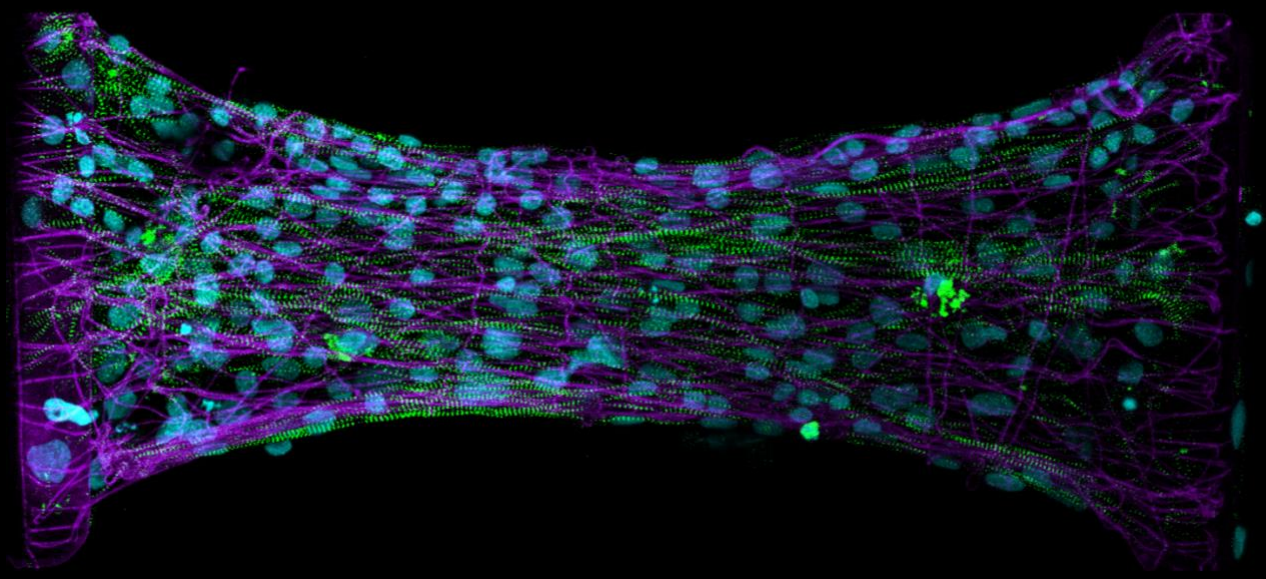
biotransport.

# *2022 Summer Biomechanics, Bioengineering, and Biotransport Conference*

June 20th -23rd, 2022
Eastern Shore, Maryland



## *Reconnecting Networks in Biomechanics, Bioengineering and Biotransport*

Funding for this conference was made possible (in part) by the National Science Foundation's Civil, Mechanical, and Manufacturing Innovation Division (Biomechanics and Mechanobiology) 2209028. Funding for this conference was also made possible (in part) by R13EB033191A from the National Institute of Biomedical Imaging and Bioengineering. The views expressed in written conference materials or publications and by speakers and moderators do not necessarily reflect the official policies of the Department of Health and Human Services; nor does mention of trade names, commercial practices, or organizations imply endorsement by the U.S. Government. Prizes and other support for the Student Paper Competition were provided by the Bioengineering Division of the American Society of Mechanical Engineers.

**The 2022 Summer Biomechanics, Bioengineering, and Biotransport Conference ($SB^3C$) organizers gratefully acknowledge the support of the National Science Foundation, the National Institutes of Health, and American Society of Mechanical Engineers.**

Congratulations to the 2021 Cover Art Contest Winner:

**Samuel DePalma, University of Michigan**
*Title: Mechanical Cues Drive the Robust Assembly of Microfabricated Stem Cell-Derived Cardiac Tissues*
Description: Engineered cardiac microtissue composed of induced pluripotent stem cell derived cardiomyocytes on a synthetic fibrous matrix (violet) suspended between two elastomeric cantilevers. Sarcomeric Z-discs were visualized via cardiomyocytes encoding fluorescently tagged endogenous Titin (green). Cell nuclei were stained with DAPI (turquoise).

**ISBN 978-1-7351808-4-7**

# SB³C 2022 Meeting Scientific Podium Sessions

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

## Machine Learning and Artificial Intelligence

**Chesapeake A-D**

**Session Chairs: Hadi Wiputra,** *University of Minnesota*
**Kritika Iyer,** *University of Michigan*

**9:30AM** **Statistical Shape Representation of Ascending Thoracic Aortic Aneurysms: Accounting for Major Branches of the Aortic Arch** SB³C2022-312
Hadi Wiputra[1], Shion Matsumoto[2], Jessica E. Wagenseil[3], Alan C. Braverman[3], Victor H. Barocas[1]
*[1]University of Minnesota, [2]University of Michigan, [3]Washington University*

**9:45AM** **A Bayesian Approach for Inverse Problems on Patient-Specific CFD Simulation of Aorta Using an MI-Based Surrogate Model** SB³C2022-162
Pan Du, Jian-xun Wang
*University of Notre Dame*

**10:00AM** **AI-Accelerated Multiscale Modeling for Platelet Adhesion Dynamics and Multi-Platelet Aggregation at Millisecond and Molecular Resolutions** SB³C2022-262
Peineng Wang, Yicong Zhu, Jawaad Sheriff, Peng Zhang, Changnian Han, Yuefan Deng, Danny Bluestein
*Stony Brook University*

**10:15AM** **A Deep Learning Method for 3D Vessel Reconstruction Using Uncalibrated X-Ray Angiography Images: Application to Coronary Hemodynamics** SB³C2022-223
Kritika Iyer, Noah C. Stevens, Brahmajee K. Nallamothu, C. Alberto Figueroa, Raj R. Nadakuditi
*University of Michigan*

**10:30AM** **Learning Whole Heart Mesh Generation from Patient Images for Computational Simulations** SB³C2022-440
Fanwei Kong, Shawn Shadden
*University of California Berkeley*

**10:45AM** **Denoising and Super-Resolving 4D Flow MRI Using Physics-Guided Neural Networks** SB³C2022-259
Neal Patel, Emily Bartusiak, Hemanth Devarapalli, Sean Rothenberger, Amy Schwichtenberg, Edward Delp, Vitaliy Rayz
*Purdue University*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Vascular Mechanics I

**Chesapeake E**

**Session Chairs: Vijay Vedula,** *Columbia University*
**Bryan Good,** *University of Tennessee*

**9:30AM** **Automatic Estimation of Mechanical and Geometrical Parameters of Abdominal Aortic Aneurysms Using 3D+T Ultrasound for Understanding Aneurysm Progression** SB³C2022-211
Esther Maas[1], Arjet Nievergeld[1], Judith Fonken[1], Mirunalini Thirugnanasambandam[1], Marc van Sambeek[2], Richard Lopata[1]
*[1]Eindhoven University of Technology, [2]Catharina Hospital Eindhoven*

**9:45AM** **Batch-Process Optimization of Kink-Resistant Vascular Grafts with High Compliance** SB³C2022-315
David Jiang[1], Andrew Robinson[2], Elizabeth Cosgriff-Hernandez[2], Lucas Timmins[1]
*[1]University of Utah, [2]University of Texas at Austin*

**10:00AM** **Biomechanical Analysis of Local Mural Defects in Angiotensin-II-Induced Thoracic Aortopathies** SB³C2022-475
Dar Weiss[1], Aaron S. Long[1], George Tellides[1], Stéphane Avril[2], Jay D. Humphrey[1], Matthew R. Bersi[3]
*[1]Yale University, [2]Mines Saint-Étienne, [3]Washington University*

**10:15AM** **Effects of Nitroglycerin Induced Vasodilation on Elastic versus Muscular Artery Stiffness in Older Veterans** SB³C2022-213
Ryan Pewowaruk[1], Amy Hein[1], Cynthia Carlsson[1], Claudia Korcarz[2], Adam Gepner[1]
*[1]William S. Middleton Memorial Veterans Hospital, [2]University of Wisconsin*

**10:30AM** **Investigation of The Regional Variations in the Mechanical Properties and Microstructure of Porcine Left Anterior Descending Artery** SB³C2022-117
Sergio A. Pineda-Castillo, Santiago Aparicio-Ruiz, Chung-Hao Lee
*University of Oklahoma*

**10:45AM** **Prediction of Analog Thrombi Mechanical Properties, Composition, and Contraction Using Computed Tomography Imaging** SB³C2022-219
Janneke Cruts[1], Jo-Anne Giezen[2], Kim van Gaalen[1], Robert Beurskens[1], Yanto Ridwan[1], Marcel Dijkshoorn[1], Heleen van Beusekom[1], Nikki Boodt[1], Aad van der Lugt[1], Frank Gijsen[1], Rachel Cahalane[1]
*[1]Erasmus Medical Center, [2]Delft University of Technology*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Mineralized Tissue Mechanics

**Chesapeake F**

**Session Chairs: Natasha Case,** *Saint Louis University*
**Hannah Dailey,** *Lehigh university*

**9:30AM** **In-Situ Bone Fracture Mechanics Assessed by 3D-Xray Microscopy** SB³C2022-360
Glynn Gallaway[1], Rachel Surowiec[2], Matthew Allen[2], Joseph Wallace[2], Laura Pyrak-Nolte[1], Thomas Siegmund[1]
*[1]Purdue University, [2]Indiana University*

**9:45AM** **Prediction of Microarchitecture and Anisotropic Elastic Behaviour of Trabecular Bone Using a QCT-Based Deep Learning Model** SB³C2022-129
Pengwei Xiao, Eakeen Haque, Tinghe Zhang, Yufei Huang, Xiaodu Wang
*University of Texas at San Antonio*

**10:00AM** **Optimizing and Validating Soft Callus Mechanical Properties in Ovine Bone Fracture Healing Models with Biomechanical Data** SB³C2022-179
Brendan Inglis[1], Peter Schwarzenberg[1], Karina Klein[2], Brigitte von Rechenberg[2], Salim Darwiche[2], Hannah Dailey[1]
*[1]Lehigh University, [2]University of Zurich*

**10:15AM** **High-Fat Diet Concurrently Alters Bone Microstructure and Nanostructure** SB³C2022-438
Yoshihiro Obata[1], Neha S. Dole[2], Claire Acevedo[1], Tamara Alliston[2]
*[1]University of Utah, [2]University of California, San Francisco*

**10:30AM** **Enthesis Mechanical Properties and Composition Are Dependent on Movement And Development** SB³C2022-370
Kaitlin McCreery, Olivia Tonti, Callan Luetkemeyer, Corey Neu, Sarah Calve
*University of Colorado Boulder*

**10:45AM** **A Comparative Study of Bone Tissue Growth Between Bioinspired and Square Scaffolds** SB³C2022-394
Marco Fielder, Arun Nair
*University of Arkansas*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Biomechanics of the Eye, Pelvic Floor, and Reproductive Track I

**Chesapeake G**

**Session Chairs: Ian Sigal,** *University of Pittsburgh*
**Megan R. Routzong,** *University of California*

**9:30AM** **Radiation Cystitis Results in Compromised Urinary Function and Decreased Bladder Distensibility** SB³C2022-397
Bernadette Zwaans[1], Marissa Grobbel[2], Laura Lamb[1], Sara Roccabianca[2]
*[1]Beaumont Health, [2]Michigan State University*

**9:45AM** **Simulations of The Gravid Human Uterus and Cervix for Patients at High- And Low-Risk for Preterm Birth** SB³C2022-384
Erin Louwagie[1], Mirella Mourad[1], Michael House[2], Ronald Wapner[1], Kristin Myers[1]
*[1]Columbia University, [2]Tufts Medical Center*

**10:00AM** **Dependence of Vaginal Tissue Creep Behavior On Applied Load** SB³C2022-29
Justin Dubik[1], David Dillard[1], Kristin Miller[2], Raffaella De Vita[1]
*[1]Virginia Tech, [2]Tulane University*

**10:15AM** **Simulation of Uterus Active Contraction During Fetus Delivery in Ls-Dyna** SB³C2022-22
Ru Tao, Michele Grimm
*Michigan State University*

**10:30AM** **Intraocular Pressure-Induced Lamina Cribrosa Deformations are Larger and More Inhomogeneous Between Quadrants in an Experimental Glaucoma Eye than in Healthy Eye** SB³C2022-381
Bingrui Wang[1], Fuqiang Zhong[1], Junchao Wei[1], Yi Hua[1], Juan Reynaud[2], Brad Fortune[2], Ian Sigal[1]
*[1]University of Pittsburgh, [2]Legacy Health Research*

**10:45AM** **Shear Properties of Collagen Crosslinked Porcine Cornea** SB³C2022-375
H Hatami-Marbini, M.E Emu
*University of Illinois*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Joint & Spine Biomechanics

**Clipper A-C**

**Session Chairs: Sagar Singh,** *University of Pennsylvania*
**Anita Singh,** *Widener University*

**9:30AM** **Why Don't Bats Tear Their Rotator Cuffs Despite Repetitive Overhead Motion** SB³C2022-411
Iden Kurtaliaj[1], Jennifer Kunes[1], Michael Rowley[2], Lynn Ann Forrester[1], Mikhail Golman[1], Guy Genin[3], Sharon Swartz[4], Stavros Thomopoulos[1]
*[1]Columbia University, [2]California State University, [3]Washington University St. Louis, [4]Brown University*

**9:45AM** **Radiofrequency Ablation of the Medial Nerve for Facet Joint Pain Alters the Biomechanics of The Spine - A Computational Study** SB³C2022-261
Faris A. Amalki, Daniel H. Cortes
*Penn State University*

**10:00AM** **Pre-Exposure to a Painful Stretch Increases Both Strains & Neuronal Calcium Activity in Neuron-Collagen Constructs across Physiologic & Supraphysiological Stretch** SB³C2022-190
Sagar Singh, Prabesh Ghimire, Beth Winkelstein
*University of Pennsylvania*

**10:15AM** **Progressive Disc and Bone Adaptations Due to Posterolateral Tethering in a Porcine Model of Scoliosis** SB³C2022-286
Axel Moore[1], Adriana Barba[2], Harrah Newman[1], Kyle Meadows[1], Benjamin Sinder[3], Alessandra Fusco[2], Rachel Hillard[2], Sriram Balasubramanian[4], Edward Vresilovic[1], Brian Snyder[5], Patrick Cahill[3], Thomas Schaer[2], Dawn Elliott[1]
*[1]University of Delaware, [2]University of Pennsylvania, [3]Children's Hospital of Philadelphia, [4]Drexel University, [5]Boston Children's Hospital*

**10:30AM** **The Influence of Personal Protective Equipment on Male and Female Spinal Loads in Vertical Impact** SB³C2022-460
Sagar Umale, Prashant Khandelwal, John Humm, Narayan Yoganandan
*Medical College of Wisconsin*

**10:45AM** **Degeneration of the Lumbar Facet Joint Occurs in Both the Facet Capsular Ligament and the Facet Joint Articular Cartilage** SB³C2022-172
Jill Middendorf, Victor Barocas
*University of Minnesota*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Mechanobiology

**Galleon A-C**

**Session Chairs: Eno Ebong,** *Northeastern University*
**Spencer Szczesny,** *Penn State University*

**9:30AM** **Increased Nuclear Compliance Enables Rapid Confined Migration in Mesenchymal Glioblastoma** SB³C2022-120
Landon Teer, Neha Anil, Dominic Armagno, Marco Munoz, Shah Tarun, Samuel Vielee, Joseph Chen
*University of Louisville*

**9:45AM** **Periventricular White Matter Hyperintensities Associated with Mechanical Changes of the Ependymal Wall** SB³C2022-21
Andreia Caçoilo[1], Madison Grigg[2], Henry Rusinek[3], Johannes Weickenmeier[1]
*[1]Stevens Institute of Technology, [2]West Virginia University, [3]New York University*

**10:00AM** **Mechanical Cues from The Environment Make Mesenchymal Stromal Cell Population Heterogeneous** SB³C2022-128
Samantha Kaonis, Soham Ghosh
*Colorado State University*

**10:15AM** **Microenvironmental Stiffness Modulates Responsiveness and Communication with Mesenchymal Stromal Cells** SB³C2022-336
Sung Yeon Kim, Edward Bonnevie, Carla Scanzello, Robert Mauck
*University of Pennsylvania*

**10:30AM** **Heterogeneity in Cell Distribution Due to Collective Organization Leads to Localized Higher Stresses** SB³C2022-469
Mahvash Jebeli, Samantha Lopez, Qi Wen, Kristen Billiar
*Worcester Polytechnic Institute*

**10:45AM** **Glaucomatous Stressors Drive Schlemm s Canal Cell Pathobiology Via Elevated Yap Activity** SB³C2022-49
Haiyan Li[1], Megan Kuhn[2], Daniel Stamer[2], Preethi Ganapathy[1], Samuel Herberg[1]
*[1]Suny Upstate Medical University, [2]Duke University*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Transport in Diagnostics

**Schooner A-B**

**Session Chairs: Lyle Hood,** *University of Texas at San Antonio*
**Zhenpeng Qin,** *University of Texas at Dallas*

**9:30AM** **Development of a Multi-Timestep Approach for Microparticle and Erythrocyte Image Velocimetry** SB³C2022-400
Simon Tupin, Joseph van Batenburg-Sherwood
*Imperial College London*

**9:45AM** **Characteristic Impedance with Exercise Testing Correlates with Right Ventricular-Pulmonary Arterial Coupling in Isolated Postcapillary Pulmonary Hypertension** SB³C2022-30
Christopher Lechuga[1], Farhan Raza[2], Naomi Chesler[1]
*[1]University of California, Irvine, [2]University of Wisconsin*

**10:00AM** **Characterization of Porcine Pancreas Tissue Plasmonic Photothermal Heating at 808 And 1064 Nm Wavelengths** SB³C2022-321
Forhad Akhter[1], Andrea Smith[1], Santiago Manrique-Bedoya[1], Chris Moreau[2], Yusheng Feng[1], Kathryn Mayer[1], Lyle Hood[1]
*[1]University of Texas at San Antonio, [2]UT Health San Antonio*

**10:15AM** **A Deep Learning Approach to Investigate the Hidden Links Between Cannabis and Cardiovascular Health** SB³C2022-459
Joseph C. E. Messou, Francis Oparaocha, Hasan Imanli, James A. Perry, Timm-Michael L. Dickfeld, Jean Jeudy, Eleonora Tubaldi
*University of Maryland*

**10:30AM** **Elucidating the Impact of Plasmonic Nanoparticle Shape on Infectious Virus Diagnosis** SB³C2022-478
Yaning Liu[1], Haihang Ye[1], Tingting Zhang[1], Qi Cai[1], Hoang Dinh Huynh[2], Jeffery Kahn[2], Zhenpeng Qin[1]
*[1]University of Texas Dallas, [2]University of Texas Southwestern Medical Center*

**10:45AM** **Patient-Specific Modeling of Obstructed Ventriculoperitoneal Shunt Performance** SB³C2022-37
Sung Min Kwon, Stephanie TerMaath
*University of Tennessee*

| Monday, June 20 | 9:30AM – 11:00AM EDT |
|---|---|

# Rehab and Assistive Technologies

**Cutter A-B**

**Session Chairs: Sara Roccabianca,** *University of Michigan*
**Ria Mazumdar,** *Widener University*

**9:30AM** **Patient-Specific Models Reveal High Interfragmentary Strain in Distal Femur Fracture Fixation** SB³C2022-181
Jordan Inacio[1], Peter Schwarzenberg[2], Richard Yoon[3], Andrew Kantzos[4], Ajith Malige[4], Chinenye Nwachuku[4], Hannah Dailey[1]
*[1]Lehigh University, [2]AO Foundation Davos, [3]Jersey City Medical Center, [4]St. Luke's University*

**9:45AM** **Exercise Therapy Improves Glenohumeral Joint Function when Reaching Behind the Back in Individuals with Rotator Cuff Tears** SB³C2022-301
Luke Mattar, Rachel McLoughlin, Adam Popchak, William Anderst, Volker Musahl, James Irrgang, Richard Debski
*University of Pittsburgh*

**10:00AM** **Predicting Joint Torque Using sEMG and Deep Neural Networks** SB³C2022-304
Heath Boyea, J. Miles Canino
*Rose-Hulman Institute of Technology*

**10:15AM** **Design and Mechanical Testing of a Shoulder-Assistive Exosuit** SB³C2022-355
Kaleb Burch, Jill Higginson
*University of Delaware*

**10:30AM** **An Analysis of Octopus Curvature for Application in Soft Robotic Prostheses** SB³C2022-113
Garrett Weidig, Emily Kelly, Brittany Bush, Galit Pelled, Tamara Reid Bush
*Michigan State University*

**10:45AM** **Evaluating the Capabilities of a Novel Device Designed to Preserve Whole Pancreases Via Oxygenated Perfusion** SB³C2022-43
Daniel Portillo, Jose Gonzalez, Carorina Villareal, Sophia Salazar, Lyle Hood
*University of Texas at San Antonio*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

# Patient Specific Flow and Physiology

**Chesapeake A-D**

**Session Chair: Jamasp Azarnoosh,** *Medical College of Wisconsin*
**Vijay Vedula,** *Columbia University*

**11:15AM** **Image-Based Temporal Quantification of Aortic Coarctation Within the Range of Severities and Durations Seen Clinically** SB³C2022-282
Jamasp Azarnoosh, Arash Ghorbannia, John F. LaDisa Jr.
*Medical College of Wisconsin*

**11:30AM** **Aortic Coarctation Assessment - In Vitro 4D Flow MRI Approach** SB³C2022-393
James Rice[1], Labib Shahid[1], Haben Berhane[2], Cynthia Rigsby[3], Joshua Robinson[3], Lindsay Griffin[3], Michael Markl[2], Alejandro Roldan-Alzate[1]
*[1]University of Wisconsin-Madison, [2]Northwestern University, [3]Lurie Children's Hospital*

**11:45AM** **Personalized Ultrasound-Based Fluid-Structure Interaction Modeling of Abdominal Aortic Aneurysms: From Model Development to Ex-Vivo Verification** SB³C2022-205
Judith Fonken[1], Esther Maas[1], Arjet Nievergeld[1], Floris Verheijen[1], Hein de Hoop[1], Marc van Sambeek[2], Frans van de Vosse[1], Richard Lopata[1]
*[1]Eindhoven University of Technology, [2]Catharina Hospital Eindhoven*

**12:00PM** **Computational Fluid Dynamics Model of Embryonic Heart and Supporting Vasculature Illustrates Temporal and Spatial Variation in Wall Shear Stress During Cardiac Cycle** SB³C2022-123
Kirsten Giesbrecht, Simone Rossi, Boyce Griffith
*University of North Carolina- Chapel Hill*

**12:15PM** **Analysis of Tracheal Air Flow Dynamics in Infant Tracheal Stenosis Before and after Repair Using 3D Printing and Computational Fluid Dynamics Modeling** SB³C2022-406
Clare Richardson[1,2], Michael Barbour[1], Seth Friedman[2], Randall Bly[1,2], John Dahl[1,2], Kaalan Johnson[1,2], Alberto Aliseda[1]
*[1]University of Washington, [2]Seattle Children's Hospital*

**12:30PM** **Analysis of Upper Airway Flow Dynamics in Infants with Robin Sequence Using 4-Dimensional Computed Tomography and Computational Fluid Dynamics Modeling** SB³C2022-398
Michael Barbour[1], Clare Richardson[1,2], Michael Bindschadler[2], Seth Friedman[2], Randall Bly[1,2], John P. Dahl[1,2], Alberto Aliseda[1]
*[1]University of Washington, [2]Seattle Children's Hospital*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

## Vascular Mechanics II

**Chesapeake E**

**Session Chairs: Chiara Bellini,** *Northeastern University*
**Lucas Timmins,** *University of Utah*

**11:15AM** **Critical Pressure of Intramural Delamination in Aortic Dissection** SB³C2022-191
Ehsan Ban, Cristina Cavinato, Jay Humphrey
*Yale University*

**11:30AM** **Effect of Renal Denervation on the Biomechanical Properties of Common Carotid Arteries in Rats** SB³C2022-365
Anastasia Gkousioudi, Margherita Razzoli, Jesse Moreira, Gianluca Harbert, Richard Wainford, Katherine Zhang
*Boston University*

**11:45AM** **Inter-Donor Variability in the Tensile and Compressive Behaviour of In Vitro Human Thrombi** SB³C2022-224
Rachel Cahalane, Judith de Vries, Moniek de Maat, Kim van Gaalen, Heleen van Beusekom, Aad van der Lugt, Ali Akyildiz, Frank Gijsen
*Erasmus Medical Center*

**12:00PM** **Measurement of stent retriever removal forces in an experimental model of acute ischemic stroke** SB³C2022-104
Demitria Poulos, Bryan Good
*University of Tennessee*

**12:15PM** **Using a Tissue-Engineered Model to Investigate the Impact of Collagen Orientation on the Local Mechanical Behavior of Atherosclerotic Plaque Caps** SB³C2022-280
Hanneke Crielaard[1], Tamar Wissing[2], Su Guvenir Torun[1], Pablo de Miguel[1], Ranmadusha Hengst[3], Gert-Jan Kremers[1], Frank Gijsen[1], Kim van der Heiden[1], Ali Akyildiz[1]
*[1]Erasmus Medical Center, [2]Eindhoven University of Technology, [3]Delft University of Technology*

**12:30PM** **Mechanical Remodeling of Murine Thoracic Aorta During Pregnancy** SB³C2022-470
Ana I. Vargas, Samar Tarraf, Rouzbeh Amini, Chiara Bellini
*Northeastern University*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

# Tendon & Ligament Mechanics

**Chesapeake F**

**Session Chairs: Benjamin Wheatley,** *Bucknell University*
**Jill Middendorf,** *University of Minnesota*

**11:15AM** **A Soft Tissue Grasping Device for Enhanced Rotator Cuff Repair Inspired By Python Teeth** SB³C2022-232
Iden Kurtaliaj[1], Ethan Hoppe[2], Yuxuan Huang[2], Mark Lipkin[2], Thomas Gardner[1], Liana Tedesco[1], Sohil Desai[1], Silvio Bentacur[1], Linda Effiong[1], William Levine[1], Guy Genin[2], Stavros Thomopoulos[1]
*[1]Columbia University, [2] Washington University*

**11:30AM** **Shear Wave Speed as a Measure of Regional Tendon Stress** SB³C2022-366
Jonathon Blank[1], Darryl Thelen[1], Matthew Allen[2], Joshua Roth[1]
*[1]University of Wisconsin-Madison, [2]Brigham Young University*

**11:45AM** **Injury Criteria: Defining Mechanical Thresholds for Collagen in Soft Tissues** SB³C2022-380
Callan Luetkemeyer[1], Kaitlin McCreery[1], Kathryn Jacobson[2], Corey Neu[1], Sarah Calve[1]
*[1]University of Colorado Boulder, [2]Purdue University*

**12:00PM** **Differences in Porcine ACL Morphology and Function are Minor Between Boars and Barrows at Early Adolescence** SB³C2022-404
Jacob Thompson[1,2], Danielle Howe[1,2], Lauren Schnabel[1], Matthew Fisher[1,2]
*[1]North Carolina State University, [2]University of North Carolina-Chapel Hill*

**12:15PM** **Biological Response of Rabbit Anterior Cruciate Ligaments To Mechanical Loading is Sex-Specific** SB³C2022-329
Lauren Paschall, Aman Dhawan, Spencer Szczesny
*Penn State University*

**12:30PM** **Effect of Mechanical Loading on the Microstructure and Diffusion Imaging Properties of Ligament-Mimicking Fibers** SB³C2022-116
Roberto Pineda Guzman, Noel Naughton, Bradley Sutton, Mariana Kersh
*University of Illinois*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

## Biomechanics of the Eye, Pelvic Floor, and Reproductive Track II

**Chesapeake G**

**Session Chairs: Andrew Feola,** *Emory University and Atlanta VA Medical Center*
**Cyrus Rezvanifar,** *University of Minnesota*

**11:15AM** **Mechanical Anisotropy of the Equatorial Sclera Does not Concur with the Primary Collagen Fiber Orientations** SB³C2022-349
Yi Hua[1], Samuel Salinas[2], Marissa Quinn[1], Fengting Ji[1], Rouzbeh Amini[2], Ian A. Sigal[1]
*[1]University of Pittsburgh, [2]Northeastern University*

**11:30AM** **The Effects of Negative Periocular Pressure on Biomechanics of the Optic Nerve Head And Cornea: A Computational Modeling Study** SB³C2022-306
Babak Safa[1], John Berdahl[2], C. Ross Ethier[1]
*[1]Georgia Institute of Technology, [2]Vance Thompson Vision*

**11:45AM** **The Strain Response of the Human Lamina Cribrosa from Intraocular Pressure Decrease** SB³C2022-354
Cameron Czerpak[1], Michael Kashaf[2], Brandon Zimmerman[1], Harry Quigley[1], Thao Nguyen[1]
*[1]Johns Hopkins University, [2]University of California San Diego*

**12:00PM** **Vaginal Biomechanical Function and Composition in Premenopausal Women with and Without Pelvic Organ Prolapse** SB³C2022-347
Qinhan Zhou[1], Benard Ogola[1], Jasmine Kiley[1], Shelby White[1], Lyndsey Buckner[2], Laurephile Desrosiers[2], Leise Knoepp[2], Sarah Lindsey[1], Kristin Miller[1]
*[1]Tulane University, [2]Ochsner Health System*

**12:15PM** **Time-Dependent Material Properties of Nonpregnant and Pregnant Human Uterus Under Spherical Nanoindentation** SB³C2022-284
Daniella Fodera[1], Shuyang Fang[1], Michelle Oyen[2], Kristin Myers[1]
*[1]Columbia University, [2]Washington University in St. Louis*

**12:30PM** **Female Pelvic Morphological Variation in the Generation of Geometries for Simulations of Vaginal Childbirth** SB³C2022-196
Megan Routzong[1], Steven Abramowitch[2]
*[1]University of California, San Diego, [2]University of Pittsburgh*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

# Brain & Injury Mechanics I

**Clipper A-C**

**Session Chairs: Johannes Weickenmeier,** *Stevens Institute of Technology*
**Brittany Coats,** *University of Utah*

**11:15AM** **In Vivo Quantification of Relative Skull-Brain Motion Using MR Elastography** SB³C2022-253
Alexa Diano[1], Grace McIlvain[1], Suhas Vidhate[2], Andrew Knutsen[2], Dzung Pham[2], Curtis Johnson[1]
*[1]University of Delaware, [2]Henry M. Jackson Foundation*

**11:30AM** **Recent Updates on the GHBMC Human Head Finite Element Model- Development of Crash Injury Index for Multiple Brain Injuries** SB³C2022-442
Ding Lyu, Shirin Phadke, Abhijeet Kumbhare, Liying Zhang
*Wayne State University*

**11:45AM** **On-Field Evaluation of Mouthpiece- And Helmet-Mounted Sensor Data from Head Kinematics in Football** SB³C2022-314
Ty Holcomb, Madison Marks, Stewart Pritchard, Logan Miller, Jillian Urban, Joel Stitzel
*Wake Forest School of Medicine*

**12:00PM** **Simulation of Murine Brain Deformation During Chimera Impacts** SB³C2022-414
Connor Bradfield, Liming Voo, K.T. Ramesh
*Johns Hopkins University*

**12:15PM** **Multi-Dimensional Morphometric Analysis of Posterior Fossa to Study Type I Chiari Malformation** SB³C2022-228
Ya-Chen Chuang[1], Alejandro Carrasquilla[2], Aymeric Pionteck[1], Javid Abderezaei[1], Addison Quinones[2], Gizem Bilgili[1], William H. Shuman[2], Shan Zhao[2], Raj K. Shrivastava[2], Mehmet Kurt[1]
*[1]University of Washington, [2]Icahn School of Medicine*

**12:30PM** **Effect of Helmet Size and Velocity on Cervical Spine Segmental Responses Under Rear Impact Acceleration** SB³C2022-419
Yuvaraj Purushothaman, Hoon Choi, Narayan Yoganandan
*Medical College of Wisconsin*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

# Cardiovascular Tissue Engineering

**Galleon A-C**

**Session Chairs: Zhijie Wang,** *Colorado State University*
**Will Richardson,** *Clemson University*

**11:15AM** **Vascular Smooth Muscle Cells Upregulate Glycolytic and Contractile Phenotype Genes in the Presence of Glutamine** SB$^3$C2022-362
Pattie Mathieu, Alisa Clyne
*University of Maryland College Park*

**11:30AM** **Development of an In Vitro Experimental Model to Study Endothelial Dysfunction from Coarctation of the Aorta** SB$^3$C2022-352
Dylan Schock[1], Hilda Martinez Ramirez[1], Joy Lincoln[1], Abdel Alli[2], John LaDisa[1,3]
*[1]Medical College of Wisconsin, [2]University of Florida, [3]Herma Heart Institute, Children's Wisconsin*

**11:45AM** **A Structural Bio-Chemo-Mechanical Model for Traction Force Microscopy of Vascular Smooth Muscle Cells** SB$^3$C2022-40
Shannon Flanary, Victor Barocas
*University of Minnesota*

**12:00PM** **Mechanical Cues Such as Shear Stress and Piezo1 Activation Generate Red Blood Cell Extracellular Vesicles** SB$^3$C2022-192
Gurneet Sangha, Callie Weber, Ryan Sapp, Morgan Pettebone, Alisa Clyne
*University of Maryland College Park*

**12:15PM** **Perturbed Cyclic Strain in Cardiac Fibroblast Cultures Results in a Mechanically-Induced Senescent Phenotype** SB$^3$C2022-418
Stephanie E. Schneider, Adrienne K. Scott, Corey P. Neu
*University of Colorado at Boulder*

**12:30PM** **Microfabricated Anisotropic Tissue Bundles for the Production of 3D Cardiac Tissue at Scale** SB$^3$C2022-332
Maggie Jewett, Amanda Bluem, Samuel DePalma, Brendon Baker
*University of Michigan*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

## Transport in Hemodynamics and Lymphatics

**Schooner A-B**

**Session Chairs: Ellie Rahbar,** *Wake Forest University*
**Jifu Tan,** *Northern Illinois University*

**11:15AM** **Material Property Changes of Polymerized Red Blood Cells in Sickle Cell Disease** SB³C2022-100
Dillon Williams, David Wood
*University of Minnesota*

**11:30AM** **Regional Differences in Perivascular Adipose Tissue Following Angiotensin II-Induced Hypertension** SB³C2022-474
Yujun Xu, J. Caleb Snider, Niyousha Karbasion, Matthew R. Bersi
*Washington University in St. Louis*

**11:45AM** **Linking Circulatory Turbulence and the Pathophysiology of Sickle Cell Disease** SB³C2022-160
Eudorah Vital[1], Alice Liu[2], Christina Caruso[3], David Bark[2], Wilbur Lam[1]
*[1]Georgia Institute of Technology, [2]Washington University in St. Louis, [3]Emory University*

**12:00PM** **Perivascular Cerebrospinal Fluid Flow is a Major Source of Interstitial Fluid and its Clearance in the Rat Brain** SB³C2022-210
Kristian Mortensen[1], Tuomas Lilius[1], Marko Rosenholm[1], Björn Sigurđsson[1], Douglas Kelley[2], Maiken Nedergaard[1]
*[1]University of Copenhagen, [2]University of Rochester*

**12:15PM** **Efflux of Cerebrospinal Fluid Through Cervical Lymph Vessels is Reduced in Aged Mice** SB³C2022-271
Aditya Raghunandan, Ting Du, Virginia Pla-Requena, Yara Izhiman, Guojun Liu, Maiken Nedergaard, Douglas Kelley
*University of Rochester*

**12:30PM** **Plasmonic Lamp: Highly Specific and Sensitive Detection of SARS-CoV-2 by Plasmonic Sensing of Isothermally Amplified Nucleic Acids** SB³C2022-310
Haihang Ye, Chance Nowak, Yaning Liu, Yi Li, Tingting Zhang, Leonidas Bleris, Zhenpeng Qin
*University of Texas at Dallas*

| Monday, June 20 | 11:15AM – 12:45PM EDT |
|---|---|

# Mechanics in Multi-Tissue Networks

**Cutter A-B**

**Session Chairs: Jacqueline Cole,** *University of North Carolina and North Carolina State University*
**Christopher Price,** *University of Delaware*

**11:15AM** **Evaluating the Effect of Pufas on Hepatic Stellate Cell Activation in a 3D Tissue Engineered Model of Hepatic Fibrosis** SB³C2022-57
L. Madison Kirk[1], Nathaniel Hauser[1], Lucy J. Price[1], Chia-Chi Chuang Key[1], Aleksander Skardal[2], Elaheh Rahbar[1]
*[1]Wake Forest University, [2]Ohio State University*

**11:30AM** **Functional Hyperemia Increases Influx of Cerebrospinal Fluid to the Brain** SB³C2022-130
Yiming Gan[1], Stephanie Holstein-Rønsbo[2], Douglas Kelley[1], Maiken Nedergaard[1]
*[1]University of Rochester, [2]University of Copenhagen*

**11:45AM** **Expression of the Injury Marker Activating Transcription Factor-3 After Exposure to MMP-1 is Decreased in a Neuron Collagen Co-Culture with Phospholipase A2 Inhibition** SB³C2022-279
Sagar Singh, Prabesh Ghimire, Beth Winkelstein
*University of Pennsylvania*

**12:00PM** **Investigating Structural Changes of Neonatal Brachial Plexus Post-Stretch** SB³C2022-431
Virginia Orozco[1], Rachel Magee[1], Mital Sahni[2], Sriram Balasubramanian[1], Anita Singh[3]
*[1]Drexel University, [2]Sunrise Children's Hospital, [3]Widener University*

**12:15PM** **Determining Effects on Pig Gait after Induced Traumatic Brain Injury: Initial Assessments** SB³C2022-187
Sloan Kanat, Paige Cordts, Alesa Hughson, Galit Pelled, Tamara Reid Bush
*Michigan State University*

**12:30PM** **Early Removal of the Infrapatellar Fat Pad in a Spontaneous Rodent Model of Osteoarthritis May Beneficially Alter the Development of Osteoarthritis** SB³C2022-165
Tammy Haut Donahue[1], Mary Afzali[2], Nicole Vigon[3], Ryan Ek[3], Gerardo Narez[3], Kelly Santangelo[2]
*[1]University of Memphis, [2]Colorado State University, [3]University of Massachusetts-Amherst*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 1: Biofluid Mechanics and Cardiovascular Imaging

**Chesapeake A-D**

**Session Chairs: Elaheh Rahbar,** *Wake Forest University*
**Joseph van Batenburg-Sherwood,** *Imperial College London*

**9:30AM** **Radiomics Features on Contrast-Enhanced and Non-Enhanced MRI are Associated with Intracranial Aneurysmal Risk** SB³C2022-105
Sricharan Veeturi, Nandor Pinter, Adnan Siddiqui, Vincent Tutino
*University at Buffalo*

**9:45AM** **A Smart-PIV Approach for In Vitro Evaluation of Coronary Hemodynamics** SB³C2022-31
Elena Torta, Giuseppe Carlo Alp Caridi, Claudio Chiastra, Diego Gallo, Umberto Morbiducci
*Politecnico di Torino*

**10:00AM** **Global and Regional Quantification of Cardiotoxicity due to Radiotherapy Using Cardiac Magnetic Resonance Imaging: A Pilot Study in Lung Cancer** SB³C2022-151
Alireza Omidi, Mihaela Rosu-Bubulac, Georgia Thomas, Elisabeth Weiss, John S. Wilson
*Virginia Commonwealth University*

**10:15AM** **Predicting Hemodynamic Indices in Coronary Artery Aneurysms Using Response Surface Method: An Application in Kawasaki Disease** SB³C2022-118
Alireza Asadbeygi[1], Simon Lee[2], John Kovalchin[2], Hoda Hatoum[1]
*[1]Michigan Technological University, [2]Nationwide Children Hospital*

**10:30AM** **Patient-Specific Finite Element Modeling to Predict Clinical Risks of Percutaneous Pulmonary Valve Implantation** SB³C2022-94
Carly Donahue, Varun Aggarwal, Victor Barocas
*University of Minnesota*

**10:45AM** **Computational Modeling of Cryoballoon Ablation for Pulmonary Vein Isolation** SB³C2022-55
Tejas Patel[1], Chris Li[1], Farshad Raissi[2], Ghassan Kassab[3], Tong Gao[1], Lik Chuan Lee[1]
*[1]Michigan State University, [2]University of California, [3]California Medical Innovations Institute*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 2: Tendon, Ligament, and Joint

**Chesapeake E**

**Session Chairs: Brianne Connizzo,** *Boston University*
**Guy Genin,** *Washington University in St. Louis*

**9:30AM** **Mechanical and Structural Changes Due to Tendon Overload in a Rat Model of Synergist Ablation** SB³C2022-112
Ellen Bloom, Lily Lin, Justin Parreno, Karin Gravare Silbernagel, Dawn Elliott
*University of Delaware*

**9:45AM** **Collagen Hybridizing Peptides Extend the Retention Time of Imaging Markers in Healthy and Osteoarthritic Rat Stifle Joints** SB³C2022-139
Emma Luke, Michael Yu, Jeffrey Weiss
*University of Utah*

**10:00AM** **Elastic Strength and its Relation to Mineral Density in Juvenile Equine Bones of the Lower Limb** SB³C2022-41
Sara Moshage, Annette McCoy, Mariana Kersh
*University of Illinois*

**10:15AM** **Mouse Supraspinatus Tendon Mechanical and Structural Properties are Dependent on Region and Age** SB³C2022-17
Michael DiStefano, Patrick Paglia, Stephanie Weiss, Snehal Shetye, Andrew Kuntz, Louis Soslowsky
*University of Pennsylvania*

**10:30AM** **Collagen Fibrils from Positional Tendons Exhibit Increased Amounts of Denatured Collagen Upon Reaching the Yield Point** SB³C2022-134
Allen Lin[1], Steven Eppell[2], Seungju Yu[1], Jeffrey Weiss[1]
*[1]University of Utah, [2]Case Western Reserve University*

**10:45AM** **Partial ACL Injury Location Impacts Biomechanics and Tissue Remodeling in a Skeletally Immature Porcine Model** SB³C2022-91
Danielle Howe[1,2], Jacob Thompson[1,2], Andre Bautista[1,2], Lauren Schnabel[1], Jeffrey Spang[2], Matthew Fisher[1,2]
*[1]North Carolina State University, [2]University of North Carolina- Chapel Hill*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 3: Tissue Engineering, Remodeling, and Emerging Areas

**Chesapeake F**

**Session Chairs: Raffaella De Vita,** *Virginia Tech*
**Andrew Feola,** *Emory University and Atlanta VA Medical Center*

**9:30AM** **Epithelial Fluid Secretion and Luminal Pressure Regulate the Patterns of Proliferation that Sculpt the Developing Bronchial Tree** SB³C2022-145
Shelby Mohr-Allen, Victor Varner
*University of Texas at Dallas*

**9:45AM** **The Heterogenous and Anisotropic Mechanics of the Airway Tree** SB³C2022-13
Samaneh Sattari, Crystal Mariano, Mona Eskandari
*University of California Riverside*

**10:00AM** **PDGF-BB Disrupts the Stiffness-Dependent Myofibroblastic Differentiation of Corneal Keratocytes in Response to TGF-B1** SB³C2022-141
Krithika Shankar Iyer[1], David Schmidtke[1], Matthew Petroll[2], Victor Varner[1]
*[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center*

**10:15AM** **Cervical Material Remodeling in Pregnancy Using a Nonhuman Primate Model** SB³C2022-125
Shuyang Fang[1], Lei Shi[1], Ivan Rosado-Mendez[2], Helen Feltovich[3], Timothy Hall[2], Kristin Myers[1]
*[1]Columbia University, [2]University of Wisconsin-Madison, [3]Intermountain Healthcare*

**10:30AM** **An Experimental and Numerical Investigation of Cardiac Tissue-Patch Interrelation** SB³C2022-76
Gozde Basara, Gokhan Bahcecioglu, Xiang Ren, Pinar Zorlutuna
*University of Notre Dame*

**10:45AM** **Patterns of Tissue Stiffness Correlate with Distributions of Proliferation and Yap Activity Along the Embryonic Ureteric Tree** SB³C2022-154
Somdutta Chakraborty[1], Thomas Carroll[2], Victor Varner[1]
*[1]University of Texas at Dallas, [2]UT Southwestern Medical Center*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# Valves

**Chesapeake G**

**Session Chairs: Jonathan Wenk,** *University of Kentucky*
**Lakshmi Dasi,** *Georgia Institute of Technology*

**9:30AM** **Measuring the Efficacy of Right Atrial Appendage Tissue to Withstand Pulmonary Hypertensive Conditions as a Functional Pulmonary Valve** SB³C2022-188
Kate Appleman[1], Katarina Lettner[1], Andrew Behrmann[1], Pirooz Eghtesady[2], Shamik Bhattacharya[1]
*[1]Missouri State University, [2]Washington University in St. Louis*

**9:45AM** **Texas TriValve 1.0: A Reverse-Engineered, Open Model of the Human Tricuspid Valve** SB³C2022-435
Mrudang Mathur[1], William Meador[1], Marcin Malinowski[2], Tomasz Jazwiec[2], Tomasz Timek[3], Manuel Rausch[1]
*[1]University of Texas at Austin, [2]University of Silesia, [3]Spectrum Health*

**10:00AM** **Bioprosthetic Leaflet Stress Following Transcatheter Aortic Valve Replacement in Bicuspid Aortic Valves** SB³C2022-424
Breandan Yeats[1], Aniket Venkatesh[1], Milad Samaee[1], Pradeep Yadav[2], Venkateshwar Polsani[2], Vinod Thourani[2], Lakshmi Dasi[1]
*[1]Georgia Institute of Technology, [2]Piedmont Hospital*

**10:15AM** **Dynamic In-Vivo Motion of the Mouse Aortic Heart Valve** SB³C2022-457
Xinzeng Feng[1], Daniel Gramling[2], Aletea vanVeldhuisen[2], David McComb[3], Christopher Breuer[4], Craig Goergen[2], Michael Sacks[1]
*[1]University of Texas at Austin, [2]Purdue University, [3]Ohio State University, [4]Nationwide Children's Hospital*

**10:30AM** **An Experimental Approach to Quantify the Pre-Strains of the Tricuspid Heart Valve Leaflets** SB³C2022-405
Devin Laurence, Chung-Hao Lee
*University of Oklahoma*

**10:45AM** **Multiscale Modeling of Cardiac Valve Disease Using Cell-Level Signals to Drive Myocardial Growth** SB³C2022-42
Hossein Sharifi, Austin Wellette-Hunsucker, Charles Mann, Kenneth Campbell, Jonathan Wenk
*University of Kentucky*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# Brain & Injury Mechanics II

**Clipper A-C**

**Session Chairs: Mehmet Kurt,** *University of Washington*
**Sarah Bentil,** *Iowa State University*

**9:30AM** **Network-Based Modeling of Alzheimer's Disease Assessing Impact of Connectome Measures on Progression Patterns** SB³C2022-110
Shima Jalalian[1], Oren Civier[2], Johannes Weickenmeier[1]
*[1]Stevens Institute of Technology, [2]Swinburne University of Technology*

