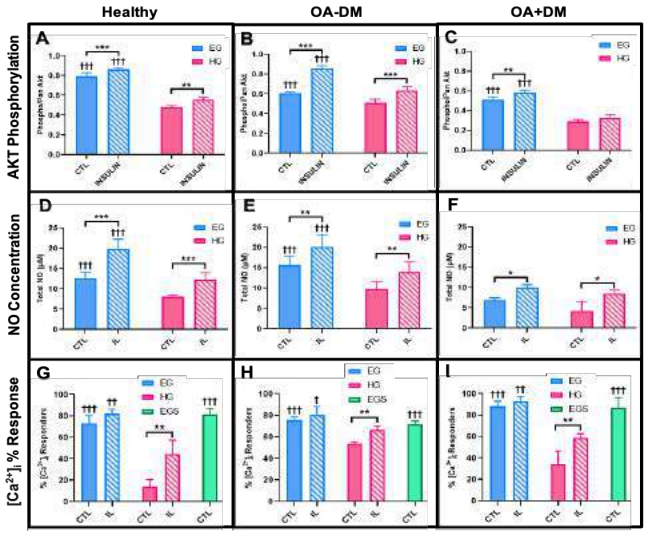

Figure 2: Healthy and OA±DM synovial explants **(A-C)** relative phospho-AKT levels in insulin and non-insulin treated groups, and **(D-F)** NO secretion with glycemic and IL-1 treatment. **(G-I)** Shear-induced $[Ca^{2+}]_i$ response with glucose, sucrose, and cytokine treatment for healthy and OA±DM FLS. *p<0.05, **p<0.01, ***p<0.0001 (control vs. insulin or IL). †p<0.01, ††p<0.002, †††p<0.0001 (EG vs. HG and EGI vs. HGI).

INTRODUCTION

Pelvic organ prolapse (POP) occurs when the pelvic muscles or connective tissues that support the vagina are weakened or injured, allowing for descent of pelvic organs into the vagina. POP often has a negative impact on a woman's reproductive health and overall quality of life. Thirteen percent of all women will undergo surgery for POP in their lifetime [1]. Vaginal delivery is the greatest epidemiologic risk factor for the development of pelvic floor disorders, yet the exact cause remains unclear [2,3]. One hypothesis is that delivery causes injury to the musculature and/or connective tissue that supports the vagina which leads to maladaptive remodeling and eventually symptoms of POP. If true, changes in vaginal shape could serve as a proxy for injury.

As a first step towards testing this hypothesis, we aimed to quantify the impact of pregnancy and vaginal delivery on vaginal shape by comparing measurements between nulliparous (have never given birth), currently pregnant, and vaginally parous (have given birth) women. Because pregnancy and delivery are the greatest risk factors for the development of POP, we expected that the vaginas of nulliparous women would be longer and more curved than those of pregnant and parous women.

METHODS

This retrospective study was approved by the Institutional Review Board at the University of Pittsburgh and considered exempt at Northshore University HealthSystem. The study included the pelvic magnetic resonance imaging (MRI) scans of 43 women between the ages of 20 and 49 acquired at Magee-Womens Hospital or Northshore University HealthSystem between 2005 and 2018 at their physician's request. For this analysis, pregnant women were only included if they were in their third trimester. Patients were sorted into three Groups: nulliparous (N=19), pregnant (N=9), and parous (N=15).

Utilizing Seg3D2 (University of Utah), MRI slices of the vagina were identified and segmented to form the 3D geometry. These models were then imported into Blender (v.2.91, blender.org) where curves were traced along the objects' anterior vaginal wall, posterior vaginal wall, and lines traced along the largest transverse width (Figure 1). Mathematica (Wolfram, Inc) was used to measure the arc length (in mm) of the anterior and posterior curves. These lengths are referred to as the anterior and posterior vaginal wall curved lengths. Those traces were also used to calculate three other measures: straight length, curvature index, and width height.

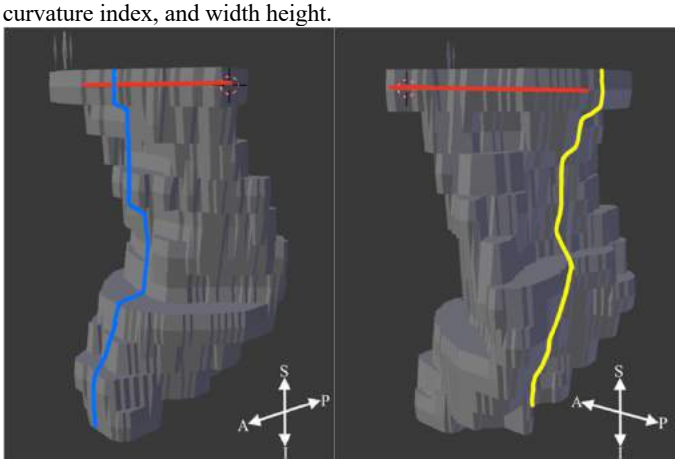

Figure 1: Anterior curved length (blue), posterior curved length (yellow), and the largest transverse width (red) used to calculate straight length, curvature index, and width height. Anterior (A), posterior (P), superior (S), and inferior (I) directions are denoted.

The straight length was defined as the distance from the midpoint of the most superior point to the midpoint of the most inferior point on the anterior and posterior curves, respectively. The curvature index was defined as the ratio of the straight length to the average of the anterior and posterior curved lengths multiplied by 100. This means a value of 100 indicates a completely straight object, while smaller values represent more curved objects. The width height was defined as the normalized height along the vaginal straight length where the largest transverse width was located, where a value of 1 and 0 would indicate the most superior and inferior point along the vagina, respectively.

Statistical analyses were conducted in SPSS™. Correlations were performed to choose which variables to include in subsequent analyses. The analyses consisted of a One-Way Independent MANOVA followed by Bonferroni test post hoc with multiple comparisons. Independent variables included vaginal measures not correlated with one another. Group (nulliparous vs. pregnant vs. parous) was the dependent variable. A p-value < 0.05 was considered statistically significant.

RESULTS

Due to significant correlations between anterior curved, posterior curved, and straight lengths, only curvature index and straight length were included in the MANOVA. Also, due to significant correlations between width and width height, only width height was included in the MANOVA.

According to the univariate ANOVAs, Group had a statistically significant effect on curvature index (p=0.010), whereas its effect on straight length (p=0.252) and width height (p=0.482) were not significant (Figure 2). The difference in curvature index between the nulliparous (88.7 ± 5.8) and pregnant (93.8 ± 3.2) groups were statistically significant (p=0.020). With pregnant women having a straighter vagina (Figure 2A). The curvature index of parous (92.4 ± 2.5) women remained statistically similar to both the nulliparous (p=0.056) and pregnant (p=1.000) groups.

DISCUSSION

Overall, these results support the idea that pregnancy affects the shape of the vagina, specifically its curvature. The fact that the curvature index of parous women did not differ from either group suggests that in some parous women the vagina maintains its straightness after childbirth, while in others it may return to its nulliparous curvature. Nonetheless, the similarities between the pregnant and parous groups from Figure 2A suggest that for most women the straightening observed during pregnancy does not revert to the nulliparous curvature postpartum.

Later in pregnancy, the levator ani muscles remodel, allowing for descent of the vaginal introitus (opening). If the vaginal apex remains supported, this would explain the straightening observed in this study. This mechanism – straightening that fails to recover postpartum – could reflect a persistent change in the muscles that support the vagina caused by pregnancy/delivery. However, further work is necessary to determine if this change reflects injury or weakness to the muscles and, if so, what degree of curvature change might be associated with the future development of POP.

This study was limited by the number of patients, and its retrospective, cross-sectional study design. This meant that the power of the statistics performed were lowered and that pregnant and parous women were not compared to their own nulliparous geometries. Nevertheless, this study demonstrates that the vaginal shape is straighter during late pregnancy, and, because of this, provides a motivation to further investigate the changes in vaginal shape during pregnancy while also evaluating recoverable vs. unrecoverable postpartum shape attributes in future prospective studies.

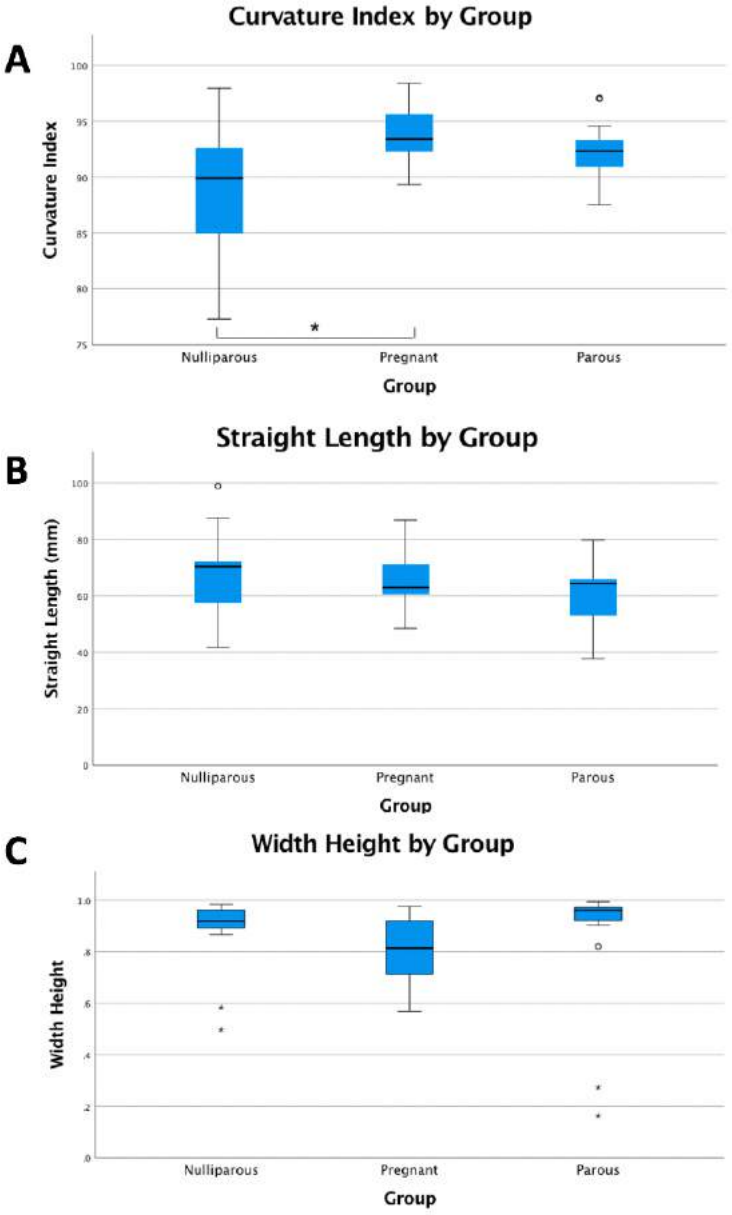

Figure 2: Compares A) curvature index, B) straight length, and C) width height across the three groups of interest (nulliparous, pregnant, and parous).

INTRODUCTION

The meniscus is a crescent shaped cartilaginous tissue found between the femoral condyles and tibial plateau of the knee joint. It functions to provide stability and distribute joint forces, which can be attributed impart to its high water content due to presence of proteoglycans [1]. Proteoglycans are composed of a core protein and 1 or more glycosaminoglycan (GAG) chains. Injuries to the anterior cruciate ligament (ACL) and meniscus can result in a loss of GAGs which is associated with the onset and progression of post-traumatic osteoarthritis (PTOA) in the knee [2].

It has been demonstrated that ACL reconstructive surgery alone does not prevent the development of PTOA [3]. Hence, additional treatment is likely necessary to treat potential occult damage to the joint tissues such as the meniscus, which is likely exposed to large joint loads during traumatic injury [4]. This study is designed to determine the efficacy of injecting a surfactant drug Poloxamer 188 (P188) into the impact area at several time points. P188 is known to increase cell viability, and therefore may prevent degenerative GAG loss within the meniscus.

METHODS

With IACUC approval, the right knees of ninety skeletally mature Flemish Giant rabbits were impacted to generate ACL tear and meniscal damage, leaving the left knee as a contralateral control group. Animals were then randomly assigned to one of four treatment groups; reconstruction only (Recon), reconstruction and P188 administration following impact (P188 D0), reconstruction and P188 administration following impact and 24 hours after (P188 D1), and reconstruction and P188 administration following impact, 24 hours after, and 7 days after (P188 D7). Two weeks following impact, ACL reconstructive surgery was performed. Animals were then euthanized one, three, or six months following impact. Menisci were harvested and prepped for histology using the Safranin-O/ Fast Green stain. Stained slides were then imaged using a microscope and CellSens GAG coverage was determined using ImageJ by isolating the area covered in red stain compared to total tissue area. Finally, the tissues were blindly graded by four trained individuals for GAG intensity using a 0-3 scoring method. A fixed effects model was used to determine statistical significance between treated samples and contralateral control. A p-value < 0.05 was deemed significant.

RESULTS

Analyzing GAG coverage concluded in a significant difference in the lateral menisci between all P188 treatment groups and their control limbs at the 1-month time point. At 3 months, P188 D0 saw a significant increase in GAG coverage from Recon. At the 6-month time point all groups saw a significant decrease from their control limb except for P188 D0.

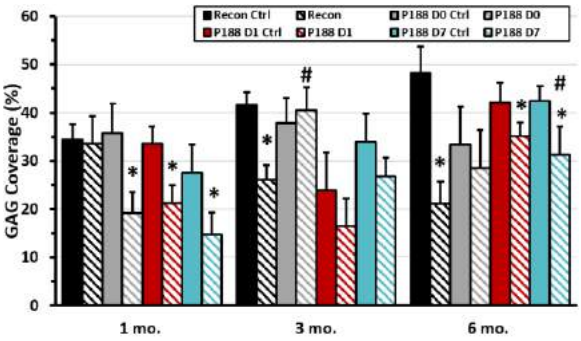

Figure 1. GAG coverage of lateral menisci across all time points and treatment groups * denotes significant differences from control # denotes significant differences from reconstruction only

Additionally, P188 D7 had a significant increase in GAG coverage from Recon (Fig 1).

In the medial menisci at 1- month, all groups saw a decrease compared to their control groups. However, P188 D7 at 3 months saw an increase in GAG coverage from Recon, and P188 D0 at 6-months also saw a significant increase from reconstruction. At 6 months, all other treatment groups saw an increase in GAG coverage from their controls, but it was not significant (Fig. 2).

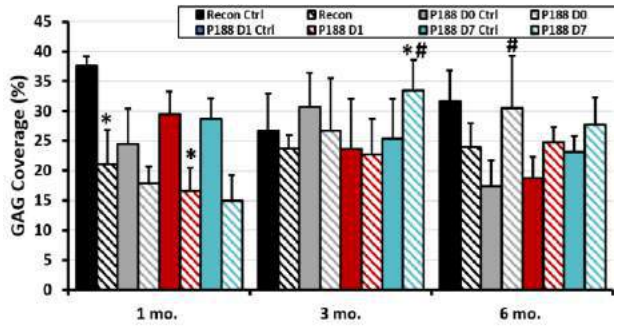

Figure 2. GAG coverage of medial menisci across all time points and treatment groups * denotes significant differences from control # denotes significant differences from reconstruction only

GAG intensity grading resulted in a significant difference in the lateral menisci between all P188 treatment groups and their control limbs at the 1-month time point. P188 D0 and D7 showed a significant decrease from Recon at the 1-month time point (Fig 3).

In the medial menisci, there was a significant decrease in GAG intensity at P188 D1 from its control and Recon. However, at the 3-month time point, there are no significant decreases in intensity. Additionally, at 6 months, there is an increase between all treatment groups and their controls, but it is not statistically significant (Fig 4).

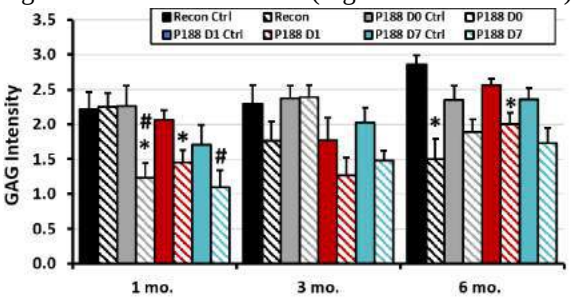

Figure 3. GAG intensity of lateral menisci across all time points and treatment groups * denotes significant differences from control # denotes significant differences from reconstruction only

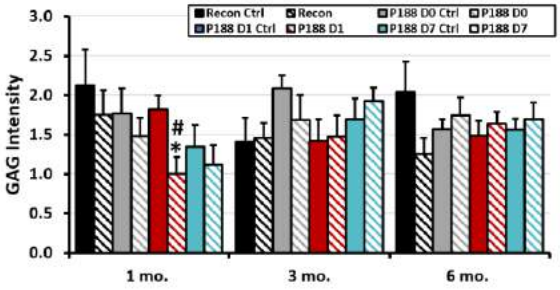

Figure 4. GAG intensity of medial menisci across all time points and treatment groups * denotes significant differences from control # denotes significant differences from reconstruction only

DISCUSSION

Injection of surfactant drug P188 helps but does not prevent degradation of menisci at later time points following traumatic knee injury. While there are not significant increases in GAG coverage or intensity across all treatments and time points, it is clear that P188 is more effective in maintaining GAG content at 3 and 6 months in medial menisci, in comparison to the 1-month time point.

Future directions include delivery of P188 into the meniscus directly. Relying on diffusion during intra-articular injection may not be sufficient enough for P188 to target the meniscus.

INTRODUCTION

Ultrasound speckle tracking can be used to study the movement of the Flexor Digitorum Superficialis (FDS), which is the tendon primarily responsible for finger flexion at the proximal interphalangeal joints. The FDS tendon is frequently engaged when fingers are involved in forceful flexion, where long term usage has been known to cause serious damage, including rupture of the tendon due to continuous manual labor [1].

Here, we present a method for calculating FDS tendon strain using high-frequency ultrasound imaging and speckle tracking. We utilized a custom-built image analysis script that allows us to calculate the strain measurements over a predetermined contraction and relaxation cycle and estimate observed strain over a period of FDS tendon stress. We hypothesize that reliable strain estimates can be determined using this high-frequency ultrasound imaging technique. Several groups have published papers on measuring tendon displacement and measuring strain in different tendons using techniques such as texture correlation [2-4], yet this study is the first to our knowledge to quantify strain values in the FDS tendon *in vivo* using speckle tracking.

METHODS

Seven participants aged 19 to 50 volunteered to have their wrists imaged during various cycles of contraction and relaxation in this initial study. All protocols were performed with Purdue Institutional Review Board Approval. Prior to imaging, each participant was familiarized with the data collection method. Each participant rested their arm on a platform near the ultrasound machine that allowed their elbow to rest at a 120-degree angle while standing (Figure 1a). The arm was then secured, and the ultrasound probe lowered into place against the skin on the anterior side of the wrist parallel to the FDS tendon.

The subject was given a hand grip Dynamometer probe (MicroFET, Hoggan Scientific, Salt Lake City, UT, United States) that can wirelessly measure grip force. A baseline test of maximum force was measured three times and averaged for each participant. This averaged max force was then used to find the target force of each duty cycle. Based on the maximal acceptable effort equation, there was a total of five conditions that varied duty cycles and force exertions which ranged from 3% to 70% of cycle time (30 seconds) and 8% to 57% of maximum force, respectively [5]. The participants performed three cycles of ramp up, hold, ramp down, and rest, which represented one cycle. This was repeated for each condition with each cycle being 30 seconds total where larger force exertions had shorter hold and longer break periods, while small force exertions had longer hold and shorter break periods. During the entire cycle, we used a Vevo3100 system (FUJIFILM VisualSonics Inc., Toronto, Ontario Canada) with a 40 MHz center frequency linear array ultrasound transducer (25-55 MHz bandwidth; MX550D) to acquire continuous B-Mode images throughout the experiment.

Using a custom-built MATLAB graphical user interface (MathWorks, Inc., Natick, Massachusetts, United States) that allowed us to manually define tendon borders and track displacement throughout each duty cycle, we were able to estimate the 2D Green-Lagrange full strain tensor using the upper and lower boundaries of the FDS tendon. For each frame of the ultrasound, the 2D version of the deformation gradient tensor (***F***) was used to estimate the Green-Lagrange strain tensor (***E; eq 1***) using the following equation:

$$\boldsymbol{E} = \frac{1}{2}(\boldsymbol{F^T F} - \boldsymbol{I}), \quad \boldsymbol{E} = \begin{bmatrix} \mathrm{E_{xx}} & \mathrm{E}_{xy} \\ \mathrm{E}_{yx} & \mathrm{E}_{yy} \end{bmatrix} \tag{1}$$

where $\boldsymbol{I}$ represents the identity matrix, $\boldsymbol{E_{xx}}$ is the component of the strain tensor corresponding to the longitudinal strain, $\boldsymbol{E_{yy}}$ is the component corresponding to the radial strain, and the $\boldsymbol{E_{xy}}$ and $\boldsymbol{E_{yx}}$ are components

corresponding to shear strain [6-7]. For the purpose of our analysis, we were primarily interested in the $\boldsymbol{E_{xx}}$ (i.e., longitudinal strain).

RESULTS

Initial analysis of strain in one subject has shown that we can estimate the longitudinal component (E_{xx}) of the 2D Green Lagrange strain tensor over a duty cycle. A representative graphical depiction of strain over 600 frames (1 duty cycle or ~30 seconds) for a 50% duty cycle is shown in Figure 1c. As the tendon begins to perform work by squeezing the force probe, the average longitudinal strain value decreases and then returns to baseline with relaxation. While preliminary results have been obtained from subject seven, a complete set of results has not yet been obtained that would allow for a meaningful comparison between all seven subjects.

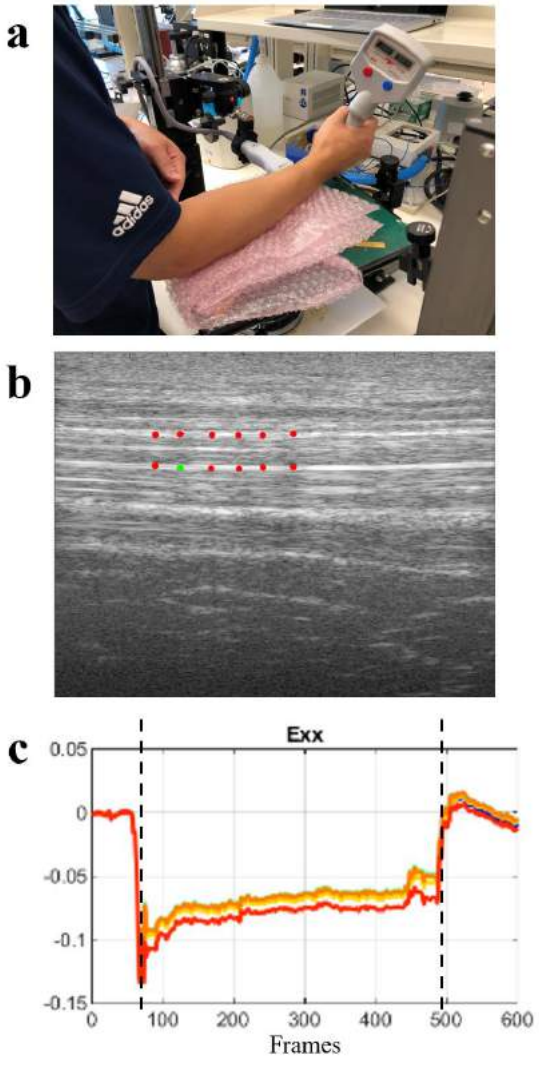

Figure 1: (a) Image of subject's wrist position when performing data collection. The angle of the elbow was positioned in approximately a 120° angle, while the hand holds the force probe off the edge of the elevated resting platform. (b) Example of manual point segmentation along the edge of the FDS tendon. (c) Longitudinal strain output for frames 1-600 from participant seven. Frames 1-600 collected at 25 frames per second represent the brief rest to start, ramp up to goal force, hold, and ramp down to rest. Dotted lines indicate the start and end of the hold period.

DISCUSSION

Based on these preliminary results, we can estimate the longitudinal strain in the flexor digitorum superficialis tendon in *vivo* using high-frequency ultrasound imaging and speckle tracking. Additionally, we found that the strain pattern during a duty cycle from our analysis occurs as a negative value that returns to baseline with relaxation, suggesting that the observed strain is the result of tendon shortening. While we continue to work on refining our methods in order to reduce intra- and inter-user variability, observing general trends are a positive start in demonstrating the efficacy of using the MATLAB graphical user interface to track manually assigned boundaries aligned along the top and bottom of the FDS tendon.

Although our results are promising, further refinement of our methods is still required. While images as shown in Figure 1c are common for one cycle, all three cycles have yet to be pieced together to find a total longitudinal strain over the entire duty cycle, and we are still refining our method to improve the sensitivity and repeatability of our estimations. We are also working to remove ultrasound artifacts from the images that that will hopefully increase the signal to noise ratio. We believe we can do this by averaging multiple frames together in an effort to reduce noise and improve speckle tracking [8]. We also hope that averaging frames will eliminate human error that occurs when manually assigning focal points for the MATLAB algorithm to track.

The results obtained in this research study are unique and can provide clarity into FDS tendon longitudinal strain. Currently there are multiple papers published that have attempted similar methods with various other tendons yet have not reported consistent results [2-4, 6-7, 9-10]. One paper found that there is a high degree of variability in strain estimation when analyzing tendon tissue with commercial ultrasound speckle tracking algorithms [3]. We found inconsistencies within our pool of strain results, but we are confident in results collected to date due to similarities in results across participants.

Our method of finding strain values opens the door to look at the long-term effects of strain on a tendon without invasive procedures. Additionally, we anticipate these results can be applied to study settings like assembly lines, where intensive wrist work is a common practice. We hope that the data obtained from this research allows recommendations to be made concerning the rest periods for workers and for improved working conditions that allow for a less strenuous use of wrist and underlying tendons.

RELATIVE DISPLACEMENTS BETWEEN THE BRAIN AND SKULL IN THE MINI-PIG: EFFECTS OF AGE AND MOTION DIRECTION

INTRODUCTION

Understanding the role of the skull and brain interface is critical to illuminating the pathology of concussion and traumatic brain injury (TBI). Here we characterize the skull-brain interface by inducing low-amplitude, harmonic motion of the head using external pneumatic actuators and measuring the resulting motion of the skull and brain using magnetic resonance elastography (MRE).

The mini-pig, which has a gyrencephalic brain with white matter tracts analogous to those in humans, has been established as a powerful animal model for TBI in humans [1,2]. In both mini-pig and human TBI, skull motion transmitted into the brain induces shear deformations in the brain [1,2]. However, the similarities and differences between mini-pigs and humans must be understood quantitatively in order to interpret research findings.

In the current study, MRE studies were performed in the Yucatan mini-pig *in vivo* with three different pneumatic vibrations applied to the mini-pig brain and skull using a jaw actuator. This induced both translation and rotation of the head. The goal was to quantitatively characterize skull-brain interactions, specifically the relative motion between the skull and brain in the mini-pig at various ages.

METHODS

Imaging: Yucatan mini-pigs (n=2) were imaged at ages 3, 4, 5, and 6 months (avg. mass = 14.06, 19.91, 24.31, 26.76 kg). Each animal underwent T1-weighted MRI and MR elastography head scans using a custom EPI pulse sequence [3] on 3T MRI scanner (Prisma^{TM}, Siemens). MRE parameters provided field of view 180 mm and voxel size 2 mm (Fig. 1). Three pneumatic actuator configurations were used to induce harmonic motion of the skull and brain at 100 Hz using a custom multi-directional jaw actuator fabricated from two flexible bottles [4]. The actuator configurations were: (1) both bottles actuated in-phase ("BA"); (2) only the left side active ("LA"); (3) only the right side active ("RA"). BA provided symmetric loading; RA and LA provided asymmetric forces on the skull. Excitation was applied by a pneumatic driver (Resoundant^{TM}, Rochester, MN) at 60% amplitude.

Image analysis: Three-dimensional (3D) harmonic motion of each voxel was estimated from MRE. Voxels in the skull and the brain were manually segmented using ITK-Snap (ITK-Snap^{TM} ,Yushkevich and Geric) in T1W image volumes. Voxels with insufficient MRE signal-to-noise (SNR) were identified from non-harmonic spectra and removed from analysis. Rigid-body ("bulk") components of skull and brain displacement were estimated by fitting these 3D displacement fields in skull and brain regions, respectively, to equations of rigid-body motion. Dynamic deformation ("wave motion") in the brain was obtained by subtracting bulk motion from total displacement in brain voxels. [5]

Because of the inherent water content in the tissue, harmonic motion was able to be measured by MRE throughout the entire brain but only in a small fraction (~12-15%) of skull voxels. Since the skull is effectively rigid (6 degrees of freedom), even this small fraction of voxels is enough to estimate skull motion. To characterize relative skull-brain displacement at the brain surface, we first constructed the virtual motion of a "skull-fixed" brain: the motion that a rigid brain would exhibit if it were rigidly attached to the skull. This skull-fixed brain motion was then compared to the total motion of the brain, specifically in voxels at the surface of the brain, to calculate relative displacement of the brain with respect to the skull

RESULTS

Fig. 2 shows translation and rotation of the skull and brain from one scan in a single mini-pig (MP2; 4 months, 17.2 kg), using actuator

configuration BA. Qualitatively both skull and brain exhibit similar harmonic translation and rotation. Fig. 3A shows the amplitude of the difference between skull-fixed brain displacement and total brain displacement on the brain surface (our estimate of relative skull-brain displacement). Fig. 3B shows the difference between skull-fixed brain motion and the bulk motion (only) of the brain.

Fig. 4A shows the mean amplitude of relative displacement between brain and skull in animals MP1 and MP2. Fig. 4B shows the mean amplitude of displacement in the skull-fixed brains. Fig. 4C shows relative brain-skull displacement normalized by the skull-fixed brain displacement. While the amplitude of skull displacement and relative skull-brain displacement both decrease with age (likely due to the increase in head mass), the ratio of relative skull-brain displacement to skull displacement remains stable over this period. This ratio is also similar for all three actuator configurations.

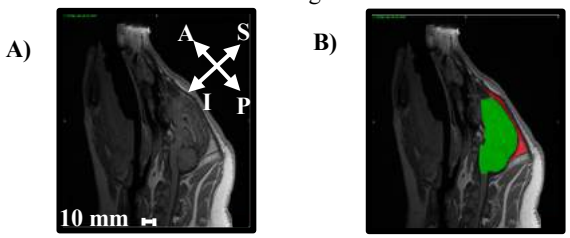

Figure 1: (A) T1-weighted sagittal slice. (B) T1-weighted sagittal slice with brain (green) and skull (red). A – Anterior, P – Posterior, S – Superior, I – Inferior, R – Right, L – Left (in and out of page).

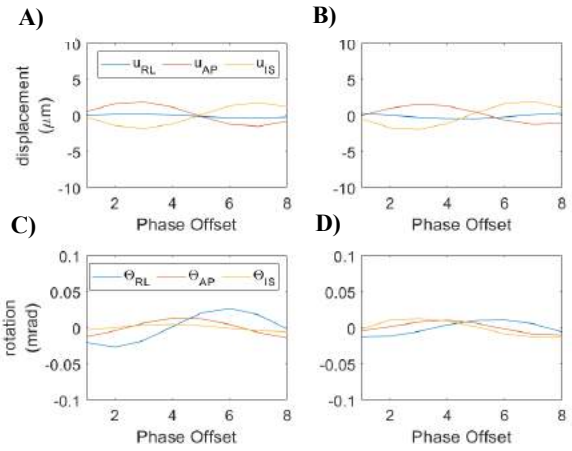

Figure 2: Components of rigid-body translation and rotation (u_{AP}, u_{RL}, u_{IS} and $\theta_{RL}, \theta_{AP}, \theta_{IS}$) of (A,C) mini-pig brain and (B,D) skull. Minipig MP2, 4 mos. Actuator BA.

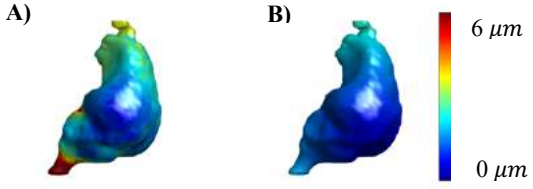

Figure 3: (A) Amplitude of the difference between the displacement of the skull-fixed brain and total brain displacement (i.e., relative skull-brain displacement) mapped on the brain surface; (B) Amplitude of the difference between skull-fixed brain displacement and brain bulk displacement. Minipig MP2, 4 mos. Actuator BA.

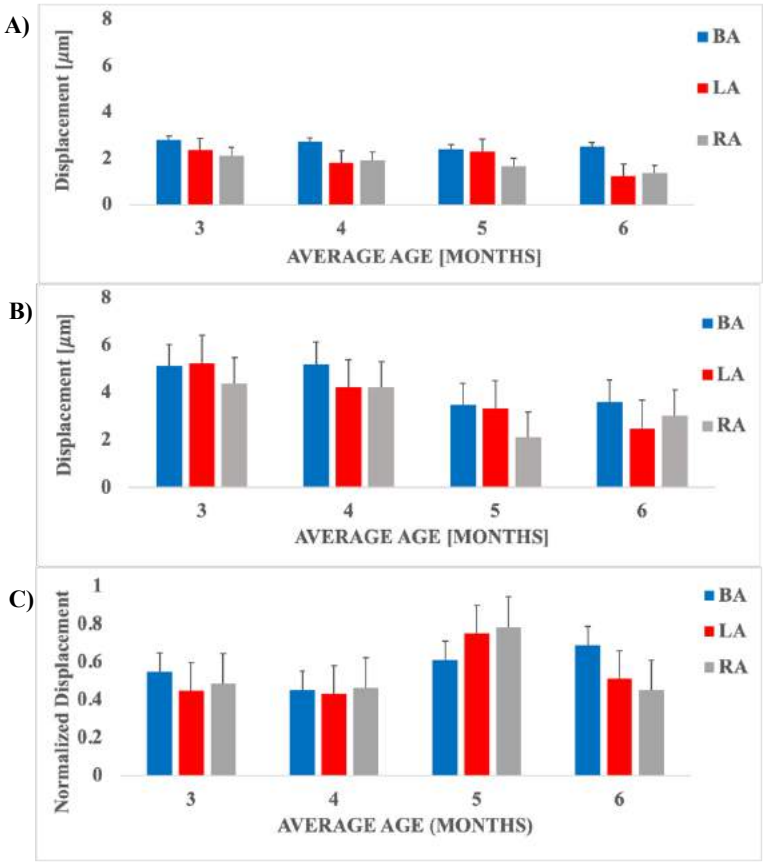

Figure 4: (A) Mean amplitude of relative displacement between the brain and skull-fixed brain; (B) Mean displacement amplitude of skull-fixed brain. (C) Mean ratio of relative brain-skull displacement to mean skull displacement. (Averages over minipigs MP1 and MP2).

DISCUSSION

Displacement fields and relative displacement between the skull and brain were measured by MRE in two mini-pigs aged 3-6 mos. Amplitude of brain and skull motion decreased with age, likely due to increasing head mass, but the amplitude of relative skull-brain displacement was consistently between 50-80% of skull displacement and exhibited no clear trend with age. This ratio did not depend on whether force was applied symmetrically (actuator configuration BA) or asymmetrically (configurations RA and LA).

These data will inform computer models of TBI and enable quantitative comparison of skull-brain interface mechanics in the mini-pig and human. Future work will investigate relative skull-brain motion in human volunteers, and in specific brain regions like the cerebellum.

METABOLISM OF CHONDROCYTES AFTER TRAUMATIC OVERLOADING DETERMINED BY CLICK CHEMISTRY TECHNIQUES

Annie Porter, Liyun Wang, X. Lucas Lu

Department of Mechanical Engineering
University of Delaware
Newark, DE, USA

INTRODUCTION

Traumatic joint injuries often induce inflammation in the joint cavity with elevated levels of pro-inflammatory cytokines, such as TNF-α and IL-1β. The cytokines act on chondrocytes, causing aberrant cell hypertrophy, over-proliferation, apoptosis, and imbalanced metabolic activities [1]. Treatment varies, given individual physician's clinical impressions and preferences, which include a non-pharmaceutical option, R.I.C.E. (rest, ice, compression, and elevation), oral or topical use of nonsteroidal anti-inflammatory drugs (NSAIDs), and intra-articular cortisone injections [2].

The objective of this study was to quantify the combined effects of traumatic overloading and inflammatory challenge on chondrocytes to inform clinical decisions on the treatment of joint inflammation after traumatic injuries. To evaluate the responses of *in situ* chondrocytes, new click-chemistry based techniques were developed to visualize and quantify cell proliferation and metabolic activities. The copper-free click chemistry reactions are bioorthogonal, *i.e.*, not interfering with native cellular processes [3]. The two aims of this study were (1) to develop new click-chemistry techniques to quantify the proliferation and metabolic activities of *in situ* chondrocytes in cartilage explants, and (2) to investigate the effects of IL-1β on chondrocytes in the trauma-damaged cartilage.

METHODS

Cartilage explants (3 mm in diameter and 2 mm in thickness) were harvested from fresh calf knee joints (1-2 months old) and cultured in chondrogenic media [4]. Four experimental groups were tested: control, overloading (OL), IL-1β (1ng/ml), and OL+IL-1β (overloading followed by IL-1β challenge). Overloading was applied to cartilage explants in an unconfined compression setup with a 50% strain in 1 second (~6-10 MPa/s in stress rate) and held for 15 seconds. Cell viability was imaged using Live/Dead™ staining 24 hours after overloading (n=3).

Proliferation Assay. Proliferation of *in situ* chondrocytes was determined using a copper-free click chemistry-based assay. Post overloading, explants were treated for 24 hours with an azide modified nucleoside AmdU (10 μM), which can be incorporated into DNA of proliferating cells by endogenous enzymes (Fig. 2a). Afterwards, samples were fixed with cellular permeabilization, and a fluorescent dye, AF488 DBCO, was "clicked" to the azide groups on the DNA of the proliferating cells. All cell nuclei were counterstained with a red tracker. Chondrocytes in explants were imaged on a confocal microscope and counted in ImageJ (n=6).

Protein Synthesis. After traumatic overloading, new GAG (in 24 hrs) and collagen (in 48 hrs) synthesized in the explant was fluorescent-labelled using click chemistry methods (Fig. 3a). To label newly synthesized GAG or collagen, a "clickable" modified monosaccharide (Gal) or methionine (AHA) with an azide functional group was supplied in the culture media, which can be used by cells and incorporated into the newly synthesized GAGs and collagens, respectively. The newly synthesized molecules were conjugated with AF488 DBCO via a click chemistry reaction. By enzymatically digesting the labeled tissue and normalizing the fluorescent intensity of the digested solution to the explant weight, the synthesis rate of GAG or collagen content can be quantified and compared between the groups (n=8).

ECM Degradation. The GAG or collagen content synthesized in each explant in 2-day culture was first fluorescent-labelled with the click chemistry methods (Fig. 3a). The explants then underwent overloading damage and/or IL-1β challenge. In the following explant culture, the longitudinal loss of GAG or collagen contents from the cartilage can be quantified by reading the fluorescent intensity of culture media every other day (n=8).

RESULTS

Chondrocyte Viability. Limited cell death (red) was observed along the explant surface in the top zone cartilage (ctrl), which was not significantly affected by 24-hour IL-1β challenge. One day after overloading, significant cell death was observed in top zone and the neighboring middle zone tissue (Fig. 1).

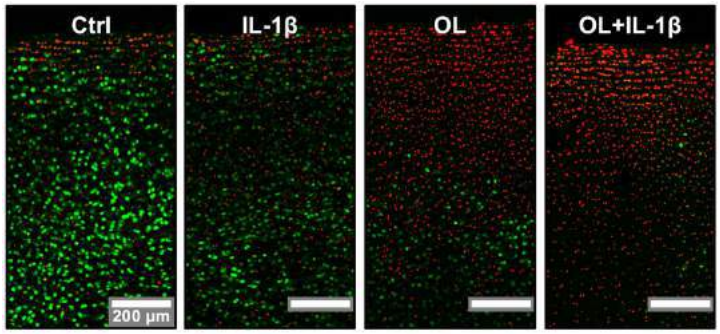

Figure 1: Cell viability in cartilage by Live/Dead™ staining.

Chondrocyte Proliferation. In the ctrl group, proliferation rate in the top zone cartilage from 2-4 month calf joints is 47.7 ± 5.7%, which is further increased to 55.9 ± 4.6% for 1-day IL-1β treated samples, and decreased to 24.7 ± 12.7% and 24.3 ± 7.6% for the OL and OL+IL-1β treated samples, respectively ($p < 0.001$, Fig. 2c,d). The proliferation of chondrocytes in the middle zone cartilage was not affected by any treatments (Fig. 2c).

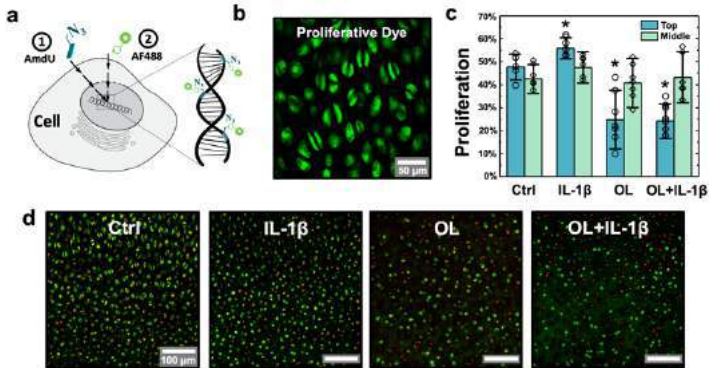

Figure 2: Chondrocyte proliferation. (a) AmdU with azide groups are embedded into proliferating DNA, on which fluorescent dye AF488 can be "clicked". (b) Confocal image of proliferative cells. (c) Proliferation rates in top and middle zones (n=6) (*: $p < 0.001$). (d) Confocal images of proliferative cells (green) in top zone cartilage with all cell nuclei stained in red.

Effects on ECM Synthesis. One-day exposure to IL-1β alone had no significant effects on GAG (in 24 hrs) or collagen (in 48 hrs) synthesis in explants (Fig. 3b). In contrast, overloading reduced both the GAG and collagen synthesis rates significantly ($p < 0.015$), as many cells dyed in the top zone. No significant difference was detected between the OL and OL+IL-1β samples (Fig. 3b).

Effects on ECM Degradation. In contrast to its prominent effects on proliferation and ECM synthesis, overloading alone had no effect on the loss of GAG or collagen content from the explant in the following long-term culture. Exposure to IL-1β caused 39.9 ± 6.2% GAG loss in 10 days and 55.6 ± 10.9% collagen loss in 44 days. For samples with overloading damage, subsequent IL-1β exposure exacerbated the loss of both GAG (67.9 ± 7.9%, $p < 0.01$) and collagen (62.6 ± 10.1%, $p < 0.01$), significantly higher than the IL-1β alone group (Fig. 3c).

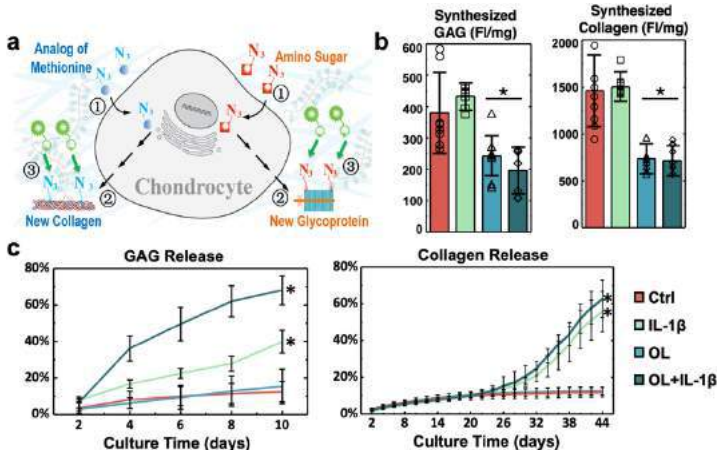

Figure 3: Effects of overloading and IL-1β on cell metabolic activities. (a) Click chemistry method to label new GAG and collagen within explant. (b) GAG (24 hrs) and collagen (48 hrs) synthesis. (c) Longitudinal GAG and collagen loss (%) from cartilage explants into culture media. (n=8) (*: $p < 0.015$)

DISCUSSION

The newly developed click chemistry methods are accurate, sensitive, and cost-effective in quantifying the proliferation and metabolic activities of *in situ* chondrocytes in cartilage. GAG and collagen measurements with click chemistry have been verified by traditional hydroxyproline and BMMB assays (data not shown). The click chemistry proliferation assay results were affirmed by known chondrocyte responses. IL-1β treatment induced chondrocyte over-proliferation, and the decrease in top zone proliferation after overloading is consistent with cell viability data [5]. These new methods represent useful tools for *in vitro* studies in osteoarthritis and regenerative medicine related research.

Chondrocyte proliferation measured at the top and middle zones in the control group were consistent with reports in literature [6]. IL-1β challenge caused chondrocyte over-proliferation. Impact overloading induced cell death in the top zone cartilage, as the top zone has a compressive modulus ~10% of the middle zone, causing large deformations resulting in damaged cells [7]. Overloading alone reduced the GAG and collagen synthesis in cartilage, possibly due to extensive cell death. Overloading, followed by IL-1β treatment, caused more severe ECM degradation than the IL-1β alone group or overloading alone group. These results indicate that while the initial traumatic overloading causes chondrocyte death and reduces new ECM synthesis, the combination of overloading and inflammation induces more damage to the cartilage. Our results support the fast ease of joint inflammation, *i.e.,* pharmaceutical treatment such as NSAIDs, after trauma injuries to avoid or mitigate the occurrence of irreversible degradation of cartilage.

INTRODUCTION

There is a clear link between increasing age and injuries in tendons. In a growing aging population, there is a need to understand these age-related changes in order to treat and reduce such injuries. Many mechanisms have been suggested to contribute; however, one of the most predominant mechanisms is believed to be advanced glycation end-products (AGEs) [1-2] due to the dominance of collagen in tendons. AGEs accumulate in tendons with age, producing non-enzymatic crosslinks in collagen that alter the mechanics of the tissue and lead to more injuries [1-2]. Exercise may combat AGE accumulation and reduce tendon injuries; however, *in vivo* investigations have yielded variable results [3-5]. It is unknown whether exercise loading reduces AGEs by increasing matrix turnover, thereby preventing AGE crosslink formation, or whether loading stimulates the breakdown of existing AGEs. To determine optimal exercise regimes, the mechanism by which loading affects AGE accumulation and tendon homeostasis must be understood. The objective of this study was to investigate how tensile loading affects AGE accumulation, breakdown, and tissue homeostasis in *ex vivo* tendons, in an effort to reduce AGEs and age-related injuries.

METHODS

Tail tendons were harvested from 2-4-month-old freshly sacrificed Sprague Dawley rats. Extracted tendon bundles were separated into individual fibers and cut into approximately 30 mm long segments. Separated tendon segments were cultured in a custom clamping device [6], to maintain viability and phenotype, for up to 4 weeks in standard media (DMEM), with or without 100 mM ribose to induce AGE formation and artificially age the tissue [1,2,7]. Tendons with and without ribose exposure were loaded with an established cyclic tensile load (5% strain at 1 Hz for 1 hour on-1 hr off-1 hr on) three times weekly for up to two weeks in a CellScale tensile bioreactor [8]. Two experiments were performed to investigate whether cyclic tensile load can prevent AGE accumulation (Fig 1A) and/or 2) can reduce existing AGEs (Fig 2A). DNA, glycosaminoglycan (GAG), collagen, total AGEs, and specific AGE crosslink pentosidine were determined via PicoGreen, DMMB, hydroxyproline (hypro), AGE fluorescence, and pentosidine assays respectively [6-7]. Confocal reflectance and fluorescence imaging were performed to observe collagen fiber organization in response to induced AGEs and tensile load. Autofluorescence of cells and AGEs were captured together at 400-470 nm (green, Fig 3). Statistical analysis was performed by 2-way ANOVA with Tukey's post-hoc (p<0.05 significant). All data are mean ± SD.

RESULTS

To investigate if loading prevents AGE formation, tendons were mechanically stimulated while AGEs were induced with ribose (Fig 1A). Weight, GAG (data not shown), and collagen (Fig 1B) of all groups remained steady or increased over 2 weeks, suggesting cells remained viable and produced matrix. Loaded tendons in DMEM increased GAG and collagen (Fig 1B) after one week before returning to baseline values, suggesting loading increases matrix turnover. Interestingly, loaded tendons in ribose did not have this increase in matrix at 1 week. Ribose treatment significantly increased total AGEs and AGE specific crosslink, pentosidine, throughout culture when normalized to wet

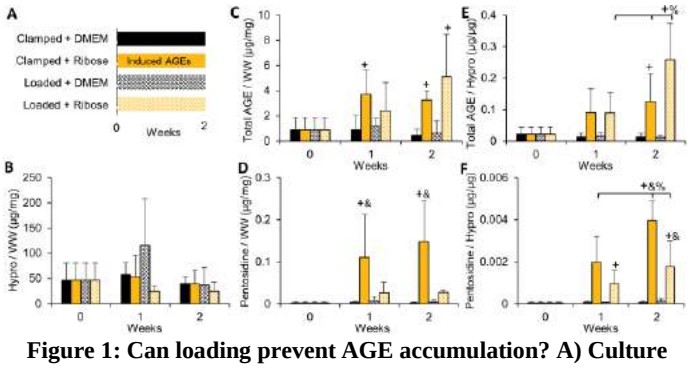

Figure 1: Can loading prevent AGE accumulation? A) Culture conditions, B) Collagen (hypro) / wet weight (WW), C-D) Total AGEs and pentosidine / WW, and E-F) Total AGEs and pentosidine / collagen. N = 4-7, Significance (p<0.05) compared to +0wk, %bracket, &all other groups within week

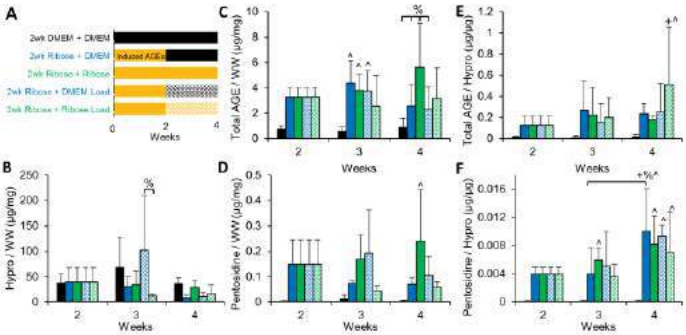

Figure 2: Can loading reduce existing AGEs? A) Culture conditions, B) Collagen (hypro) / wet weight (WW), C-D) Total AGEs and pentosidine / WW, and E-F) Total AGEs and pentosidine / collagen. N = 4-7, Significance (p<0.05) compared to +2wk, %bracket, ^DMEM control (2wk DMEM +DMEM)

weight or collagen content (Fig 1C-F). Addition of tensile load over 2 weeks reduced formation of specific AGE crosslink, pentosidine (Fig 1D&F), but had no effect on reducing total AGEs (Fig 1C&E).

When investigating if loading is capable of driving cells to reduce existing AGEs, AGEs were induced for 2 weeks prior to loading tendons with and without ribose (Fig 2A). Again, GAG (data not shown) and collagen content (Fig 2B) increased after 1 week of loading in DMEM suggesting turnover of the matrix with load, however loaded tendons in ribose did not have this increase in matrix at 1 week. Loading of AGE induced tendons in DMEM (patterned blue bars) did not significantly reduce total AGEs or pentosidine crosslinks in comparison to control AGE induced tendons cultured in DMEM (solid blue bars), suggesting loading is not capable of reducing existing AGEs (Fig 2C-D). Interestingly, AGE induced tendons loaded while still in ribose (patterned green bars) did have reduced pentosidine levels when normalized to wet weight (Fig 2D), suggesting loading may reduce pentosidine crosslinks or at least mitigate formation of additional crosslinks. However, total AGEs and pentosidine levels in all loaded tendon, whether in DMEM or ribose, did not decrease when normalized to collagen (Fig 2E-F).

Confocal reflectance revealed tendons exposed to ribose had greater fluorescence than tendons not exposed to ribose, suggesting an increase in AGEs (Fig 3). Tendons loaded while inducing AGEs revealed reduced AGE fluorescence at 2 weeks, however, injurious kinking was also observed (Fig 3A). Tendons which had AGEs induced for two weeks and were then loaded with or without additional AGE induction revealed little reduction in AGE fluorescence, but significant injurious kinking at 3 and 4 weeks (Fig 3B).

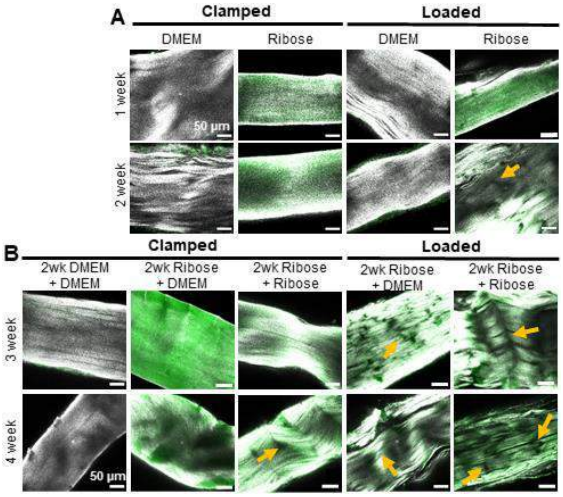

Figure 3: Confocal of tendons loaded A) during or B) after ribose induction of AGEs; Grey = collagen, Green = auto-fluorescent cells and AGEs, arrows point to injurious kink

DISCUSSION

AGEs accumulate with age and diabetes. They crosslink collagen, disrupting cellular function and altering tendon mechanics, ultimately resulting in increased injuries [1-2]. In this study we have shown that loading decreases formation of specific AGE crosslink, pentosidine, but does not mitigate formation of overall total AGEs and that the loading regime for optimal collagen turnover still needs to be determined. Specifically, control tendons maintained DNA with increasing weight in all groups (data not shown), indicating cells remained viable and produced matrix. This suggests our *ex vivo* system is not detrimental to tendon homeostasis. Further, 100 mM ribose treatment produced a significant increase in total AGEs and pentosidine, matching and exceeding AGE levels for various tissues and ages [4,7,9]. GAG and collagen concentration increased with 1 week of loading but returned to pre-load values by 2 weeks, suggesting the loading regime increases the metabolism of cells, resulting in anabolic, catabolic tissue turnover [8]. However, when loaded in the presence of ribose, there was no increase in GAG or collagen, suggesting ribose may alter cellular response to load or affect the timing of this response. Loading while inducing AGE crosslinks was capable of mitigating pentosidine formation, but not total AGE formation. Pentosidine crosslinks take longer to form than many other AGEs, including adducts which often form more quickly [7]. Thus, loading may prevent pentosidine formation by stimulating quicker cellular turnover of the matrix, providing less time for pentosidine crosslinking.

Loading after AGE induction did not reduce AGEs when compared to induced tendons cultured in DMEM, suggesting loading is not capable of reducing existing AGEs. However, when compared to induced tendons culture in ribose, loading did decrease AGEs normalized to wet weight, suggesting loading may reduce AGE crosslinks or at least mitigate formation of additional crosslinks in the continued presence of ribose. This reduction in AGEs with load was lost when normalized to collagen, suggestisng cells are turning over non-crosslinked collagen more than AGE-crosslinked collagen. Loading after induction also induced increased injurious response. This work demonstrates loading can reduce certain types of AGEs, but loading regimes need to be optimized to drive healthy matrix turnover instead of injurious response in cells. More loading regimes are currently being investigated. This study provides new insight into how cells of AGE crosslinked tendons respond to cyclic tensile load and begins to shed light on a mechanism for reduced AGEs *in vivo*. This *ex vivo* system is a valuable model for investigating effects of AGEs and methods of reducing them for treatment of age-related musculoskeletal injuries.

INTRODUCTION

Despite World Health Organization reported estimates that only 10-15% of births pose a medical necessity for caesarian section (CS) [1], about 1 in 3 babies born in the United States are delivered via CS [2]. CS is a major surgery that increases the cost of delivery and places the mother at greater risk of infection [2]. Birth is a complex process, typically split into three stages of labor. Arrest of the first stage of labor, characterized by the effacement (shortening) and dilation (opening) of the cervix, is the primary motivation for CS, cited in 15-30% of cases [2]. The mechanical function of the cervix in pregnancy is two-fold: it must be robust enough to stay closed as the fetus grows, but flexible enough to allow for the fetus's passage at the time of delivery. Given the ethical constraints to researching human tissue during delivery *in vivo*, it is convenient to use computational models to study the biomechanics of birth.

Computational research in birth simulation has shed light on many birthing complications. The work done thus far has primarily focused on the pelvic floor and related injuries, and on fetal head deformation during vaginal delivery [3,4]. These models lack attention on the uterus and cervix during delivery, and typically rely on imaging modalities which are not common in obstetric clinical care. To address this, parametric patient-specific modeling frameworks based on 2D ultrasound images have been proposed to study pregnancy biomechanics throughout gestation [5,6]. However, the resulting models were not designed to capture uterine and cervical geometry at the time of delivery, nor do they include fetal geometry. Therefore, we have developed a method to simulate the first stage of labor based on a 2D ultrasound measurement method.

MRIs of pregnant patients scheduled for CS were taken at 38-39 weeks gestation, segmented, and converted into 3D models [7]. From these models, 2D ultrasound measurements (as proposed by Louwagie et al.) were taken, and 3D parametric patient-specific models were built. Using these models, this research aims to simulate birth in order to deduce the principal strains of the cervix during the first stage of labor, potentially aiding in determining which deliveries necessitate CS.

METHODS

The geometry of the uterus, cervix, fetal head and abdomen were created in Solidworks (Dassault Systemes, Vélizy-Villacoublay, France), based on an existing 2D ultrasound measurement method. The uterine and cervical geometry build was based on an existing modeling method [6]. Because this method assumes an elliptical coronal shape, which is inaccurate for late gestation, the model was adjusted by taking 15 transverse intrauterine diameters and wall thicknesses from MRI-derived solid models and incorporating them as parameters of the coronal shape [8]. The cervix was separated from the uterus at the uterocervical junction fillet, and a surrounding supporting abdomen with a hollowed out vaginal canal was built around the uterus and cervix (Fig. 1). Given a dataset of 5 pregnant patients at term [7], the model was built using the shortest measured cervical length and widest measured cervical diameter as parametric dimensions.

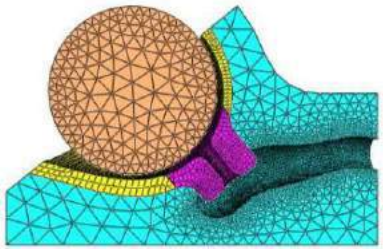

Figure 1: Meshed model viewed from the sagittal plane. The model includes the fetal head, cervix, uterus and abdomen.

The models were meshed in HyperMesh (Altair Engineering Inc., Troy, MI), using tetrahedral elements in the fetal head and abdomen. Hexahedral elements were used for the uterus and cervix. Finite element analysis (FEA) was done in FEBio Studio (v1.1.0) [9]. Within FEBio, the head was modeled as a spherical rigid body, with the diameter measured from MRI, and it followed a prescribed birthing trajectory. The cervix, uterus and abdomen were modeled as neo-Hookean materials because we are only analyzing kinematics. Sliding contact was defined between the head and the cervix/uterus. Tied elastic contact was defined between the cervix and uterus, abdomen and cervix, and abdomen and uterus. The following boundary conditions were applied: the entire system was fixed in the normal direction in the mid-sagittal plane, and the abdomen was fixed in the normal direction at the posterior and inferior ends. A contraction was simulated by pulling the faces of the uterus and abdomen perpendicular to the cervical canal, opposite the motion of the head. An image of the FEBio setup is shown in Figure 1. Symmetry across the sagittal plane was assumed, and a half model was used for computational efficiency.

RESULTS

This research is ongoing, and therefore limited comparisons between cervical geometries can be made. However, looking at a single model, several insights into the deformation of the cervix during the first stage of labor can be drawn. The simulation demonstrates effacement of the cervix, and only after effacement does dilation begin.

The maximum 1st principal Lagrange strain is 6.24, the range of the 2nd principal Lagrange strain is between -0.198 and 2.1, and the minimum 3rd principal strain is -0.494. As illustrated in Figure 2, most of the tensile strain appears concentrated as a ring at the uterocervical junction. The undeformed cervix in Figure 2 illustrates the stretch of the cervix during labor.

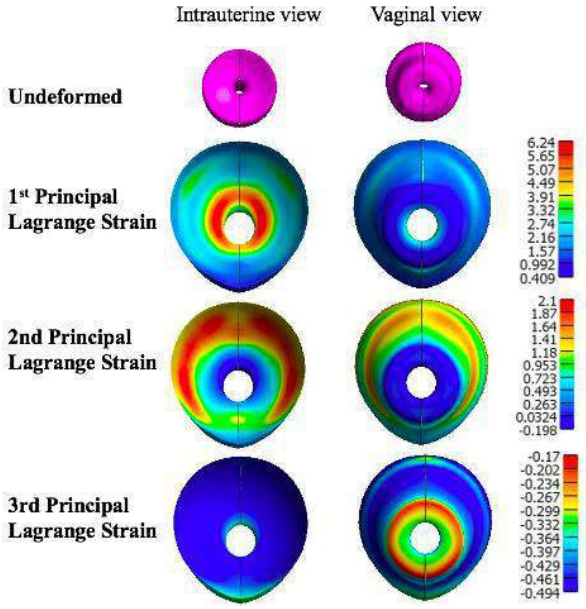

Figure 2: 1st, 2nd, and 3rd principal Lagrange strain maps of the cervix at the final time step, as well as the undeformed cervix for reference. Models are to scale. The result is mirrored over the sagittal plane for a full cervix view. The head is hidden for clarity. Views specify the vantage point from which the cervix is viewed.

Principal strain directions are consistent with expectations. The 1st principal Lagrange strain, aligned circumferentially, shows hoop strain at the internal os (uterine cervical canal opening) of the cervix as it stretches around the fetal head. The 3rd principal Lagrange strain is near minimum throughout most of the cervix, demonstrating compression of the entire cervix as it is pushed by the fetal head and pulled by the uterus.

This simulation only shows the beginning of the first stage of labor for a patient with a comparatively short and wide cervix. As we simulate more geometries, we can draw comparisons between different cervical shapes. With our current simulation metrics, the external os (vaginal cervical canal opening) dilates to 2.2cm. The simulation currently models most of the latent phase of the first stage of labor (3-6 cm dilation), and does not include the active phase, when the cervix is considered to be completely dilated at 10cm [10,11]. Future iterations of this model will aim to allow for more advanced cervical dilation, thereby modeling the process to the end of the first stage of labor.

DISCUSSION

This research simulates the latent phase of the first stage of labor and reports cervical strain during this period. The strain is most concentrated at the uterocervical junction, and is intuitively patterned with circumferential tension dominating at the internal os and compression present throughout the cervical body. The magnitude of the 1st principal strain exhibits the tension of the cervix as it is stretched around the head, and the 3rd principal strain shows large amounts of compression due to the displacement of the head onto the cervix. As we implement further geometries using this FEA method, we will compare deformation as well as strain pattern and magnitude for different cervical sizes during the first stage of labor. This research is limited by the omission of specific active and supporting pelvic structures, such as the pelvic bone and pelvic floor anatomy, whose omission required an imposed fetal head trajectory. The simulated contraction was also simplistic, acting on a single plane of the uterus rather than throughout the entire body. Also, physiologically relevant fiber-based material models were not used, and the material properties were not patient-specific. Although measurements from the model were taken from an MRI-derived model, this measurement process can be done using 2D ultrasound images. The success of a patient-specific birthing model could greatly improve patient care in labor by predicting success in the first stage of labor, the necessity of cervical ripening, or if a CS is needed. Such patient-specific modeling would allow for a more individualized and efficient approach to labor interventions.

INTRODUCTION

The tricuspid valve (TV) regulates the unidirectional blood flow from the right atrium to the right ventricle of the heart via the cyclic opening and closing of three leaflets – the anterior leaflet (TVAL), the posterior leaflet (TVPL), and the septal leaflet (TVSL). Each leaflet has four distinct anatomical layers, which are, from the atrium to the ventricle, the atrialis (A), spongiosa (S), fibrosa (F), and ventricularis (V). Each tissue layer is hypothesized to serve a particular role in the leaflet function based on their microstructural constituents. For example, the fibrosa contains a dense network of crimped collagen fibers that contribute to the load bearing capacity of the TV leaflets.

A detailed knowledge of the characteristics of individual tissue layers and the variations among the TV leaflet types is essential to understand the *in vivo* behavior of the TV. A prior study used high-fidelity *in-silico* simulations to elucidate how the layer-specific properties of the mitral valve leaflets can influence the cellular deformations, which has implications for the leaflet's mechanobiological response to pathological stimuli [1].

Our lab previously characterized the mechanical responses of the four tissue layers for the TVAL [2]; however, we did not characterize the TVPL and TVSL (each has unique microstructural morphologies), or directly compare the mechanical responses between the individual layers and the intact leaflet – a key inter-layer relationship. Further, our lab recently developed a polarized spatial frequency domain imaging (pSFDI) system [3] to quantify the load-dependent changes in the leaflet collagen fiber architecture (CFA). This system can help provide additional insight into the layer-specific CFAs. Hence, the objective of this study is to characterize the mechanical and CFA properties of the three TV leaflets and their respective tissue layers.

METHODS

• **Tissue Preparation and Characterization Overview.** To collect the intact leaflet, tricuspid valve leaflets were dissected from porcine hearts (Animal Technologies, TX), then cut into 12x12 mm specimens. Before testing was performed, the thickness of all tissue samples was determined by averaging three measurements made via a laser displacement sensor (Keyence, IL). The overall experimental protocol was as follows: (i) biaxial mechanical testing and pSFDI of the intact TV leaflets (n=10 for each TV leaflet type), (ii) microdissection of the leaflets, (iii) step (i) procedures applied to the microdissected layers.

• **Layer Microdissection.** The intact leaflet was dissected to separate the tissue into two composite layers: (i) the A/S composite layer, containing the atrialis and spongiosa layers, and (ii) the F/V composite layer, containing the fibrosa and ventricularis layers. First, the square of tissue was pulled taut, pinned to a wax board, and covered with deionized (DI) water to ensure tissue hydration. A scalpel was then used to gently cut along the edge of the tissue, penetrating the atrialis while avoiding the fibrosa underneath. Following the incision, tweezers were used to grasp the A/S and pull it away from the F/V (**Fig. 1a**). The largest sample possible of each layer was collected; however, the A/S composite layer was very thin and elastin rich, which resulted in notable planar tissue shrinkage and smaller A/S specimens.

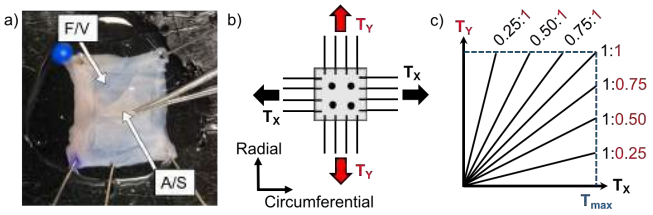

Figure 1: (a) Layer microdissection, (b) mounted tissue, and (c) biaxial testing protocols.

• **Biaxial Mechanical Testing.** The tissue was mounted on a BioTester (CellScale, Canada) using four sets of tines (**Fig 1b**). The intact tissue had a testing region of 10x10 mm while the A/S and F/V layers had

testing regions ranging from 3.3x3.3 mm to 6.6x6.6 mm. Four glass beads were glued to the surface of the tissue in an array for digital image correlation to compute tissue stretches. The tissue was then submerged in a 37 °C DI water bath for the duration of mechanical testing.

Briefly, six cycles of equibiaxial preconditioning were performed with a target peak membrane tension of 40 N/m to restore the approximate *in vivo* configuration [4]. For the thinner A/S composite layer, the targeted membrane tension was adjusted to correspond with a 200 kPa stress since stresses >200 kPa would likely tear the tissue. Following preconditioning, the specimen was biaxially characterized using a series of seven loading ratios (**Fig. 1c**), and the data from the final (third) cycle of each biaxial tension protocol was used for the stress/strain analyses [5].

• **pSFDI Collagen Imaging.** After mechanical testing, the tissue remained mounted and submerged in the DI water bath. Light was shone through a rotating polarizer lens onto the tissue. Images of the reflected light were captured at angles from 0° to 180° with 5° increments for the deformation associated with each biaxial tension ratio. The images were processed to determine the fiber orientation angle θ_{fiber} and the degree of optical anisotropy (DOA) -- indicating the collagen fiber alignment along the predicted fiber angle. Further details of the pSFDI system can be found in [3].

RESULTS

The intact tissue and microdissected layers of the representative TV leaflets exhibited nonlinear and anisotropic mechanical responses (**Fig. 2**). The F/V of the TVAL was more compliant in the circumferential direction, but stiffest in the radial direction. For the TVPL, the F/V was stiffer than the A/S for both the circumferential and radial direction. The TVSL also displayed a consistently stiffer F/V. In both directions, the F/V layer was the stiffest and the intact tissue was the most compliant. Across the three TV leaflets, the intact issue generally exhibited more distinct high-tension and low-tension regimes compared to the A/S and F/V layers. Importantly, the intact leaflet's response does not appear to be the summation of the individual layers, indicating the intrinsic contribution of layer interactions to the tissue mechanics of the intact leaflet.

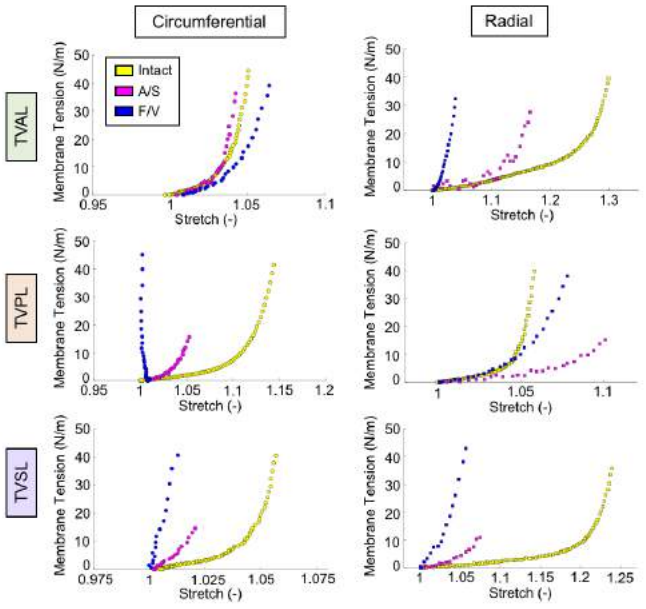

Figure 2: Representative equibiaxial results for the TV leaflets.

The results of pSFDI imaging reinforce the trends seen in the mechanical responses of the TV leaflets (**Fig. 3**). Collagen fibers in the F/V are highly aligned in the circumferential direction compared to the A/S and the intact specimens, supporting the stiffer F/V circumferential responses observed in the biaxial testing (**Fig. 2**). The DOA values across the three TV leaflets indicate notable local changes in the fiber alignment for both the intact and the F/V tissues, while these shifts were not observed in the A/S.

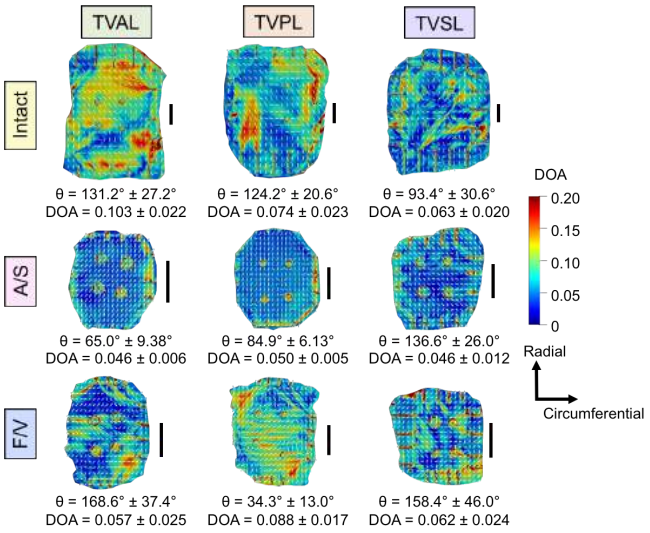

Figure 3: Collagen fiber orientation vector maps overlaid on DOA colormaps for representative specimens under equibiaxial loading. Scale bars are 3 mm. Values are in mean ± SD.

DISCUSSION

This study has provided the *first-of-its-kind* characterization of the biaxial mechanical and CFA properties for the tissue layers of the three TV leaflets. The biaxial mechanical characterization results showed the presence of influential inter-layer interactions, as supported by the quantified mechanical behavior of the A/S and F/V layers not simply summing to the mechanical response of the *intact* leaflet. Moreover, the sharper transition from the low- to high-tension regime of the mechanical response curves for the intact leaflet compared to the composite layers indicates an altered recruitment of collagen fibers. The insight into the CFA architecture as quantified by pSFDI revealed the preferential orientation of collagen fibers in the circumferential direction for the F/V composite layer. More circumferentially oriented collagen fibers within the leaflet suggested a greater resistance to stretching along this direction, generating its stiffer mechanical response. Additionally, the local variations in the fiber alignment of the intact and F/V tissues demonstrate the complex nature of the collagen network and its primary presence in the F/V layer. Overall, our comparisons of the composite layers and the original leaflet provide a better understanding of how the tissue components and inter-layer interactions influence the overall function of the TV leaflets, which can aid in future developments of microstructurally informed constitutive models. The developed models can then be incorporated into accurate finite element simulations to improve the current clinical understanding of the healthy and diseased TV function.

MR IMAGE-BASED CHARACTERIZATION OF MEDIAL AND LATERAL MENISCAL GEOMETRIES FOR PATIENT-SPECIFIC FINITE ELEMENT MODELING

INTRODUCTION

The menisci serve an essential biomechanical role, with their circumferential fibers converting compressive stresses on the knee joint into hoop stresses that reduce contact forces on the tibial articular cartilage [1]. Partial meniscectomy is a common surgical treatment for meniscal tears, however, this intervention may reduce the effectiveness of the menisci in dissipating stresses, leading to increased contact forces on the tibial cartilage and development of osteoarthritis.

Knowledge of meniscal geometries is important for allograft and implant sizing, and for patient-specific finite element modeling [2,3]. Some studies have quantified meniscal geometries for only the medial meniscus, as it is more prone to injury [2], and others have quantified different sets of geometries of the menisci, such as slope or height [3,4]. Non-MRI based approaches have also been used including laser-based non-contacting 3-D coordinate digitizing systems and calipers [5,6]. Few studies have provided a comprehensive set of both lateral and medial meniscus geometries of living subjects in the anterior-posterior (AP), medial-lateral (ML), and radial directions, and examined relationships with other patient-specific geometries.

Regional material property variations across the tibial cartilages are reported to be related to which areas of the cartilage are covered by the menisci [7,8]. Our current work is motivated by a goal to develop efficient patient-specific finite element (FE) models of the tibiofemoral joint to investigate risks for developing osteoarthritis after partial meniscectomy. Mapping these regional material properties across the tibial cartilages using the meniscal footprint, however, may be time consuming or difficult due to lack of images of the intact menisci. Information on meniscal geometry relationships may therefore be advantageous for recovering the intact meniscal footprint. Our main objectives include (1) performing MR Image-based meniscal measurements, (2) assessing the interobserver reproducibility and intraobserver repeatability of these measurements, and (3) identifying a systematic approach to make predictions of intact meniscal geometry.

METHODS

We characterized meniscal geometries by performing MR Image-based measurements on both the medial and lateral menisci of 20 subjects using 3D Slicer [9]. The subjects included 10 men and 10 women (27.9 ± 6.46 years; height: 1.68 ± 0.10 m) with normal, healthy, uninjured knees. MR Images from a previous study were used, specifically 3DGRE, acquired from a 1.5 T scanner in the sagittal plane. The field of view was 140 mm with an in-plane resolution of 0.273 mm and 1.2 mm slice thickness. Tibial plateau width (TPW) and height were also quantified [10].

Key geometries characterized in this work include (a) anterior length, (b) posterior length, (c) total meniscus length, (d) midbody width, (e) anterior radial width, and (f) posterior radial width (Figure 1). Each dimension was measured for both medial and lateral menisci.

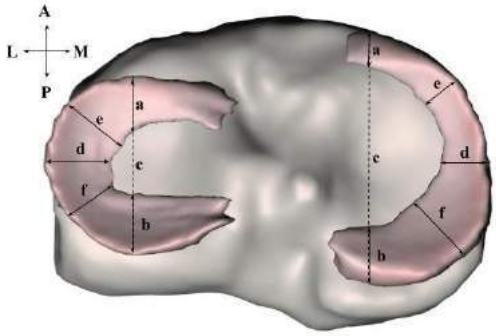

Figure 1: Diagram of meniscus geometry measurements

Knees were oriented in 3D slicer along the epicondylar axis, as previously defined for TPW measurement [10]. Anterior, posterior, and total meniscus length measurements were performed in the sagittal plane. The slice used for AP measurements was selected by locating the sagittal slice with the widest horizontal span, while maintaining the characteristic wedge-shape of the meniscus. In the coronal plane, the slice that approximately bisected each meniscus in the AP direction was used to obtain midbody widths. Measurements were made as the greatest horizontal distances to the outer edges of each geometry.

Anterior and posterior radial width measurements were performed on oblique views, obtained by rotating the MR Images 45 degrees about the inferior-superior (IS) axis, predefined by 3D Slicer. The slices used for these measurements were determined by relocating the pixel locations where the sagittal and coronal plane slices intersected from the previous AP and ML meniscus measurements.

Independent measurements were performed by two observers with similar training. Interobserver reproducibility and intraobserver repeatability of measurements were analyzed by performing linear regression analyses for each of the six parameters, for both medial and lateral menisci. Intraclass correlation coefficient (ICC) and root mean square difference (RMSD) values were also calculated to assess the reproducibility and repeatability of these measurements. Linear

regressions were performed to identify significant relationships between measurements, using Bonferroni correction ($p<0.05$). The standard error of the estimate (SEE) was used to quantify uncertainty in the meniscal relationship predictions.

RESULTS

ICC and RMSD values for reproducibility and repeatability indicated strong agreement for interobserver measurements (Table 1). Based on a grading system proposed by Koo and Li [11], 8 measurements had excellent reproducibility (ICC> 0.9), while 2 were in the good range (0.9>ICC>0.75) and 2 were in the moderate range (0.75>ICC>0.5). Results for repeatability were similar.

Table 1: Interobserver reproducibility of meniscal geometry

	Medial		Lateral	
Meniscal Geometry	**ICC**	**RMSD (mm)**	**ICC**	**RMSD (mm)**
Total Length	0.940	1.133	0.971	0.533
Anterior Length	0.774	0.747	0.909	0.578
Anterior Radial Width	0.636	0.923	0.908	0.734
Midbody Width	0.918	0.899	0.903	0.755
Posterior Radial Width	0.843	1.295	0.925	0.438
Posterior Length	0.920	0.969	0.743	0.844

Table 2: Meniscal geometries (mean ± standard deviation)

Meniscal Geometry	**Medial (mm)**	**Lateral (mm)**
Total Length	41.88 ± 3.19	33.22 ± 2.59
Anterior Length	8.64 ± 1.24	10.45 ± 1.35
Anterior Radial Width	7.14 ± 1.25	9.26 ± 1.63
Midbody Width	7.84 ± 2.09	8.36 ± 1.64
Posterior Radial Width	12.12 ± 2.39	9.12 ± 1.05
Posterior Length	15.74 ± 2.43	9.05 ± 1.16

We found only the medial total length to be significantly correlated to TPW ($p<0.05$), indicated by the bolded Pearson correlation coefficient (Table 3).

Table 3: Relationships between meniscal geometries and tibial plateau width

	Medial		Lateral	
Meniscal Geometry	**r**	**SEE (mm)**	**r**	**SEE (mm)**
Total Length	**0.674**	2.424	0.618	2.096
Anterior Length	0.090	1.269	0.413	1.260
Anterior Radial Width	0.473	1.155	0.390	1.540
Midbody Width	0.282	2.058	0.446	1.505
Posterior Radial Width	0.375	2.275	0.417	0.982
Posterior Length	0.558	2.073	0.416	1.083

Intrameniscal relationships were also investigated for the medial and lateral menisci relative to the medial and lateral midbody widths, respectively, indicating significant relationships ($p<0.05$) for 3 medial and 2 lateral meniscus geometries (Table 4).

DISCUSSION

Based on an approximate element length of 1.2 to 1.6 mm in our FE models, our SEE values for reproducibility and repeatability suggest our measurements are comparable to the size of one element on the tibial plateau (Table 1). Our average medial and lateral total length measurements were 41.88 and 33.22 mm, respectively, consistent with the average lengths reported by Elsner [2] and Stone [12], and about 3 mm less than the averages reported by Haen [13]. Similarly, our midbody width and total length measurements were 2 to 3 mm lower than those reported by McDermott, who used digital calipers to quantify meniscal geometries [6].

Table 4: Relationships between medial and lateral midbody width and other meniscal geometries

	Medial		Lateral	
Meniscal Geometry	**r**	**SEE (mm)**	**r**	**SEE (mm)**
Total Length	0.270	3.157	0.026	2.664
Anterior Length	0.479	1.119	0.520	1.182
Anterior Radial Width	**0.710**	0.904	**0.759**	1.088
Posterior Radial Width	**0.898**	1.082	**0.722**	0.748
Posterior Length	**0.746**	1.662	0.441	1.069

While total meniscus lengths were found to be significantly correlated to TPW, other dimensions did not exhibit these relationships (Table 3). In contrast, half the measured geometries were shown to be significantly related to the midbody widths (Table 4). Although some relationships were found to be statistically significant, the Pearson correlation coefficient values suggest some relationships may not indicate clinically meaningful findings. Our results show midbody width measurements could potentially serve as predictors to estimate other meniscus measurements and may be more suitable than average lengths to predict sizing, however, the weak meniscus-to-TPW relationships indicate that subject-specific FE modeling may be necessary. Only 20 knees were measured in this preliminary study, however, our data set of 100 knees may offer the opportunity to increase the confidence of our meniscus geometries and relationships. Future efforts may include considerations of covariates such as height and sex. A potential limitation of our work is that the 45-degree rotations for the radial measurements were performed about the IS axis predefined by 3D Slicer, rather than about an established and consistent coordinate system.

Our study demonstrated our ability to reproducibly measure key meniscal dimensions. Considerable variations were found between subjects with limited potential for prediction of meniscal geometries from bone measurements or midbody widths. Since posterior horn tears are most common [14], it may be helpful to be able to use intact midbody width geometries as predictors to estimate posterior horn geometries and therefore approximate the meniscal footprint.

CARBON NANO-ONION-MEDIATED DUAL TARGETING OF P-SELECTIN AND P-GLYCOPROTEIN TO OVERCOME CANCER DRUG RESISTANCE

Y. Liang (1), H. Wang (1), X. He (1)

INTRODUCTION

The drug efflux pump is a major mechanism of cancer drug resistance that results in cancer recurrence. An important element of drug efflux pumps is the transmembrane P-glycoprotein (P-gp), which is an ATP-binding cassette (ABC) transport protein that is commonly located in the plasma membrane of multidrug-resistant cancer cells.[1] Inhibiting the function of P-gp could serve as an effective approach to hindering MDR within cancer cells. However, the P-gp multidrug transporter protein also plays a crucial physiological role in protecting tissues from poisonous xenobiotics and endogenous metabolites and is widely distributed throughout the body.[2] As cellular processes within the body are also dependent on the protection of P-gp, non-targeted systemic administration of P-gp raises concerns of significant systemic toxicity.[3]

To address the challenges associated with non-targeted administration of P-gp inhibitor, this study reports on a nanovesicle-mediated delivery system targeting tumor vasculature to co-deliver P-gp inhibitor and chemotherapeutic molecules. The designed fucoidan-decorated silica-carbon nano-onion (FSCNO) hybrid nanoparticle specifically targets and binds to P-selectin that is overexpressed in tumor vasculature.[4] Furthermore, based on the properties of this designed platform, the release of P-gp inhibitor and chemotherapeutic drugs can be triggered and precisely controlled with low-power near-infrared (NIR, 800 nm) laser irradiation at tumor sites to overcome the multidrug resistant capability of tumor cells, with no evident impact on the function of P-gp in non-cancerous tissues.

METHODS

For the preparation of fucoidan-decorated silica-carbon nano-onion (FSCNO) hybrid nanoparticles, carbon nano-onions (CNOs) were utilized and treated with tetraethyl orthosilicate (TEOS) to form silica-CNO (SCNO) nanoparticles that improve solubility in organic solvents and increase drug-loading capacity. To attach the fucoidan for targeting tumor vasculature, SCNO was further then reacted with (3-Aminopropyl) trimethoxysilane (APTMS) to produce ASCNO intermediates, which were coated with fucoidan through electrostatic interaction to form the resulting FSCNO nanoparticles. Transmission electron microscopy (TEM) images of the CNOs were also recorded.

To confirm the tumor targeting and antitumor capacity of the FSCNO nanoparticles, they are encapsulated with the chemotherapy drug doxorubicin chloride (DOX or D) and the P-gp inhibitor HM30181A (HM or H) to form the FSCNO-DH nanoparticles. Furthermore, two drug-resistant (NCI/ADR-RES and A2780ADR) and one nondrug resistant (OVCAR-8) tumor models were used for growing tumor at the dorsal side of the upper hindlimb of 6-week female NU/NU nude mice. The NCI/ADR-RES, A2780ADR, and OVCAR-8 cells were incubated in medium containing various drug formulations, irradiated with laser for 1 min at 0.2 W cm^{-2}, fixed with 4% PFA, washed and analyzed using flow cytometry.

RESULTS

CNOs were treated with tetraethyl orthosilicate (TEOS) to form silica-CNO (SCNO) nanoparticles (**Figure 1a**). In order to decorate them with fucoidan for targeting tumor vasculature, the SCNO nanoparticles were further reacted with (3-Aminopropyl) trimethoxysilane (APTMS) to produce the ASCNO intermediates. Fucoidan was then coated on the surface of the ASCNO intermediates through its electrostatic interaction with APTMS to form the resultant FSCNO nanoparticles. Transmission electron microscopy (TEM) images of CNOs are given in **Figure 1b**. After coating the SCNO nanoparticles with fucoidan, the FSCNO

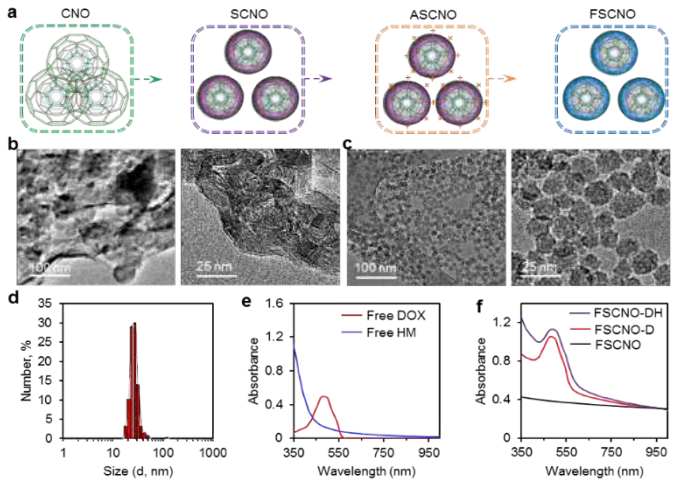

Figure 1: A schematic illustration and characterizations of the FSCNO-DH nanoparticles.

nanoparticles of ~20nm with clear nanostructure and little aggregation can be obtained (**Figure 1c-d**). Both the hydrophobic HM and hydrophilic doxorubicin hydrochloride were encapsulated in the FSCNO nanoparticles to form FSCNO-DH nanoparticles. The successful encapsulation of HM and DOX was further confirmed with UV-Vis absorbance and fluorescence spectrometry (**Figure 1e-f**).

Absorbance measurements of the FSCNO nanoparticles in the NIR region indicated that they were is 2–3 times higher than that of the FSCNT and FSGO nanoparticles when the concentration is more than 0.25 mg ml−1, implicating the superior photothermal property of the FSCNO nanoparticles (**Figure 2**).

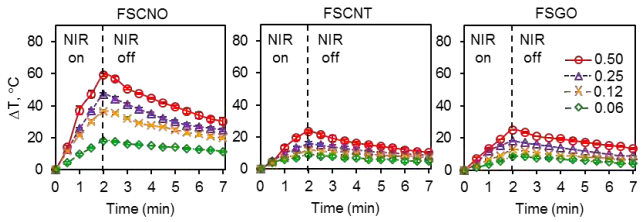

Figure 2: Photothermal effect of FSCNO nanoparticles.

Two types of multidrug-resistant human cancer (NCI/ADR-RES and A2780ADR) cells were used in this study together with a nondrug resistant type of human cancer (OVCAR-8) cells for control. Compared with OVCAR-8 cells, free DOX is inefficient in killing NCI/ADR-RES and A2780ADR cells due to the drug-resistant nature of the cells. However, the efficacy of DOX in killing NCI/ADR-RES and A2780ADR cells is significantly enhanced when administered with 1–10 μg ml^{-1} HM (dissolved with DMSO at 1 mg ml^{-1} in stock. The 1W cm^{-2} IR laser combined with FSCNO-D nanoparticles was able to effectively kill all the three different types of cancer cells due to the superior photothermal effect of the FSCNO nanoparticles (**Figure 3**).

The expression of P-selectin is evident in activated HUVECs (aHUVECs, **Figure 3a**) while it is negligible in the HUVECs without activation. FSCNO-DH nanoparticles could efficiently bind with P-selectin on the aHUVECs while the binding between SCNODH nanoparticles and aHUVECs was not observable, showing the crucial role of the fucoidan on the surface of the FSCNO-DH nanoparticles in targeting aHUVECs (**Figure 3b**).

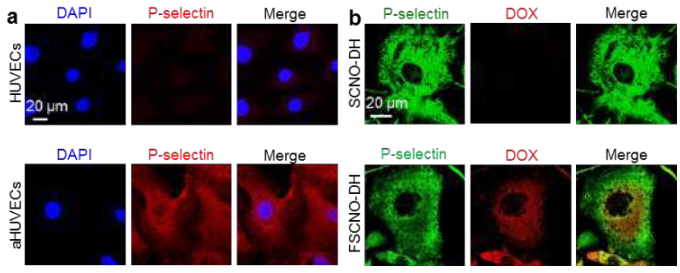

Figure 3: Tumor vasculature targeting.

In vivo whole animal imaging indicates that the FSCNO nanoparticles can efficiently target the tumor as shown in **Figure 4a**. The treatment of FSCNO-DH nanoparticles combined with NIR laser irradiation (FSCNO-DH+L) demonstrated the best antitumor efficacy, as indicated by tumor weights (**Figure 4b**). This result further confirms that controlled release of P-gp inhibitor is crucial to overcoming the multidrug-resistant capability of NCI/ADR-RES cells and for killing them in vivo. Similarly, the FSCNO-DH+L treatment is more effective in killing tumors with EC, confirming the importance of tumor vasculature targeting for enhancing the efficacy of nanoparticle-mediated cancer therapy.

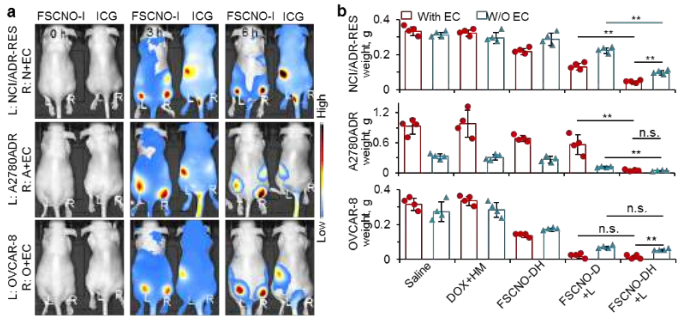

Figure 4: In vivo tumor targeting and antitumor capacity.

DISCUSSION

In this study, the sequence of encapsulating DOX and HM was further developed and investigated. The encapsulation efficiency of HM is only ~24% if mixing HM with the FSCNO nanoparticles first, which is much lower than that (~69%) of the optimized method of mixing DOX with the nanoparticle first. One possible mechanism for this is the electrostatic interaction between the negatively charged silica and the local positive charges within the HM molecule.[5]

When controlling the drug release, HM and DOX are triggered to release simultaneously from the FSCNO nanoparticles during the NIR irradiation. As a result, although some DOX may be pumped out of cells before the function of all the P-gp is inhibited, it could re-enter the cells after the HM binds with all the P-gp quickly. Data from the multidrug resistance cells (NCI/ADR-RES and A2780ADR) either pre-treated with HM (HM-DOX) or without any pre-treatment confirmed that releasing HM and DOX simultaneously from the FSCNO nanoparticles is of significance for overcoming cancer drug resistance.

In summary, this study aimed to synthesize a fucoidan-decorated silica and CNO hybrid (FSCNO) nanoparticle for targeting tumor vasculature and P-gp overexpressed on drug-resistant cancer cells. Through NIR laser irradiation, controlled release of P-gp inhibitors and chemotherapeutic drugs can be achieved. Furthermore, the FSCNO-DH nanoparticles can precisely compromise the function of P-gp pumps in multi-drug resistant cancer cells. This study holds promise in laying the foundation for further developing nanotechnology-based strategies in overcoming multidrug-resistance in cancer.

INTRODUCTION

CT-based patient-specific finite element analysis (FEA) is a proposed clinical method to identify osteoporotic patients who could benefit from pharmacological intervention[1]. The largest barrier to implementing this method in the clinic is segmentation. Segmentation is used to isolate phantom plugs in CT scans and create digital geometries. Manual segmentation (MS), the current clinical standard, is time-consuming and only repeatable for skilled operators carefully following a detailed protocol. Thus, there exists a need to improve efficiency and repeatability of segmentation. Alternatively, automated segmentation can be carried out using machine learning (ML) or deep learning (DL) techniques. The aim of this study was to compare the results of ML, DL, and MS in terms contour mesh geometry and density calibration slope.

METHODS

A $Ca_5(PO_4)_5$ calibration phantom (CIRS, Inc, Norfolk, VA, USA) including custom plug densities [mg/cc] of 100 (part: RDH357Y-23) and 400 (part: RDH362Y-24) and stock plugs of 1000 (part: 06217) and 1750 (part: 06221) were CT scanned in air. Data were captured on GE CT scanner models Discovery CT 750HD and Optima 660 (GE Healthcare, Waukesha, WI, USA) with a standard reconstruction kernel. Scan parameters were consistent with established clinical protocols[2] (slice spacing [mm]: 0.325, 0.625; slice thickness [mm]: 0.625, 1.25; voltage [kVp]: 120; current [mA]:105, 120). Phantom plugs were chosen to be the subjects of this study due to their simple geometry. An overview of the study elements and segmentation methods are detailed in Figure 1.

In Dragonfly v. 2020.1 (Object Research Systems Inc., Montreal CAN), multiple ML and DL algorithms were trained to segment plugs from a training dataset of 15 to 20 segmented frames.

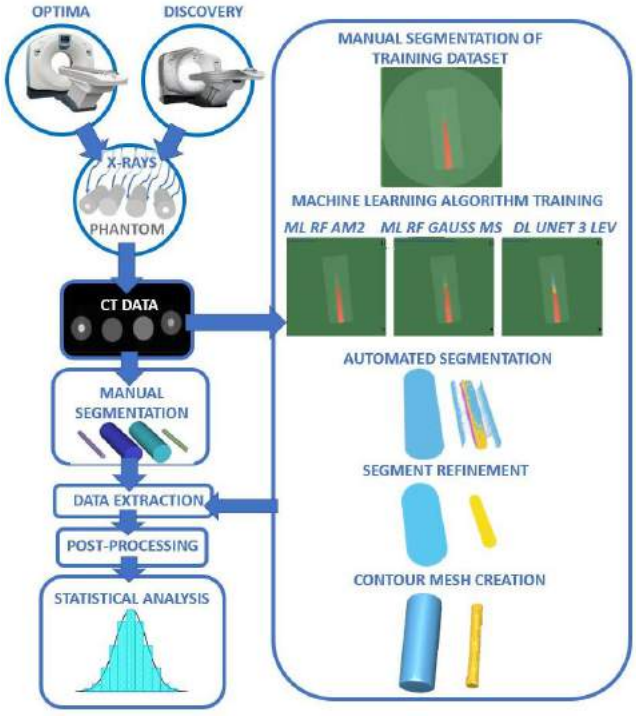

Figure 1: An overview schematic of study elements and parallel segmentation methods. Manual segmentation (MS) (Left), machine learning (ML) and deep learning (DL) segmentation (Right) are detailed.

Algorithm training and related segmentations were performed on a laptop equipped with an NVIDIA GeForce MX 230 GPU. Training was stopped when there were no changes to the loss function monitoring the performance for five iterations. Model performance was assessed based on the percentage of correctly segmented pixels in each training frame and visually by the quality of segments created by each ML segmentation model for an entire CT image stack. The most accurate ML algorithm, *Random Forest Activation Map 2 (ML: RAM)*, was applied to the CT data, to automatically segment a CT image stack of four plugs. Individual plug segments were extracted and artifacts outside of the plug were removed manually. A contour surface mesh of each plug was created from the refined meshes.

3-D geometry and volumetric statistics including standard deviation of CT Number and mean CT Number, were extracted from contour surface meshes for statistical analysis. For comparison purposes, the same types of data were extracted from MS in both Mimics v. 23 (Materialise, Leuven, BE) and Slicer v. 4.10.2 (Slicer, Boston, MA, USA). Geometrical differences in contour surface meshes were compared for results produced by ML, DL and MS using quantiative difference maps in Dragonfly. Density calibration slopes which linearly relate extracted mean CT Numbers [HU] to plug densities [mg/cc] were tested for significant differences between ML, DL, and MS using Mann-Whitney (α= 0.01).

RESULTS

ML segmentation outperformed DL and produced similar results to MS in commercial software. Both ML algorithms had higher pixel accuracy than DL with all algorithms having pixel accuracies greater than 95% (Figure 2). Despite having high pixel accuracies, ML: RGM and DL: U3 failed to correctly segment entire CT image stacks (Figure 3). The ML: RAM and MS in Mimics methods did not produce significantly different slopes (p = 0.097). The ML: RAM and MS in Slicer methods did produce significantly different slopes (p = 0.001).

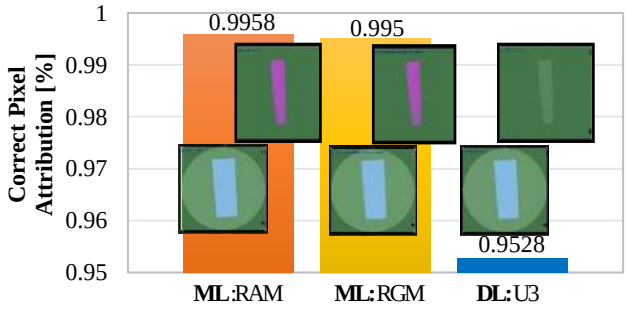

Figure 2: Accuracy measured as correct pixels are plotted for each algorithm. Overlaid are segments of two different plugs produced by machine learning (ML) and deep learning (DL); Random Forest Activation Map 2 (RAM), Random Forest Gaussian-MS (RGM), and 3-level U-Net (U3). These plugs show the varying accuracy of segmentation for each algorithm.

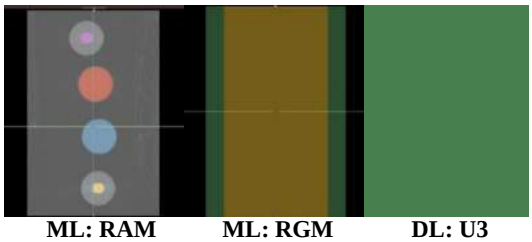

Figure 3: Only ML: RAM accurately performed segmentation on the phantom plugs. A trained operator can discern that ML: RGM and DL: U3 failed to correctly segment the plugs despite high pixel accuracy.

Surface contour meshes created by ML and by MS in Slicer were highly similar for low density plugs (<5% different) as shown in Table 1. Additionally, contour meshes created by ML and by MS in Mimics were very similar (<5% different) for plugs with densities 400 mg/cc or greater. When ML was compared to MS in Slicer and MS in Mimics, standard deviations of geometrical difference were smaller for high density plugs.

Table 1: Plug densities [mg/cc], mean difference, the distance between points [mm], and standard deviation are tabulated. Percent difference is difference normalized by plug diameter.

	Mimics - Dragonfly				Slicer - Dragonfly			
Plug Dens. [mg/cc]	100	400	1000	1750	100	400	1000	1750
Mesh Mean Dif. [mm] *(%)*	7.6 *(19)*	-1.7 *(-4.2)*	-0.3 *(-2.6)*	-0.2 *(-1.5)*	0.5 *(1.2)*	-1.69 *(-4.2)*	-1.7 *(-17)*	-1.8 *(-18)*
Dif. St. Dev. [mm]	10	12	6.8	3.1	13	0.7	0.6	0.8

It took 40 minutes to run ML: RAM for 5mm slice thickness, two hours for 1.25 mm slice thickness, and over four hours at 0.625 mm slice thickness. After which, ten minutes of operator input was necessary to finalize results. Comparatively, trained operators using established protocols for MS in Mimics and MS in Slicer took ten and twelve minutes respectively to complete segmentation.

DISCUSSION

The aim of this study was to compare the results of ML, DL, and MS in terms contour mesh geometry and density calibration slope. ML: RAM performs accurate segmentation with little user input, only requiring ten minutes of trained operator time compared to twelve minutes for an experienced operator to perform MS. However, ML: RAM required up to four hour of run time to segment one image stack of plugs. Higher power workstations intended for research or clinical use will likely perform segmentation tasks more quickly. Additionally, the current time investment for training and running is expected to reduce as technology develops. When compared to ML: RAM, DL: U3 models produced less accurate results, as noted by a trained operator. The poor performance of DL in this setting may be the result of using a small training dataset of 20 or less segmented images. DL is expected to perform better with more training data, which should be tested in future work. Future works should continue to examine the potential error introduced by ML segmentation. A potential follow-up study would be to calculate and compare the impact of ML: RAM and MS in a clinical context such as CT-based patient-specific finite element analysis.

ACKNOWLEDGEMENTS

The authors acknowledge Emily Cameron for prior segmentation used for comparison. INTRODUCTION

Engineered tissue vascular grafts (ETVGs) are composed of cells seeded on a biodegradable scaffold. These scaffold-cell constructs are created with the intention of producing a viable implant with mechanical properties similar to the damaged native tissue the graft is replacing. The scaffold is meant to provide a proper mechanical environment and structural support to the maturing tissue as the extracellular matrix develops.[1] If the scaffold degrades too rapidly, the forming engineered tissue will lose its integrity; if the scaffold degrades slowly, it may provide adverse developmental cues to the tissue and promote fibrosis.

In the body, the degradation of polycaprolactone (PCL) can take from 12 to 18 months to occur depending on scaffold properties and its design. Accelerated-degradation techniques are therefore necessary to make the study of electrospun PCL scaffolds more reasonable by decreasing its degradation time. The *in vitro* and *in vivo* degradation of PCL occurs mainly through hydrolysis of the ester bonds, which can be catalyzed by a pH increase in an alkaline NaOH liquid media.[2]

However, studies have shown that mechanical forces, in particular cyclic loads, increases the degradation rate of polymers by introducing additional mechanisms of polymer degradation. At the same time, it is generally desired to include dynamic training during incubation of engineered tissues because those are known to enhance cell proliferation, the rate of synthesis of *de novo* engineered tissue, and improve its resulting stiffness and microstructure.[3]

Therefore, it is key to study the effects of mechanical loading in the degradation profiles of tissue engineering scaffolds. In order to increase the throughput of these experimental investigations, those should be performed under accelerated-degradation conditions. Previous works have studied the degradation of polymers under static and constant loading,[4] while degradation under cyclical loading on degradation dynamics is mainly conducted for electromechanical applications.[5] Thus, there is a gap of knowledge on the characterization of polymer degradation of under physiological cyclic loading for tissue engineering applications.

The goal of this study is to characterize the accelerated-degradation profiles for PCL scaffolds under both static and dynamic loading conditions. This accelerated degradation profile can then be correlated to the behavior of a scaffold degrading in physiological conditions. This goal is achieved by first developing an accelerated-degradation chamber with both static and dynamic conditions. Ultimately, this information can be used to improve the design of biodegradable scaffolds by predicting scaffold behavior.

METHODS

Scaffold Manufacture. The degradation experiments conducted in this study utilized electrospun polycaprolactone (PCL 80,000 g/mol) scaffolds. Our manufacturing process results in tubular scaffolds with 3 mm diameter, and 160 ± 30 μm thickness. These tubular scaffolds were cut and flattened out to produce testing samples with 3 cm in length. Each sample was weighed on a high precision scale and the thickness was measured using micrometers.

Mechanical Testing. Scaffold membrane stiffness was tested using a custom-designed uniaxial-extension stretcher. The samples underwent 10 preconditioning cycles followed by one cycle mechanical test carried out up to 10% strain over the course of 720s. The deformation of the sample was measured by tracking four dots placed at the center of the scaffold. Stress vs. strain graph are generated, and the membrane stiffness is calculated as the slope of the linear region.

Microstructural Analysis. Scanning Electron Microscopy (SEM) imaging was used to characterize the scaffold microstructure: fiber diameter, fiber orientation distribution, and % porosity. SEM is taken at 3,000x magnification, and analyzed using ImageJ and DiameterJ.

Degradation Protocol. Each degradation chamber is able to hold 6 rectangular samples clamped at both ends. Accelerated-degradation conditions were produced by submerging the scaffolds in NaOH solutions at varying concentrations and pH. Preliminary results have shown that pH of 12.45 produced weight loss of 16.4% and membrane stiffness reduction of 57.6% under static conditions after 42 days, which was deemed appropriate for the accelerated-degradation on this study.

Degradation under dynamic conditions is produced by stretching the samples to 1, 2 and 5% uniaxial strain in linear ramp cycles with period of 2 seconds. Static vs. dynamic degradation is compared after several timepoints up to two weeks (3, 7 and 14 days). After undergoing static or dynamic degradation, samples are collected and dried in a vacuum oven at 40 °C and 2.06 bar vacuum for 24 hours. The samples are again weighed, their thickness measured, and then undergo destructive mechanical testing or microstructural analysis.

Statistical Analysis. We used the software JMP, Version 15.1.0 (AS Institute Inc., Cary, NC, 1989-2019.) to carry a Dunnett's test with a significance level of 5% to compare the weight, thickness, and membrane stiffness of the degraded samples (static and dynamic) to the untreated virgin scaffolds as the standard controls

RESULTS

Degradation Chamber Design and Construction. The design of pH resistant degradation chambers that are able to impose dynamic strains is challenging. The design of both the static and dynamic degradation chamber were built to withstand the highly alkaline liquid media solution required to produce adequately accelerated degradation while holding 6 samples at a time and having only the imposition of dynamic training as the only difference. The container box was machined from a PP slab to assure hermiticity. The brackets and sample holders were 3D printed on ABS. One linear actuator is driven with an Arduino board with custom-designed user interface to control the experiment during its course.

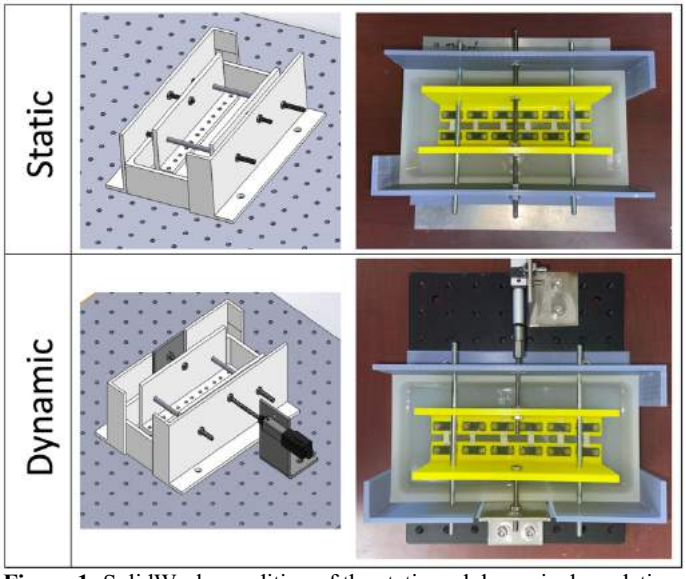

Figure 1: SolidWorks rendition of the static and dynamic degradation chambers (left) and their built instances (right).

Static vs. Dynamic Degradation under Accelerated Conditions. There appeared to be no significant change in the weight or thicknesses of the scaffolds over the course of two days of degradation. Results shown dynamic loading produced a significant decrease in scaffold membrane stiffness when compared with virgin scaffolds ($p^* = 0.041$). The membrane stiffness of the dynamic degradation samples was on average 52% lower than the stiffness of untreated samples, whereas the static group showed only difference of 31% (Figure 2). This suggest that the cyclical loads accelerate the decline of mechanical properties, nevertheless more replications are needed to gain statistical significance.

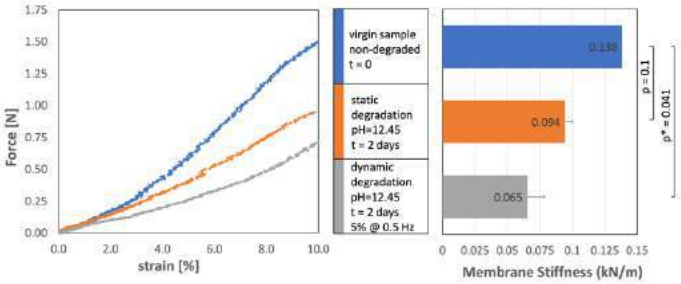

Figure 2: (left) representative load vs. strain curves for virgin and degraded scaffolds; (right) statistical comparison of membrane stiffness (force per unit length)

DISCUSSION

At physiological pH and under static conditions, it takes several months to years for PCL scaffolds to demonstrate significant mass loss, degradation, and loss of mechanical integrity. These are typically the conditions tested at the benchtop to design tissue engineering scaffolds; however, very often these are intended to function *in vivo* in a complex dynamic mechanical environment, and possibly, will be subjected beforehand to mechanically-stimulated in vitro incubation. The introduction of chemically-accelerated degradation and cyclic dynamic loading induced substantial differences in scaffold degradation profiles. The employment of accelerated-degradation conditions allowed us to observe significant differences due to the mechanical environment in a matter of days. In order to obtain insight and calibrate predictive models of mechanical properties depreciation and mass loss, the accelerated-degradation time-scale is matched with a long-term experiment (up to 2 years) we are conducting at physiological pH under static conditions.

Future work includes more thorough investigations on the influence of mechanically-induced degradation on the evolving microstructure of the PCL scaffolds and a direct quantification of the degradation scale with molecular weight determination with gel permeation chromatography. In conclusion, the employment of accelerated-degradation techniques to investigate the effects of mechanically-induced degradation of tissue engineering scaffolds allows for a decreased turnaround time in R&D applications for tissue engineering, and further insight into the degradation profile of scaffolds allows for improved tissue engineering methods.

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a complex disease defined by a mean pulmonary arterial pressure > 20 mmHg [1] which causes anatomical and physiological alterations in the pulmonary vasculature, leading to drastic changes in hemodynamics and wall mechanics. Because of the intricate nature of PAH, there is a pressing need to identify metrics to aid in early non-invasive PAH diagnosis.

Due to the current lack of prospective pediatric PAH trials, clinical diagnostic metrics are often extrapolated from adult patients [2]. Extrapolating adult data to the pediatric population can be problematic as younger subjects have significant differences in hemodynamics [3], and lower survival rates [4]. In addition, age-specific symptoms like impaired lung development and comorbidities such as congenital heart defects are found at a higher rate in pediatric populations [5]. Due to the aforementioned discrepancies in PAH pathophysiology between adults and children, there is a critical need for clinical trials focused on pediatric PAH patients to derive diagnostic metrics.

Computational models informed by patient-specific data can be used to complement clinical data and establish additional metrics of the overall pathology and progression of PAH. Computational models can provide useful quantities of interest (i.e. pressure, flow, wall shear stress, cardiac work, stiffness, contractility, etc.) at higher temporal and spatial resolutions than current diagnostic tools.

In this work, we combine prospective clinical data on anatomy, flow, and pressure with computational tools to provide a description of arterial hemodynamics in pediatric PAH. Inconsistencies were present in the acquired data due to temporal gaps between data acquisition studies, sedation, and tolerances in diagnostic tools. Mitigation strategies were developed and implemented to correct the prospective clinical data, ensuring physiologically consistent computational results. The purpose of this work is to develop a strategy to calibrate the boundary conditions and material parameters of the computational models for each PAH patient, using open-source software tools, and the physiologically consistent patient data.

METHODS

Clinical data were prospectively acquired in seven pediatric PAH patients as part of an ongoing clinical trial [6] conducted at C.S. Mott Children's Hospital at the University of Michigan. This study was approved by the University of Michigan Institutional Review Board (HUM 00117706), and informed consent was obtained from the subjects or parents.

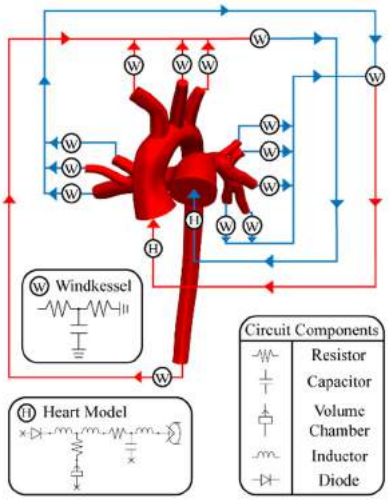

Figure 1. Modeling framework of arterial hemodynamics. (W) indicates a Windkessel model and (H) indicates a heart model.

Clinical Data. Three-dimensional (3D) vascular anatomy was acquired using a 3D steady-state free precession sequence with a magnetic resonance imaging (MRI) scanner. Phase-contrast MRI (PC-MRI) was performed to obtain dynamic data of luminal area and blood flow velocity at the ascending (AAo) and descending thoracic aorta (DTA), and the main (MPA), left (LPA), and right (RPA) pulmonary arteries. Invasive right heart catherization was performed to obtain pressure waveforms.

3D Arterial Modeling. Patient-specific 3D fluid-structure-interaction (FSI) models [7] were built using the blood flow modeling software CRIMSON [8]. Each model required specification of patient-specific arterial wall mechanical properties and inflow and outflow boundary conditions. Spatially-varying arterial wall stiffness and thickness were calculated using dynamic luminal area and pressure waveforms [9,10]. Lumped-parameter Windkessel models were coupled to each outlet of the 3D model [11] to represent the resistance and compliance of the distal vasculature. The heart was represented by a lumped-parameter network of circuits that was coupled to the Windkessel models to form a closed-loop network, resembling the cardiopulmonary circulation (**Figure 1**).

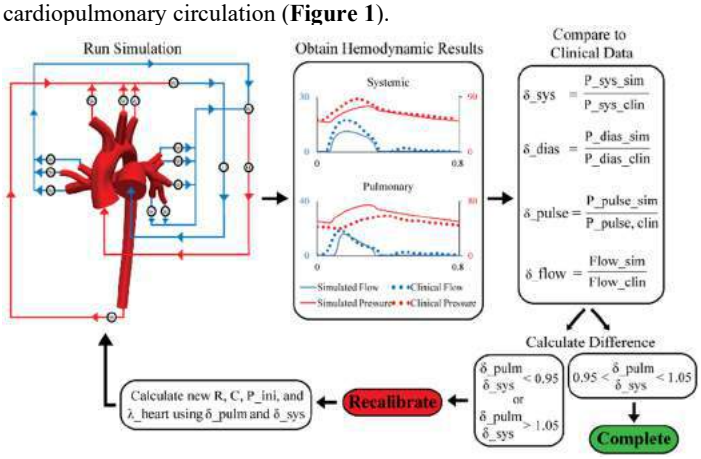

Figure 2. Workflow for calibration. Resistance (R), capacitance (C), and initial pressures (P_ini) of the circulatory Windkessel models, and heart model parameters (λ_heart), were calibrated until simulation results matched clinical data within 5%.

Windkessel parameters (resistance, capacitance, initial pressure) and heart model parameters (elastance waveform) were iteratively calibrated to match clinical data (**Figure 2**) within 5%. Reference metrics such as systolic, diastolic, and pulse pressure, and mean flow were used to compare simulated results to clinical data (**Figure 3**).

RESULTS

Following model calibration, the contributions from the 3D image-based models of the large pulmonary arteries and lumped-parameter models of the pulmonary microcirculation to the total resistance (driving mean pressure) and total compliance (driving pulse pressure) were derived (**Figure 4**). The average contributions of the large pulmonary arteries to the total resistance and compliance of the pulmonary circulation were 4% and 58%, respectively.

DISCUSSION

We established a modeling workflow to combine advanced computational analyses with prospectively acquired clinical data, including strategies to mitigate inconsistences in clinical data to ensure consistent computational results. Our results show an interesting finding: the pulmonary microcirculation contributes most to the total resistance, which mainly affects mean pressure. The large pulmonary arteries contribute most of the total compliance of the pulmonary circulation, which primarily influences pulse pressure. Assuming that, in PAH, the wall properties of the pulmonary microcirculation remodel before those of the large pulmonary arteries, our results would suggest that rises in mean pressure precede rises in pulse pressure. The combination of prospective clinical data and the proposed computational framework provides a comprehensive description of PAH pathology and can help uncover metrics to improve early PAH diagnosis.

Introduction: Previously, our lab evaluated the efficacy of ACL reconstruction surgery in preventing changes to subchondral bone architecture and composition following traumatic knee injury. We found the surgery to be helpful in preventing changes to the subchondral bone, but not completely effective in eliminating all degradation of the bone. This is consistent with previous work that suggests reconstruction surgery does not decrease the risk of developing post traumatic osteoarthritis (PTOA) [1]. We are now evaluating the use of an FDA approved nonionic surfactant, poloxamer 188 (P188), in preventing changes to subchondral bone quality and quantity. It is hypothesized that P188 delivered to the joint at three separate time points will be the most effective in mitigating changes to subchondral bone architecture and composition following traumatic injury to the knee joint.

Methods: 90 skeletally mature Flemish Giant rabbits (6.81 ± 0.34 kg) were used for this study. With IACUC approval and under general anesthesia, the right knee and paw of each rabbit was secured into a custom fixture and a controlled impact was delivered using a servo-hydraulic actuator (Instron, Norwood, MA), until ACL failure was observed. Within 2 minutes of impact, each rabbit received an intra-articular injection of either 1.5 mL of phosphate buffered saline (PBS) or 1.5 mL of 8mg/ml P188. Animals were randomly assigned to treatment groups: no P188, P188 following impact (P188 D0), P188 following impact and 24 hours post-impact (P188 D0,1), and P188 following impact, 24 hours post-impact, and 7 days post-impact (P188 D0,1,7). Surgical reconstruction of the torn ACL was performed by a licensed veterinarian 2-3 weeks post-impact. The semitendinosus (ST) tendon was transected at the musculotendinous junction while its tibial insertion was left intact. The tendons free end was rerouted through tibial and tunnel femurs (3.2mm in diameter), which overlapped the ACL footprint. The ST tendon was tensioned and then secured into the femoral tunnel using an interference fit screw and periosteal sutures. An anterior drawer test was performed to assess postoperative joint stability prior to routine closure. The left knee of each animal served as a contralateral control. Animals were euthanized one (n=30), three (n=30), and six months (n=30) post-surgery. Following mechanical testing of the articular cartilage, tibias and femurs were fixed in 10% formalin. uCT imaging and reconstruction were performed using a Skyscan 1276 (Bruker, Billerica, MA). Similar to a previous study, regions of interest were chosen to coincide with the location of mechanical testing

of the articular cartilage on the lateral and medial hemijoints [2]. CTAn software (Bruker, Billerica, MA) was used to determine bone volume/tissue volume (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), trabecular number (Tb.N) and volumetric bone mineral density (vBMD). Cortical volumetric bone mineral density (Co.BMD), cortical thickness (Co.Th), and osteophyte volume were also determined. A fixed effect model was used to determine significant differences between treatment groups with a p-value of < .05 deemed significant.

Results: Mid-substance ACL tears were documented in all animals. ACL failure force was 868.2 ± 69.9 N. Statistically significant changes in osteophyte volume observed in both femurs and tibias. Significant changes in BMD of femurs also observed between treatment and control groups.