**9:45AM** **Denoising Instrumented Mouthguards for Accurate Traumatic Brain Injury Detection with Convolutional Neural Network** SB³C2022-8
Xianghao Zhan, Yuzhe Liu, Olivier Gevaert, David Camarillo
*Stanford University*

**10:00AM** **Development of a Parameterized Microscale Axonal Injury Model** SB³C2022-26
Chaokai Zhang, Songbai Ji
*Worcester Polytechnic Institute*

**10:15AM** **Spatial Gradient in Frontal Lobe Stiffness During Brain Maturation** SB³C2022-333
Kyra Twohy, Grace McIlvain, Curtis Johnson
*University of Delaware*

**10:30AM** **Relationships Between Athletic Performance Measures and Head Kinematics in Youth Ice Hockey** SB³C2022-378
Abigail Swenson[1], N. Stewart Pritchard[1], Logan Miller[1], Chesney Oravec[1], Jason Mihalik[2], Jillian Urban[1], Joel Stitzel[1]
*[1]Wake Forest School of Medicine [2]University of North Carolina- Chapel Hill*

**10:45AM** **Infant Skull Fracture Pattern Characteristics from Low-Height Falls** SB³C2022-476
Yousef Alsanea, Tagrid Ruiz-Maldonado, Brittany Coats
*University of Utah*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

## Soft Tissue Biomechanics

**Galleon A-C**

**Session Chairs: Chiara Bellini,** *Northeastern University*
**Babak Safa,** *Georgia Institute of Technology*

**9:30AM** **Carpal Arch Space Augmentation by Volarly Applied Force on the Skin Surface- A Finite Element Study** SB³C2022-14
Hui Zhang, Zong-Ming Li
*University of Arizona*

**9:45AM** **A Discrete-Fiber Model for Understanding Cellular Mechanoadaptation** SB³C2022-247
Ryan Mahutga, Patrick Alford
*University of Minnesota*

**10:00AM** **Precise Measurement of Microparticle Viscoelastic Properties Using a Microfluidic Extensional Flow Device** SB³C2022-465
Sara Ghanbarpour Mamaghani, Joanna Dahl
*University of Massachusetts Boston*

**10:15AM** **Cortical Thickness Correlates with Cortical Morphology Among Human and Non-Human Primate Brains** SB³C2022-52
Nagehan Demirci, Maria Holland
*University of Notre Dame*

**10:30AM** **A Novel Approach for Mapping 3D Extracellular Matrix Mechanics at the Cellular Scale Using Magnetic Microparticles** SB³C2022-256
Adil Khan, Jacopo Ferruzzi
*University of Texas at Dallas*

**10:45AM** **Comparative Study of Chemical and Nanomechanical Properties of Cat and Rat Vibrissae** SB³C2022-324
Davin Sim, Donna Ebenstein
*Bucknell University*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

# Transport in Drug Delivery and Discovery

**Schooner A-B**

**Session Chairs: Govind Srimathveeravalli,** *University of Massachusetts Amherst*
**Malisa Sarntinoranont,** *University of Florida*

**9:30AM** **An Physiological On-Chip Vessel Platform to Study Vascular Transport of Circulating Tumor Cells** SB³C2022-146
Yue Wu, Yuyuan Zhou, Ratul Paul, Yaling Liu
*Lehigh University*

**9:45AM** **Drug Discovery for Selective Targeting of Pancreatic Cancer Cells Using Microfluidic Tumor-Stroma Model** SB³C2022-447
Hye-ran Moon[1], Mark R. Kelley[2], Melissa L. Fishel[2], Bumsoo Han[1]
*[1]Purdue University, [2]Indiana University*

**10:00AM** **3D Microfluidic Cell Arrays with Recirculation and Tumor-Stroma Interaction for the Development of Immunotherapeutic Drug** SB³C2022-461
Chun-Wei Chi[1], Yeh-Hsing Lao[2], A.H. Rezwanuddin Ahmed[1], Kam W. Leong[2], Sihong Wang[1]
*[1]CUNY City College of New York, [2]Columbia University*

**10:15AM** **Molecular Design of Polyelectrolyte Complex Micelles for Nucleic Acid Delivery** SB³C2022-292
Alexander Marras, Jeffrey Vieregg, Matthew Tirrell
*University of Chicago*

**10:30AM** **Minimally Invasive Blood-Spinal Cord Barrier Modulation for Drug Delivery** SB³C2022-243
Zhenghong Gao[1], Eric David[1], Tiffany Wei Leong[1], Xiaoqing Li[1], Qi Cai[1], Monica Giannotta[2], Elisabetta Dejana[2], John Wiggins[1], Sharada Krishnagiri[1], Robert Bachoo[3], Theodore J. Price[1], Zhenpeng Qin[1]

*[1]University of Texas at Dallas, [2]FIRC Institute of Molecular Oncology Foundation, [3]University of Texas Southwestern Medical Center*

**10:45AM** **Simple Analytic Model for Peristaltic Flow and Mixing** SB³C2022-51
Ruy Ibanez, Mohammad Shokrian, Jong-Hoon Nam, Douglas Kelley
*University of Rochester*

| Tuesday, June 21 | 9:30AM – 11:00AM EDT |
|---|---|

## Cartilage Mechanics & Musculoskeletal Imaging

**Cutter A-B**

**Session Chairs: Deva Chan,** *Purdue University*
**Mohammad Islam,** *University of Pittsburgh*

**9:30AM** **Superficial Zone Chondrocytes can get Compacted Under Physiological Loading: A Multiscale Finite Element Analysis** SB³C2022-455
Kimberly Kroupa, Katherine Spack, Lianna Gangi, Nadeen Chahine, Clark Hung, Gerard Ateshian
*Columbia University*

**9:45AM** **Effects of Compromised Synovial Fluid on Articular Cartilage Tribological Rehydration and Lubrication** SB³C2022-323
Shamimur Akanda, David Burris, Christopher Price
*University of Delaware*

**10:00AM** **A Chemo-Mechano-Biological Model of Evolving Osteoarthritis** SB³C2022-147
Muhammed M. Rahman[1], Paul N. Watton[2], Thomas S. E. Öst[3], Corey P. Neu[4], David M. Pierce[1]
*[1]University of Connecticut, [2]University of Sheffield, [3]Swedish Defense Research Agency, [4]University of Colorado Boulder*

**10:15AM** **Novel In Vivo Articular Cartilage Elastography Pipeline to Determine Mechanical Properties from Dynamic MRI Deformation Analysis** SB³C2022-36
Emily Miller[1], Hongtian Zhu[1], Woowon Lee[1], Stephane Avril[2], Corey Neu[1]
*[1]University of Colorado Boulder, [2]Univ Lyon Univ Jean Monnet*

**10:30AM** **Ultrasonic Analysis Reveals Layer-Dependent Shear Wave Propagation in the Patellar Tendon and Superficial Tissues** SB³C2022-343
Stephanie Cone, Lauren Welte, Darryl Thelen
*University of Wisconsin*

**10:45AM** **Accelerated Acquisition of In Vivo Cartilage Strain using Compressed Sensing and Spiral DENSE MRI** SB³C2022-185
Woowon Lee, Emily Miller, Hongtian Zhu, Corey Neu
*University of Colorado Boulder*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 4: Cardiovascular Mechanics

**Chesapeake A-D**

**Session Chairs: Sara Roccabianca,** *Michigan State University*
**Matthew Bersi,** *Washington University in St. Louis*

**11:15AM** **Aortic Structural and Functional Remodeling in Response to Chronic E-Cigarette or Cigarette Exposure in the Apoe-/- Female Mouse** SB³C2022-149
Yasmeen Farra, Jacqueline Matz, Jessica Oakes, Chiara Bellini
*Northeastern University*

**11:30AM** **Multiscale Modeling of Restenosis after Percutaneous Transluminal Angioplasty: Towards a Patient-Specific Analysis** SB³C2022-33
Anna Corti[1], Monika Colombo[2], Cemre Çelikbudak[1], Philippe Büchler[3], Francesco Migliavacca[1], Scott Berceli[4], Stefano Casarin[5], Jose Felix Rodriguez Matas[1], Claudio Chiastra[6]
*[1]Politecnico di Milano, [2]ETH Zurich, [3]University of Bern, [4]University of Florida, [5]Houston Methodist Hospital, [6]Politecnico di Torino*

**11:45AM** **Tricuspid Valve Annulus Mechanics and Geometry in Newborns with Hypoplastic Left Heart Syndrome** SB³C2022-9
Colton Ross, Elizabeth Trimble, Arshid Mir, Harold Burkhart, Chung-Hao Lee
*University of Oklahoma*

**12:00PM** **Assessing Arterial Stiffness in Human Blood Pressure Waveform Using Harmonic Distortion** SB³C2022-95
Nicholas Milkovich[1], Gary Mitchell[2], Béla Suki[1], Yanhang Zhang[1]
*[1]Boston University, [2]The Framingham Heart Study*

**12:15PM** **A 3D Computational Model of Aortic Valve Interstitial Cell Contractile Behavior within a Peg Hydrogel Medium** SB³C2022-93
Alex Khang, John Steinman, Xinzeng Feng, Michael Sacks
*University of Texas at Austin*

**12:30PM** **Post-Stretch Behavior of Vascular Smooth Muscle Cells Depends on Strain-Rate and Actomyosin Interactions** SB³C2022-23
Samuel Boland, Patrick Alford
*University of Minnesota*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 5: Orthopaedic Bioengineering and Mechanotherapeutics

**Chesapeake E**

**Session Chairs: Kyoko Yoshida,** *University of Minnesota*
**Manuel Rausch,** *University of Texas at Austin*

**11:15AM** **Large Animal Model of Meniscus Injury and Repair Shows Chondroprotection and Partially Restores Joint Kinematics as Measured via MRI** SB³C2022-24
Kyle Meadows[1], Brendan Stoeckl[2], John Peloquin[1], Adriana Barba[2], Eddie Bonnevie[2], Sonia Bansal[2], David Steinberg[2], Miltiadis Zgonis[2], Thomas Schaer[2], Robert Mauck[2], Dawn Elliott[1]
*[1]University of Delaware, [2]University of Pennsylvania*

**11:30AM** **Inhibiting Epigenetic Modifiers Rescues Chondrocyte Fate Following Cell Expansion for Cartilage Regeneration** SB³C2022-131
Adrienne Scott, Katie Gallagher, Stephanie Schneider, Corey Neu
*University of Colorado Boulder*

**11:45AM** **Mechanotherapeutics to Modulate the Foreign Body Response** SB³C2022-98
Niamh Ward[1], William Whyte[2], Debkalpa Goswami[2], Ruth Levey[1], Garry Duffy[1], Ellen Roche[2], Eimear Dolan[1]
*[1]National University of Ireland, [2]Massachusetts Institute of Technology*

**12:00PM** **Stimulating the Hedgehog Signaling Pathway to Improve Zonal Tendon-To-Bone Integration** SB³C2022-80
Timur Kamalitdinov, Keitaro Fujino, Xi Jiang, Sinaia Keith Lang, Mary Evans, Miltiadis Zgonis, Andrew Kuntz, Nathaniel Dyment
*University of Pennsylvania*

**12:15PM** **In Vivo Human Knee Varus-Valgus Loading Apparatus for Analysis of MRI-Based Intratissue Strain and Relaxometry** SB³C2022-152
Hongtian Zhu, Emily Miller, Woowon Lee, Robert Wilson, Corey Neu
*University of Colorado Boulder*

**12:30PM** **Hyaluronan, PRG4, and Cytokine Production in Synoviocytes is Sensitive to Cyclic Strain Magnitude** SB³C2022-67
Meghana Pendyala[1], Paige Woods[2], Douglas Brubaker[3], Elizabeth Blaber[1], Tannin Schmidt[2], Deva Chan[3]
*[1]Rensslaer Polytechnic Institute, [2]University of Connecticut, [3]Purdue University*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# PhD-Level Student Paper Competition Session 6: Growth & Remodeling in Injury and Disease

**Chesapeake F**

**Session Chairs: Maria Holland,** *University of Notre Dame*
**Jacopo Ferruzzi,** *University of Texas at Dallas*

**11:15AM** **APOE E4 Genotype Decreases Barrier Function and Glucose Uptake in Induced Pluripotent Stem Cell-Derived Brain Microvascular Endothelial Cells** SB³C2022-73
Callie Weber, Sophia Zic, Alisa Clyne
*University of Maryland College Park*

**11:30AM** **A Multiparameter Whole Blood Hemostasis Assessment Using a Highly Sensitive Flexible Carbon Nanotube Paper-Based Capacitance Sensor** SB³C2022-148
Praveen Kaliappan Sekar, Ye Jin, Dayong Gao
*University of Washington*

**11:45AM** **Progressive Mechanical and Structural Changes in Anterior Cerebral Arteries with Alzheimer□s Disease** SB³C2022-81
Xiaozhu Liu, Samuel Halvorsen, Nathan Blanke, Irving Bigio, Yanhang Zhang
*Boston University*

**12:00PM** **Comparison of Oscillatory Deformation Patterns Excited in the Human Brain In Vivo by Harmonic and Impulsive Skull Motion** SB³C2022-47
Jordan Escarcega[1], Andrew Knutsen[2], Ahmed Alshareef[3], Ruth Okamoto[1], Philip Bayly[1]
*[1]Washington University in St. Louis, [2]Henry M. Jackson Foundation, [3]Johns Hopkins University*

**12:15PM** **Rate and Region-Dependent Mechanical Properties of G□ttingen Minipig Brain Tissue in Oscillatory Shear** SB³C2022-6
Gregory Boiczyk[1], Noah Pearson[1], Aravind Sundaramurthy[2], Jose Rubio[2], Dhananjay Subramaniam[2], Ginu Unnikrishnan[2], Jaques Reifman[2], Kenneth Monson[1]
*[1]University of Utah, [2]Department of Defense Biotechnology High-Performance Computing Software Applications Institute*

**12:30PM** **The Relationship Between Cardiac Cycle Induced Strain in the Brainstem and Chiari Malformation Type I Symptomatology** SB³C2022-135
Mohamad Motaz Fouad Al Samman[1], Alaaddin Ibrahimy[2], Blaise Simplice Talla Nwotchouang[3], John N. Oshinski[4], Daniel L. Barrow[4], Philip A. Allen[3], Rouzbeh Amini[1], Francis Loth[1]
*[1]Northeastern University, [2]Yale University, [3]University of Akron, [4]Emory University*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# Special Session in Honor of Dr. Ajit Yoganathan

**Chesapeake G**

**Session Chairs: Lakshmi Dasi,** *Georgia Institute of Technology*
**Keefe Manning,** *Pennsylvania State University*

**11:15AM** **Flow Dynamic Differences Between Self-Expanding and Balloon Expandable Transcatheter Aortic Valves** SB³C2022-330
Hoda Hatoum[1], Milad Samaee[2], Janarthanan Sathananthan[3], Stephanie Sellers[3], Maximilian Kuetting[4], Scott Lilly[5], Abdul Ihdayhid[6], Philipp Blanke[3], Jonathon Leipsic[3], Vinod Thourani[7], Lakshmi Prasad Dasi[2]
*[1]Michigan Technological University, [2]Georgia Institute of Technology, [3]University of British Columbia, [4]New Valve Technology, [5]Ohio State University, [6]Harry Perkins Institute, [7]Piedmont Hospital*

**11:30AM** **A Novel Bi-Ventricle Mechanical Support Configuration for the Failed Fontan Circulation** SB³C2022-283
Emrah Sisli[1], Canberk Yildirim[2], Ibrahim Basar Aka[3], Osman Nuri Tuncer[4], Yuksel Atay[4], Mustafa Ozbaran[4], Kerem Pekkan[2]
*[1]Osmangazi University, [2]Koc University, [3]Istanbul Bilgi University, [4]Ege University*

**11:45AM** **The Interplay Between Transcatheter Aortic Valve Replacement Complications and Coronary Artery Disease** SB³C2022-198
Seyedvahid Khodaei, Zahra Keshavarz-Motamed
*McMaster University*

**12:00PM** **Predicting Valve Performance Using Logistic Regression** SB³C2022-218
Brennan Vogl[1], Yousef Darestani[2], Juan Crestanello[3], Brian Lindman[2], Mohamad Alkohouli[3], Hoda Hatoum[1]
*[1]Michigan Technological University, [2]Vanderbilt University Medical Center, [3]Mayo Clinic*

**12:15PM** **Hemodynamic Impact of Anterior Leaflet Laceration in Transcatheter Mitral Valve Replacement** SB³C2022-374
Keshav Kohli[1], Zhenglun Alan Wei[2], Vahid Sadri[1], Andrew Siefert[1], Philipp Blanke[3], Emily Perdoncin[1], Adam Greenbaum,[1] Jaffar Khan[4], Robert Lederman[4], Vasilis Babaliaros[1], Ajit Yoganathan[1], John Oshinski[1]
*[1]Georgia Institute of Technology and Emory University, [2]University of Massachusetts, [3]University of British Columbia, [4]National Institutes of Health*

**12:30PM** **Toward Subject-Specific Biomechanics of the Right-Noncoronary Bicuspid Aortic Valve and its Association with Molecular Gene Expression** SB³C2022-59
Hail Kazik[1], Kandail Harkamaljot[2], Benjamin Goot[3], Joy Lincoln[3], John LaDisa[1], El-Sayed Ibrahim[3]
*[1]Marquette University, [2]Cardio Consulting, [3]Medical College of Wisconsin*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# Mechanobiology and Pathology

**Clipper A-C**

**Session Chairs: Mitchel Colebank,** *University of California, Irvine*
**Giuseppe De Nisco,** *Politecnico di Torino*

**11:15AM** **A Computational Analysis of Experimental Designs to Study Pulmonary Hypertension and Right Ventricular Function** SB³C2022-20
Mitchel Colebank, Naomi Chesler
*University of California, Irvine*

**11:30AM** **Computational Fluid-Solid-Interaction Modeling of Normotensive and Angiotensin-II Infused Hypertensive Mice** SB³C2022-214
Sara Hopper[1], Dar Weiss[2], Federica Cuomo[1], Jay D. Humphrey[2], C. Alberto Figueroa[1]
*[1]University of Michigan, [2]Yale University*

**11:45AM** **Computational 13C Metabolic Flux Analysis Indicates Endothelial Cells Attenuate Metabolic Perturbations by Modulating TCA Cycle Activity** SB³C2022-161
Bilal Moiz[1], Jonathan Garcia[2], Sarah Basehore[2], Angela Sun[1], Andrew Li[1], Surya Padmanabhan[1], Kaitlyn Albus[1], Cholsoon Jang[3], Ganesh Sriram[1], Alisa Clyne[1]
*[1]University of Maryland College Park, [2]Drexel University, [3]University of California, Irvine*

**12:00PM** **Fluid-Structure-Based Computational Model of Hemodynamics-Driven Aortic Growth for FBLN4SMKO Mice** SB³C2022-68
Marisa S. Bazzi[1], Casey D. Hokanson[1], Jessica E. Wagenseil[2], Victor H. Barocas[1]
*[1]University of Minnesota, [2]Washington University*

**12:15PM** **Wall Shear Stress Topological Skeleton Variability Predicts Atherosclerotic Plaque Growth in Human Coronary Arteries** SB³C2022-237
Giuseppe De Nisco[1], Eline Hartman[2], Valentina Mazzi[1], Diego Gallo[1], Claudio Chiastra[1], Joost Daemen[2], Jolanda Wentzel[2], Umberto Morbiducci[1]
*[1]Politecnico di Torino, [2]Erasmus Medical Center*

**12:30PM** **Changes in CD44 and Drug Resistance in Ovarian Cancer Cells with Differing Mechanical Presentation of Hyaluronic Acid** SB³C2022-293
Maranda Tidwell, Gillian Huskin, Molly Buckley, Mary Sewell-Loftin, Joel Berry
*University of Alabama at Birmingham*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

## Cancer & Morphogenesis

**Galleon A-C**

**Session Chairs: Karen Kasza,** *Columbia University*
**Victor Varner,** *University of Texas at Dallas*

**11:15AM** **Spatiotemporal Dynamics of Epithelial Cell Packings and Tissue Mechanics During Morphogenesis** SB³C2022-107
Christian Cupo, Cole Allan, Andrew Pomposelli, Karen Kasza
*Columbia University*

**11:30AM** **Actomyosin Contractility Controls Organ-Scale Buckling in the Developing Small Intestine** SB³C2022-340
John Durel, Hyunjee Lim, Nandan Nerurkar
*Columbia University*

**11:45AM** **An In Vitro Model of the Tumor Microenvironment Shaped by Cancer-Associated Fibroblasts** SB³C2022-268
Sarah Shelton[1], Brandon Piel[2], Tran Thai[2], Huu Tuan Nguyen[1], Jochen Lorch[2], Kartik Sehgal[2], David Barbie[2], Roger Kamm[1]
*[1]Massachusetts Institute of Technology, [2]Dana Farber Cancer Institute*

**12:00PM** **Examining Ovarian Cancer HSP27 Regulation Via Mechanotransduction Signaling in a 3D Model** SB³C2022-132
Molly Buckley, Joel Berry, Mary-Kathryn Sewell-Loftin
*University of Alabama at Birmingham*

**12:15PM** **Core-Shelled Microcapsules Produce Tumor Aggregates with Greater Sphericity and Drug Resistance than Gold-Standard Liquid Overlay Technique in HER2+ Breast Cancer Cells** SB³C2022-70
Cassandra Roberge[1], Margarida Barroso[2], David Corr[2]
*[1]Rensselaer Polytechnic Institute, [2]Albany Medical College*

**12:30PM** **A Gravity-Driven Multi Micro Physiological System to Study Tissue Responses to Cancer Therapeutics** SB³C2022-158
Pouria Rafsanjani Nejad, Hossein Tavana
*University of Akron*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# Lung Biomechanics

**Schooner A-B**

**Session Chairs: Ed Sander,** *University of Iowa*
**Mona Eskandari,** *University of California Riverside*

**11:15AM** **MicroRNA Therapies to Prevent Ventilator Induced Lung Injury During the Acute Respiratory Distress Syndrome** SB³C2022-234
Samir Ghadiali, Qinqin Fei, Basia Gabela-Zuniga, Tricia Oyster, Vasudha Shukla, Megan Ballinger, Joshua Englert
*Ohio State University*

**11:30AM** **Mapping Strain Amplification in Lung Cancer: A Geometric Model to Test How Altered Mechanics Could Promote Tumor Progression** SB³C2022-452
Rebecca Zitnay, Keith Carney, Michael Herron, Jeffrey Weiss, Michelle Mendoza
*University of Utah*

**11:45AM** **Murine Lung Mechanics in Response to Varying Inflation Volumes and Frequencies** SB³C2022-19
Kathrine Anduaga[1], Talyah Nelson[1], Samaneh Sattari[1], Crystal Mariano[1], Arzu Ulu[1], Edward Dominguez[1], Tara Nordgren[2], Mona Eskandari[1]
*[1]University of California, [2]Colorado State University*

**12:00PM** **Image-Based Dynamic Strain Estimation of Alveolar Microstructures During Ex Vivo Mechanical Ventilation** SB³C2022-240
Jacob Herrmann, Sarah Gerard, Edward Sander
*University of Iowa*

**12:15PM** **A Novel Fibrous Finite Element Model of Soft Tissues** SB³C2022-335
Mohammad R Islam, Fengting Ji, Manik Bansal, Yi Hua, Ian A. Sigal
*University of Pittsburgh*

**12:30PM** **Reducing Skin Injuries Induced by Prolonged Usage of Respirator Masks** SB³C2022-122
Rikeen Jobanputra, Kian Kun Yap, Manoj Murali, Margarita Santos, Marc Masen
*Imperial College London*

| Tuesday, June 21 | 11:15AM – 12:45PM EDT |
|---|---|

# Biomechanics of Human Motion

**Cutter A-B**

**Session Chairs: Sriram Balasubramanian,** *Drexel University*
**Lyle Hood,** *University of Texas at San Antonio*

**11:15AM** **Thumb Metacarpal Kinematics: A Volumetric Perspective** SB³C2022-239
Adam Chrzan[1], Nicole Arnold[1], Kevin Chan[2], Tamara Reid Bush[1]
*[1]Michigan State University, [2]Spectrum Health*

**11:30AM** **The Impact of Stiffness Gain on Spine Stability** SB³C2022-427
Valerie Jardon, Sara Wilson
*University of Kansas*

**11:45AM** **Tri-Compartment Knee Loading 3 Months after ACL Reconstruction** SB³C2022-305
Jack Williams, Kelsey Neal, Abdulmajeed Alfayyadh, Ashutosh Khandha, Kurt Manal, Lynn Snyder-Mackler, Thomas Buchanan
*University of Delaware*

**12:00PM** **Lateral Distance as a Measure of Balance During 90 Degree Pre-Planned and Late-Cued Turns** SB³C2022-124
Mitchell Tillman, Antonia Zaferiou
*Stevens Institute of Technology*

**12:15PM** **Regulation of Whole-Body Angular Momentum in Persons with Parkinson Disease when Transitioning from a Regular to an Irregular Surface** SB³C2022-295
Nicholas Gomez, Kelton Gubler, Andrew Merryweather
*University of Utah*

**12:30PM** **Handrim Biomechanics and Wheelchair Fit Measures in Pediatric and Emerging Adult Manual Wheelchair Users** SB³C2022-289
Samantha Schwartz[1], Alyssa Schnorenberg[1], Hannah Frank[1], Matthew Hanks[1], Shubhra Mukherjee[2], Brooke Slavens[1]
*[1]University of Wisconsin-Milwaukee, [2] Shriners Hospital for Children-Chicago*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Vascular Mechanics III

**Chesapeake A-D**

**Session Chairs: Chung-Hao Lee,** *University of Oklahoma*
**Heather Hayenga,** *University of Texas at Dallas*

**1:45PM** **Clinical Imaging Derived Aortic Stiffness as an Aortic Dissection Risk Stratification Metric** SB$^3$C2022-339
Ronald Fortunato[1], Thomas Gleason[2], David Vorp[1], Spandan Maiti[1]
*[1]University of Pittsburgh, [2]University of Maryland*

**2:00PM** **Stochastic Optimization of a Porohyperelastic Bilayered Vascular Graft to Improve Hemocompatibility** SB$^3$C2022-87
Ali Behrangzade[1], Bruce Simon[2], William Wagner[1], Jonathan Vande Geest[1]
*[1]University of Pittsburgh, [2]University of Arizona*

**2:15PM** **Collagen Waviness Regulates the Damage of Vein Tissue** SB$^3$C2022-82
Xuehuan He, Jia Lu
*University of Iowa*

**2:30PM** **The Interplay Between Elastin and Proteoglycans and their Effect on Ascending Aortic Aneurysmal Biomechanics** SB$^3$C2022-428
Miriam Nightingale, Amy Bromley, Jehangir Appoo, Elena Di Martino
*University of Calgary*

**2:45PM** **The Influence of Plaque Structural Stress and Wall Shear Stress on Human Coronary Plaque Progression** SB$^3$C2022-177
Aikaterini Tziotziou, Jolanda Wentzel, Ali Akyildiz
*Erasmus Medical Center*

**3:00PM** **Pulmonary Artery Mechanics in Murine Models of Ageing** SB$^3$C2022-311
Abhay Ramachandra, Edward Manning, Jay Humphrey
*Yale University*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Ventricular Mechanics I

**Chesapeake E**

**Session Chairs: Zhijie Wang,** *Colorado State University*
**Emma Lejeune,** *Boston University*

**1:45PM** **Computational Modeling of the Passive Anisotropic Viscoelastic Behavior of Ovine Right Ventricles** SB³C2022-249
Wenqiang Liu[1], Kevin Labus[1], Matt Ahern[1], Reza Avazmohammadi[2], Christian Puttlitz[1], Zhijie Wang[1]
*[1]Colorado State University, [2]Texas A&M University*

**2:00PM** **Effect of Geometrical and Microstructural Remodeling on Ventricular Mechanics in Hypertrophic Cardiomyopathy** SB³C2022-290
Joy Mojumder[1], Lei Fan[1], Thuy Nguyen[2], Julius Guccione[2], Theodore Abraham[2], Lik Chuan Lee[1]
*[1]Michigan State University, [2]University of California San Francisco*

**2:15PM** **Modeling Ventricular Mechanics in Patients with Obstructive Hypertrophic Cardiomyopathy (HOCM)** SB³C2022-391
Lei Shi, Hiroo Takayama, Vijay Vedula
*Columbia University*

**2:30PM** **A Novel Model for Passive Myocardium that Incorporates Complete Diffusion Tensor Information** SB³C2022-392
Christian Goodbrake, Kenneth Meyer, Michael Sacks
*University of Texas at Austin*

**2:45PM** **Measuring the Anisotropic Mechanical Properties of Single Neonatal Mouse Cardiac Myocytes** SB³C2022-361
Taylor Rothermel, Patrick Alford
*University of Minnesota*

**3:00PM** **Myosin and Myofibril Dynamics Drive Hypertrophic Cardiomyopathy Disease Mechanisms** SB³C2022-479
Alison Vander Roest[1], Kathleen Ruppel[1], James Spudich[1], Beth Pruitt[2], Daniel Bernstein[1]
*[1]Stanford University, [2]University of California Santa Barbara*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Muscle and Spine Tissue Mechanics

**Chesapeake F**

**Session Chairs: Mariana Kersh,** *University of Illinois*
**Stephanie Cone,** *University of Wisconsin*

**1:45PM** **Transcriptional Profiling of Mouse Skeletal Muscle Following Daily Bouts of Optogenetic Stimulation** SB³C2022-84
Syeda N. Lamia[1], Elahe Ganji[2], Iman Bhattacharya[2], Megan L. Killian[1]
*[1]University of Michigan, [2]University of Delaware*

**2:00PM** **Muscle Immobilization Prevents Functional Development of Embryonic Tendons But Does Not Affect Collagen Crosslinking** SB³C2022-27
Benjamin Peterson, Spencer Szczesny
*Pennsylvania State University*

**2:15PM** **Estimating Gastrocnemius Muscle Volume by Using Panoramic Ultrasound Images in Orthogonal Planes** SB³C2022-197
Shabnam Rahimnezhad[1], Karin G. Silbernage[2]l, Daniel H. Cortes[1]
*[1]Pennsylvania State University, [2]University of Delaware*

**2:30PM** **Intervertebral Disc Geometry and Hydration are Altered From In Vivo to Segment Preparation for Mechanical Tests** SB³C2022-298
Harrah Newman[1], Natalie Thurlow[2], Kyle Meadows[1], Adriana Barba[3], Thomas Schaer[3], Edward Vresilovic[1], Dawn Elliott[1]
*[1]University of Delaware, [2]University of Florida, [3]University of Pennsylvania*

**2:45PM** **Contribution of Elastin and Collagen to the Mechanical Behavior of Bovine Nuchal Ligament** SB³C2022-86
Samuel Halvorsen, Ruizhi Wang, Yanhang Zhang
*Boston University*

**3:00PM** **Three-Dimensional Strain Assessment of the Lumbar Facet Capsular Ligament During Dynamic Motion** SB³C2022-142
Matthew MacEwen, Rebecca Abbott, Victor Barocas, Arin Ellingson
*University of Minnesota*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Emerging Methods in Biofluid Mechanics

**Chesapeake G**

**Session Chairs: Keshavarz-Motamed,** *McMaster University*
**Karol Cal□,** *Politecnico di Torino*

**1:45PM** **Comparison of Velocity and Flow-Based Methods to Calculate Wall Shear Stress from 4D Flow CMRI Data** SB³C2022-388
Elliott Hurd[1], Elizabeth Iffrig[2], John Oshinski[2], Lucas Timmins[1]
*[1]University of Utah, [2]Emory University*

**2:00PM** **4D Flow MRI Study of Large-Scale Hemodynamics Correlation Persistence in the Healthy Human Aorta Using Network Science** SB³C2022-206
Karol Calò[1], Andrea Guala[2], Diego Gallo[1], Jose Rodriguez Palomares[3], Stefania Scarsoglio[1], Luca Ridolfi[1], Umberto Morbiducci[1]
*[1]Politecnico di Torino, [2]Universitat Autonoma de Barcelona, [3]University Hospital Vall d'Hebron*

**2:15PM** **Automated Tuning of a Lumped Parameter Model for Simulating Resting Cardiovascular Physiology** SB³C2022-102
Akash Gupta, Aseem Pradhan, Surya Sharma, Tyler Schmidt, Ethan Kung
*Clemson University*

**2:30PM** **Calibration of Cardiopulmonary and Systemic Circulation Models in Pulmonary Arterial Hypertension and Cardiac Transplant Patients** SB³C2022-382
Christopher Tossas-Betancourt[1], Nathan Y. Li[1], Sheikh M. Shavik[2], Adam L. Dorfman[1], Seungik Baek[1], Lik C. Lee[1], C. Alberto Figueroa[1]
*[1]University of Michigan, [2]Bangladesh University*

**2:45PM** **Real-Time MRI-Based Computational Modeling of Urinary Flow in Urethra** SB³C2022-168
Labib Shahid, Juan Pablo Gonzalez-Pereira, Cody Johnson, Alejandro Roldán-Alzate
*University of Wisconsin-Madison*

**3:00PM** **Using Smart Phones to Select Household Fabric for Making Face Coverings: A Case Study by FDA, NIST and High School Students** SB³C2022-300
Alexander Herman[1], Matthew Staymates[2], Salvatore Trupia[3], Victoria Guerrier[3], Glenda Garcia[3], Gloria Guerrier[3], Suvajyoti Guha[1]
*[1]US FDA, [2]National Institute of Standard and Technology, [3]West Hempstead High School*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

## Thrombosis, Hemolysis and Mechanical Circulatory Support

**Clipper A-C**

**Session Chairs: Colleen Witzenburg,** *University of Wisconsin-Madison*
**Simon Tupin,** *Imperial College London*

**1:45PM** **Assessment of Interlaboratory Computational Simulations of the FDA Benchmark Blood Pump** SB³C2022-101
Sailahari Ponnaluri[1], Prasanna Hariharan[2], Luke Herbertson[2], Richard Malinauskas[2], Keefe Manning[1], Brent Craven[2]
*[1]Pennsylvania State University, [2]US FDA*

**2:00PM** **Experiment-Led Continuum Modelling of Microscale Blood Flow** SB³C2022-328
Simon Tupin[1], Stavroula Balabani[2], Joseph van Batenburg-Sherwood[1]
*[1]Imperial College London, [2]University College London*

**2:15PM** **Preliminary Modeling and Experimental Study of Thromboembolism: Effects of Shear Stress on Thrombus Behavior** SB³C2022-238
Arash Azimi, Eathan DiTullio, Keefe Manning
*Pennsylvania State University*

**2:30PM** **Platelet Adhesion is Dominated by Large Von Willebrand Factor Multimers at Device Relevant Shear Rates** SB³C2022-200
Connor Watson, Keefe Manning
*Pennsylvania State University*

**2:45PM** **In Silico Investigation of Contralateral Embolic Stroke Risks from Carotid Artery Disease** SB³C2022-425
Ricardo Roopnarinesingh, Debanjan Mukherjee
*University of Colorado Boulder*

**3:00PM** **Effect of Venous Valve Morphology on Flow Conditions Conducive to Thrombosis** SB³C2022-236
Jacob Biesinger, Matthew Ballard
*Utah Valley University*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Musculoskeletal Tissue Engineering

**Galleon A-C**

**Session Chairs: Alix Deymier,** *University of Connecticut Health Center*
**Arun Nair,** *University of Arkansas*

**1:45PM** **Functional Cartilage Tissue Engineering Does Not Require Culture Media Replenishment** SB³C2022-201
Tianbai Wang, Yanli Lyu, Yue Liu, Michael Albro
*Boston University*

**2:00PM** **Fabrication and Drug Release Kinetics Characterisation of Poly(Glycerol Sebacate Urethane) Anisotropic Scaffolds** SB³C2022-176
Andreas Samourides, Zacharoula Xenou, Irene Louca, Konstantinos Kapnisis, Andreas Anayiotos
*Cyprus University of Technology*

**2:15PM** **Dose- And Time-Dependent Effects of Collagenase Clostridium Histolyticum Injection on Stiffness and Thickness of In Vitro Transverse Carpal Ligament** SB³C2022-16
Jocelyn Hawk, Sohail Daulat, David Margolis, Zong-Ming Li
*University of Arizona*

**2:30PM** **Mechanical Anchoring Drives Stem Cell Differentiation and Tissue Maturation in Tissue Engineered Ligament-To-Bone Entheses** SB³C2022-467
Ethan Brown, Sophia Murphy, Lais Morandini, Rene Olivares-Navarrete, Jennifer Puetzer
*Virginia Commonwealth University*

**2:45PM** **Ultrasound as a Stimulus for Transdermal, Hydrogel-Based Bone Repair** SB³C2022-215
Fayekah Assanah[1], Kevin Grassie[1], Hanna Anderson[1], Will Linthicum[1], Bryan Huey[1], Yusuf Khansh[2]
*[1]University of Connecticut, [2]UCONN Health*

**3:00PM** **Development of Porous, Mineralized Collagen-Chitosan Scaffolds to Recreate the 3D Cancellous Bone Microenvironment** SB³C2022-267
Sandra Stangeland-Molo, Kathryn Benedict, Jacqueline Cole
*University of North Carolina-Chapel Hill and North Carolina State University*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

## Growth, Remodeling, and Repair

**Schooner A-B**

**Session Chairs: Kyoko Yoshida,** *University of Minnesota*
**Kristin Myers,** *Columbia University*

**1:45PM** **A Hybrid Discrete-Continuum Analysis of Remodeling In Arteries: An Assessment of Microscopic Features from Macroscopic Observables** SB³C2022-250
Ryan Mahutga, Elizabeth Gacek, Victor Barocas
*University of Minnesota*

**2:00PM** **A Constrained Mixture Model of Thoracic Aortic Aneurysm Growth** SB³C2022-216
David Li[1], Marcos Latorre[2], Jay Humphrey[1]
*[1]Yale University, [2]Universitat Politècnica de València*

**2:15PM** **Effects of Scaffold Degradation Behavior on Tissue Engineered Vascular Graft Growth and Remodeling** SB³C2022-377
Jason Szafron[1], Yuichi Matsuzaki[2], Stephanie Lindsey[3], Christopher Breuer[2], Jay Humphrey[4], Alison Marsden[1]
*[1]Stanford University, [2]Nationwide Children's Hospital, [3]University of California San Diego, [4]Yale University*

**2:30PM** **Effect of Smooth Muscle Tone and Age on Biaxial Mechanics of the Murine Vagina** SB³C2022-357
Shelby White, Qinhan Zhou, Kristin Miller
*Tulane University*

**2:45PM** **In Vivo Large Animal Evaluation of a Mechano-Responsive Fibrous Patch for Anti-Inflammatory Drug Delivery to Promote Repair after Disc Herniation** SB³C2022-48
Ana Peredo, Chet Friday, Hannah Zlotnick, George Dodge, Daeyeon Lee, Michael Hast, Sarah Gullbrand, Harvey Smith, Robert Mauck
*University of Pennsylvania*

**3:00PM** **Calibrating Mechanoregulatory Models of Fracture Repair and Remodeling Using Imaging Data from Sheep** SB³C2022-89
Tianyi Ren, Hannah Dailey
*Lehigh University*

| Wednesday, June 22 | 1:45PM – 3:15PM EDT |
|---|---|

# Undergraduate Design Competition

**Cutter A-B**

**Session Chairs: Anita Singh,** *Widener University*

**1:45PM** **Clinical Need is the Mother of Biomedical Innovation** SB3C2022
Sriram Balasubramanian
*Drexel University*

**2:00PM** **Commode for Neurogenic Bowel: A Mechanism for Achieving The Squatting Position** SB$^3$C2022-534
John Bates, Chastity Chavez, Madison Lang, Alexander Rivera, Camila Ruiz Vega, Amy Lerner, Scott Seidman, Richard Waugh
*University of Rochester*

**2:15PM** **Sixth Sense - A Hands Free and Haptic Feedback Navigation Tool for the Visually Impaired** SB$^3$C2022-509
Alyssa Taylor, Joseph Lahmann, Miles Canino
*Rose-Hulman Institute of Technology*

**2:30PM** **Dynamic Hand Brake for Manual Wheelchairs** SB$^3$C2022-495
Joshua Coombs, Nicholas Johnson, Nicholas Oram, Shelley Osterhout, Zev Sun, Noelle Tenney, Andrew Merryweather
*University of Utah*

**2:45PM** **Temperature Assessment Enabled Simulation Mannequin** SB$^3$C2022-518
Emily Eisele, Mason Klaus, Jessica Guarino, Amelia Wellmon, Sean Blade, Ria Mazumder
*Widener University*

**3:00PM** **Developmental Dysplasia of the Hip Pediatric Medical Trainer** SB$^3$C2022-514
Seth Eaby[1], Sheridan Perry[1], Joseph Sauerbrun[1], Victor Huayamave[1], Charles Price[2]
*[1]Embry-Riddle Aeronautical University, [2]International Hip Dysplasia Institute*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Vascular Mechanics IV

**Chesapeake A-D**

**Session Chairs: Matthew Bersi,** *Washington University in St. Louis*
**Jonathan Vande Geest,** *University of Pittsburgh*

**3:30PM** **Identification of Intramural Stress Distribution in Cerebral Aneurysms Using Patient Specific Wall Thickness Maps** SB³C2022-413
Ronald Fortunato[1], Piyusha Gade[1], Juan Cebral[2], Anne Robertson[1], Spandan Maiti[1]
*[1]University of Pittsburgh, [2]George Mason University*

**3:45PM** **Effect of Breaking Calcification on the Compliance of Coronary Arteries Brain** SB³C2022-451
Yasamin Seddighi[1], Aleksandra Gruslova[2], Drew Nolen[2], Deborah Vela[2], L. Maximilian Buja[2], Marc Feldman[2], Hai-Chao Han[1]
*[1]University of Texas at San Antonio, [2]University of Texas Health Science Center at Houston*

**4:00PM** **Open-Source Automation of Patient-Specific Atherosclerotic Arteries Reveals Key Biomechanically Driven Remodeling** SB³C2022-119
Jeremy Warren, John Yoo, Federico Bernardoni, Brandon Boren, Clark Meyer, Stefano Leonardi, Heather Hayenga
*University of Texas at Dallas*

**4:15PM** **Tissue-Engineered Collagenous Fibrous Cap Models to Explore Atherosclerotic Plaque Rupture** SB³C2022-208
Tamar Wissing[1], Kim van der Heiden[1], Sheila Serra[2], Anthal Smits[3], Carlijn Bouten[3], Frank Gijsen[1,2]
*[1]Erasmus Medical Center, [2]TU Delft, [3]TU Eindhoven*

**4:30PM** **Local Structural and Rupture Characteristics of Atherosclerotic Human Carotid Arteries Through Second Harmonic Imaging, Tensile Testing and Digital Image Correlation** SB³C2022-209
Su Guvenir Torun, Pablo de Miguel Munoz, Hanneke Crielaard, Hence J.M. Verhagen, Aad van der Lugt, Gert J. Kremers, Ali C. Akyildiz
*Erasmus Medical Center*

**4:45PM** **Ultrasound-Based Volume-Time Curves of the Lumen, Thrombus and Vessel Wall for Estimating In-Vivo Thrombus Compressibility and Wall Stiffness** SB³C2022-226
Arjet Nievergeld[1], Esther Maas[1], Judith Fonken[1], Frans van de Vosse[1], Marc van Sambeek[2], Richard Lopata[1]
*[1]University of Technology Eindhoven, [2]Catharina Hospital Eindhoven*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Ventricular Mechanics II

**Chesapeake E**

**Session Chairs: Lik Chuan Lee,** *Michigan State University*
**Michael Sacks,** *University of Texas at Austin*

**3:30PM** **Role of Microtubules in Right Ventricle Anisotropic Viscoelasticity with Pulmonary Hypertension Development** SB³C2022-358
Kristen LeBar, Wenqiang Liu, Kellan Roth, Matt Ahern, Erith Evans, Jassia Pang, Jessica Ayers, Adam Chicco, Zhijie Wang
*Colorado State University*

**3:45PM** **A Constitutive-Based Deep Learning Model for the Identification of Active Contraction Properties in the Ventricular Myocardium** SB³C2022-111
Igor Nobrega, Wenbin Mao
*University of South Florida*

**4:00PM** **Assessing Diastolic Function Using Mathematical Modeling of the EDPVR Curve** SB³C2022-126
Salla Kim[1], Naomi Chesler[1], Benjamin Randall[2]
*[1]University of California Irvine, [2]University of Michigan*

**4:15PM** **Construction and Initial Experience with a Four-Chambered Fluid-Structure Interaction Model of the Heart** SB³C2022-44
Marshall Davey[1], Charles Puelz[2], Simone Rossi[1], Margaret Anne Smith[1], David Wells[1], Boyce Griffith[1]
*[1]University of North Carolina-Chapel Hill, [2]Baylor College of Medicine*

**4:30PM** **Sepsis-Driven Inflammatory Responses in Cardiac Micro-Tissues** SB³C2022-331
Connor Virgile, Elise Corbin
*University of Delaware*

**4:45PM** **Automated Image Analysis of Human Induced Pluripotent Stem Cell Derived Cardiomyocytes and Cardiac Microtissue** SB³C2022-233
Hiba Kobeissi, Saeed Mohammadzadeh, Emma Lejeune
*Boston University*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Cartilage Modeling & Characterization

**Chesapeake F**

**Session Chairs: Michael Albro,** *Boston University*
**Sonia Bansal,** *University of Pennsylvania*

**3:30PM** **Independent and Synergistic Effects of Interstitial Hydration and Synovial Fluid Presence on Cartilage Lubrication** SB³C2022-344
Emily Lambeth, Meghan Kupratis, David Burris, Christopher Price
*University of Delaware*

**3:45PM** **Frictional Forces do not Cause Wear in Human Articular Cartilage** SB³C2022-422
C.V. Sise, Courtney A. Petersen, Brenna Carbone, Clark T. Hung, Gerard A. Ateshian
*Columbia University*

**4:00PM** **Parameters to Model Cartilage as Osteoarthritis Progresses** SB³C2022-255
Xiaogang Wang, David Pierce
*University of Connecticut*

**4:15PM** **Verification of Biphasic Material Parameter Identifiability by Fully Automated Sensitivity Analysis and Error Checking** SB³C2022-369
John Peloquin, Harrah Newman, Dawn Elliott
*University of Delaware*

**4:30PM** **Raman Spectroscopy Probe Assessments of Cartilage Composition and Functional Mechanical Properties** SB³C2022-430
Masumeh Kazemi[1], Dev Mehrotra[1], Juncheng Zhang[1], Chenhao Yu[1], Diya Desai[1], Mark Grinstaff[1], Brian Snyder[2], Mads Bergholt[3], Micheal Albro[1]
*[1]Boston University, [2]Beth Israel Deaconess Medical Center, [3]King, Äôs College London*