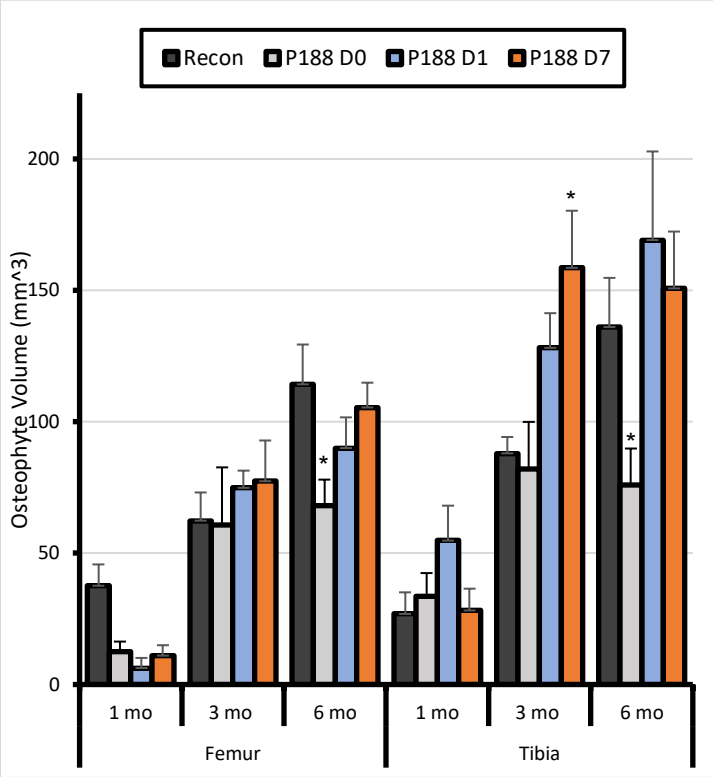

Figure 1. Osteophyte formation in tibias and femurs across all time points

Discussion: Results showed that intra-articular injections of P188 were not effective in mitigating damage to the bone. This being said, P188 delivered only at the day 0 time point showed considerably decreased osteophyte volume at almost all time points. This reduced osteophyte formation suggests less degeneration of the underlying natural bone. Multiple injections to the joint may cause increased inflammation and osteophyte formation. A limitation of this study is that the P188 was injected intra-articularly and relied on diffusion to reach the bone. Future work could investigate the effects of targeted delivery of P188 directly to the bone.

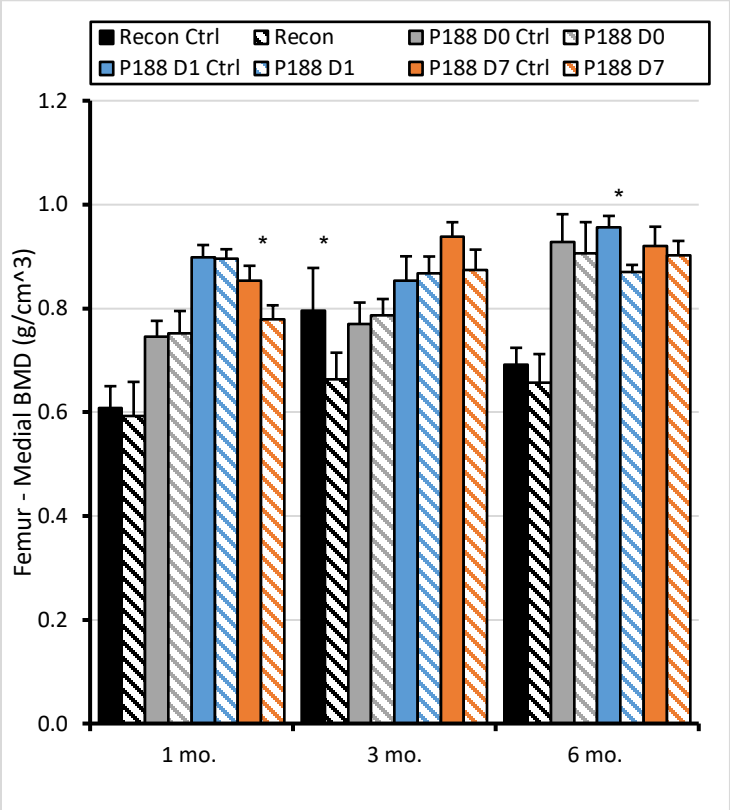

Figure 2. Comparison of volumetric bone mineral density in medial hemijoint of femurs

Conclusions: The novel closed-joint traumatic impact model was able to successfully generate ACL tears and meniscal damage comparable to what is observed in the clinical setting. Surgical repair of the damaged ACL and meniscal debridement was successfully performed as well, which replicates the current clinical gold standard. The surgical intervention proved effective in reducing changes in composition and architecture of the subchondral bone. The addition of P188 resulted in bone composition that was more comparable to the control limb than the reconstruction only animals, albeit not statistically significant. In fact, the bone quality was sometimes better than control in the P188 groups (Fig 2). Hence, P188 shows promise as a potential treatment for PTOA. Intra-articular injections of P188 may not significantly affect the bone due to the method of delivery. Targeted delivery of P188 to specific tissues may be necessary to truly access the effects of this pharmaceutical intervention.

A COMPUTATIONAL MODEL OF THE IMPACT OF CEREBRAL AMYLOID ANGIOPATHY ON VASO-RESPONSIVENESS OF CEBEBRAL ARTERIES

INTRODUCTION

Alzheimer's disease (AD) is a progressive, degenerative brain disease that results in dementia. Cerebral amyloid angiopathy (CAA) is present in over 80% of patients that have AD[1]. CAA is the result of amyloid beta, which can form plaques that surround and integrate into the small arteries. Patients that have CAA have a greater chance of intracranial hemorrhage (ICH)[2]. This elevated risk connects to AD as AD patients who have an ICH are almost twice as likely to develop dementia than AD patients who don't have an ICH[3]. While it is known that CAA can lead to the vascular dysfunction and result in an ICH, the mechanism by which CAA causes vascular dysfunction remains relatively unknown.

There are two main components of the vascular dysfunction caused by CAA: (1) loss of vaso-responsiveness and (2) loss of vaso-integrity. This study focused on understanding the mechanisms driving the loss of vaso-responsiveness in intercranial vessels due to CAA. It has been shown in animal studies that insoluble amyloid beta plaques can reduce the functional dilation of the vessel, as the plaque places a physical restriction on the dilation[4]. The plaque can exist in two forms: circumferential (surrounding the vessel) and intramural (integrating within the vessel). It has also been shown that soluble amyloid beta can lead to loss of vascular smooth muscle (vSMC) contractility[5]. The goal of this computational study was to show how circumferential plaque contributes to the overall loss in vaso-dynamics, and how the plaque formation can further exacerbate arterial loss-of-function when combined with lower vSMC contractility.

In this study, we construct a computational model of a cerebral artery with CAA to analyze the role of amyloid beta in vascular disease. The percent coverage of the circumferential plaque was varied, and the impact of both the circumferential plaque and the soluble plaque on vasodynamic dysfunction of the vessel measured. This model offers a unique perspective on the role of amyloid beta plaque on vascular mechanics.

METHODS

A finite-element model of the cerebral artery with CAA was generated using FEBio[6]. The initial model was created with 100% circumferential coverage of the amyloid beta plaque (Fig. 1A). Two tangent cylindrical constructs were generated and attached to each other, with the inner construct representing the vessel and the outer construct representing the plaque. The inner diameter of the vessel was 58.3 μm, the outer diameter of the vessel was 65.8 μm, and the outer diameter of the amyloid plaque was 67.9 μm[7]. The passive four-fiber family strain energy density model was used for the vessel with the nonfibrillar matrix defined using a Neo-Hookean model, and the fibers defined with an exponential power law:

$$W = c_1(I1 - 3) + \sum_{i=1}^{4} \frac{k_i}{2\alpha_i}(\exp(\alpha_i(I4_i - 1)^2) - 1) \qquad (1)$$

where c_1 is the Neo-Hookean modulus, $I1$ is the first strain invariant, k_i is the fiber modulus parameter for fiber family i, α_i is the fiber nonlinearity parameter for fiber family i, and $I4_i$ is the fourth strain invariant for fiber family i, dictated by the in-plane circumferential-axial fiber angle, θ and the out-of-plane radial fiber angle, ϕ. The parameters for the fibers can be seen in Table 1. The nonfibrillar component had a bulk modulus of 0.6 MPa and coefficients of 0.015 MPa. In addition, an active contraction was added to the vessel to simulate the contractility of the vessel. The material for the amyloid beta plaque was defined as a Neo-Hookean material with a bulk modulus of 0.6 MPa and coefficients of 0.25 MPa. We also modeled contractility using the prescribed active contraction model in FEBio, where we define the active contraction stress for the material.

Table 1: Parameters for the Fibers used in the Vessel Material[8]

Fiber Family #	Fiber Nonlinearity (α_i)	Fiber Modulus (k_i)	Circumferential-Axial Angle (θ)	Radial Angle (ϕ)
1	1	0.009 MPa	0°	90°
2	1	0.009 MPa	90°	90°
3	0.325	0.0018 MPa	68.6°	90°
4	0.325	0.0018 MPa	68.6°	90°

Once the FEBio model had been created for the 100% coverage scenario, the associated FEBio input file was modified to reduce the coverage to a value in the range from 0% to 100% with intervals of 10%. A set of elements from the plaque was randomly selected via a MATLAB script with the number of elements selected determined by the desired percent coverage and was used to create a new input file. A model with 50% is shown in Fig. 1B.

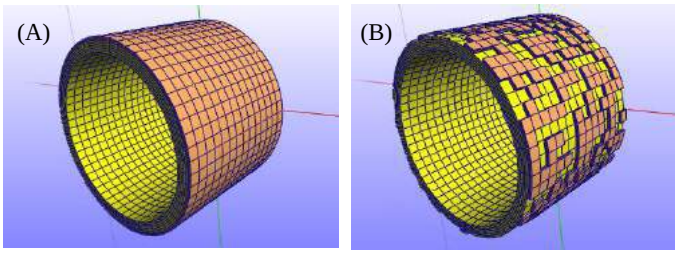

Figure 1: Computer model of vessel with (a) 100% and (b) 50% plaque coverage

For each simulation, the vessel was stretched axially to 1.17[8]. A luminal pressure load was added to the vessel and increased linearly to 80 mmHg[7]. Next, we reduced the luminal pressure to 64 mmHg, representative of mean cerebral artery pressure, and we linearly ramped the active contraction within the vessel to 0.150 MPa[5]. In this model, we use the different contractility levels to compare the insoluble plaque effects to the effects of soluble amyloid beta. The position of each of the nodes on the inside of the vessel were exported at each time step to measure the average diameter of the vessel.

RESULTS

To see how different plaque coverages affect the vessel's ability to dilate, the average inner diameter of the vessel was plotted versus the pressure load (Fig. 2A). In the healthy case (0% coverage), we see the typical lockout behavior of blood vessels. Further, as the plaque coverage is increased, we see stiffer material behavior and the material becoming more linear.

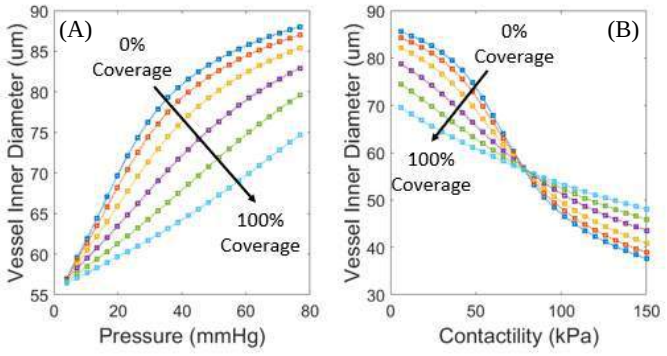

Figure 2: The average inner diameter of the vessel as the pressure load was increased (a) and the contractility was increased (b) for plaque coverages ranging from 0% to 100% with intervals of 20%

The effect of plaque coverage was also analyzed for varied contractility (Fig. 2B). We see in this figure that the shape of the contractility curve starts as a sigmoid with 0% coverage and becomes more linear as we add more stiff, non-contractile plaque. Additionally, we see an inflection point in the contractility vs diameter plot that seems to appear at the same contractility level for all plaque coverage scenarios. We also note that this inflection point occurs at the vessel undeformed diameter. Thus, the vessel contractility at this point exactly counters the internal pressure meaning the vessel stays in its undeformed configuration.

To see how the change in vascular stiffness changed as the plaque coverage was increased, the normalized vasodilation, or increase of the diameter of the vessel from its original diameter, was calculated for each of the amyloid plaque coverages with the pressure load at 80 mmHg and the contractility at 0 kPa. Fig. 3 shows a nonlinear decrease in vasodilation with increasing plaque coverage.

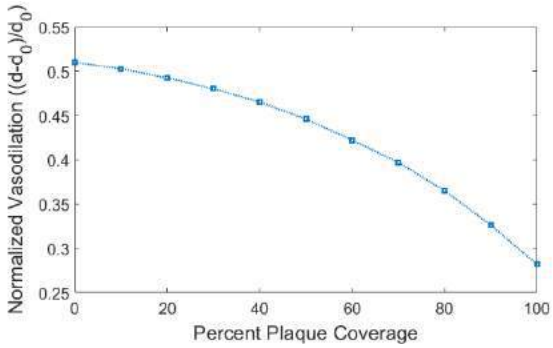

Figure 3: The normalized vasodilation when the pressure load was at maximum for the plaque coverages ranging from 0 to 100%

DISCUSSION

The impact of the circumferential plaque on the vasodynamic function of the vessel is clearly demonstrated in Figs. 2-3. The circumferential plaque makes the vessel stiffer, restricting its ability to dilate (Fig. 2A) and contract (Fig. 2B). The magnitude of loss of passive vasodynamic function specifically due to the circumferential plaque is displayed in Fig. 3, where 100% coverage reduced the normalized vasodilation of the vessel from 0.51 to 0.28 and the general trend showed nonlinear decrease in vasodilation with plaque coverage. By varying the contractility, we show that the soluble amyloid beta limits the minimum diameter that the vessel can reach, as soluble amyloid beta reduces the contractility of the smooth muscle cells.

This study is among the first computational models demonstrating both the structural and biological impacts of amyloid beta on the function of cerebral arteries. The model created presents an opportunity to continue studying various arrangements of amyloid beta plaques and their impact on the loss of vasodynamic function in vessels with CAA. Further, we can use this model as a springboard for understanding how this type of loss-of-function might impact the perfusion of the brain, and lead to long-term damage.

INTRODUCTION

Atrial fibrillation (AF) is the most common cardiac rhythm disorder worldwide and a major public health burden due to its impact on the risk of stroke, dementia, and heart failure [1]. It is estimated that the number of people diagnosed with AF will increase about three-fold by 2050 due to population aging and the rising prevalence of risk factors [2]. The Hemodynamic impairment related to AF have resulted in significant morbidity, mortality, and cost [3]. 4D Flow MRI allows the non-invasive quantification of time-resolved velocity fields in the heart and large vessels, and as a result, has increasingly been used to study cardiac flow dynamics and function [4].

Previous studies have used 4D-Flow to assess atrial hemodynamics in AF patients and compare that to healthy subjects finding a correlation between AF burdens and differences in blood flow dynamics [5-6]. However, the literature has neglected the use of 4D-Flow MRI to obtain wall shear stress (WSS) in patients with AF. Therefore, the purpose of this study is to investigate the correlation between blood flow dynamics and atrial WSS in patients with AF using 4D Flow MRI.

METHODS

In this IRB-approved and HIPAA-compliant study, 10 subjects (5 AF and 5 Healthy) were recruited. An MRI was performed on a 3.0T imaging system using bSSFP sequence and the 4D flow MRI sequence PC-VIPR [7]. The Left atria (LA) and pulmonary veins (Left Superior: LSPV, Left Inferior: LIPV, Right Superior: RSPV, and Right Inferior: RIPV) were segmented from time-averaged phase-contrast (PC) MR angiogram, using the software Mimics (Materialise, Leuven, Belgium). These segmentations provided a virtual 3D model of the LA and pulmonary veins.

Using the software Ensight, the peak velocity, net flow, and percent regurgitation were all quantified at each pulmonary vein. Figure 1A displays the 3D construction of the LA and its pulmonary veins, and 1B displays the velocity path lines calculated by Ensight.

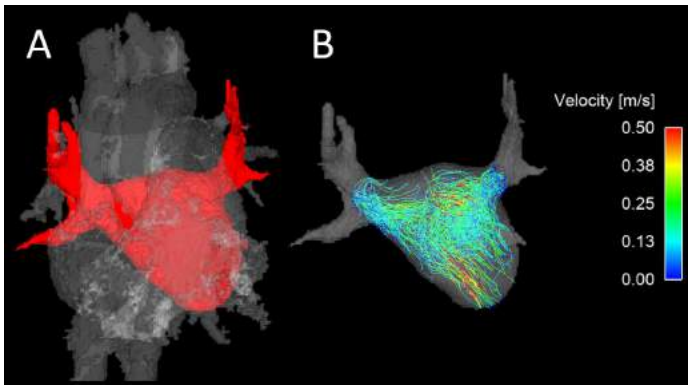

Figure 1: A. 3D construction of LA and Pulmonary veins embedded in the blood flow. B. Velocity streamlines from the pulmonary vein inlets.

LA average velocity and wall shear stress (WSS) was calculated using MATLAB. WSS was calculated from triangulated surface meshes and taking the cross product of the velocity vector and the surface normal vector and then averaged over the LA surface, as shown in equation 1,

$$\tau_w = \frac{1}{A}\int_A \mu \frac{\partial u_i}{\partial n_i} dA \quad (1)$$

where μ is viscosity (4 centipoise), and n_i is the surface normal vector. The AF and Healthy groups were compared using the student's T-Tests.

RESULTS

Peak velocity in the inferior pulmonary veins was lower in patients with AF than in healthy subjects (LIPV: 0.98 vs. 1.26 m/s, RIPV: 0.88 vs. 1.19 m/s). However, only the difference between the RIPV was significant (LIPV: p=0.129, RIPV: p=0.047). The peak velocity was not different in the LSPV (0.97 vs 0.97 m/s) and RSPV (0.94 vs 0.83 m/s). Average velocity within the atria was found to be lower in AF patients (29.70 m/s) than in healthy subjects (48.81 m/s). These results were found to be significant (p=0.012).

AF patients had lower net flow in all the pulmonary veins except the RSPV. The net flow at each of the pulmonary veins for the AF patients and controls were LSPV: 12.87 vs 19.13 ml/cycle, LIPV: 10.01 vs 21.70 ml/cycle, RSPV: 17.27 vs 16.06 ml/cycle, and RIPV: 10.786 vs 19.816 ml/cycle, respectively. The LSPV, LIPV, and RIPV differences were all significant (p<0.015), however, RSPV was not (p = 0.575). Regurgitation fraction into the pulmonary veins was higher in AF patients than healthy subjects (LSPV: 7.27 vs 0.65 %, LIPV: 6.24 vs 0.3 %, RSPV: 5.658 vs 1.39 %, and RIPV: 5.94 vs 5.24 %, respectively). Only the LSPV (p=0.006) and RSPV (p=0.011) were significant. However, both LIPV and RIPV have low p-values (p<0.135).

When analyzing the WSS maps, there is a noticeable increase in WSS around the pulmonary veins, as seen in Figure 2. This will be the area of specific interest in the more detailed analysis of WSS. Further analysis will compare the differences in WSS with the different flow parameters collected in the LA.

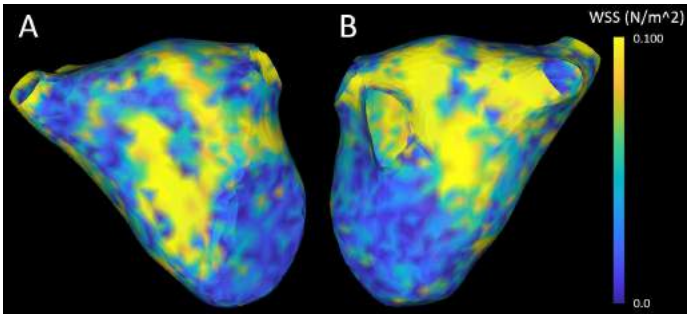

Figure 2: A. Anterior contours of left atria wall shear stress, B. Posterior contours of left atria wall shear stress

DISCUSSION

By using 4D-Flow MRI, our preliminary results indicate that AF patients have lower peak velocities in their inferior pulmonary veins, lower net flow in the LSPV, LIPV, and RIPV, and higher regurgitation fraction into all four pulmonary veins. WSS was also highest around the pulmonary veins, suggesting different regional fluid structure interactions.

Previous 4D-Flow MRI studies reported in the literature confirms most of our findings, especially the fact that velocity in the atria decreases in individuals with AF [5-6,8]. This lower velocity in the LA is likely attributed to the lower velocity in the pulmonary veins. A previously preliminary study done by our group also found that WSS was greatest in the area next to the pulmonary veins [9].

4D-Flow MRI is a comprehensive and diverse tool that has many functions, including its use to analyze quantitative blood flow dynamics metrics such as WSS. Most studies reported in the literature have only looked at how AF has affected the atrial blood flow. However, this study looks to use of 4D-Flow MRI to analyze trends in flow and WSS and correlate that to atria remodeling in AF patients.

Intra atrial flow is important when investigating the potential for thrombus formation in patients with AF. On the other hand, a comprehensive analysis of flow and structure is important because it can signal which regions are undergoing the most stress, which can then be assessed against the remodeling of the atria. Therefore, the future direction of this project is to determine in vivo patterns of regionalized WSS and flow parameters in order to understand the different regional fluid structure interactions.

INTRODUCTION

According to the global burden of disease studies, schizophrenia affects 21 million people worldwide and is one of the top 25 causes of disability [1]. Schizophrenia costs about $125 billion per year to the US economy. Existing medications are symptomatic and full recovery for sustained periods can be achieved in about 14% of patients [2]. Precise understanding of the underlying pathophysiology of schizophrenia could provide avenues to design novel treatments.

Schizophrenia is increasingly considered a "dysconnection disorder" where single regional anomaly is less important relative to the network across the brain. Structural covariance networks (SCN) that represent shared variation among brain regions is known to largely reflect the white matter connections. SCNs are represented by correlations between pairs of regions' volumes or other morphometric measures for all subjects in a group. Characteristic differences in SCNs have been found between schizophrenia patients and healthy controls (HC) [3]. In this study, our goal was to simulate targeted and systematic modification of nodal values to explore whether such simulations decrease the dissimilarity between the patient and HC SCNs so that these SCNs are statistically similar, providing information on the resilience/robustness of the patient SCN. Such findings could be of use in identifying critical network features as treatment targets.

METHODS

We generated the SCNs of first-episode antipsychotic-naïve psychosis (FEAP) patients and HC from gray matter volumes derived from the regions that were computationally parcellated using the Desikan-Killiany-Tourville atlas within the FreeSurfer V6 program. MATLAB was used to simulate "removal" and "partial removal" of the nodes by setting the correlation coefficients to 0 or by proportional reduction of correlation coefficients to mimic that of the HC nodes. We used 4 different simulation approaches to test the resilience of the schizophrenia SCN.

Simulation 1 involved "removal" of one region at a time in the FEAP group by setting correlations of all edges for a given node to zero. This was repeated for every node, one node at a time. Simulation 2: The nodes were grouped on percentile ranking of the clustering coefficient. Top 20% of the nodes (the top 18.5th percentile) were successively "removed" one at a time by setting the correlations to 0 for each node. Followed by this, correlations of these nodes were set back to the actual correlations as they were originally. Then, we selected the next set of nodes between the 18.6th and 37th percentile, and the process was repeated until all nodes were dealt with. After each step in simulations 1 and 2, graph metrics -- clustering coefficient, transitivity, strength and assortativity, were recalculated for the modified network. Results were then compared to the unmodified HC metrics. These measurements were chosen because they characterized the network on a nodal (clustering coefficient and strength) and global level (transitivity and assortativity), and reflect the integration, segregation and centrality measures of the network.

Simulation 3: Complete "removal" of a brain region has little clinical application because it does not reliably reflect biological networks, and not feasible for therapeutic development. For these reasons, similar simulations as in 1 and 2 were implemented by reducing the edge weight by 25%, 50%, and 75%. Results were again compared to the HC group's metrics.

Simulation 4: Using a different algorithm in which the volume data for FEAP nodes were altered such that the volume correlations were brought closer to that of HC. The graph metrics were again calculated following each node's volume was modified. The DeltaCon metric [4] was then used to examine the similarity between the two networks more directly. Since in the unthresholded networks, all nodes are directly

connected to all other nodes, making their similarity 1, i.e., 100%. Therefore, threshold values were determined using both intensity (values from 0 to 1) and density (values from 0.01 to 1) thresholds (both with increments of 0.01). The respective threshold value at which the networks were least similar was used (0.61 for intensity, 0.65 for density). The networks were then thresholded using these values, and FEAP nodes were replaced with data similar to the HC's. After each replacement, the FB network was thresholded again, and the DeltaCon metric between the two networks was recalculated.

RESULTS

Simulation 1: Complete "removal" of one node at a time did not make the FEAP SCN's mean clustering coefficient similar to that of the HC (Fig 1).

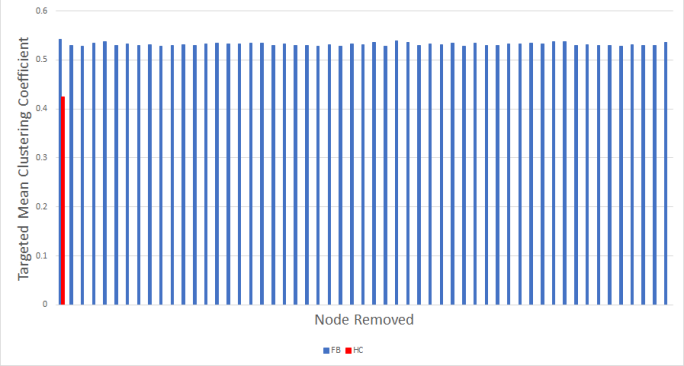

Figure 1: FEAP mean clustering coefficient after "removal" of one node at a time.

Simulation 2: "Removal" of most of the nodes in the top 18.5th percentile or all the nodes in the 18.6th to 37th percentile resulted in SCNs similar in mean clustering coefficient and mean strength but not of assortativity or transitivity of the HC SCN. "Removal" of nodes in the lower percentile ranking did not have the same influence (Fig. 2).

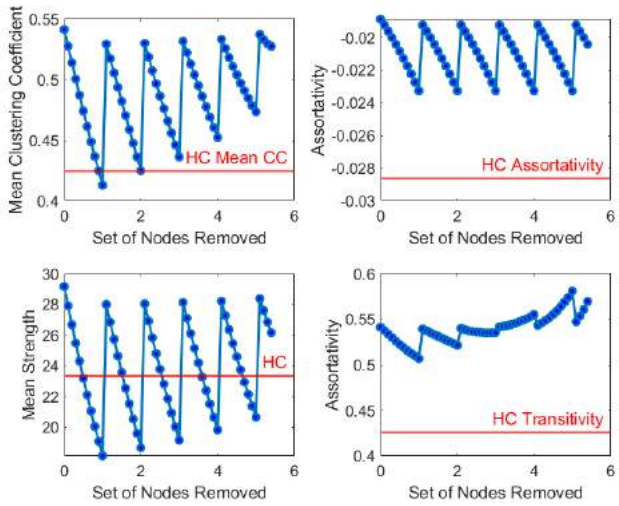

Figure 2: FEAP mean clustering coefficient, assortativity, mean strength and transitivity after targeted removal of nodes grouped by percentile ranking of the clustering coefficient.

Simulation 3: Similar to simulation 1, "partial removal" of any one node in the FEAP group did not make the FEAP SCN's mean clustering coefficient similar to that of the HC (Fig. 3).

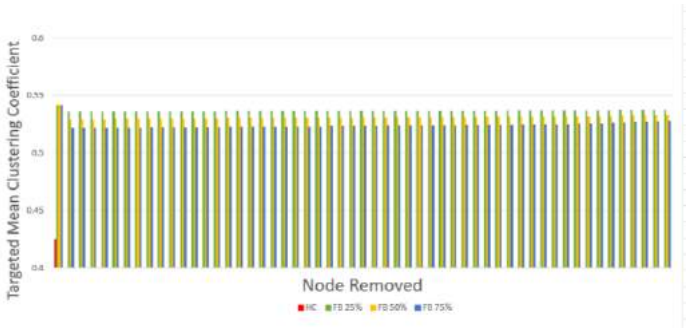

Figure 3: First Break mean clustering coefficient after partial removal of one node by 25%, 50%, and 75%.

Simulation 4: Using the volume alteration algorithm and DeltaCon metric, over 70% similarity was observed between the FEAP and HC SCNs with both intensity and density thresholding (Fig. 4). With intensity thresholding, successive replacement of FEAP nodes caused similarity to increase in almost a linear fashion.

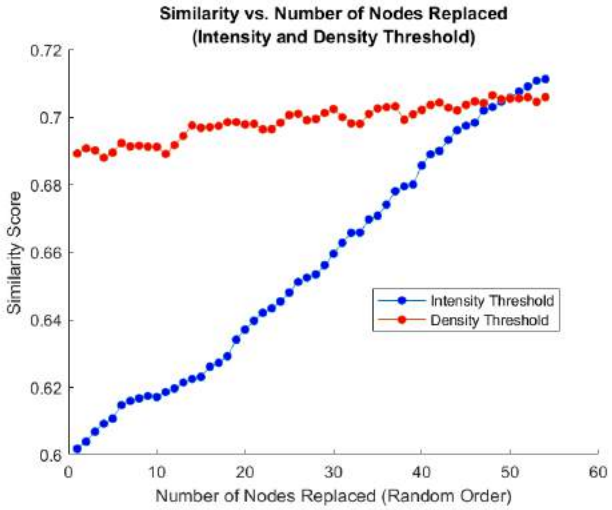

Figure 4: DeltaCon similarity scores after nodes were cumulatively replaced in random order with intensity and density thresholding.

DISCUSSION

Our overall goal was to test the resilience/robustness of the first break SCN network compared to unaltered HC network. Our first and third simulations showed that no single node had overarching influence on the patient SCN, supporting the existing neurobiological findings. Instead, "removal" of multiple regions is necessary to make the patient SCN characteristics to be more similar to the HC. Manipulation of multiple nodes may be needed to alter FEAP network to be more similar to HC's. Potential applications of our results include targeting specific groups of regions to make treatment for patients and preventive measures for high-risk individuals more effective.

INTRODUCTION

Lower urinary tract symptoms (LUTS) and changes in bladder function occur frequently as individuals age. Patients with LUTS are commonly evaluated through multi-channel urodynamic studies that determine bladder pressure and flow during voiding, however, these studies are invasive and provide little insight into the changes in bladder anatomy and detrusor muscle function that occur with aging and obstruction. Non-invasive methods of imaging the bladder are useful but can be limited by motion and chemical shift artifacts[1,2]. Although a combination of MRI and computational fluid dynamics has been used to analyze the movement of the bladder during voiding, 3D MRI acquisition has not yet been performed[3]. This study analyzes 3D MRI protocols during the voiding of an in vitro bladder model and validates them with high-speed optical imaging using different vitro models. These novel methods serve to confirm adequate spatial and temporal resolution of this 3D MRI protocol and bring us closer to utilizing this technique for regular in vivo diagnostic imaging.

METHODS

In this IRB-approved and HIPPA-compliant study, a healthy, 37-year old subject was recruited to void in the scanner during 3D MRI acquisition. Using this data, an in vitro bladder model was fabricated. The bladder was segmented from the MRI images and an STL was exported (Mimics, Materialize, Leuven, Belgium). The bladder was 3D printed using poly-vinyl alcohol (PVA) (Ultimaker, Geldermalsen, Netherlands). The bladder was then coated in silicone (SYLGARD™ 184 Silicone Elastomer, DOW Silicones Corporation, Midland, MI, USA) followed by latex (AeroMarine, Keyport, NJ). The inner PVA core was dissolved out and the remaining latex mold served as the in vitro bladder model. A ¼" diameter tube was then attached to the latex model to represent the urethra and used to fill the model with H_2O until full (approximately 300 mL). The void time of the bladder model was calibrated to approximately 35 seconds.

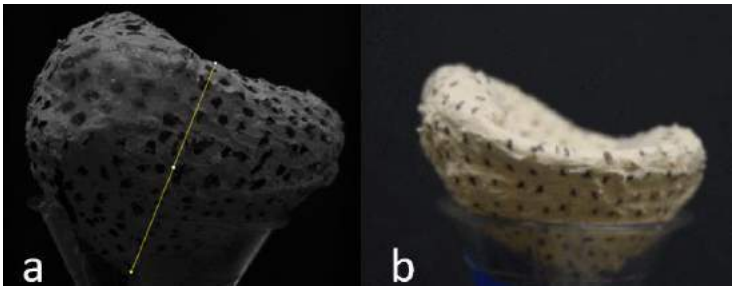

Figure 1 a) single frame from the phantom camera footage with measured segment. b) static capture from SLR footage of voiding bladder.

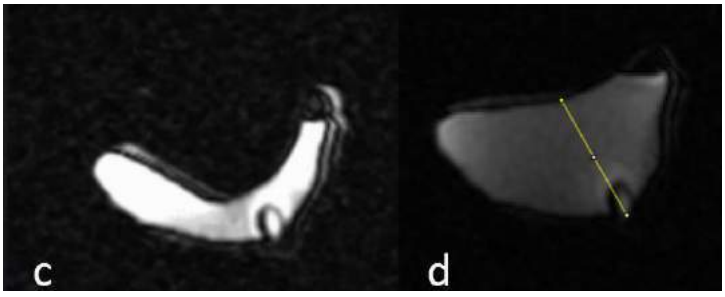

Figure 2 c) static capture from MRI sequence of voiding. d) single frame from MRI sequence with measured segment.

3D sagittal DISCO Flex images were used to analyze both in vitro and in vivo deformation over the voiding period. The in vitro MRI protocol was compared to hi-speed phantom cameras capturing deformation during identical voiding conditions. Additional hi-speed footage was acquired using an SLR camera. The MRI and phantom camera footage deformation were analyzed frame-by-frame using ImageJ (NIH, Maryland, USA) and the percent deformation rate using line segments was calculated (Figure 1a & b).

RESULTS

Figure 1 shows the side-by-side comparison of the deformation measured by the MRI sagittal 3D volumes and the SLR camera footage of the in vitro latex bladder model and the approximate line segments used to calculate percent deformation. Table 1 shows the deformation rate of both the MRI and optical imaging modalities**.** The calculated rates of deformation in both the MRI and phantom camera were 6.2% deformation per second and 5.3% deformation per second, respectively (Table 1). There was a 15% difference in the two deformation rates relative to the phantom camera value. Qualitative analysis of both methods showed similar patterns of deformation. The rate of volume decrease was also measured (Table 1).

Time elapsed (s)	MRI deformation (%)	Phantom camera deformation (%)
0	0	0
1.5	3.992	6.232
3	17.122	13.865
4.5	29.544	19.876
6	36.243	29.557
7.5	42.744	39.5507
	6.2% deform./sec	**5.3% deform./sec**

Table 1. Quantitative analysis results.

DISCUSSION

Assessment of bladder wall movement during voiding proves difficult due to various artifacts during imaging. This study utilized optical imaging and an anatomically realistic in vitro bladder model to verify the accuracy of this 3D MRI acquisition protocol. Comparison between in vitro optical imaging and MRI experiments, proved useful for studying deformation patterns and to validate our MRI approach. Further in vivo results obtained in the healthy subject demonstrated feasibility of this approach for non-invasive in vivo evaluation of bladder wall deformation during voiding.

There are many factors that differentiate the in vitro experiments conducted in this study from the in vivo bladder analysis. Although the rate of the in vitro bladder model voiding was kept similar to that of the subject trial, the pattern of bladder deformation in vivo varies greatly due to the assistance of the surrounding detrusor muscle[4]. Another limitation of the study is that the rate of the high-speed footage was only analyzed to the point at which the posterior wall of the bladder deformed below the anterior wall, making it impossible to track subsequent deformation.

To address this problem, efforts have begun towards fabricating a transparent thin-wall model to overcome this visibility limitation. For the prototype, a thin-walled mold was created (Figure 4a) in 3Matic (Materialize, Leuven, Belgium) and printed in ABS plastic (Ultimaker, Geldermalsen, Netherlands). A clear model was then created by pouring clear, flexible silicone in the mold (Solaris Clear Silicone Rubber, Smooth-on, Macungie, PA) (Figure 4b). With this model, particle image velocimetry (PIV) will be utilized to analyze fluid vorticity during the bladder voiding process. By tracking the movement of fluorescent particles in a plane of flow using PIV, instantaneous velocity vectors will be acquired within the transparent bladder[5]. We expect these measurements to provide insight into the behavior of fluid during the in vitro bladder voiding and can further validate 3D MRI imaging protocols.

INTRODUCTION

Brain tissue undergoes motion in response to blood pressure and blood flow over the cardiac cycle [1]. This cardiac-driven brain tissue motion has been previously quantified within the cerebellum and brainstem by using phase contrast magnetic resonance (PCMR) tissue velocity mapping with a low velocity encoding value [2], or by using displacement encoding with stimulated echoes (DENSE) MRI [3]. The DENSE technique directly measures displacement at multiple time points over the cardiac cycle compared to a reference location after the cardiac trigger signal (R-wave or pulse peak). To determine displacement values from PCMR measurements, velocity must be calculated using a 'tracking' algorithm to determine position.

Chiari malformation type I (CMI) is a neurological syndrome classified as the elongation of the cerebellar tonsils five millimeters below the foramen magnum, identified on static structural MRI. Patients with CMI experience symptoms including sub-occipital headaches, neck pain, and cognitive/neurological deficits [4]. In addition to altered brain morphology, CMI patients demonstrate increased tissue motion [1-3] which may be the underlying cause of CMI symptoms due to repeated compression of the cerebellum, brainstem, and upper cervical cord.

The purpose of this study was to compare brain tissue motion from PCMR-derived displacement measurements to DENSE displacement measurements in a series of patients with CMI. *We hypothesized that the displacement measurements by PCMR and DENSE would be highly correlated, but the DENSE measurements would have a lower standard deviation than PCMR as DENSE directly measures displacement.*

METHODS

Magnetic Resonance Imaging (MRI) exams were conducted in 10 CMI patients with an average age of 37.7 and consisting of 8 women and 2 men in a study approved by Emory University. Patients had CMI diagnostic criteria, including greater than 5 mm tonsillar descent below the foramen magnum and the presence of CMI symptoms. These CMI patients were referred by single neurosurgeon (Daniel Barrow, MD).

Using a 3T MRI scanner (Siemens PrismaFit, Erlangen, Germany), cardiac-gated spiral cine DENSE sequences were evaluated at the mid-sagittal plane [5]. Acquisition parameters included: two directions of in-plane motion encoding, an encoding frequency of 0.6 cycles/mm, two spiral interleaves per heartbeat, pixel size of 1.2 x 1.2 mm, slice thickness of 7 mm, four signal averages, and 16-27 frames over the cardiac cycle, depending on the heart rate. PCMR measurements were acquired in the same anatomical location and with the same field of view and spatial resolution as the DENSE measurements. Twenty-five frames were acquired over the cardiac cycle depending on heart rate, and retrospective cardiac gating was used. The velocity encoding value (VENC value) was 2 cm/sec.

Two programs developed in MATLAB (Mathworks, Natick, MA) were used to quantify brain tissue motion. One program (DENSEPro) used DENSE phase images to calculate the average displacement of the brain tissue as a function of time over the cardiac cycle; the second program (PhasePro) used PCMR images to calculate the average brain tissue velocity. The brain tissue velocity values from PhasePro were corrected to ensure there is no net displacement of the soft tissue in the brain over the cardiac cycle. These corrected velocity values were then integrated over time to calculate the brain tissue displacement at every time point.

PCMR derived displacement values, and DENSE displacement values were plotted at each cardiac cycle for each patient. In *figure* 3, all data points from all patients were combined onto one correlation plot to examine the relationship between the PCMR derived displacement and the DENSE displacement measurements.

Two regions of interest (ROIs) were identified by a single observer (David Bat) on each patient. One ROI was a 1.14 x 1.14 cm square within the brainstem, and the second ROI outlined the cerebellum for each patient, *figure 1*. The small square ROI in the brainstem was chosen to have a region where the velocity was nearly uniform (bulk motion only) and where CSF was not present. The cerebellum ROI was chosen as the cerebellum has significant motion in CMI patients. The cerebellum ROIs were drawn to conservatively stay within the cerebellum tissue such to reduce potential artifacts by unintentionally capturing CSF motion.

In order to compare the standard deviation of the displacement values from the two methods, the standard deviation of each patient was obtained at the timepoint at which maximum displacement occurs. These standard deviation values were then compared using paired sample t-test, where $p < 0.05$ was considered statistical significant.

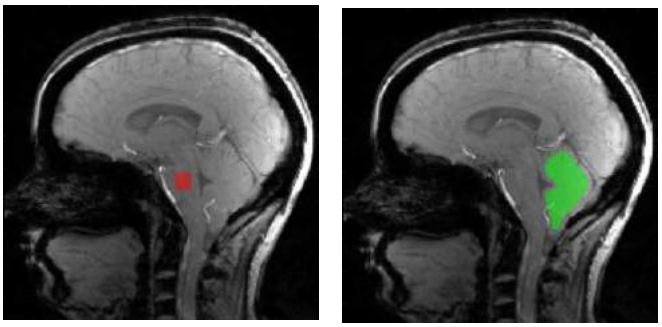

Figure 1**:** *The regions of interest (ROI) are shown on PCMR magnitude images of a patient. The brainstem ROI (red, left) is a small square located in the center of the brainstem. The cerebellum ROI (green, right) is a conservative shape of the cerebellum.*

RESULTS

Figure 2 presents an example of the results for one patient using the brainstem ROI (left) and one patient in the cerebellum ROI (right). Displacement values from DENSE and PCMR and the standard deviation of values from within the ROI are plotted as a function of time. The error bars represent the respective standard deviations at each time point. The displacement values between the two methods are similar; however, the standard deviation of the PCMR derived displacement is cumulative because of the integration and is much larger than the standard deviation of the DENSE.

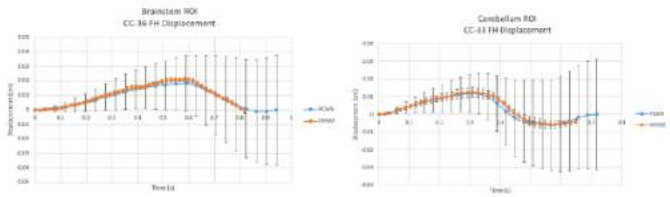

Figure 2: *The displacement of the brainstem ROI (left) and cerebellum ROI (right) is shown for both PCMR derived displacement,* and DENSE *derived displacement as a function of time across the cardiac cycle.*

Figure 3 shows correlation plots with the DENSE-derived displacement on the y-axis and PCMR-derived displacement on the x-axis for each ROI with a linear trendline to fit the data. The trendline presents relatively high R^2 values, and a slope of 0.86 and 0.92 for the brainstem and cerebellum ROI, respectively.

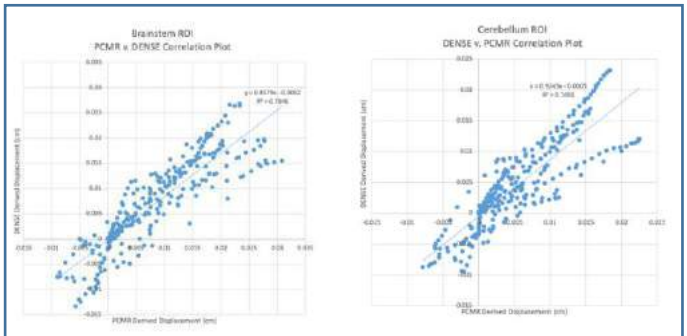

Figure 3: *Correlation plots for the brainstem ROI (left) and cerebellum ROI (right) with DENSE-derived displacement on the y-axis and PCMR derived displacement on the x-axis. A linear trendline with the R^2 value and equation is shown additionally.*

The two methods' displacement values have a relatively high correlation; however, the standard deviations within the ROI's at peak displacement between the two methods are significantly different. In the brainstem ROI, the standard deviations were 180 microns, and 10 microns for the PCMR and DENSE derived displacements, respectively. In the cerebellum, the standard deviations were 160 cm, and 40 microns for the PCMR and DENSE derived displacements, respectively. A paired t-test resulted in a $p = 2.7 \times 10^{-8}$ and $p = 6.5 \times 10^{-5}$ for the brainstem and cerebellum ROIs, respectively. This rejects the null hypothesis and shows a statistically significant difference between the standard deviations of the two methods.

DISCUSSION

The major findings of this study were that PCMR derived displacement measurements were highly correlated with the DENSE displacement measurements in both the brainstem and cerebellum ROI. This implies that PCMR images can be a valid method of measuring the displacement of soft tissue in the brain. However, the standard deviation of PCMR derived displacement measurements is significantly larger than the standard deviation of DENSE displacement measurements, which shows that using PCMR images increases the error in the measured displacement. This is likely because DENSE measurements directly measures the displacement, while PCMR velocity values are integrated over time to calculate the displacement, which leads to a cumulative standard error over time. In conclusion, PCMR derived displacement is accurate for mean displacement, but caution must be given to the results due to the high standard deviation of the results.

INTRODUCTION

Prevalence of youth baseball pitching injuries has not decreased despite adoption of safety guidelines, pitch count recommendations, and increased media coverage [1]. Strong evidence shows that high and repetitive joint kinetics (i.e., forces, torques) are a biomechanical mechanism for pitching injuries [2-3]. Further evidence suggests that flaws in pitching kinematics lead to an increase in joint kinetics and pitching injuries [4]. Studies aimed at correcting flaws in several kinematic parameters have been conducted for adults [4]. However, similar studies do not exist for youth baseball pitchers. Also, previous studies have shown that body mass index (BMI) has been linked to increased injury-related kinetic parameters [5]. However, there are no studies that have investigated relations between BMI and injury-related kinematic parameters.

The goal of this study was to investigate associations between injury-related kinematic parameters and overweight measures for youth baseball pitchers. The hypothesis was that injury-related kinematic parameters would be associated with BMI. The injury-related kinematic parameters considered were 1) measurements at foot contact (FC): stride length (SL), front foot position (FFP), shoulder external rotation (SER), shoulder abduction (SAFC), and elbow flexion (EF); 2) measurements between FC and ball release (BR): peak knee extension (KE); and 3) measurements at BR: shoulder abduction (SABR) [4].

METHODS

Participant Recruitment. Motion analysis and anthropometric data were available from three studies: 1) a published study with 18 10- to 11-year-old male baseball players [6] and unpublished studies with 2) 11 14- to 16-year-old male baseball players [7], and 3). 104 16- to 18-year-old male baseball players [8].

Details are provided below for methods used in the 1st study; generally, methods were similar in the 2nd and 3rd studies (see [6-8] for more details).

Experiments. In the 1st study [6], participants completed pre-game tests to measure body weight and height using a scale/stadiometer (LW Measurements LLC, Rohnert Park, CA, USA). Participant BMI was calculated as body mass divided by height squared (kg/m^2). In addition, participants underwent a DXA scan using a Lunar iDXA scanner (GE Healthcare, Madison, WI, USA) to determine body composition. Pitching kinematics data were captured using a motion analysis system. 12 motion analysis cameras (Motion Analysis, Santa Rosa, CA, USA) were used to track 38 retroreflective markers placed on anatomical landmarks based on the PitchTrak (Motion Analysis) software marker set. Participants pitched off a portable mound into a net 25 feet away with a scaled strike zone. Marker trajectories were recorded in Cortex analysis software (Version 7.4.6, Motion Analysis) at 200 Hz, interpolated (third-order spline), and filtered (4th order Butterworth filter, cutoff frequency 12 Hz) [9]. 10 pitches were recorded for each participant.

Analysis. In the 1st study [6], kinematic parameters were obtained using PitchTrak (a subset of Cortex). The last three pitches with usable data were analyzed independently and averaged for each participant. This study considered eight kinematic parameters that were analyzed at different parts of the pitch cycle, which is defined from FC to BR. FC was determined when the front foot segment stopped moving, and BR was determined based on how the wrist pronated during the pitch. The pitch cycle time was then normalized such that 0% and 100% represented times of FC and BR, respectively.

SL was calculated by measuring the distance between left and right toe markers at front-FC in the direction of the axis parallel to the pitching mound to home plate vector, expressed as a percent of body height (BH). FFP was calculated by taking the distance, in the lateral direction (perpendicular to the pitching mound to home plate vector), between the front ankle's position at the instant of front FC and back ankle's position at maximum knee height [4]. FFP was deemed positive when the front foot landed closed (i.e., towards the third base side for a right-handed pitcher) [4]. Both absolute and normalized (by BH) values were considered. SER (Figure 1, left) at FC, measured in degrees, was the external rotation angle of the throwing shoulder, SAFC (Figure 1, middle), also measured in degrees, was the abduction angle of the throwing shoulder at FC. EF (Figure 1, right) was the elbow flexion angle at FC measured in degrees. KE was calculated by taking knee flexion at FC minus knee flexion at BR [4]. Finally, SABR was the shoulder abduction at BR and calculated the same way as at FC.

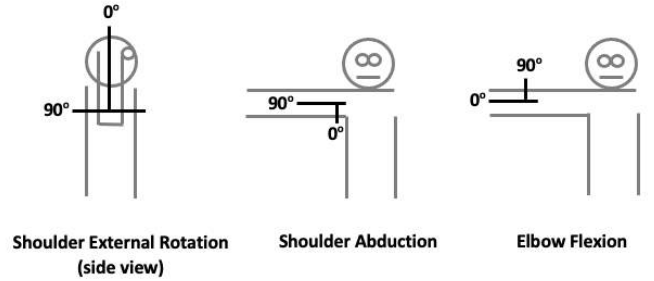

Figure 1: Anatomical shoulder and elbow angles used in analysis.

Statistics. Data were separated into three groups based on data collection site to prevent possible analysis errors from different lab environments and procedures. Linear regression analyses were performed to determine significant correlations between kinematic parameters and BMI. Statistical significance was defined by $p<0.05$.

RESULTS

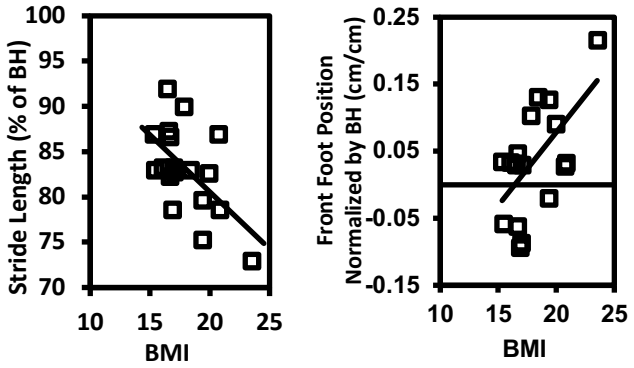

Figure 2: Correlations between stride length (SL) and front foot position (FFP) normalized by body height (BH) and BMI for 10-11-year-old participants.

A significant negative correlation was found between normalized SL and BMI for the pitchers in the 10- 11-year-old age group (p=0.013). Pitchers in the 14-16- and 16–18-year-old studies had no significant correlation between SL and BMI (p=0.532 and p=0.437 respectively) (Table 1). A significant positive correlation was found between normalized FFP and BMI for the pitchers in the 10- 11-year-old age group (p=0.009). Pitchers in the 14-16- and 16–18-year-old studies had no significant correlation between FFP and BMI (p=0.211 and p=0.421 respectively) (Table 1). Significant correlations were not found for any of the other kinematic parameters.

Table 1. Single linear regression results of stride length (SL) and front foot position (FFP) normalized by body height vs BMI. * = significant correlation with BMI; $p < 0.050$.

Population	SL	FFP
	R^2 (p)	R^2 (p)
10- to 11-year-olds	0.36 (0.013*)	0.36 (0.009*)
14- to 16-year-olds	0.045 (0.532)	.17 (0.211)
16- to 18-year-olds	0.0059 (0.437)	.0064 (0.421)

DISCUSSION

The correlations between two of the seven kinematics parameters (SL and FFP) and BMI support the hypothesis that injury-related kinematics parameters are associated with overweight measures. However, those associations were significant for only the youngest age group. The difference in SL and FFP trends between the age groups suggest that pitchers in the 10- to 11-year-old range with a higher BMI have more difficulty stabilizing their body during the pitching motion. With age, these difficulties may be resolved as prior studies have shown that pitching kinematics improve rapidly from 9-12 years [10]. Another possible explanation is that 10- to 11-year-old pitchers with flawed pitching kinematics are no longer pitching at the 14+ age range. While it is difficult to make a definitive conclusion, both arguments are in favor of placing emphasis on proper pitching kinematics at a younger age when pitching injuries begin to develop [11].

There were several limitations in the 1st study. First, the pitching distance was limited to 25 feet due to lab size constraints. Second, the total numbers of overweight and obese participants (16.6% and 5.5%) were comparable for overweight but not for obese youth baseball players [12]. Third, there is an error of approximately 3% that may occur from visually selecting frames associated with FC and wrist pronation, which signified BR. Fourth, the data came from three different experimental sites. A future recommendation would be to perform all experiments for the different age groups in one lab.

A key clinical implication of this study is that select kinematic parameters have been identified that could guide coaches and trainers when working with overweight pitchers. Also, the results suggest that future work should investigate if a coaching intervention for overweight youth pitchers can correct flaws in injury-related pitching kinematics.

INTRODUCTION

The endothelial cell glycocalyx (EC GCX) is a sugar-rich layer lining the endothelium which consists of glycosaminoglycan (GAG) chains, such as heparan sulfate (HS) and hyaluronic acid (HA)[1]. These chains are attached to core proteins such as syndecan-1 (sdc1), glypican-1 (gpc1), and CD44 and which line the endothelial cell membrane (**Figure 1**)[1]. Research has shown that EC GCX degradation can lead to atherosclerosis, which is one of the precursors to strokes, as well as other serious cardiovascular events[1,2]. Studies conducted by our lab and others have shown the presence of a degraded EC GCX in the early stages of vascular diseases, particularly in atherosclerosis[1].

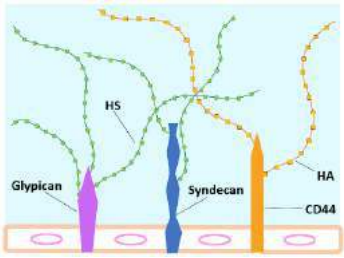

Figure 1- GAG and core protein components of the EC GCX

Because cardiovascular disease is the leading cause of death worldwide, affecting over 126 million adults in the United States alone, there is incentive to develop treatment strategies which target this structure[2]. Previous research has specifically targeted the HA and HS components of the EC GCX due to their significant composition within this structure[3]. Given that HA and HS are closely associated with their respective core proteins, understanding how these core proteins respond to flow conditions allows a crucial secondary confirmation of HA/HS presence. In this study we aim to establish the presence of the core proteins CD44 and sdc1 in Human Umbilical Vein Endothelial Cells (HUVECs) in static and uniform flow conditions. We plan to use HUVECs because they are an established and commonly used cell line when studying endothelial cells *in vitro*. In addition to HUVECs, we plan to use Human Coronary Arterial Endothelial Cells (HCAECs), a cell line more geographically relevant (within the body) in the progression of atherosclerosis.

METHODS

HUVECs were plated at a density of 62,000 cells/cm^2 on 2.2 cm x 2.2 cm fibronectin-coated glass coverslips until 100% confluency. These cells were then exposed to a uniform flow environment and static environment for 0 or 24 hours. The flow environment was modeled using a custom parallel plate flow chamber[1] (**Figure 2**).

Figure 2- A diagram of the parallel flow chamber apparatus used to simulate uniform flow.

Following exposure to the static or flow environment, the cells were then fixed and stained for CD44, sdc1 and gpc1 via immunocytochemical staining (ICC) (**Table 1**).

Component	Primary Antibody	Secondary Antibody
CD44	CD44 Rabbit anti-Human	AF488 Goat anti-rabbit IgG
Sdc1	Sdc1 Rabbit anti-Human	AF488 Goat anti-rabbit IgG
Gpc1	Gpc1 Rabbit anti-Human	AF488 Goat anti-Rabbit IgG

Table 1- Primary and secondary antibodies used for ICC

Confocal microscopy was ultimately used to image the fluorescently labeled HUVECs, and ImageJ, an Adobe-based image processor, was used to quantify fluorescence intensity. Fluorescence

intensity was assumed to be indicative of GCX component expression. GCX expression levels were then displayed as mean ± standard error of mean (SEM) and statistical significance was determined using Mann-Whitney t-tests for $\alpha = 0.05$ through GraphPad Prism software. All flow or static values (n=4) were normalized to the zero-hour static expression (Equation 1). This model, as well as its protocols, will then be translated to other future cell types, such as HCAECs.

$$Fold\ change\ in\ GCX\ Intensity = \frac{Flow\ or\ Static\ \ Intensity\ at\ x\ Hours}{Static\ Intensity\ at\ Zero\ Hours}$$

Equation 1- Method of normalization for analysis and comparison.

RESULTS

Our analysis of HUVECs found that at 24 hours, the expression of sdc1 in flow and static conditions was not statistically different (p= 0.343) (**Figure 3**). Expression of CD44 was also observed at 24 hours and was shown to significantly increase in the flow condition (p = 0.0286) (**Figure 3**).

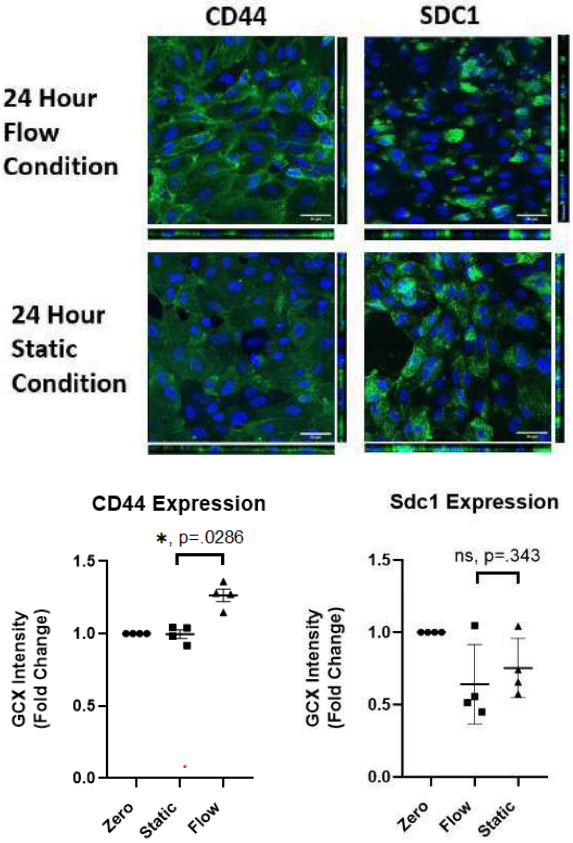

Figure 3 - Confocal images and graphs of the fold change intensities of core proteins CD44 and sdc1 in HUVECs at the 24-hour time point in uniform flow and static conditions. At 24 hours the difference between static and flow is found to be significant for CD44 but not significant for sdc1. Blue = DAPI (cell nuclei), Green = AF488 (core protein)

DISCUSSION

Our studies allowed us to confirm previous findings of sdc1 at the protein level[3], and to establish CD44 protein expression in HUVECs. We also present the novel characterization of how these core proteins respond to the uniform flow environment found in the human vasculature. Studies on CD44 expression in a context relevant to CVDs are limited, and to our knowledge only one group has investigated CD44 expression in flow[4]. However, this study was in S12NL1 cancer cells and is not comparable for understanding the role of CD44 in EC GCX mechanobiology[4]. Conversely, our observation of unchanged sdc1 protein expression in flow follows the results seen by Liu et al., where sdc1 mRNA expression in HUVECs remained unchanged after 24 hours, compared to the control[3]. These trends may be explained by differences in how the core proteins themselves interact with the surrounding EC GCX[5,6]. CD44 does not covalently bind to components of the GCX whereas sdc1 *does* interact via covalent binding[5]. Thus, it is possible that CD44 expression changes can be observed due to the simple fact that it is more accessible to antibody binding[5]. Sdc1 expression changes may not be detectable if the core protein is obstructed by covalently bound GCX components[6]. A potential study which may confirm this hypothesis would be to enzymatically degrade or silence surrounding EC GCX components to explore these core proteins free of surrounding obstruction. We also note that in our current *in vitro* model, the use of HUVECs are inherently a limitation because they are found in regions of the vasculature that are not often associated with atherosclerotic CVD. Rather, atheroprone regions are found in the coronary arteries and aortic arch, due to their branched and curved nature, respectively, and due to the associated disturbed flow. Thus, a more beneficial model would be the use of Human Aortic Endothelial Cells (HAECs) or HCAECs along with a disturbed flow environment to simulate GCX degradation. Mirroring the same methods performed with HUVECs, we plan to use HCAECs to study the effects of disturbed flow in addition to uniform flow on the GCX. In doing so, we hope to gather a more relevant understanding of core protein behavior in the diseased GCX condition.