**4:45PM** **Cartilage Mechanical Properties of Developmental Dysplasia of the Hip in a Porcine Model** SB³C2022-410
Kate Benfield[1], Amevi Semodji[1], Vidyadhar Upasani[2], Christine Farnsworth[2], Derek Nesbitt[1], Erin Mannen[1], Trevor Lujan[1]
*[1]Boise State University, [2]Rady Children's Hospital San Diego*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Device and Treatment Implications

**Chesapeake G**

**Session Chairs: Milad Samaee,** *Georgia Institute of Technology*
**Ryan Pewowaruk,** *University of Minnesota*

**3:30PM** **Performance of The Balloon-Expandable Valve in a Self-Expanding Valve at Different Implantation Heights** SB³C2022-445
Milad Samaee[1], Huang Chen[1], Pradeep Yadav[2], Vinod Thourani[2], Lakshmi Prasad Dasi[1]
*[1]Georgia Institute of Technology, [2]Piedmont Heart Institute*

**3:45PM** **Effect of Aortic Curvature on Bioprosthetic Aortic Valve Performance** SB³C2022-220
Brennan Vogl[1], Rajat Gadhave[1], Zhenyu Wang[2], Juan Crestanello[3], Mohamad Alkohouli[3], Hoda Hatoum[1]
*[1]Michigan Technological University, [2]Ohio State University, [3]Mayo Clinic*

**4:00PM** **Design and Initial Optimization of a Centrifugal Left Ventricular Assist Device** SB³C2022-408
Huang Chen, Shweta Ashishkumar Karnik, Jeyan Kirtay, Lakshmi Prasad Dasi
*Georgia Institute of Technology*

**4:15PM** **A Computational Study of Aortic Dynamic Occlusion in Type B Dissection** SB³C2022-96
Taeouk Kim, Pieter van Bakel, Nitesh Nama, Himanshu Patel, David Williams, C. Alberto Figueroa
*University of Michigan*

**4:30PM** **Quantifying the Impact of Hemorrhagic Shock and Reboa on the Endothelial Glycocalyx Layer** SB³C2022-97
Antonio Renaldo, Aravindh Ganapathy, Nathaniel Hauser, Magan Lane, James Jordan, Lucas Neff, Timothy Williams, Elaheh Rahbar
*Wake Forest School of Medicine*

**4:45PM** **Simulated Performance of a Bioprinted Pulsatile Fontan Conduit** SB³C2022-320
Zinan Hu, Erica Schwarz, Jessica Herrmann, Mark Skylar-Scott, Alison Marsden
*Stanford University*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Microfluidics, Optical and CSF

**Clipper A-C**

**Session Chairs: William Polacheck,** *University of North Carolina-Chapel Hill & NC State University*
**Jifu Tan,** *Northern Illinois University*

**3:30PM** **Feature Tracking Microfluidic Analysis Reveals Differential Roles of Viscosity and Friction in Sickle Cell Blood** SB³C2022-275
Hannah Szafraniec[1], Jose Valdez[1], Elizabeth Iffrig[2], Wilbur Lam[2], John Higgins[3], Philip Pearce[4], David Wood[1]
*[1]University of Minnesota, [2]Emory University, [3]Harvard University, [4]University College London*

**3:45PM** **Microfluidic Approach for Quantifying Vascular Permeability in the Presence of Transmural Flow** SB³C2022-138
Stephanie Huang, William Polacheck
*University of North Carolina-Chapel Hill & NC State University*

**4:00PM** **Transmural Solute Permeability, But Not Hydraulic Conductance, Increases in a Mouse Model of Ascending Thoracic Aortic Aneurysm** SB³C2022-11
Christie Crandall[1], Sean Kim[2], Jessica Wagenseil[1]
*[1]Washington University in St. Louis, [2]Saint Louis University*

**4:15PM** **Direct Numerical Simulation of Blood Flow with Cells in Retina Vascular Network** SB³C2022-468
Kacper Ostalowski, Jifu Tan
*Northern Illinois University*

**4:30PM** **Comparison of CSF Flow Resistance and Brainstem and Cerebellum Displacement for Chiari Malformation Type 1** SB³C2022-150
Saeed Mohsenian[1], Alaaddin Ibrahimy[2], John Oshinski[3], Blaise Simplice Talla Nwotchouang[4], Daniel Barrow[3], Rouzbeh Amini[1], Francis Loth[1]
*[1]Northeastern University, [2]Yale University, [3]Emory University, [4]University of Akron*

**4:45PM** **The Effect of Fluid Flow on the Leptomeningeal Cells of the Subarachnoid Space** SB³C2022-245
Mannthalah Abubaker, David Newport, John Mulvihill
*University of Limerick*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

## Emerging Tools in Tissue and Cellular Engineering

**Galleon A-C**

**Session Chairs: Ed Sander,** *University of Iowa*
**L. Grace Zhang,** *George Washington University*

**3:30PM** **Characterization of Bioengineered Tissues by Digital Holographic Vibrometry and Machine Learning** SB$^3$C2022-433
Colin Hiscox, Juanyong Li, Ziyang Gao, Dmitry Korkin, Cosme Furlong, Kristen Billiar
*Worcester Polytechnic Institute*

**3:45PM** **Dynamic Mechanical Loading of Photopolymerized Hydrogels as a Tool for Studying Pulmonary Fibrosis** SB$^3$C2022-143
Qi Wang, Jacob Herrmann, Edward Sander, Kristan Worthington
*University of Iowa*

**4:00PM** **Evaluating Bio-Sourced Photoinitiators Efficiency for Use in Sustainable 3D Bioprinting** SB$^3$C2022-53
Rion Wendland, Kristan Worthington
*University of Iowa*

**4:15PM** **Overcoming the Force-Dependent Inhibition of Collagenase Using Macrophages** SB$^3$C2022-75
Ryan Jamieson, Suzanne Stasiak, Ralston Augspurg, Nihal Bharath, Seyed Mohammad Siadat, Jeff Ruberti, Hari Parameswaran
*Northeastern University*

**4:30PM** **DNA-Based Micropatterning Approach to Create Tissues of Defined Size, Shape, and Cellular Composition** SB$^3$C2022-203
Louis Prahl, Alex Hughes
*University of Pennsylvania*

**4:45PM** **A Novel Machine Learning-Based Framework to Predict The Anisotropic Mechanical Properties in Soft Materials Using Anisotropic Indentation** SB$^3$C2022-241
Habibeh Ashouri Choshali, Juanyong Li, Taylor Paradis, Nima Rahbar, Kristen Billiar
*Worcester Polytechnic Institute*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

# Transport in Thermal Therapy

**Schooner A-B**

**Session Chairs: Fatemeh Hassanipour,** *University of Texas at Dallas*
**Sihong Wang,** *City College of New York*

**3:30PM** **Single Pulse Heating of Nanoparticle Array for Biological Applications** SB³C2022-115
Chen Xie, Peiyuan Kang, Zhenpeng Qin
*University of Texas at Dallas*

**3:45PM** **Incorporating Vascular Stasis Based Perfusion to Predict the Thermal Signatures of Cell Death Using Modified Arrhenius Equation with Regeneration of Living Tissues** SB³C2022-159
Manpreet Singh
*University of Maryland Baltimore County*

**4:00PM** **Feedback Temperature Control for Magnetic Hyperthermia Therapy to Treat Glioblastoma** SB³C2022-182
Avesh Jangam[1], Julian Low[1], Aiman Ahmad[1], Anirudh Sharma[2], Robert Ivkov[2], Anilchandra Attaluri[1]
*[1]Pennsylvania State University, [2]Johns Hopkins University*

**4:15PM** **Mitigation of Injury to Nerves During Prostate Cancer Cryoablation Using Cryoprotective Agents** SB³C2022-193
Pegah Ranjbartehrani[1], David Ramirez[1], Franz Schmidlin[2], Michael Etheridge[1], Paul Iaizzo[1], Qi Shao[1], John Bischof[1]
*[1]University of Minnesota, [2]Hirslanden Grangettes Group Geneva*

**4:30PM** **Bioheat Transfer Basis of Human Thermoregulation: Principles and Applications** SB³C2022-307
Laura Namisnak[1], Shahab Haghayegh[2], Sepideh Khoshnevis[1], Kenneth Diller[1]
*[1]University of Texas at Austin, [2]Harvard Medical School*

**4:45PM** **Characterization of Cellular Response to Endovascular Ablative Therapies** SB³C2022-463
Sean Brocklehurst[1], Danielle Stolley[2], Neda Ghousifam[1], Erik Cressman[2], David Fuentes[2], M. Nichole Rylander[1]
*[1]University of Texas at Austin, [2]MD Anderson Cancer Center*

| Wednesday, June 22 | 3:30PM – 5:00PM EDT |
|---|---|

## Emerging Methods and Multiscale Mechanics

**Cutter A-B**

**Session Chairs: Sara Roccabianca,** *Michigan State University*
**Ryan Pewowaruk,** *William S. Middleton Memorial Veterans Hospital*

**3:30PM** **Predicting Temperature Field During Thermal Ablations Using Deep Neural Networks** SB³C2022-202
Hanife Tugba Kumru[1], Anilchandra Attaluri[1], Vitaly Gordin[2], Daniel H. Cortes[1]
*[1]Pennsylvania State University, [2]Hershey Medical Center*

**3:45PM** **Automated 4D Meshing of Ex-Vivo Filling of the Murine Urinary Bladder** SB³C2022-432
Eli Broemer, Sara Purdue, Pragya Saxena, Nathan Tykocki, Sara Roccabianca
*Michigan State University*

**4:00PM** **Tensile Response of the Murine Uterosacral Ligament is Nonlinear and Spatially Inhomogeneous** SB³C2022-183
Lea Savard, Catalina Bastias, Kathleen Connell, Sarah Calve, Callan Luetkemeyer, Virginia Ferguson
*University of Colorado*

**4:15PM** **Developing a Precision-Cut Tissue Sectioning Protocol for Fresh Porcine Colonic Tissue for Downstream Mechanical Analysis** SB³C2022-180
Cliona McCarthy, Kieran McGourty, Michael Walsh, John Mulvihill
*University of Limerick*

**4:30PM** **Quantifying Tissue-Specific Differences in Compressive Material Behavior of Porcine Gastrointestinal Tissue** SB³C2022-434
Samantha Barr, Alexander McGuigan, Caroline Karczewski, Alexander Caulk
*Medtronic*

**4:45PM** **The Lasso Stitch: A Novel Suturing Technique for High-Tension Wound Repair in Plastic and Reconstructive Surgery** SB³C2022-303
Chung-Hao Lee, Colton Ross, Bradley Miyake, Henry Marsh, Parker Bryant, Guilherme Barreiro
*University of Oklahoma*

# Poster Sessions

Posters will be presented in two sessions as listed below. Please see the "Instructions for Poster Presenters' on Page 9 of the Program Book. The poster viewing area is located in the Choptank Ballroom and will be open throughout the conference.

| | |
|---|---|
| **Poster Session I** | **Monday, June 20, 12:45PM – 2:15PM EDT** |
| **Poster Session II** | **Tuesday, June 21, 12:45PM – 2:15PM EDT** |

## BS-Level Student Paper Competition Session 1: Biofluid and Cardiovascular Mechanics

**P1** **Blood Clot Removal Pressures in An Experimental Model of Aspiration Thrombectomy** SB³C2022-493
Nicole Beautz[1], Noah Robison[1], Michael Froehler[2], Bryan Good[1]
*[1]University of Tennessee, [2]Vanderbilt University Medical Center*

**P2** **4D Flow MRI Comparison of Surgical Grafts for Correction of Pulmonary Artery Aneurysms: A Case Study** SB³C2022-489
Tea Cohen[1], Melody Dong[1], Arshid Azarine[2], Francois Haddad[1], Olaf Mercier[3], Alison Marsden[1]
*[1]Stanford University, [2]Groupe Hospitalier Paris Saint-Joseph, [3]Marie Lannelongue Hospital*

**P3** **Investigating the Role of Aspirin on the Geometries and Mechanical Properties of Experimental Blood Clots** SB³C2022-504
Nolan Corbitt, Bryan Good
*University of Tennessee*

**P4** **Design and Validation of a Bioreactor for Dynamic Biaxial Mechanical Stimulation of Engineered Tissue Vascular Grafts** SB³C2022-521
Luke Dague[1,2], Hayden Nothacker[2], Sarah Saunders[2], Johane Bracamonte[2], Joao Soares[2]
*[1]Georgia Institute of Technology, [2]Virginia Commonwealth University*

**P5** **Vascular Smooth Muscle Cell Alignment on Micropattern Alters Glucose Metabolism** SB³C2022-515
Yusuf Mastoor, Pattie Mathieu, Alisa Clyne
*University of Maryland College Park*

**P6** **Estimation of Flow Data from Angiographic Time Series** SB³C2022-523
Noah Stevens, Kritika Iyer, Brahmajee Nallamothu, C. Alberto Figueroa
*University of Michigan*

**P7** **A Measure of Platelet Activation and Aggregation Across Two Flow Regimes to Minimize Thromboembolic Events in Blood Pumps** SB³C2022-510
Hannah Sturgis, Nicolas Tobin, Keefe Manning
*Pennsylvania State University*

**V1** **The Role of Actin Corralling in the Formation of Cell-Cell Adhesions** SB³C2022-497
Payton J Thomas, Tamara Bidone
*University of Utah*

**P8** **Assessment of Pressure Gradient and Recovery Following Transcatheter Aortic Valve Replacement in Bicuspid Aortic Valves** SB³C2022-529
Aniket Venkatesh[1], Breandan Yeats[1], Atefeh Razavi[1], Pradeep Yadav[2], Venkateshwar Polsani[2], Vinod Thourani[2], Lakshmi Dasi[1]
*[1]Georgia Institute of Technology, [2]Piedmont Hospital*

**P9** **Characterizing the Mechanical Heterogeneity of Porcine Carotid Artery Bifurcations** SB³C2022-492
Claire Westman, Carly Donahue, Victor Barocas
*University of Minnesota*

## BS-Level Student Paper Competition Session 2: Devices, Design, and Cell & Tissue Engineering

**P10** **Mechanical Improvement and Haptic Quantification of Digital Extenders Intubation Device** SB³C2022-499
Tristan Arias[1], Lyle Hood[2], Emma Treadway[1],
*[1]Trinity University, [2]University of Texas San Antonio*

**P11** **Establishing an Optimized Annuloplasty Ring Type Using In Vivo and Ex Vivo Biomechanical Analyses** SB³C2022-490
Katelynne Berland[1], Sanchita Bhat[1], Andrew Siefert[1], Maeve Janecka[1], Shelley Gooden[1], Beatrice Ncho[1], Takayuki Kawashima[2], Mori Kazuki[2], Satoshi Kozaki[2], Robert Gorman[2], Joseph Gorman[2], Ajit Yoganathan[1]
*[1]Georgia Institute of Technology, [2]University of Pennsylvania*

**V2** **The Influence of Emboli Size and Density on their Transport in a Cardiopulmonary Bypass Flow Loop** SB³C2022-513
Amy Chandler, Bryan Good
*University of Tennessee*

**P12** **Prediction of Diabetes Mellitus Progression using Supervised Machine Learning** SB³C2022-326
Apoorva Chauhan, Mathew Varre, Kenneth Izuora, Mohamed Trabia, Janet Dufek
*University of Nevada Las Vegas*

**P13** **Low-Intensity Vibrations Induce Changes in Microtubule Dynamics In Vitro** SB³C2022-527
Chase Crandall, Nina Nikitina, Gunes Uzer
*Boise State University*

**P14** **EMG Analysis of Vastus Lateralis and Vastus Medialis with Different Bicycle Crank Lengths, Pedaling Rate, and Pedal Speed** SB³C2022-531
Jackson Crovella, Karoline Wucherer, Christiane O'Hara
*California Polytechnic State University*

**P15** **Open-Source System for Real-Time Functional Assessment of Engineered Multicellular Filtration Barriers** SB³C2022-498
Tess Fallon[1], Alan Stern[2], Nanditha Anandakrishnan[2], Ilse Daehn[2], Evren Azeloglu[2]
*[1]Columbia University, [2]Icahn School of Medicine*

**P16** **Optimization of ECM/Gelatin Solution in a Near Field Electrospinning System for Engineering Tendon** SB³C2022-508
Aasim Hussain, Zachary Davis, Matthew Fisher
*University of North Carolina-Chapel Hill & North Carolina State University*

**V3** **In Vitro Human Lung Fibroblast-To-Myofibroblast Transition from Profibrotic Growth Factor Stimulation** SB³C2022-484
Catherine Sano, Julie Leonard-Duke, Shayn Peirce-Cottler
*University of Virginia*

**P17** **IPSC-Derived Brain Microvascular Endothelial Cells Increase Glycolysis and Glucose Transport in Hyperglycemia** SB³C2022-511
Sophia Zic, Callie Weber, Alisa Clyne
*University of Maryland College Park*

## BS-Level Student Paper Competition Session 3: Solid Mechanics

**P18** **Gadolinium-Infused Silicone: A New Material for Cyclically Deforming MRI Phantoms** SB³C2022-526
Andrew Baldassarre[1], Caroline Buckley[1], Sebastian Ardila[1], Francis Loth[1], John Oshinski[2], Rouzbeh Amini[1]
*[1]Northeastern University, [2]Emory University*

**P19** **The Effect of Pregnancy on Mechanical Injury Criteria in Murine Uterosacral Ligaments** SB³C2022-488
Catalina Bastias, Lea Savard, Kathleen Connell, Sarah Calve, Callan Luetkemeyer, Virginia Ferguson
*University of Colorado*

**P20** **Laboratory and On-Field Evaluation of a Padded Football Helmet Shell Cover** SB³C2022-528
Ashlyn Callan, Nicholas Cecchi, Yuzhe Liu, Landon Watson, Xianghao Zhan, Gerald Grant, Michael Zeineh, David Camarillo
*Stanford University*

**P21** **Visual Characterization of Aponeurosis Microstructure** SB³C2022-491
Olivia Dyer[1], Mark Seeley[2], Benjamin Wheatley[1]
*[1]Bucknell University, [2]Geisinger Medical Center*

**P22** **Physiochemical Mechanisms of Bone Dissolution Play a Significant Role in Regulating Bone Composition and Function in Acidosis** SB³C2022-494
Margaret Easson, Stephanie Wong, Mikayla Moody, Tannin Schmidt, Alix Deymier
*University of Connecticut Health Center*

**P23** **The Impact of Hyperglycemia and Ovariectomy on Host Response to Vaginal Prolapse Mesh Implants** SB³C2022-520
Abigail Fisk[1], Gabrielle King[2], Kristina Weber[2], Rui Liang[1]
*[1]University of Pittsburgh, [2]Magee Women's Research Institute*

**P24** **The Relationship Between Intramuscular Pressure and Compression of Skeletal Muscle** SB³C2022-487

Sabrina Lorza[1], Pierre-Yves Rohan[2], Mark Seeley[3], Benjamin B Wheatley[1]
*[1]Bucknell University, [2]Arts et Métiers, [3]Geisinger Medical Center*

**P25** **Exercise Therapy Does Not Alter Kinematic Repeatability in Individuals with Rotator Cuff Tears when Reaching Behind the Back** SB³C2022-530
Rachel McLoughlin, Luke Mattar, Adam Popchak, William Anderst, Volker Musahl, James Irrgang, Richard Debski
*University of Pittsburgh*

**P26** **Effect of Development Slow Elongation in Driving Hierarchical Collagen Fiber Formation in Engineered Tissues** SB³C2022-524
Kelly Ott, Jennifer Puetzer
*Virginia Commonwealth University*

**P27** **Development of 3D Brain Structures from Histology Images** SB³C2022-482
John Sayut, Maria Holland
*University of Notre Dame*

## MS-Level Student Paper Competition Session 1: Solid and Biofluid Mechanics of Cardiovascular, Lung, and Soft Tissues

**P28** **An Iterative Approach to Assign Tumor-specific Flow Boundary Conditions for Liver Cancer Using Multi-modal Image Analysis** SB³C2022-477
Summer Andrews, Premal Trivedi, Debanjan Mukherjee
*University of Colorado*

**P29** **Spectral Analysis of Kinetic Energy in a Healthy Aorta** SB³C2022-99
David Büchner[1], Emily Manchester[2], Xiao Yun Xu[2]
*[1]University of Stuttgart, [2]Imperial College London*

**P30** **Bioengineered Three-Dimensional Lung Airway Model To Study Neonatal Intratracheal Surfactant Delivery** SB³C2022-186
Hannah Combs, Hossein Tavana
*University of Akron*

**P31** **Phosphorylation Patterns of Vascular Endothelial Growth Factor Receptor-2 and Angiogenesis are Driven by Biomechanical Forces** SB³C2022-342
Bronte Miller, Molly Buckley, McKenzie Johnson, Joel Berry, M.K. Sewell-Loftin
*University of Alabama*

**P32** **Layer-Specific Aortic Aneurysm Biomechanics Suggest Relationship Between Medial Stiffness and Interfacial Strength in Patients with Bicuspid Aortic Valve** SB³C2022-423
Louise Neave[1], Tais Sigaeva[2], Paul Fedak[1], Elena Di Martino[1]
*[1]University of Calgary, [2]University of Waterloo*

**P33** **Fabrication and Characterization of 3D-Printed Anisotropic, Hydrogel Lattices** SB³C2022-269
Margrethe Ruding, Daniel Yoon, Charlotte Guertler, Annabella Mascot, Philip Bayly
*Washington University in St. Louis*

**P34** **Predictive Urodynamics of Bladder Voiding Using MRI-Based CFD: A Pilot Study** SB³C2022-167
Labib Shahid[1], Juan Pablo Gonzalez-Pereira[1], Cody Johnson[1], Yanheng Li[2], David Rowinski[2], Alejandro Roldán-Alzate[1]
*[1]University of Wisconsin-Madison, [2]Convergent Science, Inc.*

**P35** **Hemodynamic Changes in the Aortic Root Upon Transcatheter Aortic Valve (Tav) Implantation** SB³C2022-401
Hunter Tashman[1], Mia Bonini[1], Marc Hirschvogel[2], Yunus Ahmed[1], George Deeb[1], Stanley Chetcuti[1], Nicholas Burris[1], David Nordsletten[1]
*[1]University of Michigan-Ann Arbor, [2]King's College London*

## MS-Level Student Paper Competition Session 2: Musculoskeletal and Cardiovascular Mechanics, Tissue Engineering, and Biosensors

**V4** **Development of a Continuum Damage Model to Predict Accumulation of Sub-failure Damage in Tendons** SB³C2022-78
Alexandra Allan, Jared Zitnay, Steve Maas, Jeffrey Weiss
*University of Utah*

**P36** **Flow and Pressure Calibration of Polyvinylidene Fluoride Polymer for Biosensor Applications** SB³C2022-399
Matthew Danley, Jack Kloster, Ping Zhao, Victor Lai
*University of Minnesota Duluth*

**P37** **Non-Muscle Myosins are Critical Regulators of Skeletal and Connective Tissue Formation** SB³C2022-390
Mary Kate Evans[1], Tonia Tsinman[1], Xi Jiang[1], Ellie Ferguson[1], Joel Boerckel[1], Lin Han[2], Eiki Koyama[3], Robert Mauck[1], Nathaniel Dyment[1]
*[1]University of Pennsylvania, [2]Drexel University, [3]Children's Hospital of Philadelphia*

**P38** **Assessment of Bladder Biomechanics Using MRI** SB³C2022-353
Juan Gonzalez-Pereira, Cody Johnson, Wade Bushman, Shane Wells, Alejandro Roldan-Alzate
*University of Wisconsin-Madison*

**P39** **Disc Geometry Measurement Methods Alter Reported Compressive Mechanics by Up To 65%** SB³C2022-12
Shiyin Lim, Reece Huff, Joanna Veres, Divya Satish, Grace O'Connell
*University of California, Berkeley*

**P40** **Computational Modeling of iPSC-Derived Engineered Cardiac Microtissues** SB³C2022-364
Jason Lo, Javiera Jilberto, Samuel DePalma, Brendon Baker, David Nordsletten
*University of Michigan*

**V5** **Continuous Separation of Biological Cells Using a New Type of Dielectrophoresis-Based Microfluidic Device** SB³C2022-173
Yoshinori Seki[1], Aoi Nagasaka[1], Tsukushi Gondo[1], Masanori Eguchi[2], Shigeru Tada[1]
*[1]National Defense Academy, [2]National Institute of Technology Kure College*

**P41 Macromolecular Uptake affects Cartilage Mechanics and Chondrocyte Vulnerability** SB$^3$C2022-195
Yingjie Wu, Alexander Kotelsky, Mark Buckley
*University of Rochester*

## Biotransport

**P43 Carrier Solution Composition affects Recovery of Cpa-Perfused Rat Hearts** SB$^3$C2022-246
Casey Kraft, Baterdene Namsrai, Diane Tobolt, Zhe Gao, Michael Etheridge, Erik Finger, John Bischof
*University of Minnesota*

**P44 Cysteine Chemical Modifications as the Regulatory Response to Dimethyl Sulfoxide Exposure** SB$^3$C2022-458
Neda Ghousifam, Mahboobeh Rezayeeyazdi, Chris Riley, Dwight Romanovicz, Marissa Nichole Rylander, Matthew Uden
*University of Texas at Austin*

**P45 Spinal Cord Injury Increases Arterial Stiffness and Perivascular Adipose Tissue Inflammation in Mice** SB3C2022-178
Ryan Sapp[1], Swathi Swaminathan[2], Pattie Mathieu[1], Annie Barnes[1], Gurneet Sangha[1], Valerie Bracchi-Ricard[2], Alisa Clyne[1]
*[1]University of Maryland College Park, [2]Drexel University*

**P46 Transcranial Blood-Brain-Tumor Barrier Modulation for Enhancing Drug Delivery To Glioblastoma** SB3C2022-309
Qi Cai[1], Xiaoqing Li[1], Hejian Xiong[1], Xiaofei Gao[2], Ryan Margolis[1], Monica Giannotta[3], Kenneth Hoyt[1], Robert Bachoo[2], Zhenpeng Qin[1]
*[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center, [3]FIRC Institute of Molecular Oncology*

**P47 Probing Molecular Diffusion in the Brain and Tumor Extracellular Space by the Fast Release from Plasmonic Nanovesicles** SB3C2022-385
Hejian Xiong[1], Blake Wilson[1], Aditi Naik[2], Sabina Hrabetova[2], Robert Bachoo[3], Zhenpeng Qin[1]
*[1]University of Texas, [2]SUNY Downstate Health Sciences University, [3]University of Texas Southwestern Medical Center*

**P48 A Timescale-Guided Microfluidic Synthesis of Hydrophobic Drug Nanoparticles with Metal-Phenolic Network Coatings** SB3C2022-403
Yingnan Shen, Simseok Yuk, Yoon Yeo, Bumsoo Han
*Purdue University*

**P49 Digital Plasmonic Nanobubble Detection (Diamond): Improved Nanoparticle Formulation for Clinical Sample Testing** SB3C2022-114
Yaning Liu[1], Haihang Ye[1], Hoang D. Huynh[2], Jeffrey S. Kahn[2], Zhenpeng Qin[1]
*[1]University of Texas at Dallas, [2]University of Texas Southwestern Medical Center*

**P50 A Hydraulic Resistance Model for Interstitial Fluid Flow in the Brain** SB$^3$C2022-338
Helena E. Schreder, Jia Liu, Douglas H. Kelley, John H. Thomas, Kimberly A. S. Boster
*University of Rochester*

**P51** **PCR-Based Approach to Measure Intravasation and Metastasis of Mouse Cancer Cells in the Chick Chorioallantoic Membrane Assay** SB$^3$C2022-260
Molly Brennan, Susan Leggett, Celeste Nelson
*Princeton University*

**P53** **Mathematical Model for Combined Effects of Heat Transfer and Pressure in Causing Soft Tissue Injury** SB$^3$C2022-308
Gary McGregor[1], Bruno Rego[2], Kenneth Diller[1]
*[1]University of Texas at Austin, [2]Yale University*

**P54** **Performance of Skin Cooling Device in Cooling Penetration in Tissue-Experiments and Simulations** SB$^3$C2022-242
Manpreet Singh, Jacob Lombardo, Alexander Caporale, Liang Zhu
*University of Maryland Baltimore County*

**P55** **Design and Development of In Vitro Medical Induction Heating System** SB$^3$C2022-270
Robert Yasalonis, Julian Low, Ahmad Aiman, Ma'Moun Abu-Ayyad, Matthew Garner, Anilchandra Attaluri
*Pennsylvania State University*

**P56** **Role of Thermal Contact Resistance in Induction Heating of Implants** SB$^3$C2022-276
Aiman Ahmad, Nathan Werkheiser, Ma'Moun A. Abu-Ayyad, Matthew R. Garner, Anilchandra Attaluri
*Pennsylvania State University*

**P57** **Influence of Vascular Stasis Based Blood Perfusion on Magnetic Nanoparticles Migration Using Modified Thermal Damage Model: An Illustration of Thermal By-Stander Effect** SB$^3$C2022-285
Manpreet Singh
*University of Maryland Baltimore County*

**P58** **Mathematical Modeling of PAR2 Signaling and Receptor Photoinactivation with Molecular Hyperthermia** SB$^3$C2022-426
Blake Wilson, Chen Xie, Xiaoqian Ge, Peiyuan Kang, Theodore Price, Zhenpeng Qin
*University of Texas at Dallas*

**V6** **Laser-Induced Calcium Influx and Propagation for Temporary Blood-Brain Barrier Opening** SB$^3$C2022-106
Xiaoqing Li, Ayesha Ahmad[1], Qi Cai[1], Monica Giannotta[2], Elisabetta Dejana[2], Robert Bachoo[3], Theodore Price[1], Zhenpeng Qin[1]

**P66 Development of Fiber Optic Probes to Detect Visceral Arteries for In Situ Fabrication of Stent-Grafts** SB$^3$C2022-472
Timothy Chung, Nicholas Lagerman, Cyrus Darvish, Mohammad Eslami, David Vorp
*University of Pittsburgh*

**P67 Effects of Micropipette Handle Diameter and Inclusion of Finger Rest on Basilar Thumb Joint Contact Mechanics** SB$^3$C2022-235
Nolan Norton, Kenneth Fischer
*University of Kansas*

**P68 Pressure Injuries and Wheelchair Users: Understanding the Role of Friction Between Pant Fabrics and the Seat** SB$^3$C2022-229
Archana Lamsal, Tamara Reid Bush
*Michigan State University*

**P69 Analysis of Air Flowrate Standards for Portable Suction Devices** SB$^3$C2022-133
Saketh Ram Peri, Robert A. De Lorenzo, Robert Lyle Hood
*University of Texas at San Antonio*

**P70 Seated Shear Forces are Affected by Pants and Cushion Cover Materials** SB$^3$C2022-230
Justin Scott, Tamara Reid Bush

*Michigan State University*

**P71 Though I Walk Through the Shadow of The Valley Of Death... Hard Lessons Learned Through Development of the DREEM Machines** SB³C2022-337
Alan Eberhardt
*University of Alabama at Birmingham*

## Education

**P72 Comparing In-Person Biomedical Engineering Laboratory Teaching to Virtual Reality Teaching Approach** SB³C2022-429
Anita Singh[1], Sriram Balasubramanian[2]
*[1]Widener University, [2]Drexel University*

**P73 A Stand-Alone Module to Introduce Medical Image Segmentation into the BME Curriculum** SB³C2022-389
Donna Ebenstein, James Baish, Christine Buffinton
*Bucknell University*

**P74 Community Based Capstone Design Projects at The University of South Floria (USF)** SB³C2022-351
Stephanie Carey, Stephen Sundarrao, Rajiv Dubey
*University of South Florida*

**P75 Confidence Expression in Personal Statements from a Biomedical Engineering REU Site** SB³C2022-496
Elisabeth Reed, Daniella Cotto, Stephanie George
*East Carolina University*

## Fluids

**P77 ViT-FNO□A Robust Model For Tracking Motion in 4D-MRI** SB³C2022-421
Agamdeep Chopra[1], Aymeric Pionteck[2], Javid Abderezaei[2], Mehmet Kurt[2]
*[1]Stevens Institute of Technology, [2]University of Washington*

**P78 Automated Vascular Design and Simulation For 3D Bioprinting** SB³C2022-437
Zachary Sexton[1], Jessica Herrmann[1], Andrew Hudson[2], Jonathan Pham[1], Mark Skylar-Scott[1], Adam Feinberg[2], Sean Wu[1], Alison Marsden[1]
*[1]Stanford University, [2]Carnegie Mellon University*

**P79 Real-Time Shape Optimization of the Total Cavopulmonary Connection in Fontan Surgical Planning Via Reduced Order Modeling** SB³C2022-367
Imran Shah[1], Lakshmi Dasi[1], Traian Iliescu[2], Omer San[3], Alessandro Veneziani[4]
*[1]Georgia Institute of Technology, [2]Virginia Tech, [3]Oklahoma State University, [4]Emory University*

**P80 Effect of Bulging Sinus on Hemodynamic Performance of Polymeric RV-PA Conduit for Pediatric and Adult Patients** SB³C2022-444
Srujana Joshi[1], Hieu Bui, Milad Samaee[1], Susan James[2], Lakshmi Prasad Dasi[1]
*[1]Georgia Institute of Technology, [2]Colorado State University*

**P81 Flow Dynamics Assessment in a Physiological Aortic Arch Using a Validated Computational Framework** SB³C2022-231

Zhenyu Wang[1], Brennan Vogl[2], Ahmed El Shaer[3], Juan Crestanello[3], Mohamad Alkohouli[3], Hoda Hatoum[2]
*[1]Ohio State University, [2]Michigan Technological University, [3]Mayo Clinic*

**P82 Microbiome Metabolic Network Expansion Following Muscadine Grape Extract Intervention of Hypertensive Rats** SB³C2022-266
Brian Westwood, Pooja Patil, Ann Tallant, Patricia Gallagher
*Wake Forest University*

**P83 Fluid Structure Interaction Modeling of the Migration and Trapping of Physically Realistic Blood Clots in an Inferior Vena Cava Filter** SB³C2022-345
Ebrahim M. Kolahdouz[1], Brent A. Craven[2], Kenneth I. Aycock[2], Boyce E. Griffith[3]
*[1]Flatiron Institute, [2]US Food and Drug Administration, [3]University of North Carolina*

**P84 An In-Vitro Study of the Flow Past a Transcatheter Aortic Valve Using Time-Resolved 3D Particle Tracking** SB³C2022-409
Huang Chen[1], Yasaman Farsiani[2], Lakshmi Prasad Dasi[1]
*[1]Georgia Institute of Technology, [2]Nationwide Children's Hospital*

**P85 Evaluation of Shear Stress Variability along Capillaries in Angiogenic Rat Mesenteric Microvascular Networks** SB³C2022-448
Nien-Wen Hu[1], Lomel Banks[1], Peter Balogh[2], Walter L. Murfee[1]
*[1]University of Florida, [2]New Jersey Institute of Technology*

**P86 Restructuring of the Endothelial Glycocalyx after Pneumonectomy** SB³C2022-517
Taylor Paradis[1], Natasha Cruz-Calderon[1], Lydia Masse[1], Gillian Miller[1], Samantha Raskind[1], Aaron Waxman[2], Solomon Mensah[1]
*[1]Worcester Polytechnic Institute, [2]Brigham and Women's Hospital*

**P87 Fabrication of Polymeric Heart Valves Through Additive Manufacturing** SB³C2022-449
Hieu Bui, Adam Verga, Srujana Joshi, Scott Hollister, Lakshmi Prasad Dasi
*Georgia Institute of Technology*

**P88 Left Atrial Hemodynamics after Catheter Ablation** SB³C2022-58
Brennan Vogl[1], Ahmed El Shaer[2], Martin Van Zyl[2], Ammar Killu[2], Mohamad Alkohouli[2], Hoda Hatoum[1]
*[1]Michigan Technological University, [2]Mayo Clinic*

**P89 An Open Loop System for the Computational Investigation of Suspected Coronary Disease with the Patient-Specific CT-Data** SB³C2022-83
Sumit Kumar[1], BV Rathish Kumar[1], Sanjay Kumar Rai[1], Om Shankar[2], Ashish Verma[2]
*[1]Indian Institute of Technology (BHU), [2]Institute of Medical Sciences*

**P91 Fusiform Vs. Saccular Intracranial Aneurysms: Image-Based Blood Flow Simulations can Help to Understand Formation and Treatment Effects** SB³C2022-227
Jana Korte[1], Laurel Morgan Miller Marsh[2], Sylvia Saalfeld[1], Janneck Stahl[1], Daniel Behme[3], Philipp Berg[1]
*[1]Research Campus STIMULATE, [2]University of Washington, [3]University Hospital Magdeburg*

**P92 Subjects with Carotid Webs Exhibit Different Hemodynamic Flow Patterns than Subjects with Atherosclerotic Lesions** SB³C2022-263
Alireza Sharifi, Retta Al Sayed , Charlie Park, Diogo Haussen, Jason Allen, John Oshinski

*Emory University*

**P93 An Ultrasound Based One-Dimensional Modeling Framework for the Assessment of Peripheral Arterial Disease** SB³C2022-396
Milan Gillissen[1], Frans van der Vosse[1], Marc van Sambeek[2], Richard Lopata[1]
*[1]University of Technology Eindhoven, [2]Catharina Hospital Eindhoven*

**P94 Evaluation of Pressure Drop Across Aortic Coarctation: A Comparison of Zero-Dimensional and Three-Dimensional Models** SB³C2022-439
Priya Nair, Martin Pfaller, Seraina Dual, Daniel Ennis, Doff McElhinney, Alison Marsden
*Stanford University*

**P95 Analysis of the Short-Term Effects of Inhaled Nitric Oxide on Pulmonary Artery Hemodynamics Time-Resolved 1D and 3D Phase-Contrast Magnetic Resonance Imaging** SB³C2022-443
Johane Bracamonte, Nickolas Roberts, Raymond Hang, Daniel Grinnan, Elizabeth Sonntag, Janet Pinson, Uyen Truong, Joao Soares
*Virginia Commonwealth University*

**P96 Hemodynamics and Vascular Wall Mechanics of the Pulmonary Artery in Patients with Pulmonary Hypertension and Arteriovenous Fistula** SB³C2022-450
Fatemeh Bahmani[1], Daniel Pearce[2], Ali Vahdati[1], Veeranna Maddipati[1], Stephanie George[1]
*[1]East Carolina University, [2]University of Wisconsin-Madison*

**V7 The Analysis of Urethral Biomechanics During Voiding Using MRI** SB³C2022-506
Maxwell Kounga, Cody Johnson, Juan Gonzalez-Pereira, Shane Wells, Wade Bushman, Alejandro Roldan-Alzate
*University of Wisconsin-Madison*

**P98 Computational Modeling of Arteriovenous Fistula Hemodynamics in Pulmonary Hypertension Patients** SB³C2022-512
Kaitlin Southern, Veeranna Maddipati, Stephanie George, Fatemeh Bahmani
*East Carolina University*

**P99 Computational Nucleotyping in Acute Ischemic Stroke Clot Histopathology is Predictive of Underlying Etiology** SB³C2022-153
Briana Santo, Tatsat Patel, Andre Monteiro, Muhammad Waqas, John Tomaszewski, John Kolega, Adnan Siddiqui, Vincent Tutino
*University at Buffalo*

**P100 Simulation of Thrombus Formation in Microfluidic Constriction at Supraphysiologic Shear Rate** SB³C2022-257
Rodrigo Méndez Rojano, Grant Rowlands, Samuel Schirmacher, James Antaki
*Cornell University*

**P101 Hemodynamics Describing the Localization of Clot Formation in Patients with Carotid Web** SB³C2022-264
Alireza Sharifi, Retta El Sayed, Charlie Park, Diogo Haussen, Jason Allen, John Oshinski
*Emory University*

**V8 Correlation Between Anosmia and Airflow in the Nasal Cavity** SB³C2022-169
Shashwat Shah[1], Zachary Soler[2], Ethan Kung[1]

[1]*Clemson University,* [2]*Medical University of South Carolina*

**V9** **The Impact of Disturbed Flow-Induced Arterial Stiffness on Mechanotransduction in Endothelial Cells** SB³C2022-502
Andrea Alonso, Mahsa Dabagh
*University of Wisconsin-Milwaukee*

**V10** **Post-Operative Vena Cava Boundary Condition Prediction for Fontan Surgical Planning** SB³C2022-2
Wenyuan Song[1], Reena Ghosh[2], Mark Fogel[2], David Frakes[1]
[1]*Georgia Institute of Technology,* [2]*Children's Hospital of Philadelphia*

**V11** **Two Way Coupled FSI Analysis of Patients' Specific Stenosed Left Coronary Artery (LCA) with Multiphase Pulsatile Blood Flow** SB³C2022-171
Abdulgaphur Athani[1], Nik Nazri Nik Ghazali[1], Irfan Anjum Badruddin[2]
[1]*University of Malaya,* [2]*King Khalid University Abha*

**V12** **Patient-Specific Computational Fluid Dynamic Simulation of Cerebrospinal Fluid Flow in the Intracranial Space** SB³C2022-103
Patrick Fillingham, Michael Levitt, Swati Rane Levendovszky
*University of Washington*

## Solids- Cardiovascular

**P102** **Vessel Wall Enhancement is Associated with Increased Wall Stress in Intracranial Aneurysms** SB³C2022-395
Sricharan Veeturi, Seyyed Mostafa Mousavi Janabeh Sarayi, Ammad Baig, Andre Monteiro, Adnan Siddiqui, Vincent Tutino
*University at Buffalo*

**P103** **Image-Based 3D Anatomical Models for Characterization and Surgical Planning of Biatrial Drainage and Sinus Venosus Atrial Septal Defects** SB³C2022-441
Raymond Hang, Johane Bracamonte, Nickolas Roberts, Uyen Truong, Scott Gullquist, Thomas Yeh, Joao Soares
*Virginia Commonwealth University*

**P104** **A Doppler-Exclusive Non-Invasive Computational Framework for Personalized Valve Dynamics in Patients with Aortic Stenosis and Transcatheter Aortic Valve Replacement** SB³C2022-166
Nikrouz Bahadormanesh, Zahra Keshavarz-Motamed
*McMaster University*

**P105** **Effect of Residual Stress on Ring-Test Mechanical Analysis** SB³C2022-334
Manoj Ghosh, Marissa Grobbel, Lik Chuan Lee, Sara Roccabianca
*Michigan State University*

**P106** **Mitral Valve Parameterization** SB³C2022-356
Shelley Gooden[1], Mani Vannan[2], Konstantinos Boudoulas[3], Vinod Thourani[2], Pradeep Yadav[2], Lakshmi Dasi[1]
[1]*Georgia Institute of Technology,* [2]*Piedmont Heart Institute,* [3]*Wexner Medical Center*

**P107** **Mitral Valve Leaflet Coaptation in the Post-Myocardial Infarction Heart** SB³C2022-376

Natalie T. Simonian[1], Hao Liu[1], Alison M. Pouch[2], Joseph H. Gorman III[2], Robert C. Gorman[2], Michael S. Sacks[1]
*[1]University of Texas at Austin, [2]University of Pennsylvania*

**P108 A Computational Rule-Based Semi-Automatic Method for Creating Left Atrial Fiber Architecture** SB³C2022-417
Simone Rossi, Laryssa Abdala, Boyce Griffith
*University of North Carolina*

**P109 Estimation of Myocardial Material Parameters in Developing Zebrafish Using Inverse Finite Element Analysis** SB³C2022-420
Aaron Brown[1], Lei Shi[2], Vijay Vedula[2], Tzung Hsiai[3], Alison Marsden[1]
*[1]Stanford University, [2]Columbia University, [3]UCLA*

**P110 Computational Analysis of Papillary Muscle Approximation for Functional Mitral Regurgitation Repair** SB³C2022-453
Gediminas Gaidulis, Daisuke Onohara, Muralidhar Padala
*Emory University*

**P111 Replacement Heart Valve Simulations Using a Neural Network Finite Element Surrogate Model** SB³C2022-454
Shruti Motiwale, Christian Goodbrake, Wenbo Zhang, Michael Sacks
*University of Texas at Austin*

**P112 Topographical Micropatterning Induces an Anti-Inflammatory Endothelial Transcriptome** SB³C2022-62
Meghan Fallon, Anthony Barnes, Monica Hinds
*Oregon Health & Science University*

**P113 Changes in Anisotropic Viscoelasticity of Right Ventricle with Pulmonary Hypertension Development** SB³C2022-204
Kellan Roth, Wenqiang Liu, Kristen LeBar, Matt Ahern, Zhijie Wang, Adam Chicco
*Colorado State University*

**P114 Nuclear Morphology of Valve Interstitial Cells in the Presence and Absence of Native Elastin in Porcine** SB³C2022-456
Samuel Salinas, Julia Clarin, Rouzbeh Amini
*Northeastern University*

**P115 Active/Passive Mechanical Properties of Aorta Explants from a Mouse Model of Diet-Induced Medial Arterial Calcification** SB³C2022-92
Breanna Pederson, Mengistu G. Gebere, Mohamad Azhar, Narendra R. Vyavahare, Susan M. Lessner, John F. Eberth
*University of South Carolina*

**P116 Computational Modeling of Connectivity-Driven Cortical Scaling and Folding** SB³C2022-287
Xincheng Wang, Maria Holland
*University of Notre Dame*

**P117 The Effects of Formation Conditions on Embolus Analog Nonlinear, Time-Dependent Mechanical Properties** SB³C2022-184

Jose Monclova, Gretchen Hiller, Priyanka Patki, Francesco Costanzo, Keefe Manning
*Pennsylvania State University*

**P118 Factors Causing Interventricular Interactions in the Heart Implanted with Left Ventricular Assist Device** SB³C2022-189
Lei Fan[1], Jenny Choy[2], Ghassan Kassab[2], Daniel Burkhoff[3], Lik Chuan Lee[1]
*[1]Michigan State University, [2]California Medical Innovations Institute, [3]Cardiovascular Research Foundation*

**P119 Determining the Risk of Post-TAVR Cardiac Conduction Abnormalities in Tricuspid and Bicuspid Valves in a Beating Heart Using a Computational Approach** SB³C2022-199
Salwa Anam[1], Symon Reza[1], Brandon Kovarovic[1], Matteo Bianchi[1], Ashraf Hamdan[2], Rami Haj-Ali[3], Danny Bluestein[1]
*[1]Stony Brook University, [2]Rabin Medical Center, [3]Tel-Aviv University*

**P120 A Predictive Simulation of Core Valve Implantation in a Patient with Three Bioprosthetic Valves in Place - A Case Study** SB³C2022-322
Fateme Esmailie[1], Breandan Yeats[1], Huang Chen[1], Milad Samaee[1], Atefeh Razavi[1], Sri Krishna Sivakumar[1], Pradeep Yadav[2], Venkateshwar Polsani[2], Vinod Thourani[2], Lakshmi Prasad Dasi[1]
*[1]Georgia Institute of Technology / Emory University School of Medicine, [2]Piedmont Hospital*

**P121 Reduced Order Modeling Framework for Rapid Simulations of Transcatheter Aortic Valve Replacement Procedures** SB³C2022-363
Imran Shah[1], Milad Samaee[1], Atefeh Razavi[1], Fateme Esmailie[1], Alessandro Veneziani[2], Lakshmi Dasi[1]
*[1]Georgia Institute of Technology, [2]Emory University*