ACKNOWLEDGEMENTS

A METHODOLOGY TO MEASURE THE TRUE FLEXURAL STRENGTH OF BRITTLE CYLINDERS

Michael P. MacIsaac (1), Ghatu Subhash (1), Salil Bavdekar (1)

(1) Mechanical & Aerospace Engineering
University of Florida
Gainesville, FL, USA

INTRODUCTION

Four-point bend tests are used to experimentally obtain the flexural strength of ductile materials. As plastic deformation is the primary mode of failure in ductile cylindrical samples, failure always occurs at the point under maximum tension. However, this is not always the case with brittle samples, as their failure is governed by the growth of microstructural flaws [1]. These flaws, being randomly distributed, can lead to orientation-dependance of the measured flexural strength. If the point under maximum tension contains the critical flaw in the sample, the measured flexural strength will be its true value. However, if the cylinder is rotated to any other orientation, this critical flaw will be under a lower tensile stress, resulting in a higher measurement of flexural strength, due to the brittle materials strength in compression.

In this study, the goal is to measure the true flexural strength of the sample by ensuring that failure occurs at its weakest point. This can be achieved by loading a solid or hollow cylindrical sample as it rotates along its longitudinal axis, thereby activating its critical flaw during a four-point bending test. This allows every point on the sample's surface to experience a state of maximum tension at any given load.

METHODS

The materials tested using the develop methodology are borosilicate glass rods, ceramic (alumina) tubes, and 3D printed tubes. The glass rods and ceramic tubes were chosen because they are typical brittle materials with well-established material properties. 3D printed tubes were chosen because, although the majority of printing filaments are plastics, the printing process can produce tubes that fail in a brittle manner. Their brittle behavior can be attributed to failure due to delamination between filament layers. The 3D printed materials selected were Z-HIPS, Z-ULTRAT, and Z-GLASS.

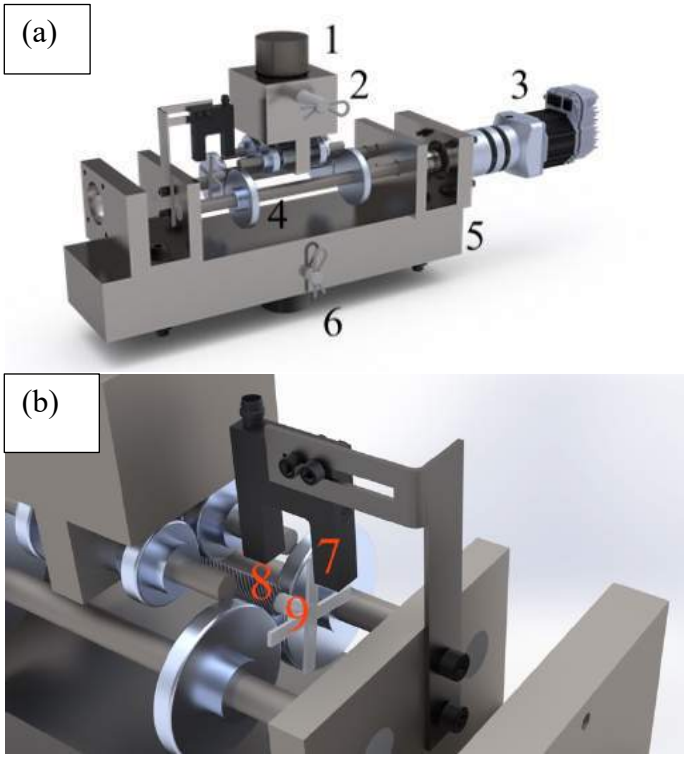

Figure 1. (a) CAD rendering of flexural test fixture. 1. top post, 2. head, 3. motor, 4. roller, 5. base, 6. bottom post. (b) Close up CAD rendering of fork sensor. 7. fork sensor, 8. sample, 9. propeller

Z-HIPS was selected because it is a commonly used filament, Z-ULTRAT was selected because it is the strongest filament offered by Zortrax™, and Z-GLASS was selected because it is a transparent filament. The 3D printed samples were printed vertically to obtain a circular cross-sections, whereas horizontal printing would result in a polygonal cross-section, due to limitations of the 3D printing process.

CAD renderings of the fixture developed to determine a sample's true flexural strength are shown in Figure 1. The fixture was developed for use with an Instron™ 5900 series Universal Testing System. Like a standard four-point bend fixture the base (part 5 in Figure 1) remains stationary as the head (part 2 in Figure 1) travels down (at a rate of 5 - 15 x10^{-3} mm/s to achieve quasi static loading) to apply the bending load. Unlike a standard four-point bend fixture, where the sample (part 8 in Figure 1) rests on two support anvils and load is applied via two loading anvils, the sample here is cradled between eight rollers (part 4 in Figure 1). The sample is rotated (at consistent rates ranging from 80-125 rpm) via a driveshaft connected to a Teknic™ servo motor (part 3 in Figure 1), model #CPM-MVC_2311S_RQN. In order to reduce undesired force concentrations, it is important that sample rotation speed remain consistent. Consistent rotation is accomplished by attaching a lightweight 3D printed propeller (part 9 in Figure 1) to the end of the sample where propeller blade passes can be recorded by an Automation Direct fork sensor (part 7 in Figure 1), model #PSUR-0N-3F. The speed of the sample is calculated and autonomously adjusted by an Arduino based controls system that uses fork sensor readings and elapsed time as key inputs.

The bending moment applied by the head onto the sample at failure is given by

$$M = Fd \tag{1}$$

where F is half of the load applied by the head and d is the distance between a lower roller and an upper roller (40.9375 mm in this case).

The resulting bending strength of each sample is given by

$$\sigma_{bending} = \frac{My}{I} \tag{2}$$

where y is the radial distance, and I is the second area moment of inertia of the sample, given by

$$I = \frac{\pi}{4}(r_o^4 - r_i^4) \tag{3}$$

where, r_i is the inner radius of the sample and r_o is the outer radius of the sample.

RESULTS

Preliminary tests were conducted on the Z-HIPS samples and the borosilicate samples. These results are shown in Table 1.

Table 1: Flexural strengths of glass rods and 3D printed tubes

Material	Measured	Literature
Z-HIPS	19.20±0.842 MPa	29.30 MPa [2]
Borosilicate	64.12±3.05 MPa	150 MPa [3]

DISCUSSION

As discussed earlier, the objective of this experiment was to measure sample's true flexural strength by ensuring failure occurs at the weakest point via critical flaw activation. Comparing the measured flexural strengths of the borosilicate and Z-HIPS to strength values found in literature [2-3], it is seen that the measured flexural strength is lower than the literature value for both materials. This is due to the critical flaws of the samples experiencing maximum states of tensile stress due to sample rotation. The Z-HIPS samples failing at lower stress levels than predicted by literature may be due to the 3D printing manufacturing process. Variables in the tube printing process that could affect strength include: tube printing orientation [4], cooling rate of filament, print quality, and layer thickness. It has been observed that printing orientation affects strength [4], therefore utilizing a vertical printing process may have produced a weaker sample, that fails via delamination. This occurs because the interlayer strength of a 3D printed part is less than its intralayer strength, and the bending stress is oriented perpendicular to the printed layers in a vertically-printed sample. Additionally, two factors of the printing process that were adjusted for greater print speed (i.e., layer thickness and print quality) may have also affected the strength. The borosilicate samples also failed at lower stress levels than predicted by literature, likely due to surface defects. Surface defects would result in stress concentrations, damaging the samples and reducing their strength.

The advantage of this methodology lies in the activation of the critical flaw in each sample, causing it to experience a maximum state of tensile stress. Hence, the true flexural strength of the samples can be measured. However, there are limitations to this methodology that must be mentioned. Principally, this methodology is applicable to cylindrical samples that fail in a brittle manner. Ductile samples cannot be used, because upon plastic deformation rotation ceases. Secondly, due to the rotation of the specimen, the specimen may endure fatigue effects as each point on the surface is cycled between a stage of max tension and max compression per revolution. Thirdly, there is rolling fatigue at the roller/sample interfaces. Issues that may present are crushing effects and sample surface degradation. These issues may contribute to sample failure at a contact point, which would result in a lower than actual flexural strength value. The findings of this developed methodology are applicable to where understanding a material's true flexural strength is paramount.

KNEE CONTACT FORCES IN TRANSTIBIAL AMPUTEES: IMPLICATIONS FOR REHABILITATION AND LIFELONG FITNESS EXERCISES

INTRODUCTION

Osteoarthritis (OA) is a degenerative disease affecting joint cartilage and bone tissues. Transtibial (TT) amputees are at high risk for knee OA due to their abnormal knee biomechanics and high prevalence of overweight/obesity [1-3], both of which likely lead to increased knee joint contact compressive forces (KJCCFs) [4]. While one study suggested that regular participation in exercise may lead to better physical and mental well-being [5], most previous studies of TT amputee knee biomechanics were focused on gait, while few studies have considered non-impact exercises such as cycling and elliptical training [6,7]. Thus, there is a need to better characterize OA-related TT amputee knee biomechanics among different exercises in an effort to provide evidence-based guidelines for rehabilitation and lifelong fitness sustainment exercises that mitigate knee OA in TT amputees.

Thus, the objective of this study was to calculate KJCCFs during gait, cycling, and elliptical exercises for TT amputee and control participants. Hypotheses were (H1) KJCCF would differ due to exercise type (gait, cycling, and elliptical) for the amputee group, (H2) KJCCF would differ due to exercise type (gait, cycling, and elliptical) for the control group, and (H3) KJCCF would differ due to participant status (amputee, control) for the same exercise (gait, cycling, and elliptical).

METHODS

Experimental Procedure. Experimental data were available from a prior study [6]. All protocols were approved by our Institutional Review Board. Control and amputee participants were in good health with no history of cardiovascular/respiratory diseases, diagnosis of psychiatric illnesses, restrictions in physical activities, or extreme weight loss/gain in the past six months. Women who were pregnant or were trying to conceive were excluded from this study. Ten unilateral transtibial amputees (7 males and 3 females, aged 32.2±6.7, BMI 25.2±2.6) and ten control participants (8 males and 2 females, aged 22.1±1.8, BMI 24.4±3.1) performed a minimum of three trials for gait, cycling, and elliptical exercises. Amputee participants performed these three exercises with an Energy Storage and Release (ESAR) prosthesis (Vari-Flex, Ossur, Reykjavik, Iceland) fitted by a certified prosthetist. An enhanced Helen Hayes marker set with 32 markers was used to identify anatomical landmarks. Kinematic data were recorded with 12 cameras at 150 Hz using Cortex (Motion Analysis Corp., Santa Rosa, CA, USA). Kinematic data were processed and filtered (4th order Butterworth, 6 Hz cutoff frequency) in Cortex. Gait trials were conducted at self-selected speeds with 4 force plates (AccuGait AMTI, Watertown, MA, USA). Cycling and elliptical trials were performed at a cadence of 70 RPM at moderate machine resistance levels for 30 seconds using a stationary bike (Lifecycle GX, Life Fitness, Schiller Park, IL, USA) and elliptical machine (XE-795, Spirit Fitness, AR, USA). Experimental setups for gait, cycling, and elliptical exercises are shown in Figure 1.

Figure 1. Experimental setups for gait (left), cycling (middle), and elliptical (right) experiments for control and amputee participants.

Both cycling and elliptical pedals were instrumented with 6-axis load cells (AD2.5D, AMTI) and fitted with a custom marker configuration to track pedal position and orientation relative to a global coordinate system [6]. MATLAB (MathWorks, Natick, MA, USA) was used to filter force plate and load cell data (4th order Butterworth, 10 Hz cutoff frequency) and to format kinematic and kinetic data for use in OpenSim (Stanford University, Palo Alto, CA, USA).

OpenSim Analyses. An OpenSim musculoskeletal model [8] developed for relatively large knee flexion angles (as observed for cycling and, to a lesser extent, elliptical) was used. The OpenSim scaling tool was utilized to scale the model for each participant. The Inverse Kinematics tool was used to calculate joint kinematics. Those results were then loaded into the Residual Reduction Algorithm tool to correct the joint kinematics and optimize the scaled model using ground/pedal reaction force data. The Static Optimization tool predicted muscle forces that were subsequently inputted to the Joint Reaction tool to calculate KJCCFs. Those results were interpolated to one full gait cycle (0% = 1st heel strike, 100% = 2nd heel strike) or one crank revolution for cycling (0% = 1st top dead center [0 deg.], 100% = 2nd top dead center [360 deg.]) and elliptical (0% = 1st pass most anterior position [0 deg.], 100% = 2nd pass most anterior position [360 deg.]). Three trials for each exercise were averaged for each of the control dominant and amputee intact legs. KJCCFs were normalized by body weight.

Statistical Analysis. Maximum normalized KJCCF values that were two standard deviations (SDs) away from the mean were considered outliers and were subsequently removed from statistical analysis. Significant differences were conducted using a two-factor repeated measures of variance (ANOVA) and post-hoc Tukey tests at 95% confidence. A Bonferroni adjustment of three (due to three types of exercise) was applied on the maximum kinetic values for each hypothesis, with statistical significance defined as $p<0.0167$.

RESULTS

Kinetic data from nine controls and eight amputees were included for statistical analysis. Maximum gait KJCCF for one control and elliptical KJCCF for one amputee were 2 SDs higher than average, and another amputee exhibited abnormally low walking speed (2.5 SD below average), so data for those three participants were excluded. Significant differences for maximum KJCCF due to exercise type were found within each population ($p<0.001$) (Figure 2), supporting H1 for amputees and H2 for controls. Specifically, KJCCF was lowest in cycling compared to gait and elliptical for both control and amputee groups (gait>elliptical>cycling). Significant differences were found across control and amputee legs with the KJCCFs of the intact amputee legs higher than the dominant control legs (supporting H3) in gait ($p=0.004$) but not in cycling ($p=0.998$) or elliptical ($p=0.499$).

DISCUSSION

Novel results of this study predicted KJCCFs for TT amputees in gait, cycling, and elliptical exercises using OpenSim. These findings suggest that non-weight bearing and non-impact activities (such as cycling) are preferred exercises for reducing joint contact loading and, consequently, minimizing OA risk for both TT and control populations. Clinical implications of the results indicate that cycling should be emphasized for rehabilitation and fitness to minimize risk of knee OA. This conclusion generally agrees with earlier research [6] which suggested that, for TT amputees, cycling likely produce normal (i.e., similar to controls) cartilage loading patterns due to their non-weight bearing mechanism that constrains the feet with pedals. Because this current study found that KJCCF in elliptical exercise was lower than gait, elliptical exercise should be preferred over gait. This study also demonstrated that ESAR prostheses do not completely restore natural knee biomechanics in gait [9-11]. However, lack of significant differences between controls and amputees for cycling and elliptical exercises suggest that ESAR appears to be suitable for those exercises.

This study has several limitations. First, the number of participants were relatively low, partly due to difficulty recruiting amputee participants that met the exclusion/inclusion criteria. Second, cycling and elliptical experiments were performed with only one resistance level; future work should consider varying resistance levels. Third, only one specific type of ESAR (Vari-Flex) was used. A prior study suggested that prosthetic design may influence biomechanics in TT amputees [12]. Fourth, the Static Optimization tool predicted muscle-tendon forces from published literature; future work should predict KJCCF with EMG data using the Computed Muscle Control tool in OpenSim.

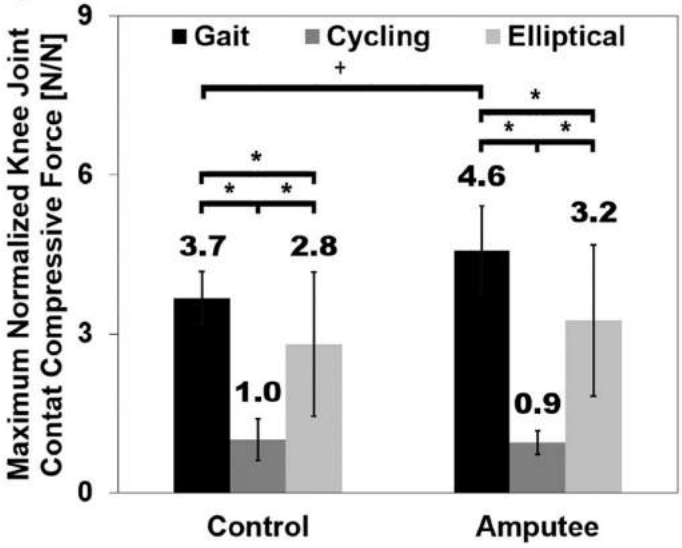

Figure 2. Maximum normalized knee joint contact compressive forces [N/N]. Mean ± 1 standard deviation values shown. * = significance due to exercise type within a group (gait vs. cycling vs. elliptical; $p<0.0167$). + = significance due to participant status within an exercise (amputee vs. control; $p<0.0167$).

A REPEATABLE METHOD FOR IN-SITU JOINT ALIGNMENT OF DISARTICULATED HUMAN KNEES DURING IN-VITRO MECHANICAL TESTING

Zachary A. Pinkley (1), Kate J. Benfield (1), Trevor J. Lujan Ph.D. (1)

Boise, Idaho, USA

INTRODUCTION

Accurate kinematic alignment is crucial for in-vitro biomechanical testing of human joints in a laboratory setting. Misalignment of knee joints leads to significant errors in joint kinematics and resultant forces, with joint alignment variations causing a 2-3 times increase in kinematic errors [1]. For example, minor positional changes due to alterations in testing procedures, such as removing the joint from the testing apparatus, have been shown to cause significantly larger forces during position-control testing [2]. Further, in total knee arthroplasty (TKA), joint misalignment can cause component loosening, increased wear, and early failure [3]. For these reasons, accurate positioning of the knee joint is critical.

While previous in-vitro studies have developed methods to accurately align whole human knee joints prior to biomechanical testing [1,2], no such study has developed a method to re-establish natural alignment for disarticulated knees. Joint disarticulation, where soft tissue restraints are removed prior to testing, can be a necessary step in research that requires early access to the joint capsule [4]. For example, meniscus and cartilage experiments may require imaging of these tissues prior to testing. Therefore, the objective of the current study is to define and quantify a method to repeatedly position disarticulated knees to their natural intact alignment (in-situ position).

METHODS

This study used a surrogate bone model consisting of a cortical foam replica of a human knee joint (Sawbones) to address the study objective. To simulate a natural human knee, the tibia-replica was fitted with foam pads to represent the medial and lateral menisci, and elastic bands were attached with screws on the medial and lateral epicondyles to imitate the medial cruciate ligament and lateral cruciate ligament. Bone replicas were cut 17 cm distal from the joint line using a custom-made cutting guide. Both the femur and the tibia replicas were cut perpendicular to the anatomic axis of the tibia in order to preserve natural joint angles of the leg during testing [3,5]. Anatomical landmarks of the tibia and femur were marked with screws and digitized to embed joint coordinate systems using the Grood-Suntay (G-S) convention [6]. The transformation matrix between embedded coordinate systems was established using intermediate "marker" coordinate systems by attaching kinematic markers on each bone (**Fig 1A**). This simplified the digitizing process during testing [7].

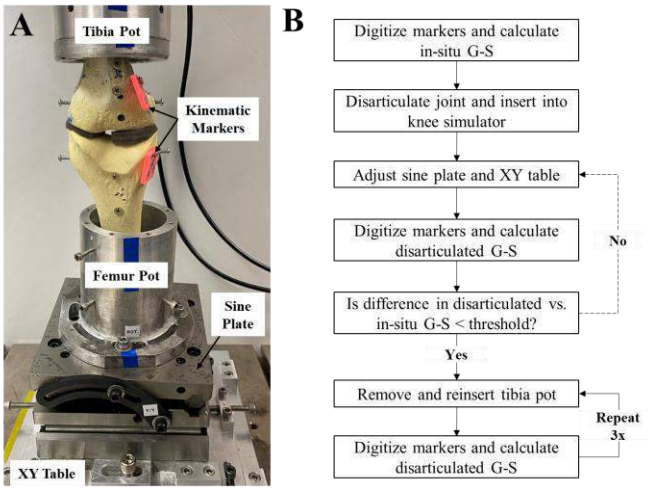

Figure 1: Test methods. A) A Sawbones model was inserted in a knee motion simulator. B) Flowchart of test procedure. In-situ kinematics were calculated, the joint disarticulated, and the kinematics were then re-established and tested for repeatability.

The tibia-replica was potted in a cylindrical mounting pot using a catalyzed polymer resin (Bondo) and inserted into a custom-made knee fixture device attached to an Instron E10000 mechanical test system (**Fig 1A**). The knee fixture device allowed for adjustments to clinical rotations and translations following the G-S convention. Medial/lateral (M/L) and anterior/posterior (A/P) adjustments were made using an XY table while flexion/extension (F/E) and varus/valgus (V/V) rotations were adjusted using a compound sine plate (**Fig 1A**). Axial translations were controlled by the Instron mechanical testing system, and internal/external (I/E) rotation adjustments were measured using a digital angle finder and rotating the femur pot.

An experimental protocol was developed to quantify errors in joint positions after disarticulation (**Fig 1B**). First, the "intact" joint was allowed to freely hang from the tibia pot, and marker locations were digitized (Revware Inc, accuracy ±0.05 mm). These locations were input into a custom MATLAB code that calculated the in-situ G-S data. The joint was then disarticulated and the femur pot was bolted into the testing apparatus. The "disarticulated" kinematic markers were then digitized and adjustments to the femur and tibia were made incrementally until the joint was within ±0.5 degrees for rotations and ±1.0 mm for translations of the in-situ position (this required 5-8 iterations). Once the in-situ position had been re-established, the tibia was removed and reinserted into the test apparatus, and the kinematic markers were re-digitized. The tibia removal-insertion process was done 3 times for each trial. In total, three trials were conducted of the entire protocol (**Fig. 1B**). Differences in G-S rotations and translations at each time point were calculated relative to the in-situ position (i.e. error), and a repeated measures ANOVA test was performed to determine the effect of time points on these errors ($p < 0.05$).

RESULTS

The errors between the in-situ and disarticulated joint positions did not significantly change after repeated removal of the tibia from the test system (**Fig. 2**). Errors in re-establishing the in-situ rotations never exceeded a difference larger than 0.60 degrees, with an average rotational difference of 0.33 degrees. Errors in re-establishing the in-situ translations never exceeded a difference larger than 1.05 mm, with an average translational difference of 0.50 mm.

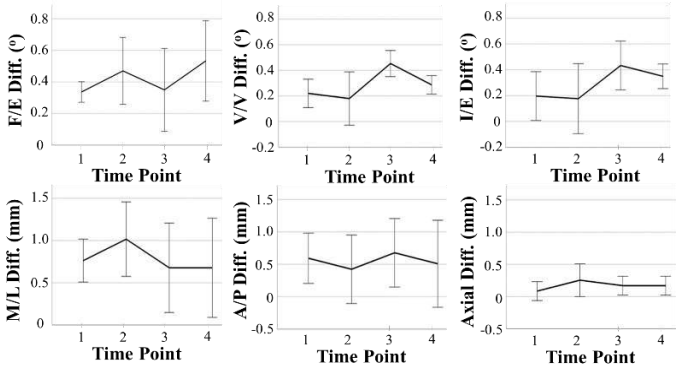

Figure 2: Error in reproducing in-situ knee position (rotations and translations). Errors were less than 1° and 1.05 mm at all time points.

DISCUSSION

For the first time, this study provides a method to re-establish natural joint alignment accurately and repeatedly for disarticulated human knees using G-S clinical rotations and translations. Using this method, the disarticulated femur and tibia were positioned on average to be within ±0.33 degrees and ±0.50 mm of the targeted in-situ rotations and translations respectively. While we saw some relatively high standard deviations, they can be explained in part by the inherent error of using the digitizer, which was found to be ±0.07 degrees for rotations and ±0.13 mm for translations (data not shown).

Future in-vitro mechanical experiments of cadaveric joints can benefit from this developed method. For example, our lab has previously simulated knee motion in whole knee joints to visualize meniscus wear using 3D optical scanning [4]. This requires disarticulating the knee joint prior to testing and then removing the knee joint at various time points, similar to our test protocol (**Fig. 1B**). While this experiment was successful in visualizing meniscus wear (**Fig. 3**), the findings had limited clinical significance due to improper kinematic alignment which led to significant damage on the articular surface of the tibia when subjected to joint loading. This misalignment caused an uneven distribution of force on the joint leading to crack propagation on the lateral region of the tibial surface (**Fig 3B**). This method can therefore be used to ensure that significant force concentrations due to malalignment are avoided. Additionally, this method can benefit in-vitro research and development of TKA implants. Misalignment of TKA implants has been shown to cause increased wear, premature component loosening, and even implant failure in in-vivo cases [3]. This method using G-S kinematics can provide a way to avoid such problems for in-vitro testing or design of TKA devices.

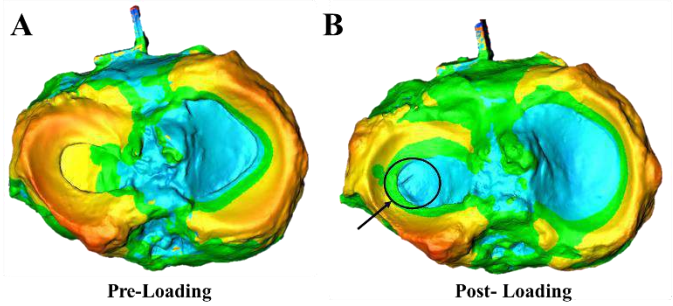

Figure 3: Meniscus wear testing of a disarticulated knee joint using optical 3D imaging A) pre- and B) post loading (1 million cycles). Damage occurred to the tibia due to malalignment [7].

Limitations of this study include the use of foam inserts and rubber bands as substitutes for menisci and ligaments, which led to a significant internal compressive force being applied to the knee joint replica while in-situ. This force was recreated during the digitization of disarticulated marker positions and may have caused slight movements of the potted femur replica when disarticulated. Another limitation is the lack of testing on variable knee geometry. Human knees can vary greatly, which may result in greater variability in error when re-establishing the in-situ joint position in knee cadavers.

In summary, this is the first study to our knowledge to define and quantify a method to re-establish in-situ knee joint alignment accurately and repeatedly for disarticulated human knees. This was accomplished by using the G-S convention to quantify the in-situ position and guide joint positioning after disarticulation. By improving joint alignment, this study can help advance clinically impactful research in knee biomechanics and TKA technology.

INTRODUCTION

Aortic aneurysms result from structural changes to the aortic wall tissues leading to altered mechanical behavior. Current criterion for aortic aneurysm surgery intervention is based on the size of the aneurysm, with elective surgery recommended for a maximal diameter of 4.2 – 5.5cm [1]. However, mechanical behavior of the aortic wall tissue also plays an important role in predicting the rupture/dissection risks. Structure-based constitutive models can relate changes in structural constituents of aortic wall tissue (elastin and collagen fibers) to altered stresses and deformations. This research focuses on the prediction capabilities of these models in capturing the stress-stretch nonlinear aortic tissue behavior curves, when samples are categorized by structural changes (level of elastin fragmentation, EF – graded by a pathologist) [2] or in vivo imaging parameter (wall shear stress, WSS). Categorizing samples based on non-invasive indices (such as WSS) potentially improves Finite Element Analysis for clinical application as different constitutive models can be used for areas under different state of mechanical loading.

METHODS

Experimental planar biaxial mechanical testing data (3 protocols of controlled stretch ratio, 1:1, 1:05, and 05:1, both circumferential-11 and axial-22 directions) of 46 ascending thoracic aortic tissue samples taken from 12 patients post-surgery (age: 55.5 ± 9 years old, 11:1 male to female, all patients have Bicuspid Aortic Valve) were fitted by a commercial modeling software called HYPERFIT [3] to the Holzapfel-Ogden-Gasser 2005 (shortly, HOG-2005) model [4]. Samples were categorized into Normal and High WSS, 0- (normal) and 1- (mild) graded elastin fragmentation (EF). By randomization, 70% of the behavior curves in each category were used to obtain the average mechanical behavior (see Figure 1). The model parameters of this curves were applied towards the other 30% (named the predictive group). The Normalized Root Mean Square Error (NRMSE) values between the model and experimental data were calculated to assess the predictability of HOG-2005 model for the predictive group. Prediction capabilities were compared between the models constructed on categorized data versus *no categorization* (the average mechanical behavior was determined from 70% of all samples) through paired t-tests. The process was repeated 10 times in each category to ensure good distribution of samples in the predictive group.

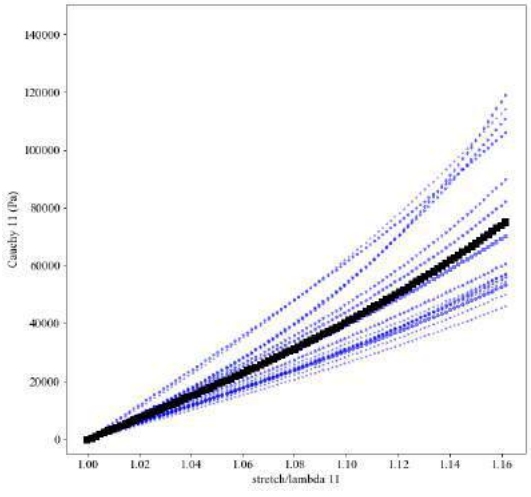

Figure 1. Construction of the Average Mechanical Behavior (black data points) from sample-specific mechanical behaviors (blue data points) by taking average of sample-specific Cauchy stress values at each stretch data point

HOG-2005's Strain Energy function:

$$\psi = \mu(I_1 - 3) + \sum_{i=1,2} \frac{k_1}{2k_2}(e^{k_2(1-\rho)(I_1-3)^2+\rho(I_{4i}-1)^2} - 1) \quad (1)$$

$$I_{4i} = A_{0i} : C \quad (2) \quad \text{and} \quad A_{0i} = a_{0i} \times a_{0i} \quad (3)$$

$$a_{01} = \begin{bmatrix} cos\ \varphi \\ sin\ \varphi \\ 0 \end{bmatrix} \text{ and } a_{02} = \begin{bmatrix} cos\ \varphi \\ -sin\ \varphi \\ 0 \end{bmatrix}$$

where μ is the stress-like material parameter referenced to matrix properties, I_1 is the (pseudo-) invariants of C, C is the right Cauchy-Green tensor, $I_{4i,\ i=1,2}$ are the (pseudo-) invariants of C, $A_{0i,\ i=1,2}$ are the structural tensors referenced to individual family of members, $a_{0i,\ i=1,2}$ are the direction vectors defining the orientation of fiber families, k_1 is the stress-like material parameter referenced to fiber properties, k_2 is the dimensionless material parameter referenced to fiber properties, φ is the structure parameter defining the mean orientation angle of fiber families from circumferential direction in the undeformed configuration, ρ is the dimensionless parameter (weight factor) within [0; 1]. The modeled Cauchy Stresses in circumferential and axial directions are then calculated, respectively, as:

$$\sigma_{11,i} = \left(\lambda_1 \frac{\partial \psi_{11}}{\partial \lambda_1}\right)_i \quad (4) \quad and \quad \sigma_{22,i} = \left(\lambda_2 \frac{\partial \psi_{22}}{\partial \lambda_2}\right)_i \quad (5)$$

where σ is the Cauchy Stress, λ is the stretch, 11 represents circumferential direction while 22 represents axial direction of the aortic wall tissue.

NRMSE values were calculated as:

$$NRMSE = \frac{\sqrt{\frac{1}{n} \times \sum_{i=1}^{n} (y_e - y_m)^2}}{|y_a|} \quad (6)$$

where y_e is the experimental value, y_m is the model value of the fitted function, i is the data-point index, n is the number of data points while y_a is the mean value from experimental values calculated as follows:

$$y_a = \frac{1}{n} \times \sum_{i=1}^{n} y_e \quad (7)$$

RESULTS

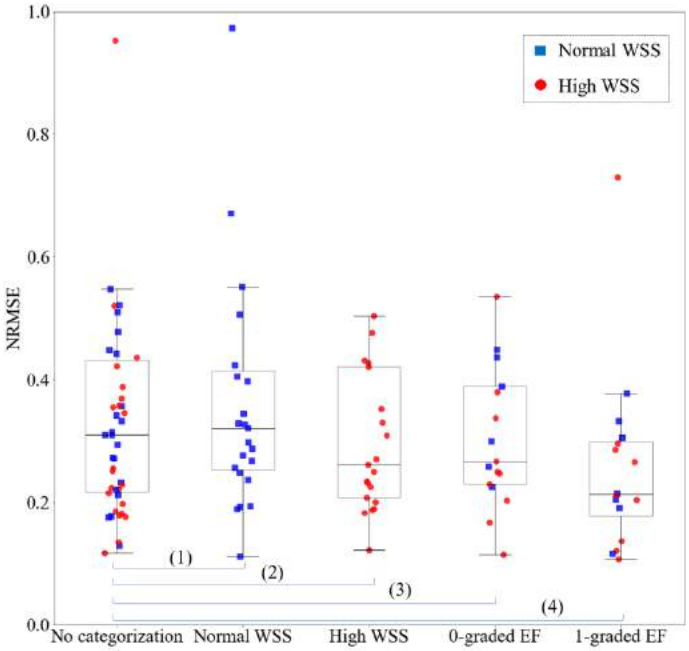

Figure 2. NRMSE comparison (each data point represents the average values of NRMSE for the sample over the 10 iterations)

Table 1. p-values from paired t-tests between No Categorization and respective category

NRMSE comparison (sees Figure 2)				
Test #	(1)	(2)	(3)	(4)
p-value	0.0511	0.0161*	0.6160	0.0220*

**Statistically significant at 0.05*

It can be observed that by categorizing samples into groups such as High WSS or 1-graded EF, the average mechanical behavior can predict better the mechanical behavior of samples that belong to the predictive group (by statistically lowering NRMSE values).

DISCUSSION

This abstract demonstrated the potential of incorporating useful information such as in vivo imaging (WSS) and histological (EF) data to improve the predictability of constitutive model on a new experimental mechanical behavior dataset (see Table 1).

This method of constructing the average material mechanical behavior is also applicable to screen other factors that may contribute to the rupture/dissection risks such as level of Collagen Distribution and Alterations. In-vivo measurable parameters have the added potential of being able to be measured non-invasively through medical imaging. Research on a larger population dataset will further investigate the role of WSS and other mechanics-based parameters that can be estimated in vivo.

INTRODUCTION

The Research Experiences for Undergraduates (REU) Site in Biomedical Engineering in Simulations, Imaging, and Modeling (BME-SIM) at East Carolina University was funded by NSF in 2014 (EEC-1359183), 2017 (EEC-1659796), and 2020 (EEC-1950507). The goal of the BME-SIM REU program is to broaden participation by providing authentic research experiences to students who are traditionally under-represented in engineering. Historically, women have been underrepresented in STEM fields- from 2017-2018, women made up only 21% of those awarded with a BS in Engineering [1]. This underrepresentation is thought to be caused by sexism in the field, a lack of role models, and low self-efficacy beliefs [2]. Self-efficacy is our own perceived ability to perform certain tasks, influenced by our previous mastery experiences, watching others perform the task, or receiving feedback regarding our abilities to perform the task [3].

Research experiences can be vital in developing one's sense of competence within a domain [4]; Interestingly, however, it's been found that mastery experiences, or accomplishments, have a higher influence on males' self-efficacy, while women's self-efficacy is influenced more by vicarious experiences and verbal persuasions [5]. Women may lack this sense of self-efficacy due to a small number of role models in the field and little encouragement due to subtle gendered biases [5].

Women are stereotyped as warm, kind, and nurturing, often having communal goals, whereas men are defined as competitive, logical, and competent, often pursing more agentic goals [5]. STEM fields are characterized with more masculine traits leading women to feel as though the female gender is not as STEM-oriented as male counterparts, thus pursuing lower positions and feeling a lowered sense of confidence and self-efficacy [5]. Moreover, women tend to be modest when discussing their academic achievements, notably in public spaces, whereas men tend to overestimate their achievements [6]. Daubman et al.'s study questions that it is not lack of confidence that influences how one presents their academic achievement, but rather a need to maintain presentation of gender roles [6]. Studies have shown that women who chose to self-promote, thus violating gender norms, were perceived more negatively than male counterparts who behaved in a similar manner [7]. This modesty could potentially be damaging to a woman's career- if she fears social back-lash due to self-promotion and competitiveness or feels she is not as competent as her male counterparts, she may be inadvertently opting out of career-enhancing opportunities [3, 7].

Given that women will alter their self-promotion based on social contexts, this project will investigate gender differences in confidence of research abilities before and after participating in a Biomedical Engineering REU program. Confidence will be assessed by reviewing personal statements, essays that should highlight an applicant's reasons for pursuing a program as well as their past accomplishments, and student self-reported confidence levels.

METHODS

This study was approved by the Institutional Review Board at ECU and informed consent was received by all participants. The BME-SIM program is a 10-week residential summer program that provides students with an authentic research experience, professional development, including writing and communication workshops, and mentoring opportunities [4]. During the application process, students are asked to submit a personal statement. This statement is a critical component of the applicant reviewal process, shedding light on the student's personality, goals, and accomplishments. At the end of the program, students are asked to submit an updated personal statement as if they were applying to graduate school. Student surveys were completed on the first and last day of the program. Students reported

their progress towards mastery of knowledge and skills using a 10-point Likert scale, including confidence in research abilities. These data indicated that women who participate in the program have a significantly lower sense of self-efficacy in research abilities when compared to male counterparts in both pre- and post-program participation, but no differences in actual performance [4]**.** A total of 55 students have participated in the program from 2014-2019.

A sub-set of the students (n=16) were selected for further analysis in this study, with eight being men and eight being women. Pre- and post-program personal statements were evaluated by a group of 11 faculty reviewers of varying gender and STEM disciplines. Each statement was carefully anonymized removing references to gender, home university, and other identifiers. Each personal statement was assigned to three faculty reviewers. Faculty reviewers were asked to highlight portions of statements they found to be good in green, bad in red, and interesting in yellow. Along with highlighting, they were asked to make comments elaborating on why they chose to highlight specific portions of text. Following statement mark-up, reviewers were asked to fill out a survey rating perceived characteristics of students, notably perceived confidence (five-point Likert scale). To enable comparison, student self-reported scores were converted to a five-point scale.

A total of 639 comments from reviewers were categorized by varying themes, garnering an 85% interrater reliability rating; however, this study will focus on only confidence categorizations. Comments categorized as confidence must either include the word "confidence," or mention the student's achievements, strengths, or positive attributes; however, these comments could discuss these characteristics in a positive or negative way. A few examples of how these confidence-related comments can be either positively or negative received are as follows: "the writer shows humility through the word choice --grateful--and therefore described his ability to get scholarships without bragging" coded as green; "This is not for the writer to say, it is boastful and in fact may not be true" as red; and "self-conscious" as yellow. Once all data was collected, faculty survey results, highlights, and commenting were compared to students' self-reported characteristics.

Quantitative data was compared using a Student's *t-test (paired or two-sample unequal variance)* to find if confidence in research skills was statistically different pre- and post- program, and across gender.

RESULTS

Prior REU data found that women's self-reported confidence levels were not as high as male counterpart's when surveyed both pre- and post-program [4]. For this sample of the participants, self-reported confidence was lower both pre- and post-program for women as compared to men (Table 1). Although statistically significant in the total cohort, these differences were not significant in our sub-population. Faculty's perceptions of confidence from the women's writing was lower than their perceptions of the males in the pre-program personal statements; however, the women's faculty-perceived confidence made a leap in the post-program statements, even being higher than the male's faculty-perceived confidence (Table 1). However, none of these differences were statistically significant in our small sample.

Table 1: Comparison of Faculty's Perceived Confidence Compared to Students' Self-Reported Confidence

	Faculty Confidence Rating		Student's Self-Reported Confidence	
	Pre	**Post**	**Pre**	**Post**
Men	4.1 ± 0.87	4.18 ± 0.73	3.0 ± 1.2	4.25 ± 0.89
Women	4.0 ± 1.09	4.35 ± 0.65	2.5 ± 0.76	4.13 ± 0.84

Of all comments between pre- and post-program statements, about 9.4% of comments were categorized as confidence related. Men were found to have the most green confidence comments in both the pre- and the post-program statements (Table 2).

Table 2: Comparison of Confidence Comment Amount by Statement and Gender

	Pre		Post	
	Men	**Women**	**Men**	**Women**
Green	18	9	13	6
Yellow	2	1	1	4
Red	0	4	1	1

DISCUSSION

The increase of faculty-perceived confidence in the women's personal statements seems to correlate with the women's self-reported self-efficacy levels. However, the faculty perceived limited increase in confidence in the men compared to their self-reported increase in self-efficacy. Men had more green coded confidence comments, indicating a possibility that their personal statements are being perceived more positively than their female counterparts. This correlation may reveal that writing could have a role in conveying one's level of confidence in relation to the writing-topic. Moreover, it seemed that faculty reviewers appreciated confident students, but were wary of overly confident students. Comments such as "overly confident" were coded as red, indicating the reviewer saw the comment as negative, whereas comments such as "student is confident without being cocky. they are aware of how they would benefit from the program" were coded as green to indicate the reviewer's positive perception. However, this possible link between highlighting, perception, and comment categorization is still being investigated.

Overall, confidence in research ability did increase following participation in the BME-SIM program. Data found differences between how men and women perceive themselves, and how faculty seem to perceive students based on their writing. This may have further implications of investigating how confidence is displayed between men and women, and possibly have implications for future research regarding how review boards evaluate personal statements; notably, in how confidence is perceived. It is not a question of one being too confident, but how we decide to characterize confident individuals.

ACKNOWLEDGEMENTS

A COMPUTATIONAL TOOL TO AUTOMATE THE ANALYSIS OF STRESS-STRAIN DATA FROM TENSILE TESTS OF SOFT TISSUE

Miranda L. Nelson, Derek Q. Nesbitt, Trevor J. Lujan

Mechanical & Biomedical Engineering
Boise State University
Boise, Idaho, United States

INTRODUCTION

Stress-strain curves are commonly generated to analyze the mechanical tensile behavior of biological materials. In soft tissue, several key material properties can be calculated from these curves, including ultimate tensile strength (UTS), yield strength, energy to failure, and the transition point. The transition point is at the intersection of the toe region and the linear region, which physically represents the point where the crimped collagen fibers are collectively straightened.[1] The transition point defines a safe strain range below the threshold of microtears,[2] and is explicitly included in some constitutive equations used to model soft tissue. Despite its importance, there is no standard method to find the transition point. While a variety of methods have been used,[3-8] no study has reported the accuracy or robustness of their method. Furthermore, there are currently no software tools available to automate the calculation of the transition point, or other material properties of interest. This lack of standardization makes it difficult to compare results across studies and is time inefficient, as each research group has to create their own method. A need therefore exists to develop a standard, fast, and accurate method to calculate the transition point and other tensile mechanical properties in soft fibrous tissue.

Objective. The objectives of this study are to 1) develop a user-friendly program that automates the calculation of mechanical properties from stress-strain curves, and 2) identify the optimal settings to minimize error when calculating the transition point by using synthetic and experimental data.

METHODS

Program Development. A custom graphical user interface (GUI) was created using Python. This GUI allows users to upload stress-strain data and then automatically generates a stress-strain curve with marked points of interest (**Fig. 1**), as well as a .csv file that appends the following mechanical properties: tangent modulus, energy to failure, and stress and strain at ultimate, yield and transition points. The GUI first finds yield as the point of maximum slope[9] and then calculates tangent modulus as a linear fit to the data from yield to 1% strain below yield.[7] The transition point is found when the slope of the stress-strain curve deviates by a certain percent from the tangent modulus. GUI settings allow for users to customize the slope deviation threshold to determine this point. The UTS is the point of maximum stress and rupture occurs 50% below UTS. Energy to failure was approximated using trapezoidal integration to UTS and to rupture.

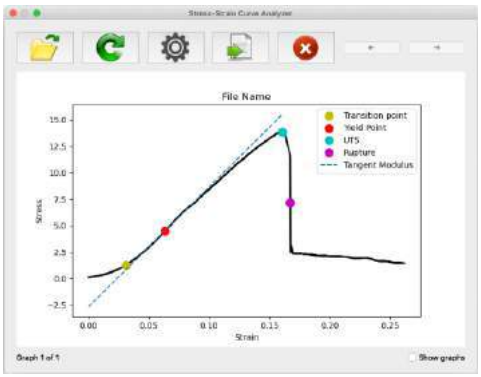

Figure 1: The new GUI automates the generation and analysis of stress-strain curves. Multiple files can be simultaneously uploaded.

Synthetic Data. The software's accuracy was evaluated using synthetic stress-strain curves with known transition points. This data was generated using FEBio studio, a free finite element software program.[10] A single element cube was created with sliding elastic

contact between the cube and the dynamic rigid body. For the constitutive model, a transversely isotropic fiber matrix[11] was selected with a Veronda-Westmann hyperelastic ground substance.[12] Damage evolution was modeled using a quintic polynomial cumulative distribution function. Importantly, one of the user-specified material parameters for this model is the strain at the transition point. This allows for the calculation of error between the stress at the known transition strain predicted by the software (**Fig. 1**) and the actual transition stress being modeled. The effect of modulus slope (low, medium, high) (Fig. 2) and rate-of-damage (low, medium, high) (Figure 2B) on error was analyzed. In addition, the effect of % slope deviation to determine the transition point was tested at 1, 2, 3, 5, 10 and 20%.

Experimental Data. The software's accuracy was also evaluated using tensile test data from our previous study on human meniscus.[8] First, the parameters of the aforementioned constitutive model were calibrated to stress-strain curves from 10 different meniscus specimens pulled to failure along the primary circumferential fiber axis. This resulted in excellent fits for all 10 cases (**Fig. 2**; RMSE = 0.14 ± 0.09). Transition stresses were determined as the stress at the optimized value of transition stretch. The model parameters were optimized with the Levenberg-Marquardt algorithm in FEBio. This experimental data was then analyzed with the GUI (**Fig. 1**) using % slope deviations of 1, 2, 3, 5, 10 and 20%. Error was calculated as the percent difference in the transition point calculated by the GUI and the transition parameter optimized in FEBio.

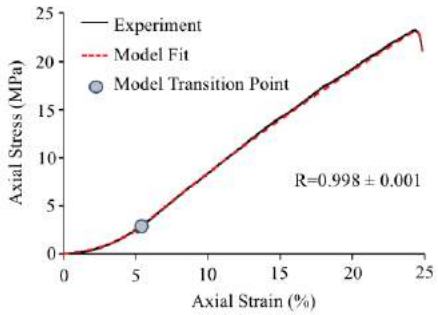

Figure 2: Representative model fit to experimental data.

Statistics. Effect of slope variation on transition error was measured using a one-way ANOVA with Tukey HSD post-hoc for both the experimental and synthetic data. The effect of changing the damage rate and moduli on transition error was measured using a MANOVA with Tukey HSD post-hoc. Significance was set at $p<0.05$.

RESULTS

There were no significant differences in transition stress error due to changing the tangent modulus (**Fig. 3**; $p=0.56$). Similarly, there were no significant differences in transition stress error due to changing the curvature of the stress-strain curve with damage (**Fig. 3**; $p=0.35$). When analyzing synthetic data, the least error in calculating the transition stress was 10.7%, and occurred when using slope deviations of 2% and 3% (**Fig. 4A**). Using slope deviations of 10 and 20% resulted in errors exceeding 72%. When the GUI was used to analyze experimental data, the slope deviation that produced the lowest error for transition stress was 2%, with an error of 3.3% (**Fig. 4B**).

DISCUSSION

A GUI was created that can quickly and accurately find points of interest on a stress-strain curve and calculate material properties. Our GUI was used to identify the optimal settings of a scalar threshold used to find the transition point. Notably, the GUI closely predicted the same transition point calculated using a more complex FE optimization routine. We found that a 3% slope deviation returned the lowest error for transition stress in this study. The error in calculating the transition point was insensitive to changes in the modulus and damage rate of the stress-strain curve (**Fig. 3**). This means that this methodology for calculating the transition point should be relatively robust for the large variations in stress-strain curves typical of soft fibrous tissue.

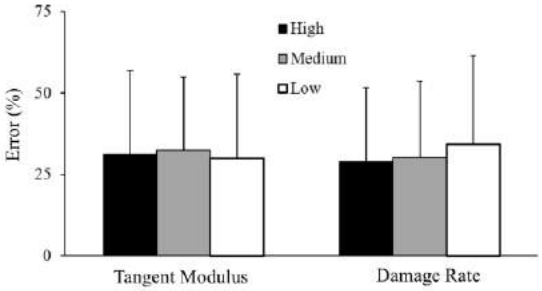

Figure 3: Changes to tangent modulus and damage rate did not affect the error in calculating the transition point (all tests pooled except changing variable; n=18 for each bar).

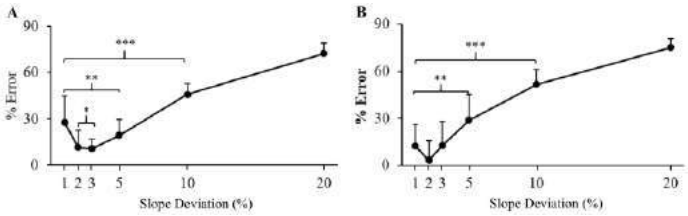

Figure 4: Error in calculating transition stress is lowest when using slope variations between 2% to 3% in A) synthetic and B) experimental data. Significance for all groups under brackets is defined as: *less than 5% group; **less than 10% group; ***less than 20% group ($p < 0.05$).

The material properties calculated by our GUI are typically calculated using custom semi-automated methods that differ between research groups. Our program can help standardize this process and with a runtime under 3 seconds, can dramatically reduce calculation time. In addition, all results can be exported as PDF files (with figures) and .csv files that summarize the material properties of multiple experiments.

The next step for this program is to make it accessible to the biomedical research community be creating a web-based version. We also would like to continue evaluating the accuracy of the software by testing experimental data with more noise. In conclusion, by creating an accurate computational tool to automate the analysis of stress-strain curves, this study can advance the standardization of biomechanical testing in soft fibrous tissue.

INTRODUCTION

Deaf-blindness refers to concurrent vision/hearing impairments that compromise the ability of ~1.5 million Americans to study, work, and live independently [1]. To communicate, the deaf blind community uses a combination of tactile American Sign Language (ASL) and Braille. Although the former is their primary conversation language, it requires an interpreter – deaf blind individuals place their hands over an interpreter's hands to follow the movements as the interpreter signs ASL. While reading Braille does not necessitate an interpreter, it is ~30% slower than ASL, it requires frequent breaks [2-3], and reliable Braille displays are costly. As a result, there is an urgent need to develop low-cost communication aids for deaf blind users that (1) are efficient and easy to use, (2) can be integrated into mainstream communication devices, and (3) can be used independently (without an interpreter).

ASL grammar and vocabulary are expressed using a combination of facial and hand gestures with bodily positional references for context. The language is also complete with a 26-letter alphabet that is finger spelled with single-hand gestures used to convey proper nouns or pop culture references (brands, songs, movies, etc.). Several attempts have been made to design a robotic device capable of fingerspelling. The first prototype developed by SouthWest Research Institute in 1977 has been progressively refined to complete 24 letters of the ASL alphabet, although with low recognition rates in validation studies [4]. These fingerspelling hands often featured dexterous manipulators made from rigid components. Since tactile ASL requires the deaf blind user's hand to be placed on the robotic device, traditional designs are not safe (e.g., the user's fingers could be pinched between a revolute joint when the robotic hand performs flexion).

The PARLOMA project was the first to develop a robotic hand + wrist system specifically targeted to develop a deaf blind remote communication device. While the authors claimed a 90% recognition rate of the handshapes, validation was based on visual observations alone (without tactile feedback) and did not include hard-to-render letters (e.g., E, G, J, M, N, Q, R, T, U, Z) [5]. Furthermore, their system lacks an anthropomorphic feel, has not been evaluated for tactile ASL with deaf blind participants, and cannot discern between words that share the same handshape and motion but need different spatial positioning (e.g., the handshape for "man" and "woman" are the same, but the former requires placement of the hand on the forehead, the latter on the chin).

In an effort to overcome these drawbacks, the goal of project TATUM (Tactile ASL Translational User Mechanism; powered by Interpres) is to develop, validate, and disseminate a low-cost, open-source, 3D printed anthropomorphic robotic arm capable of signing tactile ASL with required positional references. TATUM can be used independently, which is especially important to prevent the isolation of the deaf blind community in times of social distancing, when close contact between people (e.g., a deaf blind individual and interpreter) is discouraged.

METHODS

Design. The hand (Figure 1) component of the system was designed to achieve an anthropomorphic appearance both by sight (as other existing prototypes) and touch (novel design aspect).

First, the portions of the hand that encounter the user are 3D printed from flexible thermoplastic polyurethane (TPU) instead of rigid polylactic acid (PLA). Furthermore, we based our design on an open-source scan of a human hand, that we modified to include flexure joints and attachment methods (Figure 1). To sign the 26-letter ASL alphabet, the hand features 14 degrees of actuation (DOAs) that are supported by pulley-tendon mechanisms distributed across the fingers. The ring and pinky fingers include 2 DOAs each, the first attached to the flexion of

the metacarpophalangeal (MCP) joint, the second coupled to both the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints. The index and middle fingers contain an additional DOA each to sign letters like 'R' or 'V', which require abduction of the fingers (Figure 2). The thumb consists of 2 DOAs allocated to the opposition of the finger and the flexion of its MCP and DIP joints. The final 2 DOAs are reserved for flexion and abduction of the wrist.

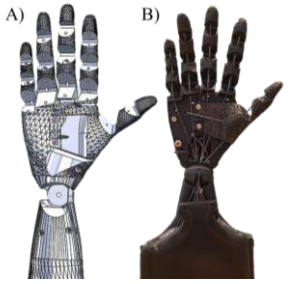

Figure 1: (A) SolidWorks CAD model of the designed hand. (B) 3D printed and actuated hand.

Actuation. The robotic hand includes 14 servo motors. We used 10 Goteck GS-9025MG, 9-gram servos for actuating the fingers and 4 FEETECH FS5103B servos for the wrist and thumb. We selected a microcontroller (Arduino Mega) to control the device in active flexion and passive extension under the contact pressure exerted by the user, while maintaining a signing speed of 1.95 signs per second [3]. TATUM utilizes Interpres (software as a service, SaaS) to translate the communication (e.g., a text input) and send it along to the robotics with the necessary instructions for the motors to produce the desired finger and handshapes.

Validation. To validate the design, we conducted human-subject trials to determine the user's recognition rate of the ASL alphabet. The testing protocol (approved by Northeastern University's IRB) first introduced participants (both deaf blind, n=3 and blind with vision, n=2) to all the letters as signed by TATUM in alphabetical order. Later, participants were asked to recognize the handshapes when presented in a random order. At the end of the session, we solicited feedback from each participant on the speed, feel, and overall ease of use of the device.

RESULTS

Operation of the robotic hand did not cause any harm to the users. Since most deaf blind individuals put their hand on the back of the device, the choice of flexure joints (Figure 2) prevented pinching of the skin. Additionally, the robotic hand transitioned smoothly from one letter to the next, which was achieved by building sufficient compliance into the joints (i.e., they become increasingly thinner more distally, towards the point of flexion to reduce the torque). Furthermore, the robotic hand required a maximum of 6V and 6amps to achieve any handshape. The wrist and thumb motors (which need the most torque to actuate) are current-regulated, preventing overheating of the board.

Overall, we found a 75% recognition rate of the 26-letter ASL alphabet handshapes. Four of the participants struggled differentiating between 'U' and 'V', which have very similar fingerspelling. Secondly, handshapes that need a very precise thumb placement, such as 'M', 'T', and 'O', were often confused. Lastly, participants also failed to recognize the 'R', which requires to move the middle finger behind the index finger by abduction. Since both fingers are acting in the same plane, the movement did not produce a clear enough cross, causing confusion with the letter 'U'.

Nonetheless, the subjects believed the hand 'felt like a woman's hand,' making the device easier to recognize. Also, when the fingers moved into position, the users did not believe that they would be hurt, and they were not concerned about the speed of the movement. This feedback suggests that users can easily acclimate to the device, and minimal design changes could greatly improve the handshapes fingerspelling recognition rates.

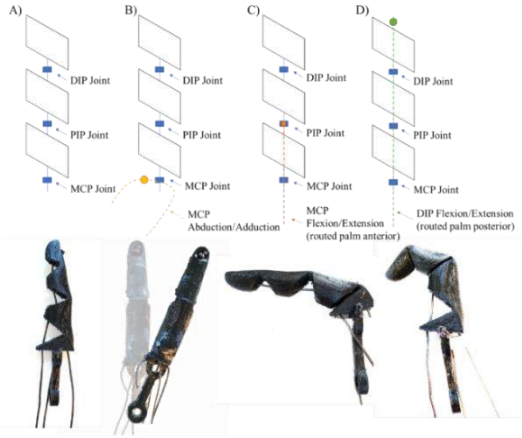

Figure 2: (A) Side-view of the 3D printed finger. (B) Finger abduction at the MCP joint. Finger flexion around the MCP (C) and DIP-PIP (D) joints.

DISCUSSION

Physical restrictions imposed over the past year have emphasized the need for a device that can facilitate independent interactions between deaf blind individuals and their community, while continuing to use their primary conversational language, tactile ASL. To answer this need, we successfully designed a robotic hand with anthropomorphic shape and feel that can sign ASL. While we already achived a recognition rate that is comparable to that of existing solutions, we will leverage the feedback from the users to increase it to at least 90%. We will change the actuation scheme of the thumb to better drive it toward the MCP of the fingers, thus improving the signing of 'M', 'N', and 'T'. Additionally, we will reduce the spacing between the index and middle fingers to better sign bent handshapes ('O', 'C', 'M', 'N', etc.). Finally, we will decrease the size of the proximal phalanx to ensure proper abduction of the middle finger for rendering of the 'R' handshape.

Next, we will develop an elbow platform to perform flexion, abduction, as well as translational motions of the arm, in order to communicate complex words and phrases that require precise spatial references. A body reference platform will also be designed to provide reference points within the body (e.g., forehead and chin). Finally, we will include hybrid Wi-Fi & Bluetooth Chip (ESP32) to connect the system to electronic devices (e.g., computers and cellphones to access documents, emails, and texts). Once these new features are implemented, project TATUM will provide millions of deaf blind individuals with a tool for communicating independently via mainstream communication systems.

ACKNOWLEDGEMENTS

We are grateful for Northeastern University support through the PEAK Summit Award providing preliminary funding for development and validation.

COLLAGEN MICROSTRUCTURAL ORGANIZATION CONTRIBUTES TO NEOVESSEL GUIDANCE DURING ANGIOGENESIS

INTRODUCTION

Angiogenesis, the growth of new blood vessels, provides vascularization to native tissues and is fundamental to engineering new tissues. A limiting factor in tissue engineering is insufficient perfusion across the host-implant interface of tissue grafts [1]. Typically, perfusion is provided through angiogenesis as neovessels sprout and navigate toward regions with insufficient vascular supply. However, interfaces separating distinct tissues have been shown to inhibit neovessel growth between tissues. [2]. Moreover, mechanical factors contribute to limited neovascularization across interfaces [2].

Angiogenic growth is modulated by mechanical factors as sprouting neovessels receive and respond to cues from the surrounding tissue [3]. Advancing neovessel tip cells exert tension on the extracellular matrix (ECM), inducing regions of alignment. Tension-driven realignment of collagen fibrils enables force transmission and cellular mechanosensing over relatively long distances, enabling neovessels to respond to cues from the ECM [3,4]. Previous studies have demonstrated that collagen microstructural organization influences vascular networks, but the underlying mechanisms modulating neovessel guidance remain poorly understood [2,3].

Our objective was to study neovessel guidance by the collagen microstructural organization within the tip cell microenvironment. We developed an image analysis method to quantify the collagen fibril organization adjacent to advancing neovessels and identify regions of tension-driven collagen realignment. We calculated the distance of influence, or the distance from which collagen fibrils were realigned by tension forces. We gained insights into the reach of tip cell tension forces and examined the collagen microstructural organization near an advancing neovessel over time.

METHODS

3D In Vitro Model of Angiogenesis: We used a type I collagen ECM (3 mg/ml) seeded with intact microvessel fragments (30,000 fragments/ml) [5]. This model recapitulates all aspects of the sprouting phase of angiogenesis as neovessels spontaneously sprout from "parent" microvessels, grow over millimeters in length over 3-10 days, and create a perusable vascular network [6].

Multiphoton Time-Series Imaging: After 48 hours of preliminary incubation, a culture was transferred to an incubator on a multiphoton microscope (Bruker Ultima, Billerica, MA). Multi-channel volumetric mosaic images (2 x 2 x 0.9 mm) were acquired every two hours for five days using an excitation wavelength of 780 nm [5]. The collagen ECM and vascular network were imaged using second-harmonic generation (SHG) and autofluorescence signal, respectively.