**P122 Changes in the In-vivo Functional State of the Mitral Valve in Percutaneous MitraClip Repair** SB³C2022-446
Hao Liu[1], Natalie Simonian[1], Sneha Vakamudi[1], Mark Pirwitz[1], Joseph Gorman[2], Robert Gorman[2], Michael Sacks[1]
*[1]University of Texas at Austin, [2]University of Pennsylvania*

**P123 Predictive Modeling of Coronary Artery Occlusion During Transcatheter Aortic Valve Replacement** SB³C2022-473
Sri Krishna Sivakumar[1], Breandan Yeats[1], Atefeh Ravazi[1], Ignacio Santos[2], Susan O'Neil[3], Scott Lilly[3], Pradeep Yadav[4], Venkateshwar Polsani[4], Vinod Thourani[4], Lakshmi Dasi[1]
*[1]Georgia Institute of Technology, [2]HCU Valladolid, [3]Ohio State University-Wexner Medical Center, [4]Piedmont Heart Institute*

**P124 Carotid Artery Stiffness Mechanisms Associated with Cardiovascular Disease Events and Incident Hypertension: The Multi-Ethnic Study of Atherosclerosis (MESA)** SB³C2022-212
Ryan Pewowaruk[1], Claudia Korcarz[2], Yacob Tedla[3], Gregory Burke[4], Philip Greenland[5], Colin Wu[6], Adam Gepner[1]
*[1]William S. Middleton Memorial Veterans Hospital, [2]University of Wisconsin, [3]Vanderbilt University, [4]Wake Forest School of Medicine, [5]Northwestern University, [6]National Heart, Lung, and Blood Institute*

**P125 Machine Learning Prediction of Abdominal Aortic Aneurysm Wall Strength and Evaluating Factor Sensitivity** SB³C2022-140
Pete Gueldner, Isabelle Chickanosky, Timothy Chung, David Vorp

*University of Pittsburgh*

**V13 Biomechanical and Microstructural Characterizations of Human Healthy and Hypertrophic Septal Tissues** SB³C2022-316
Katherine Copeland[1], Uday Chintapula[1], Alan Taylor[1], Yi Hong[1], Kytai Nguyen[1], Matthias Peltz[2], Pietro Bajona[3], Jun Liao[1]
*[1]University of Texas at Arlington, [2]University of Texas Southwestern Medical Center, [3]Allegheny Health Network*

**V14 Evaluation of Tachycardia Pacing Therapy Response in a Whole Heart HFpEF Model: Therapy Design Implications** SB³C2022-258
Kevin Sack, Josh Blauer, Richard Cornelussen, Troy Jackson
*Medtronic, Inc*

**V15 Dimensional Variability in Tensile Strength of the Tricuspid Annulus** SB³C2022-7
Andrew Behrmann, Anya Anokhin, Shamik Bhattacharya
*University of Missouri*

**V16 Assessing Local Delivery Capability of a Novel Septal Ablation System via an Ex Vivo Pig Heart Model** SB³C2022-317
Katherine Copeland[1], Uday Chintapula[1], Joyita Roy[1], Yi Hong[1], Liping Tang[1], Matthias Peltz[2], Pietro Bajona[3], Kytai Nguyen[1], Jun Liao[1]
*[1]University of Texas at Arlington, [2]University of Texas Southwestern Medical Center, [3]Allegheny Health Network*

**V17 Biomechanical Wall Thickness and Stiffness Uncertainty Quantification in an Idealized Model of the Pre-stretched Dissected Aorta** SB³C2022-88
Lise Gheysen[1], Lauranne Maes[2], Mathias Peirlinck[3], Annette Caenen[1], Nele Famaey[2], Patrick Segers[1]
*[1]Ghent University, [2]KU Leuven, [3]Delft University of Technology*

## Solids- Growth and Remodeling

**P126 Simulations of Cellular Guidance by 3D Matrix Orientation and Anisotropy Via Deformable Continuous Fibril Distributions** SB³C2022-291
Steven LaBelle, Steve Maas, Adam Rauff, Jeffrey Weiss
*University of Utah*

**P127 Computational Modeling of Brain Bilayer Under Cerebrospinal Fluid Pressure** SB³C2022-302
Fatemeh Jafarabadi, Maria Holland
*University of Notre Dame*

**P128 Multiscale Model of Pregnancy-Induced Heart Growth Applied to Postpartum Recovery** SB³C2022-66
Molly Kaissar, Kyoko Yoshida
*University of Minnesota*

**P129 A Multilayer Mechanical Cellular-Potts Model of Migrating Mesendoderm** SB³C2022-252
Tien Comlekoglu[1], Gustavo Pacheco[1], Bette Dzamba[1], David Shook[1], T.J. Sego[2], James Glazier[2], Shayn Peirce-Cottler[1], Douglas DeSimone[1]
*[1]University of Virginia, [2]Indiana University*

**P130 Multiscale Modeling of Tissue Growth and Remodeling Coupled with Mechanosensitive Cell-scale Systems Biology** SB³C2022-313
Mohammadreza Soltany Sadrabadi[1], Seungik Baek[2], Mohammad R. K. Mofrad[3], Amirhossein Arzani[1]
*[1]Northern Arizona University, [2]Michigan State University, [3]University of California*

**P131 A Combined Mechanical and Biological Approach to Quantify Failure in Human Skin** SB³C2022-34
Jack Hayes, Claire Higgins, Marc Masen
*Imperial College London*

**P132 Distortional Strain Definition for Finite Element Fracture Healing Algorithm** SB³C2022-296
George Morgan, Hana Fox, Lucas Low, Arul Ramasamy, Spyros Masouros
*Imperial College London*

**P133 Overstretch-Induced Softening is Independent of Strain Rate in Cerebral Arteries** SB³C2022-359
Noah Pearson, Gregory Boiczyk, Kenneth Monson
*University of Utah*

**V18 Modeling of Organ-Specific Tumor Microenvironments to Analyze Cell-To-Cell Interactions** SB³C2022-500
Morgan Connaughton, Mahsa Dabagh
*University of Wisconsin-Milwaukee*

## Solids- Injury and Brain Biomechanics

**P134 A Continuum Model for Transition Between Cell-Dense and Cell-Sparse Tissues: Application to Cerebral Aneurysms** SB³C2022-50
Elizabeth Shih, Ryan Mahutga, Victor Barocas, Patrick Alford
*University of Minnesota*

**P135 A Study on the Triaxial Mechanical Properties of Silicone Elastomers for Potential Use as a Brain Tissue Surrogate** SB³C2022-71
Ahsanul Torza, Johannes Weickenmeier
*Stevens Institute of Technology*

**P136 Mechanical and Structural Characterization of the Human Meninges and Falx** SB³C2022-221
Darragh Walsh, David Newport, John Mulvihill
*University of Limerick*

**P137 Recent Updates on the GHBMC Human Head Finite Element Model- A New Visco-hyperelastic Brain Material Model and Brain Strain Validation** SB³C2022-278
Ding Lyu, Runzhou Zhou, Liying Zhang
*Wayne State University*

**P138 How Signal-To-Noise Ratio Impacts the Apparent Stiffness of Brain Tissue in MR Elastography At 7T** SB³C2022-297
Emily Triolo[1], Oleksandr Khegai[2], Jelle Veraart[3], Akbar Alipour[2], Priti Balchandani[2], Mehmet Kurt[1]

[1]*University of Washington,* [2]*Icahn School of Medicine,* [3]*New York University*

**P139 Regional Maximum Principal Strain Response of an Anatomically Accurate Finite Element Human Brain Model** SB³C2022-350
Tyler F. Rooks, Jamie L. Baisden, Narayan Yoganandan
*Medical College of Wisconsin*

**P140 Creating a Platform to Study Headbanging Patterns in a Virtual Heavy Metal Concert Environment** SB³C2022-436
Aymeric Pionteck[1], Devlin Stein[2], Javid Abderezaei[1], Lyndia Wu[3], Mehmet Kurt[1]
[1]*University of Washington,* [2]*Stevens Institute of Technology,* [3]*University of British Columbia*

**P141 Computational Assessment of Stress Distribution in the Brain: Biomarkers of White Matter Lesion Formation** SB³C2022-466
Tyler Diorio[1], Kevin McIver[1], Noah Mehringer[1], Sean Bucherl[1], Eric Nauman[2], Yunjie Tong[1], Vitaliy Rayz[1]
[1]*Purdue University,* [2]*University of Cincinnati*

**P142 Novel Biomechanical Approach to Improve Controlled Cortical Impact Testing for Studying Rodent Closed-Head Traumatic Brain Injury** SB³C2022-35
Emilie Potts[1], Lihong Lu[1], Xiaoyun Xu[2], Arthur Brown[2], Haojie Mao[1]
[1]*University of Western Ontario,* [2]*Robarts Research Institute*

**P143 A Multi-Method Approach for Assessing Non-Lethal Cutaneous Impact Injuries** SB³C2022-155
Omar Elsafty, Christopher Berkey, Reinhold Dauskardt
*Stanford University*

**P144 Head Acceleration Measurement in Youth Football Athletes Using a Mouthpiece-Based Sensor** SB³C2022-281
Madison Marks, Ty Holcomb, N. Stewart Pritchard, Logan Miller, Joel Stitzel, Jillian Urban
*Virginia Tech & Wake Forest University*

**P145 A Hybrid Paradigm to Develop Regional Throaco-Abdominal Criteria for Behind Armor Blunt Trauma** SB³C2022-294
Narayan Yoganandan[1], John Humm[1], Brian Stemper[1], Cameron Bass[2], Salzar Robert[3], Joseph McEntire[4]
[1]*Medical College of Wisconsin,* [2]*Duke University,* [3]*University of Virginia,* [4]*USAARL*

**P146 Development and Validation of Two-Dimensional Finite Element Model of the Neonatal Brachial Plexus** SB³C2022-54
Sarah Trapp, Michele Grimm
*Michigan State University*

**P148 Identifying Micro-indentation Testing Parameters Suitable for Brain Tissue Testing** SB³C2022-46
Xuesong Zhang, Johannes Weickenmeier
*Stevens Institute of Technology*

**V19 I-PREDICT: Developing a Full Human Body Model in FEBio** SB³C2022-348
Lance Frazer[1], Dan Nicolella[1], Brian Stemper[2], Rob Salzar[3], Narayan Yoganandan[2], Dale Bass[4], Matthew Davis[5], Tim Bentley[6], Barry Shender[7]

*[1]Southwest Research Institute, [2]Medical College of Wisconsin, [3]University of Virginia, [4]Duke University, [5]Elemance LLC, [6]Office of Naval Research, [7]Naval Air Warfare Center Aircraft Division*

**V20 The Correlation Study of Brain Tissue Between Mechanical Frequency Properties and Microscopic Structures** SB³C2022-327
Suhao Qiu[1], Linghan Kong, Runke Wang[1], Fuhua Yan[2], Yuan Feng[1]
*[1]Shanghai Jiao Tong University, [2]Ruijin Hospital*

## Solids- Joint and Spine

**P149 Finite Element-Based, Kinematically-Driven, Subject-Specific Model of Human Cervical Facet Capsule Ligaments** SB³C2022-77
Maryam Nikpasand, Rebecca Abbott, Craig C. Kage, Victor H. Barocas, Arin M. Ellingson
*University of Minnesota*

**P151 The Risk of Recurrent Disc Herniation Following Decompression Surgery with Surgical Detachment of the Posterior Extensor Muscles** SB³C2022-346

# POST-OPERATIVE VENA CAVA BOUNDARY CONDITION PREDICTION FOR FONTAN SURGICAL PLANNING

**W. Song (1), R. Ghosh (2), M. Fogel (2), D. Frakes (1,3)**

## INTRODUCTION

The Fontan procedure was introduced as surgical repair for single ventricle patients such as those with hypoplastic left heart syndrome and tricuspid atresia [1-3]. It is a palliation creating a univentricular circulation that channels caval return directly into the pulmonary arteries bypassing the heart altogether. Although the development of imaging and simulation technologies has given rise to opportunities for clinicians to pre-operatively select among surgical options for the optimal geometry of the systemic venous pathway to the lungs, the robust prediction of boundary conditions, i.e., realistic characterizations of post-operative flows into the Fontan connection, remains a critical issue. Because of the dissimilarity between the pre-operative and post-operative flows, it would be useful to predict post-operative conditions rather than use pre-operative conditions as boundary conditions for computational fluid dynamics (CFD) simulations aimed at surgical planning [4]. Our research proposes for the first time the application of machine learning to predict post-operative vena cava flows based on pre-operative vena cava flows from cardiac magnetic resonance (CMR) imaging.

## METHODS

We began by configuring our patient cohort data for machine learning. The data sets consist of both pre-operative and post-operative inferior vena cava (IVC) and superior vena cava (SVC) velocity maps (magnitude and phase images), organized as time series over a single cardiac cycle. Data were available for 6 serial pediatric patients having had Fontan surgeries. For each CMR sequence, manual segmentations of either the IVC or SVC region were executed on each magnitude image, and the resultant caval flow velocity over the cycle was tracked from the corresponding phase image by decoding the grey values of the pixels within the region. An example of a segmentation is presented in Figure 1.

We then resampled each flow sequence to uniformly have 30 datapoints and stacked the sequences into two 6 × 30 matrices paring the pre-operative data with post-operative data for both IVC and SVC training. A two-layer stacked LSTM network [5] with 100 units in each layer, followed by a 30-unit fully connected layer, was adopted as our machine learning model that underwent leave-one-out-cross-validation (LOOCV) to elevate reliability given the small training cohort. A total of 12 independent predictors were generated as a result of the LOOCV procedure, where each of the 6 patients was left out to generate a predictor for both IVC and SVC, respectively.

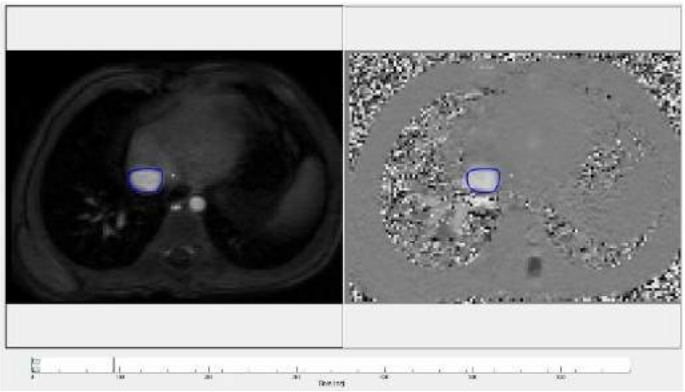

**Figure 1: IVC segmentation example (captured in Medviso AB's Segment v3.2 R8531). The region of interest was first outlined (in blue) manually on the magnitude image (left panel), then automatically transferred to the associated phase image (right panel) to track the flow velocity.**

## RESULTS

As we are motivated to use post-operative vena cava boundary conditions in lieu of pre-operative ones towards Fontan surgical planning, we need to determine if post-operative flow is predictable from pre-operative flow, i.e., to determine if our machine-learning-based post-operative predictions appear to be more similar to the measured post-operative flow curves than pre-operative flow curves. An intuitive comparison in the case of IVC prediction is demonstrated in Figure 2, where the six patients are sequentially left out of training and used for validation, as mentioned in the LOOCV procedure above. Notably, we have applied 5-order polynomial fitting to all the prediction curves to reduce noise.

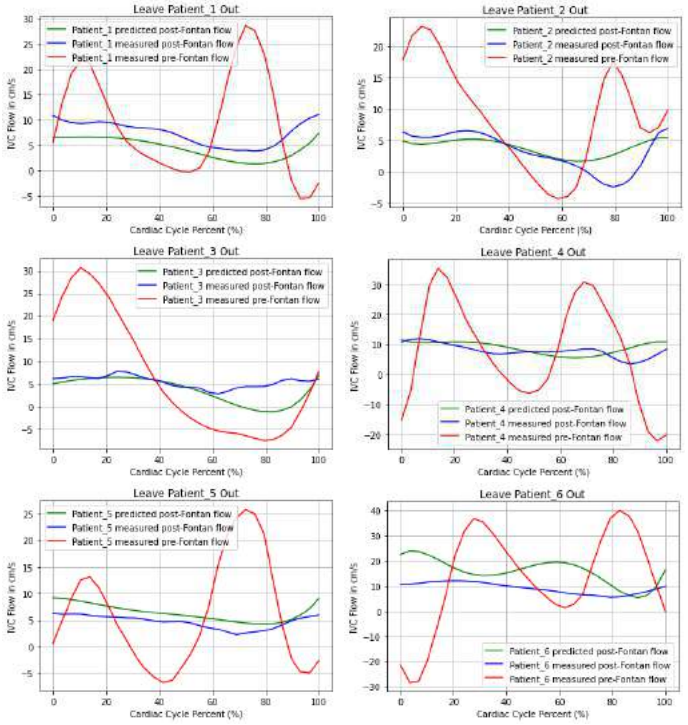

**Figure 2: Post-operative IVC flow velocity prediction and comparison. Each of the 6 patient-specific models shows the prediction's (green) greater similarity to the measured post-operative flow (blue) than the measured pre-operative flow (red), which indicates the predictability of post-operative boundary conditions with machine learning methods.**

In Table 1, we quantify flow curve similarities by calculating the mean-square errors (MSE) between flow curves for each of the 12 predictors. Results show that the overall MSE (averaged across all LOOCV-produced models) between post-operative measurements and predictions is smaller (marked in bold) in both IVC and SVC cases, which is aligned with the intuitive results from the plots above. Specifically, the MSE (cm/s) is 16.10 between the post-operative predictions and the post-operative measurements, and 224.18 between the former and the pre-operative measurements in the case of IVC, and those values become 56.81 and 67.53 in the case of SVC. It is also interesting to note that the gaps in the case of SVC are small compared to those in IVC, and that the similarity comparison may even reverse in isolated cases (an example is given by the 2nd patient in the table). This is aligned with, and explainable by the finding in our previous research where we implemented least square (LS) method to predicting post-operative flow from pre-operative flow using transfer functions in the frequency domain. The transfer functions simulating the Fontan procedure act as a damping system for the IVC, while appear to be flat for the SVC, which indicates that the SVC flow after surgeries does not change much in each time frame within the cardiac cycle, so the predictors do not add additional information [6].

**Table 1: Quantitative description of the similarities between post-operative predictions and measurements across all LOOCV models in both IVC and SVC cases.**

| Vena Cava (cm/s) | MSE between the predicted post-operative flow and the measured … | | | |
|---|---|---|---|---|
| Left-out patient ID | pre-operative flow | | post-operative flow | |
| | IVC | SVC | IVC | SVC |
| 1 | 139.14 | 58.46 | **9.58** | **18.38** |
| 2 | 84.93 | **166.00** | **4.64** | 238.11 |
| 3 | 130.22 | 86.25 | **8.38** | **43.25** |
| 4 | 306.25 | 18.33 | **6.88** | **9.77** |
| 5 | 114.44 | 54.51 | **3.50** | **17.14** |
| 6 | 570.11 | 21.60 | **63.63** | **14.21** |
| Average | 224.18 | 67.53 | **16.10** | **56.81** |

## DISCUSSION

This study introduces a machine learning method to predict post-operative caval return from pre-operative caval flows toward CFD-based surgical planning in Fontan patients. Evaluations of both IVC and SVC cases indicate the predictions' similarity to the post-operative states and thus justify their predictability from pre-operative states. The study shows potential for shifting the current surgical planning paradigm in which pre-operative states are often used as post-operative boundary conditions. We foresee that a more robust predictor will be developed as we enrich the training data, and will advance to pixel level for more detailed boundary condition specification in Fontan surgical planning. Future work will also quantify the impact of the proposed boundary condition prediction approach on key surgical planning metrics extracted from CFD such as hepatic flow split.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge the Additional Ventures Fund for their generous support of this work.

## INTRODUCTION

Blast-induced traumatic brain injury (TBI) is a major cause of injury and death in the US military [1]. Finite-element simulations allow investigation of brain strain distribution during blast exposure, but accurate material models of brain tissue are needed for these simulations to achieve a high degree of biofidelity. Experimentally derived constitutive models should be validated over a range of strain rates which can be on the order of several hundred per second in blast injury [2]. To date, high-rate characterization of brain tissue in shear is lacking, with much of the literature focusing on low oscillatory frequencies and strain rates [3] or high oscillatory frequencies but low strains, resulting in peak strain rates below 100 $s^{-1}$ [4].

A major post-mortem finding of severe TBI is axonal injury in regions of white matter within the brain [5]. This suggests that modeling of deformations in these regions is critical to better understanding TBI. White matter is structurally different from gray matter, consisting of myelinated axons which often travel in a highly aligned direction. It can thus be hypothesized that axons may act as a reinforcing fiber in the tissue with a preferred loading direction along the fibers. This is further backed up by the influence of myelin content on brain tissue stiffness [6]. Tissue in the brainstem has previously been shown to be transversely isotropic [7] in shear. To date, no study has conclusively demonstrated anisotropy or isotropy in the cerebrum or cerebellum.

In this work, brain tissue from the cerebrum and cerebellum was harvested from Göttingen minipigs and tested via oscillatory frequency sweeps between strain rates of 0.025 and 250 $s^{-1}$. Tissue was tested in three perpendicular directions to define anisotropy.

## METHODS

Brain tissue from 20 adolescent male Göttingen minipigs (age 23-25 weeks) was harvested immediately after euthanization. All animal protocols were approved by the University of Utah IACUC and the Department of Defense ACURO. Dissected tissue was immersed in a 7.5% polyethylene glycol buffered saline solution and cut into 8 x 8 x 5 mm samples corresponding to one of three fiber orientations (**Figure 1**).

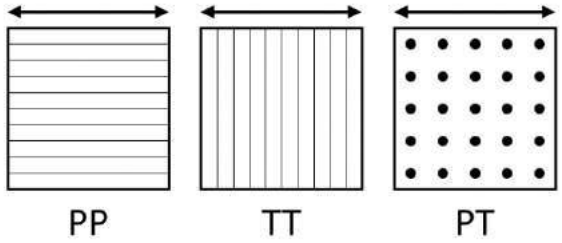

**Figure 1** | Fiber direction for the Parallel-Parallel (PP), Transverse-Transverse (TT), and Parallel-Transverse (PT) directions

Tissue samples were subjected to simple-shear frequency sweeps about a mean strain of K = 0 with a shear strain amplitude of K = 0.2 (strains of K = -0.2 to K = 0.2) at 8 strain rates ranging from 0.025 to 250 $s^{-1}$ (5 cycles each). Mean strain was then increased to K = 0.05 and held for two minutes of stress relaxation. Following stress relaxation, another set of frequency sweeps was performed around a mean strain of K = 0.05 (strains of K = -0.15 to K = 0.25). The same procedure was then repeated for a mean strain of K = 0.1 (strains of K = -0.10 to K = 0.3). Strains did not exceed K = 0.3 during these tests, which was below the failure strain of K = 0.35 observed in high-rate shear tests we have previously performed on brain tissue [8].

Load and displacement data were converted to stress and strain and then averaged within each group to create average stress and strain vs. time curves. To evaluate anisotropy, the average dynamic modulus was computed for each oscillation within a group. Using strain rates and directions as independent variables, two-way ANOVA were performed to identify differences in moduli. Where statistical significance was detected, pairwise comparisons were performed using a Bonferroni adjusted p-value of 0.025.

## RESULTS

Average ± standard deviation dynamic modulus vs strain rate plots for all directions of the cerebrum and cerebellum around a mean strain of K = 0 are shown in **Figure 2**. For both the cerebrum and cerebellum, the tissue shows a trend towards stiffer responses up to a strain rate of 50 $s^{-1}$ after which there is a slight drop off in stiffness. In the cerebrum the tissue is stiffest at a rate of 50 $s^{-1}$ before softening at higher strain rates, while in the cerebellum the tissue is stiffest at 250 $s^{-1}$. Overall, the preferred direction in the cerebrum (PP) is stiffer than the preferred direction in the cerebellum (TT) at all rates.

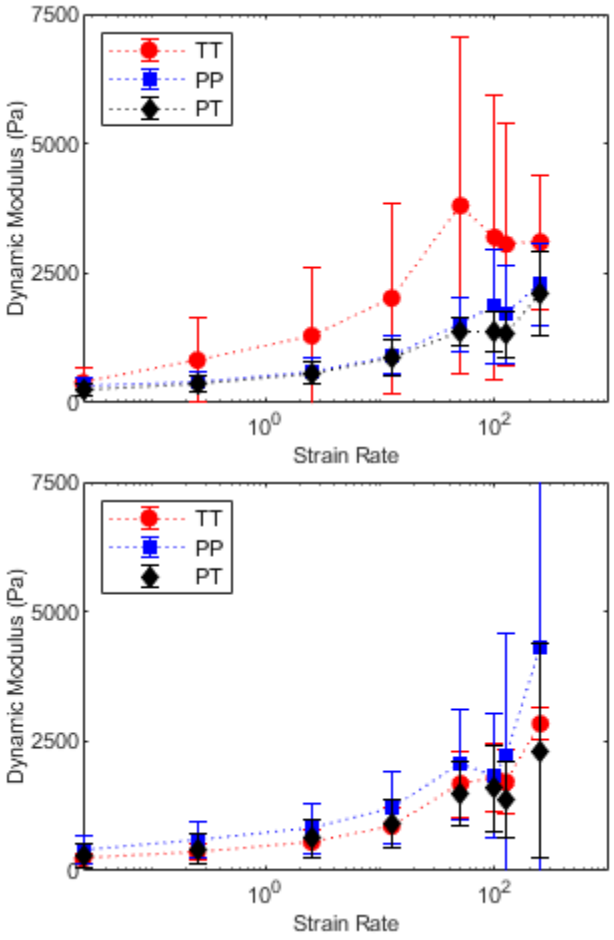

**Figure 2** | Dynamic moduli vs oscillatory strain rate around a mean strain of K = 0 for the cerebrum (N = 11-12, top) and cerebellum (N = 13-15, bottom)

The ANOVA showed a significant effect of direction ($p < 0.001$) on dynamic moduli. Further statistical characterization via pairwise comparisons in the cerebrum showed a statistically significant difference between the Transverse-Transverse (TT) direction and both the Parallel-Parallel (PP) and Parallel-Transverse (PT) directions ($p < 0.001$), with the tissue being stiffest in the TT direction. No significant difference was present between the PP and PT directions ($p = 0.58$). In the cerebellum a statistical difference was present between the PP direction and the PT direction ($p < 0.01$) but no difference between the PP and TT directions ($p = 0.08$) or the PT and TT directions ($p = 0.76$). However, the PP direction was noticeably stiffer than the PT and TT directions. The ANOVA showed no significant difference for region ($p = 0.18$) or the combination of rate and region ($p = 0.32$)

## DISCUSSION

Both the cerebrum and cerebellum showed pronounced rate stiffening with increasing strain rates up to a rate of 50 $s^{-1}$, as would be expected with a viscoelastic material. Interestingly, both regions then show a subsequent decrease in dynamic modulus at higher rates. At higher rates, the displacement waveform starts to show larger variations, contributing to larger variations in loads, potentially reducing the mean stiffness. This can be further seen from the larger standard deviations above a rate of 50 $s^{-1}$. This may also be a physical phenomenon of the tissue itself, warranting further evaluation through finite element simulations and constitutive modeling.

Generally, the mean dynamic moduli in the preferred direction in the cerebrum (TT) (299.5 ± 232.8 to 3803 ± 3242 Pa) was greater than that in the cerebellum (PP) (390.2 ± 270.8 to 2317.5 ± 2052 Pa) for all strain rates below 250 $s^{-1}$. This phenomenon could possibly be explained by increased white matter content in cerebral samples versus cerebellar samples, though we did not quantify the relative proportion of white and gray matter in each region in this work. It should be noted that higher variability was present for this direction in the cerebrum as indicated by the larger standard deviations. Results show that both regions had one direction that was statistically stiffer than at least one other direction. The stiffest directions were the Transverse-Transverse (TT) direction for the cerebrum and the Parallel-Parallel (PP) direction for the cerebellum. In a single fiber family model in simple shear, only the TT direction should show fiber contributions. This suggests that the assumption of predominant fiber angle was correct in the cerebrum (fibers running in the rostral-caudal direction) but incorrect in the cerebellum, where fibers appear to predominantly run in the medial-lateral direction as opposed to running perpendicular from the brainstem as hypothesized.

The work presented in this abstract represents the first characterization of the response of porcine brain tissue in the cerebrum and cerebellum in harmonic oscillation over a range of strain rates and strain levels relevant to injury modeling. Future work with this experimental data will be used to develop constitutive models and finite element simulations of the experiments.

## INTRODUCTION

Geometric changes of the tricuspid annulus can lead to functional tricuspid regurgitation, a heart valve disease associated with high morbidity and mortality rates. These geometric changes include dilation of the tricuspid annulus as well as flattening of the annulus to a point that it loses its native bimodal saddle shape and becomes planar [1]. Previous studies have investigated the tensile strength of the three distinct tricuspid annulus segments (septal, anterior, posterior) and found the annulus has the lowest elastic moduli at the points showing the highest amounts of dilation in the clinical setting, the posterior and anterior free wall segments. Collagen content of each annulus portion was directly correlated with tensile strength, finding the highest strength and collagen content in the septal segment of the annulus [2]. This determined tensile strength when stretching the annulus in the circumferential dimension but did not answer anything about the longitudinal plane of the annulus that becomes flattened in the pathologic state [2,3]. Thus, the current study aimed to determine if there was a difference in tensile strength of tricuspid annulus tissue when it is stretched in the longitudinal dimension compared to being stretched in the circumferential dimension. This may be used to better inform the design of tricuspid annuloplasty rings and percutaneous repair devices by determining which section of the annulus needs greater support and in which annular plane that support is needed; circumferential or longitudinal. These results may also better inform computational models of tricuspid regurgitations and right ventricular remodeling.

## METHODS

Ten porcine hearts were stored at -80℃ and thawed in a warm saline bath the day of experiments to a temperature of 37℃. The tricuspid annuli were removed from the porcine hearts using a scalpel and surgical scissors. The annulus was then divided into its three distinct segments, anterior, posterior, and septal which corresponds with the three leaflets of the tricuspid valve. Annulus segments were trimmed into segments measuring 32 mm in length, 8 mm in width, and 2 mm in thickness. Thickness was measure with Vernier calipers along the entire sample to ensure a uniform thickness was achieved. These annulus segments were then divided into a 24 mm long segment to be stretch circumferentially, and a shorter 8 mm by 8 mm square of annulus tissue to be stretched in the longitudinal dimension (figure 1A). Tensile testing was performed using a U-stretch precision uniaxial tensile machine (CellScale) with samples immersed in 37℃ saline solution and pierced with bio-rake tines (figure 1B).

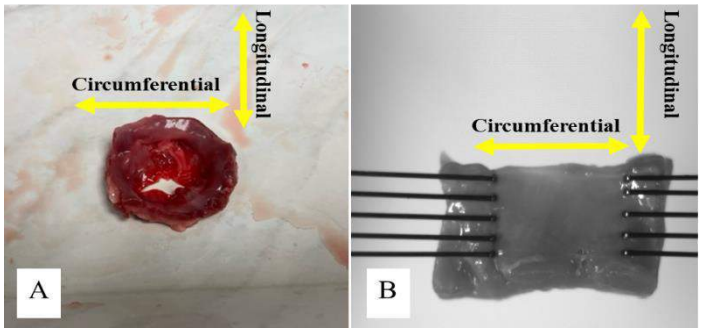

**Figure 1: A) Resected tricuspid annulus and valve with arrows denoting circumferential and longitudinal directions. B) Annulus sample loaded in U-stretch tensile testing machine.**

**Equation 1:** $Stress = \frac{Force\ required\ to\ stretch\ the\ sample}{Initial\ cross\ sectional\ area\ of\ the\ sample}$

All tissue samples were preconditioned at a load rate of 1 mm/s to 10% strain. Following preconditioning, samples were stretched at a rate of 0.2 mm/s to 20% strain [1]. This was performed in tissues that were stretched in the circumferential and longitudinal axes, respectively.

Strain was measured using video extensometery, and stress was calculated using equation 1. Stress-strain curves were developed from these results and the modulus of elasticity was calculated from these curves for all samples between strain ranges of 8% to 13% ($R^2 > 0.99$). The stress-strain curves for all samples are shown in figure 2. A students t-test was performed in R statistical software to determine the differences in longitudinal versus circumferential tensile strength in each of the three respective annulus segments. A one-way ANOVA was performed in R to compare the elastic moduli of the three annulus segments in the longitudinal dimension, and a second one-way ANOVA to compare the elastic moduli of each annulus section in the circumferential dimension.

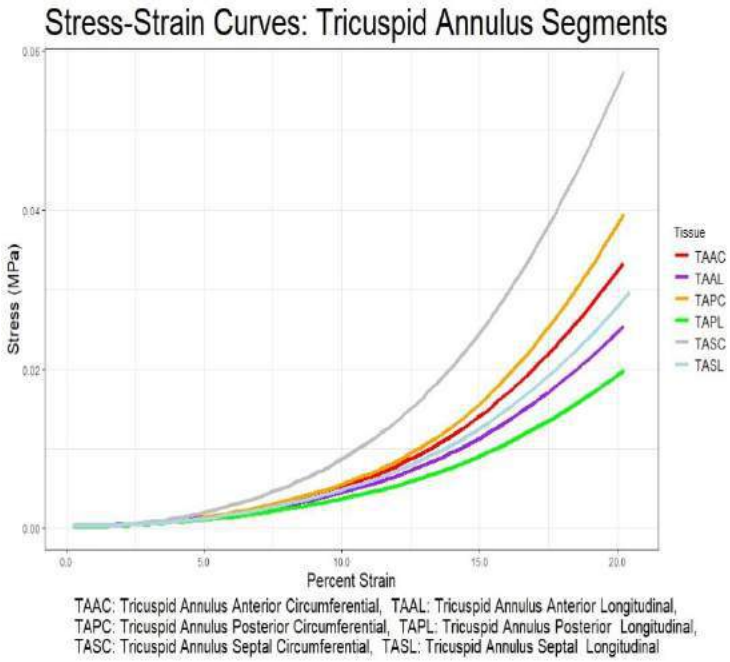

**Figure 2: Stress-strain curves of annulus segments.**

## RESULTS

The average elastic moduli of the tricuspid annulus segments in the longitudinal direction were 0.123±0.019 MPa in the anterior segment, 0.081±0.013 MPa in the posterior segment, and 0.140±0.020 MPa in the septal segment. The average circumferential elastic moduli of each segment was 0.173±0.028 MPa for the anterior segment, 0.188±0.020 MPa in posterior segment, and 0.140±0.020 MPa in septal segment (figure3). Each annulus segment's circumferential elastic modulus is significantly higher ($p<0.05$) than its longitudinal modulus. In the one-way ANOVA that was performed on each segment, septal segment moduli were significantly greater in both circumferential and longitudinal directions than each of the other segments' respective moduli (figure 3). The average elastic modulus in the longitudinal plane of the posterior annulus was significantly less than both anterior and septal segments. Average modulus values of all tissue sample for each directionality can be found in table 1.

| | Septal Moduli (MPa) | Anterior Moduli (MPa) | Posterior Moduli (MPa) |
|---|---|---|---|
| Circumferential | 0.268±0.036 | 0.173±0.028 | 0.188±0.020 |
| Longitudinal | 0.140±0.020 | 0.123±0.019 | 0.081±0.013 |

**Table 1: Average elastic modulus values.**

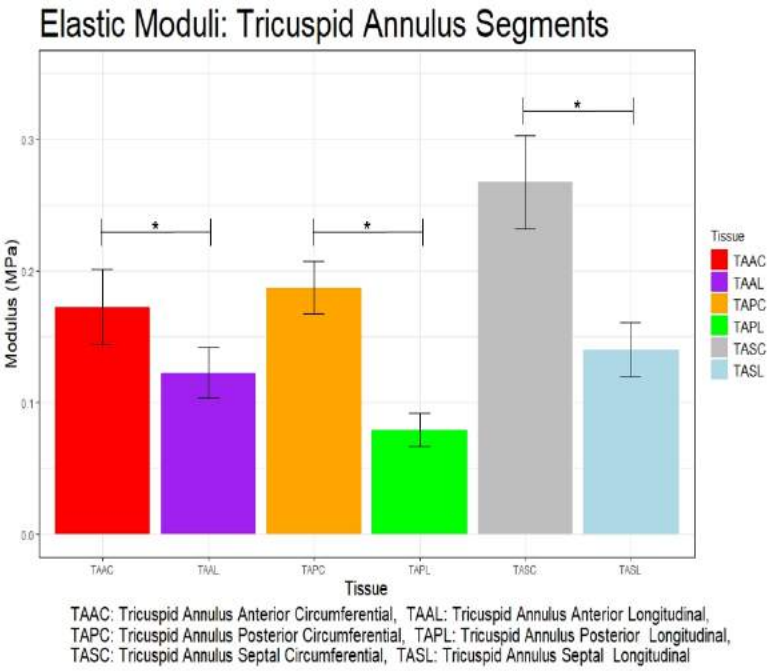

**Figure 3: Average elastic moduli of tricuspid annulus segments. * Indicates $p<0.05$**

## DISCUSSION

These preliminary results suggest that there is a significant difference ($p < 0.05$) in tensile strength of all three tricuspid annulus segments when comparing circumferential versus longitudinal planes. Thus, this is the first study to report that the tricuspid annulus differs in tensile strength depending on the tissue plane being studied. The weakest point of longitudinal tensile strength corresponds to the tricuspid annulus' two high points that fall into a flattened planar shape upon annular dilation. This may indicate a greater amount of vertical support in the longitudinal plane from tricuspid annuloplasty rings is needed within these regions in order to maintain or re-establish the taut bimodal saddle shape of the native annulus. These findings may also be used to inform computational models of tricuspid annulus dilation and ventricular remodeling seen in right heart failure. This study used bio-rake tines that pierced the tissue in order to avoid crushing and slipping of the tissue that may occur when clamping the tissue for uniaxial tensile testing, but this may come with its own end effects on the tissue's strength. These studies were performed in anatomically normal porcine hearts and there may be a pathologic difference in tensile strength of hearts undergoing tricuspid annulus dilation compared to unaffected hearts. Porcine tricuspid annulus mechanics may also differ from human. In conclusion, this study aimed to add a new dimension to the understanding of the tricuspid annulus and has provided another variable to be considered when designing tricuspid annuloplasty rings and other percutaneous tricuspid annulus repair techniques.

## INTRODUCTION

Traumatic brain injury (TBI) has become a global health threat. In 2016, over 27 million cases of TBI were reported globally [1]. The fast diagnosis and early warning approaches of TBI are significant to helping prevent repetitive sport-related TBI [2]. Conventionally, brain injury criteria (BIC) have been developed to estimate TBI risks [3]. More recent studies have shown brain strain (maximum principal strain, MPS) and strain rate (MPS rate, MPSR) based on brain-physics-based finite element modeling (FEM) are promising mechanical parameters well correlated with TBI pathologies including blood-brain-barrier disruption and axonal injury. The head kinematics are the input to compute BIC, brain strain and strain rate. Researchers have developed wearable sensor technologies to precisely measure the head kinematics with systems like head impact telemetry system (HITS), Xpatch and instrumented mouthguard [4]. The instrumented mouthguard attaches the sensors to the dentition and enables the rigid coupling with the skull for more precise measurement of the head rotation.

Although the instrumented mouthguards showed the capability to precisely measure the head kinematics [4] that correlates well with TBI results, the measurement are deviated from the reference kinematics measured by sensors directly implanted into the anthropomorphic test dummy (ATD) head due to the potential loosening of the mouthguard and electronic noises of the sensors. For example, Liu et al. compared five different types of instrumented mouthguards on laboratory impacts [5]. With the measurement of ATD sensors as the reference, the mouthguards show an average of 2.5% to 32.4% relative error in peak of magnitude (REPM) in linear acceleration measurements and an average of 2.3% to 7.6% REPM in angular velocity measurement. The errors in the kinematics can further lead to ~10% errors in the estimation of 95th percentile MPS. In this study, we apply the deep learning to denoise the mouthguard kinematics to better represent head kinematics measured by sensors in dummy head.

## METHODS

With a pneumatic impactor system and anthropomorphic test dummy (ATD) headform [5], we collected two datasets with 163 independent impacts in total. The ATD headform was impacted at the locations including front, facemask, oblique, side and back (dataset 1) and at every 15° from front to back (dataset 2). The impact velocities ranging from 3 m/s to 9.3 m/s were used considering the impact velocity in NFL helmet testing protocol [6]. . The impacts were measured with kinematics sensors both in instrumented mouthguards and in the ATD head. Linear acceleration at the head center of gravity (Lin. Acc.) and angular velocity (Ang. Vel.) were measured in three anatomical axes (x: posterior-to-anterior, y: left-to-right, z: superior-to-inferior) respectively. Two different types of instrumented mouthguards were used to collect the data and the sensor measurement in the ATD head was referred to as the reference kinematics signals as the target.

We then partitioned the datasets into the training (113 impacts), validation (25 impacts) and test datasets (25 impacts). To improve the model accuracy, we augmented the training data by partitioning the impacts into 100ms frames using a sliding window (width: 100ms, stride: 5ms). Each validation or test impact was partitioned into 2 100ms impacts for model testing. We then used the training dataset to train a one-dimensional convolutional neural network (1D-CNN) to predict the ATD sensor kinematics with the mouthguard measurement as the input. Considering the different physics mechanisms of noises, we modeled the six channels of Lin. Acc. and Ang. Vel. independently. To further optimize the accuracy, we tested out two different modeling methods: 1) to predict the ATD sensor kinematics from the mouthguard kinematics; 2) to predict the difference between the two kinematics and add the difference onto the input mouthguard kinematics. The validation dataset was used to tune the hyperparameters of the 1D-CNN model and choose the modeling method. The test dataset was used to assess the model performance on unseen impacts. We evaluated the model accuracy on the test dataset on three levels: 1) kinematics level: we calculated mean absolute error (MAE), root mean squared error

(RMSE), coefficient of determination ($R^2$), peak absolute error (PAE) and signal-to-noise ratio (SNR); 2) BIC level: we computed Head Injury Criterion (HIC[7]), Kinematic rotational brain injury criterion (BRIC[8]), Generalized acceleration model for brain injury threshold (GAMBIT[9]) and Kleiven's linear combination (KLC[10]), and evaluate $R^2$ and RMSE over test impacts; 3) strain and strain rate level: we used KTH head model [10] to compute the whole-brain peak MPS and MPSR and computed the brain-element-wise absolute error, with the MPS/MPSR calculated by ATD sensor kinematics as the reference.

## RESULTS

The kinematics-level results are shown in Fig. 1. After denoising, the kinematics signals better correlate with the reference, with smaller MAE, RMSE and higher $R^2$ and SNR. The RMSE and PAE are significantly reduced with the 1D-CNN denoising models for all six channels of linear acceleration and angular velocity ($p<0.05$, Wilcoxon signed-rank test). The example linear acceleration from three test impacts before and after denoising is visualized in Fig. 2, which shows the effectiveness of the denoising: the denoised kinematics are closer to the reference ATD sensor measurement.

## DISCUSSION

We develop 1D-CNN models to denoise the mouthguard measurement of head impact kinematics with the reference kinematics measured by the sensors implanted in dummy test head. The models are effective in generating kinematics better correlated with the reference kinematics. The error between the denoised kinematics and the reference kinematics is significantly smaller than that between the raw mouthguard measurement and the reference kinematics. Furthermore, the 1D-CNN denoising models significantly reduce the errors of brain injury criterion (BIC) calculation and the brain strain and strain rate calculation based on the kinematics measurement, which enables more accurate brain injury risk estimation and early warning for potential patients of TBI. Following on this study, future studies could develop similar deep learning models to denoise the helmet sensors and skin-patch sensors for broad applications in clinical TBI management.

# TRICUSPID VALVE ANNULUS MECHANICS AND GEOMETRY IN NEWBORNS WITH HYPOPLASTIC LEFT HEART SYNDROME (HLHS)

**Colton J. Ross (1), Elizabeth J. Trimble, (2), Arshid Mir (3), Harold M. Burkhart (2), and Chung-Hao Lee (1)**

(1) Biomechanics and Biomaterials Design Laboratory, School of Aerospace and Mechanical Engineering, The University of Oklahoma, Norman, OK, USA

## INTRODUCTION

Hypoplastic left heart syndrome (HLHS) is a congenital defect affecting 1 in every 3,841 newborns in the United States and is associated with a 20.6% mortality within the first two weeks of life [1]. HLHS is characterized by an underdevelopment of the left ventricle, mitral valve, and/or the ascending aorta, which consequently inhibits the systemic blood circulation. Cardiac palliation for HLHS is initiated immediately after birth and progresses over three stages during the first 2-3 years of life of the newborn. Throughout the three cardiac palliation stages, tricuspid regurgitation (TR) arises in 32% of newborns before the second palliation stage (Glenn operation) and is associated with a high mortality rate [2]. The occurrence of TR may be due to adverse tissue remodeling instigated by surgical corrections during the palliation stages. One avenue to improve HLHS treatments, including inter-staged TV repair, is to identify the geometric and biomechanical differences between the healthy (functional) and HLHS-afflicted tricuspid valve (TV) to better replicate a more desirable TV function.

Previous studies have quantified the unique features of the right-side heart anatomy and function in HLHS, as compared to the healthy patients. For example, the ventricular cavity is more circular in the HLHS condition due to a change in intraventricular septum shape, and the septal leaflet is supported by additional free-standing papillary muscles [3]. The circumferential strains of the right ventricle have also been found to be similar between healthy and HLHS newborns; however, the longitudinal strains are reduced in HLHS [4]. Despite these advances in our knowledges of congenital patients, the information on the biomechanical and geometric features of the HLHS-afflicted TV annulus remains lacking.

Thus, in the present work we present an *in vivo* TV annulus analysis pipeline for HLHS and healthy patients using 4-dimensional echocardiograms. This framework allows for quantification of the clinical/geometric indices for the TV annulus (e.g., the annular area) and the biomechanics metrics such as the strain rate and curvature. **Our objective** is to provide insight into the fundamental differences in those functional metrics between healthy and HLHS-afflicted TV annuli.

## METHODS

The study protocol was reviewed and approved by the University of Oklahoma Health Sciences Center institutional review board (IRB#14112). The patient cohort consisted of $n$=8 HLHS patients without TR and $n$=4 healthy patients. For all patients, 4D full-volume transthoracic echocardiographic data was collected for a full cardiac cycle (Philips EPIQ ultrasound machine). The imaging data was then imported to the open-source 3D Slicer software for segmentation of the TV annulus (**Fig. 1a**, next page), which was performed through manual point placement within the 3D Slicer GUI, targeting a resolution of 8°-9° between each segmentation point to capture the unique annular shapes. The three commissure locations were also identified: anterior-septal (AS), posterior-septal (PS), and the anterior-posterior (AP). The segmentation process was repeated at five distinct timepoints over the cardiac cycle: the right ventricular minimum pressure ($RVP_{min}$) chosen as the reference configuration in the subsequent strain analysis, end diastole (ED), end isovolumetric contraction (EIVC), end systole (ES), and end isovolumetric relaxation (EIVR).