Analysis of Collagen Microstructural Organization: SHG projections around neovessel tips were divided into rectilinear blocks (30x30 microns) to quantify the preferred collagen fibril orientation, the anisotropy of the orientation distribution, and the relative density. Relative collagen density was determined as the mean intensity of each block normalized to the maximum intensity [2]. A custom program based on the discrete Fourier transform was used to determine the principal fibril direction and fractional anisotropy of the orientation distribution (Matlab, Natick, MA) [5, 7].

Quantifying the Distance of Influence: The distance of influence was determined from the tension-driven realignment of collagen fibrils. Realignment was characterized by collagen fibrils aligned with the neovessel direction with high anisotropy and density (Fig 1). For five independent neovessel tips, data was sampled at five-micron intervals extending 100 microns from the neovessel tip. The distance of influence

was computed as the minimum of the following distances: 1) the average anisotropy dropped below 0.35 or 2) the average angle between the preferred collagen fibril direction and neovessel orientation was greater than 20 degrees.

Neovessel Guidance Analysis: A sprouting neovessel with a well-defined collagen microenvironment was tracked over five time points (Fig 2a). For each time point, the preferred direction was determined from the collagen organization within the tip cell microenvironment. Discretized growth paths spanned +/- 90 degrees from the neovessel's direction at 10-degree increments over a radius of 40 microns (Fig 2b). The path with the highest anisotropy was determined the preferential direction and was compared to the actual growth trajectory (Fig 2c).

RESULTS

Quantifying the collagen microstructural organization around neovessel tips revealed the distance of influence from cellular tension (Fig 1a-b). The following trends were observed with increasing distance from the neovessel tip: 1) decreasing anisotropy and collagen density (Fig 1c) and 2) increasing deviation angle between the neovessel and collagen fibrils (Fig 1d). The average distance of influence was 45 microns (std = 16.6, n=5).

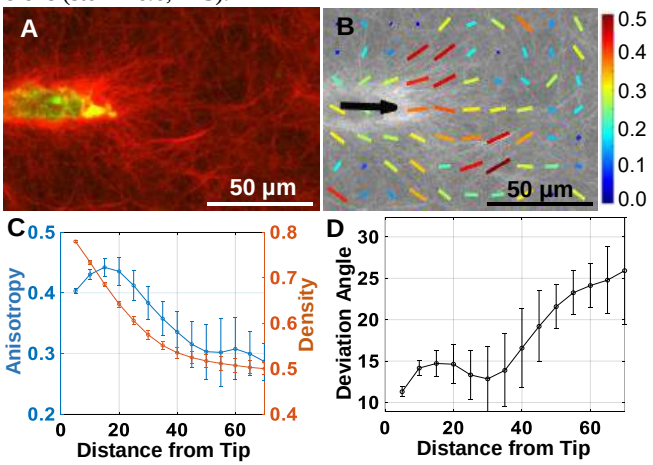

Figure 1. Distance of Influence. (A) Collagen fibril realignment (red) observed in front of a neovessel (green). (B) Collagen around the neovessel tip (grayscale image) with local direction and anisotropy (color). (C-D) Collagen microstructural data from 5 independent neovessels.

The preferred direction of the collagen microenvironment around a sprouting tip cell nearly coincided with the subsequent growth trajectory in 2 of the 5 examined time points. The errors were 10 and 9 degrees at hours 88 and 92, respectively (Fig 3). During this time, the neovessel made a course correction which followed the preferred directions (Fig 3). At hour 94, two filopodia extended from the neovessel tip, possibly contributing to the higher error observed (Fig 3). The average error between the preferred direction and growth trajectory was 17.1 degrees (std = 7.7, n = 5).

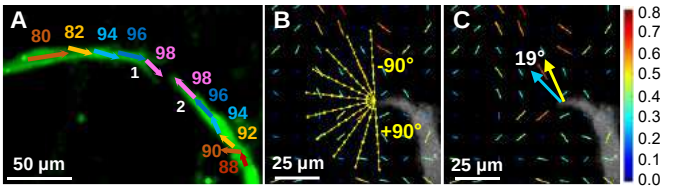

Figure 2. Neovessel Guidance Analysis. (A) Neovessels (green) with superimposed growth trajectories. The collagen microenvironment of neovessel 2 was analyzed. (B) Neovessel 2 at hour 90 (grayscale image) with local ECM directions and anisotropy (color). The discretized growth path (yellow lines) with the highest anisotropy was the preferred direction. (C) The preferred direction (yellow arrow) and growth trajectory (blue arrow) differed by 19 degrees.

DISCUSSION

Using measurements of the ECM anisotropy and density, we quantified the tip cell distance of influence to gain insights into the space from which neovessels sense mechanical cues from the ECM. In fibrous ECM constructs, Rudnicki et al. found that fibroblasts could sense stiff structures from distances over 65 microns [8]. We calculated our distance of influence as the distance over which tension-driven collagen realignment extended. Our distance of influence was more consistent with a study by Abhilash et al. [4]. They found that circular cells interacted via overlapping regions of tension-realigned collagen from distances up to 50 microns [4].

Analysis of time-series data revealed a relationship between the neovessel growth trajectory and the preferred direction of the collagen in the tip cell microenvironment. The larger difference observed between these directions at hour 94 could be due, in part, to the presence of two filopodia. Each presented a path with relatively high anisotropy, and the neovessel growth trajectory followed the filopodium path most oriented towards the nearby neovessel (Fig 3). Like Abhilash et al., we observed overlapping regions of tension-realigned collagen between the tip cells at hours 94 and 96 (Fig 3) [4]. Furthermore, the similarities between the growth trajectories and preferred directions of hours 88 and 92 indicate that that the collagen organization of the tip cell microenvironment contributed to neovessel guidance. Further work is needed to study neovessel guidance by the collagen microstructural organization to improve neovascularization at tissue interfaces.

INTRODUCTION

Mammals such as human or mouse have little ability to regenerate body tissues completely, including tendons and ligaments. On the other hand, amphibians are well known for their remarkable ability to regenerate not only limbs, but also brain, spinal cord, or retina [1]. Therefore, amphibians may be used as the emerging experimental animals to study the mechanisms of the complete regeneration of tendons and ligaments in adult, and the findings would be useful as a roadmap for tendon and ligament regeneration in adult mammals. However, there have been no experimental model for tendon regeneration study of amphibians. In the present study, we aimed to develop a biomechanical study model of tendon regeneration using Iberian ribbed newt (*Pleurodeles waltl*) (Fig. 1) through microscopic observation of regenerated tendon and the establishment of tensile testing system for its functional analysis.

Fig. 1 Experimental model (*Pleurodeles waltl*, female)

METHODS

Animal model

Iberian ribbed newts (9-month-old, female) were purchased from Amphibian Research Center, Hiroshima University, and kept in a water chamber at room temperature in the laboratory. The following experiments were approved in the animal experiment committee of Nagoya University (#20-10). Six newts were used in this work. First, we tried to find which tendon is used for the regeneration study, and determined the digital flexor tendon (DFT) as an experimental material.

Tendon transection surgery

Two types of tendon transections were tested on DFT: partial transection and complete transection. The newt was anesthetized by placed in 0.2% MS-222 solution in water. A straight incision was made on the skin of the ventral side of the digit, and DFT was exposed. The animal, including DFT exposed and its surrounding tissues, was kept moist by dipping Holtfreter's (HF) solution. DFT was either transected half of the tendon width (Fig. 2), or transected completely (Fig. 3). The damaged tendon was returned to its original position, and the skin was closed but not sutured. The newt was kept in the chamber and normal activity was allowed for 6 weeks.

Biomechanical analysis of original DFT

We characterized the mechanical properties of unoperated original newt DFTs as the first step, using a custom-made tensile tester. After DFTs were isolated from newts under anesthesia, their cross-sectional area (CSA) was obtained. They were hung in a clear acrylic chamber filled with HF solution and rotated with a stepping motor, and a photograph of the front view of DFT was captured every 14.4° for 25 times. The width of DFT, measured with ImageJ (NIH), was used to reconstruct the cross-section of the tendon, from which the CSA was calculated.

Fig. 4 shows a schematic of the tensile testing system for newt DFT. The sample was maintained in a reservoir filled with HF solution during the test. A load cell of 5 N and a linear actuator were positioned on the both sides of the reservoir. The actuator was controlled by a LabVIEW program on a PC, which also collected the data from the load cell.

Tensile test was performed on a stereo microscope (M165FC, Leica), so that a movie of the test was recorded by its CCD camera.

To measure tissue strain, either nigrosine or microspheres (UVPMS-BO-1.00, Cospheric) was placed on the surface of the isolated DFT as strain markers. The specimen was held with acrylic jigs and attached to the load cell or the actuator. The specimen was stretched slowly until tensile load of 0.02 N was applied, at which the zero point was defined. This was followed by preconditioning between 0-1% of tensile strain at a rate of 0.17%/s 10 times. Finally, the sample was stretched at the same rate until rupture. Nominal stress was calculated by dividing the load by the CSA. Strain was calculated by the changes in the position of strain markers. Stress at rupture point was defined as tensile strength and elastic modulus was determined as a slope of the stress-strain curve between 20-60% of tensile strength.

Microscopic observation

At 6 weeks after the transection surgery, the animal was sacrificed and healing DFT was isolated. Cell nuclei were fluorescently stained with ethidium homodimer-Ⅲ (Nacalai Tesque). Multiphoton microscopy (A1RMP, Nikon) was performed to observe fluorescence of nuclei and second harmonic generation (SHG) of collagen of the DFT.

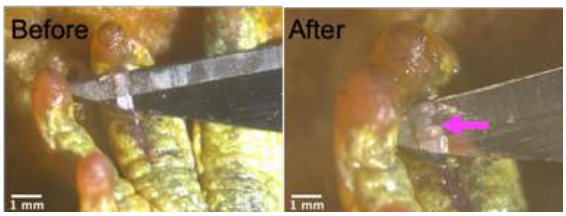

Fig. 2 Partial transection. Arrow indicates the transection.

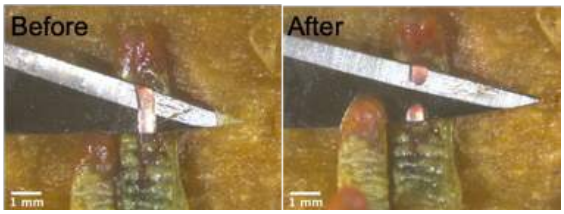

Fig. 3 Complete transection.

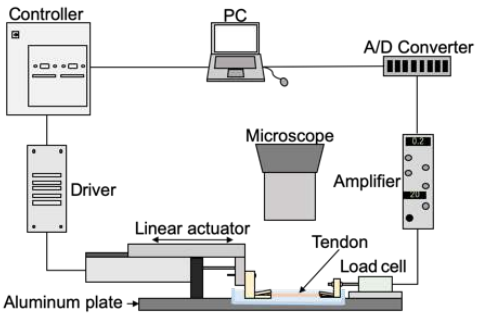

Fig. 4 Schematic of tensile testing system for newt DFT.

RESULTS AND DISCUSSION

Microscopic observation

Original DFT showed a robust SHG signal from the main body of the tendon, in which tendon cell nuclei were aligned longitudinally (Fig. 5(a)). In healing tendons, a similar pattern of SHG signal from collagen was observed at the site of transection in the partial transection model (Fig. 5(b)) as well as the complete transection model (Fig. 5(c)), suggesting that tendon-like collagen structure was regenerated.

Mechanical properties

Fig. 6 shows the stress-strain curves of three original DFTs obtained from two animals. Although there were some variations in tensile strength, tangent modulus and failure strain, these were relatively smaller than those reported in the literature determining mechanical properties of rabbit DFT [2]. Therefore, the variations observed here may present sample-related differences. Tensile strength (MPa), tangent modulus (MPa) and failure strain were 39.5 ± 7.79 (mean ± SD), 227 ± 64.8 and 0.285 ± 0.061, respectively. The strength and the modulus of the newt DFT were 34.7% and 64.7% lower, respectively, than those of rabbit DFTs, which may reflect the differences in the collagen types and/or intensity of animal activity.

In summary, tendon regeneration was suggested in newt DFT after 6 weeks of healing period and mechanical properties of original newt DFT were characterized. In future work, the comparison of mechanical properties between original and regenerated tendon will be performed.

INTRODUCTION

Previous research shows that the functioning of the brain is related to its structure and that mechanical forces are a significant factor in neural growth [1]. Atypical patterns in the thickness of the cerebral cortex, the outer layer of the brain, can be linked to Autism Spectrum Disorder, Alzheimer's disease, Williams syndrome, schizophrenia, and epilepsy [2-4].

In our previous work [5], we found that the gyral regions (on outer folds) are thicker than sulcal regions (in inner folds) in humans. This study showed that physical factors alone could produce the variations found in the gyral and sulcal regions during cortical folding without genetic factors at work. The purpose of the present study is to investigate the thickness of gyral and sulcal cortical areas across different primate species. If we consistently find thick gyri and thin sulci in other mammalian species, then it would support our previous findings and suggest that intrinsic mechanical forces are an important cause of cortical morphogenesis.

METHODS

To calculate the cortical thickness of the cerebral cortex, T1-weighted MRI scans were obtained from University of Utrecht [6] via the International Neuroimaging Data-Sharing Initiative's PRIMatE Data Exchange (INDI PRIME-DE) [7] database and the National Chimpanzee Brain Resource (NCBR) (supported by NIH grant NS092988). We manually segmented the MRI scans using BrainBox (Paris, France) into two masks: one of the entire brain and one of the cortex. After the manual segmentation process, we analyzed the morphology of the brain via our custom Python pipeline. First, a subtraction of the cortex from the complete brain mask resulted in a mask of the subcortex, which was visually validated and edited, as necessary. Next, the binary volumetric masks of the pial surface and the subcortical surface were converted to volumetric meshes using the Marching Cubes algorithm [8], which converts a three-dimensional binary matrix to a tessellated mesh by "marching" through the matrix to determine where there are borders between the ones and zeros.

The cortical thickness was then calculated for each node on the pial surface, or the outer surface of the cortex, as the three-dimensional Euclidean distance to the nearest neighbor on the cortex-subcortex interface.

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2} \quad (1)$$

The topography of the pial surface was then quantified. The gyrification index, or the ratio between the total surface area and the exposed surface area, was calculated as a measure of degree of folding which allows for comparisons between different brains [9]. The exposed surface area of the pial surface was approximated from an alpha shape of the brain's surface. The topography of an individual subject's brain was quantified by the mean curvature, where a positive mean curvature correlates with a gyrus and a negative value indicates a sulcus. These calculations utilize the surface area of the mesh, which is calculated using Heron's formula, and the neighborhood information from the mesh.

RESULTS

Over the course of the present study, we analyzed nine brains, each from a unique primate species (Table 1). The mean thicknesses were found by averaging all calculated cortical thicknesses for the subject. A distribution of the cortical thickness for each subject is shown in Figure 1. The relationship between curvature and the cortical distribution for the brain of *Macaca mulatta* is shown in Figure 2.

Table 1. The mean cortical thickness of the species represented in the present study. The brain volumes were calculated using the binary masks and voxel dimensions.

Common Name	Brain Volume (cm^3)	Mean Cortical Thickness (mm)
Grey Mouse Lemur	0.838	1.215
Prince Demidoff's Bushbaby	1.96	1.661
Squirrel Monkey	9.55	1.233
Ring Tailed Lemur	12.7	1.476
Mongoose Lemur	14.6	1.682
King Colobus	40.7	1.751
Brown Wooly Monkey	49.6	1.897
Green Monkey	53.9	1.436
Rhesus Macaque	78.6	2.127

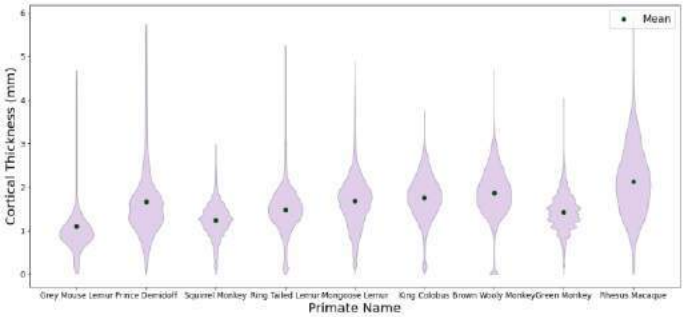

Figure 1. A violin plot of the cortical thickness for each primate where the x-axis is arranged in terms of increasing brain volume.

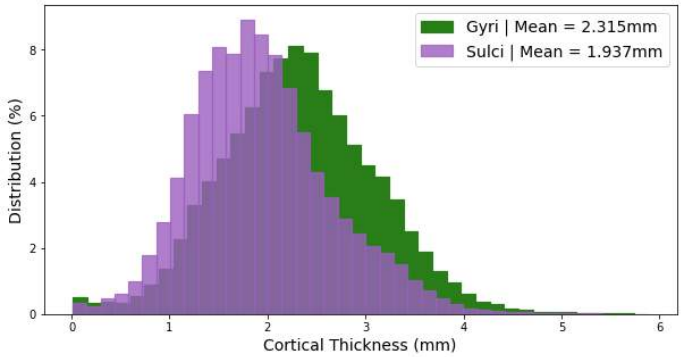

Figure 2. The cortical thickness distributions for the gyral and sulcal regions of a Rhesus Macaque brain, where the curvature differentiation is based on the mean curvature.

DISCUSSION

Figure 1 shows that the cortical thickness tends to increase with brain volume, which aligns with previously held knowledge. However, there are a few subjects for which this trend is not seen and the cause of this is being investigated to determine whether this reflects the true morphology of the subject or is due to an error in the analysis pipeline or manual segmentation.

Holland et al. 2018 [5] found that the gyri are universally thicker than the sulci in human brains. The results from this study here show that above a certain brain volume gyral regions are distinctly thicker than sulcal regions. Our current work has been unable to identify the exact threshold at which this distinction occurs, but it appears to happen between 50 cm^3 and 75 cm^3. A possible future investigation could be into the morphology that is necessary for this phenomenon to occur. This phenomenon may also be related to the degree of folding in the brain.

The work described in the current paper details the development of a Python pipeline that is capable of analyzing mammalian brains at large, human fetal brains, and disorders that result in atypical growth of the human brain, such as microcephaly and macrocephaly. Current automated and semi-automated methods of brain morphological analysis, such as FreeSurfer or AFNI, were developed to study the adult human brain using a brain atlas that helps to map brain regions to a common template. As such, these software are challenged when tasked with analyzing a brain of different morphology. The presently described pipeline of analysis tools aims to provide similar outputs of morphological markers as the human-focused software already in use. Future work will include a study of multiple individuals of the same species to establish standard cortical thicknesses for the species. The inclusion of multiple subjects of the same species will also serve to verify the findings in the present paper at large.

Connexone: A Medical Application for Protection Against Opioid Overdose

Hirschel M. Nambiar

Food and Drug Administration, 10903 New Hampshire Ave, Silver Spring, MD 20993

INTRODUCTION

Opioids are a class of drugs that include the illegal drug heroin as well as powerful pain relievers available legally by prescription, such as oxycodone (OxyContin®), hydrocodone (Vicodin®), codeine, morphine, fentanyl, and many other substances. These drugs are related and interact with opioid receptors on nerve cells in the body and brain to produce pleasurable effect and relieve pain. Opioid overdose is the leading cause of accidental death. Opioid addiction is driving this epidemic. In the US in 2015, there were 52,404 deaths due to opioid abuse which is higher than car crash deaths or gun violence deaths. In the world, almost 207,000 die due to opioid overdose. Nearly 14% high school students use opioid and that is a large number. In Maryland there were 1,259 deaths due to opioid in 2015 and 2,000 deaths in 2016. So opioid overdose now ranks with cancer, stroke, and heart attack among top killers in MD. CDC data clearly show that opioid use is increased among most demographic groups and death rate is also increasing. The main problem is that after overdosing, on an average, 911 is called only 33% (range 10-56%) of the time due to the fear of arrest. The healthcare costs for treating victims are almost 37 billion dollars per year.

I developed a smart lifesaving medical app for opioid, drugs, and substance abuse, called as Connexone. The novel medical app Connexone has features to get help for opioid overdosed victims with a press of a button and much faster than 911 responders. It can also identify the closest naloxone carrier for treatment.

METHODS

After brainstorming the ideas to develop a medical app for protection against opioid overdose, I narrowed down the key features of the app to include a large button in the center for an emergency use. The large help button can make it easier to press once the person is intoxicated (Figure 1). When that is pressed, it triggers other essential features. Including three emergency contact information of the opioid user in the app can alert them once the button is pressed. The press of the help button will alert the three emergency contacts who can come and help the victim. The press of the help button can also trigger a 911 call.

Another important feature of the App included the connection to GPS for identifying location of the victim. The GPS system can also help to identify the closest opioid antidote, naloxone carrier and needle exchange place to obtain the treatment immediately.

I used MIT App Inventor and Java Eclipse to code for the Medical App. After few trial and error, I could design and develop a functional app. This smart lifesaving Mobile Medical App, called as Connexone, can help to solve a current national crisis and major public health issue.

RESULTS

The prototype of the app was functional, and testing did show that it alerts the three pre-considered contacts without any failure. The app also helps to identify the nearest naloxone (opioid antidote) carrier while informing the closest 3 people

identified earlier by the overdose victim to come and administer the drug.

To implement this overdose response, a program is developed with the certified Naloxone carrier. The app notifies the Naloxone career and emergency contacts by SMS messaging. Finally, it contacts the 911 as backup.

The app also has information on opioid. Legal information is also provided. States with Good Samaritan Laws protects the caller or victim from arrest or prosecution for possession and under influence.

Figure 1 Connexone Key App Features

DISCUSSION

I have developed a smart lifesaving app for opioid, drugs, and substance abuse, called as Connexone. Opioids are a class of drugs that include the illegal drug heroin as well as powerful pain relievers available legally by prescription, such as oxycodone (OxyContin®), hydrocodone (Vicodin®), codeine, morphine, fentanyl, and many other substances.

These drugs are related and interact with opioid receptors on nerve cells in the body and brain to produce pleasurable effect and relieve pain. Addition is a chronic brain disease characterized by pursuing substance abuse and dangerous behaviors.

Opioid addiction and overdose are the leading causes of accidental death. Since very few people call the 911 after an overdose, a method such as Connexone app is required to protect these victims. By the switch of a button the app can perform many features to protect an overdose victim. The app also provides legal information to protect the victim from arrest or prosecution for possession or under influence.

My next step is to include coverage for other drugs and make it accessible to consumers.

EFFECT OF STRESS-FIBER CONTRACTION ON THE 3D SHAPE OF THE AORTIC HEART VALVE INTERSTITIAL CELL

Quan Nguyen, Alex Khang, Xinzeng Feng, Michael S. Sacks

Austin, TX, USA

INTRODUCTION

Calcification of the aortic valve (AV) affects leaflet stiffness, typically preventing the AV from opening completely. The main treatment for calcific AV disease (CAVD) is valve replacement with prostheses, which continues to suffer from limited durability. Currently, there are no pharmaceutical approaches for CAVD, in part due to our lack of understanding of the role of AV interstitial cells (AVIC). AVICs are known to undergo phenotypic activation in periods of growth or disease. This can result in changes in shape, increases in overall contractility due to expression of alpha smooth muscle actin stress fibers, and lead to an increase in collagen production and matrix remodeling. While it is widely accepted that cell shape is intimately connected to cell function; we have little understanding on how AVIC shape regulates mechanical function. In this study, we quantify the 3D shape of AVICs locally and globally.

METHODS

3D Traction Force Microscopy. 3D traction force microscopy was used to obtain AVIC surfaces. AVICs and fluorescent tracking beads were imbedded within poly (ethylene glycol) hydrogel (PEG) and incubated for 3 days. For the normal state, AVICs were treated with Tyrode's Salt solution. After 40 minutes, we took an image stack of a single AVIC and the surrounding beads. AVICs were then treated with Cytochalasin D for 40 minutes to reach their inactive state. We took a second image stack of the same field of view. To obtain surface meshes of AVICs in their normal and inactive state, we analyzed the image using out custom software FM-track [1].

Local curvatures of AVIC surface. To obtain a quantitative descriptor of the local shape, AVIC local curvatures were computed through a surface patching method [2,3]. First, the method defines a center node and obtains a patch of nodes surrounding the center node. Since the global x, y, z system does not provide a single-valued function, a local coordinate system u, v, n is defined. The local surface curvature of AVIC was described with a reduced biquadric surface

$$S(u,v) = au^2 + 2buv + cv^2, \quad (1)$$

where a, b, and c are fit constants. With the fit constants, the local principal major curvature, k1, and principal minor curvature, k2, were computed [2,4]. This is iterated across all nodes on the surface mesh.

$$k_1 = \mathrm{a} + \mathrm{c} - \sqrt{(a-c)^2 + 4b^2} \quad (2)$$

$$k_2 = \mathrm{a} + \mathrm{c} + \sqrt{(a-c)^2 + 4b^2}. \quad (3)$$

Global shape of AVIC. To analyze the global shape of AVIC, we used Spherical Harmonics (SPHARM) [5,6]. AVIC surface is parameterized onto a unit sphere using a one-to-one mapping to minimize distortion. The mapping results in the transformation from cartesian to spherical coordinates $[\mathrm{x}(\theta,\varphi), \mathrm{y}(\theta,\varphi), \mathrm{z}(\theta,\varphi)]$. The resulting parameters can be expressed with respect to the SPHARM basis function

$$Y_l^m(\theta,\varphi) = \sqrt{\frac{(2l+1)(l-m)!}{4\pi(l+m)!}} P_l^m(cos\theta) e^{im\varphi}, \quad (4)$$

where l and m are the degree and order of SPHARM, and $P_l^m(cos\theta)$ is the following Legendre polynomials

$$P_l^m(x) = \frac{(-1)^m}{(2^l l!)} (1+x^2)^{\frac{m}{2}} \frac{d^{l+m}}{dx^{l+m}} (x^2-1)^l. \quad (5)$$

The SPHARM expansion of the parameterized surface is as follow:

$$\mathbf{v}(\theta,\phi) = \sum_{\mathrm{l}=0}^{L_{max}} \sum_{\mathrm{m}=-\mathrm{l}}^{\mathrm{l}} \mathbf{c}_{\mathrm{l}}^{\mathrm{m}} \mathrm{Y}_{\mathrm{l}}^{\mathrm{m}}(\theta,\phi), \quad (6)$$

where $\mathbf{v}(\theta,\phi) = (\mathrm{x}(\theta,\phi), \mathrm{y}(\theta,\phi), \mathrm{z}(\theta,\phi))^T$, $\mathbf{c}_{\mathrm{l}}^{\mathrm{m}} = (\mathbf{c}_{\mathrm{xl}}^{\mathrm{m}}, \mathbf{c}_{\mathrm{yl}}^{\mathrm{m}}, \mathbf{c}_{\mathrm{zl}}^{\mathrm{m}})^T$ are the SPHARM coefficients. Using a SPHARM software adapted from Shen et al. [6], we can input a maximum degree L_{max} to calculate the

SPHARM coefficients. The power spectra of AVIC can be created by plotting its coefficients against the degrees and orders.

RESULTS

The major principal curvature is a sensitive descriptor of AVIC shape. The magnitude of k_1 (0.01 to 4.92 μm^{-1}) is larger than that of k_2 (-0.98 to 0.89 μm^{-1}) (Fig. 1). Since the values of k2 are miniscule, k_1 can be used to analyze the shape of AVIC.

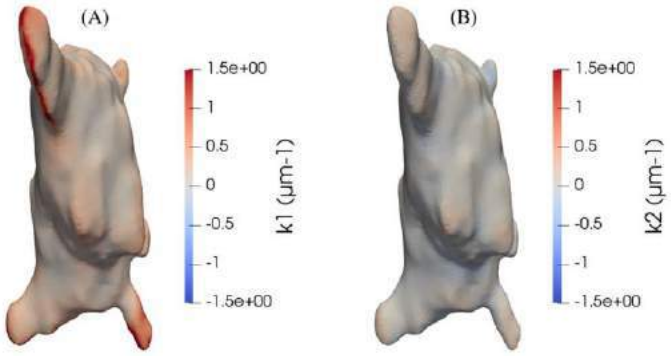

Figure 1: (A) Major principal curvature k_1. (B) Minor principal curvature k_2 for a reconstructed AVIC surface (normal state).

AVIC protrusions have higher k1 values than k2 which suggests that they are cylinder-like (Fig. 1).

As the harmonic degree increases, precision of AVIC fitting increases. An AVIC surface mesh is reconstructed with SPHARM (Fig. 2). A harmonic degree of 47 produces a surface mesh with a mean-squared error of 0.0532 μm^2 relative to the original mesh.

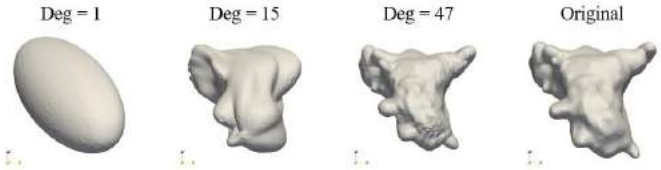

Figure 2: An AVIC surface mesh reconstructed in SPHARM, from degree 1 to degree 47.

AVIC contracts going from its inactive to normal state. The difference between an AVIC inactive and normal state shows mostly contraction (Fig. 3).

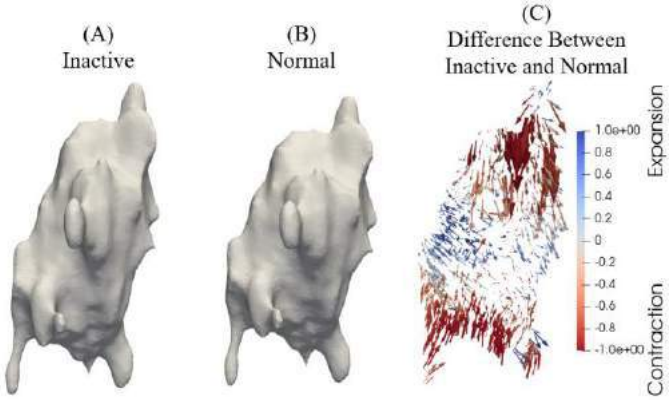

Figure 3: (A) An AVIC inactive state. (B) An AVIC normal state. (C) The difference between inactive and normal state.

Inactive cells are more spherical than normal cells. The SPHARM coefficients for an AVIC's inactive state are much larger than that of the normal state (Fig. 4). A positive difference between the two states suggests that the cell becomes more spherical as it contracts.

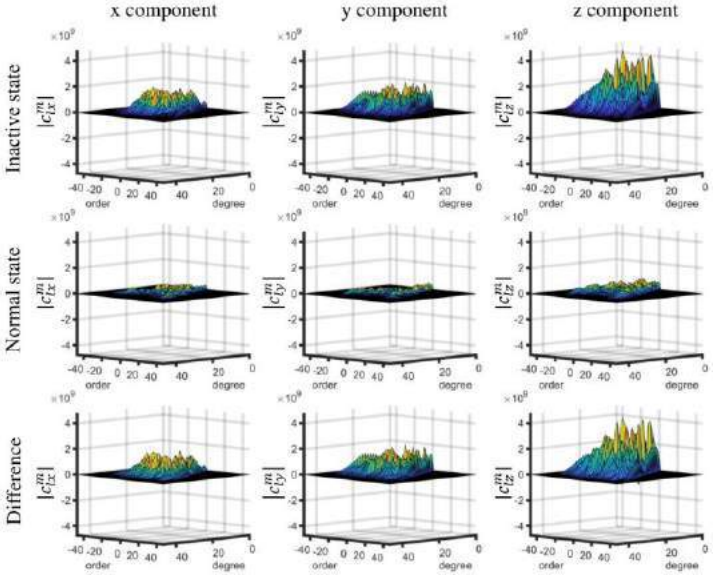

Figure 4: The power spectra of an AVIC in its inactive state, normal state, and the difference between the states. The inactive state power spectrum has higher SPHARM coefficients (0 to 4.71×10^9) compared to the normal state (0 to 6.33×10^7). This results in a positive difference.

DISCUSSION

In this study, we assessed the global shape and local curvatures of AVICs in several states. By displaying the major and minor principal curvatures visually onto the surface mesh, we observed that the major principal curvature is significantly larger and therefore more useful for understanding the shape of the cells. We report that k1 >> k2, particularly at protrusions, which suggests that AVIC protrusions are cylinder-like. When AVICs transition from the inactive to normal state, the cell contracts, wherein the AVIC becomes more spherical overall, and contracts the greatest at its protrusions. Overall, our results suggest that AVIC shape and contractile behaviors are intimately linked. Future work is focused on relating these contraction patterns to 3D subcellular structures through finite element modeling.

ANALYSIS OF BOUNDARY CONDITIONS IN NUMERICAL ASSESSMENT OF PARAVALULAR LEAKAGE IN TRANSCATHETHER AORTIC VALVE REPLACEMENT

Kyra M. Halbert-Elliott (1), Zhenglun A. Wei (1,2), Huang Chen (1), Sri Krishna Sivakumar **(1)**, Breandan A Yeats **(1), Ajit P. Yoganathan (1), Prasad Dasi (1)**

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a less invasive alternative to surgical aortic valve replacement (SAVR), principally preferred in patients considered high risk for open heart surgery [1, 2]. Though general outcomes for TAVR are promising, complications - including paravalvular leakage (PVL), aortic rupture, and coronary occlusion - have hindered the expansion of TAVR to wider swaths of patients seeking treatment for aortic stenosis [3].

The use of finite element analysis (FEA) in combination with computational fluid dynamics (CFD) has proved invaluable in advancing TAVR surgical planning, enabling investigation of potential outcomes and means of maximizing beneficence for patients. Previous papers have illustrated the utility of FEA and CFD in modelling TAVR deployment on potential root rupture [4], leaflet calcium displacement [5], and PVL [6].

However, there is no consensus on numerical settings on the FEA and CFD in TAVR modeling. We focused on CFD for studying PVL and found that previous studies employed various boundary conditions (BCs). For example, many studies have used a constant pressure gradient (dP), principally 32 mmHg [6-8] or 90 mmHg [9], in their PVL simulations and provided little physiological justifications. Recently, pulsatile pressure waveforms were prepared from post-TAVR readings in patients' aorta and left ventricle [10]. Though pulsatile BCs are more physiological, they demand more computational time and may not fit the timeline of interventional planning for TAVR.

Therefore, it is worth exploring the impact of using different BCs in TAVR simulation. This study conducts a CFD simulation to investigate the impact of BCs on PVL severity.

METHODS

This study will retrospectively include 15 patients from Cardiovascular Fluid Mechanic Lab's TAVR database, all of whom received 26-mm Edwards Sapien valve and were classified as exhibiting (1) No, (2), Mild, or (3) Moderate PVL. This retrospective, deidentified data analysis was approved by the Georgia Institute of Technology Institutional Review Board ("Transcatheter Heart Valve Imaging and Hemodynamics"). Written informed consent was obtained through the Cedars Sinai Institutional Review Board-approved study.

ITK-Snap was used to segment each patient's aorta, left ventricle, calcifications, and stent from post-deployment CT scans at end-systole with a semi-automatic snake algorithm. Segmentations were further refined manually. The stent and balloon delivery system were constructed from in-house μ-CT scans of a 26 mm Edwards Sapien 3 and Commander Delivery System (Edwards LifeSciences). Mimics was employed to refine the geometry and prepare computational meshes. ABAQUS\Explicit was used to conduct FEA to simulate the valve deployment. The deployment parameters, including deployment angle and depth, were adjusted iteratively until the absolute value of error between the FEA stent and CT stent was less than or equal to twice the stent thickness (approximately 1 mm). Ref 11 further details the FEA simulation methods.

The geometry of the aorta, calcifications, and stent post-deployment were exported from ABAQUS to Mimics for the generation of CFD mesh. The exterior of the stent was sealed to account for the accompanying skirt and native leaflets covering the stent. The left ventricle side of the aortic valve was also sealed to model the effect of the stent leaflets. The calcifications and stent were then merged and exported, along with the aorta geometry, to ANSYS Fluent,which was later used for CFD simulation.

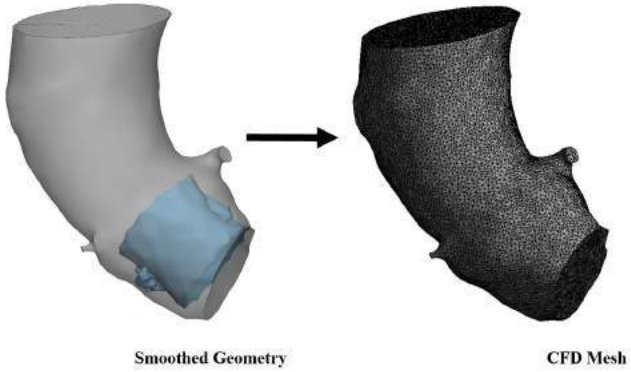

Figure 1: Aorta, Calcifications, and Implanted Stent

Examined BCs inlcude constant dP = 32 mmHg, 63 mmHg and 90 mmHg, as well as time varying dP, as shown in Fig. 2. It is worth noting that the constant dP = 63 is the maximum pressure gradient between the Aorta and LV during diastole in the time-varying dP waveform.

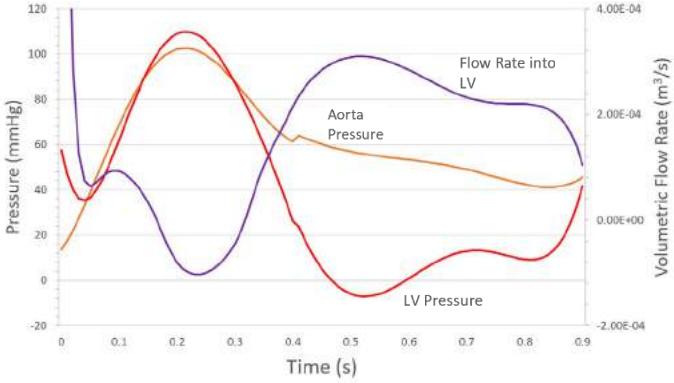

Figure 2: Time-Varying dP and corresponding VFR

Volumetric flow rate (VFR) across the left ventricle end of the aorta was calculated to estimate PVL volume. In pulsatile cases, VFR was integrated across diastole to obtain a time-averaged PVL regurgitation volume.

RESULTS

Fig. 3 tabulates the PVL volume comparison for a sample case between using different BCs. Fig. 4 shows corresponding flow fields. Average regurgitant volume was 63.19% greater in the steady 90 mmHg case than in the pulsatile pressure gradient case (Fig. 3). Streamlines (Fig. 4) showed stark differences in velocity at the LV end of the stent and at the LV-aortic root interface, and that the pressure gradient reversed flow throughout the aorta, not just at the LV-aortic root interface. The remaining cases will be segmented, implanted, and modelled with both pulsatile and steady flow boundary conditions.

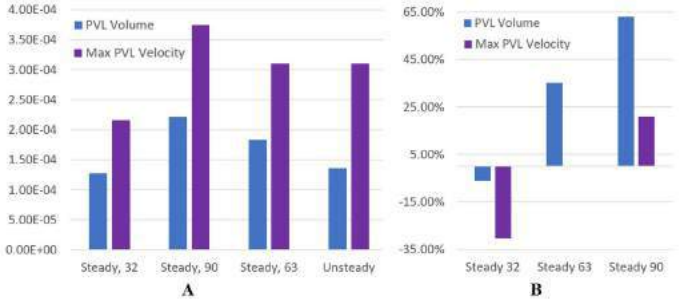

Figure 3: (a) Effect of boundary conditions on PVL volume (m^3) and maximum PVL velocity (m/s) (b) percent difference with respect to unsteady

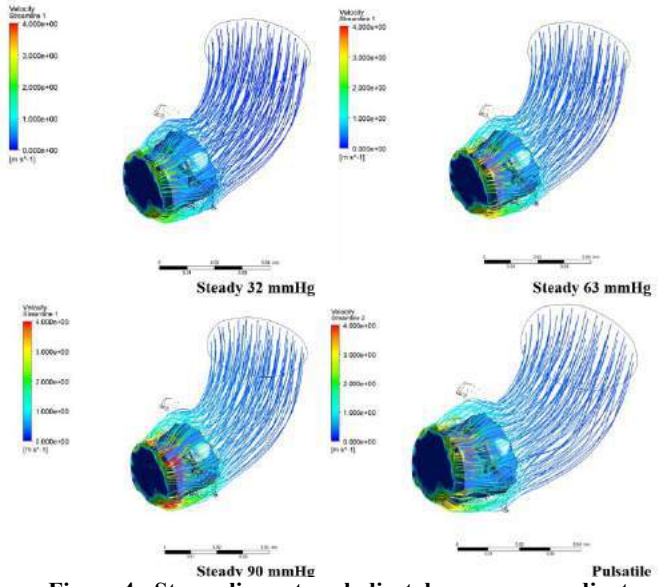

Figure 4: Streamlines at peak diastole pressure gradient

DISCUSSION

The results of the sample case shows that using different BCs has considerable impact on the PVL volume. It may affect shear stress, and other hemodynamics considerations impact clinical decision making. Once we finish CFD simulation for other cases, we will examine the effect of using different BCs on determine the PVL severity (No, Mild, or Moderate PVL).

The authors acknowledge that the Sapien valve leaflets were not included in the simulation. As every case must be consistent, this limitation should not affect the finding of this study.

INTRODUCTION

Right heart catheterization (RHC) is a clinical procedure to measure pulmonary hemodynamic data such as the mPAP mean pulmonary arterial pressure (mPAP), wedge pressure (PW), and cardiac output (CO). In an invasive cardiopulmonary exercise test (iCPET), pulmonary hemodynamics are measured at different workloads. Alpha distensibility, which is a measure of resistance vessel stiffness, is determined from multi-beat exercise pulmonary pressure and flow plots. Alpha distensibility associates with the severity of the clinical outcomes for patients with PAH. Calculation of alpha distensibility requires fitting a non-linear equation to pressure-flow data that can be difficult in clinical settings. The aims of this project were to 1)investigate changes in alpha distensibility from pressure-flow plots in repeat RHCs and 2)develop an interactive application to standardize the analysis of exercise pulmonary hemodynamic data

METHODS

Participants with repeat exercise RHCs and PAH were identified from the University of Arizona (UA) PH Registry (n = 30). Resting and exercise hemodynamics were included in the analysis. Alpha distensibility (α) was computed from exercise pressure-flow plots using the Linehan model [1]:

Linehan Model

$$\mathrm{mPAP} = \left([(1 + \alpha * \mathrm{PW})^5 + \alpha \mathrm{R_0 CO}]^{(1/5)} - 1\right)/\alpha \qquad (1)$$

where mean PA pressure (mPAP) is a function of pulmonary artery wedge pressure (PW), cardiac output (CO), total resting resistance (R_0) and α distensibility. Alpha distensibility is a measure of the percent change in vessel diameter per mmHg increase in pressure. Total Pulmonary Resistance (TPR) was calculated using the ratio of mPAP and CO(Eq. 2)

TPR Equation

$$\mathrm{TPR} = \mathrm{mPAP}/\mathrm{CO} \qquad (2)$$

Statistical Analysis: A p-value < 0.05 was considered significant. A two way ANOVA test with repeated measures was performed to compare the effects of visit and exercise on the mPAP, CO and TPR values. A TukeyHSD test was used to test pairwise comparisons. A paired t-test was performed to assess significant change in the alpha values between visit 1 and visit 2.

Development of Python Based GUI analysis Program:

A Python based GUI program was developed to expand the capabilities as well as improve the speed of analysis compared to the Matlab-based prototype. Requirements for the program included the ability to 1) generate pressure-flow plots from the RHC exercise data, 2) run the analysis to return the α distensibility and Pulmonary Vascular Resistance (PVR) values, and 3) generate a report (pdf) of the graphical outputs and corresponding data tables (csv) for later reference.

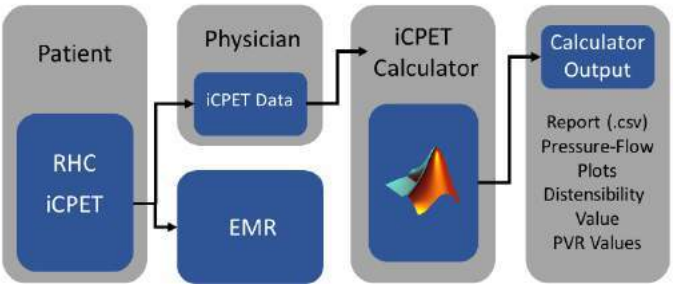

Figure 1: Data workflow from RHC pressure measurements to analysis outputs.

RESULTS

RHC Exercise Data Analysis:

Data from the UA PH Registry (n=30) was analyzed using a custom MATLAB Program to generate pressure-flow plots and calculate the α values for each exercise RHC. Exercise increased mPAP, cardiac output but had no effect on TPR at both the first and second visit (**Figure 2**). Resting mPAP decreased at visit 2 (55 ± 24 mmHg vs 62 ± 23 mmHg, p = 0.0002) but there was no significant change in cardiac output between visits (9.8 ± 3.1 L/min vs. 9.4 ± 4.3 L/min, p = 0.35) . Resting TPR decreased at visit 2 (5.9±3.1 mmg*min/L vs 7.4±5.5 mmg*min/L, p = 0.006). The alpha distensibility values were analyzed between the two visits and the median at visit one was 0.17± 0.27 and 0.2 ± .43 at visit two.

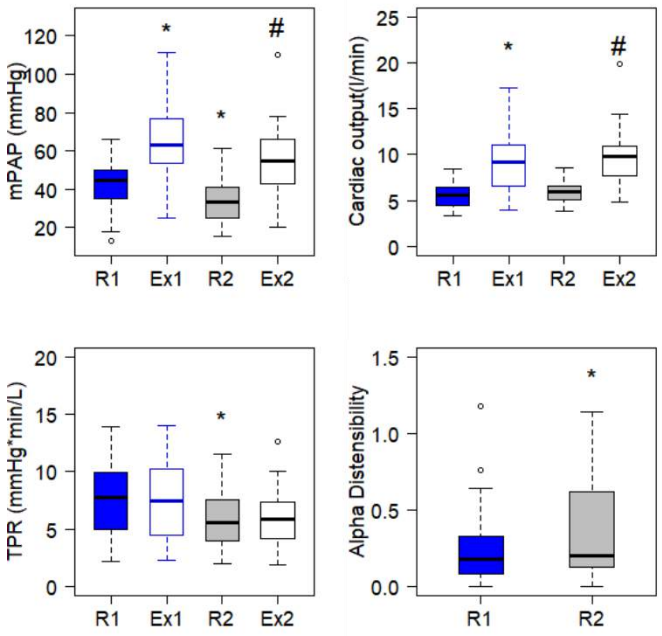

Figure 2: RHC hemodynamics data at rest (R1 and R2) and peak exercise (Ex 1 and Ex 2) for both visits. *p< 0.05 vs R1 and # p<0.05 vs R2

Python GUI Development

The Python program is capable of generating the pressure-flow plots as well as determining the PVR and α distensibility values. In initial testing, the Python program is capable of generating the same outputs as the MATLAB prototype.

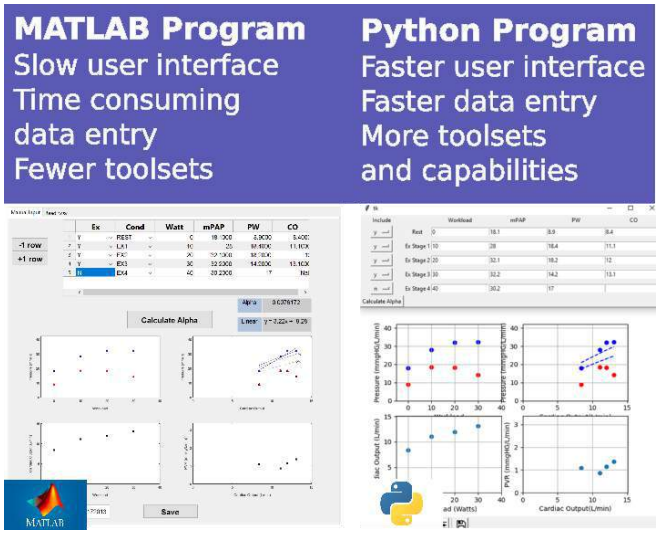

Figure 3: Side by side comparison of the Matlab (left) and Python (right) interfaces.

DISCUSSION

Pulmonary Hypertension (PH) is higher than normal blood pressure in the vessels in the heart and lungs. In pulmonary arterial hypertension (PAH) there is a narrowing of pre-capillary pulmonary blood vessels. As a result, the flow of blood is slowed through the lungs and the blood pressure is increased in the pulmonary arteries and vessels that results in increased pressure, resistance, and vascular stiffness. In response to increased pressure, the right ventricle has to work harder and eventually leads to impaired right ventricular (RV) function and eventually heart failure (HF). In analysis of the RHC exercise data in patients with PAH, there was a significant decrease in mPAP and TPR between the two visits. This indicates the values for visit two are closer to normal range, indicating a decrease in severity. The normal range for the CO is 4 - 8 L/min, both the average CO for visit one and visit two were higher than this range, likely due to the higher mPAP, however there was no significant change in CO at each visit. The analysis also showed a significant increase the α values for each visit, indicating a larger increase in vessel diameter in response to pressure, which could indicate decreased vessel stiffness.

INTRODUCTION

Cartilage tissue engineering (TE) is a promising osteoarthritis treatment strategy whereby cellularized tissue constructs are surgically implanted into cartilage defect sites to promote the generation of hyaline cartilage repair tissue. In current clinical practice, implanted autologous chondrocyte-seeded scaffolds begin to synthesize and elaborate a cartilaginous extracellular matrix (ECM) with the aim of recapitulating the functional mechanical properties required for long-term survival [1]. To date, clinical TE platforms have had limited success, encumbered by fibrocartilage formation and eventual tissue failure. This has led to expansive efforts in recent years to improve clinical outcomes through optimization of cell sources, cell expansion protocols, scaffold biomaterials, and delivered anabolic growth factors agents. However, a major hurdle in the field remains the lack of diagnostic platforms to monitor the growth and stability of implanted engineered tissues *in vivo*. Conventional imaging platforms (e.g., radiographs, CT, MRI) possess poor resolution of cartilage composition assessments, thus limiting the ability to assess the efficacy of TE novel platforms in clinical trials and to monitor regeneration in individual patients.

Raman spectroscopy is an inelastic light scattering technique that provides an optical fingerprint of a tissue specimen that reflects specific molecular building blocks (amides, sulfates, carboxylic acids, hydroxyls) [2]. As such, it has the potential to monitor the composition of engineered cartilage tissues with an exceptional specificity and accuracy. In our recent work, we developed a novel needle-based Raman arthroscopic probe capable of performing intra-articular assessments of articular cartilage composition for diagnostics of degeneration during osteoarthritis [3,4]. Results demonstrated that this platform in conjunction with spectral multivariate analytical models can assess cartilage GAG depletion, swelling, and collagen alignment loss with outstanding accuracy. In the current study, we aim to advance Raman arthroscopy as a novel platform for monitoring the growth of engineered cartilage *in vivo*. Towards this goal, we perform an initial assessment of this platform *ex vivo* by assessing the capability of our Raman arthroscopic probe and spectral analysis to predict the mechanical and biochemical property changes of engineered cartilage constructs during growth in culture. Here we analyze the growth of bovine chondrocyte-seeded agarose constructs with and without growth factor supplementation at different time points to serve as a model system to examine the platform's diagnostic potential.

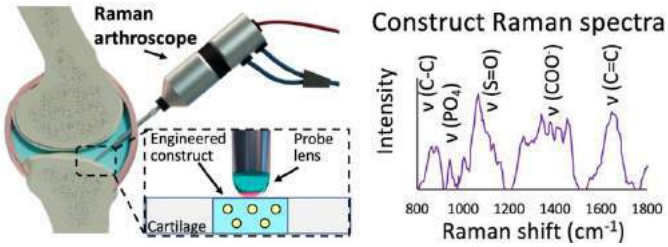

Fig 1: Raman needle arthroscopy platform for intra-articular monitoring of engineered cartilage construct growth *in vivo*.

METHODS

Raman probe: Our custom Raman needle arthroscope was designed for intra-articular entry through a hypodermic needle (Fig.1), consisting of an NIR diode laser (λ_{ex}=785nm, 500mW, B&W Tek) and a fiber-coupled spectrograph (QEPro, Ocean Optics). Laser light is directed through the distal part of the probe and through the needle

probe (ø=2mm, l=50mm), and tightly focused onto the tissue using a 2.0mm sapphire ball lens that achieves a 250μm depth of penetration into the tissue [4].

Tissue constructs: Immature bovine chondrocytes were encapsulated in 2% agarose hydrogel scaffolds at a density of $45x10^6$ cells per mL. Cell seeded constructs (∅4×2mm) were cultured for up to 56 days in high glucose DMEM supplemented with ITS+ premix, dexamethasone, L-proline, antibiotic-antimycotic, ascorbate, and with or without 10ng/mL TGF-β3 for the initial two weeks of culture [5]. **Raman analysis:** After 0, 14, 28, 42, and 56 days of culture, Raman spectra of constructs were acquired (n=4 constructs per each TGF-β group/time point). Raman spectra in the fingerprint range (800-1800 cm^{-1}) were collected and preprocessed, as described [3], and subjected to multivariate linear regression, using the following model:

$$\boldsymbol{Cartilage_{spectra}} = GAG_{score} * \boldsymbol{(GAG_{REF})} + COL_{score} * \boldsymbol{(COL_{REF})} + H_2O_{score} * \boldsymbol{(H_2O_{REF})} + Agarose_{score} * \boldsymbol{(Agarose_{REF})},$$

where GAG_{REF}, COL_{REF}, H_2O_{REF} , $Agarose_{REF}$ are the component spectra of purified reference chemicals (GAG [chondroitin-6-sulfate; Shark cartilage], collagen [type-II; chicken sternal cartilage], water [PBS], agarose [type-VII]) used to extract the corresponding regression coefficient or "score" that reflects the contribution of the spectra of each constituent element [3]. **Mechanical/biochemical analysis**: Following Raman analysis, constructs were analyzed for their equilibrium compressive modulus (E_Y) and GAG content (DMMB assay) [5].

RESULTS

Table 1: Mean values of Raman multivariate regression coefficients (scores) and property measures of construct groups.

		Raman scores				Property Measures		
TGF-β [ng/mL]	Day	Agarose	GAG	COL	H_2O	GAG [%ww]	H_2O [%ww]	E_Y [kPa]
NA	0	0.59	0.01	0.14	0.35	0.3	96.0	3.1
0	14	0.46	0.08	0.18	0.38	0.7	96.3	3.8
0	28	0.42	0.08	0.20	0.40	1.0	97.4	5.6
0	42	0.31	0.18	0.24	0.36	1.0	95.4	7.3

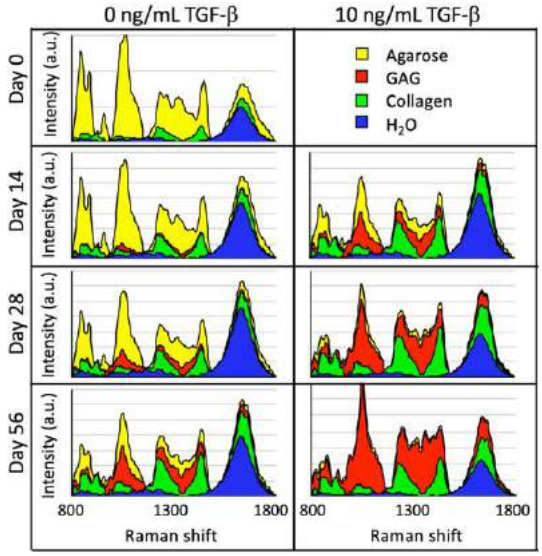

Fig 2: 2D stacked area plot of cumulative contribution of agarose, GAG, collagen, and H_2O spectra to composite Raman spectra of constructs after multivariate linear regression. Contribution of GAG & COL increases with time and TGF-β exposure.

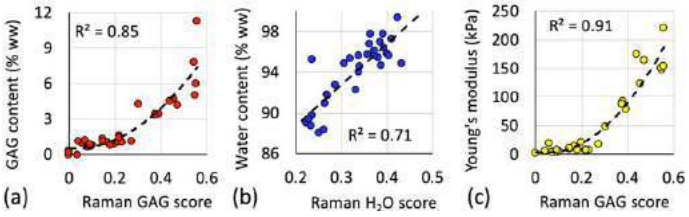

Fig 3: Bi-variate regression between (a) Raman GAG score and GAG content, (b) Raman H_2O score and water content, and (c) Raman GAG score and E_Y in tissue constructs.

Construct GAG content and E_Y increased with culture time and TGF-β supplementation while water content decreased (Table 1). Multivariate regression models were able to describe the measured Raman spectra, as the cumulative contribution of the individual ECM constituents accounted for 75% ± 6% of the variation of the composite construct spectra (Fig 2). Raman GAG and COL scores generally increased with culture duration and TGF-β supplementation while Raman agarose and H_2O scores decreased (Table 1). Linear regression was performed between Raman GAG scores and GAG content, Raman GAG scores and E_Y, and Raman H_2O scores and water content. Raman GAG scores predicted 85% and 91% of the variation in construct GAG content and E_Y, respectively. Raman H_2O scores predicted 81% of the variation in construct water content (Fig 3).

DISCUSSION

Raman spectroscopy represents a promising technology to achieve highly specific diagnostics of the chemical composition of musculoskeletal connective tissues. In the current study, we demonstrate that our newly developed Raman arthroscopic probe, in conjunction with multivariate spectral analysis, can achieve strong predictions of the composition (GAG and water content) and mechanical properties of engineered cartilage tissues. A major strength of this platform is the use of multivariate regression to ascertain the individual contributions of the agarose scaffold, interstitial water, and newly deposited ECM constituents (GAG and COL) to the cumulative Raman spectra, allowing for quantitative assessments of their evolution over time and in response to growth factor treatment. Clinically, we envision that Raman arthroscopy can be performed intra-articularly via a hypodermic needle cannula, allowing for minimally invasive assessments of engineered cartilage growth and stability *in vivo*. Raman arthroscopy can serve as a transformative research tool, evaluating the efficacy of emerging tissue engineering platforms in clinical trials. Further, Raman arthroscopy can evolve into a low cost, minimally invasive, clinical office-based procedure to monitor the growth and stability of engineered cartilage after surgical implantation procedures.

THE EFFECT OF SHEAR STRESS ON HUMAN LUNG MICROVASCULAR ENDOTHELIAL CELL GLYCOCALYX

INTRODUCTION

Endothelial Glycocalyx (GCX) is an extremely important determinant in vascular permeability and endothelial integrity [1]. GCX plays a role in mediating blood-cell and plasma and shear stress due to blood flow interactions with the endothelium [1].

The endothelial glycocalyx layer is a structure on the surface of the endothelial cells at the luminal side of the blood vessel. It regulates vascular permeability and molecular interaction with endothelial receptors [4]. This layer is responsible for flow-mediated responses in the endothelial cells.

Vascular endothelial cells form an interface between blood vessel walls and circulating blood, subjecting them to shear stress, and tensile and compressive strain [1]. Morphology, physiology, gene expression and inflammatory responses are regulated by these forces. [2,3] The reliance on these forces can result in pathological responses to an altered mechanical state and lead to various diseases such as atherosclerosis, abdominal aortic aneurysm [2], lack of vasomotion [4], or lack of immune response [5]. It has been shown that mechanotransduction of GCX increases vascular health [3].

When GCX are damaged, the flow-mediated responses are impaired leading to pathological responses from the endothelial cells [5]. Studies have determined that GCX expression is vital for the endothelial layer to properly function and respond to stimuli and serve as a protective barrier to pathogenic molecules [6].

The goal of this project is to understand the role of shear stress in pulmonary endothelial glycocalyx health. We hypothesized that subjecting human lung microvascular endothelial cells (HLMVEC) to shear stress in our flow chamber will result in an increase in expression of the GCX compared to control conditions.

METHODS

To introduce shear stress to HLMVEC on the glycocalyx, a parallel plate flow chamber was developed. Using SolidWorks to run simulations, we confirmed that the cells in the flow region would be exposed to a shear stress of 10 dynes/cm^2 with an average flow velocity of 171.3 mL/min. This flow rate was determined by equation 1 where σ is shear stress, in dynes/cm2, w is the width of the flow chamber, h is the height of the flow chamber, and v is the viscosity of the flow media.

HLMVEC for the experiment were cultured on glass slides, one control and one experimental. The cells were seeded for two days prior and were assessed to ensure confluence. Once confluent, the cells were transferred to the flow chamber. The flow chamber was placed in an incubator to ensure a controlled environment with a temperature at 37 °C and 5% CO2. In the first set of experiments, the cells were exposed to uniform flow for 4 hours. Flow was later increased to 6 hours. This was done to develop a trend for the relationship between GCX expression and time. Following exposure to shear stress, HLMVEC were fixed with a solution of 2% paraformaldehyde (PFA), 0.1% glutaraldehyde in phosphate-buffered saline (PBS) for 30 minutes at room temperature. They were later stained with wheat germ agglutinin (WGA; Vector Labs), for 30 minutes, being incubated at 4°C to label the GCX. For secondary detection Alexa Flour 488-conjugate at a concentration of 1:1000 was used. The GCX samples were covered with VECTASHIELD anti-fade mounting medium (Vector Labs) with 4′,6-diamidino-2-phenylindole, or DAPI, to stain the cell nuclei. The samples were sealed with clear nail polish to prepare them for imaging. The stained cells were imaged using confocal microscopy. This allowed for different planes of the cell layers to be captured. Coverage and thickness of the GCX was quantified using the NIH (National Institutes

of Health) Software ImageJ. The coverage was determined by looking at the composite images of each sample and measuring the percentage of the cell surface that was stained with WGA. The thickness was quantified by measuring the glycocalyx in the orthogonal view using the built-in measuring capabilities in ImageJ. The measurements of the thickness and total coverage from the control and uniform flow experiments were statistically analyzed using an unpaired t-test on the fold change values. This was done to show if the changes were statistically significant.

$$Q = (\sigma * w * (\frac{h^2}{1000 * v})) \quad (1)$$

RESULTS

Simulations revealed that cells in the flow area can be exposed to shear stress of up to 12 dynes/cm^2 (Fig 1). For the purpose of this project the flow area cells were exposed to 10 dynes/cm^2 with an average flow velocity of 171.3 mL/min (Fig 1). The average coverage of GCX for the experimental group was at 79.37% ± 0.02 and the thickness was at 1.25µm ± 0.05 while the control average coverage was at 74.82% ± 0.01 and average thickness at 1.13µm ± 0.03. The coverage and thickness of the GCX between control and experimental groups can be observed visually by changes in cell morphology between control and experimental groups (Fig 2 A-D). The data was found to be statistically significant through statistical analysis with a students *t*-test.

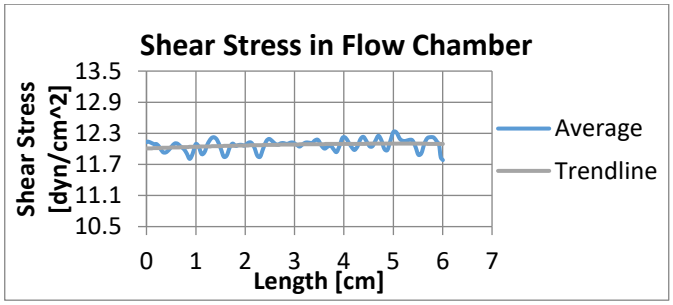

Figure 1: Simulation Data. Graph shows average shear stress along the length of the glass slide.

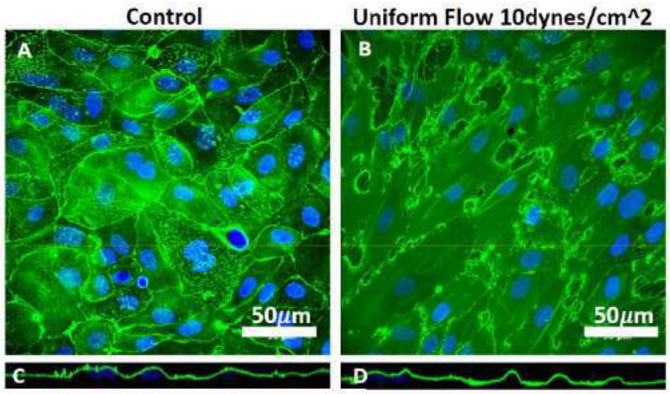

Figure 2: Effect of shear stress on the GCX. A. Coverage and thickness (C) are significantly lower in the no flow experiments (Green is WGA-labeled GCX and blue is DAPI-labeled nuclei.). B. Coverage and thickness (D) of GCX is significantly increased under uniform flow (UF) conditions.

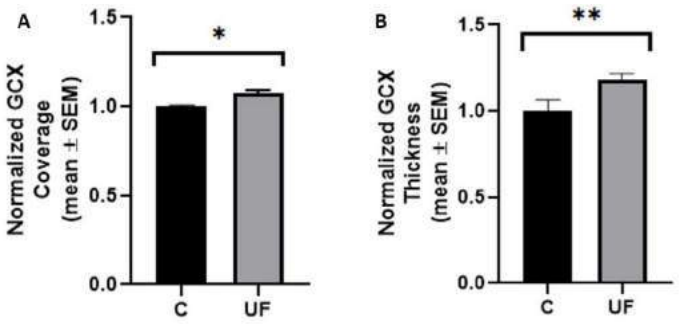

Figure 3: Data quantification for GCX coverage and thickness for control vs UF. All data normalized with control. Students *t*-test was used to compare control vs UF. Sample sizes: control N = 4, UF N = 3. Significance denoted as *P < .05, **P < .01.

DISCUSSION

The results show that HLMVEC GCX expression is shear stress dependent. Our results provide insight into the effect of shear stress on the expression of the GCX, demonstrating that consistent shear stress due to blood flow is important for GCX health. The data trend also implies that increasing the time of exposure to shear stress could correlate to the increase in GCX expression of HLMVEC.

The immediate future direction of this project is to increase the time of exposure. To confirm the relationship between exposure time and GCX expression, we plan to increase the time of exposure of HLMVECs to shear stress to 8 hours and then up to 24 hours. This increase in exposure time will further confirm the trend for the relationship between time and GCX expression.

In the next set of experiments, we will be staining for heparan sulfate, and sialic acid, which are GCX components.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. Solomon Mensah for valuable direction, support and discussions, and WPI for providing laboratory space and funding for the project through the startup package provided to Dr. Solomon Mensah. We would also like to thank Victoria Huntress from the Bioengineering Core Facility for help with confocal imaging.

STRESS-RELAXATION RESPONSE OF PORCINE AND HUMAN SYNOVIUM IN CONFINED COMPRESSION

INTRODUCTION

The synovium is a heterogeneous tissue that separates the diarthrodial joint space from systemic circulation. This thin, layered connective tissue consists of a cell dense intimal layer and a loosely connected extracellular matrix (ECM) in the subintimal layer [1]. Previous studies have measured the transport of solutes across synovial tissue both *in vivo* and *in vitro* to determine factors that regulate drug transport following intra-articular delivery [2-5]. In our prior work, we developed a finite element (FE) model of synovium as a fluid-filled, porous, and permeable solid using open source FEBio (University of Utah, Salt Lake City UT) to better study the factors that regulate solute diffusivity in the synovium [6-7]. Given a lack of information on the mechanical properties of native synovium, the model predictions of solute diffusivity depended on assumed values for hydraulic permeability, porosity, modulus, and Poisson's ratio. Here, we perform confined compressions of human and porcine synovial explants in order to quantify an equilibrium compressive modulus and hydraulic permeability through optimization to FE predictions of stress-relaxation testing. Our results provide one of the first-available measures for the modulus and hydraulic permeability of human and porcine synovium from direct compression that can be used to construct models of healthy and diseased tissue.

METHODS

Mechanical Testing: Synovial explants were harvested from the knee joints of human donors and porcine tissues and immediately flash-frozen to devitalize the tissue [6]. Explants were then trimmed to less than 1 mm thickness with a sledge microtome (Leica SM2400, Allendale NJ) and a 0.25" diameter test sample was obtained using a biopsy punch. Stress-relaxation tests were performed on the prepared samples in confined compression using the displacement-controlled features of a materials test system (Enduratec ELF 3200, TA Instruments). The tissue was placed in a confining ring in contact with a stainless-steel porous platen with a pore size of 40 μm (McMaster-Carr 9446T31, Elmhurst IL) to allow fluid flow during compression and in line with a load cell (45N). A solid stainless-steel platen interfaced with the test system actuator was first placed in contact with the tissue surface. The testing chamber was submerged in a 1x PBS bath to maintain hydration throughout testing.

The tissue was seated by applying a tare load of 0.1 N (100s relaxation, 3x), after which unloaded tissue thickness was measured as the distance between the porous platen and actuator positions. Samples underwent cyclic sinusoidal pre-conditioning of 0-1% peak-to-peak strain for 200 seconds at 0.25 Hz with a subsequent hold of 800 seconds at 1% strain. This strain pre-conditioning was followed by application of five successive compressive ramp and hold displacements (strain increments of 2% at 0.01% s^{-1}, 800 s relaxation). An equilibrium stress was calculated from the sample area and force averaged over the last 40s of the 800s relaxation period; linear regression of the equilibrium stress on strain for strains from 4-10% was used to determine an equilibrium compressive modulus.

Model Development: Specimen-specific FE models of synovium tested in confined compression were developed using FEBio. The synovium samples were modeled as a biphasic material with a porous and permeable, deformable Neo-Hookean solid and a constant and isotropic permeability. The Poisson's ratio was assumed to have a value of 0.2, the solid volume fraction was 0.19, and the fluid and solid density were both 1 kg/m^3. Experimentally determined thickness and equilibrium modulus were used to estimate a Young's modulus on a per sample basis. Each cylindrical synovial sample was modeled as a 3° wedge to simplify computational time and intensity (Figure 1).

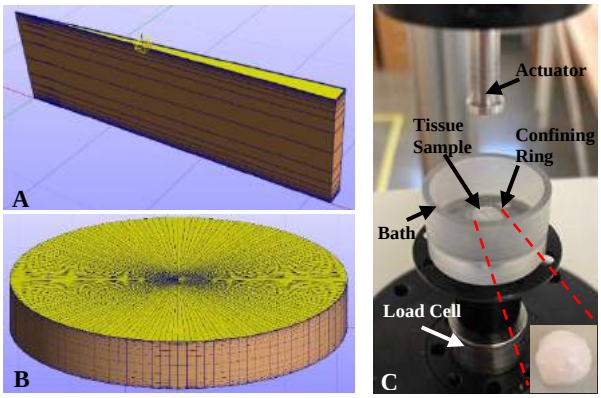

Figure 1: A) Modeled 3° wedge. Horizontal lines in the synovial tissue indicate the FEM mesh. This model was meshed with slices parallel to the xy-plane. B) Full cylindrical model example. C) Mechanical testing chamber with inset of tissue sample.

Boundary conditions in this one-dimensional problem enforced at the bottom face allowed for zero displacement and no resistance to fluid-flow; boundary conditions applied to the top face matched axial displacement to that of the actuator for each successive compressive strain (2% increments). For each sample, model predictions of transient compressive force in the platen were numerically matched to experimental force data following a moving average filter with a window size of 20s, using nonlinear optimization algorithms available within FEBio. In this manner, the FE model was optimized to fit the experimental data in order to determine a single parameter at each strain increment, the hydraulic permeability, *k*. Values of *k* were determined by optimization to the final ramp and hold waveform from 8%-10% strain.

RESULTS

Confined compression experiments were run on *n*=20 porcine samples and *n*=12 human samples. Stress-relaxation data for synovium tissue were matched moderately well by the FEM (Figure 2) as determined by average values for RSS of 0.0159 N^2 and 0.0127 N^2 for porcine and human synovium, respectively.

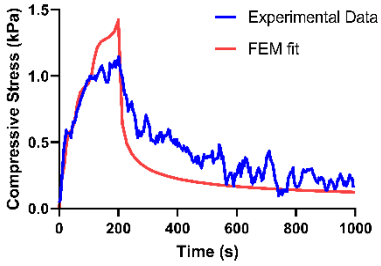

Figure 2: FEM output overlaid on experimental stress data between 8-10% strain. The optimized permeability for the curve shown is 5.41E-19 m^4/N-s while the modulus value is 3.48 kPa and RSS value is 0.00884 N^2.

For each curve fit, the model best matched the experimental stress during the ramp portion of the stress-relaxation curve and at longer times following periods of relaxation. The model often overshot the peak stress and predicted a faster relaxation at the beginning of the hold period than seen in the experimental data.

There was no statistically significant difference between porcine and human results for either equilibrium modulus or *k* (Figure 3, p>0.05, t-test, GraphPad Prism).

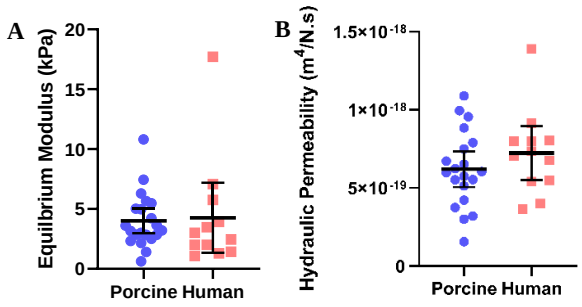

Figure 3: Mean with 95% confidence intervals for A) Equilibrium modulus and B) Hydraulic permeability

For porcine samples, the mean equilibrium modulus was 4.00 kPa (95% CI 2.97 – 5.04 kPa), and the mean *k* was 6.19E-19 m^4/N-s (95% CI 5.05E-19 – 7.33E-19 m^4/N-s). For human samples, the mean equilibrium modulus was 4.27 kPa (95% CI 1.34 – 7.19 kPa), and the mean *k* was 6.188E-19 m^4/N-s (95% CI 5.52E-19 – 8.95E-19 m^4/N-s).

DISCUSSION

This work represents the first study to report multiphasic mechanical properties of human and porcine synovium from direct compressive testing and FE model optimization. Here we report average values for compressive moduli that fall between 1-8 kPa, not unlike those reported in a recent conference paper using AFM testing [8]. The moduli were well-determined by a linear fit to compressive strains between 4-10%, suggesting that our assumption of a constant and linear modulus was appropriate at these strain levels. The values for *k* are among the lowest reported for any connective tissue, with an order of magnitude corresponding to 10^{-19} m^4/N-s.

This finding and our observation of poor model fits at the peak compressive stress may reflect our use of a strain-independent, constant permeability value; this assumption sets the stage for future work incorporating model complexity of strain-dependent permeabilities and possibly tissue viscoelasticity or nonlinear stress-strain behaviors for the synovial tissue.

With new and experimentally determined values for the modulus and permeability of human and porcine tissues, we are able to refine our prior estimations for model solute diffusivity constants in the synovium. Taken together, these studies bring us closer to building models that better predict factors regulating solute clearance and distribution in healthy and pathological synovium.

DEVELOPMENT OF A SOFTWARE TO COLLECT AND ANALYZE WORLDWIDE COVID-19 CLINICAL DATA AND ANALYSIS

Marshall M. Nambiar

National Institutes of Health
Besthesda, MD

INTRODUCTION

Over the course of the past year, I have worked on gathering, storing, parsing, and analyzing COVID-19 data from all around the world. The emergence of COVID-19 over the past year has changed lives in numerous ways. Not much research has been conducted on the prevalence of the disease and how it has affected individuals. Numerous hospitals in countries all over the world have stored data regarding COVID-19 but to effectively analyze it, we must bring in the data and standardize the format.

METHODS

Over the summer and school year, I worked on creating a questionnaire to help standardize the data received from other countries and parse it. The questionnaire included data regarding patient comorbidities, phenotypes, oxygen treatment received. Since countries send patient data for over one hundred patients, creating scripts to parse the data into a format accepted by the LabKey survey would help efficiency. Python and VBA was used to translate the received questionnaires into English and then parse out certain sections into viable formats for entry into the LabKey survey. To help with this process, we created mappings that showed a mapping process of how each part of the questionnaire is mapped into different sections and which information is captured.

RESULTS

We successfully created the software that is being used across the world to collect covid-19 clinical data, especially with people who have comorbidity conditions such as diabetes, hypertension, smoking, alcohol, opioid use and pregnant women.

We are analyzing the covid-19 clinical data using this software regularly.

DISCUSSION

We are analyzing the covid-19 clinical data using this software regularly.

ACKNOWLEDGEMENTS
National Institutes of Health for supporting this research work.

INTRODUCTION

Although endovascular technology has revolutionized treatment of complex vascular pathology,[1] surgical procedures are complicated by the need to use multiple catheters and guiding sheaths to access distal peripheral arterial networks, as no one device is both highly navigable and supportive.[2,3] Interventionalists rely on these devices to support the transport of therapeutic devices such as balloons, stents, or thrombectomy devices. However, no engineering basis currently exists for determining which devices are best suited for peripheral arterial procedures in the lower extremities and the neurovascular system.[4] We hypothesized that flexural rigidity of catheters can serve as a quantitative metric for device selection.

Mechanical factors have long been considered in the process of catheter design and integration.[5-9] Flexural rigidity is a sensible target in determining a catheter's capacity to navigate tortuosity in the vasculature: a catheter or sheath with low flexural rigidity can buckle during advancement, but one with high flexural rigidity can suffer limited maneuverability and risk injuring the arterial lumen. Small strain, Euler-Bernoulli methods used to characterize the earliest endovascular catheters are not accurate for the more compliant catheters in current use. Therefore, there is a compelling need for protocols to quantify the flexural rigidity of these tools, and to evaluate commercial devices. To test our hypothesis and meet this need, we evaluated the prediction that catheters and sheaths for the treatment of arterial structures in the neurovascular and lower extremity peripheral arterial vasculature would have distinct flexural rigidities. To test this hypothesis, a nonlinear beam theory approach was developed and applied to a range of endovascular devices used for lower extremity peripheral arterial and neurovascular procedures.

METHODS

To characterize flexural rigidity, a nonlinear beam theory solution was developed, and an integrated test was developed. These were applied to a range of commercial endovascular devices.

Device testing procedure: 9 catheters and 12 sheaths used in interventional procedures at Washington University were tested, ranging in diameter from 4-12 French (1.33-4 mm). Devices were cut into 25 cm specimens. The proximal 10 cm of each specimen was placed into a clamp to create a 15 cm fixed-free cantilever beam. Images were taken of the initial position, and as a series of F = 12.3-259 mN loads attached L_0 = 4-8 cm from the fixed end. This was repeated three times for each specimen. The final length L and angle of deflection θ (Fig. 1), were measured as described below from images taken using a calibrated 10-megapixel smartphone camera.

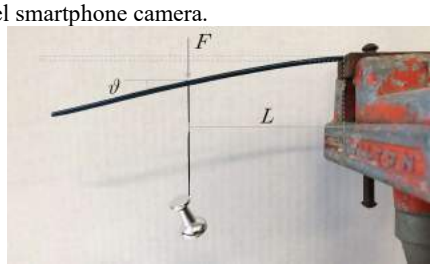

Figure 1: Testing fixture for measuring the flexural rigidity of catheter specimens. For the nonlinear beam theory approach, the method required measuring both the angle of deflection θ and the position L of the applied dead load in the deformed configuration.

Models for flexural rigidity quantification: While linear beam theory is sufficient to analyze cantilevered beams under small deflections, it proved inadequate, as described below. The nonlinear solution started with the standard linear constitutive law[10]:

$$M(x) = -EI\kappa(x) \quad (1)$$

where $M(x)$ is the local moment, E is the elastic modulus, I is the second area moment of the area of the cross section, and $\kappa(x)$ is the local curvature. The combined term EI is defined as flexural rigidity. For small curvature, the usual linearization of slope and curvature applies, and flexural rigidity can be approximated as:

$$EI = (FL^2)/(2\tan\theta) \quad (2)$$

where F and L are defined above, and θ is the rotation angle at the point of the load. Using the exact relation between slope and curvature, the flexural rigidity was derived for nonlinear systems:

$$EI = (FL^2\sqrt{1+\tan^2\theta})/(2\tan\theta) \quad (3)$$

FE validation: To verify the framework, an FE simulation was developed in COMSOL (COMSOL Inc., Burlington, MA). A 450 mm hollow tube was subject to a load applied 420 mm from the fixed end of the fixed-free cantilever beam. The beam was made of a neo-Hookean material, and a finite strain formulation was applied. The angle of deflection θ was derived from trigonometry comparing deflections at the loading point (x = 420 mm) and the end of the beam (x = 450 mm). Gravitational loading was neglected. The measured angle was applied using Eqs. 2-3 to estimate flexural rigidity of the beam under varying loads from 0.25-1.5 mN. The dimensions matched standard 6F catheter models with an elastic modulus of 0.4 GPa. Estimated values were compared to the predetermined input flexural rigidity (EI). Tests were repeated for a short 35 mm beam with the load applied 30 mm from the fixed end. Convergence tests were performed, and all models achieved convergence with between 2238 and 423906 degrees of freedom (DOF).

Image analysis: The FEM simulations and experimental images were examined using ImageJ to obtain the deflection angle θ for Eqs. 2-3. Images were 1024x1024, with at least 512 pixels over the free end length of the device past the loading point. The angle was measured as a difference in angle between initial and final tangents at the load. The length L was measured from the fixed end to the applied point load.

RESULTS

The FEM validation in COMSOL indicated that the nonlinear flexural rigidity calculations are precise and accurate at high angles while linear values are less accurate with increasing deflection angle θ (Fig 1-2). The image analysis technique validation test accurately estimated the flexural rigidity using the nonlinear approach and was less precise for the linear approach at high angles. The validated framework was applied to characterize a range of commercial catheters and sheaths used for endovascular procedures in the neurovascular and lower extremity peripheral arterial systems. Measured values were plotted and clustered based on device type and procedure (Fig. 3).

DISCUSSION

The flexural rigidity values measured revealed key differences between catheters and sheaths used for neurovascular and lower extremity peripheral arterial procedures. First, catheters clustered into a single range of values. This is logical since catheters are commonly employed as the flexible tool used for navigation through the entire the peripheral arterial system. In contrast, sheaths clustered into two distinct groups based on the anatomical destination. Lower extremity peripheral arterial sheaths were measured to be more rigid than neurovascular sheaths. This is justified procedurally since neurovascular sheaths must traverse acute bends across the aortic arch and proximal carotid arteries.[11] Drastic differences between sheaths are justified since they scale with diameter along the trendlines, showing similar elastic moduli.

The methods are simple but have limitations that should be noted. Nonlinear beam theory is valid for the geometric nonlinearity, but not for material nonlinearity.[12] Flexural rigidity measure can evolve with flexure for nonlinear materials, and it is possible for this to change over time if the material is viscoelastic.[13] Precision was limited by image quality, requiring use of megapixel cameras.

The measured flexural rigidity of common sheaths and catheters provide parameters for increased procedural efficiency and future device development. Our technique will enable assessments of endovascular tools to determine suitability for specific interventions. The stiffness ranges identified serve as baselines for evaluating and developing new products within these procedural device ecosystems.

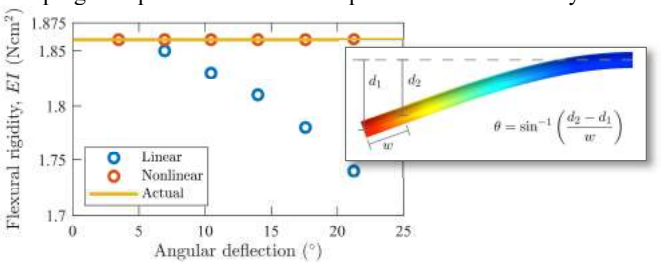

Figure 2: Validation of finite the experimental method using synthetic images generated using finite element analysis. The linear approximation was accurate to within ~5%, while the nonlinear approach was accurate to within a fraction of a percent.

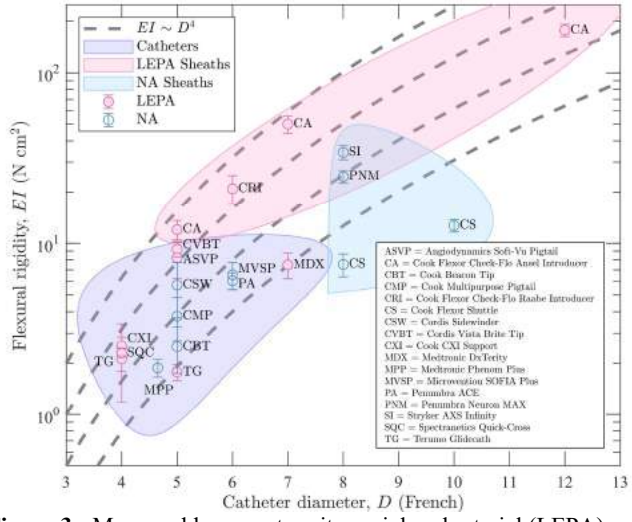

Figure 3: Measured lower extremity peripheral arterial (LEPA) and neurovascular (NA) catheter and sheath flexural rigidity measurements based on diameter are clustered by procedure.

INTRODUCTION

Cerebral aneurysms are weak or thin sections of the artery wall in the brain that bulge and fill with blood with the potential of placing pressure on nerves or brain tissue[1]. Ruptured aneurysms spill blood into the surrounding tissue and can cause serious health complications or even death. One of the most established risk factors of aneurysm rupture is size[2]; larger aneurysms are typically more likely to rupture. Because of this, many aneurysm management plans and prognoses are assessed by size of the aneurysm. However, smaller aneurysms can and do rupture, demonstrating the need for additional risk assessment[3]. Other risk factors of rupture include location, high blood pressure, smoking, and family history of cerebral aneurysms[1]. While these can improve prediction of rupture, they still do not provide complete accuracy.

Previous studies have identified hemodynamic predictors for aneurysm rupture, including low wall shear stress (WSS), low WSS area, high oscillatory shear index (OSI), lower systolic and mean arterial pressures in the aneurysm, narrow pulse pressures in the aneurysm dome, and high relative residence time in the aneurysm, as well as morphological predictors such as larger size, aspect ratio, size ratio, and height-width ratio[4,5,6,7]. In contrast to the focus of these existing studies on ruptured aneurysms, we aim to identify and assess hemodynamic predictors of cerebral aneurysm *growth* to enable earlier clinical detection and prevention of rupture.

METHODS

From MRA and CTA scans, we will model 15 matched pairs (30 total) of cerebral aneurysms using 3D segmentation tools in the Vascular Modeling Toolkit (www.vmtk.org). Each pair consists of one non-growing cerebral aneurysm and one growing aneurysm of a similar size in the same location. Given the limitations of current 3D segmentation methods, models were manually smoothed in MeshMixer (www.meshmixer.com), and all vessels were truncated normal to the vessel centerline. All models were meshed with linear tetrahedral elements and 3 boundary layers with a layer decreasing ratio of 0.8 in TetGen.

All computational fluid dynamics (CFD) simulations were performed using the open-source software SimVascular (simvascular.org). Clinically measured flow waveforms from published studies were prescribed at the inlets with a parabolic velocity profile, and outflows were distributed proportionally to outlet areas[8,9]. Wall compliance was neglected and no-slip boundary conditions were applied at the walls.

We systematically tuned our outlet boundary conditions to achieve systolic, diastolic, and mean aortic pressures at the inlets as well as the target area-based outflow splits. With steady inflows prescribed, outlet resistances were first tuned to achieve mean aortic pressures. In progressing to pulsatile inflows and outlet RCR Windkessel boundary conditions, these tuned outlet resistances were then distributed, and the proximal:distal resistance ratio and capacitances were tuned to achieve target aortic pulse pressures. Simulations were run for 4-18 cardiac cycles to enable convergence of all inlet and outlet pressures to

a limit cycle. Upon completion of outlet boundary condition tuning, mesh refinement was performed to ensure WSS convergence.

We will compute the temporally and spatially averaged WSS, minimum WSS, maximum WSS, and mean OSI over various spatial regions, including the dome, parent artery, and neck, and further determine the most appropriate means of normalizing these metrics across the patients. These metrics will be statistically compared for the growing and non-growing aneurysms using a non-parametric Wilcoxon signed-rank test to account for the paired samples.

RESULTS

We have constructed anatomical models of two growing aneurysms with smoothed geometries and truncated inlets and outlets (**Figure 1**) and will model the remaining 28 aneurysms over the next few months**.**

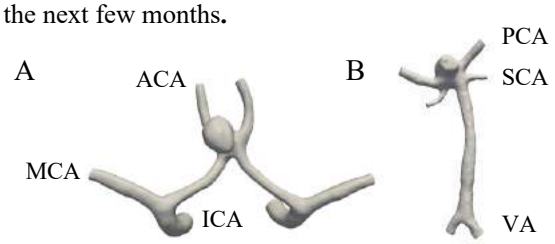

Figure 1: (A) Aneurysm of the anterior communicating artery with internal carotid artery (ICA) inlets and anterior cerebral artery (ACA) and middle cerebral artery (MCA) outlets, and (B) aneurysm of the basilar apex with vertebral artery (VA) inlets and superior cerebral artery (SCA) and posterior cerebral artery (PCA) outlets

Beyond modeling, we have completed boundary condition tuning (see **Figure 2**) and achieved time-averaged WSS (TAWSS) convergence (see **Figure 3**) via mesh refinement for case A, as well as the steady tuning of case B. The target systolic and diastolic pressures of case A were reached within 5% error in the simulation, but the mean pressure is slightly high, likely because the target mean pressure was not patient-specific. The TAWSS spatially averaged over the dome was 3.69 Pa, which was in agreement with previously published values[6]. In case B, the target flow splits and target inlet mean pressures were reached within 5% error.

Statistical analyses comparing hemodynamic quantities of interest between the growing and non-growing cohorts, as well as preliminary observations regarding optimal hemodynamic predictors of growth, will also be presented.

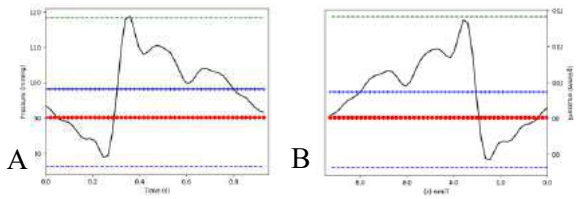

Figure 2: Target inlet pressures were reached for (A) the left ICA and (B) the right ICA in case A. The green and blue dashed, blue crossed, and red dotted lines represent target systolic and diastolic, simulated mean, and target mean pressures, respectively.

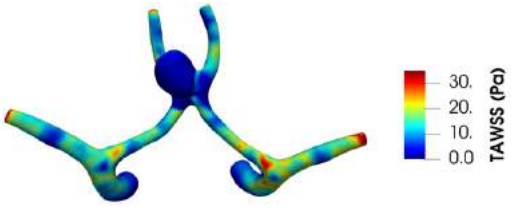

Figure 3: TAWSS distribution for case A

DISCUSSION

While previous studies have investigated hemodynamic predictors of growing cerebral aneurysms, limitations in their sample size and computational methods have precluded any conclusive clinical consensus. A study completed by Brinjikji et al. at Mayo Clinic suggests that the area under low WSS is lower in growing cerebral aneurysms, but the study had a small sample size of only 12 pairs of matching aneurysms[11]. Another study, completed by Sforza et al. at George Mason University, found that growing cerebral aneurysms tend to have complex flow patterns that lead to non-uniform WSS[12]. The growing and non-growing aneurysms in the study, however, were not matched in location or size. Further, both studies neglected to mention pressures in their papers, making the methods for simulation and outflow boundary conditions unclear.

Both studies also computed flow splits using Murray's law, which tends to be more accurate for smaller arteries; however, we found a large variation of flow splits in literature, leading us to believe that an area-based assumption would better match our data set. We also made a point to perform a mesh convergence study for WSS, to include validated pressures to account for pressure pulse in boundary conditions, and to increase the sample size in order to increase the reliability of our results.

CFD simulations have the potential to greatly improve care and treatment for cerebral aneurysms. Knowledge of hemodynamic predictors for growth could provide an opportunity for faster, potentially more preventative treatments without the need for a second imaging scan to detect growth.

INTRODUCTION

Embolization therapy has become an increasingly common approach to treat liver tumors [1]. Catheter directed microparticles are injected into the arterial circulation, which are often loaded with drug (e.g. Trans-arterial Chemo-embolization or TACE) [3] or radiation agents (e.g. Y90 radio-embolization) [2]. The particles perfuse the tumor vasculature, and can lead to ischemic conditions to reduce tumor size, or lead to efficient and targeted local drug or radiation delivery. With a growing utility in treatment, several fundamental questions pertaining to release, transport, and distribution of embolic drug particles in the vascular pathways into the tumor need further exploration. These questions are intimately connected to treatment efficacy and success. However, systematic evaluation of how various drug release and delivery parameters affect the treatment outcomes remains a challenge. With advancements in medical image-based modeling techniques, *in silico* or computational approaches provide a viable alternative to explore these questions. Such platforms can support clinical practice and decision making by enabling pre-treatment virtual simulations of various intervention scenarios. Here, we outline the development of a full-scale patient-specific computational model for intravascular delivery of embolic drug particles into the hepatic vessels for applications in liver cancer (hepatocellular carcinoma).

METHODS

Image-based modeling: A patient-specific model of the abdominal aorta upto the ilio-femoral bifurcation was constructed from abdominal CT scans using SimVascular [4]. Two generations of branches for the celiac trunk, which specifically includes the left and right hepatic arteries and the gastro-duodenal artery, are included in the model (as shown in Figure 1). Pre-procedural Dyna-CT/Cone-beam CT [5] images are used to identify the path taken by the embolic delivery catheter, and a 2 mm (6 French) catheter is segmented out of the arteries along this identified path. The catheter is placed such that the delivery tip is located approximately midway into the common hepatic artery. The final computational model is obtained from a Boolean intersection operation between the segmented catheter and the artery model obtained from CT scans. For comparative evaluation of local hemodynamics at the drug release site, the same arterial network with and without the catheter in place were analyzed.

Hemodynamics: Blood is modeled as an incompressible Newtonian fluid with viscosity 4.0 cP and density 1.06 g/cm^3. The Navier-Stokes equation for fluid momentum balance, and the continuity equation for mass balance, were solved using a stabilized finite element method implemented in SimVascular [4]. A specified physiologically realistic inflow profile was employed at the abdominal aortic inlet face to drive the flow. At all other arterial branch outlets a resistance-based boundary condition was imposed. Resistances were calculated by assuming that approximately 30 percent of incoming flow is routed to the femoral arteries, approximately 34 percent routed to the renal arteries, and the remaining portion of the flow is distributed to all other arterial branches such that $Q_b \propto A_b^3$; with A_b the cross-sectional area of the artery outlet. To mimic the release of particles without any additional fluid injection, the catheter tip was assumed to be a fixed impermeable wall. The fluid flow was simulated for three cardiac cycles with a numerical time-step of 0.001 seconds, and flow velocities and pressures from the third cycle were used for embolic drug particle modeling.

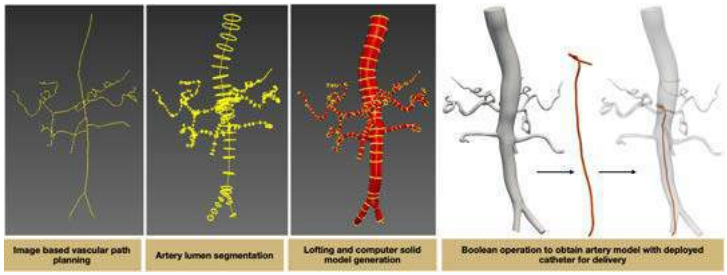

Figure 1: Illustration of the steps involved in image-based modeling of the vascular network of interest with delivery catheter in place.

Drug particle modeling: Embolic drug particles were modelled as spherical inertial particles with diameter 100 µm, using a one-way coupled scheme (that is, particle is influenced by the flow but not vice versa). Fluid-particle interactions are modeled using a custom modified form of the Maxey-Riley equation [6] proposed in prior work for embolic transport through arterial hemodynamics [7]. Briefly, this equation accounts for the dominant forces on the drug particle from the flow including drag, shear-induced lift, fluid stresses and pressure, and added mass effects. Particle interactions with vessel wall were accounted for using a viscoelastic contact mechanics model with model details and parameters as outlined in [7]. A fixed number concentration of drug particles was released at the start of one cycle, and simulated for four successive cycles using a 4'th order Runge-Kutta scheme with numerical time-step 0.0005 seconds. Number fraction of drug particles reaching each hepatic artery branch outlet was computed based on the positions of the particles at the end of the fourth cycle.

RESULTS

Hemodynamics with delivery catheter in place: Flow velocity across the entire arterial model is visualized using streamlines viewed at four instants during the cardiac cycle - mid acceleration, peak systole, mid deceleration, and mid diastole in Figure 2. For the model with catheter in place, a close-up view of the streamlines at these four instances are presented in Figure 3 (where the catheter is highlighted in green). To fur-

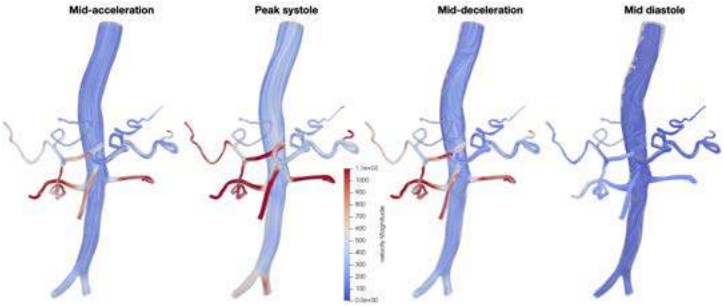

Figure 2: Blood flow streamlines visualized at four successive instants in a cardiac cycle for model with catheter. Velocity units in mm/sec.

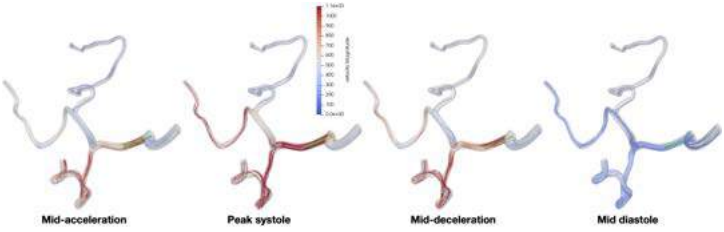

Figure 3: Close-up view of flow velocities (mm/sec) in the hepatic artery network in presence of delivery catheter (marked in green).

ther illustrate local hemodynamic features at the catheter site, slices along the common hepatic artery at three locations (midway along catheter from common hepatic entry, tip of the catheter, and immediately distal to the catheter) are presented for both models at each of the stated instances during the cardiac cycle - as presented in Figure 4. Results indicate that while larger scale flow patterns and velocity regimes between models with and without catheter remain similar, locally around the catheter there are significant hemodynamic differences as indicated in Figure 4, which originates from the catheter-hemodynamics interactions.

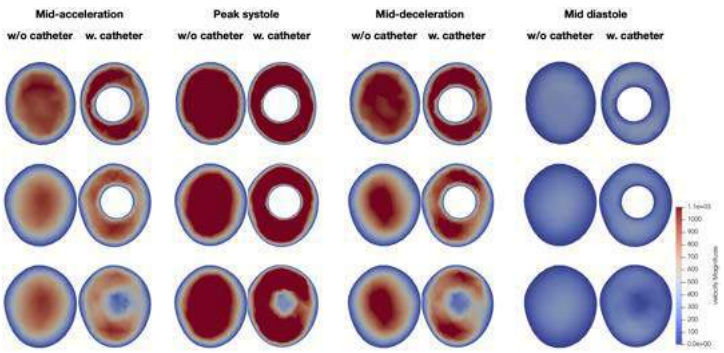

Figure 4: Cross-sections along common hepatic artery for models with and without delivery catheter, illustrating differences in local hemodynamics (units in mm/sec) around the drug release site.

Quantitative analysis of embolic drug delivery: The distribution of the embolic drug particles across the hepatic artery branches are shown in Figure 5. A total of 2126 particles released across the catheter face were tracked. At the end of four cycles, we observed that 30 percent of the drug particles reached a destination vessel. The biggest proportion, around 22 percent, reached the right hepatic artery, while the left hepatic artery received around 0.3 percent, and none reached the gastro-duodenal artery. The embolic drug particle distribution was observed to be dominantly into the right hepatic artery for the simulated case for this study. Analysis of the particle dynamics patterns revealed that as particles traverse the right hepatic vessel, owing to their inertia, the dominant flow direction, and the nearly 90 degree branching angle for the left hepatic artery, the particles predominantly continue their motion along the right hepatic artery. Similar particle inertia effects have been demonstrated in prior works on inertial embolic particles causing a stroke [8].

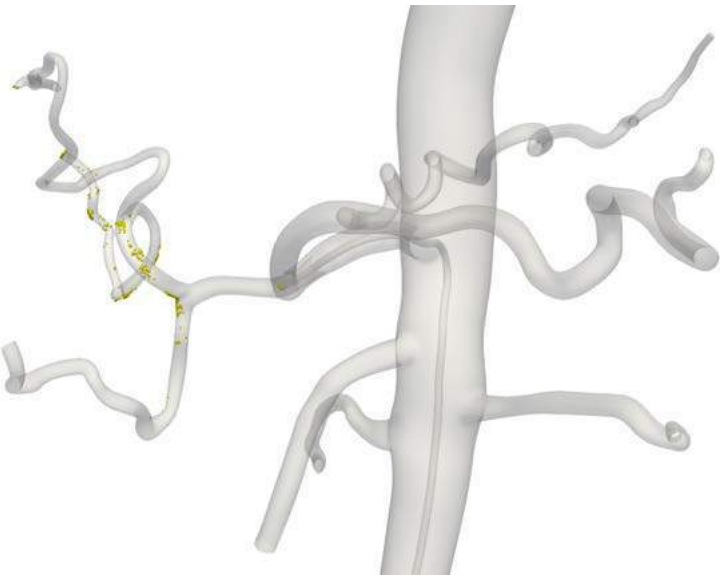

Figure 5: Distribution of 100 micron embolic drug particles (shown in yellow) across hepatic vessels after four cardiac cycles.

DISCUSSION

Implications: We have established a comprehensive *in silico* modeling approach for embolic drug particle delivery, with applications in liver cancer. Results from simulations establish the efficacy of the proposed framework in evaluating extent of drug particle delivery to various vessels of interest. This has broad implications in terms of treatment planning prior to intervention, and assessment of treatment efficacy metrics. Additionally, the results also illustrate the importance of accounting for local hemodynamic environment at particle release site from delivery catheter. For example, over 60 percent of particles remain stuck close to the catheter site for our simulations, mainly because of the local flow separation phenomena around the catheter tip that likely entrains particles and prevents them from migrating towards a destination artery. Hence, specifically, local state of flow at the release site will serve as the initial conditions that ultimately determine the particle trajectories and their distribution. Determining the final particle destination requires consistent characterization of local drug-release hemodynamics.

Assumptions and limitations: The focus of this work was on development of the computational framework. Hence, several aspects have not been accounted for, which are key goals for ongoing and future work. Specific details about the cancer site itself have not been considered here. Similarly, release parameters like drug injection volume, injection flowrate, and injection pressure have not been accounted for at the catheter tip. For the sake of computational costs, we simulated drug particles only for four cycles. We note that particle trajectory computations over a longer duration will provide a more detailed estimation of delivery to various branches, albeit at a higher cost. Finally, interactions between individual drug particles have not been considered here. While for typical number densities of drug particles this may not be a major factor, when number density is increased, we may see an influence of these interactions on particle fate. We remark that, despite these assumptions, the underlying flexibility of the modeling approach we devised here enables easy incorporation of these factors into the computational model - an aspect that we are currently continuing to investigate.

INTRODUCTION

Knowledge of cardiovascular pathologies relies largely on an understanding of the fluid dynamics of the circulatory system. Fluid dynamics, however, can be difficult, computationally expensive, and sometimes impossible to study through traditional experimental techniques like magnetic resonance imaging. Reduced-order computational models, specifically 0D and 1D models, offer the potential to simulate physical and dynamic systems with significant accuracy while maintaining minimal computational resources. Existing models, on the other hand, do not account for changes of energy at junctions.[1]

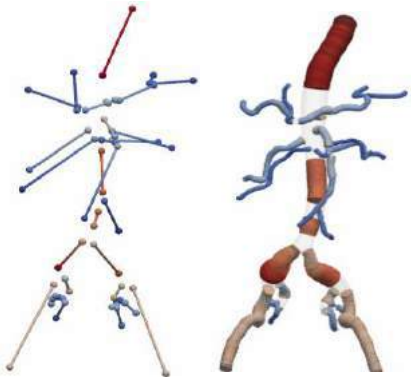

Figure 1: The gaps in the 3D model (left) and 1D model (right) illustrate the lack of junction modeling.

When addressing the accuracy of these models, changes in energy can cause significant discrepancies. Current methods for estimating pressure change employ phenomenological models that are specialized for certain junction geometries and specific blood flow conditions. We compare the performance of such a model for a large database of vascular models from multiple patients. Collectively, these vascular models compose of a total of approximately 3,000 junctions. Such a large comparison has not been done before. Based on our results we suggest improvements of the junction model so that it can be applied to a variety of junction parameters.

METHODS

Constructing reduced-order models from a 3D vascular model requires identifying various blood vessel properties such as vessel lengths, radii, blood viscosity, and flow rates. These parameters can be derived using an image segmentation or a centerline technique. [2,3] We used the open-source SimVascular software (simvascular.org) to extract these characteristics. [4] SimVascular's pipeline takes a 3D model as its input and extracts the geometry's centerlines.

The software generates a 1D solver input file using vessel connectivity, vessel length, and cross-sectional area obtained from the 3D model. The pipeline then maps each anatomical vessel to a corresponding lumped parameter element and computes its value. From this process we derive centerline section normal vectors, flow rate measurements at multiple time steps, area, and a point representation of every branch.

When a blood vessel splits, the original vessel is called the inlet and the resulting blood vessels are referred to as the outlets. Resistance R_k at a given outlet, k, can be calculated by applying the parameters produced by the SimVascular pipeline to

$$R_k = \frac{\rho Q_i}{2\pi^2 r_i^4}\left[\frac{1}{Q_k} + \frac{Q_k r_i^4}{Q_i r_k^4} - \frac{2r_i^2}{Q_i r_k^2}\cos\left(\alpha_{(i,k)}\right)\right] \quad (1)$$

where ρ represents the density of the fluid, blood, Q_i and r_i represent inlet flow rate and inlet radius respectively, Q_k and r_k represent outlet flow rate and outlet radius respectively, and $\alpha_{(i,k)}$ represents the supplementary angle between the inlet and outlet.[5]

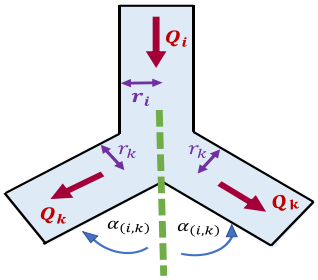

Figure 2: A junction with two outlets and the location of its parameters illustrated.

After solving for resistance, R_k, we can calculate change in pressure, ΔP_k, using the Hagen-Poiseuille equation

$$\Delta P_k = Q_k R_k \tag{2}$$

We programmed the junction model in Python using equations (1) and (2) as its numerical basis. The program outputs the change in pressure at the specified outlet upon being provided with the appropriate inlet and outlet properties as specified above.

RESULTS

We tested the robustness of the junction model using patient-specific data. We used 105 distinct vascular models from an open-source repository (vascularmodel.org). Each model contains pressure and flow data from each model captured at different time steps. The vascular models can be grouped into seven different categories: aorta, cerebrovascular, pulmonary, aortofemoral, congenital heart disease, coronary, and animal and miscellaneous. We calculated the error, e, between the pressure change between inlet and outlet, k, from the repository, ΔR_k, and the change in pressure produced by the junction model from equation (2), using

$$e = \left| \frac{\Delta R_k - \Delta P_k}{\Delta R_k} \right| \tag{3}$$

We calculated error for all the outlets of all the junctions, which produced a total of 3,886 outlets.

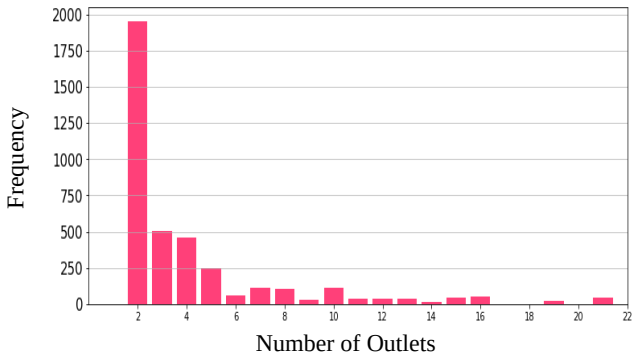

Figure 3: The distribution of outlet counts for every junction of every model in the repository.

In order to determine which vessel parameters produce junction model values closest to the repository values, i.e. which parameters produce the smallest errors, we created our own vascular models using SimVascular. SimVascular provides a complete pipeline from medical image segmentation to patient-specific blood flow simulation and analysis.[6] Creating our own models granted us anatomy of junction bifurcations as well as blood flow conditions. We created models with one inlet and two outlets that have a 45° angle between them and initialized a 50% flow rate between the outlets, meaning half of the inlet's flow traveled through each outlet. We experimented with different flow rates, specifically 8, 16, 24, and 32 cc/s.

Our current results and error analysis demonstrates that the lossy junction model does not accurately predict the pressure loss of the set of over 3,000 patient-specific junction geometries analyzed in our study. There are multiple possible reasons for this behavior. The original lossy junction model that employs formulas (1) and (2) had only been applied to bifurcation junctions simulated under steady flow. Furthermore, prior applications analyzed junctions with only two outlets whereas the anatomies we considered in this study include junctions with outlet counts varying from 2 outlets to 21 outlets. Finally, the vascular models we used were simulated under realistic, unsteady conditions with pulsatile flows.

DISCUSSION

In this work, we used actual patient-specific data and specially designed SimVascular models to test and suggest improvements for a model that measures pressure change at blood vessel junctions. Altering the junction model will aid its application to a variety of junction parameters. After improving the junction model, we can implement it to reduced-order models for cardiovascular blood flow, thereby ensuring that pressure change measurements are not neglected. Its implementation has the potential to improve the accuracy of current blood flow analysis.

We are in the process of creating more SimVascular models to test the junction model. Given the various parameters involved in the junction model, there are various control and experimental variables that we can use. For example, we can control or test the inlet and outlet lengths, the angles between the inlets and outlets, the number of outlets, the amount of blood flow through the inlet, and the distribution of flow between outlets. This lends itself to a further project that involves machine learning. We can use our current and future understanding of the specific effects that these junction parameters have on blood flow measurements to create a network that outputs the best version of the junction model based on the parameters that it is given, such as inlet flow rate, outlet count, and blood flow boundary conditions. Furthermore, the network would possess the potential to learn to differentiate between different vessel anatomy such as the seven categories that the repository vascular models are grouped into.

BIAXIAL MECHANICAL PROPETIES OF RIGHT VENTRICULAR MYOCARDIUM IN ADVANCED PULMONARY ARTERIAL HYPERTENSION

Michael Bennington (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering
University of California, San Diego
La Jolla, CA, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive vasculopathy characterized by sustained elevated mean pulmonary arterial pressure imposing right-ventricular (RV) afterload.[1] Previous studies in early PAH have shown ventricular remodeling, hypertrophy, and myocardium properties.[1][3]. Here, we extended the disease timeline and investigated how the myocardium properties changed in advanced PAH using a well-established rat model of Sugen-hypoxia (SuHx).

METHODS

Tissue preparation. PAH was induced in the male Sprague-Dawley rats through a 20 mg/kg injection of Sugen 5416 (a vascular endothelial growth factor receptor blocker), followed by three weeks of hypoxia (10% O_2). The animals were then returned to normoxia for an additional 15 to 18 weeks to allow the disease to progress to advance PAH. Control animals were kept at normoxia for the same time period. Hypertension was confirmed in an open-chest surgery. The RV free wall was excised, and a square sample was cut from the middle of the tissue aligning one axis with the apex to outflow-tract (AOT) direction (x_1) and the perpendicular axis ran circumferentially (x_2). Five graphite markers were placed on the center region of the tissue surface to track tissue displacement. Side length and thickness measurements were taken, and four custom-made hooks were attached to each side of the sample. The sample was loaded on the Bose Electro-Force planar biaxial testing device. During the biaxial tests, the tissue kept in a 37°C bath of phosphate-buffered saline.

Mechanical testing. RV samples were pre-stretched with a 3.0 g tare load and subjected to displacement control biaxial testing. The x_1:x_2 stretch ratios were 1:1, 1:0.5, 1:0.25, 1:1, 0.5:1, 0.25:1, 1:1, with a maximum stretch of 10% of the *ex vivo* length. Each block consisted of 15 loading-unloading cycles at 0.5 Hz. The first block was used to ensure the tissue was pre-conditioned and the last 3 cycles of blocks 2-6 were point-wise averaged and used for analysis.

Constitutive equation. Loads measured on each axis were used to calculate the first Piola-Kirchhoff (PK1) stress tensor $\boldsymbol{P}$ using the unloaded dimensions measured before the test. The pixel location of the four exterior markers measured with an overhead camera sampling at 200Hz were used to calculate the deformation gradient tensor $\boldsymbol{F}$ *via* isoparametric mapping to a bilinear finite element. The reference configuration β_1 (**Fig. 1**) was defined to be the tare-loaded configuration, with the Green strain tensor $\boldsymbol{E}$ defined with respect to β_1:

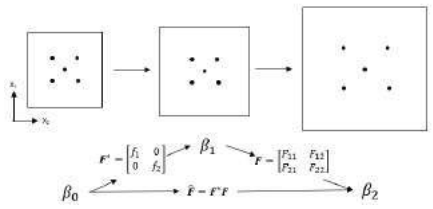

Figure 1: Mapping from stress-free reference state $\boldsymbol{\beta_0}$ to arbitrary test state $\boldsymbol{\beta_2}$.

$$\boldsymbol{E} = \frac{1}{2}(\boldsymbol{F}^T\boldsymbol{F} - I). \quad (1)$$

The second Piola Kirchhoff (PK2) stress tensor $\boldsymbol{S}$ relative to the tare state was calculated as $\boldsymbol{S} = \boldsymbol{F}^{-1}\boldsymbol{P}$.

The myocardium was assumed to be a planar hyperelastic material described by a Fung-type exponential strain-energy function defined as

$$W(\widehat{\boldsymbol{E}}) = C\left(e^{Q(\widehat{\boldsymbol{E}})} - 1\right) \quad (2)$$

where

$$Q(\widehat{\boldsymbol{E}}) = \hat{a}_1\widehat{\boldsymbol{E}}_{11}^2 + \hat{a}_2\widehat{\boldsymbol{E}}_{22}^2 + \hat{a}_3\widehat{\boldsymbol{E}}_{11}\widehat{\boldsymbol{E}}_{22} \quad (3)$$

is the Green strain tensor $\widehat{\boldsymbol{E}}$ referenced to the unloaded state (β_0). The

PK2 stress with respect to β_0 is thus

$$\widehat{\boldsymbol{S}}_{ij} = \widehat{\boldsymbol{F}}^{-1}_{ik}\boldsymbol{P}_{kj} = \frac{\partial W(\widehat{\boldsymbol{E}})}{\partial \widehat{\boldsymbol{E}}_{ij}} = Ce^{Q(\widehat{\boldsymbol{E}})}\frac{\partial Q(\widehat{\boldsymbol{E}})}{\partial \widehat{\boldsymbol{E}}_{ij}} \quad (4)$$

Using the mapping from β_0 to β_1 ($\boldsymbol{F}^*$), the deformation from the unloaded state β_0 to the current configuration β_2 is $\boldsymbol{F}^*\boldsymbol{F}$. Using this total deformation, (4) can be reformulated in terms of the experimental stretches Λ_i (β_1 to β_2):

$$S^M_{ii} = Cf_ie^{Q(\boldsymbol{\Lambda})}\left(4a_i((f_i\Lambda_i)^2-1) + 2a_3\left(\left(f_j\Lambda_j\right)^2-1\right)\right) \quad (5)$$

where

$$Q(\boldsymbol{\Lambda}) = \sum_i^2 a_i((f_i\Lambda_i)^2-1)^2 + a_3((f_i\Lambda_i)^2-1)\left(\left(f_j\Lambda_j\right)^2-1\right), \quad (6)$$

$i \neq j$, $a_k = \hat{a}_k/4$, and S^M_{ii} the PK2 stress with respect to β_1. In (5), f_i are the pre-stretches in the normal direction.

Numerical implementation. Data were then fit to these reformulated model equations using the following objective function:

$$\phi(\theta) = \sum_i^2\sum_j^n\left(S_{ii}(t_j) - S^M_{ii}(t_j;\theta)\right)^2 \quad (7)$$

where θ is the set of parameters $\{C, a_1, a_2, a_3, f_1, f_2\}$ and $S_{ii}(t_j)$ is the experimentally-derived stress tensor. The parameter estimation was carried out in SciPy using the Limited Memory BFGS algorithm. The material parameters were bounded to be positive and the pre-stretches greater or equal to 1. Using the optimal set of parameters, the strain-energy surface for each animal was generated. Within each group, the surfaces were point-wise averaged with their respective upper and lower bounding surfaces. The averaged and bounding surfaces were then fit to the strain-energy function to obtain a set of parameters representative of the control and SuHx RVs. The stresses at equibiaxial strains of 0.06 were compared between axes and groups using two-factor ANOVA. Significance was determined at α of 0.05.

RESULTS

Hypertension was confirmed in the treated group (RV end-systolic pressure of 65±11 mmHg in the disease *vs* 23±6 mmHg in control). RV thickness increased from 1.46±0.16 mm to 1.8±0.6 mm in and RV mass increased from 0.33±0.5 g to 0.64±0.11 g. The mechanical data from the control and treated animals were closely fitted with a coefficient of determination (R^2) ranging from 0.82 to 0.95 (**Fig. 3**). The mean strain energy surface was steeper for the SuHx animals, and the largest change (percent difference) in parameters being the stiffness scaling parameter *C*, and the circumferential exponential coefficient $\hat{a}_2$. The RV myocardium was anisotropic, but the differences between AOT and circumferential stresses were only statistically significant in PAH (**Fig. 2**). The shear components of the strain tensor were negligible throughout the tests for control and treated animals.

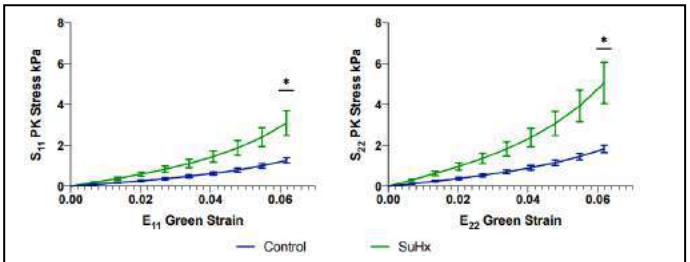

Figure 2: Mean and standard errors of the mean equibiaxial stress-strain relations obtained from normo- and hyper-tensive right-ventricular myocardium.

DISCUSSION

In the advanced stage of PAH, there was a significant increase in stiffness on both axes, which is consistent with previous findings in the early-stage PAH[1]. This study provides evidence that, while the tissue remodels along the fiber and transverse axes, there are larger changes in the circumferential direction, leading to a greater level of anisotropy in the PAH ventricle. In addition, while there was an increase in the free wall thickness from control to PAH, this change was far lower than was seen in the studies of the early stages of PAH. While in those experiments there was a two-fold increase in RV thickness[1], the increase in thickness of these later SuHx animals was ~25%. This indicates that the RV continues to remodel, with a thinning of the wall.

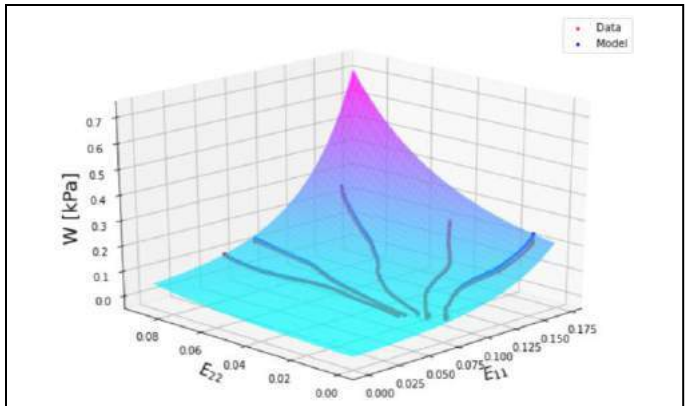

Figure 3: Strain-energy surface generated with biaxial.

The adjusted Fung model used in this study was able to approximate the experimental data well while also taking into consideration the tare applied to the tissue. Given that shear components were negligeable in the tests, the mapping from β_0 to β_1 being only in the normal directions was a valid assumption. By incorporating the preload stretches into the model, we can better back extrapolate the toe region of the tissue within the context of the model and map all the tissues to a common reference configuration, independent of preload stretch, which itself depends on the mass and tissue dimensions. This is critical because a fixed tare load will lead to different levels of initial stretch between axes and between tissues, meaning different regions of the strain-energy surfaces are being compared. With this modification, corresponding regions can be properly compared.