The ($X$,$Y$,$Z$) coordinates from image segmentation were imported to MATLAB (MathWorks, MA) for curve fitting and geometric and biomechanical quantification. In brief, the segmented 3D point cloud of the TV annulus was fitted using 1D moving least-squares (MLS) shape functions $\Psi$ in a cylindrical coordinate system $(r, \theta, z)$ [5]:

$$C(X,Y,Z) = \left(\sum_{j=1}^{NP} \Psi_j(\theta) r_j\,,\ \theta,\ \sum_{j=1}^{NP} \Psi_j(\theta) z_j i\right), \qquad (1)$$

where $NP$ is the set of discrete points representing the annulus curve.

SB³C2022-009

Then, using the fitted curve, 300 uniformly spaced material points were generated around the TV annulus circumference (**Fig. 1b**), and the following engineering metrics were determined:

$$\text{Strain: } \varepsilon_i = s_i^t / s_i^0, \tag{2}$$

$$\text{Strain Rate: } \dot{\varepsilon}_i = \Delta s_i / \Delta t = (s_i^{t_2} - s_i^{t_1})/(t_2 - t_1), \tag{3}$$

$$\text{Curvature: } \kappa_i = \frac{|\boldsymbol{d}^{(1)}(X,Y,Z)_i \times \boldsymbol{d}^{(2)}(X,Y,Z)_i|}{|\boldsymbol{d}^{(1)}(X,Y,Z)_i|^3}, \tag{4}$$

where $t$ denotes a timepoint in the cardiac cycle, $\mathbf{d}^{(1)}$ and $\mathbf{d}^{(2)}$ are the first- and second-order derivatives of the annulus curve, and $i$=1~300.

For the geometric indices, we also quantified the AP diameter ($D_{AP}$) and the septal-lateral diameter ($D_{SL}$), annular height, bending angle, circumference, area, and sphericity ($D_{AP}/D_{SL}$), see **Fig. 1c** [6]. All geometric quantities were normalized by the patient's body surface area for comparisons between patients.

All quantities are reported as mean±SEM. Due to data normality and uneven variances, the Welch's $t$-test was used in statistical analysis between healthy and HLHS patients with $p$<0.05 considered significant.

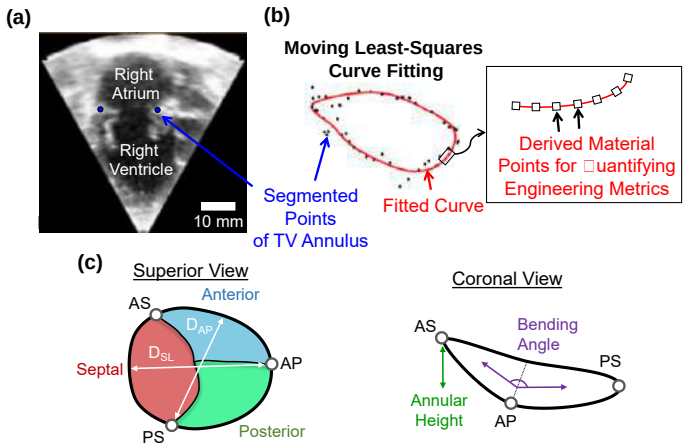

**Figure 1: (a) Echocardiogram from HLHS newborn. Schematic: (b) moving least-squares curve fitting, and (c) geometric indices.**

## RESULTS

For the geometric indices (**Fig. 2**), the TV annulus of the HLHS patients was found to become more circular during the valve closure (EIVC), as evidenced by a decreased $D_{AP}$ (−12.9±4.0%). At the same time, the annulus became more "bent" (143.9°±8.1°). Comparing the HLHS and healthy newborns, the annular circumference was smaller for the healthy patients at all five timepoints (20-30% smaller, 0.001<$p$<0.040). We also found that the healthy newborns had a more elliptical annulus with the major axis along the $D_{SL}$ direction (i.e., $D_{AP}/D_{SL}$<1) as compared to the HLHS newborns having a more circular annulus (i.e., $D_{AP}/D_{SL}$≈1) (0.017<$p$<0.040).

In terms of the quantified biomechanics-focused metrics, the HLHS patients had the largest strains in the posterior and septal annulus segments at ED (−5.7±2.2% and −8.7±3.8%, respectively), whereas the anterior segment underwent the smallest strain during the cardiac cycle (<5% at all timepoints) (**Fig. 3**). For the strain rate, the largest changes were at EIVC: posterior segment, 5.2±63.0%/s; anterior segment, 60.9±66.6%/s; septal segment, −158.8±96.1%/s. The greatest change in the curvature was found to be in the septal segment, with variations within ±2.0mm$^{-1}$. In addition, comparing the HLHS and healthy and newborns, we only observed significant differences in the strain of the anterior segment (HLHS vs. healthy): −0.1±2.6% vs. −13.3±2.9% at ED ($p$=0.010), and −1.7±3.0% vs. 6.8±0.9% at EIVR ($p$=0.026).

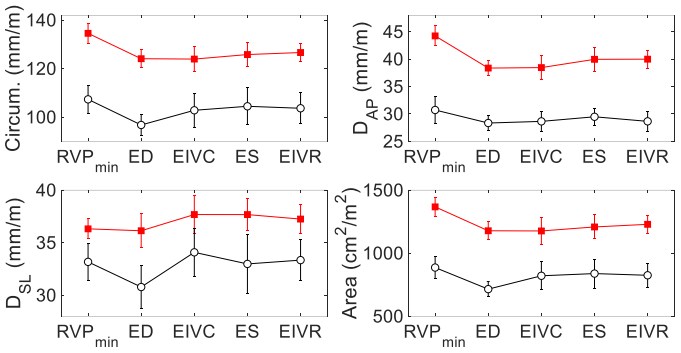

**Figure 2: Quantified geometric indices of the TV annulus (■ HLHS, $n$=8; ○ Healthy, $n$=4). Values are reported as mean±SEM.**

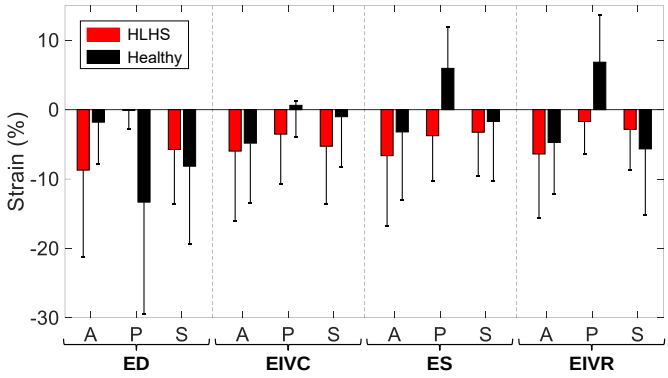

**Figure 3: Quantified strain in each TV annulus segment for: (a) the HLHS newborns ($n$=8), and (b) the healthy patients ($n$=4). Values are mean±SEM. (A: Anterior, P: Posterior, S: Septal)**

## DISCUSSION

We have presented a *novel*, comprehensive TV annulus analysis framework based on 4D echocardiographic images. This framework has been shown to be potentially useful for completing our understanding of the annulus biomechanics. For example, we have found that the HLHS-afflicted TV annulus is significantly larger and geometrically distinct from the healthy ones; however, the tissue strains are similar, suggesting that in both scenarios the tissue may maintain a homeostatic strain state during embryonic development. While a larger cohort is warranted to validate this postulation, *the implication of our findings* is that constriction of the TV annulus in HLHS may disrupt the homeostatic tissue strain, and alternative repairs may be necessary to avoid adverse TR initiation and development. Further, our framework serves as an important foundation for future longitudinal studies and determination of *biomechanics-based TR factors for risk stratification*.

## INTRODUCTION

Nearly 80% of women who undergo vaginal delivery will experience some degree of laceration of the vagina and surrounding tissues.[1] To make recommendations for preparatory treatment or an alternative mode of delivery (i.e. cesarean section), obstetricians need real-time computational tools which can predict the trauma from vaginal delivery. While the mechanics of birth-related vaginal lacerations have been investigated experimentally[2], computational methods have not been applied to the modeling and prediction of said trauma. Unfortunately, performing such predictions using sophisticated finite element (FE) models of the reproductive system is computationally expensive, making it impractical for real-time interventions. In this study, we propose reduced order modeling (ROM) techniques to capture the deformations of a torn vaginal canal, showing the potential of these techniques as real-time predictive tools for maternal birth trauma.

## METHODS

For this study, we used the commercial FE software, *Abaqus*, to create an FE full order model (FOM) simulation of the vagina undergoing inflation. The FOM geometry and boundary conditions were chosen to resemble the experimental setup used by McGuire et al. to investigate vaginal inflation and rupture.[2] Figure 1(a) displays the FOM geometry, which resembles a hollow prolate spheroid, with an initial outer diameter at mid-span of 10.2 mm, a uniform thickness of 0.3 mm, and a height of 12 mm. The inner diameter at the top surface was 4.2 mm and the inner diameter at the bottom surface was 5.16 mm. An elliptical hole was placed on the geometry's surface to represent a tear in the vagina. The tear was 5.4 mm long and 1.08 mm wide at mid-span.

For our material model, we selected the Holzapfel-Gasser-Ogden strain energy (c=6 kPa, D=0.05, $k_1$= 10 MPa, $k_2$=10, κ=0.25, N=2) with fiber orientations that differed in three equally sized regions along the longitudinal axis of the vagina (the anterior, middle, and posterior vagina).[3,4] Fiber families' orientations, $\beta$, were defined with hoop direction of the vagina representing 0° in the anterior and middle regions, and the longitudinal direction representing 0° in the posterior region. Within a given region, the orientation angle of one family of fibers would be positive and the other would be negative, but both families would have the same magnitude (either $\|\beta_1\| = \|\beta_2\| = 35^\circ$ or $\|\beta_1\| = \|\beta_2\| = 25^\circ$). These two fiber orientation angle magnitudes varying across the three regions of the vagina yielded eight total fiber orientation combinations. Each combination was used to simulate 30 internal pressure steps in equal increments from 2.5 to 75 kPa to produce the 240 solutions which made up our FOM snapshots. One representative solution is shown in Figure 1 (b).

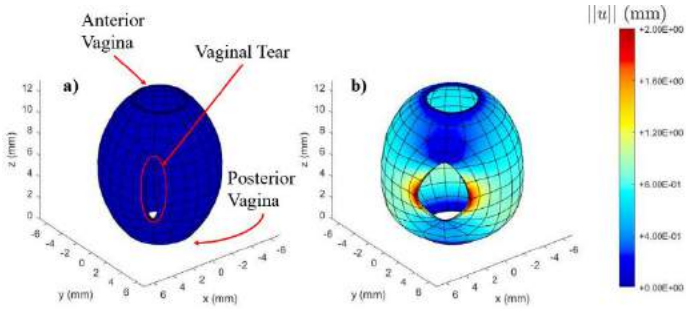

**Figure 1. (a) Undeformed FOM geometry and (b) fully deformed FOM geometry ($p_i$ = 75 kPa; $\beta$ = 35° in all regions).**

For our first reduction method, Galerkin ROM (G-ROM), we used the proper orthogonal decomposition (POD) method[5] to determine the POD basis of rank $l$ for the set of displacement vectors spanned by our snapshots, $\{\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_n\}$ in $\mathbb{R}^m$ ($m$ = 10,257; $n$ = 240; $l \leq \min\{m, n\}$). Let $\boldsymbol{U}$ be the $m$ x $n$ matrix whose columns are the snapshots: $\boldsymbol{U} = [\boldsymbol{u}_1, \ldots, \boldsymbol{u}_n]$. Let $\boldsymbol{\Psi}$ be the $m$ x $l$ matrix whose columns are the POD

basis: $\boldsymbol{\Psi} = [\boldsymbol{\psi}_1, \dots, \boldsymbol{\psi}_l]$. The snapshot matrix, $\boldsymbol{U}$, is then approximated by the $m$ x $n$ matrix $\boldsymbol{U}^{ROM} = [\boldsymbol{u}_1^{ROM}, \dots, \boldsymbol{u}_n^{ROM}]$ with

$$\boldsymbol{u}_i^{ROM} = \boldsymbol{\Psi}\boldsymbol{\zeta}, \tag{1}$$

where $\boldsymbol{\zeta}$ is an unknown $l$ x 1 column vector.

The substitution of the $\boldsymbol{u}_i^{ROM}$ into the finite element system of equations, $\boldsymbol{K}\boldsymbol{u} = \boldsymbol{f}$, where $\boldsymbol{K}$ is the $m$ x $m$ stiffness matrix, $\boldsymbol{u}$ is the $m$ x 1 displacement vector, and $\boldsymbol{f}$ is the $m$ x 1 load vector, yields: $\boldsymbol{K}\boldsymbol{\Psi}\boldsymbol{\zeta} = \boldsymbol{f}$. By multiplying both sides of said equation by $\boldsymbol{\Psi}^T$we obtain

$$\boldsymbol{\Psi}^T\boldsymbol{K}\boldsymbol{\Psi}\boldsymbol{\zeta} = \boldsymbol{\Psi}^T\boldsymbol{f}. \tag{2}$$

On the left side of Eq. (2), $\boldsymbol{\Psi}^T\boldsymbol{K}\boldsymbol{\Psi}$ is an $l$ x $l$ matrix, and on the right side, $\boldsymbol{\Psi}^T\boldsymbol{f}$ is an $l$ x 1 column vector, so Eq. (2) can be solved to find an $l$ x 1 column vector, $\boldsymbol{\zeta}$. Thus, the $m$-dimensional FOM (FE) system of equations is reduced to the $l$-dimensional system of equations (2) ($l \ll m$). We then solve for $\boldsymbol{\zeta}_i$ and $\boldsymbol{u}_i^{ROM}$ for $i = 1, \dots, n$.

Next, we leveraged the *data-driven variational multiscale ROM* (DD-VMS-ROM) framework to increase the accuracy of the ROM at a modest computational overhead. In addition to $\boldsymbol{\Psi}$, we introduce the $m$ x ($d$ – $l$) matrix, $\boldsymbol{\Psi}' = [\boldsymbol{\psi}_{l+1}, \dots, \boldsymbol{\psi}_d]$ of additional POD basis functions where $d > l$. Thus, Eq. (1) becomes

$$\boldsymbol{u}_i^{ROM} = \boldsymbol{\Psi}\boldsymbol{\zeta} + \boldsymbol{\Psi}'\boldsymbol{\zeta}', \tag{3}$$

where $\boldsymbol{\zeta}'$ is a ($d$ – $l$) x 1 vector of unknowns corresponding to $\boldsymbol{\Psi}'$. Substituting Eq. (3) into the FE equations and performing Galerkin projection onto the space spanned by the POD basis, we get

$$(\boldsymbol{\Psi}^T\boldsymbol{K}\boldsymbol{\Psi})\boldsymbol{\zeta} + (\boldsymbol{\Psi}^T\boldsymbol{K}\boldsymbol{\Psi}')\boldsymbol{\zeta}' = \boldsymbol{\Psi}^T\boldsymbol{f}. \tag{4}$$

We then make the following ansatz:

$$(\boldsymbol{\Psi}^T\boldsymbol{K}\boldsymbol{\Psi}')\boldsymbol{\zeta}' \approx \widetilde{\boldsymbol{\Psi}}\boldsymbol{\zeta}, \tag{5}$$

where $\widetilde{\boldsymbol{\Psi}}$ is an $l$ x $l$ matrix which we can use data-driven modeling[6] to solve for via least-squares:

$$\min_{\widetilde{\boldsymbol{\Psi}} \in \mathbb{R}^{l \times l}} \sum_{i \in \{1,\dots,n\}} \left\| (\boldsymbol{\Psi}^T\boldsymbol{K}_i\boldsymbol{\Psi}')\boldsymbol{\zeta}_i'^{\boldsymbol{FOM}} - \widetilde{\boldsymbol{\Psi}}\boldsymbol{\zeta}_i^{\boldsymbol{FOM}} \right\|^2, \tag{6}$$

$$\boldsymbol{\zeta}_i^{\boldsymbol{FOM}} = \boldsymbol{\Psi}^T\boldsymbol{u}_i \text{ for } i = 1, \dots, n, \tag{7}$$

$$\boldsymbol{\zeta}_i'^{\boldsymbol{FOM}} = (\boldsymbol{\Psi}')^T\boldsymbol{u}_i \text{ for } i = 1, \dots, n. \tag{8}$$

Thereafter, $\boldsymbol{\zeta}_i$ for the DD-VMS-ROM can be determined by

$$(\boldsymbol{\Psi}^T\boldsymbol{K}_i\boldsymbol{\Psi} + \widetilde{\boldsymbol{\Psi}})\boldsymbol{\zeta}_i = \boldsymbol{\Psi}^T\boldsymbol{f}_i. \tag{9}$$

From the DD-VMS-ROM framework, we also construct the ideal ROM (I-ROM) which represents the ideal performance of the DD-VMS-ROM. The I-ROM is determined by solving Eq. (9) assuming $\widetilde{\boldsymbol{\Psi}}\boldsymbol{\zeta}_i^{\boldsymbol{FOM}} = (\boldsymbol{\Psi}^T\boldsymbol{K}_i\boldsymbol{\Psi}')\boldsymbol{\zeta}_i'^{\boldsymbol{FOM}}$ rather than solving for $\widetilde{\boldsymbol{\Psi}}$ via Eq. (6).

## RESULTS

Normalized $L^2$-norm error was calculated between the ROM solutions and the projection of the FOM solutions onto the POD basis. Errors for G-ROM, DD-VMS-ROM, and I-ROM were recorded for a range of POD bases with rank $l = 1, \dots, 150$ (Figure 2). Both the G-ROM and DD-VMS-ROM exhibited severe diminishing returns in error improvements for $l$ > 50. Neither method achieved the full potential suggested by the I-ROM with the given POD bases.

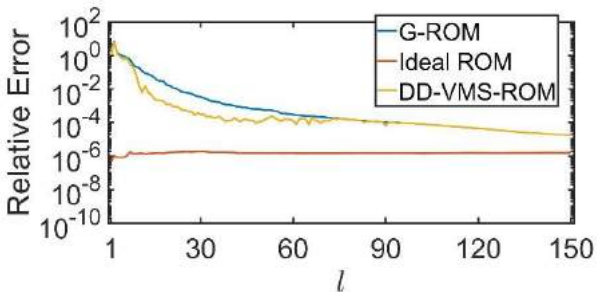

**Figure 2. $L^2$-norm error of ROM solutions vs. FOM projection for $\boldsymbol{l = 1, \dots, 150}$.**

In addition to the accuracy of our ROM methods, we compared their computational costs. We chose to measure such costs by the ratio of FOM on-line time to the on-line time of each ROM method which we call the Speed-up Factor (SUF). Table 1 shows SUFs for our ROM methods using POD bases of various ranks.

**Table 1. Comparison of SUFs for G-ROM and DD-VMS-ROM at selected values of $l$ from 1 to 150.**

| | Speed-up Factor | |
|---|---|---|
| $l$ | G-ROM | DD-VMS-ROM |
| $l$ = 1 | $5.34i \times i10^6$ | $4.32i \times i10^6$ |
| $l$ = 30 | $2.72i \times i10^6$ | $4.57i \times i10^5$ |
| $l$ = 60 | $1.15i \times i10^6$ | $2.15i \times i10^3$ |
| $l$ = 90 | $7.42i \times i10^5$ | $1.16i \times i10^3$ |
| $l$ = 120 | $1.69i \times i10^5$ | $6.30i \times i10^2$ |
| $l$ = 150 | $1.25i \times i10^5$ | $4.50i \times i10^2$ |

## DISCUSSION

We have successfully implemented a proof-of-concept for applying G-ROM and DD-VMS-ROM methods to an FE model of a vagina with a tear. The DD-VMS-ROM outperformed the G-ROM in terms of $L^2$ error for POD bases of rank $l = 10, \dots, 70$, after which our ansatz (5) did not appear to hold (Figure 2). We also noted the drastic increase in computational cost of the DD-VMS-ROM over the G-ROM as $l$ increased (Table 1), which indicated that the DD-VMS-ROM is only applicable in real-time for lower values of $l$. Given these limitations, our future work will involve either the improvement of our ansatz or pivoting to a new approach to model reduction, such as machine learning, for improving the accuracy and reducing computational costs of our FOM approximations.

# TRANSMURAL SOLUTE PERMEABILITY, BUT NOT HYDRAULIC CONDUCTANCE, INCREASES IN A MOUSE MODEL OF ASCENDING THORACIC AORTIC ANEURYSM

**Christie L. Crandall (1), Sean Y. Kim (2), and Jessica E. Wagenseil (1)**

## INTRODUCTION

Aortic aneurysms are ballooning or weakening of the aortic wall. Aneurysms occur in the thoracic or abdominal region, but rupture of thoracic aortic aneurysms (TAAs) accounts for twice as many deaths as abdominal aortic aneurysms[1]. Disruption of the extracellular matrix proteins, particularly the elastic fibers, are common in aneurysm walls[2]. Mutations in genes that regulate synthesis of the elastic fiber network are directly associated with TAAs[3].

Previously, we found that genetic and chemical disruption of the elastic fibers altered transmural fluid and solute transport in carotid arteries. Ascending thoracic aortas (ATAs), where genetic TAA are located, have a much higher elastin content and number of elastic fiber layers (called laminae) compared to the carotid artery. We hypothesized that similar disruption of the elastic fibers in TAAs may lead to altered fluid and solute transport and contribute to aneurysm growth, rupture, or be leveraged for local treatment options.

Here we investigated mass transport using a genetic mouse model of TAA caused by a heterozygous missense mutation in the lysyl oxidase gene that was identified in human patients. We present data from experiments which measured fluid flux values from solute present and solute absent in the ATA wall. Using measurements of solute flux we were also able to optimize values of tissue solute permeability and reflection coefficients to better understand wall mass transport.

## METHODS

**Mouse model.** A mouse line with a heterozygous missense mutation in lysyl oxidase (c.857T>G encoding M292R) was used in this study[3]. Male and female $Lox^{M292R/+}$ mice (n = 17) were compared to wild-type control $Lox^{+/+}$ (n =13). Mice were sacrificed at 4 months of age and the ATA was isolated by dissection.

**Solute Absent.** Each ATA was mounted in a 37°C PBS bath of a myograph (DMT) using 7-0 sutures. A pressure column was attached to the fluid inlet and the ATA was pressurized to 100 mmHg. The fluid column was filled with PBS and a bubble was introduced along the tubing. Length was measured using the myograph micrometer and the ATA was stretched to a 1.1x stretch ratio. Loaded diameter was additionally measured using a microscope. Assuming one-dimensional flow in the radial direction, fluid flux, $J_v$, was calculated directly from tracking the bubble displacement over time and the ATA dimensions[4].

**Solute Present.** Fluid in the pressure column was replaced with a solution of 5 mg/mL 4 kDa fluorescein isothiocyanate (FITC) Dextran (#46946, Sigma-Aldrich Co.). The ATA was allowed to equalize for 30 minutes, then rinsed with PBS and transferred, still mounted at 100 mmHg, to a bath of fresh PBS. Samples of the external bath concentration were taken every 10 minutes for 70 minutes. Solute flux, $J_s$, was calculated using the change in concentration of the bath over time and ATA dimensions[4]. During these 70 minutes, bubble displacement in the tubing was also tracked and $J_v$ was calculated.

**Solute Permeability.** Mass transport by advection and diffusion were considered by a 1-D transmural flow in response to a pressure ($\Delta P$) and solute ($\Delta c$) gradient. Hydraulic conductance ($L_p$) can be measured by the solute absent experiment ($\Delta c = 0$) using the equation below[5];

$$J_v = L_p(\Delta P - i\sigma RT\Delta c), \quad (1)$$

where $\sigma$ is the reflection coefficient, and $R$ and $T$ are the gas constant and temperature, respectively. Solute diffusivity is determined by the material's solute permeability ($\omega$). Combining this with the average concentration of solute ($c_s$) moved by advection we can calculate solute flux ($J_s$)[5],

$$J_s = \omega RT\Delta c + (1 - \sigma')c_s J_v, \quad (2)$$

where $\sigma'$ is a reflection coefficient. Eqn. 2 was evaluated both by placing the solute absent experimental value of $L_p$ into Eqn. 1 with the

experimental parameters, and by using the values of $J_v$ from the concentration present experiment ($\Delta ci \neq 0$). Relative errors of the squared calculated values for $J_s$ were used in an error function to solve for solute permeability and the two reflection coefficients.

**Statistics.** Outliers were first removed using ROUT in GraphPad Prism. All statistical comparisons shown were done using a single comparison in an ordinary one-way ANOVA and p-values <0.05 were considered significant.

## RESULTS

When pressurized to 100 mmHg on the myograph system and loaded at a 1.1x axial stretch ratio, length and diameter of the ATAs were measured. Although measurements in the *Lox*$^{M292R/+}$ group trended higher, there were no significant differences (Fig 1).

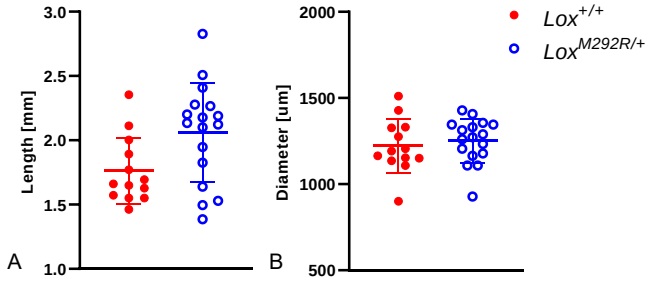

**Figure 1: Length (A) and diameter (B) of dissected ATAs loaded at 1.1x stretch ratio and 100 mmHg internal pressure.**

Using the bubble tracking system to measure fluid flux in both a solute absent and present experiment, the solute absent data were used in Eqn. 1 to solve for hydraulic conductance. No significance difference was found when comparing the hydraulic conductance, however, fluid flux when solute was present, $J_{v_s}$, was significantly higher by 115% in the *Lox*$^{M292R/+}$ group compared to wildtype (Fig. 2).

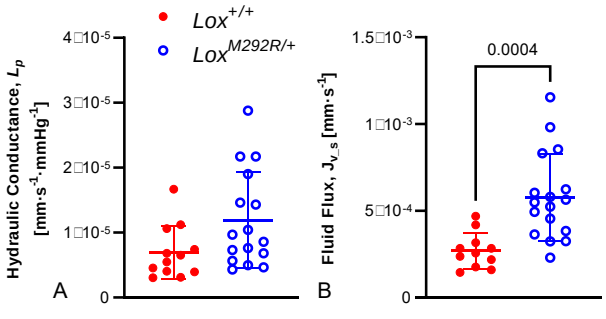

**Figure 2: Hydraulic conductance (A) and fluid flux (B) from solute absent and solute present experiments.**

With solute present, the change in concentration of the external bath was measured and used to solve for solute flux. The bath concentration was significantly higher in *Lox*$^{M292R/+}$ ATAs beginning at 30 minutes, which resulted in a 146% higher solute flux (Fig. 3). Using the data from Figs. 2 and 3 in Eqns. 1 and 2, we were able to optimize parameters of solute permeability and reflection coefficients. The *Lox*$^{M292R/+}$ group had a 147% higher permeability and 0.9% lower reflection coefficients (data not shown).

## DISCUSSION

The *Lox*$^{M292R/+}$ mutation is associated with TAA due to disrupted

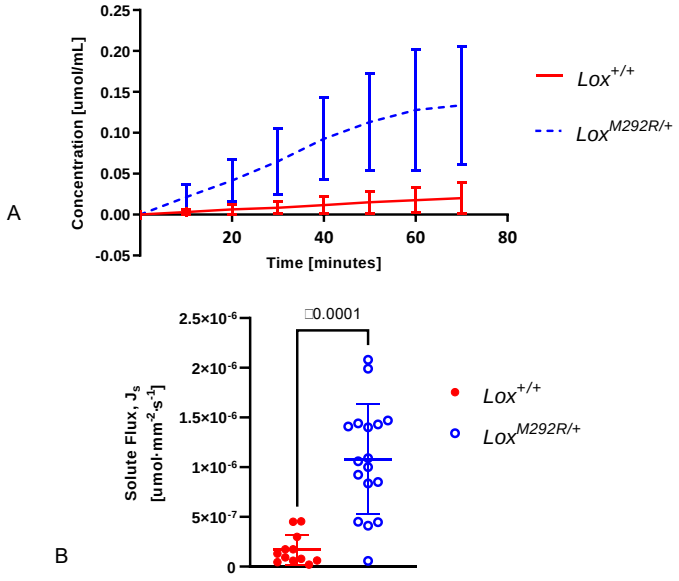

**Figure 3: Concentration of the external PBS bath over time (A) and calculated solute flux through the wall (B).**

elastic laminae organization[3], which we hypothesized would affect mass transport. Here, we measured properties of both fluid and solute transport through the wall of ATAs with and without the TAA model mutation. Our measured geometry values were not significantly different, indicating no aneurysm formation in this model. Previously, additional conditions like hypertension were used to push the aneurysm phenotype[3]. Despite the lack of aneurysm formation, the *Lox*$^{M292R/+}$ group had greater solute permeability.

Determining the contributions of advection and diffusion in mass transport can be useful in understanding TAA pathology and potential drug delivery. Peclet numbers were calculated for all experiments and were < 1 in 65% of the *Lox*$^{M292R/+}$ ATAs compared to 0% of the wildtype ATAs. This means that diffusion dominated in most of the *Lox*$^{M292R/+}$ ATAs, but not in the wildtype ATAs. Combined with a lower reflection coefficient in *Lox*$^{M292R/+}$ ATAs, this indicates that the flow of solute is less dependent on fluid flow in the TAA model.

Our study provides an initial understanding of transmural mass transport in the ATA for wildtype mice and a TAA model. Future investigations will examine differences in the laminae wall structure to identify mechanisms for the increase in solute permeability. Elastic laminae have fenestrations that could differ in the TAA model and allow for more mass transport. There may also be differences in proteoglycan content, which provide pathways of transport for molecules and growth factors. We additionally will study other TAA models to determine if alterations in mass transport are a common finding that may contribute to TAA pathology or be leveraged for disease treatments.

## INTRODUCTION

Lower back pain (LBP) is a common and often debilitating condition that affects between 70% and 80% of adults[1], with socioeconomic costs totaling over $100 billion a year[2]. In many cases, LBP is caused by intervertebral disc degeneration, a progressive condition that is thought to be triggered by mechanical overloading[3]. Mechanical testing has been performed extensively on human and animal disc joints to better understand disc degeneration, develop detailed computational models[4,5], and guide biological repair strategies[6]. However, obtaining material properties is not always straightforward, as slight deviations in sample preparation or testing methodology can greatly impact reported findings[7].

Disc geometry is a necessary metric for normalizing material properties, but disc area and height are measured using different techniques. While some research groups use magnetic resonance imaging (MRI), computed tomography (CT), or X-ray imaging, others may rely on excising the disc to measure disc area. Because this removes constraining boundary conditions, we hypothesized that the method used to measure disc area and height would have a significant impact on reported material properties of the disc joint. To test this hypothesis, we evaluated three different methods for measuring disc height and six methods for measuring disc area. Axial compressive testing was conducted, and material properties were calculated using different disc geometry measurements for comparison.

## METHODS

**Sample Preparation.** Skeletally mature bovine tails were sourced from a local abattoir (n = 12). Surrounding musculature was removed and vertebrae were cut at the mid-transaxial plane to create bone-disc-bone motion segments, which were potted in polymethyl methacrylate (PMMA) to ensure plano-parallel loading faces. During sample preparation, discs were wrapped in gauze soaked with 0.15M phosphate buffered saline (PBS) to prevent dehydration. After joint segment preparation, disc geometry was measured at six different points.

**Geometry Measurement.** After potting, joint segments were CT scanned at 0.092 mm resolution to measure pre-swell height and area (Pre.CT). Segments were then hydrated in 0.15M PBS for 18 hours at 4°C and immediately rescanned to measure post-swell height and area prior to mechanical testing (Pos.CT). After testing, the disc width was measured *in situ* with calipers (In.Cal). The disc was then carefully excised using a scalpel, and disc height and width were remeasured (Ex.Cal). The transverse plane of the excised disc was imaged with a millimeter scale (Ex.ImJ). Finally, the disc was cut to the mid-transverse plane using a freezing stage microtome and reimaged (Mt.ImJ).

**Table 1. Geometry measurement methods.**

| Name | Method | Outcome |
|---|---|---|
| Pre.CT | Pre-swell CT scan | Area, Height |
| Pos.CT | Post-swell CT scan | Area, Height |
| In.Cal | Disc measured *in situ* with calipers | Area |
| Ex.Cal | Disc measured *ex situ* with calipers | Area, Height |
| Ex.ImJ | Disc measured *ex situ* with ImageJ | Area |
| Mt.ImJ | Disc microtomed, measured with ImageJ | Area |

Disc height and area were collected from CT scans using a custom written MATLAB code[8]. Briefly, disc area was measured in the mid-transverse plane and disc height was measured by dividing the midsagittal cross-sectional area by the midsagittal disc width. ImageJ was used to calculate the disc area from images of excised and microtomed discs. Unless otherwise specified, measurements were taken in triplicate using digital calipers, and average widths were used to calculate area assuming a circular cross section[9].

**Mechanical Testing**. A 50N compressive preload was applied for 5 minutes before applying cyclic compression between 0-10% strain (based on Pre.CT height; 0.5 Hz, 15 cycles). Sample dehydration was prevented by wrapping segments with saline soaked gauze. The last loading cycle was used for analysis, and data was adjusted for machine compliance. Conversions to stress and strain were calculated using

SB³C2022-012

different combinations of geometry measurement. Stress-strain curves were generated and normalized compressive modulus was calculated as the slope of the linear region between 0.4 MPa and 0.6 MPa[10].

**Statistical Analysis.** Because data was paired and did not fit a Gaussian distribution, comparisons between groups were made using Friedman tests with Dunn's multiple comparisons adjustment. Statistical significance was assumed at $p \leq 0.05$.

## RESULTS

**Disc Geometry.** CT scanning of the bone-disc-bone segment resulted in an average disc height of 10.7±2.1 mm prior to swelling and 11.6±1.9 mm after swelling. There were no significant differences between Pre.CT and Pos.CT height (adj. p-val. = 0.3074), but Ex.Cal height was significantly smaller than both Pre.CT (-36%, adj. p-val. = 0.0128) and Pos.CT height (-44%, adj. p-val. < 0.0001; Fig. 1A). Disc area measurements demonstrated clear increasing trend, as boundary conditions were removed (Fig. 1B). Disc areas for Ex.ImJ and Mt.ImJ were both greater than Pre.CT area (+31%, p=0.0049 and +52%, p <0.0001, respectively; Fig. 1B).

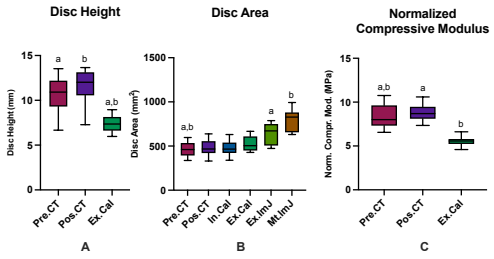

**Fig. 1. (A) Disc height and (B) disc area differences by method. (C) Normalized compressive modulus based on measurement method. Groups with the same letter represent p < 0.05.**

**Mechanics.** Due to variations in disc height between samples, the maximum applied load varied between 285N and 1250N (mean=655±341N). When load and displacement were transformed to stress and strain using Pre.CT values, normalized compressive modulus was 8.39±1.38 MPa. This was not significantly different when load and displacement were transformed using Pos.CT values (8.79±0.91 MPa, p = 1.0). However, the compressive modulus decreased significantly when load and displacement were transformed using Ex.Cal values (5.52±0.54 MPa, p=0.004; Fig. 1C). Figure 2 shows the effect of disc area measurement and disc height measurement on the calculated normalized compressive stress. When holding height constant, modulus calculated with Mt.ImJ area was 25% lower than the modulus calculated with Pre.CT area (8.39MPa vs 6.51MPa, p<0.0001), while modulus calculated with Ex.ImJ area was 13% lower (8.39 MPa vs. 7.36 MPa, p=0.0177). On average, using Ex.Cal disc height resulted in a 36% difference between reported modulus values when compared to Pre.CT height (Fig. 2, light grey vs. black bordered bars).

## DISCUSSION

Mechanical testing is an important measurement of disc health and function but comparing between studies can be challenging. This study investigated the contribution of methods for measuring disc geometry on compressive modulus.

Disc heights reported in the literature vary widely from ~5.5 mm to over 9 mm, partly due to differences in measurement approach[7,9-12]. Our values were closest to those reported by Beckstein *et al.* (9.18±0.65mm), who utilized fluoroscopic imaging of the disc joint; however, CT or X-ray imaging does not always correspond to greater disc heights. Disc height measured from CT images of intact bovine tails (6.8±0.90[9] mm and 6.90±0.35 mm[11]) are closer to disc height measurements reported after excising the disc (7.01±1.23mm[12] and 7.44±0.97mm). This may be due to disc expansion once surrounding soft tissue is removed and residual stresses are released[13].

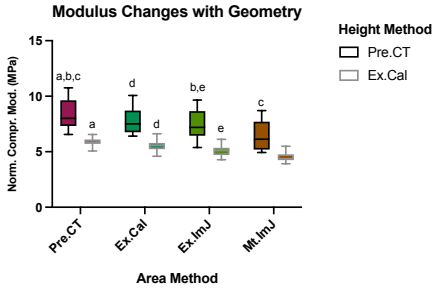

**Fig. 2. Modulus calculated with different height-area combinations. Groups with the same letter represent p < 0.05 (comparisons are made within groups – i.e., between solid fill groups and dark versus light bordered groups).**

While disc area measurements also varied by method, measurements were consistent while the disc remained bound by vertebral bodies. Pre.CT (465±79mm$^2$), Pos.CT (483±96mm$^2$), and In.Cal (480±89mm$^2$) area measurements agreed well with existing literature[7]. Area increased once the disc was excised and imaged, resulting in significantly higher measurements partly because disc boundary delineation is more challenging on an image. The highest disc area was reported when microtomed to the mid-transverse plane and measured using ImageJ (794±121 mm$^2$), which agreed well with publications that utilized the same method. While previous work by O'Connell *et al.* used this approach to compare disc geometry across species, the reported values have since been used to calculate disc mechanics.

The decrease in disc area and increase in disc height observed here had a significant effect of lowering the calculated compressive modulus (Fig. 2). Thus, we recommend using CT or X-ray imaging after preparing the motion segment to determine disc geometry, as it gives the best approximation at time of testing. If imaging is prohibitive, measuring the excised disc height at the outermost boundary may provide the closest approximation of disc height. Similarly, disc area can be measured *in situ* and approximated based on disc geometry, depending on species (*i.e.,* circle or ellipse).

Mechanical testing has been invaluable for understanding disc health and degeneration, but utilizing existing works requires a thorough understanding of the methods used and how those methods may impact reported values. As most studies report comparisons within a study, differences discussed here do not impact comparative outcomes. However, reliable comparisons between studies are valuable for reducing the need to re-test study groups in future studies. In summary, findings from this study showed that differences in reported moduli up to 65% may be attributed to differences in measuring geometry and not inherent mechanical properties.

## INTRODUCTION

Pulmonary diseases lead fatalities worldwide and annually cost more than $50 billion in the United States alone [1,2]; these staggering statistics exclude the respiratory impact of the ongoing COVID-19 pandemic. Exploring lung tissue characterization and its remodeling due to pathologies are necessary to better understand and prevent pulmonary diseases. While most previous airway characterization studies have been limited to the trachea [3], the distal airways are the main site of pulmonary pathologies and remain understudied [4]. Furthermore, due to the lack of experimental investigations, most computational analyses seeking to predict airway occlusion behavior in order to understand diseases, such as asthma and chronic obstructive pulmonary disease (COPD), model airways as an isotropic and homogenous material and are limited to extrapolating trachea properties for use in whole bronchial tree analyses[4].

To fill this major knowledge gap, we investigate the heterogenous and anisotropic material properties of airway tree, including proximal and distal airways, using biaxial mechanical tensile testing for the first time. Here we present quantified airway mechanics as assessed by measures of elasticity (initial and ultimate stiffness moduli) and energetics (hysteresis and energy loss) to examine the differences between circumferential and axial tissue orientations in four regions: the trachea, trachealis muscle, large bronchi, and small bronchi. This experimental data can inform computational predictive models and establish the much needed baseline for future examinations of healthy versus diseased bronchial mechanics.

## METHODS

Fresh lungs from seven pigs (200-250lb) were obtained from local abattoir and were tested within 75hrs, storing the whole lung in 1X phosphate-buffered saline (PBS) until testing [4]. The samples were collected from three levels of the airway tree including the trachea, large bronchi, and small bronchi with inner diameters averaging $18.57\pm2.6$, $8.39\pm1.45$, $4.94\pm0.96$mm, respectively. Tracheal specimens were obtained from two locations of the proximal ring: the posterior region which included the trachealis muscle, and the contralateral region termed as the trachea in this study [5]. Three samples were collected from each region of each pig and a total of 147 specimens were analyzed (excluding specimens which exhibited obvious tearing and damage during testing). The specimens were prepared by isolating the soft tissue from the cartilage and dissecting a square testing sample using a scalpel similar to past works [4,6]. The two orthogonal circumferential and axial orientation of the airway tissue was noted.

Specimens were loaded in a commercial planar biaxial machine (BioTester, CellScale Biomaterials Testing) and were hydrated using 1XPBS bath at 37°C [7]. Four cycles of preconditioning to 60% strain followed by a fifth cycle for analysis were implemented at a strain rate of 1%/s. The first Piola-Kirchhoff engineering stress and engineering strain were calculated.

Similar to past studies, the initial and ultimate moduli were defined as the slopes of the beginning and final portions of the bilinear stress-strain curves, fitted by setting the coefficient of determination $R^2$ to >0.90 [8]. Hysteresis was calculated as the area between the fifth loading and unloading stress-strain cycle, and it was further normalized by the area under the loading curve to define the energy loss.

Statistical comparisons of the circumferential and axial directions were performed by using one-way analysis of variance, and regional group comparisons were executed using two-way analysis of variance (MATLAB Statistics Toolbox, MathWorks Inc.). Significance was defined as $p<0.05$ with p-values reported in Figures 1 and 2.

## RESULTS

Figure 1 illustrates the regional dependance of airway tree for both circumferential and axial directions in terms of initial and ultimate moduli, as well as hysteresis and energy loss. Amongst specimens in the circumferential direction, the trachea was the stiffest overall (Figure

1A-B), with the greatest degree of hysteresis (Figure 1C) compared to other regions of the large bronchi, small bronchi, and trachealis muscle. The circumferential trachealis muscle exhibited the greatest energy loss compared to other circumferential regions (Figure 1D). Axial results were similar to that of the circumferential direction, where the trachea was significantly different compared to other regions in terms of the

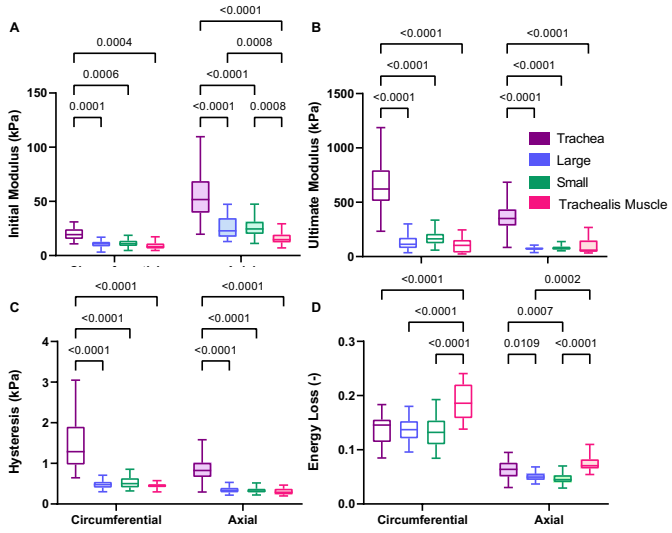

**Figure 1: The heterogeneity of airway tree elasticity (initial and ultimate modulus) and energetics (hysteresis and energy loss).**

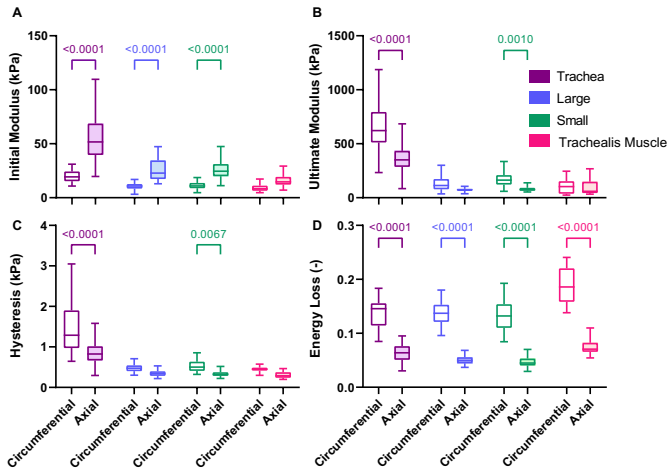

**Figure 2: The anisotropy of the airway tree assessed as measures of the initial modulus, ultimate modulus, hysteresis, and energy loss.**

initial modulus, ultimate modulus, and hysteresis (Figures 1A, 1B, 1C). Interestingly, while the trachea was the stiffest region both circumferentially and axially, its posterior region, the trachealis muscle, was significantly more compliant (Figure 1A-B). The axial trachea and trachealis muscle also exhibited the greatest energy loss compared to axial distal airways (Figure 1D).

The circumferential and axial mechanics of the airways were also evaluated as shown in Figure 2. The initial modulus of the specimens was observed to be stiffer axially compared to their circumferential counterparts (Figure 2A). However, the ultimate modulus transition demonstrated the reverse trend: the circumferential stiffness surpassed that of the axial direction, albeit this difference was only significant in the trachea and small bronchi samples (Figure 2B). When the directions were compared energetically, specimens had greater hysteresis in the circumferential orientation compared to the axial direction, with statistical significances noted in the trachea and small bronchi (Figure 2C). Energy loss was also found to be significantly greater in the circumferential rather than axial orientation for all four regions (Figure 2D).

## DISCUSSION

This study characterizes the biaxial mechanical properties of the bronchial tree for the first time, analyzing heterogeneous and anisotropic tendencies via measures of elasticity and energetics. Our results demonstrate significant directional and regional dependencies, highlighting current assumptions of airway isotropy and homogeneity to be an improper representation of respiratory mechanics. Furthermore, our findings emphasize the fact that the trachea cannot accurately exemplify the mechanics of the airway network. Additionally, the notable difference within tracheal ring underscores the importance of specifying regionality within tracheal specimens and motivates further histological assessments to understand the differences between the trachea and trachealis muscle.

Regional comparisons demonstrate that the trachea exhibits markedly different mechanics compared to the distal airways, both circumferentially and axially (Figure 1). This is in contrast to our past uniaxial experiments, which reported no regional dependency among axial specimens [4]. This difference may be attributable to biaxial versus uniaxial mechanics of testing, and histological differences observed between the trachea and distal airways: glycosaminoglycan (GAG) concentration is significantly decreased in proximal airways compared to distal bronchi [9]. Moreover, collagen and elastin fibers constituents are more taut and straightened in small bronchi, while they appear crimped in the trachea [1,9].

Our previous uniaxial investigations of the whole airway tree reported anisotropy with more compliant behavior in the circumferential direction [4]. The biaxial measurements reported in this work are in agreement (Figure 2A), with the initial modulus values consistent with previous values reported at 15% strain [4]. Notably, the circumferential stiffness of the trachea and small bronchi significantly increases to greater values than axial counterparts at greater strains, as measured by the ultimate modulus (Figure 2B). Conversely, the trachealis muscle is rather isotropic with similar initial and ultimate moduli in both circumferential and axial directions (Figure 2A, 2B). Specimens from all regions are more energy efficient axially compared to circumferentially, likely attributable to the axial orientation of the collagen and elastin fibers [4,10].

This first biaxial characterization of the airway tree serves as a foundation for future studies to explore deviations due to remodeling and diseased states, and facilitates computational modeling.

# CARPAL ARCH SPACE AUGMENTATION BY VOLARLY APPLIED FORCE ON THE SKIN SURFACE—A FINITE ELEMENT STUDY

**Hui Zhang, Zong-Ming Li**

Hand Research Laboratory, Departments of Orthopaedic Surgery and Biomedical Engineering,
University of Arizona, Tucson, AZ, United States

## INTRODUCTION

The carpal tunnel is a confined space that encases the median nerve and nine flexor tendons. Its narrow structure predisposes the median nerve to compression. If the compression continued, the nerve impair may deteriorate and eventually devolve into carpal tunnel syndrome. The standard surgical treatment is to transect the tunnel's volar boundary, i.e., the transverse carpal ligament (TCL). Meanwhile, non-surgical solutions serve as alternatives for patients who are not suitable for surgeries (e.g., mild or temporary symptoms). For example, manipulating carpal tunnel mechanics without transecting the TCL—either by radioulnar wrist compression [1, 2] or thenar muscle loading [3, 4]—was demonstrated effective to expand the tunnel and to provide additional space for the median nerve. In like manner, we proposed a new carpal tunnel augmentation approach by applying external dorsal-to-volar force on the volar skin surface of the wrist. The force influence may be propagated to the TCL through the connective tissues (such as fat or muscles) between the skin and TCL, bowing the ligament to enlarge the area under the ligament-formed carpal arch. Thus, the purpose of this study was to examine the effects of this carpal arch space augmentation approach by volarly applied force. We hypothesized that the carpal arch could be expanded by volarly applied forces on the wrist skin, and the arch morphological changes (quantified by carpal arch area, width, and height) would vary with respect to the force magnitude.

## METHODS

To obtain precise control of the force magnitude, we adopted finite element analysis. Moreover, considering that the median nerve at distal carpal tunnel is more prone to compression than other tunnel levels [5], our focus was narrowed down to the distal carpal arch. Therefore, we used a 2D finite element model of the distal carpal arch previously developed and validated in our laboratory [6]. To build the model, a cadaveric hand (male; left; age 74 years; BMI 30.3kg/m$^2$) was imaged by ultrasonography at distal carpal tunnel to obtain a cross section at the hook of hamate level. The image was segmented to obtain the geometrical information of the hamate, trapezium, thenar muscles, skin, fat, and TCL (Figure 1A). Then the cross section was extruded with 1-mm thickness.

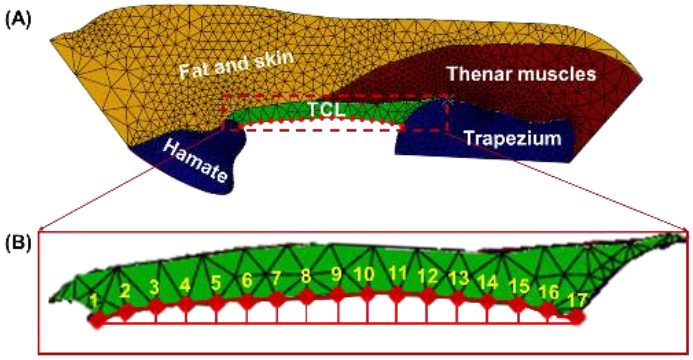

**Figure 1: Finite element model of the distal carpal arch with components and zoomed transverse carpal ligament (TCL). (A) Model components: the hamate, trapezium, thenar muscles, fat and skin, and TCL. (B) Nodes on the dorsal surface of the TCL.**

Material properties of these structural components were set on the basis of literature [6, 7]. In particular, the ligament's anisotropic modulus was implemented by adding tension-only nonlinear springs to strengthen the transverse modulus. To compensate for the missing of wrist bones, intercarpal ligaments and their functions, strings were added between the hamate and trapezium to simulate structural stiffness of the carpal arch based on a previous study [7]. As for boundary conditions, a tie constraint was set for all the interfaces with an assumption of ''no-slip" contact. All components had displacement boundary condition free in-plane but fixed out-of-plane. The hamate, along with the bottom edge of the fat-skin tissue adjacent to the hamate, was rigidly fixed. Pressure at 24 mmHg was applied to the dorsal surface of the TCL to simulate physiological intratunnel pressure.

A mesh convergence analysis was performed using h-refinement method. Three mesh sizes—the medium mesh, medium to fine mesh,

SB³C2022-014

and fine mesh—were tested on the TCL, thenar muscles, and skin-fat tissue with the same boundary conditions and material properties. The carpal arch's tensile strain and area were evaluated among the three meshes. The carpal arch's tensile strain was defined as the ratio of the TCL's dorsal length change to its original length. The deformed carpal arch area (under 24 mmHg) was normalized with respect to the corresponding initial arch area (0 mmHg). Among the three mesh sizes, the largest error for tensile strain was 1.9%, and for normalized carpal arch area the value was 1.8%. Therefore, the medium mesh was considered adequate. The validation process of the model was described in our previous paper [6].

To simulate dorsal-to-volar forces on the skin surface, we assumed that the force was evenly distributed on the wrist's volar surface, a squire of 20 mm × 20 mm (20 mm is the tunnel's length). As the model represented one slice (the distal level with 1-mm thickness) of the entire carpal tunnel, the magnitude of force applied on the model would be 1/20 of the total force on the wrist. Given five levels of forces on the wrist (from 2 to 10 N with an increment of 2 N), the corresponding force magnitudes on the distal carpal arch were from 0.1 to 0.5 N with an increment of 0.1 N. These forces were applied on the volar surface of the fat-skin tissue as pressure.

To quantify morphological changes of the carpal arch, the arch's area, height, and width were analyzed. The carpal arch area (CAA) was defined as the area enclosed by the TCL's volar edge and the line connecting node 1 and node 17 (Figure 1B). The carpal arch height (CAH) was defined as the distance from the most palmar node (node 10) on the TCL to the line connecting node 1 and node 17. The carpal arch width (CAW) was defined as the distance from TCL's node 1 to node 17. Moreover, the distances from rest nodes (nodes 2-16) to CAW were used to measure carpal arch bowing.

## RESULTS

The initial CAA without volarly applied forces was 13.15 mm$^2$. CAA increased under volarly applied forces, and the area increased more as the force magnitude increased (Figure 2A). The largest CAA was 22.96 mm$^2$, at 10 N force application. Similarly, CAH was increased during volar force application, and the height change increased as the force magnitude increased (Figure 2B). Under 10 N force application, CAH was increased from 1.13 mm to 2.03 mm. CAW, however, decreased under volarly applied forces (Figure 2C). The largest decrease in CAW occurred at 10 N was 0.27 mm (from 17.35 mm to 17.08 mm).

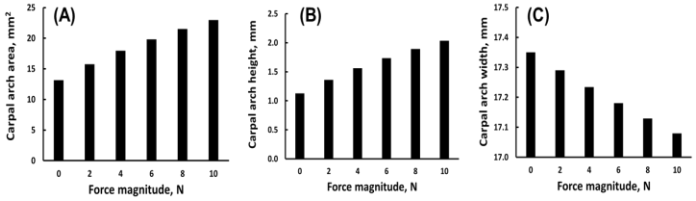

**Figure 2. Carpal arch area (A), height (B), and width (C) for different force magnitudes.**

The TCL was more bowed, shown by increases in the distance between the TCL's volar surface's nodes and CAW (Figure 3). All the nodes (except its two ends: node 1 and node 17) on the TCL's dorsal surface were volarly migrated, and the migration increased as the force magnitude increased. The greatest displacement of the TCL was 0.90 mm at its midpoint, and the displacement decreased towards the ligament's two ends.

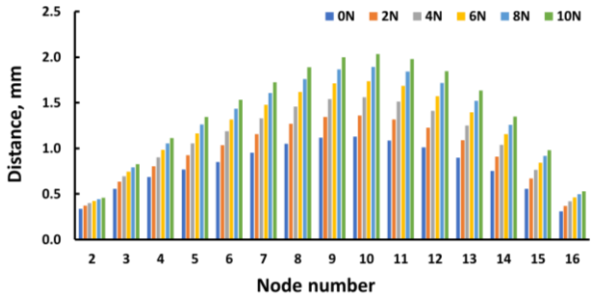

**Figure 3. Distance between the nodes and the CAW line at different force levels.**

## DISCUSSION

The simulation demonstrated that the carpal arch can be expanded by volarly applying forces on the skin surface of the wrist. As the force was applied, the fat and skin, thenar muscles, and TCL were pulled volarly. In the dorsal-volar direction, the largest displacement occurred at the skin surface where the force was applied. Then the force effect started to diminish dorsally as the influence propagated towards the TCL via connective tissues between the skin and ligament (such as fat or muscles). On the TCL, the force deforming effect still remained. The largest displacement on the TCL happened in the middle section and tapered down towards the ligament's two ends, which can be explained by the ligament's two ends being restrained by the hamate and trapezium (Figure 3). These displacements resulted in the increase in CAH and the decrease in CAW, which leads to an increase in CAA and to an expansion of the carpal arch.

Regarding carpal tunnel manipulation, many factors impact the mechanical effect on the carpal arch morphology, such as mechanical properties of the soft tissues, intratunnel pressure level, magnitude of the manipulation force [6]. As for volarly applied force on the skin surface, these factors may still affect carpal arch changes. In this simulation, we focused on the factor force magnitude. Within the current range of force magnitudes, larger forces deformed the carpal arch morphology more, shown by further increases in CAA and CAH and decreases in CAW as the force magnitudes increased. Moreover, larger forces further increased the bowing of the TCL, shown by larger volar displacements of the nodes on the ligament's volar surface. We expect these changes, however, may finally reach a plateau due to biomaterials' nonlinear mechanical properties.

The study has some limitations. First, the model is two-dimensional, which limits its findings to the distal level of the carpal tunnel. To get a comprehensive evaluation of the force effects on the entire carpal tunnel, future studies should expand the current model to a three-dimensional one. Second, *in vitro* or *in vivo* experiments can help confirm the current findings. In these experiments, we should apply volar force onto the wrist and image the carpal tunnel simultaneously. Furthermore, the experimental results could be used to validate future three-dimensional models.

# THREE-DIMENSIONAL RECONSTRUCTION AND ANALYSIS OF THE MEDIAN NERVE USING ROBOT-ASSISTED ULTRASONOGRAPHY

**David Jordan, Hui Zhang, Zong-Ming Li**

Hand Research Laboratory, Department of Orthopaedic Surgery, University of Arizona College of Medicine, Tucson, Arizona, US

## INTRODUCTION

Carpal tunnel syndrome is a compression neuropathy that affects a large portion of the population[1] and is characterized by the compression of the median nerve within the carpal tunnel. The degree of nerve compression is often determined using two-dimensional ultrasonography, whereby an ultrasound probe is positioned transversely at the wrist crease with a fixed position and inclination angle. Given the subjective positioning of the probe, the resulting two-dimensional outcomes can vary between examiners. The discrete nature of the measurements also limits the extent of the available analysis methods. These limitations can potentially be overcome by utilizing a method which can accurately reconstruct the three-dimensional median nerve geometry using ultrasonography.

The two-dimensional properties of the median nerve within the carpal tunnel of healthy individuals have been studied with respect to a variety of influences and compared to the outcomes for individuals with carpal tunnel syndrome. These measurements include nerve cross-sectional area which has been shown to be larger for individuals with carpal tunnel syndrome[2]. Changes in transverse nerve position, perimeter and circularity resulting from active finger motion have also been quantified[3,4]. These studies have shown the difference in median nerve properties between healthy and patient groups. Near the carpal tunnel, these measurements are often taken at the distal or proximal wrist crease.

The properties of the median nerve outside the carpal tunnel have also been evaluated and proposed as a potential comparison tool for the nerve conditions within the tunnel. These studies include using a wrist-to-forearm cross-sectional area ratio as a potential evaluation measure, showing that individuals with carpal tunnel syndrome have a significantly larger ratio[5]. These studies highlight the complexity of the nerve properties within the carpal tunnel and along the forearm.

In order to advance the analysis methods of the median nerve relevant to the understanding of carpal tunnel syndrome, a method which can accurately reproduce the three-dimensional nerve geometry would be useful. This method would need to minimize the subjectivity of probe positioning and produce a continuous nerve model of arbitrary length which can be analyzed for a variety of anatomic measurables at any location along the nerve.

## METHODS

The subject was seated with their arm lying supine on a table with their elbow flexed at ninety degrees. A custom fixation device was used to secure the arm in this stable position and prevent forearm and finger motion. An ultrasound probe was attached to a six degree of freedom COBOTTA robot (Figure 1). The initial position of the robot and probe was set at the distal carpal tunnel, where a clear image of the median nerve and hook of hamate could be visualized.

A custom LabView program was used to control the motion of the robot. The motion of the robot was defined with respect to a coordinate system approximately centered at the location of the median nerve within the participant wrist. The coordinate axes were defined as +y distal, +x ulnar and +z dorsal (Figure 1).

**Figure 1. Robot and ultrasound scanning configuration**

The prescribed motion consisted of a series of 1 mm proximal translations in -y. At each proximal translational increment, the robot

rotated the ultrasound probe ±5˚ about the x-axis (transverse axis). At each position, an ultrasound image was programmatically taken. This continued for a total proximal translation of 30 mm, resulting in 341 ultrasound images (31 translations x 11 rotations).

Using a custom MATLAB script, the median nerve was manually segmented from each image. Images where the nerve could not be distinguished were discarded. The two-dimensional segmentation coordinates (u,v) measured with respect to the ultrasound imaging plane, were then transformed into three-dimensional coordinates (x,y,z) measured with respect to the robot base coordinate system. This was done using Equation (1), where $[T_{EI}]$ and $[T_{RE}]_i$ were the kinematic transformations from the respective coordinate systems of the ultrasound image to the robot end-effector (EI) and from the robot end-effector to the robot base (RE), for probe position i.

$$\begin{bmatrix} x \\ y \\ z \\ 1 \end{bmatrix} = [T_{RE}]_i [T_{EI}] \begin{bmatrix} u \\ v \\ 0 \\ 1 \end{bmatrix} \quad (1)$$

The transformed discrete data was then meshed and smoothed in order to produce the three-dimensional nerve model (Figure 2). The centroidal data of the segmentations was used to form the centroidal curve of the nerve. This curve was parameterized in the form of Equation (2). Equations (3) and (4) were then used to make measurements of nerve curvature κ and centroidal nerve length s. At any length s, the cross-sectional area of the nerve mesh was measured in a plane whose normal vector was parallel to the tangent vector of the centroidal curve*. The area distribution A(s), calculated for the entire nerve, was used to compute the nerve volume $\mathcal{V}$, between any two nerve lengths $s_a$ and $s_b$ (Equation 5). Nerve circularity $\mathcal{C}$, was calculated as shown in Equation (6), where P(s) was the nerve perimeter.

$$\mathbf{r}(t) = h(t)\hat{\mathbf{i}} + g(t)\hat{\mathbf{j}} + f(t)\hat{\mathbf{k}} \quad (2)$$

$$\kappa = \frac{|\mathbf{r}'(t) \times \mathbf{r}''(t)|}{|\mathbf{r}'(t)|^3} \quad (3)$$

$$s = \int_{t_a}^{t_b} \left[ \left(\frac{dh(t)}{dt}\right)^2 + \left(\frac{dg(t)}{dt}\right)^2 + \left(\frac{df(t)}{dt}\right)^2 \right]^{\frac{1}{2}} dt \quad (4)$$

$$\mathcal{V} = \int_{s_a}^{s_b} A(s)\,ds \quad (5)$$

$$\mathcal{C} = P(s)^2 / 4\pi A(s) \quad (6)$$

## RESULTS

Figure 2 shows the results for the three-dimensional nerve mesh, centroidal curve and parametric basis vectors ($\hat{\mathbf{e}}_1$-tangent, $\hat{\mathbf{e}}_2$-normal, $\hat{\mathbf{e}}_3$-binormal) at a given location of total nerve length.

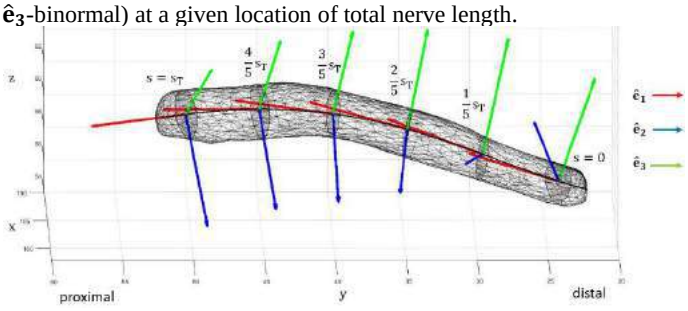

**Figure 2. Three-dimensional median nerve.**

Tables (1) gives the results for two-dimensional nerve measurements taken at given locations of the total nerve length. Table (2) gives the volume results for the corresponding nerve segments.

**Table 1. Median nerve CSA, curvature and circularity.**

| Nerve Length | $s = 0$ | $\frac{1}{5}s_T$ | $\frac{2}{5}s_T$ | $\frac{3}{5}s_T$ | $\frac{4}{5}s_T$ | $s = s_T$ |
|---|---|---|---|---|---|---|

## DISCUSSION

The scanning method provided a thorough means of collecting ultrasound images of the median nerve. The sequential probe translation along the proximal direction and rotation around the transverse axis helped to reduce some of the positional biases commonly experienced with taking a limited number of single images. The large collection of images, combined with the three-dimensional transformation process, helped to generate a comprehensive reconstruction of the three-dimensional median nerve.

Reconstruction of the three-dimensional nerve provided a continuous model which helped to reduce the limitations experienced with taking traditional discrete measurements. With the continuous model, measurements can be taken at any location along the nerve. The parameterization of the centroidal curve and the calculation of nerve length, allowed for the measurement of nerve cross-sectional area, curvature and circularity at any fraction of the total nerve length. Describing the results with respect to position along the nerve, as opposed to position along the forearm, is important because the nerve may not be entirely straight within the forearm, as quantified by the curvature. The parameterized basis vectors provide a dynamic right-handed system (Frenet Frame) which can be used to describe the in-vivo nerve orientation.

With traditional imaging, it can be difficult to obtain a standardized representation of the nerve cross-section between individuals. With the continuous model, the nerve cross-section can be mathematically defined and consistently reproduced between subjects. The measurements of nerve volume can potentially be used as a three-dimensional evaluation criteria of nerve compression by observing how the volume of the nerve changes along the nerve length.

In conclusion, this work provides a method for generating a three-dimensional model of the median nerve, for which continuous measurements of nerve features relevant to the evaluation of carpal tunnel syndrome can be made. Limitations include the inherent errors associated with manual segmentation, automated surface generation and surface correction operations. Although the large collection of images can help to minimize these errors, they are likely to still be present and affect the nerve shape and measurement results.

# DOSE- AND TIME-DEPENDENT EFFECTS OF COLLAGENASE CLOSTRIDIUM HISTOLYTICUM INJECTION ON STIFFNESS AND THICKNESS OF IN VITRO TRANSVERSE CARPAL LIGAMENT

**Jocelyn Hawk, Sohail Daulat, David Margolis, Zong-Ming Li**

Department of Orthopaedic Surgery, University of Arizona, Tucson, AZ, USA

## INTRODUCTION

The transverse carpal ligament (TCL) is a band of tissue constituted by collagen fibers types I and III and is relevant to carpal tunnel syndrome due to its volar restriction of the median nerve. The most common surgical procedure for carpal tunnel syndrome is to transect the TCL, which can disrupt the important biomechanical functions of the TCL and result in side effects such as pillar pain and hand weakness [1]. A possible alternative to surgery is to decompress the median nerve by biochemically altering TCL stiffness and thickness.

Collagenase Clostridium Histolyticum (CCH) is an enzyme that breaks down collagen fibers, and has previously been used in injection to treat Dupuytren's contracture, a condition characterized by formation of collagen cords in the hand, causing finger contractures and impaired hand function [2]. Similar to its use for Dupuytren's contracture, CCH injection to the TCL could potentially be used as a treatment for carpal tunnel syndrome. In order to decrease TCL stiffness and thickness without disrupting the anatomy of the TCL, determining an effective and safe dose of CCH to deliver to the TCL is needed. Therefore, the objective of this study was to assess the time- and dose-dependent effects of CCH on the stiffness and thickness of the TCL in vitro.

## METHODS

The TCLs of 9 fresh-frozen cadaveric hands were removed from the hand and each sutured to a fabric platform. On each TCL specimen, five injection points were marked on the volar surface of the TCL using tissue marking dye. These points were the center of the TCL (O), and four radial (A), ulnar (B), distal (C), and proximal (D) to the center by 5mm, respectively. The platform was then rigidly fixed in an incubator with the temperature set to 37ºC.

A coordinate system for each injection point was established by digitizing each of the five injection points using a MicroScribe digitizer (Figure 1). The x-axis was defined as the AB vector, the z-axis as the cross product of vectors AB and CD, and the y-axis as the cross product of the z-axis and x-axis.

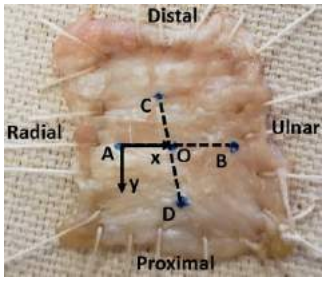

**Figure 1. A TCL specimen and one of the five injection point coordinate systems**

An 18L6 linear array transducer (SuperSonic MACH 30, Hologic Inc., Marlborough, MA, USA) was rigidly fixed to a 6-degree of freedom robot using a custom-made probe mount. A footprint coordinate system was established with its origin at the center of the probe footprint, its x-axis aligned with the horizontal axis of the image, its z-axis aligned with the vertical axis of the image, and its y-axis determined by crossing the z-axis with the x-axis.

CCH with a specific activity ≥125 Collagenase Digestion Units/mg solid (Sigma-Aldrich, St. Louis, MO) was dissolved in phosphate buffered saline to create five solutions of different concentrations such that the units of CCH per 5µL of each solution were 50U, 100U, 150U, 200U, and 250U, respectively. A microliter syringe with a 30G needle was used to inject 5µL of each solution into one of the five marked injection points at the middle of the TCL thickness.

A thin layer of ultrasound gel was applied to the surface of the TCL, and an ultrasound scan was done of each injection point immediately, 2 hours, 4 hours, 6 hours, 8 hours, and 24 hours after

injection (Figure 2). For each scan, the robot was programmed to move the probe to an initial position by superimposing the footprint coordinate system with each injection point coordinate system, except that the footprint coordinate system was offset 5mm in the negative-z direction. After the probe was moved to each initial position, the robot translated the probe 2mm in the positive and 2mm in the negative y-directions in the injection point coordinate system in 0.2mm steps. A shear wave elastography image and B-mode image were captured at each step.

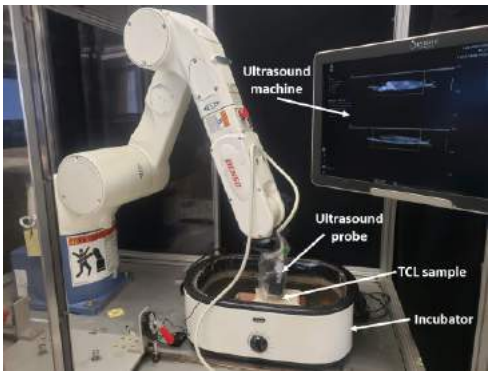

**Figure 2. Experimental setup for scanning procedure**

A region of interest for each injection point was defined as a rectangular prism centered on the injection point with a width of x=1mm, a length of y=1mm, and a height z that contained the entire TCL thickness. A custom LabVIEW program was used to determine the average shear wave speed of the TCL within the region of interest for each injection point from the shear-wave elastography images collected at each timepoint. TCL thickness was measured at each injection point from the B-mode image taken at that point using ImageJ.

Two-way repeated measures ANOVAs were performed with factors of dose and time using SigmaPlot 14 (Systat Software Inc. Chicago, IL). Analyses were performed with an alpha level of 0.05.

## RESULTS

Figure 3 shows shear wave speeds of each dose over time. There were no significant changes in shear wave speeds from time zero to any of the following timepoints within the doses of 50U, 100U, or 150U. For the dose of 200U, shear wave speeds decreased from time 0 by 12.05% and 18.70% at 8 and 24 hours, respectively. For the dose of 250U, shear wave speed decreased from time 0 by 11.96%, 11.46%, 11.20%, 13.92%, and 20.01% at 2, 4, 6, 8, and 24 hours.

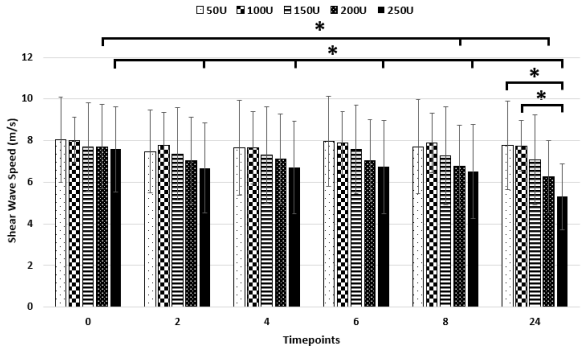

**Figure 3. Shear wave speed of individual doses at different timepoints**

Figure 4 shows the TCL thicknesses of each dose over time. TCL thickness for the 50U and 100U doses did not significantly change from time zero to any timepoint. For the 150U dose, TCL thickness significantly decreased after 8 hours and 24 hours by 4.74% and 7.28%, respectively. For the 200U dose, TCL thickness significantly decreased after 8 hours and 24 hours by 6.78% and 10.97%, respectively. For the 250U dose, TCL thickness significantly decreased after 6 hours, 8 hours, and 24 hours by 6.06%, 11.75%, and 14.92%, respectively.

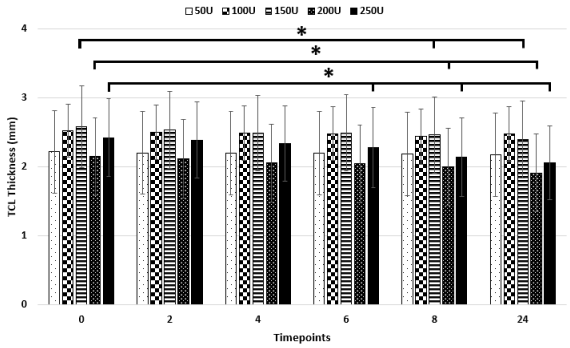

**Figure 4. TCL thickness of individual doses at different timepoints**

## DISCUSSION

As the first steps in assessing CCH injection as a viable treatment for carpal tunnel syndrome, we examined the dose- and time-dependent effects of CCH on TCL stiffness and thickness using isolated TCLs from cadaveric hands. Robot-assistance allowed for precise and accurate probe positioning, and shear-wave elastography imaging was used to measure shear-wave speeds within the TCL. Because elastic modulus can be determined by multiplying shear-wave speed with tissue density, changes in TCL stiffness could be represented by changes in shear-wave speed.

For injection of doses less than 150U, the enzymatic activity is not apparent as there were no significant changes in shear wave speed at any timepoints. As the dose increases to 200U and 250U, the tissue breaks down as indicated by decrease in shear wave speed. None of the doses of CCH resulted in high enough degradation to visibly change the outer surface of the TCL or break through the entire TCL thickness and create holes, suggesting that the effects of the CCH were contained within the boundaries of the TCL. Too much degradation not contained within the boundaries of the TCL could affect the biomechanical function of the TCL or allow the CCH to leak out and affect the surrounding structures.

This study found that higher doses of CCH result in greater and faster degradation of the TCL. Furthermore, injecting 150U or less of CCH has no significant impact on the mechanical properties of the TCL. Injecting 200U of CCH decreased TCL stiffness and thickness after a prolonged time (greater than 8 hours). A dose of 250U was the most effective for TCL degradation, significantly decreasing stiffness after 2 hours and thickness after 6 hours, as well as having the greatest percent decrease in stiffness and thickness after 24 hours. Future studies can investigate the effect of multiple CCH injections to the TCL on carpal arch morphology in situ.

## INTRODUCTION

Musculoskeletal pathologies such as rotator cuff tendon disorders of the shoulder are prevalent in the aging population[1]. Dysregulation of tendon homeostasis due to aging can result in premature sub-rupture damage accumulation, degeneration, and ultimately injury. Such changes occur primarily in regions of high and complex stresses, such as at the supraspinatus tendon insertion site of the shoulder[2]. While recent studies in patellar tendons showed inferior dynamic structural response to load, reduced elastic and viscoelastic mechanical properties, and altered fibril structure with aging[3], region and age dependent changes in the rotator cuff of the shoulder remain unknown. Therefore, the objective of this study was to elucidate region-dependent mechanical and structural differences in aging mouse supraspinatus tendon. We hypothesized that aging would result in region-specific mechanical and structural changes, such as inferior elastic and viscoelastic mechanical properties as well as altered collagen fiber realignment and fibril morphology, with larger alterations at the insertion site due to the complex functional demands in this region[2].

## METHODS

Animals: Forelimbs were collected from male wildtype mice sacrificed at either 300 (P300, n=20) or 570 (P570, n=20) days of age (UPenn IACUC approved), corresponding to ~40 and ~65 years of age in human[4], respectively. Elastic and Dynamic Viscoelastic Mechanics: All mice for mechanical testing were frozen at -20ºC until the day of testing. Mice were thawed at room temperature and the supraspinatus tendon-humerus complex from the left limb of each mouse was carefully dissected to remove extraneous tissue. Stain lines were applied for optical strain tracking of the insertion and midsubstance regions and a laser device was used to measure cross-sectional area of the supraspinatus tendon. The myotendinous junction was placed between two sandpaper tabs with cyanoacrylate glue to prevent slippage. The humerus was secured in a custom construct with polymethyl methacrylate and the construct was mounted on a material testing machine (Instron 5848). All testing was conducted in a phosphate buffered saline bath at 37ºC. Each sample was preloaded to 0.025N. The testing protocol consisted of 10 cycles of preconditioning, followed by stress relaxations at 3%, 5%, and 7% strain. Following each stress relaxation, frequency sweeps of 10 cycles of 0.125% amplitude sinusoidal strain at 0.1, 1, 5, and 10 Hz were performed. Following a 10-minute rest at zero displacement, a quasistatic ramp-to-failure at a strain rate of 0.1%/s was completed. Data were collected at 100Hz. Elastic parameters stiffness, modulus, maximum load, and maximum stress were quantified. Viscoelastic parameters dynamic modulus (E*), phase shift (tan $\delta$), and percent relaxation were quantified for each stress relaxation and frequency sweep. Fiber Re-Alignment: Throughout mechanical testing, dynamic collagen fiber realignment was quantified using cross-polarization imaging, and regional fiber alignment data was interpolated in MATLAB with a polynomial fit as a function of strain from the load-displacement data. Images were also used to optically measure strain and modulus in the insertion and midsubstance regions. Transmission Electron Microscopy: Supraspinatus tendons (n=4/age group) were isolated, fixed, and embedded in epon resin blocks. 85nm sections were cut using an ultramicrotome, stained with uranyless and phosphotungstic acid, and imaged at 60,000x using a transmission electronic microscope (JEOL 1010). Fibril diameter frequency distribution was quantified. Statistics: Region-specific tendon elastic mechanical properties and collagen fiber realignment were compared using two-way ANOVAs across age and region followed by Bonferroni post-hoc tests. Viscoelastic properties were compared using two-way ANOVAs across age and strain levels followed by Bonferroni post-hoc tests. Fibril diameter distributions were compared using Kolmogorov-Smirnov tests. Significance was set at $p<0.05$.

## RESULTS

Elastic and Viscoelastic Mechanics (Fig. 1): Cross-sectional area was greater at the insertion than in the midsubstance region in both age

groups. Stiffness and modulus were lower at the insertion than in the midsubstance region in both age groups. Midsubstance modulus had an interaction and decreased with age. The viscoelastic response was preserved with aging across strain levels. Specifically, there were differences in stress relaxation and dynamic modulus at 5 and 7% strain relative to 3% strain with aging. P300 tendons exhibited more relaxation at 3% relative to both 5 and 7% strain than P570 tendons. Phase shift was not altered across strain levels for either age group. As expected, all supraspinatus tendon samples failed at their insertion sites.

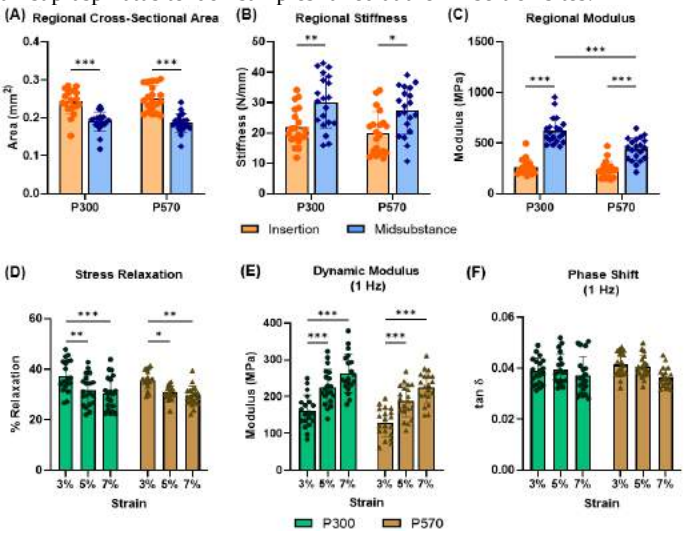

**Figure 1: Insertion regions demonstrated greater (A) cross-sectional area while midsubstance regions had greater (B) stiffness and (C) elastic modulus for both age groups. Elastic modulus was (C) reduced with aging. Viscoelastic properties were conserved with aging with similar differences across strain levels in (D) stress relaxation and (E) dynamic modulus and no differences across strain level in (F) phase shift in both age groups. Data as mean ± standard deviation (*p≤0.05, **p≤0.01, ***p≤0.001).**

Collagen Fiber Realignment (Fig. 2): Collagen fiber realignment had a significant interaction with region, but not age, in both age groups. Specifically, normalized circular variance was greater in the insertion than in the midsubstance region (indicative of less fiber alignment) between 3 and 9% strain in both the P300 and P570 age groups.

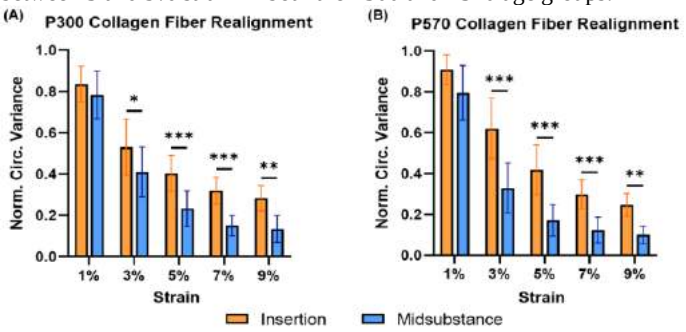

**Figure 2: Insertion regions demonstrated lower collagen fiber realignment (greater normalized circular variance) at strain values between 3 and 9% in the (A) P300 and (B) P570 age groups. Data as mean ± standard deviation (*p≤0.05, **p≤0.01, ***p≤0.001).**

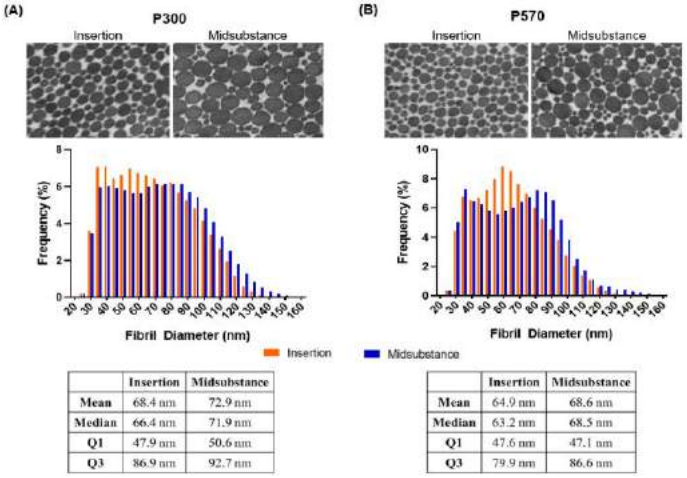
Fibril Morphology (Fig. 3): Fibril distributions were significantly different across region and age with smaller diameter fibrils at the insertion compared to the midsubstance within each age group. Insertion region fibrils had narrower distributions compared to the midsubstance fibril whereas midsubstance fibrils demonstrated typical bimodal distributions for both age groups. Aging resulted in a shift towards smaller diameter fibrils in the midsubstance region.



| | Insertion | Midsubstance |
|---|---|---|
| Mean | 68.4 nm | 72.9 nm |
| Median | 66.4 nm | 71.9 nm |
| Q1 | 47.9 nm | 50.6 nm |
| Q3 | 86.9 nm | 92.7 nm |

| | Insertion | Midsubstance |
|---|---|---|
| Mean | 64.9 nm | 68.6 nm |
| Median | 63.2 nm | 68.5 nm |
| Q1 | 47.6 nm | 47.1 nm |
| Q3 | 79.9 nm | 86.6 nm |

**Figure 3: Fibril diameter distributions for (A) P300 and (B) P570 age groups are similar with shifts towards smaller diameter fibrils in the insertion compared with the midsubstance region. Aging also resulted in a shift towards smaller fibrils in the midsubstance.**

## DISCUSSION

We studied regional properties in aging mouse supraspinatus tendons. Supporting our hypothesis, insertion regions exhibited inferior elastic mechanical properties and reduced collagen fiber realignment compared to midsubstance regions. Additionally, insertion region fibril size distributions shifted towards smaller fibril diameters. Previous studies in flexor tendons demonstrated that mechanical properties and fibril diameter distributions can differ from the bone-tendon junction to the myotendinous junction[5]. Interestingly, aging did not influence regional and whole tendon elastic and viscoelastic properties and collagen fiber realignment but did influence fibril morphology.

Multiscale regression analyses have shown that two strong predictors of mechanical properties at the insertion and midsubstance regions were collagen fiber realignment and fibril diameter[6]. Our results suggest potential multiscale structure-function mechanisms relating macroscale tissue mechanical behavior to microscale collagen fiber realignment and nanoscale fibril morphology. Specifically, in the insertion regions, decreased collagen fiber realignment, indicative of a reduction in dynamic structural response to load, in conjunction with smaller diameter fibrils unable to withstand the same loading magnitude results in inferior mechanical properties relative to the midsubstance region. This induces earlier accumulation of damage at the fiber and fibril levels propagating to the macroscale, ultimately leading to premature tendon failure at the tendon insertion[2], as observed in all supraspinatus tendon samples. Clinically, these structure-function mechanistic findings may further explain why supraspinatus tendon tears predominantly occur at its insertion on the proximal humerus[7].

This study reveals critical mechanical and structural differences in supraspinatus tendon region and age. Future studies will consider additional region-specific multiscale structural, functional, and compositional mechanisms in aging supraspinatus tendons.

## INTRODUCTION

In recent decades, pulmonary diseases, such as chronic obstructive pulmonary disease (COPD), have become one of the most common causes of death around the globe [1]; COPD alone is the third leading cause of death in the United States, with an $800 billion estimated cost in direct medical expenses over the next 20 years [2]. And now, COVID-19's impact on lung function is the most recent respiratory threat [3]. Various types of pulmonary diseases impact lung mechanical behavior differently: for instance, the fibrotic lung exbibits greater stiffness than the healthy lung, due to its increase in collagen fiber deposition [4]. These remodeling and disease effects, in turn, influence pulmonary function, and are assessed by global (bulk) lung mechanics. However, local lung behaviors and tissue level alterations can offer insights to better understand the effect of respiratory pathologies compared to global assessments [5]. These key considerations are thus far absent in the field. As such, we interface digital image correlation (DIC) with a custom pressure-volume ventilation device to simultaneously characterize local strain and associated global lung measures [6].

In this study, we quantify tissue level strain in healthy and diseased murine pulmonary specimens over a range of volumes and breathing rates for the first time. We hypothesize that lungs with fibrosis will be less distensible than that of healthy counterparts, and thus will exhibit decreased strain contours, particularly when compared at higher inflation volumes. To characterize the difference between healthy and fibrotic lung strains, we systematically section regions of interest (ROI) across specimens to evaluate potential disparate stretch capabilities that may manifest due the spatial arrangement of matrix constitutive elements in disease [7].

## METHODS

Male C57BL/6J mice (ages 8-12 weeks old) were procured from Jackson Laboratory (Bar Harbor, ME, USA). For 21 weeks, subjects were intranasally exposed three-times weekly to agricultural dust, per an established fibrosis disease manifestation in-vivo model protocol [8]. Mice were euthanized and sacrificed (IACUC approved), and lungs were removed. Tracheal cannulation was performed to allow for inflation testing. Lungs were speckled to enable collection of DIC data and were tested within 8 hours post-sacrifice. During tests, specimens' hydration was maintained with 1X phosphate-buffered saline solution to minimize deterioration. The test sequence, executed via our electromechanical, volume-controlled, pressure-measuring ventilation apparatus, included an initial preload of the lung specimens to 5cm$H_2O$ to create a common datum state between specimens [9]. Similar to previous studies [4], various inflation volumes of 0.3, 0.5, 0.7ml were applied at rates of 5 and 20 breaths per minute (BPM) using three inflation-deflation preconditioning cycles followed by an analyzed cycle. During ventilation, an imaging system was used to collect DIC data [Trilion Quality Systems, King of Prussia, PA, USA]. Additionally, the global maximum change in lung volume response (which is always lower than the applied volume due to air compressibility and is accounted for in real-time by our device), was examined, as well as local displacement and strain contrasts between healthy and diseased lungs.

Tissue specimens' principal major strain means, ranges, and maximums were obtained via DIC at peak inflation stages for varying rates and volumes [10, 11]. Each lung lobe was sectioned into 3x3 ROI divisions, using the cranial-caudal length of the specimen as the orienting axis to ensure positioning independence across each murine sample and equidistant sections. Healthy versus diseased specimens' metrics were assessed for each rate and volume using a two-way ANOVA with a significance level of $p<0.05$ [GraphPad Prism, San Diego, CA, USA].

## RESULTS

Figure 1 illustrates the strain contour of a representative specimen and the associated nine ROIs used for the left, superior and inferior

lobes. Healthy and fibrotic whole lung strain distributions were both observed to be spatially heterogeneous (Figure 1A). Direct ROI comparisons between healthy versus diseased specimens for mean strain, range, and maximum revealed limited regions with significant differences across all considered breathing volumes and rates. ROI 9 of the healthy specimens' inferior lobe exhibited significantly higher strain measures in for an applied volume of 0.5ml and a frequency of 20 BPM ($p<0.05$, shown in Figure 2). At the same applied volume and slower rate of 5 BPM, ROI 8 of the superior lobe also yielded significantly higher strain range and maximum for healthy specimens ($p<0.01$, not shown).

While no other significant differences at other breathing volumes or rates were revealed, there was a general tendency for healthy specimens' mean strain to be higher than their fibrotic specimen counterparts. In diseased specimens, there were intermittent regions that experienced a sharp increase in maximum strain, as well as strain range.

Despite shared applied volumes between healthy and diseased specimens, differences in the global lung volume change were observed between groups: albeit statistically insignificant, healthy specimens tended to exhibit greater changes in lung volumes compared to diseased lungs, particularly for the slower rate (5 BPM) and greatest applied volume (0.7ml).

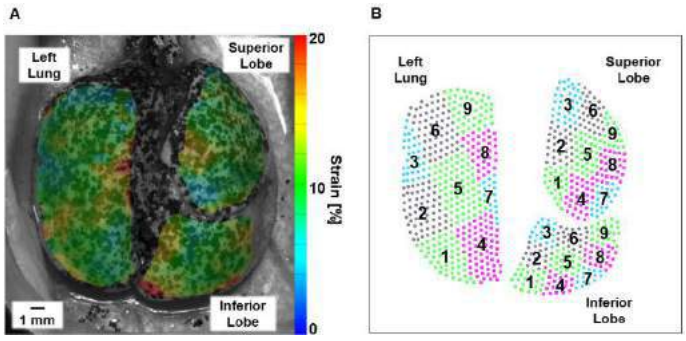

**Figure 1. A: Representative murine lung's topological strain contour map. B: Corresponding ROIs illustrating nine sections per lobe to compare each region's strains in healthy versus fibrotic specimens.**

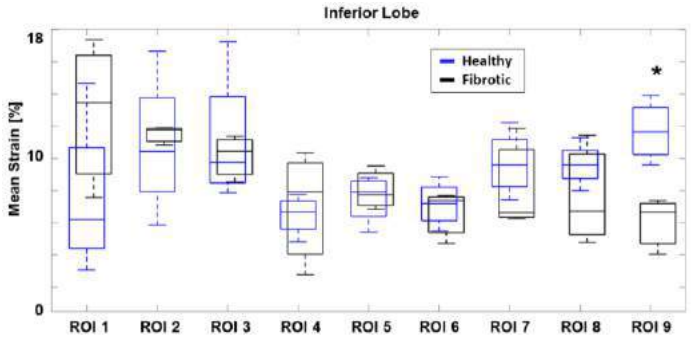

**Figure 2. Box plot representation of healthy and fibrotic specimens' inferior lobe surface mean strain for each ROI, at peak inflation for an applied volume of 0.5ml and breathing rate of 20 BPM. Healthy and fibrotic specimens are depicted in blue and black, respectively.**

## DISCUSSION

In this study, we provide a novel exploratory comparison of tissue strains in ventilated healthy versus fibrotic murine lungs under varying applied volumes and frequencies in order to assess potential differences. One limitation of this study is the ventilation system's reduced ventilation frequency capabilities compared to murine physiological breathing; nonetheless, our testing capabilities are faster than previous studies [4, 12]. We observe that fibrotic specimens generally tend to exhibit a reduction in mean tissue strain values in comparison to healthy counterparts, as hypothesized by other studies [13]. Furthermore, fibrotic lungs tend to reach lower global maximum lung volumes than healthy counterparts when delivered the same amount of air, and often exhibit greater inflation pressures. Together, these findings suggest that healthy tissues have greater adaptability and distention capabilities when ventilated. These local and global outcomes align with previous observations of increased stiffness and reduction in lung volume in fibrotic lungs [4, 7].