While the model fit well and provided insights about the remodeling in advanced PAH, it was unable to explain the asymmetrical axis coupling that was noticed in both the control and disease state tissues, where the strains in the circumferential direction had a larger contribution to the stress on the AOT axis than the AOT strains had to the circumferential stress. In the current formulation of the Fung-type model only has a single coupling term $\hat{a}_3$, which is not sufficient to explain this phenomenon. This, in addition to the increased thickness in both the control and disease state tissues, suggest that the transverse axis contributions to the planar stress may be more significant in older animals and in the more advanced stages of the PAH.

INTRODUCTION

The most recent report published by the Global Asthma Report enumerates over 300 million people suffer from asthma, killing an estimated 1000 people daily [1]. Despite existing methods to alleviate asthma related symptoms, such as inhalers and nebulizers, there are still no known cures; lung mechanics is a vastly underexplored area of research, and airway mechanics specifically is misunderstood: recently, our lab disproved the long-standing concept of smaller bronchi being more compliant, sparking reconsideration of the role of distal airways in breathing systems, such as ventilators, which have built on these concepts [2]. Here in this study, we use finite element modeling to investigate the beneficial or harmful effects of remodeling on airway obstruction by comparing the development of healthy versus asthmatic airways.

A 2007 experimental study by Plopper et al. considered the disrupted growth of airways in monkeys by toxin and pollutant exposure [3]. From 1 to 6 months, normal airways grow by one-third in diameter and double in length. In comparison, grown asthmatic airway dimensions were significantly altered (relatively shorter in length and with a narrower diameter), and notable variations in the contractile smooth muscle orientation, responsible for bronchoconstriction and obstruction of the airway lumen, was observed. Here we implement bronchoconstriction via smooth muscle pressure loading using SolidWorks and Abaqus to compare the obstruction in healthy and diseased cases. Additionally, a third theoretical scenario is constructed, where the altered diseased airway dimensions are paired with the healthy smooth muscle orientation to evaluate the extent of the roles of morphology and bronchoconstriction. All analyses are informed by experimental parameters from the literature. We hypothesize this remodeling is a protective mechanism and that the narrowing of the airway will be greatly impacted by the angle of the pressure induced by the smooth muscle, but decreased growth in asthmatic airways may help to maintain structural integrity of the lumen.

METHODS

Bronchial models were constructed using the 6 month old healthy and asthmatic (ozone exposed) airway geometry of infant rhesus monkeys [3]. The third theoretical airway used the dimensions of the asthmatic model and the smooth muscle orientation of the healthy case (detailed below). The standardized diameter (d) as illustrated in Plopper 2007 was set to 0.5mm, based on anthropometric relationships [4], and was used to calculate the airway diameter (D) and length (L) 6 month grown parameters. The thickness of the airway walls (the inner mucosa thickness t_i and outer submucosa thickness t_o) are matched to the dimensionless, experimentally-specified, geometric ratios by airway generation, as shown in Table 1 [3,4]. The inner radius (R_2) refers to the distance from the center of the airway to the submucosa layer, while the innermost radius (R_1) refers to the distance from the center of the airway to the mucosa layer [4].

Bronchoconstriction was implemented by applying pressures via a smooth muscle wrapped around the airway cylinder, either orthogonally oriented relative to the airway axis for the healthy and theoretical case, or at 30 degrees for the diseased case, (with matched surface areas for all three study cases). The maximum contractile load of 0.147 MPa [5] was used and the instance where the lumen collapsed and inner layer self-contacted (in the limiting asthma model only) was analyzed for equivalent comparisons. An elastic modulus of 30 kPa and Poisson's ratio of 0.45 was used, in accordance with the literature [2,3,6]. Hybrid elements are used to account for the near compressible nature of the airways and model parameters are also listed in Table 1 [6]. The extent of obstruction is quantified (as a percent of final to initial lumen cross-

section), and the maximum principal stresses induced due to bronchoconstriction are compared.

Table 1: The geometric, material, and loading parameters used to construct and analyze the healthy and asthmatic airways are listed. The third theoretical airway utilized asthmatic model dimensions and the healthy smooth muscle orientation.

Geometric Parameters		
	6 mo Healthy	6 mo Asthmatic
D (mm)	0.675	0.475
L (mm)	1.2	1.001
t_o (mm)	0.1125	0.0792
t_i (mm)	0.0045	0.00317
R_2 (mm)	0.225	0.1583
R_1 (mm)	0.2205	0.15517
Smooth Muscle Orientation	0 º	30º
Material & Loading Parameters		
Pseudoelastic modulus (Young's Modulus)		30kPa
Poisson's Ratio (Submucosa & Mucosa)		0.45
Maximum Pressure of Smooth Muscle		0.147 MPa
Linear Hybrid Elements		71 – 92K
Nodes		78 – 103K

RESULTS

Figure 1 illustrates the obstruction pattern and stress distribution of the deformed (A) healthy, (B) asthmatic, and (C) theoretical airway configurations. The asthmatic airway is seen to self-contact and greatly obstruct. Maximum principal stress magnitudes, areas and percent obstruction are listed in Table 2.

Table 2: Quantification of obstruction and principal stresses in the healthy, asthmatic, and theoretical airways.

Airway Obstruction			
Model	Original Cross-Sectional Internal Area [mm^2]	Internal Cross-Sectional Area after Deformation [mm^2]	**% Obstruction**
Healthy Airway	0.1527	0.1195	21.7%
Asthmatic Airway	0.0755	0.0091	87.9%
Theoretical Airway	0.0755	0.0556	26.4%
Principal Stresses in Obstructed Region			
Healthy Airway			4.863e-04 MPa
Asthmatic Airway			1.659e-02 MPa
Theoretical Airway			4.672e-04 MPa

DISCUSSION

In this study we characterize obstruction mechanics in silico, comparing experimentally measured airway dimensions and smooth muscle orientations in healthy and asthmatic rhesus monkeys to examine the potential advantages versus disadvantages of pulmonary remodeling. We find that the asthmatic airway with 30 degree smooth muscle results in much greater obstruction (87.9%) compared to orthogonal smooth muscle models (21.7% and 26.4%). This model also buckles into a 2 fold pattern, where reduced folding patterns are known to cause greater obstruction than higher modes [4,5]. Furthermore, the principal stress magnitudes are multiples greater in the asthmatic airway.

The theoretical airway model (with the smooth muscle orientation of the healthy scenario and dimensions of the asthmatic lumen), exhibits slightly greater stresses than the healthy case but much lower stress values than the asthmatic model; this suggests the smooth muscle orientation plays a more notable role in airway mechanics than the geometry. Conversely, the theoretical (asthmatic) dimensioned airway does not obstruct to the same extent as the healthy model, suggesting the narrowed geometry inhibits collapse of the airway under identical loads.

This model has limitations. For instance, here we use a representative length of the airway with a single smooth muscle instead of the physiologically observed stacks of muscle spirals wrapped in series along the length of the bronchi; contractile neighboring effects are not considered [3]. However, models of airway collapse are primarily 2D, and this 3D approach considering the angle of the smooth muscle for the first time yields new insights [4,5]. Additionally, this model does not account for the tethering effects of cartilaginous bronchial scales or the parenchyma, which will enable elastic recoil and resist lumen collapse [3]. While this simplified approach provides new practical considerations to explore further, it is idealized and can benefit from including additional complexities including airway anisotropy [2].

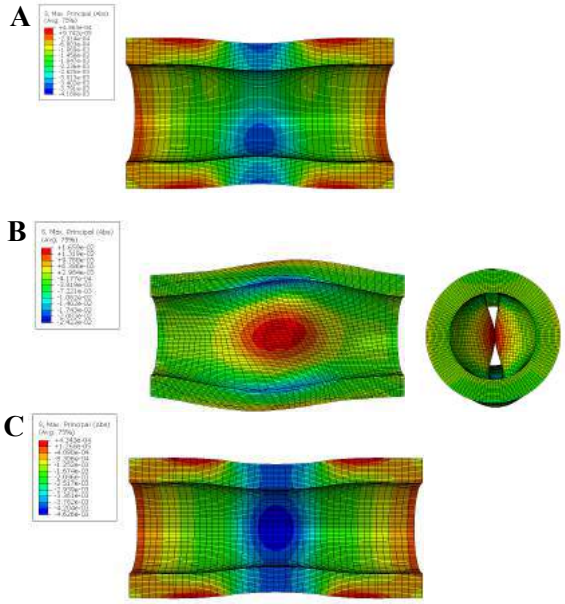

Figure 1: (A) healthy, (B) asthmatic (side and cross-sectional view), and (C) theoretical airway deformations with principal stress illustrations.

We hypothesized bronchial remodeling to have beneficial effects but conclude that while narrowed airway morphology may maintain structural integrity and keep the lumen unobstructed, the orientation of the smooth muscle dominates lumen behavior and resulting stresses. These findings may have implications for clinical interventions aimed at targeting bronchoconstriction and smooth muscle mechanisms, such as bronchial thermoplasty.

INTRODUCTION

Physical characteristics of a cell's environment impact cellular function and development. Rigidity of the extracellular matrix (ECM) is sensed by adherent cells, eliciting multiple protein signaling pathways, which ultimately activate DNA in the nucleus. Force across cell-ECM adhesion molecules induces a conformational change which can accommodate binding or phosphorylation of other cytoskeletal molecules. It is important to comprehend the traction force transmission from cells to the ECM as a function of ECM stiffness, as it determines the force across the adhesion structure. Ultimately, this understanding can lead to better therapeutic strategy in cancer metastasis, atherosclerosis, stem cell differentiation, and other fields[1,2,3].

Investigation of potential mechanisms of the relationship between traction force transmission and substrate stiffness has unearthed some contradictory results. Studies ranging from 2005-2017[2,4,5,6] indicate a monotonic (linear) relationship between stiffness and focal adhesion (traction) force, consistent with current knowledge of mechanotransduction. However, some have shown opposite findings: decreased traction with increasing stiffness[7]. These studies support their data with a molecular clutch mathematical model.

To reproduce either of these findings, a graduate student in Han lab at MTU has measured traction force of 3T3 (mouse fibroblast) cells with varying gel stiffness. The result was consistent not with the monotonic trend but with the biphasic trend; that is, after a short rise until 5kPa, traction decreases with increasing stiffness. This is surprising, as cell types and stiffness range was consistent between this study and Roca-Cusachs et al[1]. After interpretation of the plot and with the understanding about the stiffness-sensing theory, we hypothesized that most-likely cause of this different response is the difference in mechanical and chemical characteristics of the silicone gel used in Han lab (Q-gel, made of two components QGel 920A and 920B) and the polyacrylamide (PAA) hydrogel, formula (C3H5NO)n.

In this study, we show that Qgel and PAA gel differ significantly in hydrophobicity, although they can be similar in stiffness; with an understanding of this data, we propose that hydrophobicity dominates cell spreading and adhesion.

METHODS

Polyacrylamide (PAA) hydrogel was synthesized on acid washed coverslips using a mixture of acrylamide and bisacrylamide at different ratios, yielding different stiffnesses. Qgel920 from Quantum Silicones was synthesized with different ratios of components A and B to manipulate stiffness. Contact angles were photographed using a microscope attached to a camera; the images were analyzed using ImageJ software with the LB-ADSA plugin[8] to quantify the contact angles for each gel. Plasma treatment of Qgel and subsequent contact angle measurement established that the contact angle (hydrophobicity) of Qgel can be easily adjusted. Gels' attractive capabilities (stickiness) and stiffnesses were measured via Atomic Force Microscopy, although first the Qgel had to be coated with 1% Bovine Serum Albumen (BSA) for one hour to minimize the surface charge-induced attractive force to the cantilever (Fig. 3). Storage moduli (G') for Qgel's stiffness spectrum at all mixing ratios was quantified using a DHR-2 hybrid rheometer time sweep program in TRIOS software (Fig. 1).

RESULTS

First, rheometry tests over the range of Qgel mixing ratios (1:1 - 1:2) produced stiffness values within a range similar to that of PAA (Table 1). Gutierrez et al[9] have calculated the stiffness of Qgel by applying a known shear hydrodynamic stress using a microfluidic device and measuring the resulting shear strain, but rheometry experiments have given slightly different values. See Fig. 1 for an example of how storage modulus, G', increases with time, coming nearly to a plateau at 10 hours.

Table 1: Rheological Spectrum of Qgel

Mixing ratio	1:1.0	1:1.1	1:1.2	1:1.5	1:2.0
G' (kPa)	0.7	1.3	2.7	6.0	13.0
G' reported by Gutierrez et al.	0.7	3.7	N/A	N/A	18.0

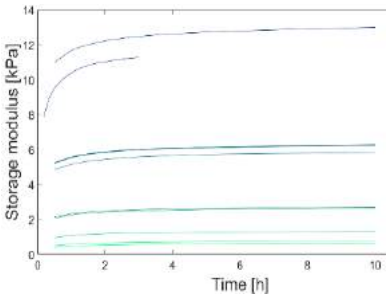

Figure 1. Qgel storage modulus (G', Pa) as a function of time during the curing process. Lines progress from light to dark with increasing amount of Qgel component B added (1:1, 1:1.1, 1:1.2, 1:1.5,1:2).

Secondly, however, contact angle measurement showed that Qgel (120º-130º) was much more hydrophobic than PAA (20º-30º). (Fig. 2A,B,D). This suggests that the effect of surface hydrophobicity on cell adhesion, and thus on spreading, could potentially contribute to inconsistency between literary PAA and laboratory Q gel results.

Interestingly, we also found that while Qgel remained consistently hydrophobic across multiple stiffnesses, PAA showed inverse correlation between stiffness and hydrophobicity; the higher PAA stiffness, the lower its contact angle (Fig. 2D). The effect of stiffness on hydrophobicity was measured for both gels using a Mann-Whitney U-test; the null hypothesis was rejected for PAA gel only.

To make the Qgel surface more hydrophilic, we treated Qgels with plasma for 30 seconds and measured the contact angle. This treatment made the surface successfully hydrophilic, with an average angle of 53º (Fig. 2C,D), again with no stiffness dependency. Longer plasma treatment has been attempted; however, the contact angle did not decrease further.

To further test the surface characteristics of the Qgel, we have performed nano-indentation tests using atomic force microscopy (AFM). Even in PBS, we reproducibly observed that there was a huge attractive force to the AFM cantilever well before actual contact to the gel surface. Treating the gel with a bovine serum albumin (BSA), we were able to remove the attractive force and obtain a flat baseline (Fig. 3, see positions indicated by arrows). We are in the process of estimating Young's moduli from the force-displacement curves.

DISCUSSION

Our data show that the high-refractive silicone gel surface, i.e., Qgel, is extremely hydrophobic compared to a common hydrogel, i.e., PA gel. This hydrophobicity is reduced when treated with plasma. Future experiments will utilize plasma-treated Qgels and untreated Qgels to test how hydrophobicity affects cell adhesion and spreading, independently of stiffness. This will determine whether plasma treatment, by decreasing hydrophobicity, allows cells to mimic the results found using PAA gel: spread increasing with stiffness. We anticipate the result that the substrate hydrophobicity dominates cell spreading and adhesion; this will resolve at least some of the discrepancies between stiffness-sensing studies utilizing silicone and hydrogels.

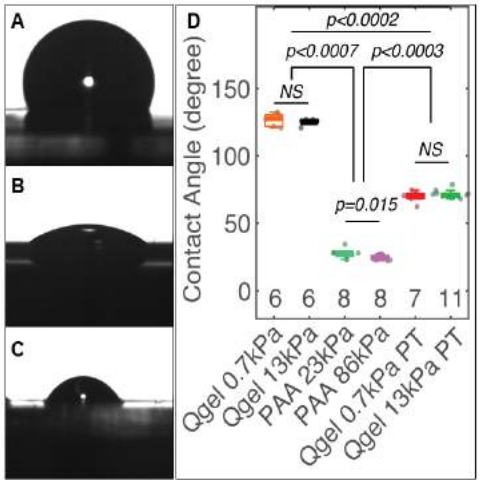

Figure 2. A: 0.7 kPa Qgel ; B: 13.0 kPa Qgel ; C : 13.0kPa Qgel with 30s plasma treatment; D : Box plot of contact angle for each gel type and condition. PT indicates Plasma Treated; numbers on X axis represent sample number *n* for each stiffness.

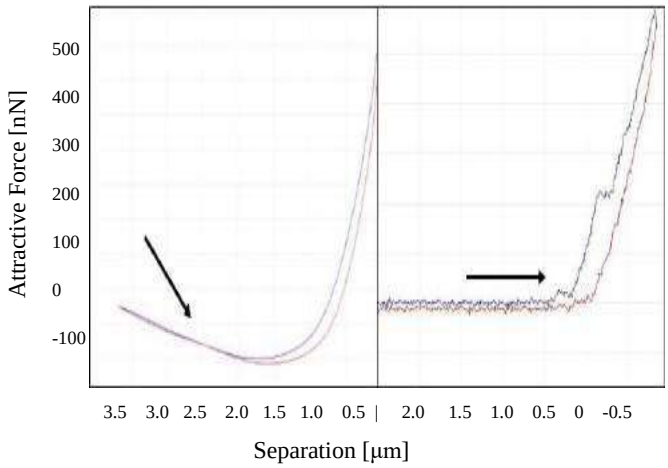

Figure 3. AFM Force-Distance Curve with Qgel before (L) and after (R) BSA coating. Note the large attractive force causing a curved baseline (see direction of arrows), even when the tip is 3 μm away from the gel surface. The blue curve represents the approach of the AFM tip to the gel ("trace"), whereas the red curve shows the "retrace" force as the cantilever leaves the gel's surface.

COLLAGEN V PROMOTES CELL CONTRACTILITY COMPARED TO COLLAGEN I

Shaina P. Royer (1), Nikhil Mittal (1), Sangyoon J. Han (1)

(1) Department of Biomedical Engineering
Michigan Technological University
Houghton, MI 49931, USA

INTRODUCTION

Collagen is the primary structural protein in the human body. Most types of collagen have a fibrillar triple helix structure. Collagen I is by far the most common type of collagen. It is frequently found alongside collagen V whose globular N terminal is thought to play a regulatory role in the formation of collagen fibrils [1]. Yet, collagen type-specific cell behavior has not been fully understood. Differences in the behavior of fibroblast have been observed in fibroblasts cultured on collagen I compared to collagen V. While fibroblasts cultured on collagen V initially display similar levels of proliferation to those cultured on collagen I. This drops off on the 3rd day and by the 5th day there is less coverage of the plate than there was on the 3rd day. Additionally, fibroblasts cultured on collagen V form a ball on the 3rd day with pieces of collagen V from the substrate remaining attached to the cells in the ball [2]. We hypothesized that this behavior is due to an increase in contractility via strong integrin mediated adhesions causing the collagen V to get ripped off from the underlying glass substrate.

To test this hypothesis, we have used traction force microscopy (TFM), a technique used to quantify the contractile force a cell exerts on the deformable substrate, to compare traction transmitted by cells on collagen I vs. collagen V by coating them on a high-refractive silicone gel. Compared to the previous study [2], our bonding of collagen to the gel was covalent, i.e., amine-carboxyl interaction, thus prevents the potential rupture of collagen layer from the gel layer. Thus, the deformation and traction would well represent the contractile state of the cells on each collagen.

METHODS

To fabricate high-refractive index TFM gel with an elastic modulus of 2 kPa, Q-gel 920 (Quantum Silicones) parts A and B were mixed in a 1:1.2 ratio for 2 minutes on a vortex at high speed followed by gentle hand mixing. The gel mixture was pipetted into a glass bottom dish then spin-coated to a thickness of 45 µm and cured in an oven at 80 °C for 2 hours. The cured gel was stored in PBS. Silane coating was performed by liquid deposition using a 5% solution of (3-Aminopropyl) triethoxysilane in absolute ethanol. Bead coating was performed by sonicating a mixture of 50 µL of 100x 1-Ethyl-3-(3-dimethyl aminopropyl)carbodiimide (EDC), and 1 µL of 0.04 µm diameter carboxyl-coated dark-red polystyrene microspheres in DI water for 15 minutes then applying it to the silane coated gel for 10 minutes. To coat the collagen, collagen I or V was diluted in 1% EDC solution in PBS to a concentration of 1 µg/mL. The silicone gel was submerged in the collagen solution for 30 min and rinsed with PBS. NIH 3T3 fibroblasts expressing mRuby-paxillin were cultured in DMEM with 10% fetal bovine serum, 1% Penicillin/Streptomycin, and 1% L-Glutamin and seeded onto the TFM substrate. After incubating the cells at 37 °C for 4 hours, imaging was carried out using total internal reflection with a 60x oil-immersion objective for both beads and mRuby-paxillin. Bead images were taken with Cy5. After imaging, the cells were lysed using 10% bleach and reference images for relaxed gel configuration were taken. From bead images, traction reconstruction was done using MATLAB-based TFM package [3]. From paxillin images, focal adhesion morphologies and populations were analyzed using a custom-built function written in Han Lab [4].

RESULTS

To compare overall contractility of cells on the two collagens, we plated 3T3 fibroblasts on a soft, 2kPa silicone bead-coated gel that were further coated with collagen I or collagen V. Using bead images, we quantified traction distribution (Fig. Overall traction distribution showed that traction magnitude was greater for cells cultured on collagen V (Fig. 1B) than cells cultured on collagen (Fig. 1A1A, C).

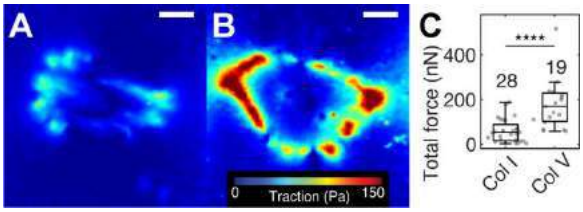

Figure 1: (A-B) Representative traction maps of a cell cultured on collagen I (A) and a cell cultured on collagen V (B). Scale bar = 10 μm. (C) A boxplot of the total force per cell on collagen I vs. on collagen V. ****: p<1e-6 by Mann-Whitney U test.

The measuring total force in cell, which was the integration of traction over whole cell area.

To seek how the force became higher, we performed adhesion imaging and quantified basic morphological parameters and densities using focal adhesion (FA) segmentation and detection of diffraction-limited spots, i.e., nascent adhesions (NAs) (Fig. 2). Qualitatively, we observed that compared to cells on collagen I, which showed lots of adhesions in both perimeter and interior (Fig. 2A), cells on collagen V exhibited primarily only focal adhesions along the perimeter (Fig. 2B). Quantification of FAs showed that there was no significant difference in FA area (Fig. 2C), whereas top 10 percentile of FAs of cells on collagen V were longer than those of cells on collagen I (Fig. 2D). Also, the bottom 30 percentile of FAs in cells, as well as the entire FA population (data not shown) on collagen V were wider than those in cells on collagen I (Fig. 2E). These suggest that collagen V promotes a subset of strong FAs, preferentially at cell perimeter. Quantification of the adhesion density made this interpretation clearer. Traction at all adhesion types is dramatically increased at all types of adhesion types for cells cultured on collagen V as well as a broader distribution of traction per adhesion (Fig. 2I). Densities of both FAs (Fig. 2F) and NAs (Fig. 2G) of cells on collagen V were lower than those on collage I, suggesting that the high force observed on collagen V-coated gel was not from the quantity of adhesions but from strong cytoskeletal tension induced by cells' collagen V binding. Furthermore, cell spreading was much larger for cells on col V than cells on col I (Fig. 2H). By reading traction magnitudes at the locations of identified adhesions from the traction maps, we sampled traction per adhesion type and per collagen type. We found that in general there were increasing amount of traction from NAs to focal complexes (FCs) to FAs regardless of the type of collagen. However, we also found that the increase in force on collagen V per adhesion was much greater than traction at the matching adhesion types (Fig. 2I). This represents that indeed cells, even with fewer adhesions, transfer much larger force through them.

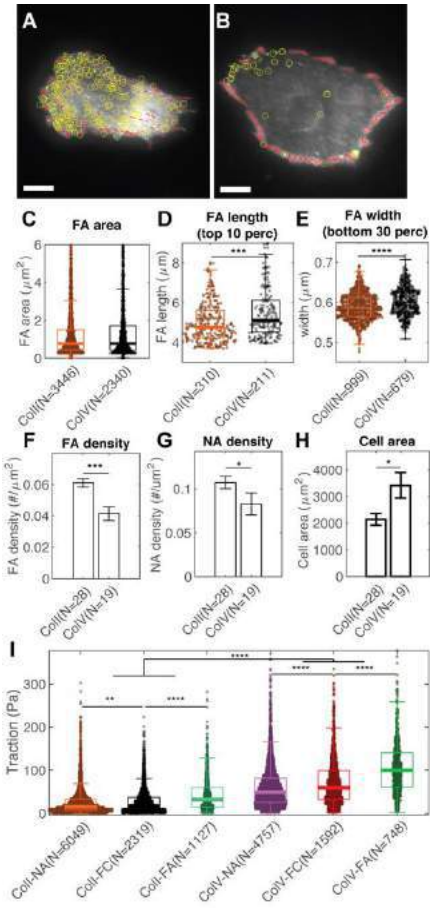

Figure 2: (A,B) Representative paxillin images overlaid with adhesion segmentations (red: focal adhesions (FAs), green: focal complexes (FCs), yellow: nascent adhesions (NAs)) for a cell cultured on Collagen I (A) and on Collagen V (B). Scale bar = 10 μm. (C-E) Box plots of areas (C), lengths (D) and widths (E) of focal adhesions. (F-H) Bar plots of focal adhesion density (F), nascent adhesion density (G), and cell area (H). (I) Average traction magnitude measured from NA, FC and FA. N represents the number of adhesions. The data is from M=25 cells for collagen I and M=28 for collage V condition. *: p<0.05, **: p<1e-3, ***: p<1e-5, ****: p<1e-10 by Man-Whitney U test.

DISCUSSION

Our results on the increased in total force in the cells cultured on collagen V compared to collagen I tentatively confirm our hypothesis that collagen V induces a strong myosin contractility. The exact pathway that leads to myosin contractility remains to be determined. A likely candidate is the integrin heterodimer $\alpha_{11}\beta_1$ that specifically binds to collagen V but not to collagen I [5]. To test this hypothesis, we plan on using anti-integrin α_{11} antibody to block the ability of the integrin $\alpha_{11}\beta_1$ and repeat the TFM experiment outlined in the methods section.

Another possible biomechanical explanation is when the local elasticity of the collagen I coating is significantly lower than that of the collagen V coating and also the underlying gel. If this is true, the displacement would primarily happen in the collagen coating rather than the silicone gel, therefore said displacement would not be recorded via the displacement of the fluorescent beads, resulting in relatively little bead displacement for the contractility of the cell. To investigate this possibility, we plan on performing an atomic force microscopy (AFM) wherein a glass slide is coated with collagen and the AFM tip is chemically bonded to a collagen fibril and retracted. Since this setup will allow for measurement of the local collagen stiffness I and V, we will be able to determine if the experimental data for cells cultured on collagen I is accurate.

Additionally, an increase in cell spread area had been previously reported to cause an increase in cell contractility, therefore the increase in spread area may be involved in the increased contractility of cells cultured on collagen V [6]. In light of the substantial increase in total force the reduction in focal adhesion density in cells cultured on collagen V is surprising given that a decrease in focal adhesion density has been previously correlated with a decrease in contractility [7]. Taken together, out data suggest that collagen V induces mechanoresponses of cells to generate high contractility with fewer focal adhesions.

INTRODUCTION

Blood viscosity is often an overlooked aspect when it comes to healthcare. Currently, critically ill patients diagnosed with severe acute respiratory syndrome coronavirus 2 (COVID-19) exhibit elevated levels of fibrinogen and inflammatory indicators, which have been seen to reflect intravascular thrombosis (clot formation). One study found thrombotic incidences were 48% in COVID-19 patients admitted into the ICU [1]. Increases in fibrinogen and inflammatory factors can increase blood viscosity, which can lead to thrombosis and impact perfusion rates. A higher blood viscosity indicates less blood and nutrients being delivered to tissues. Increased blood viscosity decreases cardiac output and tissue perfusion [2]. Decreased perfusion rates coupled with other health problems have been shown to increase the prevalence of cardiovascular events and thrombogenesis [3].

In the context of COVID-19, a high-risk patient could have a history of hypertension, diabetes, inflammation, and respiratory distress. These factors combined with COVID-19 infection could lead to a cascade effect and form a thrombosis due to elevated fibrinogen levels and erythrocyte aggregation. A thrombosis can then break loose and travel to the pulmonary arteries, which impedes gas exchange [4]. To understand how increases in blood viscosity due to COVID-19 infection can affect blood flow, a computational fluid dynamics (CFD) simulation of the pulmonary artery was undertaken.

METHODS

An analysis of vascular behavior was conducted using ANSYS computational fluid dynamics (CFD) software. An open-source geometry model of a carotid artery was augmented to resemble a subsegmental pulmonary artery. The diameters of the arteries were 63 mm for the inlet, 44 mm for the large output, and 3 mm for the small output, which were used to make the mesh. These dimensions are very similar to vessel sizes of the subsegment branches from the pulmonary artery, as initial branches have diameters of 6-7 mm and taper down to even 1.5 mm before the alveoli in the lung [5]. Thus, the mesh can be applied in the context of pulmonary embolism and understand the pulmonary arterial flow. The fluid model used was laminar flow, as it best describes the motion of blood through a vessel. Poiseuille's Equation (1) was used to implement blood viscosity and the dimensions of the mesh model [6]. Other parameters can be seen in Table 1, where the fluid, "Blood", was defined [7,8]. These parameters define the conditions in which blood flows through average human arteries. The velocity was chosen to be 0.6 m/s as it represents a normal peak pulmonary arterial velocity [9].

$$Q = \frac{4\pi r \Delta P}{8\mu l} \quad (1)$$

Table 1: Parameters for circulating blood.

Variable	Value
Density	1060 kg/m^3
Specific heat	3513 J/kg K
Thermal conductivity	0.44 W/mK
Viscosity	0.010; 0.013; 0.020 kg/m*s
Temperature	37°C
Velocity	0.60 m/s

The only fluid property varied was viscosity based on varying fibrinogen levels, *f*. Normal fibrinogen levels in healthy adults are 2-4 g/L, but critically ill COVID-19 patients often present with fibrinogen levels >7 g/L [10]. Three fibrinogen levels were used, 2, 4, and 8 g/L, to calculate viscosity at the shear rate of 0.07 s^{-1} according to Equation 2 [11]. Although blood is non-Newtonian, this study models steady-state flow in vessels >2 mm so Newtonian viscosity was assumed. To

accurately approximate blood viscosity at 1000 s^{-1}, the amplitude, A, of a power law equation reported in [12] was modified for each fibrinogen level used.

$$\mu(\dot{\gamma} = 0.07s^{-1}) = 0.085 \times f + 36.4 \quad (2)$$

$$\mu = A(\dot{\gamma})^{-0.172} \quad (3)$$

RESULTS

Both outlet velocity and pressure changed as viscosity increased. From Figure 1, there is a greater variation of static pressure magnitude as viscosity decreases. The maximum pressure output was nearly 40 Pa at low viscosity. While the outlet pressures at lower viscosity were higher for many points, the contour maps in Figure 2 show that the inlet pressure was higher by over 400 Pa (1449.71 Pa compared to 1031.70 Pa for high and low viscosities, respectively) as well as the pressure at the bifurcation. Given that there was no vascular resistance to account for and the same velocity and model was used, it can be theorized that this increase in pressure can negatively impact endothelial tissue integrity.

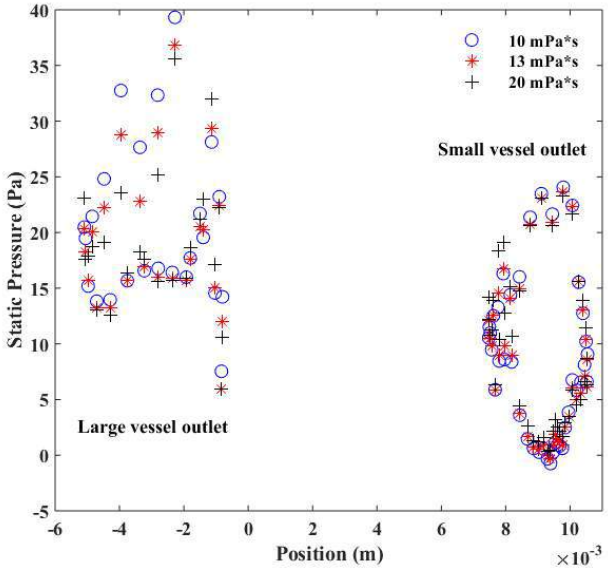

Figure 1: Plot of static pressure on both large (left) and small (right) outlets based on blood viscosity.

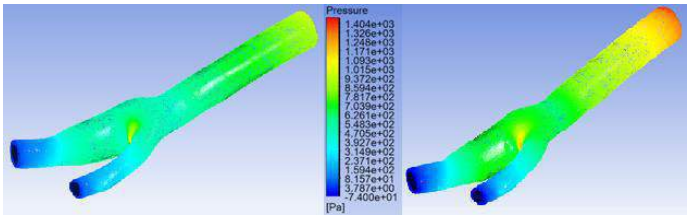

Figure 2: Contour maps of arterial pressure for viscosity at 0.01 kg/m*s (left) and 0.02 kg/m*s (right). The arterial pressure is seen to be greater in the presence of higher viscosity.

Velocity is also known to be a factor in thrombosis formation and is critical for tissue perfusion. The maximum velocity of the large outlet was from the high viscosity model of 20 mPa*s (Figure 3), particularly noticeable in the center of the vessel. However, the small outlet experienced lower velocity as viscosity increased.

DISCUSSION

COVID-19 infections have had a profound effect on both individuals with underlying health conditions and apparently healthy

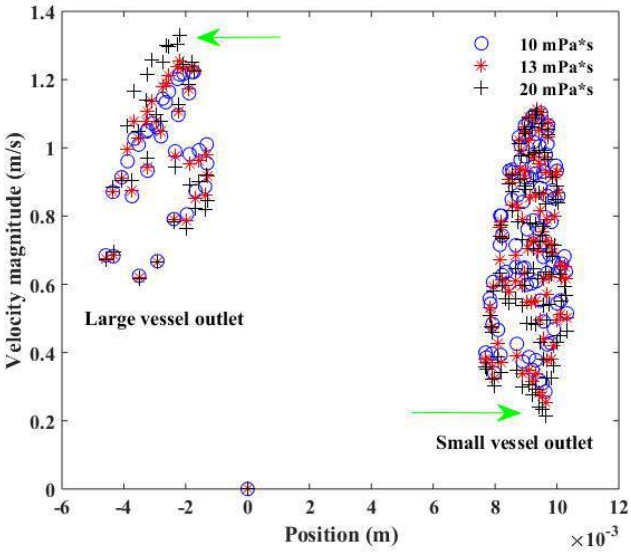

Figure 3: Plot of output velocity based on varying viscosity. Arrows show areas of increased and decreased velocity for high viscosity blood.

populations. The increase in fibrinogen along with other inflammatory factors increases blood viscosity which decreases tissue perfusion and increases the risk of thrombosis formation in vessels throughout the body. From this CFD study, the increase in blood viscosity specifically on the pulmonary artery increased output velocity and pressure that could activate a thrombosis cascade as described by Sloop et al. [4] that can lead to ischemia and compromised tissues.

For the case of COVID-19, further investigation can hope to illustrate blood viscosity as a point-of-care test in mitigating an exacerbation of the pulmonary system. This exploration is very novel but superficial. It lacks the accuracy of differential fluid models and makes a lot of assumptions from the geometry to fluid parameters. Nevertheless, it is unique in its scope and reviews how viscosity can play a role as a potential factor in the development of cardiovascular and pulmonary diseases.

INTRODUCTION

Body weight support systems have been widely used in rehabilitative medicine to aid users in improving their motor recovery after suffering from symptoms of neuromuscular disorders as a result of genetics or injury. Gait training can aid users in improving balance [1], however many solutions are expensive [2] and rely on the user to build strength through other physical therapies prior to use.

Alternatively, elliptical training allows patients to both improve strength and gait simultaneously [3]. When elliptical training was used in physical therapy for stroke patients, patients were able to improve endurance, balance, and functional mobility [3]. Functional Electrical Stimulation (FES) has been shown to be more effective in improving patients' balance after stroke than non-actuated exercise [3, 4]. By implementing a body weight support system to be used in conjunction with FES and elliptical training, these results could likely be reproduced while increasing muscle mass in patients with neuromuscular disorders.

The DynaCon PLS solves problems presented by current body weight support systems by providing a controllable weight offset while differentiating the weight supported by each leg. It can be implemented into rehabilitation techniques utilizing elliptical training and FES, saving time, and cost over purchasing multiple systems for strength training and motor recovery. With the added security provided by DynaCon PLS, rehabilitation becomes more efficient both in recovery time as well as reducing the number of therapists needed to assist with the exercise. Investment into the DynaCon PLS body weight support system would facilitate in-home training for a more affordable price compared to the expenses of facility-led physical therapy, although clinics could also benefit from the use of the DynaCon PLS system in their facility for the reasons listed above.

PRODUCT DESIGN

The DynaCon PLS features a Unistrut-based I-beam ceiling mount system, an in-house manufactured trolley capable of one-dimensional powered translation and braking, an energy chain to protect cables that supply power to the system, a dynamic, dual NEMA motor system equipped with an electromagnetic (EM) brake system capable of preventing injury to the patient in the event of power loss, and a series of safety mechanisms and fail-safes to prevent catastrophic failure. DynaCon PLS is equipped with a network of Unistrut adapters which allow it to be mounted to any system of ceiling rafters. Additionally, the unique ceiling mounted design allows for free floor space up until DynaCon PLS is ready to be used. A translational lock mechanism secures the patient in any location along the I-beam during rehabilitation. In the event of an accident or power loss scenario, an electromagnetic braking system ensures that the patient stays supported until proper assistance can be provided. With a spacious layout, simple wiring, and consistent fastener sizes, this design allows maintenance to be quick, easy, and cost effective.

Once the patient is ready to begin therapy, a full body harness will secure them to the DynaCon PLS. Utilizing the servo motors and the dual-axis motion allowed by DynaCon PLS, the user can safely be lifted and transported above any physical therapy equipment. During exercise, the patient's weight is offset using the response from two load cells added in line with the harness supports. The load cells output a voltage to be read by an onboard Arduino that communicates with the motor controller to adjust the voltage being sent to each motor. By controlling the motors in this manner, the weight offset system will respond to only the patient's generated forces. This is important because it provides a fully custom experience that changes based on the ability of each user. An encoder is installed on each motor to get a baseline location when the patient was first lifted prior to operation, so that each motor knows how far to return as weight offset is being applied. The motors respond instantaneously based on the amount of tension or lack thereof read by the force sensors as the patient is using the elliptical and applying forces associated with gait.

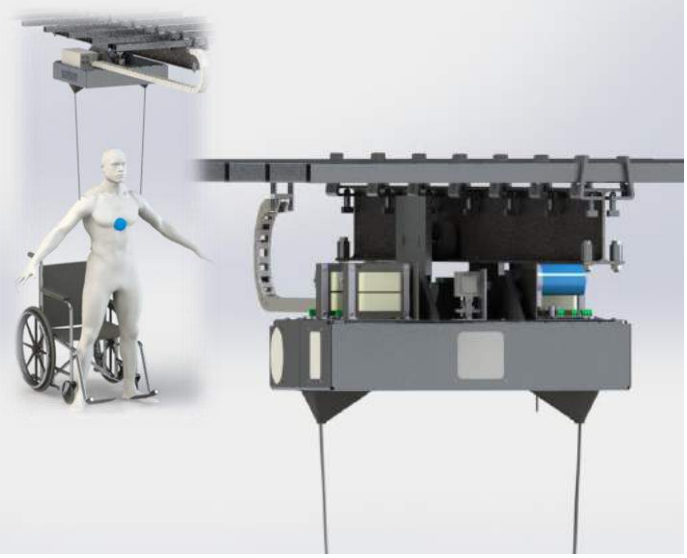

Figure 1: DynaCon PLS rendering with example of patient being lifted from wheelchair.

BUDGET & MARKET ANALYSIS

Budget: The total budget for the design, build, and testing of the prototype is $5,200 which was covered by the University of Florida and the MERGE Laboratory. The design and testing portions of the budget were absorbed by the student participation in senior design courses. Widespread production of the DynaCon PLS would incur additional costs for manufacturing power consumption and assembly.

Market Analysis: To identify the market, the end user of this project must be considered. The end user of this project is someone who has suffered injuries which limit lower body mobility. Our ideal user is an individual who is seeking lower body rehabilitation using functional electric stimulation (FES). The need for FES rehabilitation derives from the following debilitating injuries: paralysis, stroke, spinal cord injuries (SCI). With the end user in mind, the primary market is for at home use. The secondary market for this product is comprised of physical therapy clinics and research institutes.

Every year in the USA there are approximately 17,000 new spinal cord injuries [5] and 610,000 new strokes [6]. Those injured individuals are the targeted users and primary market for the DynaCon PLS. The secondary market for this product includes hospitals, orthopedic institutes, physical therapy centers, and research institutes. The potential market size, based on the total targeted market, is approximately 515,000 clients. The primary market of at-home users is totaled to the fraction of stroke and SCI patients (75%) that could use the DynaCon PLS at home. This is estimated at three quarters of total SCI and stroke patients to 470,000 potential clients. In the United States, there are 6090 hospitals [7], 38,800 physical therapy clinics [8], and 233 physical therapy schools or institutions. The secondary market is totaled to 45,123 potential clients. Totaling the primary and secondary market size creates a final market of 201,123 potential clients.

The expected manufacturing costs (Table 1), per unit, with a market of this magnitude is $4,000.00. The projected sales price of a single unit will be $10,000 including installation. Investments in engineering costs and tooling will be initially absorbed by the University of Florida, though they will be further explored for future fabrication and mass production. The total return on investment, assuming all possible clients purchase a unit, is 350%.

Table 1: Budget for the DynaCon PLS Manufacturing

Type	Price ($)
Off the Shelf Parts	$4250
Raw Materials	$700
Assembly Costs	$250
TOTAL	**$5200**

ACKNOWLEDGEMENTS

We would like to thank the MERGE Lab at the University of Florida, as well as the Nonlinear Controls and Robotics Group for their support and resources provided. We would also like to recognize the work of Mechanical Engineering Design III students that tested and developed the initial prototype of the DynaCon PLS.

INTRODUCTION

According to the Amputee Coalition, up to 80% of amputee patients worldwide suffer from a condition called phantom limb pain. This condition is characterized as a painful sensation felt in the amputated limb [1]. While the limb is absent, the pain that is felt by the patient is very real.

When an amputation takes place, the nerves leading into the limb are rerouted into the surrounding muscle. This technique is done in order to prevent neuromas (an abnormal growth on the nerve). It is suggested that the cause of PLP is the lack of sensory input from the nerves that were part of the amputated limb.

Fundamentally, the amputated limb's nerves are still present within the body, but are not supplying any sensory input to the brain, causing a disconnect that results in a painful sensation. Very little research has been done pertaining to the cause of PLP, and existing treatments are either expensive or rudimentary. Current treatments are designed to numb the pain and there has been no focus on either tracking the progress of the pathology, or finding a treatment that permanently decreases the presence of PLP.

PRODUCT DESIGN

The PLP Strap's current design will greatly increase the quality of life for each amputee using the device. When an amputee experiences pain near the amputated area, it can be observed as a large spike in the electrical signal that is produced by the musculature; an electromyograph (EMG) can be utilized to collect these electrical signals. In the design for the PLP Strap, the electromyograph (EMG) will be programmed to switch on and off alternately with a transcutaneous electrical stimulation (TENS) unit. The TENS unit will provide electrical stimulation to the amputated limb to quiet the misfiring of the salvaged/local remaining nerves. The new EMG signal, post-TENS stimulation, will then be compared to the initial or baseline EMG signal. The goal is to observe lower levels of neuronal activity after electrical stimulation. If lower levels are observed, then the device can be considered a successful alternative to common TENS units as well as over-the-counter and prescription drugs. The EMG component elevates the design in comparison to generic TENS units because it connects to an online mobile application that is accessible to medical professionals, allowing PLP trends to be monitored more closely for proper diagnosis and long-term personalized treatment. Thus, if the device only abates PLP rather than fully treat it, doctors can provide additional feedback and treatment options catering to a more quantitative pain analysis. The system further allows quantification of pain that will give the medical field useful information on treating individuals with varying degrees of PLP.

The solution is technically feasible as the design includes already existing hardware and software meaning that the design simply combines these mechanisms into a coordinated, efficient system. The Pocket Box iteration is, also, physically possible as existing devices on the market are comparable in size. With the more compact design, the consumer will be able to handle and transport the device easily; thus, lessening the likelihood of damage to the device. All connecting wires in this model are enclosed within the Pocket Box, to reduce the amount of wear on the wires; thus, increasing the longevity of the device's life expectancy. The Pocket Box design iteration prioritizes the customer attributes of comfort, accessibility, saftey, and ease of use, while maintaining a low cost.

Referring to the CAD drawing included in Figure 1, the Pocket Box will be a 3D printed structure composed of plastic and used as housing unit for the electrical components, such as Arduino, Raspberry Pi, EMG, and TENS unit. The Pocket Box design iteration allows for all processors, sensors, electrodes, and the battery to be detached, allowing the strap to be washed and lightweight. The strap portion of the Pocket Box design will be made of polycotton that will have electrodes embedded in the fabric. The consumer will be able to remove the electrodes via the two portholes seen in the auxiliary view (upper right-hand corner) in Figure 1. This design iteration increases the device's safety and effectiveness, which along with its compact design allows ease on the user

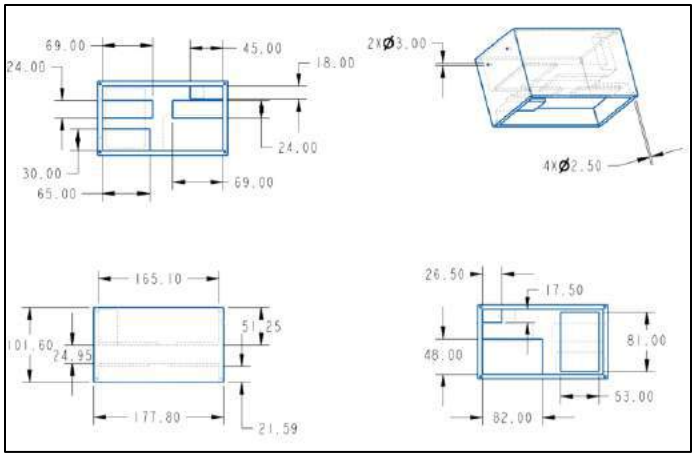

Figure 1: PLP Pocket Box Design. Main portion of the design, housing all electrical components as well as docking ports for EMG electrodes for proper user function. Within the box are 3D representation of the compiled component layout. All dimensions are denoted in millimeters [mm].

BUDGET & MARKET ANALYSIS

The total projected cost of the PLP strap is $355.91 (prototype). This estimate includes the following components necessary for the development of the prototype:

2 - GROVE Relay Unit ($2.84)
2 - TENS 3000 3 Analog TENS Unit with Timer ($18.90)
1 - MFI Medical Bar EMG Electrode ($51.03)
1 - MFI Ground Electrode ($40.16)
1 - Raspberry Pi Zero ($5.00)
2 - Poly Cotton Broadcloth 60” Fabric by the Yard ($7.90)
2 - Arduino Nano 33 BLE Sense with Headers ($33.40)
2 - 9 Volt Lithium Battery GP ($11.99)
2 - Breadboard ($5.00)
2 - LCD Displays ($10.95)
6 - AD620 ($11.26)
2 - Jump Switches ($2.44)
6 - Capacitors ($0.76)
4 - Rectifying Diodes ($0.19)

The above breakdown shows the quantity of each component utilized, the name of the component, and the unit price of each component, respectively. This total projected cost is subject to change due to alterations in the design and/or unforeseen circumstances (i.e., component damage).

Based on the current market for technologies that noninvasively treat peripheral neuropathy, the PLP Strap would be entering a market upwards of 3 million individuals. Of the 30,000 amputations conducted annually in the United States, approximately 6% of amputees report experiencing prolonged phantom limb pain because of the amputation [2]. Utilizing the above total projected cost of production with the addition of manufacturing and labor expenses and then applying a traditional 100% markup, the PLP Strap is estimated to have a market price of approximately $800 per unit. Meaning the expected gross profit, annually, of the Phantom Limb Pain Strap would be $720,000. With the inclusion of just 10% of consumers with pre-existing amputations purchasing the product, the gross profit increases to over $120 million dollars annually.

INTRODUCTION

According to the American Academy of Dermatology, over 85 million Americans suffer from skin disease [1]. While many skin conditions like acne, rosacea, and atopic dermatitis have minor implications for patients, severe skin diseases such as scleroderma, and systemic sclerosis require medical treatment. The multilayered structure of skin leads to a complex mechanical response to external loads and functional behavior to bio-chemical stimuli. Moreover, skin behavior changes profoundly with age, lifestyle, and disease [2]. Strikingly, to date, no clinical tools exist to reliably assess the biomechanical state of skin, including the thickness of individual skin layers or their relative interactions. Our senior design project seeks to develop an ultrasound video-based software tool to determine a person's mechanical skin properties. The ultimate goal of our software, called Ultrasonics, is to evaluate the subject's skin health and to inform dermatologists or estheticians about possible treatment options. Ultrasonics is a software program that tracks full-thickness skin deformations in ultrasound videos. The deformation profile of full-thickness skin is a reliable indicator for the stiffness of individual layers and the interaction properties between layers. This information can be used to assess skin conditions and recommend possible treatment. The software will provide a user-friendly interface to make this technology available in the clinical setting for the monitoring of severe skin diseases as well as for professionals in the skin care industry.

PRODUCT DESIGN

Ultrasonics will provide a biomechanics-based assessment of a person's skin features. Our software determines the thickness of individual layers, such as the epidermis, dermis, and subcutis, and determines deformability of the full-thickness skin. The deformability of the skin is a reliable indicator for its state of healthy and is dependent on the interaction between individual layers and their respective stiffness. *Figure 1* shows a representative ultrasound image from the forehead region and clearly depicts the three most superficial layers, as well as the thick adipose tissue layer. The forehead region is of particular interest to the cosmetic industry, for example, as it is prone to wrinkle with age.

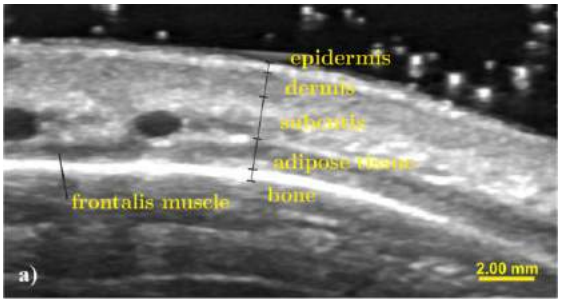

Figure 1: Representative ultrasound image of the forehead showing the multi-layered structure of the skin. Ultrasound is particularly useful to visualize full thickness skin and will be used to obtain video recordings of skin deformations.

As input to Ultrasonics, the operator will apply a small displacement on the skin surface while recording with the ultrasound probe. This is shown in *Figure 2*, in step 1. Ultrasound is a readily available, non-invasive and cost-effective medical imaging technique to visualize soft tissues. This process creates a video that captures the displacement of all skin layers. In step 2, we show a representative 2D image of skin. This video is then imported into Ultrasonics for analysis. The operator manually clicks at the boundary of each layer, to determine the thickness of each layer. Next, the tracking grid is defined, as shown in step 3. Once the grid is defined, Ultrasonics uses OpenCV combined with Optical Flow and the Lucas-Kanade method to track all grid points in each frame. The Lucas-Kanade method takes a 3x3 box around a point constructed of 9 nodes that are all assumed to have similar displacement and outputs the 2D vector field where each vector is a displacement vector showing the movement of points from the first frame to the second. The displacement field of all the points is then derived into a deformation field. Finally, in step 4, we analyze grid deformation in each frame and determine the spatiotemporal evolution of critical mechanical properties. Using standard continuum theory, we will use nodal displacements to determine the element-wise deformation gradient $\mathbf{F}$ and the Green Lagrange strain tensor $\mathbf{E}$ via $\mathbf{E}=1/2*(\mathbf{C}-\mathbf{I})$, where $\mathbf{C}$ is the right Cauchy Green deformation tensor, $\mathbf{C}=\mathbf{F}^T\mathbf{F}$, and $\mathbf{I}$ is

the second order identity tensor. Moreover, we use the deformation of each grid point to construct the full thickness skin deformation profile. We calculate the average horizontal displacement component of all nodes in each row of our grid and generate a deformation profile ranging from the surface to the deepest layer of skin. As output, Ultrasonics will provide thickness of each skin layer, the deformation profile, any abnormalities detected in the deformation profile, and a comparison of the subject's deformation profile to a database of other healthy patient profiles. Since skin properties differ from subject to subject and will be heavily affected by skin disease, we consider these output measures as a diagnostic measure of skin health.

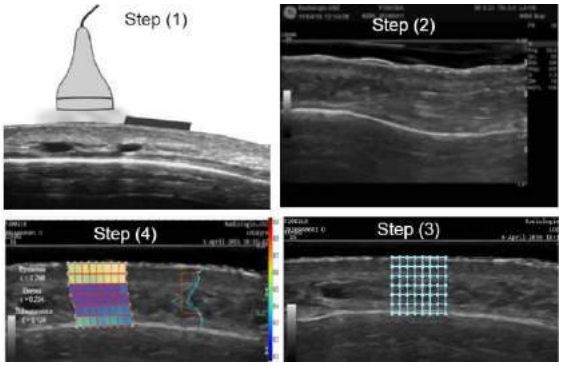

Figure 2: Schematic outline of the skin evaluation process with Ultrasonics. 1) We first record a video showing minor skin displacements, then 2) import that video into Ultrasonics, 3) define a tracking grid to quantify the full thickness skin deformation profile, and 4) derive several skin health measures.

In *Figure 3*, we show preliminary data of our software in the form of a strain map and a deformation profile. We observe that epidermis is rather stiff and shows little strain. The dermis is a softer layer and exhibits increased shear strain, also reflected in the belly in the of the deformation profile. The final version of Ultrasonics will provide a user-friendly output format to allow doctors and users to easily interpret our results. In previous studies on skin deformation, it has been shown that skin deformation is non-uniform across layers [2,3]. Specifically, it has been shown in shear tests of pig skin that the shear modulus varies throughout full thickness skin and is subject to sharp stiffness changes at the epidermis-dermis interface [3]. Each layer will deform differently due to cellular composition and stiffness of each layer. Moreover, skin layers have variable connectivity, all of which leads to a non-uniform deformation profile. This is particularly relevant for our product and requires Ultrasonics to accurately track tissue displacements across all skin layers.

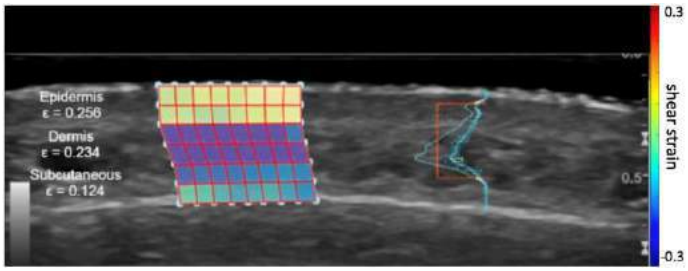

Figure 3: Preliminary results from a volunteer with deformation profile (green line) and strain field (color map).

We are currently in the programming phase and developing the tracking algorithm, data analysis, a user interface, and are implementing a database. Through frequent use of Ultrasonics, we will begin building this database with each patient's skin assessment that includes healthy subjects from a wide age-range, as well as patients in varying states of health, and their treatment plans. Through the collection of this data, we will be able to identify indicators of abnormal skin properties and provide personalized recommendations for treatment.

BUDGET & MARKET ANALYSIS

The team plans to market this project to dermatologists and estheticians. We aim for Ultrasonics to become part of every dermatological checkup in order to reliably and continuously monitor a patient's skin changes over time. Understanding the mechanical properties of skin is also important in the clinical settings to find better plastic surgery techniques, and better treatments for skin diseases. Moreover, we will try to market Ultrasonics as a real-time service for estheticians which would use this software to advise their customers on the right cosmetic products to improve their skin health and prevent typical signs of aging. Our product can be used to test the efficiency of cosmetic products as well as recommend different cosmetic products based on the layer specific properties of each patient's skin.

Under FDA regulations for the Medical Device User Fee Amendments (MDUFA), the Ultrasonics is considered a Class II non-510(k) medical device. The registration cost for our device with the FDA would be $3,108 under the classification of a small business. Revenue for this product prior to launching would not exceed $100 million for the tax year, thus classifying it as a small business product and is not anticipated to reach that following. An annual registration fee of $5,546 is also collected from the FDA to ensure our product can go to market.

According to IBIS World, there are 5,952 dermatology businesses and 151,193 estheticians in the US [3]. The national average cost for a visit to an esthetician is $80, and to see a dermatologist without insurance will cost about $150. We want to ensure that this product can be covered by insurance when it is medically necessary. For example, if a patient is using this product to track the progression of skin disease. However, if a patient simply wants an analysis of their skin, it may not be covered by insurance, but we want to make sure it remains affordable. If we are able to license our software at $600/year, we anticipate a revenue stream of $600,000 per year. Moreover, we will identify a portable ultrasound machine vendor, to offer software and hardware as a package for $1000/year. We expect that 1,000 estheticians will be interested in our product initially, and as the product becomes more refined, it can continue to expand in the market.

Product cost is primarily limited to software development, FDA licensing, and marketing. Once the product is ready to go to market, we will look into working with a consulting company to help us market the product. Also, as the market grows, we will look to hire a software developer in order to improve the user interface for a wider group of dermatologists and estheticians.

ACKNOWLEDGEMENTS

The Mechanical Engineering Department at Stevens is supporting this project with a $700 stipend. Moreover, we thank Ahsanul Torza and Dr. Johannes Weickenmeier for their advice and guidance throughout this project.

INTRODUCTION

Although minimally invasive endovascular catheter surgeries are poised to revolutionize the treatment of neurovascular pathologies such as stroke and aneurysm, adoption has been slow because of two key challenges.[1] First, the classic approach for diagnostic and therapeutic catheterization, a transfemoral approach in which the catheter is inserted at the groin and advanced through the vasculature to the brain, is difficult because it requires catheters with stability over long distances and flexibility around tight bends. Second, for the alternative transradial approach, in which the catheter inserts through the arm, around the aorta, and to the brain, requires stability around the tight bends of the aorta but also flexibility to navigate these same bends.[3] The transradial approach has more favorable patient outcomes,[2] but is also associated with increased vascular tortuosity,[3] and thus with increased risk of adverse events such as catheter kinking or entanglement, and catheter-induced coronary dissection.[4,5] In both cases, there is strong need for a catheter that can navigate to a surgical site, then be stiff enough to maintain stability as surgical tools are advanced to the surgical site.[6]

Therefore, an endovascular catheter of switchable stiffness would be of great utility. Our team has successfully created such a device, which we call the MultiFlex catheter.

PRODUCT DESIGN

Conceptual design and proof of principle calculations. The MultiFlex catheter consists of 3 main layers – an inner layer, a string layer, and an outer layer (Fig. 1). In the flexible state, the string layer does not connect the inner and outer layers, and the flexural rigidity is sum of those of the inner and outer layers. In the stiff state, the application of a vacuum draws the inner and outer layers together into frictional contact, causing what we estimated to be a ten-fold increase in flexural rigidity. In characterizing the range of commercially available tools, as described in a separate paper submitted to this conference,[7] this range would be suitable to shift a device from the stiffness of a guide catheter to that of a stiff sheath (Fig. 2). Proof-of-principle estimates (not shown here) of shear stresses associated with flexure from advancing a tool through the inner catheter indicated that the frictional resistance vacuum applied by a Luer lock syringe or indeflator would be adequate to maintain the increased stiffness during tool advance. We received provisional patent protection for the design of MultiFlex and the use of a vacuum to change a catheter's flexural rigidity.

Figure 1: CAD model of the layered MultiFlex catheter design.

Prototype and benchtop test. A "9 French" (3 mm diameter) prototype of the MultiFlex catheter was developed in partnership with Nordson Medical (Fig. 2). Benchtop testing to measure its change in flexural rigidity. The prototype could shift from compliant to sufficinly stiff to hold a bent shape when vacuum was applied by a Luer lock system (Fig. 3). This prototype achieved a 6.3-fold increase in flexural rigidity (3.9 N cm^2 - 25 N cm^2), a transition that spans the stiffness profiles of both sheaths and catheters (Fig. 2).