The spatial organization of fibers in the fibrotic lung is thought to influence mechanical behaviors, especially as regions of high collagen content cause an imbalance in expansion [7], translating to over- or underinflated regions [14]. Such regions are susceptible to increased deformation, often associated with ventilator induced lung injury (VILI) [13]. This behavior is reflected in the varying levels of strain experienced for different regions in the lung tissue (Figure 2): occasional spikes in the maximum and range of strain are observed, which may be attributable to these areas of varying inflatability and highlight areas that may be prone to injury. Our segmentation method and analysis of tissue strain data via ROIs lays the groundwork for future comparison of regions to one another to methodically evaluate the imbalance of expansion in fibrotic lungs. This will enable unique insights regarding the compromised pathological material response of other prominent pulmonary illnesses, such as asthma or COVID-19, as well.

From this study, healthy and fibrotic lungs' regional tissue strains are not observed to significantly differ, and the few instances of significance warrant future studies to more closely inspect these specific regions and augment mechanical measurements with histological analyses to evaluate the underlying constitutive material and pathological remodeling cause. However, the indications that the fibrotic lung is seemingly less stretchable and subject to more areas of intense deformation yields important insights for considerations of VILI, particularly in respiratory patients undergoing mechanical ventilation, considering their abnormal lung function.

## INTRODUCTION

Chronic pulmonary diseases are costly lifelong conditions affecting over 600 million people worldwide [1]. A large portion of the disadvantageous expenses associated with these conditions relate to diagnosis and treatment, which often focus on locating and defining the altered state of biological responses, such as lowered oxygenation levels or reduced available lung volume. While disease dangerously diminishes biological function, changes are not often unique enough to aid in exact diagnosis, requiring expensive imaging to ascertain damage level and type. The root of the experienced decreased function stems from the altered internal structure of the lung, which also changes the mechanics of the breathing cycle. Investigation of the modified mechanics tendencies in diseased subjects, as contrast to diminished biological outputs, could reveal insightful information and aid in furthering the development of more efficient diagnostic and treatment practices.

Mice are often used as valuable testing specimens to advance diagnostic development. However, accurate measurement of murine mechanics has historically been difficult due to the small physical size. Recent innovations in non-discrete and real-time measurement devices have facilitated material characterization, which has thus far been absent [2-4]; our custom-designed electromechanical apparatus allows continuous volume inflation control and measurement of actual real-time lung volume and transpulmonary pressure [4].

Here we utilize our apparatus to study healthy mice specimens and establish baseline measurements that can later be compared to diseased samples to identify possible energetic or elastic dependent mechanics. Examination of mechanical trends in response to varying controllable ventilation settings, such as inflation volume and cycling frequency, will provide comprehensive respiratory mechanics insights, much needed in the field.

## METHODS

Five mouse lungs (C57BL/6J, male, 29-33 weeks old, 31.3 ± 4.5g) (Jackson Laboratory, Bar Harbor, ME, USA) were collected after sacrifice by anesthesia overdose. To prevent airway collapse, a 1ml syringe was used to push 0.5ml of air into the trachea. Within 3 hours after sacrifice, the lung was placed in our custom apparatus for testing [4]. Establishment of volume history was done via three preconditioning inflation-deflation cycles prior to each test cycle. To achieve a shared datum state and evaluate a range of testing conditions, a preload pressure, 5cm$H_2O$, was applied prior to cycling and twelve flow combinations were tested: four volumes (0.3, 0.5, 0.7, 0.9ml) and three breathing frequencies (5, 10, 20 breaths per minute, BPM).

Figure 1A demonstrates compliance of deflation $C_{def}$ [5] and hysteresis calculations: $C_{def}$ was calculated as a tangent via linear regression ($R^2$>0.99) using MATLAB [6]. Hysteresis was defined as the enclosed area of the pressure-volume (PV) curve for volumes of 0.5, 0.7, 0.9ml. Hysteresis was normalized to account for varied PV size and defined as energy loss. Statistical analysis of mean +/- standard deviation of all samples was investigated by one-way ANOVA with repeated measures in R Studio (*p<0.05, **p<0.01, ****p<0.0001) [7].

## RESULTS

Deflation compliance decreased as cycling rate increased. This was significant at 0.3, 0.5, and 0.7ml for the transition between 10 and 20 BPM as shown in Figure 1B. Differing volume dependencies were found depending on frequency tested: deflation compliance increased with volume at 5 and 10 BPM between 0.5-0.9ml, and at 20 BPM increased between 0.3-0.7ml. Percent relaxation tended to increase with increasing volume (except for the decrease from 0.7 to 0.9ml), significant at only 5 BPM between 0.5-0.7ml. No cycling frequency dependency was found for percent relaxation (Figure 1C). Figure 1D and 1E demonstrate significantly increasing hysteresis across all

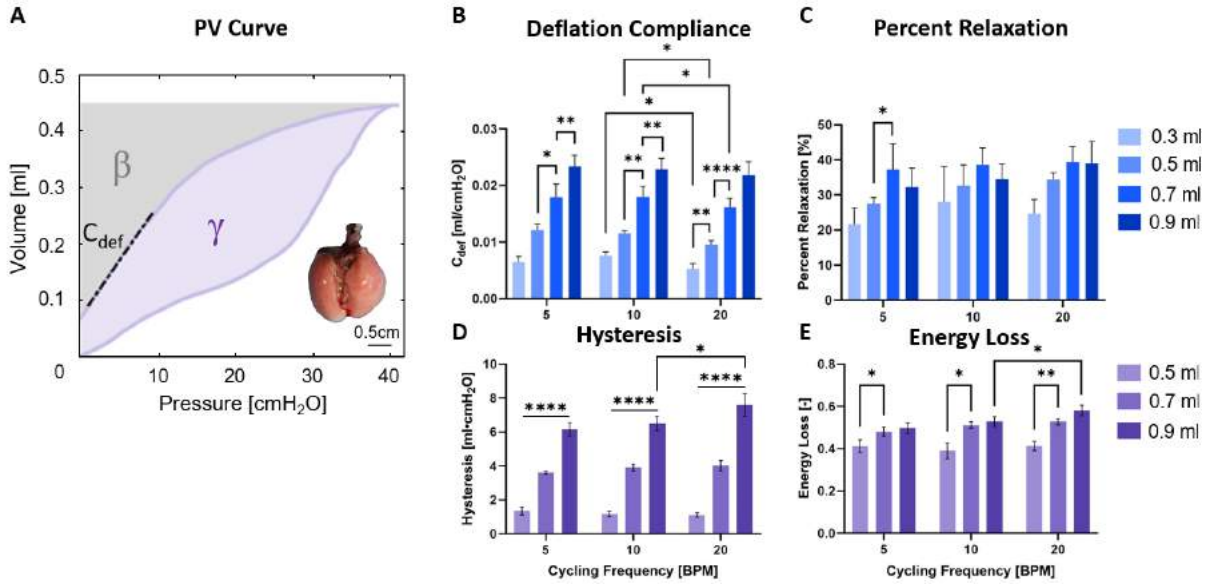

**Figure 1: (A) Quasi-static PV curve demonstrating calculation of $C_{def}$, hysteresis [γ], and energy loss [γ/(γ +β)]. Values on bar graphs are plotted as mean ± standard deviation for (B) deflation compliance, (C) percent relaxation, (D) hysteresis, and (E) energy loss.**

inflation volumes, while energy loss significantly increased across a single volume transition: 0.5 to 0.7ml. Cycling frequency significantly increased both energetic measurements at 0.9ml from 10 to 20 BPM.

## DISCUSSION

Deflation compliance ($C_{def}$) is commonly used as the measurement of murine lung compliance, and yet the effect of varying volume and frequency are understudied [3,8]. In our study, $C_{def}$ decreases with increasing BPM consistent with static and dynamic compliance, which exhibit this behavior in cat and dog lungs and diseased human lungs [9-11]. This frequency dependence may well only be present in ex vivo specimens due to the absence of the chest wall and may be partially attributable to the viscoelastic nature of lung [12].

Tissue viscoelasticity and the presence of surfactant give rise to the observed breathing cycle hysteresis [13]. In our study, we further observe the role of volume on frequency dependencies, contradictory to previous works. Previous investigation by Grotberg and Hildebrandt in dog lobes and cat lungs, respectively, resulted in differing findings [9,11]: Grotberg detected, as we do, that a volume dependency exists for frequency trends in isolated individual lobes, while Hildebrandt found no such tendency for the whole organ despite testing a range of values. Grotberg hypothesized that this distinction occurred because of the divergent nature of testing individual lobes versus the bulk intact organ. However, we find a slight volume dependency consistent with Grotberg, despite testing the whole organ similar to Hildebrandt.

In addition to analyzing hysteresis, we investigated energy loss to normalize the effect of inflation volumes. Frequency dependent trends of energy loss were comparable to hysteresis, indicating the observed frequency trends were not influenced by the growing PV loop. However, normalization resulted in fewer energy loss volume dependencies such that increasing the inflation volume only significantly increased energy loss across the transition from 0.5 to 0.7ml at all three BPMs.

Whole lung viscoelastic relaxation has been previously documented as a sharp decline that quickly asymptotes partially due to the documented stress relaxation of constituents (i.e., parenchyma and airway tissues) [12-15]. Previous viscoelastic investigations have focused on biological responses, including cytokine production and body temperature, with a few studies focusing on mechanical alterations [15-17]. One such study examining the influence of varying inflation volumes in rabbits found the percent relaxation of the asymptotic portion increases with inflation volume [15]. In this study, we similarly note a volume dependent trend (most were statistically insignificant). We also find percent relaxation tends to increase with increasing volume up to the 0.7 to 0.9ml transition where percent relaxation is then observed to decrease for all breathing frequencies. In contrast, the aforementioned previous study found percent relaxation continued to increase with increasing volume until specimen rupture. Discrepancies may be due to our extended two-minute hold in accordance with previous methods [4] compared to their one-second hold, our inclusion of the initial decrease in pressure, or expected differences in tissue response considering the mice versus rabbits.

# A COMPUTATIONAL ANALYSIS OF EXPERIMENTAL DESIGNS TO STUDY PULMONARY HYPERTENSION AND RIGHT VENTRICULAR FUNCTION

**Mitchel J. Colebank (1), Naomi C. Chesler (1)**

(1) University of California Irvine – Edwards Lifesciences Foundation Cardiovascular Innovation and Research Center, and Department of Biomedical Engineering, University of California, Irvine, Irvine, CA, USA

## INTRODUCTION

Computational modeling of the cardiovascular system can provide significant insight into disease mechanisms. When combined with *in-vivo* experimental data, model parameters can be estimated and correlated with disease severity [1,2]. This is especially important for pulmonary hypertension (PH), an understudied disease that draws heavily from animal disease models. PH affects both the pulmonary vasculature and the right ventricular (RV), leading to RV failure if left untreated. A computational model of hemodynamics and biventricular interaction can provide insight into RV failure and the progression of disease [1,2]. *In-silico* modeling can provide insight into which *in-vivo* designs are most informative, reducing uncertainty in model forecasts.

In this study, we use a multiscale cardiovascular model that simulates sarcomere shortening, ventricular interaction, and zero-dimensional hemodynamics in mice. We consider four experimental designs common for *in-vivo* models of PH research, and study parameter identifiability using sensitivity analyses, profile-likelihood confidence intervals, and Markov chain Monte Carlo (MCMC). We extend our analysis by providing uncertainty bounds in model forecasts and contrast predictive uncertainty across different experimental designs. With this approach, we optimize the synergy between *in-silico* and *in-vivo* approaches to ensure the most informative experimental design.

## METHODS

The computational model includes a phenomenological model of cardiac contractility and sarcomere shortening, a three-segment model of biventricular function and interaction [1], and a zero-dimensional model of the systemic and pulmonary circulations [2]. The model has 49 parameters, 18 differential equations, and 2 algebraic constraints. We consider four experimental designs for *in-vivo* data collection: (1) dynamic RV pressure only, (2) dynamic RV pressure-volume (PV) data, (3) dynamic RV PV data and systolic and diastolic pressure and volume data in the LV, and (4) dynamic PV data in both ventricles. Parameters are scaled to match parameter magnitudes typically found in mice [3].

We use Morris screening to quantify parameter importance by constructing coarse approximations of model sensitivity, $\mathrm{EE}_{i,f}^{i} \approx df/d\theta_i$ [2,3], where $f$ is the output for a given design and $\boldsymbol{\theta}$ are the parameters. Parameters are fixed if they are consistently non-influential using the following indices

$$\mu_{i,f}^{*} = \frac{1}{K}\sum_{j=1}^{K}\left|\mathrm{EE}_{i,f}^{j}\right|, \qquad \sigma_{i,f}^{2} = \frac{1}{K-1}\sum_{j=1}^{K}\left(\mathrm{EE}_{i,f}^{j} - \mu_{i,f}\right)^{2} \tag{1}$$

where $K$ is the number of samples. We subsequently use a derivative based local sensitivity analysis to test for parameter inter-dependence and reduce the subset [1,3]. Structural identifiability is tested by constructing 95% profile-likelihood confidence intervals

$$CI(\theta_i) = \left\{\theta_i \middle| -2PL\left(\theta_j\right) \leq -2\mathrm{LL}(y|\boldsymbol{\theta}) + icdf(\chi_1^2, 0.95)\right\} \tag{2}$$

where $PL(\theta_i)$ is the likelihood for fixed $\theta_i$, $\mathrm{LL}(y|\boldsymbol{\theta})$ is the data likelihood given model-generated data $y$, and $icdf(\chi_1^2, 0.95)$ is an upper bound constructed from the chi-squared distribution with one degree of freedom. After reducing the full 49 parameter set to a smaller, identifiable, and influential subset, we test for practical identifiability using MCMC. We first generate noise-corrupted data from the model and then estimate parameters using the delayed rejection adaptive Metropolis (DRAM) algorithm. DRAM constructs the parameter posterior distributions, providing information about parameter uncertainty for each experimental design. We run DRAM with 12 random initializations to ensure consistency in our results. Lastly, we sample from the posteriors and quantify forecast uncertainty in PV loops and LV, RV, and septal wall (S) engineering strain.

## RESULTS

The global and local sensitivity analysis reduces the original 49 parameter subset to a common set of 13 influential parameters for all

four experimental designs. Table 1 displays the profile-likelihood confidence interval width for 4 of the parameters describing LV and RV wall volume ($V_{wall}$) and reference area ($A_{m,ref}$). The confidence intervals are finite and bounded for all 13 parameters, suggesting that all are identifiable. In addition, confidence interval bounds shrink as more data are included in the experimental design. Figure 1 illustrates 3 of the 12 posterior distributions obtained using the DRAM algorithm. The true parameter values, shown in red, are contained within each posterior, and the posterior variances decrease with more data in the experimental design. Parameter realizations are drawn from the posteriors in Figure 1 to generate uncertainty in model simulations. Figure 2(a) shows that uncertainty in LV and RV PV loops decrease with increased data. LV, RV, and S engineering strain uncertainty is provided in Figure 2(b), and also decreases with more informed experimental designs.

## DISCUSSION

This study investigates parameter identifiability and model uncertainty for four different experimental designs in which *in-vivo* data relevant to PH and RV function are collected. Using a combination of local and global sensitivity analyses, a reduced subset of model parameters is determined as done previously [1-3]. We thoroughly test

| | Confidence interval width | | | |
|---|---|---|---|---|
| Parameters | Design 1 | Design 2 | Design 3 | Design 4 |
| $V_{wall,LV}$ ($mm^3$) | 5.86e-3 | 7.70e-4 | 1.16e-3 | 5.70e-5 |
| $V_{wall,RV}$ ($mm^3$) | 3.48e-3 | 8.40e-5 | 8.39e-5 | 1.80e-5 |
| $A_{m,ref,LV}$ ($cm^2$) | 1.39e-2 | 4.18e-3 | 3.53e-3 | 2.00e-4 |
| $A_{m,ref,RV}$ ($cm^2$) | 1.27e-2 | 8.00e-4 | 5.10e-4 | 4.85e-4 |

**Table 1: Profile-likelihood confidence interval widths.**

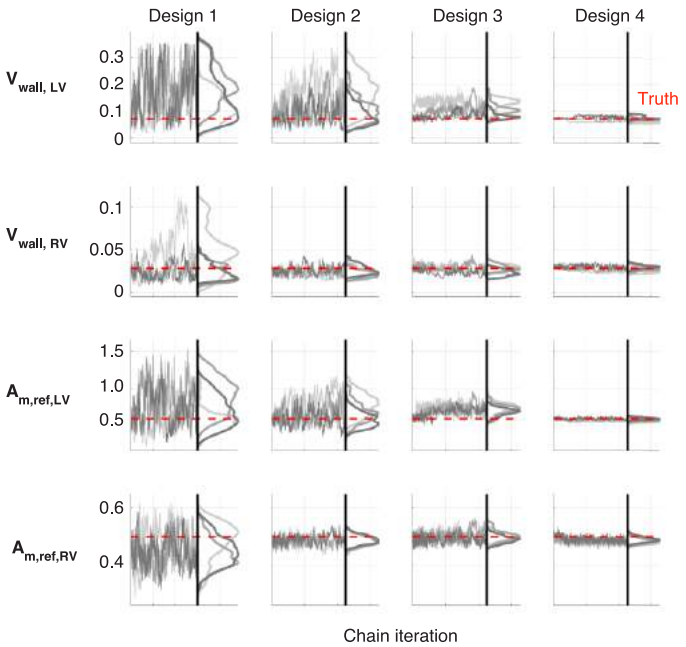

**Figure 1: Posterior chains and density estimates from 4 of 13 parameters using MCMC.**

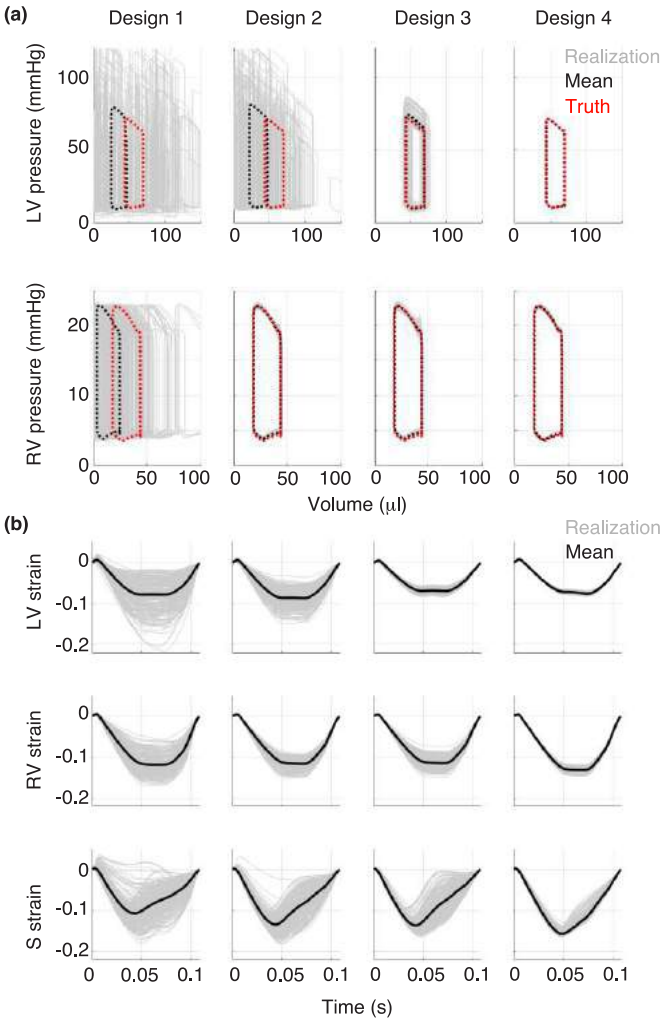

**Figure 2: (a) Uncertainty in LV and RV PV loops. (b) Uncertainty in chamber wall engineering strain.**

for structural identifiability using profile-likelihood confidence intervals, which decrease in width with more informative experimental designs. DRAM results show that designs with PV data in both ventricles reduced parametric and output uncertainty. These results suggest that a coupled *in-silico, in-vivo* investigation of PH and RV failure is optimal when RV PV loops are coupled with LV data. Moreover, *in-silico* forecasts of wall strain are better informed with additional LV data, and may provide more insight into the mechanisms of RV failure during PH. We conclude that biventricular functional data is pivotal in matching model predictions to *in-vivo* data. Designs with RV and LV data minimize the forecast uncertainty in biventricular interactions; hence these designs should be used when investigating the progression of RV failure due to PH using *in-vivo* experiments [2].

# PERIVENTRICULAR WHITE MATTER HYPERINTENSITIES ASSOCIATED WITH MECHANICAL CHANGES OF THE EPENDYMAL WALL

**A. Caçoilo (1), M. Grigg (2), H. Rusinek (3), J. Weickenmeier (1)**

## INTRODUCTION

Areas of high signal intensity on fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) are known as white matter hyperintensities (WMHs). WMHs are classified into periventricular white matter hyperintensities (pvWMHs) or deep white matter hyperintensities (dWMHs) regions. PvWMHs are characterized by their unique locations near the boundary of the lateral ventricles (LVs), while dWMHs are diffusely spread out in deep white matter (WM) tissue [1]. Throughout the life, tissue degeneration causes cerebral atrophy which results in ventricular enlargement. With age, this causes structural changes in the ependyma and surrounding brain tissue. With the expansion of the ventricles, stretching of the ependymal surface occurs with flattening and compression of the ependymal cells, leading to rupture and degradation of the ependymal epithelium in specific locations along the ventricular surface [2]. Some authors believe that the onset of pvWMHs is linked to a progressive disruption of the ependymal cell wall, also known as ependyma [3,4]. With the ependyma degradation, fluid exchange between the ventricles and the brain substance is not regulated, facilitating the entry of CSF into the brain tissue and leading to the formation of edema in WM tissue [6]. The expansion of the ventricles also results in areas of gliosis, which can lead to glial scar development where the ependymal cells are replaced by dense astrocytic patches [2,6]. Shook *et al.* stated that the astrocytic ribbon layer is consistently thicker in regions with decreased ependymal cell coverage; consequently, the deterioration of the ependymal wall compromises the periventricular ISF homeostasis and disrupts trans-ependymal bulk flow mechanisms required to clear proteins and metabolites from the brain parenchyma [7]. The presence of WMHs is commonly associated with older subjects with cognitive impairment and neurological pathologies, such as stroke or dementia, and their severity has been shown to be correlated with age [8]. Some studies proposed that WMHs are associated with an increase of tissue water content, demyelination and axonal damage due to small vessel disease [9]. In this study, it is hypothesized that the mechanical loading on the ependymal cells of the ventricular wall leads to the emergence and gradual growth of pvWMHs due to the wall's disruption and subsequent CSF leakage into the brain tissue. Computational models were developed to simulate ependymal cell stretch at peak hemodynamic loading, aiming to predict the onset location of pvWMHs.

## METHODS

Brain images used in this work were obtained from cognitively normal subjects in the database of the New York University Alzheimer's Disease Research Center. From a cohort of healthy patients, four male and four female subjects were sorted by cerebrospinal fluid volumes ($20^{th}$, $40^{th}$, $60^{th}$ and $80^{th}$ percentile of the CSF volume distribution), aiming to capture a wide range of ventricular shapes. A finite element model (FEM) of the brain based on a semi-automatic segmentation approach was developed from the respective MR images. The MPRAGE images were used for segmenting the different regions of interest in the brain, such as the LVs, WM, the gray matter (GM), and the subarachnoid space (SAS), using the ScanIP software environment of Simpleware (Synopsis Inc., Mountain View CA) (see Fig. 1(a)). The segmentation process was then manually adapted to make it suitable for conversion to a FE model. Segmentation masks are converted into a volumetric model discretized by tetrahedral elements, as shown in Fig. 1(b). The FE program Abaqus (Dassault Systèmes SE) was used to simulate the mechanical loading of the ventricular wall and its surrounding tissues at peak ventricular pressure during the hemodynamic cycle. A normal pressure was applied to the ventricular wall and the GM-SAS interface to reproduce the effects of the CSF pulsations in the cranial cavity, which occur due to the periodic beating heart. Thus, a pressure of 300 Pa was applied on the LVs and a pressure of 290 Pa was applied on the GM-SAS interface. These values are line with findings available in the literature [10,11,12]. The skull is

SB³C2022-021

replaced here by applying zero displacement boundary conditions on the outer surface of the SAS layer, as can be seen in Fig. 1(c).

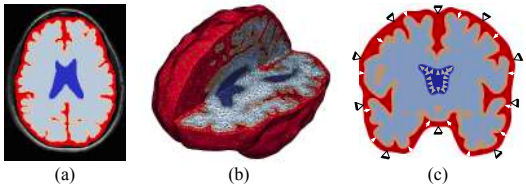

**Figure 1: (a) Segmentation of the subarachnoid space (red), gray matter (orange), white matter (light blue), as well as the lateral ventricles (dark blue); (b) assembling of the 3D FEM of the brain; (c) boundary conditions applied to the ventricular wall and to the outer GM-SAS surface.**

GM and WM tissues were modeled as an Ogden-type hyperelastic material and was implemented in a user-defined material subroutine (UMAT). The material was assumed to be nearly incompressible, with a Poisson's ratio of 0.45, and a white-gray matter stiffness ratio of 2 was assumed [13]. The CSF in the SAS was modeled as a soft compressible material with a Young's modulus of 1 Pa and a Poisson's ratio of 0.30 [13]. For all eight subjects, WMHs were segmented on FLAIR images. As for pvWMHs, Chen *et al.,* Milhorat *et al.* and Fazekas *et al.* reported that although they are more frequently found at anterior and posterior horns, they can also be found in the body of the LV and temporal horns [1,2,14], and that finding was also observed in this study, as shown in Fig. 2.

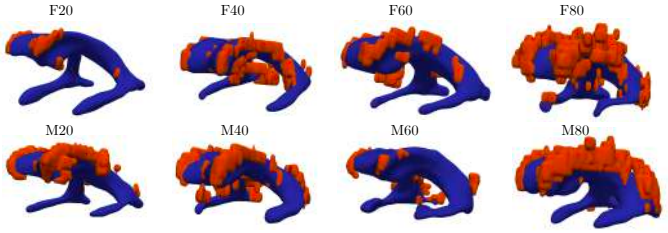

**Figure 2: Reconstruction of the lateral ventricles (in dark blue) and the pvWMHs (in red).**

## RESULTS

Maximum tangential stretch is 1.138, 1.099, 1.100, and 1.113 for female subjects F20 through F80, and 1.133, 1.133, 1.123, and 1.125 for male subjects M20 through M80. The maximum ependymal cell tension for F20 and M20 models is approximately 1.13, which represents an elongation of the ependymal cells of 13%. Peak stretches of models with smaller CSF volume (F20 and M20) are higher compared to the models with larger CSF volumes. The maximum tangent stretch plots, as can be seen in Fig. 3, show consistency with respect to spatial stretch distributions across all the models, and it is visible that the peak stretch is mostly located in the central part of the lateral ventricles. Despite pronounced variations in lateral ventricle geometry across all subjects, peak cell tension is consistently located between the anterior and posterior horns (upper part of the LVs). All other locations of the ventricular wall experience negligible cell stretch, with values around 1.

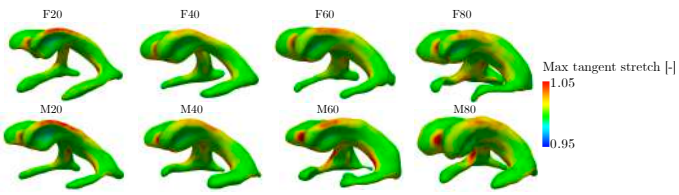

**Figure 3: Distribution of maximum tangent stretch for all subjects.**

A comparison with the location of pvWMHs along the ventricular wall reveals that tissue stretching co-localizes in regions of peak cell stretches. Figure 4 shows mean curvature of all eight models to illustrate the spatial correlation between ventricular wall geometry and the location of pvWMHs, by highlighting surface patches exposed to pvWMHs. Maximum mean curvature is 0.8 $mm^{-1}$, 0.78 $mm^{-1}$, 0.63 $mm^{-1}$, and 1.0 $mm^{-1}$ for female models (F20 to F80); and 0.95 $mm^{-1}$, 0.95 $mm^{-1}$, 1.37 $mm^{-1}$, and 0.64 $mm^{-1}$ for male models (M20 to M80). Thus, the smallest ventricles, i.e., F/M20 and F/M40, exhibit higher mean curvatures along the edges of the main body in comparison to larger models, i.e., F/M60 and F/M80. This is key to the hypothesis that mechanical loading of ependymal cells is one of the most important factors in pvWMH formation and the early growth phase. Inferior horns exhibit very high mean curvature values without corresponding pvWMHs. It appears that elevated mean curvature and high stretch must coincide to create a mechanical loading state that exceeds the physiological limit of the ependymal cells to prevent CSF leakage.

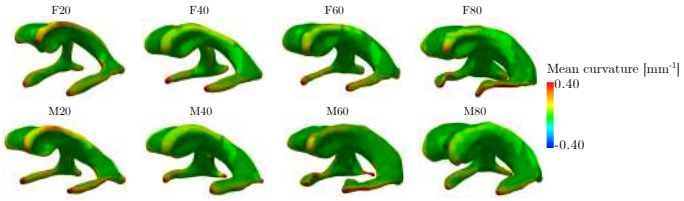

**Figure 4: Mean curvature across the ventricular wall is a geometric property that serves as a marker for regions of elevated LV loading.**

## DISCUSSION

The present work tests the hypothesis that mechanical loading of the ventricular wall is a critical factor for the emergence of white matter hyperintensities. The models included here cover a broad range of ventricular geometries representative of ventricular enlargement observed across a large age-span and provide extensive insight into ventricular wall loading. Ventricular curvature is a surrogate for mechanical loading and showed good spatial agreement with pvWMH locations. In summary, ependymal cell loading along the ventricular surface may serve as a mechanomarker for pvWMH onset locations. The eight subject-specific finite element models consistently demonstrated that peak mechanical loading of the ventricular wall spatially overlaps with pvWMHs locations for a broad spectrum of ventricular shapes and volumes.

# SIMULATION OF UTERUS ACTIVE CONTRACTION DURING FETUS DELIVERY IN LS-DYNA

**R. Tao (1), M. Grimm (1,2)**

(1) Department of Mechanical Engineering, Michigan State University, East Lansing, MI, US
(2) Department of Biomedical Engineering, Michigan State University, East Lansing, MI, US

## INTRODUCTION

Normal biomechanical function and regulation of the uterus is vital for childbirth. Poor quality uterine contractions contribute to many labor problems, including labor dystocia (a delay in labor progression), which has proven to be a significant reason for the rising Caesarean section rate [1]. In addition, the interaction of the uterus, the fetus, and the maternal pelvis results in both the normal cardinal movements of labor and abnormalities of descent that can result in a shoulder dystocia (delay in delivering the shoulders after the head delivers). Therefore, it is important to be able to model uterine contraction behavior during the delivery process in order to better understand the pathomechanics.

The uterine wall consists of three layers: the endometrium, the myometrium, and the perimetrium (from inside to outside). The myometrium is composed of millions of smooth muscle cells (SMC). Such SMCs are organized in different directions to resemble fibers that contribute to uterine contraction [2]. The contraction behaviors of the uterus are summarized in Grimm's review [3]. The typical contraction pattern of the uterus resembles a bell-like curve [4], which takes on average 60 s for one cycle [5]. The active contraction is a force wave that is initiated from the fundus and then propagates to the lower part of the uterus, which takes 10 to 20 seconds [6]. While the contraction in different regions starts at different times, the peak force occurs almost at the same time and then relaxation occurs synchronously [6].

Due to ethical issues, human experiments during labor and delivery are difficult to conduct. Computer modelling has become a promising way to investigate uterine behaviors; however, simulation of uterine contraction is still a relatively new research area. In 2009 and 2013, Buttin *et al*. [7-8] established an FEM model of the female reproductive system containing the pelvis, uterus, and fetus to investigate how the different forces influence the fetus delivery process. However, in these simulations, the uterus's active contraction was not simulated directly, but rather an external force was applied through the uterus to the rigid fetal model to simulate what was assumed to be the resulting force. In 2015, Cochran *et al*. [9] developed a 3D electro-mechanical coupling model of the uterus to calculate the mechanical and electrical properties and the peak uterine pressure. A similar model was developed by Yochum *et al*. [10] in 2016, where the mechanical and electrical behaviors were analyzed on multiple scales. However, the geometries were highly simplified, and the strain was too small to represent the large deformation of the uterus during delivery. In 2019, Pouca, *et al*. [11] developed a chemo-mechanical coupling model to simulate uterine contraction and fetal delivery. However, the effects of fibers contributing to the contraction were not considered. Overall, the existing models in this area still include many limitations.

In this study, we developed an FEM uterus model in LS-DYNA to simulate the uterine active contraction, where the contraction forces were driven by contractile fibers. Multiple mechanical contraction properties of the uterus were included in this model.

## METHODS

The geometry of the uterus was designed in NX software with a length of 35 cm, a maximum width of 15.6 cm, a thickness of 1 cm, and diameter of 10 cm at the cervix, as shown in Figure 1a. Meshing was done in Hypermesh software using hexahedral elements (Figure 1b), which was then exported to LS-DYNA. Each element was bonded with four truss beam elements oriented in the longitudinal direction. These beams were assigned to one of seven regions in LS-DYNA (Figure 1c. These beams were used to provide the contraction force based on the Hill material model [12] (MAT_156 in LS-DYNA). The activation curves for the seven beam regions were assumed (Figure 1d), where the starting time for region one was at time 0 s. Each of the subsequent regions began contracting 2 s later than the previous region to simulate the propagation of the contraction wave, and all of the regions reached the fully activated status and began to relax synchronously based on physiologic behavior [6]. At time = 50 s, the activation returned to zero. The solid portion of the model, representing the non-contractile portions

SB³C2022-022

of the tissue, had a Young's modulus of 2 kPa and a Poisson's ratio of 0.495. For the boundary conditions, the nodes on the cervix were fixed in x, y, z translation directions. No external loads were applied.

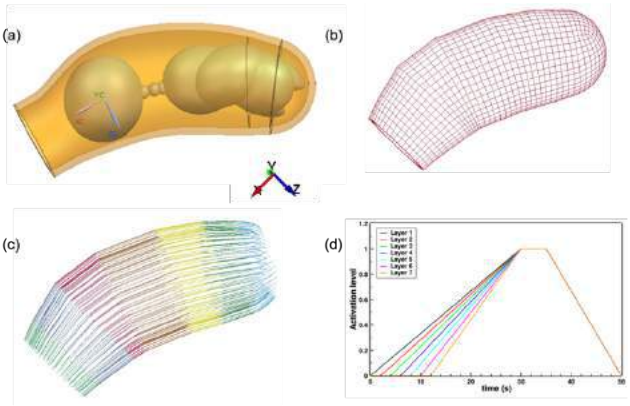

**Figure 1: Modeling details: (a) uterus geometry; (b) meshwork; (c) seven regions of beams; and (d) activation level curves.**

## RESULTS

The simulation result is shown in Figure 2. At t = 0 s, there is no deformation (Figure 2a). After that, the uterus starts to contract from the top, fundus region and the contraction wave starts to propagate to the lower part. By t = 5 s, the first three regions have started to contract, which causes the uterus to shorten in the longitudinal direction while expanding slightly in the transverse direction in these three layers. There is no deformation for the lower uterus, and the largest effective strain is 9.5% (Figure 2b). By t = 10 s, the contraction wave has propagated to the first five regions, causing the contracting portion of the uterine structure to further shorten in the longitudinal direction and expand more in the transverse plane. The largest strain was 17.2% (Figure 2c). By t =15 s, all of the regions have started to contract, and the largest strain is 23.5% (Figure 2d). The entire uterus continues to contract until about 32 s, where the largest stain is 36.1%. The uterus becomes much shorter and wider. From 35s, with the decrease of the activation level, the uterus starts to relax due to the elastic response of the non-contractile tissue. At t = 50 s, the uterus has almost returned to its initial state, and the largest strain was 3.8%.

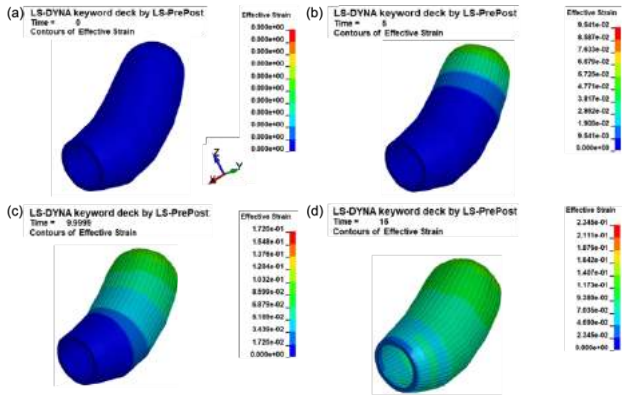

**Figure 2: Representation of the deformation for the uterus at times of (a) 0 s, (b) 5 s, (c) 10 s, and (d) 15 s.**

## DISCUSSION

In this study, we developed a uterus FEM model with contractile fibers. Our model can simulate active contraction directly rather than applying external loading conditions. Existing multi-scale electro-mechanical coupling models are usually mathematically complex, physiologically complicated, and computationally intensive [9-10], and therefore would need an extremely large amount of computer memory and high computational speeds to predict macro-level mechanical behavior. Due to these challenges, these models highly simplified their geometries and were not able to simulate big deformation, while our model can perform large deformation simulation on a complicated geometry. It is known that the variation of the fibers' orientation through the muscle thickness has a significant effect on uterine behavior [2]. The fibers in our current model were organized only in the longitudinal direction, which caused an expansion in the transverse direction during contraction that is not seen clinically. The results also demonstrate how important it is for the simulation to consider the arrangement of the fibers inside the uterus wall, which we plan to investigate with our model in future work. Moreover, our model includes more aspects of uterine mechanical behaviors -- such as the contraction wave propagation phenomenon, synchronous arrival at the peak force for different regions through the uterus, and synchronous relaxation -- by defining multiple regions and independent activation curves for each region.

One limitation of our model is that it is not linked to the cellular level models to study how electrical, chemical, and mechanical behaviors influence tissue and organ-level behaviors. However, such cellular-level models could be incorporated into the Hill muscle model to develop a new multi-scale constitutive model in the future. In addition, the propagation wave is not continuous through the uterus in this version of our model. More regions should be defined to make the propagation smoother. However, this is an important step forward in the simulation of macro-scale contraction behavior of the uterus.

# POST-STRETCH BEHAVIOR OF VASCULAR SMOOTH MUSCLE CELLS DEPENDS ON STRAIN-RATE AND ACTOMYOSIN INTERACTIONS

## INTRODUCTION

Vascular smooth muscle cells (VSMCs) encircle blood vessels and modulate blood flow through active contraction in response to chemical and mechanical cues. In the vasculature, VSMCs are exposed to deformation at rates ranging from 1% per year during aneurysm growth[1] to 1000% per second during traumatic brain injury (TBI).[2] Though VSMC function and gene expression have previously been linked to applied stretch[3,4], our understanding of VSMC response to rate of deformation is still fundamentally lacking. Here, we utilize cellular microbiaxial stretching (C$\mu$BS) to benchmark VSMC mechanical behavior following stretch at different rates. We hypothesized that VSMCs will display viscoelastic characteristics with higher stress following high strain-rate stretch. Surprisingly, we find the opposite to be true: VSMCs generate lower stress following high strain rate stretch. Subsequently, we utilize pharmacological agents to identify actin-myosin binding affinity as a key factor of decreased stress generation following high strain-rate stretch.

## METHODS

**Substrate Fabrication and Cell Culture.** Human umbilical artery VSMCs were micropatterned with aspect ratio 1:4 (AR4) on a fluorescent-bead-doped polyacrylamide (PA) gel with a Young's modulus of 13.5 kPa (Fig. 1A) as previously described[3,5]. VSMCs were cultured using a standard protocol to induce a physiological phenotype[3,5].

**Cellular Microbiaxial Stretching (C$\mu$BS).** C$\mu$BS experiments were performed using a custom-built microscope-mounted device to perform traction force microscopy (TFM) experiments (Fig. 1B). VSMCs were stretched to an engineering strain of 0.15 at rates of 0.001 $s^{-1}$ or 0.1 $s^{-1}$. Following stretch, cells were imaged at 40X using a confocal microscope to obtain traction images. VSMCs were imaged once per second in a time lapse, with the stretch time and imaging time totaling 5 minutes for each condition (Fig. 2A). For example, for cells stretched at 0.001 $s^{-1}$, the time to stretch to a strain of 0.15 is 2 min and cells are imaged for 3 min while the cell is held at a strain of 0.15. Brightfield images were acquired of the VSMC at the first timepoint and fluorescent images were taken of the respective underlying bead layer in the PA gel at every timepoint. Cells were then returned to a strain of 0 and the same imaging protocol was performed. Three cycles of stretch were performed on each cell. The cells were then lysed with SDS and the bead layer of the gel was imaged again at the location of each cell at 0 and 0.15 strain.

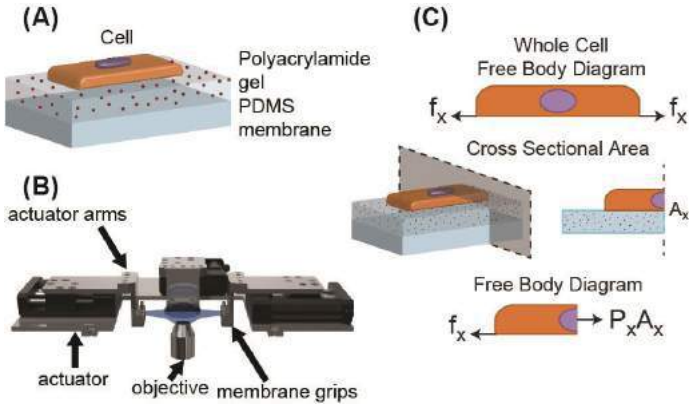

**Figure 1: (A) AR4 VSMC micropatterned on PA gel. (B) Section view of C$\mu$BS apparatus. (C) $P_x$ calculation from VSMC free body diagram. Adapted from Win et al.[5] and Rothermel et al.[3]**

Traction forces at each timepoint were calculated using previously described methods[5,6]. The first Piola-Kirchoff stress, represented by $P_x = f_x/A_x$, where $f_x$ is the total traction force and $A_x$ is the undeformed cell cross-sectional area, was calculated at the mid-plane of the cell (Fig. 1C). Stress is presented as normalized $P_x$, where stress at any time point is normalized to the basal stress at $t$ = 0 s prior to stretch.

**Pharmacological Treatment.** VSMCs were treated with one of four pharmacological agents to induce changes in the cytoskeleton: 20 $\mu$M nocodazole to inhibit polymerization of microtubules, 1 $\mu$M paclitaxel to inhibit microtubule disassembly, 0.1 nM calyculin-A to inhibit myosin dephosphorylation (promote actin-myosin binding), or 3 $\mu$M Y-27632 to promote myosin phosphorylation (inhibit actin-myosin binding). Cells were treated 30 minutes prior to undergoing the stretch protocol.

**RESULTS**

VSMCs were strained at either 0.001 $s^{-1}$ or 0.1 $s^{-1}$ according to the protocol in Fig. 2A. Prior to stretch, VSMCs generate a non-zero basal stress (Fig. 2B(i)). Immediately following strain to 0.15, stress shows a sharp increase (Fig. 2B(ii)) and gradually decreases over time as the cell is held at a constant strain (Fig. 2B(iii)). When cells are returned to 0 strain, stress shows a sharp decrease (Fig. 2B(iv)) and gradually increases over time as the cell is held at 0 strain (Fig. 2B(v)). VSMCs display stress relaxation-like behavior, as displayed in the full normalized $P_x$ vs. time plot for a representative cell (Fig. 2C).

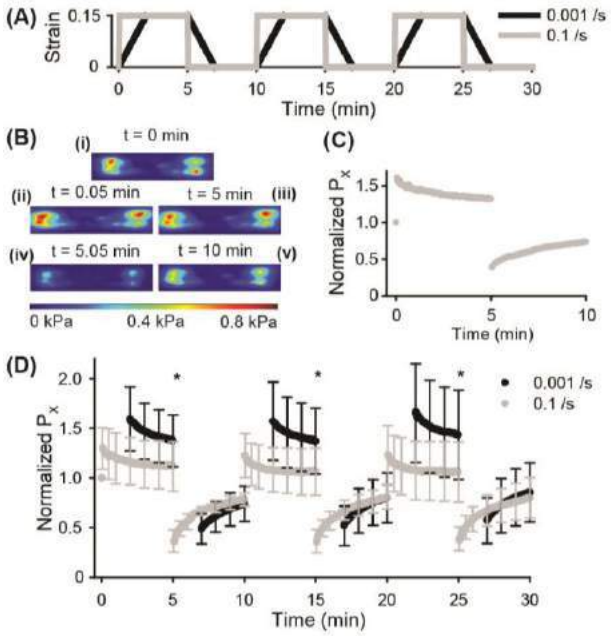

**Figure 2: (A) VSMC strain protocol at 0.001 $s^{-1}$ (black) and 0.1 $s^{-1}$ (gray). (B) Traction stress maps of a cell strained at 0.1 $s^{-1}$ before strain (i), immediately after strain (ii), after being held at 0.15 strain (iii), immediately after return to 0 strain (iv), and after being held at 0 strain (v). (C) Normalized $P_x$ vs. time plot for the cell shown in (B). (D) Average normalized $P_x$ vs. time plots for VSMCs stretched at 0.001 $s^{-1}$ (n=18) or 0.1 $s^{-1}$ (n=20). * = p<0.05**

Surprisingly, VSMCs stretched at 0.1 $s^{-1}$ consistently generated lower stress than cells stretched at 0.001 $s^{-1}$ (Fig. 2D), conflicting with predictions of viscoelastic models commonly used for representing contractile cells. Stress generation is significantly different at the end of the relaxation phase ($t$ = 5, 15, 25 min) but there is no significant difference in stress at the end of the recovery phase ($t$ = 10, 20, 30 min).

VSMCs treated with microtubule-affecting drugs nocodazole or paclitaxel showed stress vs. time plots roughly identical to Fig. 2D (data not shown). After treatment with 0.1 nM calyculin-A, the stress vs. time plots for VSMCs stretched at 0.001 $s^{-1}$ or 0.1 $s^{-1}$ show similar trends independent of strain rate (Fig. 3A). VSMCs treated with 3 $\mu$M Y-27632 show more pronounced differences in stress between cells stretched at 0.001 $s^{-1}$ or 0.1 $s^{-1}$, and display decreased stress with each successive stretch cycle (Fig. 3B). The ratio of stress produced by cells strained at 0.001 $s^{-1}$ compared to cells strained at 0.1 $s^{-1}$ immediately after stretching and after 5 minutes of relaxation is shown in Fig. 3C and 3D, respectively. Calyculin treatment decreases the difference in stress between cells strained at 0.001 $s^{-1}$ or 0.1 $s^{-1}$ compared to untreated VSMCs, while Y-27632 treatment slightly increases the difference.