Animal testing. To validate that the prototype could sustain sufficient stiffness with the insertion of a surgical tool and with normal blood flow through the vasculature, the prototype was tested in a porcine model. All animal protocols were approved by the Institutional Animal Care and Use Committee at Washington University, and the procedures were performed by a trained vascular surgeon in conjunction with a team of veterinary surgical staff. Results show that the catheter was sufficiently compliant to navigate through the animal's vasculature,

and then, under vacuum, was sufficiently stiff to support medical devices *in vivo* compared to other neurovascular catheters (Figs. 4-5).

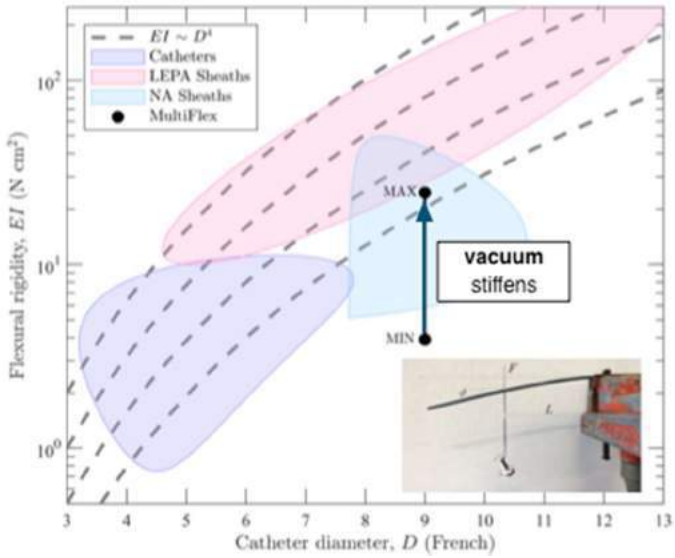

Figure 2: Benchtop tests of vascular catheters, neurovascular (NA) sheaths, and lower extremity (LEPA) sheaths, as well as the MultiFlex catheter. Tests were performed using cantilever loading interpreted via nonlinear beam theory. Application of vacuum to the MultiFlex device stiffened it, reversibly, from the range of catheters to the range of sheaths. 1 French = 3 mm.

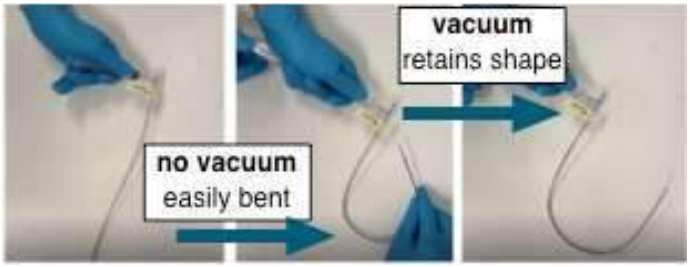

Figure 3: Benchtop testing revealed that the MultiFlex prototype switched from compliant to stiff with the application of vacuum.

BUDGET & MARKET ANALYSIS

Initial investment costs will come from further prototype development, FDA approval, and manufacturing costs totaling an estimated $2 Million. It is estimated that the U.S. accounts for 125,000 embolic strokes each year,[8] representative of $437.5 Million in catheter products used for embolic stroke treatment alone (at $3500 of catheter products used per surgery). With an initial market penetration of 6%, a product price of $2,000, and an average annual market saturation rate of 6%, the return on investment would be $20 Million/year 6 years after initial product release, considering the market for embolic stroke treatment alone. There is potential for utilizing this technology in numerous other neurovascular, peripheral arterial, and cardiovascular procedures, as well as potential for application outside the realm of vascular surgery.

DISCUSSION AND FUTURE WORK

The device shows promise for improving the efficiency of intravascular neurointerventions by meeting a well-defined need for radial-entry specific tools. Future endeavors seek to scale the design down to a 6 French outer diameter which is the maximum allowable catheter size for neurovascular interventions. Going forward, efforts will be made to prototype these to obtain FDA approval via the 510k pathway as the device is substantially similar to predicate devices, despite its novel functionality and its optimization for neurovascular procedures.

Figure 4: An animal test of the MultiFlex prototype in a porcine model showed that the device has sufficient flexibility to navigate through tortuous vasculature to distal sites.

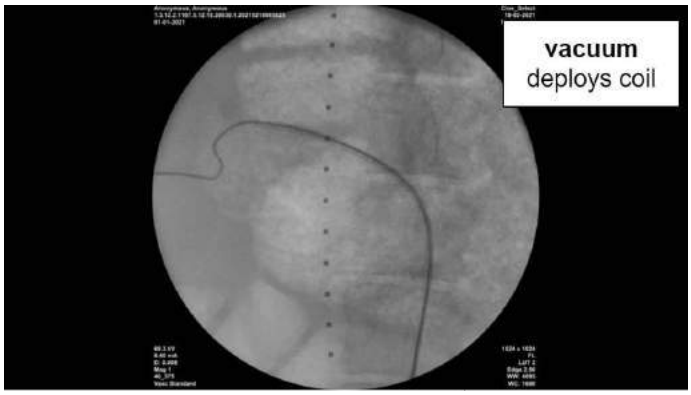

Figure 5: An animal test of the MultiFlex prototype in a porcine model showed that the device, with vacuum applied, was sufficiently stiff for tools to be passed to a distal surgical site.

INTRODUCTION

Children are spending more time in car seats, which increases the possibility that a child will fall asleep in an unsafe position. Sleeping in an unsafe position can then lead to a head slump, which happens when the chin falls onto their chest causing discomfort, difficulty in breathing, and in the worst-case scenario, positional asphyxia which happens when the child cannot inhale enough air to breathe. Positional asphyxia contributes to 48% of non-accident-related car seat deaths. In 2017, 900 deaths were related to scenarios involving accidental suffocation (positional asphyxiation).

The size of the global baby car seat market was valued at USD 7.0 billion in 2018. A rising concern about fatal accidents involving children, has increasing the market across the globe as well as nationwide. In USA, the baby car seat market size was approximately 2.0 billion and the this will increase to 3 billion by 2025, and to 11 billion worldwide.

PRODUCT DESIGN

This design has two bases, a lower base which attaches to the latch anchors in the car, and an upper base to house a mechanism for the translation of the seat (Figure 1 top-left). The upper base also has a mechanism to allow for seat rotation, and to provide attachment points for the baby seat itself (Figure 1 top-right).

The design mechanism consists of a stepper motor, ball screw, two linear slides, connecting rods, and appropriate bearings, along with the necessary structural frame, which contains a curved slot to promote the reclining of the car seat. After the stepper motor receives a signal from the microcontroller, the ball screw rotates, and the two bearing slides translate freely along the slider rods. The slides also serve to support the car seat weight, and are connected via two connecting bars to prevent jamming because of the wide span that exists between the linear slides. This allows only one stepper motor to be required (thereby reducing cost and complexity), and to provide room for the electronic components. The rear bottom of the baby car seat is connected to the two platforms using two small shafts which have a ball bearing on both ends to reduce friction between the car seat connector and the shafts during the rotation. From the front view shown in figure 1 (top-right), there are two fixed small shafts at the front bottom part of the car seat which slide along a curved slot on both sides of the frame. To reduce friction between the slots and the shafts, two flange bearings were added to the end of each sliding rod. Figure 1 shows how the mechanism was attached to the car seat frame. This figure also shows the overall view of the seat in its original and final positions (Figure 1 bottom left and bottom right).

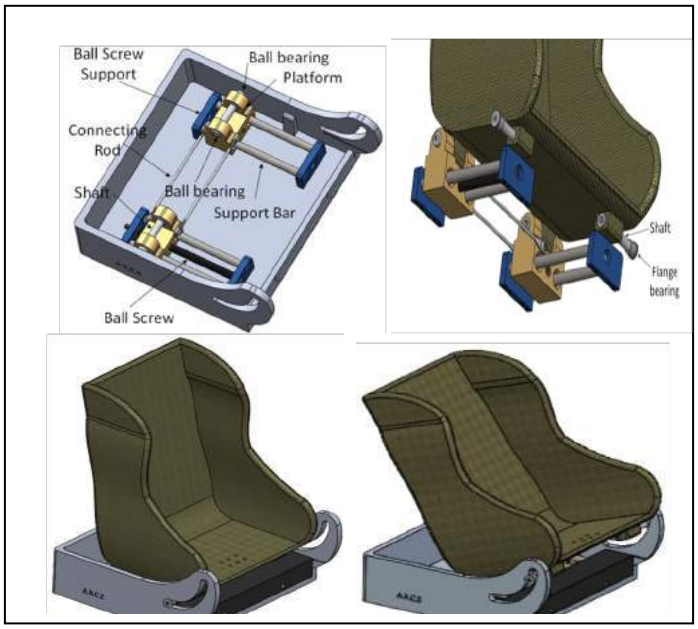

Figure 1: Lower base (top-left), Upper base (top-right), Initial position of seat (bottom-left), final position of seat (bottom-right).

Consequently, for a child to sleep in a safe position the seat should be reclined at an angle of between 30-45 degrees. The arc cut-out of the sides of the base allows for a 39 degrees angle of inclination, which fits well within the required range for the child to be in a safer sleeping

position. Also, in this design, the translation and rotation occur at the same time thereby reducing the total repositioning time, which addresses concerns about the stability of the seat should an accident occur.

Control of the system can be achieved either manually, via a Bluetooth™ interface with a cellphone, or via a built-in controller that employs a heart rate monitor which would be installed on the baby's wrist. This device would constantly capture the baby's heart rate during the time of use, and if a rate associated with sleep is detected an Arduino microcontroller automatically reclines the car seat (Figure 2).

This mode of control is based on the fact that a baby's heart rate falls significantly during sleep. This significant change of heart rate is observed by the microcontroller that processes input signal to initiate the seat motion. The microcontroller sends a signal to the stepper motor which would then rotate at a fixed RPM for a certain period of time. Then once the car seat reaches the desired position, it would lock the system in place. Subsequently, when the baby wakes up, the reverse process takes place, and the car seat is moved to its more upright position.

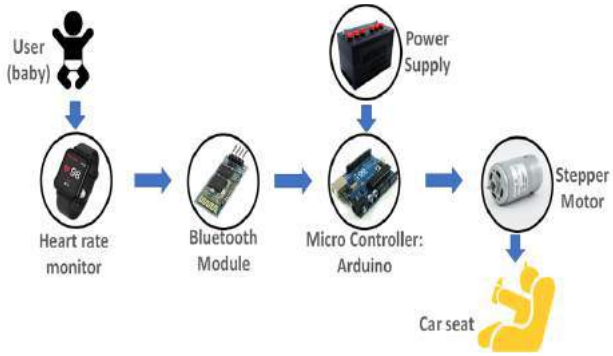

Figure 2: Control elements for the operation of the system

BUDGET & MARKET ANALYSIS

Table 1 is a list of the components used in the design and provides information about the component names, material, dimensions, quantity, costs, and service qualities of the selected materials. The materials have been selected based on a finite element analysis (FEA), that allowed a fatigue, kinematic, and visual analysis of the system to be performed. The price for manufacturing the product seems to be high but mass production would reduce the price by three quarter.

Selected materials and their costs of Automatic Reclining Baby Car seat

Component's name	Types of materials	Dimensions	Qty.	Costs ($)	Service quality
Base of seat	HDPE	18x18x1/2(LxWxH)	1	18.00	Good
Base wall	HDPE	24x12x1/2(LxWxH)	1	17.00	Good
Turnbuckle style connecting rods	6061 Aluminum	12 (L), Ø5,0.197 HØ0.315	2	35.00	Good
Flange sleeve bearing	Stainless steel	OD(0.75), ID(0.59)	2	16.00	Good
Linear ball bearings	Stainless steel	1.42(L), OD(1)	4	24.00	Good
Lead screw end supports	6061 Alloy	12x1/2 (LxD)	2	35.00	Good
Flanged Ball Bearings	Stainless steel	OD(0.91), ID(0.354)	2	12.00	Excellent
Lead screw	1018 Carbon Steel	10.36(L)), M(0.394.1.18)	1	21.00	Excellent
Front seat shaft	6061-T6	3.94(l), Ø0.60	2	40.00	Good
Platform	6061-T6		2	60.00	Excellent
Platform support bars	6061-T6	9.84(L), Ø0.63	4	30.00	Good
Motor	n/a	n/a	1	35.00	n/a
Power supply	n/a	n/a	1	30.00	n/a
Screws	Stainless steel	n/a	#24	22.00	Good
Sit cover	Leather	n/a	1	30.00	n/a
Sensors	n/a	n/a	2	10.00	n/a
Heart rate Monitor	n/a	n/a	1	100.00	n/a
Estimation of total costs				= 535.00	

Table 1: Selected materials and associated costs

The baby car seat market growth CAGR of 6.4% during the period of 2017-2021. Current baby car seat manufacturer making good revenue each year despite the safety concern of the existing car seat. Our redesign product with highest safety and low cost would replace 80-90% of the current car seat market which turns out to be approximately 3 billion dollars every year.

INTRODUCTION

According to the American Academy of Family Physicians (AAFP), ankle injury is one of the most common musculoskeletal injuries in athletes and sedentary persons, accounting for an estimated 2 million injuries per year and 20 percent of all sports injuries in the United States [1]. The largest contributor to ankle injury is Achilles tendonitis, the overuse of the tendon at the back of the heel bone. Achilles tendon tears happen mostly in recreational athletes (75%) and over 80 percent of AT ruptures also occur during sport or recreational activities [2]. Achilles tendonitis affects competitive and recreational athletes, specifically collegiate athletes aging between 18-25 years old. There are currently 460,000 NCAA student-athletes, with 170,000 in Division-1 sports. In a 2017 study, the NCAA Injury Surveillance Program found that 63.7% of athletes playing basketball, volleyball and gymnastics faced Achilles tendonitis. Surgery is required in about 25% of athletes with Achilles tendon overuse injuries, with patient age and duration of symptoms causing an increase in the frequency of surgical intervention. However, about 20% of injured athletes require a re-operation for Achilles tendon overuse injuries, and about 3 to 5% are compelled to abandon their sports career because of these injuries [3].

Orthotic devices such as foot orthoses, splints, taping, and bracing are recommended for Achilles tendinopathy (AT) [4]. Current braces used for treatment are bulky, heavily weighted, and prevent the user from walking with a normal gait, while other options such as kinesiology tape do not provide sufficient support to allow for proper rehabilitation. These devices also lack any quantified levels of tension, often leading to patients using more or less tension than is needed, lengthening recovery time. Customer discovery was performed and revealed that clinicians face issues in quantifying the level of pressure that is applied to the patient's ankle to promote healing.

PRODUCT DESIGN

The stepped tension Achilles tendonitis brace (STAT-B) is a lightweight and low form factor ankle brace for the treatment of Achilles tendonitis. The device utilizes a novel stepped tension mechanism to precisely apply stabilizing force to users' ankles and provide support to their Achilles tendon. A clearly marked scale enables different quantified levels of tension to be applied to the user's Achilles tendon, with the level depending on the severity of their injury and stage of the healing process. By clearly delineating different steps of tension and quantifying the levels of force associated with each, we can build a biomechanical profile of how each setting affects the Achilles tendon. This will allow us to design treatment regimens of different force settings over the course of device use in order to speed up healing time.

The device itself provides tension using two elastic bands pulled from the bottom of the foot to different points of a linear scale fixed to a cuff above the ankle. The more the two tension straps are pulled medially along the length of this cuff, the higher the force that will be applied to the Achilles tendon. One benefit of this design is the overall simplicity of the construction and use; it is constructed only of soft and flexible materials and incorporates no complex mechanical parts. A working prototype has already been constructed and experimented with. Efforts are ongoing to identify more innovative and effective methods of ratcheting tension through the elastic bands as well as types of material used in the device in order to enhance comfort, adjustability, and functionality.

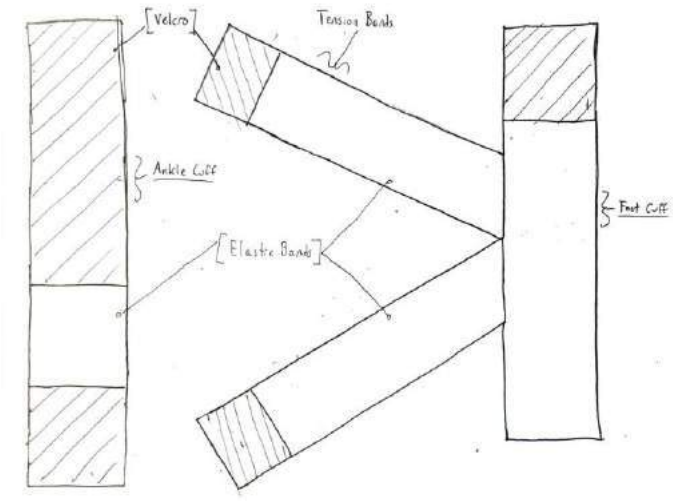

Figure 1: Overview of the three main components of the device, the ankle cuff, the elastic bands, and the foot cuff.

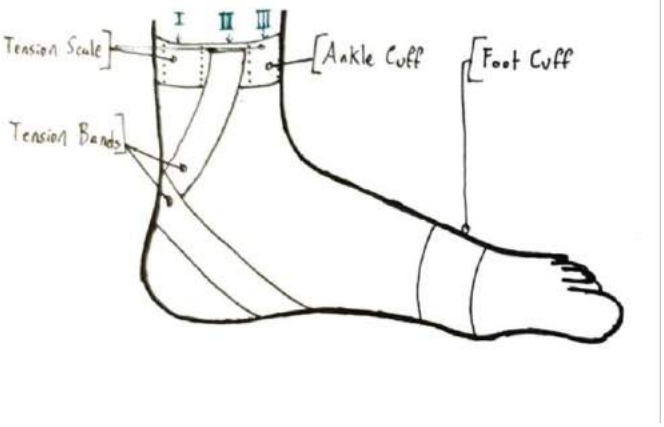

Figure 2: Side view of STAT-B device on human foot, highlighting tension scale and bands for customizable compression.

BUDGET & MARKET ANALYSIS

The global orthopedic braces and support market currently has an estimated value of $3.1B with a CAGR of 5.8% with expected market growth until 2025, with the growth being driven by the prevalence of orthopedic diseases and rising number of sports and accident-related injuries [5]. North America had the largest market share across the globe in 2016 and is expected to maintain its position within the forecast period, with ankle braces being used for a myriad of reasons to immobilize and support the joint. The target current market segment is athletic adults from 18-25 years old, the specific niche market segment for performance-related injury. The product would be marketed to sports medicine therapists who work with collegiate athletes. Leveraging connections to Pittsburgh sports centers and Division I athletes, the focus will be on establishing a foothold with university PTs to gain their trust in the brace.

Given the personalized functionality of the STAT-B brace, the estimated cost of the device is $80, putting the device in the price range of mid- to high-end range of Achilles Tendonitis braces. After revising the final design of the device, the expected manufacturing costs at this volume would be approximately $50 per unit. The Stat-B device will be sold to the 38,800 physical therapy centers across the US. With each center catering to approximately 257 Achilles tendonitis injuries per year, the total available market per year would be 797.7 million dollars. Taking only 5 percent to address the serviceable available market, the target market would be approximately 39.8 million dollars.

Budgetary amounts for development and testing of prototype is listed in Table 1. From Q4 of 2020 to Q1 of 2023, preliminary testing on the current prototype will be performed, including finite element analysis and validation testing with collegiate athletes from the University of Pittsburgh. Clinical trials will occur in Q2 2023 to Q4 of 2025. With the prevalence of Class I orthopedic braces, a similar 510(k) regulatory pathway can be pursued with the same third-party product code ITW. A utility patent will be filed in Q4 of 2025.

Table 1: Budget for STAT-B device development and testing.

Task	Amount	Time Frame
Finite Element Analysis	$10,000	Oct 2020-Aug 2021
Validating Testing	$100,000	Aug 2021-Mar 2023
Phase I Clinical Trial	$500,000	Apr 2023-May 2025
510(k) Submission	$25,000	May 2023-Nov 2025
Utility Patent	$20,000	Dec 2025

ACKNOWLEDGEMENTS

This project originated out of a bioengineering senior design team project at the University of Pittsburgh. Part of the fundamental work for the development of this device came from team members who have opted out of applying to SB^{3}C. These members include Neeshil Patel, Ashlinn Sweeney, Nick Ferchak, Austin Sims and Sean Hartwick. We would also like to thank Dr. Mary Murray of the University of Pittsburgh and Dr. Robroy Martin of Duquesne University for consulting with us on the development of this device.

INTRODUCTION

Characterized by excessive accumulation of cerebrospinal fluid (CSF) within the ventricles of the brain, hydrocephalus is a neurological disorder that affects more than one million patients in the United States alone [1]. This build-up may originate from issues of CSF occlusion, absorption, or production due to a range of congenital or developmental conditions; these complications cause an increase in intracranial pressure (ICP) which causes white brain matter atrophy, permanent disability, and death [2]. One treatment option is the implantation of a ventriculoperitoneal (VP) shunt, which allows CSF to drain through a catheter-valve system from the ventricles of the brain to the peritoneum. While this reduces ICP, shunts often malfunction due to obstruction, infection, disconnection, and fracture, or from common activities such as submersion in water or flying on a plane [3]. In fact, about 40% of shunts fail within two years after implantation [3]. Shunt failure causes untreated hydrocephalus, with symptoms that include headaches, vision alteration, nausea, and lethargy [4]. However, some symptoms are identical to symptoms of benign diseases, meaning patients have constant stress about their shunt function and must frequently visit clinics for valve adjustments and check-ups [5], impeding daily life.

Development of an assistive device serving as an ICP monitoring system can obviate unnecessary appointments, relieve emotional distress about symptom origin, and alert the patient of life-threatening pressure levels. There currently exists no device that is fully internal and directly measures ICP, providing accessible and continuous data to the patient and physician [4,6,7,8,9]. Therefore, to address the unmet need for this assistive device, we are prototyping an implantable, continuous, rechargeable ICP-monitoring system that communicates wirelessly with an application on a patient's iOS device. This will provide continuous and reliable readings, alleviating patient stress and permitting physicians to monitor hydrocephalus progression, thereby enhancing the mental and physical health of the patient.

In the US alone, 40,000 hydrocephalus operations are performed annually [11], and the global hydrocephalus shunt market is predicted to reach $322.01 million by 2027 [12], making this device a worthy and profitable area of research and development.

PRODUCT DESIGN

Device Requirements: To permit robust knowledge of the patient's ICP trends, this device must accurately and constantly measure ICP while not interfering with shunt function, and this ICP data must then be accessible to the patient and physician through the iOS application. The device also must be straightforward to implant during VP shunt insertion surgeries, be biocompatible, and have a 10-year longevity to outlast the longevity of over 50% of shunts [3].

Device Design: This device will consist of four main components: the catheter-integrated pressure sensor, electronic components, battery, and iOS app, as seen in Figure 1. The pressure sensor will measure the ICP and transmit that value to the electronic components, which will be powered by the battery. The electrical components will then transmit the value to our iOS app where it can be easily visualized.

To accurately measure ICP, a specialized microelectromechanical system (MEMS) sensor will integrate into the outer sheath of the proximal catheter. This pressure sensor will measure ICP within the range of 0-100 mmHg with an accuracy of ±2 mmHg at a frequency of 2 Hz to allow for near-instant ICP updates for the patient [4]. For our prototype, we will use an off-the-shelf MEMS pressure sensor by Millar. However, for the final device, we will collaborate with Millar engineers to create a custom pressure sensor integrated with an antibiotic-impregnated proximal catheter.

The electrical components consist of a Bluetooth Low Energy (BLE) device to transmit the pressure values to the iOS app, a micro-SD card to provide long-term and backup storage of pressure values,

and a microcontroller to integrate the system. For our prototype, we will use an Arduino Nano 33 BLE microcontroller, 64 GB Micro SD card, and Micro SD card adapter. However, these components will be miniaturized for the final product so they can be stored within the shunt housing. To power the electrical components, we will use an implantable, rechargeable Lithium-Ion battery in tandem with Qi charging. To prevent brain tissue damage due to battery heat, the battery will be stored in the armpit and connected to the device with subcutaneous wires [10]. Using Qi charging will improve the patient's quality of life by eliminating invasive surgeries to replace the battery.

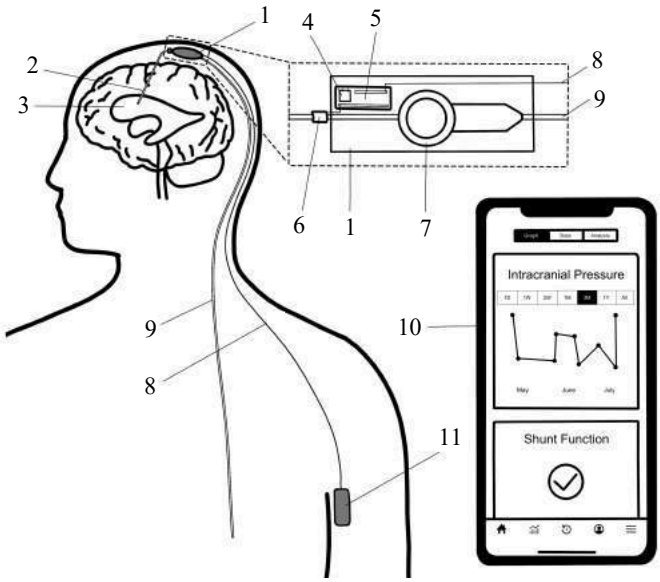

Figure 1: Diagram of Intracranial Pressure Sensing Device
Labels: 1) shunt casing, 2) proximal catheter, 3) enlarged ventricle, 4) micro-SD card, 5) microcontroller with BLE capabilities, 6) catheter-integrated pressure sensor, 7) shunt components, 8) wire connecting microcontroller to battery, 9) distal catheter, 10) iOS app displayed on iPhone, 11) battery

Lastly, the pressure values will be transmitted to our iOS app, which will display a graph of smoothed pressure values in real-time, as the physician needs to visualize the raw data collected to determine if there is a need for repair or adjustment.

Novelty: There are several methods to directly measure ICP including using a catheter with external drainage system or an intraparenchymal device. While these methods are effective, they are noncontinuous, inaccessible, and require neurosurgery to implement. Telemetric devices can also be used to directly measure ICP, but these require extensive external devices, are not continuous, and must be used at a physician's office [4,6,7]. There are also devices that promote accessible and non-invasive ICP measurements, but these require an external measurement device, indirectly measuring ICP by measuring CSF flow, and are non-continuous [8,9]. With our device, we propose a novel idea and method of directly measuring ICP using a fully internal device in which the pressure data is continuous and accessible.

Technical Feasibility: To ensure building the prototype is feasible, we will be using macro-scale components (such as our Arduino microcontroller). These components often come with tutorials and are relatively easy to troubleshoot. Our main technical challenge will be integrating the Millar pressure senser with our Arduino system and eliminating background noise. However, we are in contact with representatives from Millar and are troubleshooting this issue. Once our prototype is built, we will simulate ICP using a water column, and perform robust testing to see how pressure changes when the catheter-shunt system fails, simulating the catheter becoming blocked or disconnected from the shunt *in situ*.

BUDGET & MARKET ANALYSIS

It's estimated that, globally, one of every 770 babies are born with hydrocephalus, which is as common as Down's syndrome [11]. Hydrocephalus can also develop later in life due to tumors, infections, or injuries to the brain and spinal cord, making it a pervasive disease that affects patients of all ages across the globe [11].

The global hydrocephalus shunt market size is predicted to reach $322.01 million by 2027 [12], making shunt optimization a worthy area of research. Since nearly half of shunts experience failure within the first 5 years of implementation, our method of continuous and accurate ICP monitoring would be beneficial to hydrocephalus patients. Our device will have three main groups of patient consumers: infants born with hydrocephalus, infants/children/adults who acquire hydrocephalus, and current hydrocephalus patients with implanted shunts looking to improve their mental and physical health.

Since our device is designed to integrate within the casing of most shunts currently on the market, our product could theoretically be implanted in every new and preexisting hydrocephalus patient. Thus, our market size equals that of the shunt market; in the US alone, if our device were to be implanted during 25% of the annual procedures, we would sell approximately 10,000 units yearly [11].

We estimate that our current budget for prototype design, building, and testing will not exceed $1,000, which includes a microcontroller, Qi charging system, battery, memory card and adapter, and pressure sensors. We were also gifted shunts to use for implementation testing and validation purposes. When developing the final device, we will invest in a custom pressure sensor from Millar and a custom microcontroller from Microchip. We have spoken with representatives from these companies, and the cost for engineering these custom parts would likely be several thousand dollars. However, once created, we will be able to purchase these devices in bulk, paying approximately $20 per microchip and $400 per pressure sensor, making the total cost of our device, including manufacturing costs, approximately $700. By selling this device at $1,000 per unit, we estimate to make $300 per unit, and selling 10,000 units, we will make $3,000,000 in annual profits. The estimated median cost of a programmable shunt is $3,320 [13], and therefore adding our product would increase the price by less than 33%; we believe patients and physicians will deem its positive impact on their mental and physical health worthy of the financial investment.

ACKNOWLEDGEMENTS

This project was funded by the Northeastern University Bioengineering department. Shunts were gifted by Medtronic. This device concept is pending provisional patent, application #63093154.

INTRODUCTION

The scope of this project is specific to Ghana and arose in response to the COVID-19 pandemic which highlighted many global issues in healthcare, including a world-wide ventilator shortage [1]. As of April 18, 2020, there were only 200 ventilators available in Ghana, meaning that there were more than 145,000 people per ventilator. Of countries in Africa suffering from ventilator shortages, Ghana has been ranked number 22 [2]. For these reasons, Ghana serves as an excellent platform to develop a ventilator design specific to the needs and resources available in that region.

Before the SARS-CoV-2 virus was discovered, Dr. Craig Smallwood already developed the first model of his non-invasive ventilator for Ghana, called the Smallwood Unit. The Smallwood Unit was used on one patient at the Korle Bu Hospital in Accra, Ghana. Before using the Smallwood Unit, the patient had a heart rate near 140bpm and an SpO2 of 87%. After using the Smallwood Unit for an hour, the patient's heart rate dropped to 80-90bpm with an SpO2 of 100%. These improved statistics showed that the Smallwood Unit was a success, however, specific design improvements were required before this ventilator could fully satisfy the needs of developing countries like Ghana.

This project looks to re-engineer the Smallwood Unit to optimize its functionality and features specific to developing areas. This opens the possibility of deploying this device all over Africa. This device will be designed to be used in regional hospitals and to treat adult patients in low resource areas with respiratory issues, COVID-19 or others, that require the use of a non-invasive way to provide EPAP. This target population requires specific constraints to fill the gap in the market including being low in cost (less than $60), electricity free, reusable, and easy to use for treating patients in poor resource areas.

PRODUCT DESIGN

The original design of the Smallwood Unit functions as follows. A mask is placed over the patient's mouth and nose creating an airtight seal. When the patient inhales, the one-way valve opens allowing the patient to breath in air. When the patient exhales the one-way valve closes and the breath is released into the tubing. The opposite end of the tubing is placed in a basin of water to a depth of about 15 cm H_2O to maintain a positive end expiratory pressure (PEEP) in the system to keep the lungs from collapsing during exhalation. When pressure is applied solely during exhalation, it is called expiratory positive airway pressure (EPAP). This breath is then released through the end of the tube in the basin generating bubbles that break the fluid surface and exit the system as aerosols via the expiratory port. The Smallwood unit also allows for an oxygen tube to attach at the facemask should a physician decide that this is something the patient needs.

The main engineering principle that allows for pressure to be maintained in the column is the hydrostatic pressure equation which states:

$$P_h=\rho g h \quad (1)$$

Equation 1: Hydrostatic Formula

Where P_h is the pressure in the liquid, ρ is the density of the liquid, g is the acceleration of gravity and h is the depth in the fluid where the pressure is measured [3]. This equation tells us that only the density of the fluid and the depth that the tube is inserted in the water contribute to the pressure.

Although the Smallwood Unit is a functioning design, the goal of this project is to improve upon the achievements that have already been made by Dr. Smallwood and his team. Potential changes to this system revolve around the expiratory port, bubble diffuser, the basin itself, stability, and the sanitation of the system. The new design for the Smallwood Unit can be seen below in Figure 1. Here, the changes to the design are highlighted with the red circles.

Currently, the expiratory port is a hole in the top of the lid that allows aerosols to leave the system and enter the surrounding environment. This is particularly dangerous if used on patients with infectious diseases such as COVID-19. It is known that aerosol particles between the sizes of 0.5-10 micrometers are the most likely to transmit viral infection [4]. The COVID-19 pandemic has shown it is necessary to capture expired aerosols from the Smallwood Unit in case they are

infectious. To design for this concern, the new iteration of the Smallwood Unit will include a filter at the end of the aerosol tubing that connects to the basin. This will eliminate infectious aerosols before they reach the inside of the basin which will reduce the risk of potential exposure.

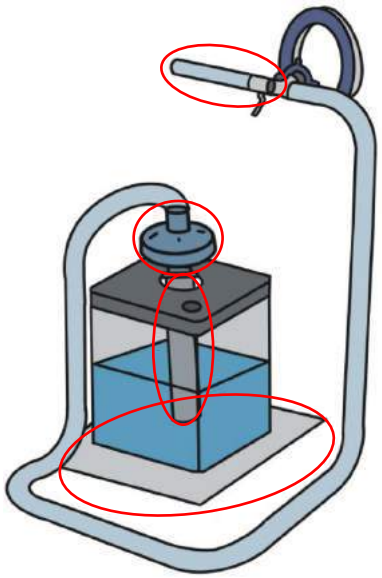

Figure 1: Re-engineered Smallwood Unit

The original design incorporated a bubble diffuser which was designed to reduce the amount of bubbles created upon exhalation. However, the decisions made about the positioning of the filter mitigated these concerns because the aerosols in the basin are no longer infectious. This will end up reducing the overall cost of the system which will help to meet the design requirement of a low-cost ventilator.

Another important change is regarding the basin itself which must be modified to include markings that indicate how far to lower the tube. Equation 1 shows that the most significant variable in ensuring a proper pressure within the system is the depth at which the tubing is inserted in the water. The markings will help to ensure that the tube is at this prescribed height.

Another improvement for the Smallwood Unit is an increase in stability of the basin. If the device tips over during use, all function will be lost. Therefore, a larger piece of plastic will be attached to the bottom of the basin. This uses geometry to increase the surface area of the bottom of the basin to increase the force needed to tip the basin over.

Lastly, improvements involving the reusability and sanitation of the system were made in order to reduce the overall cost of the system. In Ghana and other developing countries, a dilution of household bleach is used to clean medical supplies because it is an accessible and affordable chemical [5],[6]. The basin and base were chosen to be reusable because they are the largest components of the device. This means they must be able to undergo multiple uses while not degrading in the cleaning reagent and still maintain functionality.

The final improvement made to the Smallwood Unit is the addition of an oxygen reservoir at the input valve. This reservoir will help conserve oxygen which will lower the price for the hospitals using the Smallwood Unit.

BUDGET & MARKET ANALYSIS

Cost is a very important element of this project, as making the Smallwood Unit affordable is an essential design requirement for making it available in developing countries. The overall budget for this project to design, build, and test the prototype is $1,000. However, the cost of a single Smallwood unit is broken down in Table 1.

Table 1: Current Smallwood Unit price breakdown

Smallwood Unit Price Estimate			
Component	**Price (USD)**	**Quantity**	**Price per Unit (USD)**
Aerosol Tubing [7]	$3.99	6 feet	$3.99
NIF-Tee Adapter [8]	$68.49	12 adapters	5.70
Oxygen Tubing [9]	$1.13	1 segment	1.13
Anesthesia Mask [10]	$3.59	1 mask	$3.59
Reusable Mask Harness [11]	$56.00	5 harnesses	$11.20
Polycarbonate Container with Lid [12]	$18.99	1 container	$18.99
Rubber Grommet [13]	$12.00	8 pieces	$1.50
CPAP Oxygen Port [14]	$4.95	1 adapter	$4.95
Example Filter [15]	$5.95	1 filter	$5.95
Estimate Cost per Smallwood Unit			**$52.55**

Since low cost is an important design requirement it is expected that each Smallwood Unit is sold for $60. Based off Table 1, this means that a profit of $7.45 will be made off each unit sold. This profit margin is expected to grow as this device is manufactured on a larger scale because the cost per unit will decrease as each component is bought in larger bulk. The rest of the money in the budget will go towards testing equipment such as a pressure transducer, force gauge, Ambu bag, and in-line flow meter. The cost of the testing equipment is still being determined but is not expected to exceed the $1,000 budget.

This project is unique because it will be the only ventilator on the market that is low cost, electricity free, reusable, noninvasive and easy to use. This coupled with the fact that the COVID-19 pandemic has effected developing countries at a higher rate than developed countries makes the market for this device untapped.

ACKNOWLEDGEMENTS

We would like to acknowledge the creator of the Smallwood Unit, Dr. Craig Smallwood, who designed the original model of this device. We would also like to thank our faculty advisors Professor Michael Jaeggli PhD, Professor Lee Makowski PhD and Dr. Mark Fuller PhD along John Thompson who helped guide us through the improvements of this device.

INTRODUCTION

The World Blind Union estimates that there are 253 million people worldwide who are fully blind or partially sighted [1]. The blind and visually impaired (BVI) are challenged with independent mobility, especially in public environments. Lack of vision is a vast disadvantage when traversing foreign land, whether it relates to changes in elevation or obstructing objects such as walls, people, trees, etc. The lives of the BVI can be improved through the development of new assistive technologies that could aid their independent mobility.

Historically, the white cane has been the gold standard for assisting locomotion. This device works by giving haptic feedback directly to the user over the length of a 3 to 4-foot aluminum stick. Advantages of the white cane include quick and reliable haptic feedback, ease of use, and higher movement stability through contact with the physical environment. Some notable flaws of the white cane include a lack of verticality, (i.e., the sweeping motion usually only covers the ground plane, lacking sensory feedback for hanging objects) lack of concealability, limited distance of sensing range, and the constant occupation of an entire hand of the user, limiting overall freedom. Also, the sweeping motion could increase energy consumption, create a dual-task interference, and is limited to giving feedback only at the location of the cane at any given moment. Finally, the white cane is designed to be relatively long, making it difficult to conceal or stow in public places; however, the overall length of the cane gives it a finite sensing range for the BVI user. With these limitations in mind, an additional assistive device that can be used in conjunction with the white cane or as a replacement for the white cane would be a major asset for the BVI community.

Currently, there are three categories of electronic walking assistants for the BVI: sensor based, computer vision based, and smartphone based [2]. Each system can be evaluated by five properties: capturing device, feedback, coverage area, weight, and cost. Many types of sensors can be used to detect objects, including ultrasonic, infrared, laser, and radar. Most devices that have already been produced use a complex system of multiple sensors and different outputs such as haptic feedback, audio, or verbal commands to aid the BVI. Some examples of current devices are wearable navigation devices mounted on the head, waist, or chest; specialized canes; and smartphone applications. Many of these solutions result in complicated and expensive devices that would not be affordable to most of the BVI community.

By utilizing modern technology, our team is dedicated to designing a new device that will revolutionize the way the BVI can traverse the unknown at a reasonable price. The device will use ultrasonic sensors in conjunction with vibrotactile haptic feedback to give the BVI user a multidirectional sensory feedback that is proportional to the distance of the obstacles, thus providing a comprehensive scope of the environment.

PRODUCT DESIGN

The team plans to design the device with four ultrasonic sensors enclosed in a 3D-printed case (Figure 1). The case will ensure that the sensors are pointed in the correct directions with the predefined angles of detection. One sensor will be angled upward, encompassing the head and neck area of the BVI user to detect hanging objects such as tree limbs. Two sensors will point in front of the BVI user with one angled slightly to the left and the other slightly to the right. These two sensors will encompass the scope in front of and in the peripheral areas of the BVI user. The sensing ranges of these two sensors are flat cone shapes on the left and right sides in front of BVI users; therefore, objects on the left of the user will produce haptic feedback on the left side of the users' chest, objects on the right side will produce feedback on the right side, and objects in the middle will produce feedback on both sides. The final sensor will be angled downward toward the ground with a shortened sensing range. This sensor will detect changes in elevation in front of the BVI user such as stairs, ramps, or holes in the ground. PING ultrasonic sensors were chosen because they are much cheaper in relation to other considered sensors or radars, and they are simple to program. However, these sensors are still capable of detecting both moving and stationary objects with a resolution of 1 cm and a range of 3 m.

The case will also contain an Arduino Nano, which will be used to process the information gathered from the ultrasonic sensors into haptic feedback. The Arduino Nano is a small and simple processing

board that is relatively inexpensive. However, it processes information quickly enough to convey the objects in front of the BVI user with a resolution of 0.001 seconds. The 3D-printed case will be attached to a vest worn around the chest of the BVI user (Figure 1).

Figure 1. Trimetric View of 3D Printed Case for Sensors (left) and Device Worn on Chest (right)

Sensory feedback will be relayed through vibrating motors attached to the interior of the vest. There will be 4 groups of 2 motors: 2 on the chest slightly below the neck corresponding to the top sensor, 2 on the right pectoral muscle corresponding to the right sensor, 2 on the left pectoral muscle corresponding to the left sensor, and 2 just below the sternum near the rib cage corresponding to the bottom sensor. The motors will vibrate with varying frequency depending on the relative distance of the detected object from the BVI user. When an object is initially detected, the motors will vibrate with a slow frequency. Then, the frequency will increase when the object is sensed between 1 and 2 m. Finally, the motors will vibrate at the maximum frequency when the object is within 1 m of the sensor. Vibration motors were chosen for providing feedback because they are the least intrusive on the senses while also providing consistent feedback.

Considering the design specifications above, the proposed device will sense objects in front of the BVI user at distances of 1 centimeter to 3 meters, whether the objects are moving or stationary. Then, it will convey the locations of the objects through varying frequencies of vibration motors attached to the chest of the BVI user. Therefore, whether the device is used in conjunction with a white cane or without a white cane, it will enhance the ability of the BVI user to traverse unfamiliar territories by yielding more information about surroundings with a comfortable, nonintrusive, and inexpensive solution.

MARKET ANALYSIS & BUDGET

In 2015, 36 million people were fully blind with 217 million people having moderate to severe blindness. The Vision Loss Expert Group projects the number of people with visual impairments to rise over the next 30 years. Accordingly, this figure is projected to rise to 55 and 330 million in the year 2030.[3] According to NORC at the University of Chicago, the average of expected annual expenses related to vision loss is approximately $15,900 and $26,900 for each BVI user [4]. These costs include everything from medical vision aids, vision assistive devices, and medical services. In 2017, the global assistive technologies for the BVI market was valued at approximately $3.40 billion [5]. According to Fior Markets, this market is forecast to grow to $6.57 billion in 2025.

The Perkins School for the Blind reports that only 2 to 8 percent of BVI utilize the white cane. The overwhelming majority of these users use either a guide dog or a sighted dog [6]. The ultrasonic haptic feedback device will provide a modern, economic, sleek solution that is more concealable than the white cane, and will eliminate the need for another conscious guide while providing more effective feedback when supplementing or substituting for the white cane.

The entire cost of the device is covered in a budget of $190 (Table 1). The intended market product will most likely cost less than our prototype budget, as ordering materials and manufacturing in bulk will lower the production cost of a single unit. However, some of the utilities necessary for the construction of this project have been provided by the University of Alabama (e.g. soldering station, 3-D printers, and more).

Table 1. Project Budget

Item Name	Unit Cost	Quantity	Item Subtotal
Vibration Motors	$1	10	$10
PING Ultrasonic Distance Sensor	$30	4	$120
3D Printed Case	$5	1	$5
Battery	$10	1	$10
Vest	$40	1	$40
Arduino Nano	$5	1	$5
Total			**$190**

ACKNOWLEDGEMENTS

The team would like to acknowledge The University of Alabama ME 489/490 course professors and administrators for assistance and budget allowance, in addition to the individual and institutional benefactors of the University that generously provide their resources and monetary contributions. The University has provided $1,000 from the Mildred Hire fund and has donated various critical components necessary for the prototyping of this device.

INTRODUCTION

Comfort is a complex characteristic to quantify, subject to a combination of physical, physiological, and psychological perception. While short-term comfort has been extensively studied in most seat designs, long-term comfort testing has its own set of challenges, including human participant trials. Many drivers experience discomfort when driving for extended periods of time [1]. Drivers who suffer from arthritis, osteoporosis and spinal conditions are even more likely to experience discomfort. Not only can discomfort make traveling difficult, but it can also distract drivers from the road. For these reasons, automotive companies have made comfort a high priority in recent years, with "Comfort Lab", such as the one at Lear Corporation established as part of the Research and Development to pursue this work. In the hopes of reducing the costs and variations associated with using human participants, Lear has tasked our team with developing a testing method for automotive seating that provides quantitative results to indicate occupant comfort for at least 45 minutes in a laboratory setting, without the use of human participants. The Shear, Pressure, and Vibration (SPV) Comfort System is designed to collect data pertaining to the three most important variables regarding seat comfort: Shear, Pressure, and Vibration [1]. The ability to successfully collect data on these variables aids automotive companies in developing seats that provide long-term comfort for passengers.

PRODUCT DESIGN

The first step was to identify if products already existed on the market that would satisfy the needs of the project. We found that there were currently no cost-effective products on the market that could measure seat comfort for an extended period. We brainstormed four variations of how sensors could be attached to the equipment or seat: a simple seat cover, a transparent indentor, only using current Lear equipment, or creating a manikin suit. Our 5th idea was to solely collect enough data to create computer modeling software. The most achievable design with the team's skillset and resources was to make the SPV Comfort system that attaches to the current indentor Lear uses.

The first step in fabricating the SPV Comfort System was the construction of its tissue-mimicking silicone component, which is encapsulated by athletic clothing and can be tightly fit onto butt-form manikin, seen in Figure 1.

This material improved the manikin's ability to simulate loads from a human's own body, by mimicking the mechanical properties of the skin and superficial tissue layers (epidermis, dermis, etc.). This component improved pressure distributions from the manikin, showing more human-like load distributions on the seat. The tissue-mimicking material (Smooth-On Silicone Rubber, Table 1) was cast in a butt-form mold and encapsulated between two layers of athletic shorts.

The second component consists of the sensors that measure shear, pressure, and vibration. For measuring pressure and shear, an array of sensors was integrated superficial to the shorts and tissue-mimicking materials. This array consists of piezoelectric pressure force sensors and stretch force sensors. The pressure force sensors change in resistance due to compressive forces on them, while the stretch sensors change in resistance as they are stretched.

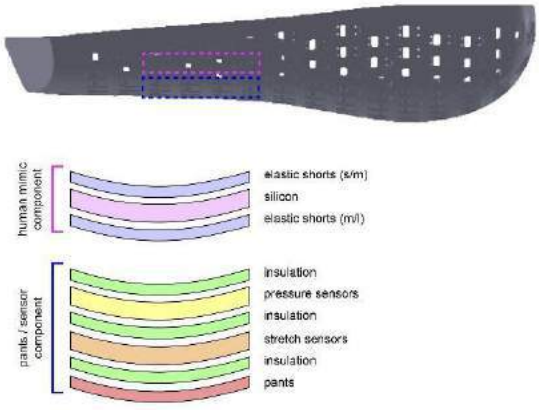

Figure 1: Overall Sensor Suit Design. This demonstrates the primary components of the SPV Comfort System.

Configuring these sensors as variable resistors in a circuit results in voltage/signal changes, which can be converted into force readings. Combining one stretch sensor with one pressure force sensor in a voltage-divider circuit configuration creates a sensor "node", with each node connected to a microprocessor board (Arduino Uno). Multiple nodes of these sensors were combined into an array that covers the areas of interest on the buttocks or back of the manikin's suit (Figure 2). The program running on the microprocessor converts

the sensor outputs into force outputs for display and recording. Each node is representative of a force reading at a "pressure point" on the manikin's buttocks, leg, or tailbone. The combination from the tensile and compression force readings was used to calculate a shear force estimate. Stress transformation principles show that if an object experiences tension and compression in one orientation, then it has to experience pure shear in another orientation. This principle is the route the team took to measure shear between the seat and driver/manikin, as measuring shear is an underdeveloped area of study. A 2-D map of shear and pressure readings were used to determine the highest points of potential discomfort in the buttocks, proximal thigh, and tailbone regions.

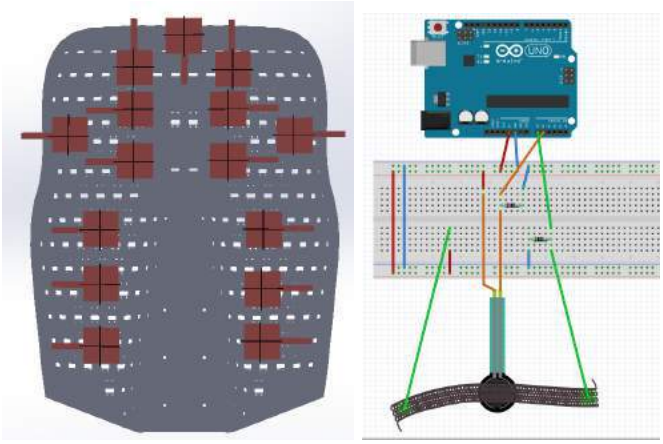

Figure 2: Node Array on Butt-form. This simplified CAD schematic (left) shows the butt-form manikin along with the array of pressure force sensors and stretch cord sensors, forming several nodes. Each node is wired to an Arduino board (right).

As a final addition, two tri-axial accelerometers measured vibration. These sensors were placed according to the ISO 2631 standard, with one on the shaker table in the laboratory, and one was placed on the butt form-seat interface [2]. This setup can give insight into how well the seat absorbs shock/vibration from the road [1]. This accelerometer setup is not directly attached to our manikin suit but part of our overall system measuring these important parameters. The successful combination of these sensors for the collection of data regarding pressure, vibration, and shear allows automotive seat manufacturers to accurately measure the driver's experience. This design and testing process improves the comfort and safety of the driver.

BUDGET & MARKET ANALYSIS

The market for this product includes automotive seating, medical seating, office seating, and can be adapted for the shoe industry. The automotive seat industry alone is an over $50 billion industry with testing facilities around the world [3]. While the other markets available are smaller they still contribute to the available market for the SPV comfort system. The market size allows for an estimated hundreds of devices sold per year.

The focus of the device is shear force reading capabilities. To have a shear force output the device needs to include pressure sensors and piezoelectric stretch sensors. The team ordered various sensors and began testing for the sensors with the lowest drift over time. Once the ideal sensors were chosen, more were bought for the final prototype. The prototype consists of 24 stretch sensors and 14 pressure sensors.

To adjust the pressure distribution of the indentor silicone was added to the device to replicate human tissue. The silicone molding equipment was purchased from Smooth-On. Some silicone molding was bought to run compression tests with. The needed testing equipment was already available in the school laboratories and Lear testing site. Accelerometers used were also available through a previous project at Lear. This allowed for a cost of $621.95. Future material costs to replicate the prototype would cost $234.99 without accelerometers or $2,474.99 with accelerometers, as shown in Table 1.

Table 1: Bill of Materials for One Testing Device.

Product	Company	Quantity	Unit Cost	Cost
P1364 Knit Jersey Conductive Fabric	Adafruit	2	$14.95	$29.90
FSR01CE	OHMITE	14	$8.71	$121.94
Polyester Fabric	Amazon	6	$8.49	$50.94
Ecoflex 00-30 Super Soft Platinum Silicone	Smooth-On	1	$32.21	$32.21
				$234.99

The SPV comfort system can be used to run tests repeatedly, allowing buyers to only purchase one device for years of use. To create a greater profit the SPV comfort system needs to be continuously improved with newer system releases for manufacturers to purchase. Maintenance costs to keep a system running are unknown but can be estimated at around $10 per sensor or $1,000 for the accelerometers that need to be replaced. Other maintenance needs are less likely but could include, silicone replacement, wiring replacement, coding bugs, fabric repairs, and shell replacement.

The estimated number of yearly sales is in the hundreds, based on the industry's number of testing facilities. The manufacturing cost for 100-800 units a year is projected to be $2,177.25 per unit with accelerometers. At this cost, the sales price will be in the range of $3000's for systems with accelerometers and the range of $300's for systems without accelerometers. The profit per unit will be $800+ ($140 without accelerometers), providing for a profit of $300,000+ a year, creating a strong return on the investment.

ACKNOWLEDGEMENTS

We thank Lear Corporation for sponsoring this project through Lawrence Technological University. We would also like to thank Missy Pereny and Steve Gamche from Lear for their support and guidance.

INTRODUCTION

Surfactant is a fluid located within the alveoli, small spherical sacs within the lungs that enable gas exchange [1], [2]. The alveoli do this by decreasing in surface tension, preventing lung collapse and allowing expansion [1]. However, underdeveloped Type II alveolar cells of neonatal infants under 35 weeks of gestational age do not produce enough surfactant for sufficient breathing [3]. These preterm neonates are prone to developing respiratory distress syndrome (RDS), which affects approximately 1% of all newborns and is the leading cause of death for preterm infants [3], [4]. Symptoms of RDS include apnea (temporary cessation of breath), shallow breathing, and prolonged gaps between breaths [3]. RDS may lead to asthma, vision problems, neurological issues in other organs, or lifelong breathing problems due to inadequate oxygen and carbon dioxide exchange within the alveoli [5], [6].

The prevailing treatment for RDS is liquid surfactant replacement administered with the INSURE (INtubation-SURfactant-Extubation) method [7], where liquid surfactant is delivered through an endotracheal tube inserted in the neonate's trachea. This invasive method interrupts respiration support (i.e. Continuous Positive Airway Pressure or CPAP) [8]. Large amounts of fluid within neonatal lungs from liquid surfactant can lead to dyspnea (difficulty breathing), pneumothorax, airway obstruction, decreased oxygen levels, or hemorrhage [9]. Aerosolized surfactants, on the other hand, are non-invasive and present the potential for improved pulmonary distribution and oxygenation [8], [10].

Although aerosol delivery systems exist as an alternative, they are inefficient, [11] as jet nebulizers typically have a delivery efficiency below 1% [12], [13]. The most effective nebulizers, including eFlow, can get 20x greater drug delivery compared to the jet nebulizer but are prohibitively expensive ($1,275 for the entire eFlow system) [13],[14]. Thus, there is no optimized aerosol delivery system on the market for neonates receiving respiratory support [8].

We are designing a non-invasive device delivering surfactant through a CPAP interface that synchronizes automatic aerosol delivery with inhalation to increase the amount of surfactant that reaches the alveoli. This proof-of-concept drug delivery system does not interrupt CPAP and provides an efficient alternative to existing treatments for infants with RDS.

PRODUCT DESIGN

The device consists of two major functions: breath synchronization and aerosol delivery. In order to detect inhalation, the device collects the infant's electrocardiogram (ECG) signal, a routine measurement for this population. This is achieved using a 3-lead system and an AD8232 signal conditioning ECG block. The ECG signal is then filtered to acquire a signal corresponding to respiration. The respiratory signal is derived from the change in position of the heart as the chest rises. As the heart moves back in the chest, a low-frequency respiration signal wave is embedded in the ECG signal. A respiratory signal can thus be obtained by filtering the ECG signal within the frequency range of respiration, typically 0.33-1 Hz in a neonate [15]. The onset of inhalation or exhalation can be determined by calculating a derivative to identify the peaks and troughs of this new respiratory signal. In this system specifically, the detection is done by finding the difference between two adjacent data points to determine where the respiratory signal switches from decreasing to increasing, a trough. The information obtained will be used to actuate aerosol propulsion at an appropriate time to maximize drug delivery using the system in **Figure 1**.

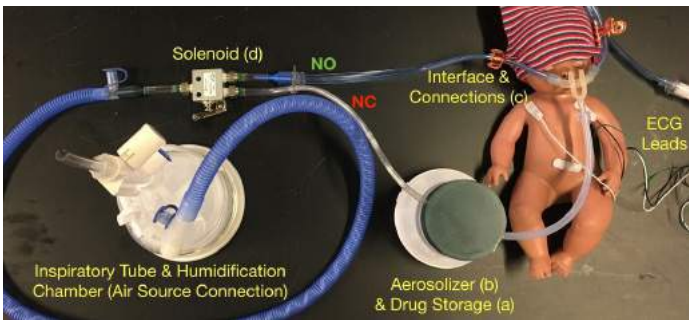

Figure 1: Drug Delivery Configuration

The Aerosol Delivery System in **Figure 1** is comprised of: (a) **drug storage:** a receptacle to hold a dose of liquid surfactant, (b) **aerosol generation:** a high-frequency vibrating piezoelectric that converts liquid to aerosol, (c) **physical connections:** a connection to the infant's cannula interface, and (d) **aerosol propulsion:** a 3/2 solenoid valve that redirects the CPAP flow from its normal route (normally opened position, NO) to push the aerosol into the infant's nose (normally closed, NC). Airflow to the infant is never interrupted and positive pressure is always maintained.

To evaluate the accuracy of inhalation detection, ECG data was first collected from an adult team member, with the described filtering and inhalation detection conducted afterwards. Inhalation start and duration times were compared to those recorded using a button pressed during inhalation and released during exhalation, while the ECG signal was simultaneously acquired. A graph of this test is shown in **Figure 2**, in which RESP data refers to that acquired using the button press.

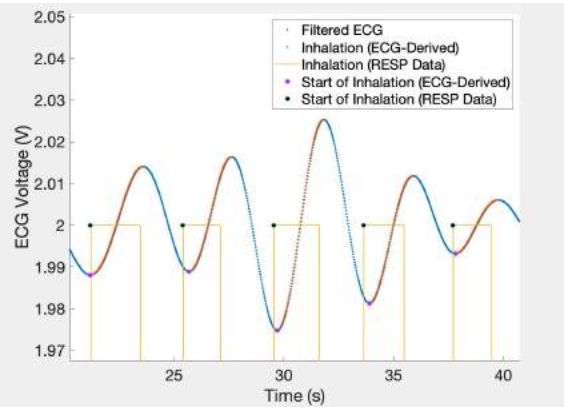

Figure 2: Graphical Evaluation of Inhalation Detection

For this test, the difference between the ECG-derived starting inhalation times and the corresponding button press respiratory times was an average of -0.32 sec, with a standard deviation of 0.44 sec. A two-sample t-test (α = 0.05) to compare the inhalation durations resulted in a p-value of 0.103, indicating that there was no statistical evidence that the means of the ECG and respiratory inhalation durations were unequal. The detection system has also been implemented in real-time, allowing inhalation start times to be displayed within approximately 81 ms of computation time.

A typical CPAP for a preterm infant has a 4-8 lpm flow rate. In initial testing at 8 lpm of crossflow, we propelled over 1.1 mL of aerosolized drug through the interface over an 8-minute treatment window. This successfully coated the entire surface of our test lung with much less drug than the traditional dose of 3 mL/kg infant weight for liquid surfactant. To validate the particles are small enough to reach the alveoli (.5-5 μm), we developed a particle size evaluation method using high speed photo analysis, as seen in **Figure 3**. With this method, we qualitatively compared aerosol particles with larger particles from a nebulizer and preliminarily determined that the particles are in the appropriate size range. Looking forward, we plan to use darkfield microscopy for more accurate size characterization.

BUDGET & MARKET ANALYSIS

The total budget allocated to the team for designing, building, and testing the prototype is $2500. Our current proof-of-concept prototype costs around $100, split approximately evenly between electronics and physical components. Future testing costs include materials to build a spirometer to verify the breath sensing functionality, as well as costs to buy parts of a CPAP circuit, a compressor if the device is used in a setting without a wall air source, a neonate model, and materials to generate duplicates of the device system for usability testing.

The primary market for the final device is the U.S. preterm infants (400,000/year) [16]. We estimate that over $55.2 million is spent annually on surfactant treatment for this population [17]. Our sponsor projects that the total market reach—including different age ranges and drug types—would move 1 million units/year, reducing the expected manufacturing cost to less than $50, including tooling costs for injection molds. To maintain affordability, the sale price would be $80-100, on par with many commercially available nebulizers. The device's automation and efficient use of surfactant will reduce labor and drug costs, expanding accessibility in non-US markets.

Existing surfactant treatments drastically reduce mortality rates for preterm infants. However, there is an acute need for an optimized, non-invasive neonatal drug delivery system. Our device combines the benefits of breath synchronization, automation, and aerosolized surfactant with a non-invasive, CPAP-integrated design to effectively help the littlest lungs get the breath they need.

ACKNOWLEDGEMENTS

Thank you to our sponsor at Zewski Corp. and to our faculty in the Rice University Bioengineering department for their financial support and mentoring through the Rice University Bioengineering Design course.