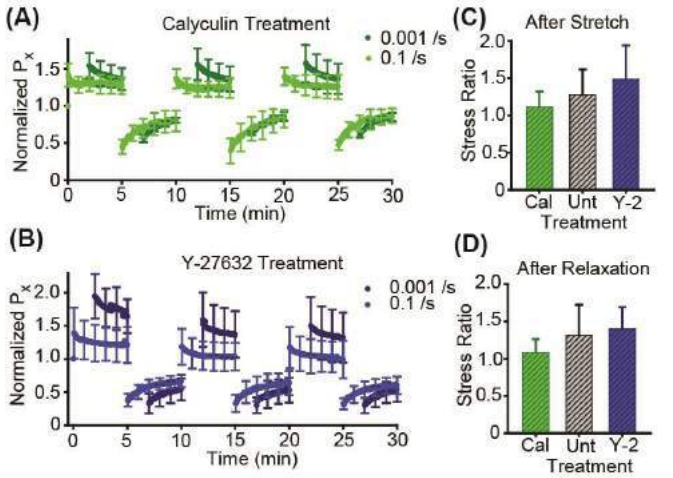

**Figure 3: (A) Average normalized $P_x$ vs. time plot for VSMCs treated with calyculin-A and stretched at 0.001 $s^{-1}$ (dark green, n=5) or 0.1 $s^{-1}$ (light green, n=5). (B) Average normalized $P_x$ vs. time plot for VSMCs treated with Y-27632 and stretched at 0.001 $s^{-1}$ (dark blue, n=5) or 0.1 $s^{-1}$ (light blue, n=5). (C) Average ratio of $P_x$ for cells strained at 0.001 $s^{-1}$ over cells strained at 0.1 $s^{-1}$ immediately after stretch for untreated (Unt), calyculin-A-treated (Cal), and Y-27632-treated (Y-2) VSMCs. (D) Average ratio of $P_x$ for cells strained at 0.001 $s^{-1}$ over cells strained at 0.1 $s^{-1}$ after 5 minutes of relaxation.**

**DISCUSSION**

In this study, we demonstrate that VSMCs show decreases in stress following stretch at high strain-rates. This finding directly contradicts conventional viscoelastic interpretations of contractile cells. Treatment with calyculin-A, which reinforces actin-myosin binding, decreased the difference between stress in VSMCs strained at 0.001 $s^{-1}$ vs. 0.1 $s^{-1}$, while Y-27632 treatment slightly increased the difference. This suggests that decreases in stress generation due to high strain-rate stretch may result from decreased actin-myosin binding. We intend to develop a new model based on our Hill-type active fiber model[7,8] incorporating strain-rate dependent instantaneous rupture and gradual reformation of actomyosin bonds. Understanding how VSMC contractile function depends on rate of applied stretch will help better understand cerebrovascular dysfunction following TBI[9] and may inform the development of long-term arterial remodeling models.

# LARGE ANIMAL MODEL OF MENISCUS INJURY AND REPAIR SHOWS CHONDROPROTECTION AND PARTIALLY RESTORES JOINT KINEMATICS AS MEASURED VIA MRI

## INTRODUCTION

The meniscus serves key functions in knee loadbearing and in protecting the underlying articular cartilage. The meniscus is commonly injured, which in turn impairs its ability to distribute loads and predisposes the joint to developing osteoarthritis (OA). Surgical meniscus repair is chondro-protective and can delay OA but does not halt degeneration for many patients. The unknown altered joint kinematics with meniscus injury and repair are a barrier to addressing this clinical problem. While joint contact measurements do show improved load distribution [1], these methods disrupt the joint capsule and are a 1D measurement. Therefore, a 3D non-invasive MRI-based method that applies physiologic loads to an intact joint is needed [2]. Large animal models of medial meniscus injury develop similar cartilage pathology as humans [3, 4, 5], yet it remains unknown whether surgical repair in these models can restore meniscus function and prevent cartilage OA. Therefore, the objective of this study was to evaluate joint kinematics and cartilage degeneration following injury and repair in a large animal surgical model. We hypothesized that repair would restore near-intact kinematics and prevent cartilage degeneration. Establishing the relationship between joint kinematics and cartilage OA is critical for improving clinical outcomes of meniscus repair.

## METHODS

Meniscus injury and repair were performed in Yucatan minipig joints in 1) a cadaver model (n=3 knees, 18 months old, ~70 kg) and 2) an established surgical model with sacrifice at 6 weeks post-op (n=4 knees per group, 12 months old, ~50 kg), with IACUC approval. The three treatment groups were Intact, Injury, and Repair. The injury was performed by cutting the anterior attachment of the medial meniscus; in the *in vivo* surgical model this cut removed 5 mm of attachment en bloc. The repair was made using a suture anchor. Joint kinematics were quantified using a custom MRI-compatible loading device that compressed the intact knee joint at 30° flexion and held that position during imaging. MRIs were acquired for each joint at 50 N (Preload) and 1X body weight (Full Load) using a 0.2 mm isotropic T1 VIBE sequence. Meniscus motion (kinematics) was calculated from MRI between Preload and Full Load by aligning the tibia, labeling the meniscus boundary, and then calculating its displacement between loads. Initial meniscus position was calculated at Preload relative to the medial intercondylar tubercle ("+" in Fig 1B). Meniscus displacement and position were averaged across the anterior and mid-body (Fig 1B); the posterior meniscus had little motion (Fig 1B), so it was not included.

In the surgical model, additionally, a T2 CPMG image was acquired at Preload, and cartilage T2 time was calculated using noise corrected exponential decay as a measure of degeneration [6]. After MRI, knee joints were dissected, and tibial plateaus were assessed for cartilage wear using India Ink. Further, cartilage indentation testing was performed using a 2mm spherical indenter at four locations, two each on cartilage regions previously covered by the meniscus or on more central uncovered regions. These are denoted as the cartilage-meniscus (C-M) and cartilage-cartilage (C-C) contact regions, respectively. Fifteen-minute duration creep tests at a 0.1N load were fitted to a model of Hertzian biphasic creep [7], and values for compressive modulus, tensile modulus, and permeability were determined. Values for the C-M and C-C contact regions were averaged. Synovium sections were stained with Hematoxylin & Eosin. Osteochondral tissues were scanned via μCT at 70kVp, 85μA, with a voxel size of 10.3μm. Trabecular thickness and bone volume fraction were calculated for 3mm diameter cylindrical regions of interest just below (0-1mm) the C-M and C-C contact regions. Decalcified osteochondral sections were stained with Safranin O/Fast Green.

Cadaveric data was compared between treatment groups by one-way ANOVA followed by a paired t-test with pooled variance. All surgical data was compared with one-way ANOVA followed by post-hoc Tukey HSD; significance was set at $p<0.05$.

## RESULTS

In cadaver knees, large meniscus displacements occurred with load in the Injury group and were restored to near-Intact levels in the Repair group (Fig 1A,B). Quantitatively, the initial position at preload was not different between groups ($p>0.05$ for anterior and medial distance, Fig 2A, circles). Compared to Intact, Injured menisci displaced more medially with loading ($p<0.05$), although anterior displacement was not different (Fig 1C and vectors in Fig 2A). The Repair displacement was not significantly different from Intact (Fig 1C and vectors in Fig 2A).

In the surgical model after 6 weeks, the initial meniscus positions for Injury and Repair were 3 mm more medial than Intact ($p<0.05$) and, for Injury, 1 mm more anterior ($p>0.05$, Fig 2B, circles). However, for Repair, initial position along the anterior axis was similar to Intact (Fig 2B). Displacement with load (Fig 2B, arrow length + direction) was not statistically different between treatments.

In the cartilage 6 weeks after surgery, quantitative MRI T2 trended higher in Injury vs. Intact ($p=0.08$, Fig 3A,B), indicating degeneration. Injury showed more macroscopic signs of degeneration than Intact, with a significantly greater area of the medial tibial plateau positive for India ink staining. Qualitatively, Repair showed less wear than Injury and was not significantly different from the Intact group. Histologically, the Injury group showed more degeneration and greater proteoglycan loss compared to the Intact or Repair groups (Fig 3C), and the synovium in the Injury group showed the greatest signs of inflammation. From indentation tests, tensile and compressive moduli were not significantly different between groups, but the C-C contact region permeability trended higher ($p=0.084$) in the Injury vs. Intact and in Repair the permeability was the same as Intact (Fig. 4). The bone volume fraction in the C-M contact region subchondral bone of the Injury group was significantly higher than that of the Intact group, and trended higher than that of the Repair group ($p=0.054$). Intact and Repair were not significantly different.

## DISCUSSION

This study evaluated changes in meniscus kinematics and cartilage changes in a porcine animal model of meniscus injury and repair. Overall, our data support that surgical repair provides some restoration of meniscus kinematic and cartilage protection at 6 weeks. Acutely, severing the meniscus attachment caused large displacements under physiological load, while suture repair re-established meniscus kinematics nearer to intact values. 6 weeks after surgical injury and repair, the meniscus position at preload was near-normal anteriorly but was displaced medially, and displacements during loading were not different from injury. Despite this, the repair was protective of the cartilage, based on T2 times, gross morphology, histology, mechanical testing and μCT. Ongoing work will address limitations in sample size and add longer post-surgical time points. The significance of this work is that we used an MRI-based technique to quantify physiological knee kinematics and changes with meniscus injury and repair in an intact joint. Combined with a large animal model, we demonstrated that meniscus repair was chondroprotective and established a platform to quantify kinematics after meniscus injury and repair.

# APPLICATION FORCE FEEDBACK REDUCES THE MEASUREMENT VARIABILITY OF A SHEAR WAVE TENSIOMETER

**Lesley R. Arant (1), Joshua D. Roth (2, 3)**

## INTRODUCTION

Although proper ligament tensioning plays a key role in the success of ligament reconstructions [1] and total knee arthroplasties [2], surgeons do not have the tools they need to directly and noninvasively measure ligament tension. To meet this need, our research group is developing a shear wave tensiometer that uses the speed of shear waves propagating along a ligament to gauge its tension [3,4].

Our tensiometer is a handheld device composed of a piezoelectric tapper and two downstream miniature accelerometers. The tapper excites shear waves in the ligament and the downstream miniature accelerometers track the shear wave propagation. Similar to the sensitivity of shear wave elastography measurements to ultrasound probe pressure [5], measured shear wave speeds are sensitive to the application force of the tensiometer components against the specimen [6,7]. As such, variable forces applied by a user can result in erroneous measurements of shear wave speed and thus ligament tension.

Although application force is a determinant of tensiometer accuracy [7], current tensiometer designs do not have onboard, real-time application force monitoring. Furthermore, the effect of application force on the *variability* of measured shear wave speeds remains unknown. Achieving small variability is important for measuring ligament tension with high precision and repeatability, as required for a clinically translatable tensiometer.

Accordingly, the objectives of this work were to 1) incorporate application force monitoring into our ligament tensiometer, and 2) use this monitoring to determine the effect of application force user-feedback on the variability of measured shear wave speeds. We hypothesized that providing users with real-time feedback on their application force would decrease the variability of measured shear wave speeds.

## METHODS

We incorporated an application force monitor into our tensiometer using a Hall effect sensor, spring, magnet, brass rod, and 3D printed tip in series (Figure 1) [8]. When a user holds the tensiometer against the specimen, the spring compresses, causing the magnet to move closer to the Hall effect sensor and change the sensor's output voltage. We used the voltage-distance calibration curve for the Hall effect sensor to determine the spring displacement. Using this spring displacement and the spring constant, we computed the application force based on Hooke's law. We placed two such application force monitors in parallel to monitor the application force of the contact points of the two accelerometers used to track shear wave propagation (Figure 1).

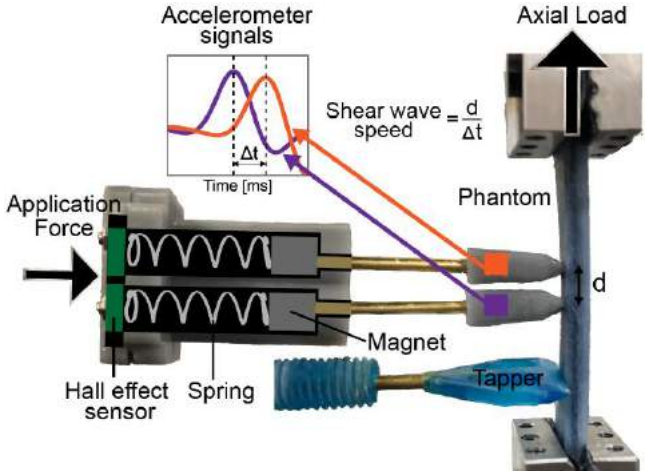

**Figure 1: Schematic showing the tensiometer used to measure shear wave speeds and the onboard application force monitors.**

We measured shear wave speeds in a yarn-silicone ligament phantom because it is less variable than a biological ligament [9,10]. A handheld piezoelectric tapper excited shear waves in the phantom using a 50% bandwidth Gaussian wavelet with a 700 Hz center frequency. We embedded an accelerometer into each of the two 3D printed tips to track the shear waves. We cross-correlated the transient portion of the accelerometer signals at each tap event to find the time delay between wave arrivals. We then computed the shear wave speed by dividing the spacing of the tips (7.25 mm) by the time delay (Figure 1) [3].

We recruited five users to measure shear wave speeds in the phantom under application forces and axial loads that varied following a full factorial design of experiments (Figure 2). First, each user measured shear wave speeds during 15-second trials at phantom axial loads of 100 N, 200 N, and 300 N using a self-selected application force without knowing the magnitude of that force. Then, at the same phantom axial loads, each user measured shear wave speeds using target application forces of 2 N, 5 N, and 8 N in a randomized order. During these trials, two dials displayed the target and measured application forces on each tip in real-time (Figure 2).

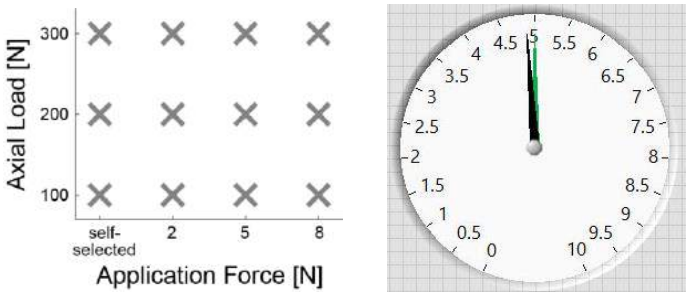

**Figure 2: Full factorial experimental design for application force and axial load (left). Dials provided a real-time display of the target (green) and measured (black) application forces (right).**

For the self-selected application force trials, we averaged the measured application forces across the 15-second static hold and across both application force monitors to yield one application force per user per axial load level. We then computed the range of these average application forces across users at each axial load level to quantify the variability in the self-selected application force across users. For all application force trials, we computed the mean and standard deviation of the measured application forces pooled across all users for each axial load – target application force combination. We also computed the standard deviation of the measured shear wave speeds across all users for each axial load – target application force combination.

For each axial load level, we applied Levene's test to determine whether the standard deviation of shear wave speeds across all users was significantly different for at least one of the four application forces. We also applied Levene's test with Bonferroni correction for pairwise comparisons of the standard deviation of shear wave speeds between each target application force and the self-selected application force.

## RESULTS

Across users, the average self-selected application forces ranged from 0.4 to 2.6 N, 0.5 to 2.5 N, and 0.4 to 2.6 N at axial loads of 100 N, 200 N, and 300 N, respectively. Small differences between the target and average measured application forces indicate that users were able to control application force with high accuracy (Table 1). However, both the bias and precision errors of the measured application forces tended to increase with increases in the target application force (Table 1).

There was a statistically significant difference in the standard deviation of the shear wave speeds for at least one of the four application forces ($p < 0.001$ for all axial loads) and between each target application force and the self-selected application force ($p < 0.001$ for all pairwise comparisons for all axial loads) (Table 1). The standard deviation of shear wave speeds tended to decrease with increases in application force (Table 1).

**Table 1: Statistics quantifying the measured application forces and the variability of shear wave speeds. Asterisks (*) indicate significant differences in the standard deviation of the shear wave speeds between the target and self-selected application forces.**

| Axial Load | Target Application Force | Measured Application Force [N] | | Shear Wave Speed [m/s] |
|---|---|---|---|---|
| | | Mean | Std. Dev. | Std. Dev. |
| 100 N | self-selected | 1.1 | 0.8 | 40.7 |
| | 2 N | 2.0 | 0.1 | 9.7* |
| | 5 N | 4.9 | 0.2 | 4.6* |
| | 8 N | 7.8 | 0.3 | 3.0* |
| 200 N | self-selected | 1.1 | 0.7 | 63.3 |
| | 2 N | 2.0 | 0.1 | 8.2* |
| | 5 N | 5.0 | 0.2 | 5.8* |
| | 8 N | 7.7 | 0.4 | 4.6* |
| 300 N | self-selected | 1.1 | 0.8 | 139.9 |
| | 2 N | 2.0 | 0.1 | 38.7* |
| | 5 N | 5.0 | 0.2 | 3.0* |
| | 8 N | 7.8 | 0.4 | 2.3* |

## DISCUSSION

We found that users tended to apply self-selected forces to the tensiometer that were lower than the target application forces and variable from user to user. With application force feedback, each user accurately achieved the target application forces, suggesting that the design of the application force monitor facilitates precise control.

Consistent with our hypothesis, shear wave speeds were highly variable when the users did not have application force feedback. Interestingly, although higher target application forces were more difficult to control (i.e., larger bias and precision errors), they yielded the least variable shear wave speeds. This may be because higher application forces provide a better coupling between the motions of the specimen and the accelerometers. To determine the cause of the high variability in shear wave speeds at the self-selected application forces, we plan to explore the effects of feedback at lower application forces better matched to user-selected forces. We also plan to incorporate application force monitoring into the tapper.

Previous work found that application force affects measured shear wave speeds [6] and the accuracy of shear wave tensiometers [7]. We extend upon these findings by identifying that self-selected application forces vary between users and that controlling application force decreases the variability of measured shear wave speeds. These insights underscore the importance of providing users with application force feedback to reduce the measurement variability of the tensiometer.

## INTRODUCTION

Traumatic brain injury (TBI) is a serious public health threat that occurs across the length scales from the whole brain to individual cells . Diffuse axonal injury (DAI) is one of the most common types of injury leading to damages to neuronal axons. However, its injury mechanism at the microscale, cellular level, remains elusive. Experimental observations have led to various hypotheses, such as microtubules (MTs) tear [1], strain concentration around the Ranvier node, [2] and interaction among various axonal substructures [3], among others.

To-date, studies on axonal injury mechanisms are limited to specific geometries of selected axonal substructures. Different axonal models have adopted different subsets of substructures, and for common substructures, they do not always have the same geometry either. This makes it difficult to compare findings across studies.

To enhance the understanding of axonal injury mechanism at the microscale, here we develop a parameterized finite element (FE) axonal injury model, where parameters regarding the geometry of each axonal substructures can be specified and adjusted. This allows automatic generation of a model with details of axonal substructures adaptable according to specific needs and/or anatomical regions. Finally, we report results of model validation and injury risks to the microtubules in typical axonal stretches.

## METHODS

A representative volume element (RVE) of an axonal injury model was developed, including major substructures such as microtubules (MTs), microtubule-associated protein (MAP), tau, neurofilament (NF) network, Axolemma, myelin sheath, and the Ranvier node. The baseline model uses average geometrical parameters for each substructure according to the literature [2–4]. Their values are reported in (Table 1). Values for each continuous geometrical parameter are adjustable. The number of MTs across the axonal cross-section is a discrete number. The baseline model choses to use 7 so that to allow a hexagonal staggering, which corresponds to the axon of a female subject [5].This parameter can also be adjusted to 19 when two layers of MTs are present (corresponding to the axon of a male subject). The MT length was found to have a range [6]. Their gaps are then randomly generated based on the statistic distribution that each microtubule has an average length of 4.02 ±5.28 um [6].

**Table 1 | Geometrical features of Axon substructures**[2–4]

| Axolemma radius | # of MTs | MT. spacing | MT inner radius | MT outer radius | g-ratio* |
|---|---|---|---|---|---|
| 200 nm | 7 | 20 nm | 7 nm | 12.5 nm | 0.5 |

*g-Ratio: The ratio of the inner axonal diameter to the total outer (myelin sheath) diameter

Each axon model is composed of hexahedral elements for the MTs, axolemma, myeline sheath, as well as connector elements for tau, NF, and NF-MT connections. Most axonal substructures were assigned with linear viscoelastic material properties based on the literature [2,3].

Nevertheless, material properties for the neurofilament have not been well-characterized. Therefore, we calibrated the NF stiffness by replicating the hertz contact experiment conducted with AFM [7]. Specifically, the indenter tip reaction force was collected and compared with the AFM data to calibrate the NF stiffness. Finally, considering that the connector components play an import role on maintaining the integrity of axonal substructures, a failure model was also included to prescribe the behaviors of the connectors, where a strain failure threshold was set to be 100% strain [1].

After calibration of the NF material properties, the model was validated against in-vivo experimental tension dataset [8]. Axonal model was then used to simulate axonal stretch from a real-world impact. Specifically, a strain history curve in the corpus callosum obtained by simulating a concussive NFL head impact using the anisotropic

SB³C2022-026

Worcester Head Injury Model V1.0 was used as the boundary condition to drive the baseline axonal injury model. The strain curve was scaled so that its peak axial strain was 18%, corresponding to an average injury threshold found from an *in vivo* animal injury model. The peak strain rate for the loading and unloading phases were $\dot{\epsilon}$ = 9.5 $s^{-1}$ and $\dot{\epsilon}$ = -19 $s^{-1}$ respectively. The strain history was then applied as a periodic boundary condition (PBC) to the axonal RVE model.

To further explore how the MT gap configurations affect peak MT strains, we randomly generated 1000 female axonal models with the MT gap locations along each bundle independently following a normal distribution. We then used a range of "critical lengths" to count how many MTs within the given length had a gap. Effectively, this was also to count how many MTs remained intact a within the given length. The classification was based on the first occurrence of maximum number of MTs having gaps in the given length. The critical lengths were chosen as discrete percentages of the average MT length, ranging from 5% to 25%, with a step size of 5%. Then, we used stratified sampling to select 250 from the 1000 total gap configurations to apply the same PBC for numerical simulations.

Due to the extremely small dimension of the axonal models, all simulations were performed in SIMULIA Abaqus Standard using the implicit non-linear FEA solver (32 CPUs, 64GB).

## RESULTS

Figure 1 shows MT undulation pattern of a female (7 MTs) and a male (19 MTs) model (**Fig. 1a**) occurring during unloading. Qualitatively, this matched well with the experiment result observed from dynamic stretch injury analysis (**Fig. 1b**) [4]. We found that unloading (i.e., strain from peak to zero) was critical for the undulation, which did not happen during the loading phase. We also found that gaps along MT bundles critical for the formation of undulation, without which no undulation was observed (**Fig. 1c**). In addition, MT deformation strongly depended on the gap configuration (**Fig. 1d**).

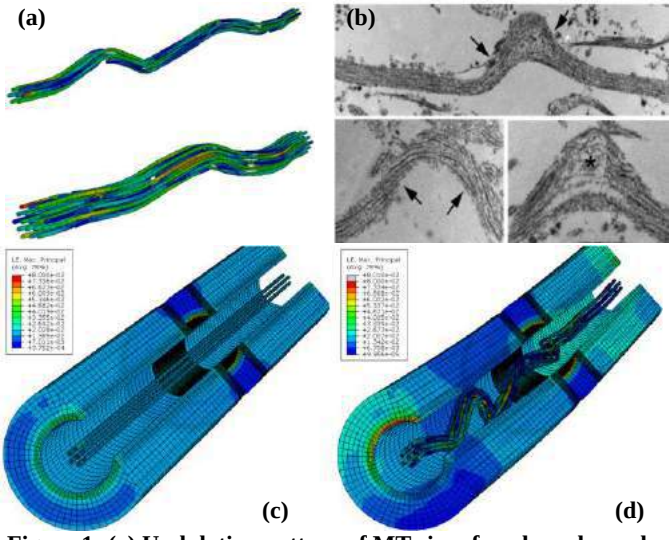

**Figure 1: (a) Undulation pattern of MTs in a female and a male axonal injury model; (b) MT undulation in dynamic stretch injury test [6]; (c) No undulation if no gaps along MT bundles; (d) Undulation strongly depends on MT gap configuration.**

Figure 2 summarizes peak MPS of the MT bundles resulting from the 250 random axonal models. Each grid represents a gap configuration, i.e., within x% of the MT as the critical length, how many MTs having gaps. The numerical values indicate the average peak MPS of those corresponding models. Evidently, the more MTs having gaps within a shorter range, or, equivalently, the less MTs remaining intact within a shorter range, the higher peak strains would occur. Some grids had no peak strain values, because there were no models satisfying the specified MT gap configuration, due to the random nature of how axonal models were generated following the statistical model.

The highest MT peak strain was 32.4%, when there were 5 MTs having gaps within a critical length of 10% of the average MT length. This represented an 80% increase of the peak input strain of 18%. When fewer MTs having gaps within a larger critical length, peak MPS was much reduced, to about 10% higher than the peak input strain.

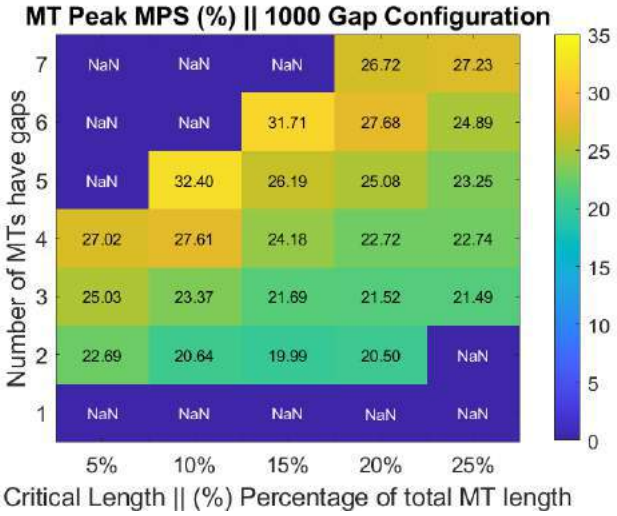

**Figure 2: Peak MPS of MT bundles disaggregated by gap configuration from 250 numerical simulations.**

## DISCUSSION

Our parameterized axonal injury model offers an efficient approach for future large-scale studies of axonal substructural damages. We find that unloading is critical to the formation of MT undulation, which has not been reported previously. In addition, we find that the MT gap configuration plays an important role in peak strain amplification. The strain amplification map (**Fig. 2**) indicates that the more MTs having gaps (or equivalently, the less intact MTs) within a shorter length, the higher the peak strain amplification. This is consistent with expectation, and suggests the effectiveness of our classification strategy of the MT gap configurations. These findings may lead to improved understanding of injury mechanisms of microscale axonal injury.

# MUSCLE IMMOBILIZATION PREVENTS FUNCTIONAL DEVELOPMENT OF EMBRYONIC TENDONS BUT DOES NOT AFFECT COLLAGEN CROSSLINKING

## INTRODUCTION

To date, no tissue engineered tendon construct has successful replaced a tendon or ligament in a human patient[1]. Understanding how tendon naturally develops can provide critical insights into advancing tissue engineering strategies. In particular, chick tendons experience a critical period during late embryonic development in which there is a rapid increase in the tissue multiscale mechanics[2,3,4]. While various structural changes contribute to this behavior, our recent work suggests that this transition is mediated by less interfibrillar sliding and increased fibril loading due to collagen fibril lengthening[4]. Additionally, both the change in tissue mechanics and collagen fibril lengthening were dependent on muscle activity[4]. However, it's unclear what other structural changes may contribute to tendon development. For example, lysyl-oxidase (LOX) activity, which mediates collagen crosslinking, also increases during late embryonic development and is dependent on muscle activity[5]. Still, it's unclear whether the effects of muscle paralysis on tendon tensile mechanics are due to reduced collagen crosslink formation. Therefore, the objective of this study was to measure the change in functional collagen crosslinking following muscle paralysis and investigate the effects of LOX inhibition on the tensile multiscale mechanics of developing tendons. We hypothesize that muscle paralysis and LOX inhibition will reduce the macroscale mechanics but paralysis will decrease the fibril:tissue strain ratio (i.e., increase fibril sliding) while LOX inhibition will increase the fibril:tissue strain ratio (i.e., increase fibril strain). Additionally, we hypothesize that muscle paralysis will not alter the enthalpy or temperature required to denature embryonic tendons, suggesting that functional crosslinking is not dependent on muscle activity. This study will provide essential knowledge regarding the structure-function processes driving tendon development, which will aid the advancement of tissue engineered tendon constructs.

## METHODS

Chicken eggs were obtained under IACUC approval and windowed at embryonic day 3 (E3). Rigid or flaccid paralysis was induced by an injection of decamethonium bromide (DMB) or pancuronium bromide (PB), respectively. Specifically, at E13 eggs were given 100 ul of a 0.02% DMB or PB, followed by daily 50 ul injections from E14-E19 of the same concentration. LOX mediated crosslinking was inhibited with 2 mg of BAPN at E15. Controls for both groups consisted 3of saline injections with matching treatment protocols. Embryos were sacrificed at E20 for testing.

Mechanical testing was conducted using a custom micotensile device mounted atop a confocal microscope[5]. The flexor brevis tendon was dissected and stained with 5 µg/ml DTAF. Samples were mounted at a gauge length of 10 mm and preloaded to 0.1 g. Image stacks were acquired to measure the major/minor diameter to calculate the cross-sectional area assuming an elliptical cross-section. Three sets of photobleached lines (PBL) (4 lines, 80 µm apart) were bleached at the sample center and ±1.5 mm from the center. Samples were then loaded to failure in 2% grip-to-grip strain increments. After each increment, samples were allowed 20 min of stress relaxation and then image stacks were acquired at all PBL locations. The stage positions of the two peripheral PBL sites were used to calculate the macroscale tissue strain. Fibril strains were calculated using custom MATLAB code as the change in distance between the individual photobleached lines at each site[5]. The fibril:tissue strain ratio was calculated by dividing the mean fibril strain by the bulk tissue strain at each increment.

Differential scanning calorimetry (DSC) was performed to determine the degree of functional collagen crosslinking in developing tendons and paralysis/BAPN treatments[7]. Samples were hermitically sealed in an aluminum pan, equilibrated at 30°C, and then ramped to 80°C at 3°C/min. Endotherms were analyzed using TA Universal Analysis software for peak denaturation temperature and total enthalpy of denaturation (ΔH). The percentage of enthalpy absorbed at a lower peak temperature (Peak 1 ΔH / Total ΔH) was calculated to assess the relative amount of collagen with reduced crosslinking.

SB³C2022-027

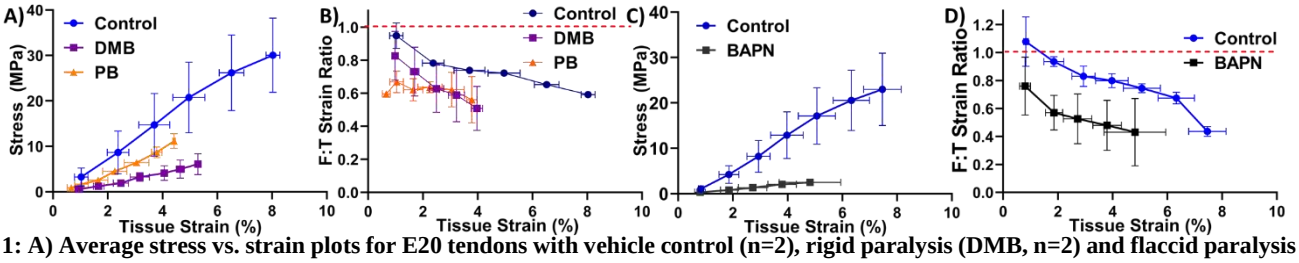

**Figure 1: A) Average stress vs. strain plots for E20 tendons with vehicle control (n=2), rigid paralysis (DMB, n=2) and flaccid paralysis (PB, n=2). B) The decrease in the fibril:tissue strain ratio with applied strain with paralysis was not significant (DMB: p = 0.32, PB: p = 0.35) C) Average stress vs. strain plot for E20 tendons with vehicle controls (n=2) and LOX inhibited (BAPN, n=4) treatment. D) The fibril:tissue strain ratio was significantly reduced with LOX inhibition (p < 0.01).**

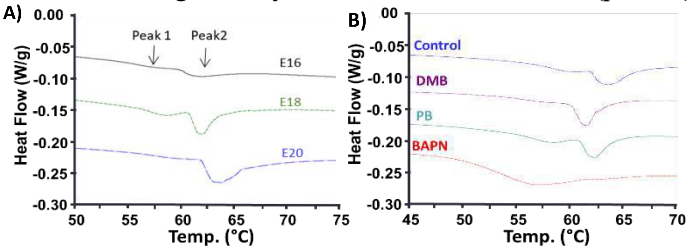

**Figure 2: A) Representative endotherms as a function of development. Arrows mark the two peaks of enthalpy absorption. B) Representative endotherms of E20 tendons after rigid paralysis (DMB), flaccid paralysis (PB), or LOX inhibition (BAPN).**

Statistical differences in fibril:tissue strain ratio were evaluated using a linear mixed model with strain as a covariate. A one-way ANOVA with a Dunnett's post-hoc test was used to evaluate differences in modulus and thermal properties with respect to paralysis or BAPN treatments. A one-way ANOVA with a Tukey's post-hoc test was used to evaluate differences in thermal properties as a function of development. Significance was set at $p < 0.05$.

## RESULTS

Both forms of skeletal paralysis significantly reduced the macroscale modulus of developing tendons (Control: 462 ±86.2 MPa, DMB: 125 ± 49.0 MPa p<0.001, PB: 249.8 ± 19.3 MPa p< 0.05) (**Fig. 1A**); however, there was no change in the fibril:tissue strain ratio (DMB: p=0.31, PB: p=0.35). BAPN treatment significantly impaired the macroscale modulus (51.41 ± 31.84 MPa, p<0.001) (**Fig.1C**) and reduced the fibril:tissue strain ratio in comparison to vehicle control (p< 0.01) (**Fig. 1D**). With development, increases in the total enthalpy (p<0.05) and the peak temperatures (p<0.01) were observed (**Fig. 2A, Table 1**). Paralysis treatments resulted in no change in total enthalpy, but PB treatment increased the proportion of enthalpy absorbed by temperature peak 1 (p<0.05). Both PB & DMB paralysis reduced peak denaturation temperatures ($T_{Peak}$) (p<0.05) in comparison to controls (**Table 1**). BAPN treatment created a large shift in the endotherm curve (**Fig. 2B),** characterized by a significant increase in the relative enthalpy absorbed in peak 1 (p<0.001) and a reduction in peak temperatures (p<0.05) despite no net change in total enthalpy.

## DISCUSSION

This study has demonstrated that, while tendon development requires musculoskeletal activity and LOX mediated crosslinking, they are independent of each other. That is, while both paralysis and BAPN treatments caused similar effects on tendon multiscale mechanics, they exhibited very different effects on functional crosslinking as measured via DSC. This is evident from the endotherm curves (**Fig. 2B**) and the amount of enthalpy absorbed at the lower temperature peak (**Table 1**). Specifically, nearly 90% of the enthalpy required for denaturation occurred in peak 1 for BAPN treated tendons, which is characteristic of an abundant population of collagen with reduced crosslinking[7].

Consistent with prior studies showing a decrease in LOX activity after paralysis[5], there was an increase in the Peak 1 ΔH / Total ΔH in the PB treated animals. However, the overall net effect is minimal in comparison to the direct LOX inhibition. This suggests that functional collagen crosslinking is not dependent on muscle activity and that the effect of muscle paralysis on tendon mechanics is not due to decreased crosslinking. This further reinforces the conclusion from previous work that impaired tendon development with loss of muscle activity is due to an impairment of collagen fibril elongation.

Interestingly, rigid muscle paralysis (DMB treatment) at E13 resulted in a significant reduction in the macroscale modulus (**Fig. 1A**). This conflicts with our prior findings that induced paralysis two days later at E15[4], suggesting that embryos in our earlier work were not fully immobilized. The similar effect of both rigid and flaccid paralysis suggests that there is no difference between complete unloading and static tendon loading and that limb motility is the stimulation driving tendon development. While the reduction in the fibril:tissue strain ratio was not significant for both paralysis treatments, this was likely due to a small sample size (n=2)[4]. It was also interesting that BAPN treatment significantly reduced the fibril:tissue strain ratio, indicating that collagen crosslinking is necessary to transmit load between the fibrils. It is possible that this is due to a weakening of small diameter collagen fibrils that possibly transfer load between the larger diameter collagen fibrils in tendon[8]. Additional work is required to characterize the unique effects of muscle paralysis and crosslink inhibition on the hierarchical collagen network and the mechanisms of interfibrillar load transfer.

## INTRODUCTION

Red blood cells carry hemoglobin molecules in the bloodstream, delivering oxygen to peripheral tissues and returning to the lungs where deoxygenated hemoglobin can again bind to oxygen. Pulse oximeters measure the percentage of absorbed light in circulating hemoglobin bound to oxygen, or the ratio of oxygenated to deoxygenated hemoglobin. Pulse oximeters emit two frequencies of light through the hand, foot, and ear of infants or fingertip of adults, then, a sensor on the other side of the appendage detects how much light and of what frequency was absorbed by the hemoglobin in the bloodstream [1]. The sensors' data is then displayed to an external reader showing the percentage of the patient's hemoglobin that is bound to oxygen of the patient.

Pulse oximetry is commonly used in delivery rooms, especially during the resuscitation of newborns requiring some assistance to begin breathing at birth. Around 10 million of 136 million babies born annually require assistance to breathe at birth. Each year 1.03 million neonatal deaths result from complications of prematurity and 814,000 from intrapartum-related events in term babies (previously "birth asphyxia") [2]. Within the first minutes of an infant's life, doctors must obtain an accurate oxygen saturation level and electrocardiogram (ECG) signals as well as provide adequate thermoregulatory, respiratory and circulatory support, and administer intravenous medications and fluids as needed. Both oxygen saturation levels and the ECG determine the next course of action for the infant's treatment. As the provider works through the neonatal resuscitation algorithm, if any of these aspects are below standard, the doctor must quickly support the establishment of breathing and circulation [3]. The initial rapid establishment of adequate oxygenation and ventilation is of such importance to neonates that this first sixty seconds of resuscitative effort has been named "the Golden Minute."

During the resuscitation process, there are several problems in obtaining an accurate and reliable reading from the pulse oximeter. The main problem is to provide a secure and rapid attachment of the pulse oximeter device to the infant's hand or foot. Most pulse oximeters for neonatal applications use an adhesive band to secure the device as shown in Figures 1a, b. [4].

**Figure 1a.: Hand attachment of a Masimo Pulse Ox band**

**Figure 1.b: Foot attachment of a Masimo Pulse Ox band**

In the hand attachment method, a natural response from infants after birth is to ball their hands into a fist. Opening the infant's hand to attach the device can be difficult, dangerous to fingers, and time-consuming. Both in hand and foot attachment, the alignment of the emitter with the sensor on each side is difficult to achieve because of the difference in body size of each infant. Even though the balled hand problem does not exist in the foot attachment, the adhesive (in both hand and foot) is often ineffective because of the presence of some combination of vernix, amniotic fluid, blood, and meconium [5]. Cleaning away these substances can be time-consuming in a situation where time is of the essence. The adhesive can also be dangerous to neonate's skin,

especially premature neonates during the removal. In addition, when the device is fully attached, a consistent contact pressure of sensor and the emitter is required for reliable and accurate reading. Extraneous motion can detach the sensor and cause false alarms and erroneous readings from the device [5]. In neonates, extraneous movement can include kicking, stretching, crying, and flexing, as well as the movement created by providers administering cardiopulmonary resuscitation to an otherwise unresponsive patient. Other reasons a pulse oximeter may give inaccurate readings include ambient light interruption and low light perfusion [6]. Inaccuracies in pulse oximetry can leave providers in the dark making their determination of correct treatment method very difficult. Lastly, the previously mentioned Pulse Ox band requires two hands from the neonatologist or nurse for attaching the device to the baby's hand or foot.

In this paper, we developed and prototyped a pulse oximeter device with a clamping mechanism for rapid, secure, and safe attachment to the infant's hand or foot. Using this device, the neonatologists can attach the sensors with only one hand, ensuring a perfect alignment of sensors at all times with consistent contact pressure.

## METHODS

As mentioned in the last section, an accurate and reliable reading of pulse oximeter sensors requires adequate alignment of emitter and sensor, minimizing the movement of sensors, and providing a consistent sensor contact on the skin to maintain light transmission from the emitter to the detector. This also serves to protect fragile skin and soft tissue. In addition, in a neonatal resuscitation process, a fast while safe attachment of sensors may be lifesaving. To meet all the requirements above, we developed a spring-loaded (0.879 in.lbs) parallel clamping mechanism where the top clamp is padded (using medical-grade silicone gel) and the bottom clamp is a solid bar with round edges and a soft and smooth surface to help to open a balled (fist) hand if needed (Figure 2). Each clamp has a sensor mounted on the surface. The hook and loop band at the tip of the clamps ensures the device is not sliding out of the infant's hand due to the sudden movements during the reading.

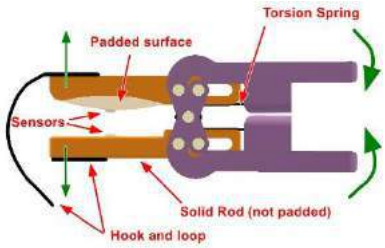

**Figure 2.a: Our clamping Pulse Ox when open**

**Figure 2.b: Clamping Pulse Ox when closed**

The main risk associated with our device is the amount of force applied to the infant's hand. Our device is designed to provide a gentle pressure to avoid any damage to the skin, bones, or underlying soft-tissue while maintaining contact. To measure the force created by the clamps, a Sparkfun SEN-09376 force sensitive resistor is placed between the clamps and the analog signal is measured using an Arduino Mega 2560. The same experiment is conducted on a Masimo neonate Pulse Ox and a Face Lake fingertip Pulse Ox (Fig 3a, b, and c).

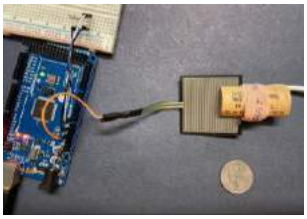

**Figure 4.a: Masimo neonate Pulse Oximeter**

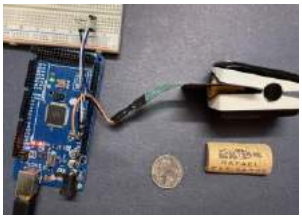

**Figure 4.b: Face Lake fingertip pulse oximeter**

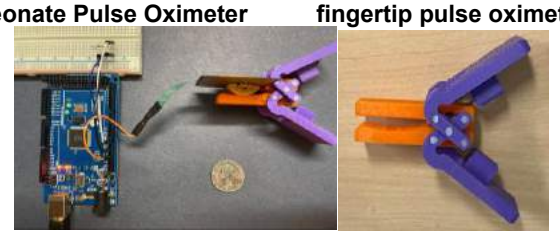

**Figure 3.c: Our parallel clamp device prototype**

## RESULTS

The results of these experiments showed that the force from the Masimo device was 0.05 lb., the Face Lake device was 0.524 lb. and our device was 1.75 lb. These results show that our force is larger than the other two devices and needs to be lowered down to a safe value by choosing a lighter spring while providing a secure connection during the reading. The 0.05 lb. from the Masimo Pulse Ox band is not adequate to provide consistent pressure. Therefore, we decided to use the 0.5 lb. force value from the fingertip device as our baseline for choosing the new torsion spring since our attachment mechanism is more similar to this device where it ensures that the device won't slide off the patient's finger during the screening process. Since the load value needs to be reduced to 0.5 lb. from 1.75 lb. (3.5 times less), the torsion spring load should be lowered to 0.879/3.5=0.251 in.lbs. Using this spring, we ensure that a secure connection with consistent pressure is provided while the baby's hand is protected.

## DISCUSSION

Our pulse oximeter device provides fast, easy, secure, and reliable attachment of the sensors to the infant's hand during the resuscitation process. Unlike the hinged fingertip device that touches the skin in a slope with varied force (higher closer to the hinge), our device with parallel attachment mechanism always provides consistent pressure across the contact surface. Also, our device can be easily mounted by one hand with no adhesives to avoid damaging the infant's skin in a wet environment.

## ACKNOWLEDGEMENTS

A special thanks to Emily Cazes and Sarah Cheatham, undergraduate students at the University of Texas at Austin, for their collaboration in this project.

## INTRODUCTION

Of the nearly 4 million women who give birth each year in the U.S., roughly a third undergo Cesarean delivery [1], where the baby is delivered via an abdominal incision rather than vaginally. This rate is one of the highest in the world, more than double that of the global average and the upper limit on medically necessary Cesarean deliveries as estimated by the WHO [2]. Cesarean deliveries introduce risk of maternal morbidities [3]. While the United States Department of Health and Human Services has identified a need to reduce the number of Cesarean procedures performed in the United States, there are currently no scientific-based criteria for their recommendation or administration [4].

Cesarean procedures are intended for cases when the mechanically intensive process of vaginal delivery is not possible or safe for a mother, avoiding trauma to the vaginal canal such as lacerations. As such, knowledge on the mechanical properties of vaginal tissue could provide a basis for deciding when Cesarean sections are recommended and performed. There is currently a paucity of knowledge on the viscoelastic properties of the vaginal canal. In this study, we utilize free-extension inflation to characterize the creep behavior of the rat vagina under biaxial loading.

## METHODS

The vaginal canals of 10-week-old virgin female Sprague Dawley rats were isolated via dissection. Cross-sectional images were captured under dissection microscope, from which vaginal radius and thickness were measured using ImageJ (NIH, Bethesda, MD). Specimens (n=13) were mounted onto vertically aligned concentric dispensing needles as described in [5], such that one needle could freely extend from the other as the vagina was inflated (Figure 1). Once mounted, the specimens were speckled with spray paint to create a pattern for non-contact strain measurements using digital image correlation (DIC).

Specimens were submerged in a phosphate buffered saline (PBS) bath during testing. Specimens were preconditioned to 150% of their initial volume and back for 20 cycles by a computer-controlled syringe pump. After a 600 second rest period, the specimens were then inflated with PBS to 4 psi for 50 minutes (creep test 1), then immediately to 8 psi for 50 minutes (creep test 2), then immediately to 12 psi for 50 minutes (creep test 3). There was no rest period between creep tests. Throughout testing, two CMOS cameras (Basler ace acA2440-75$\mu$m, Basler Inc., Exton, PA) captured images of the dorsal wall of the specimens at a rate of 2 Hz as the pressure increased and 0.2 Hz under constant pressures.

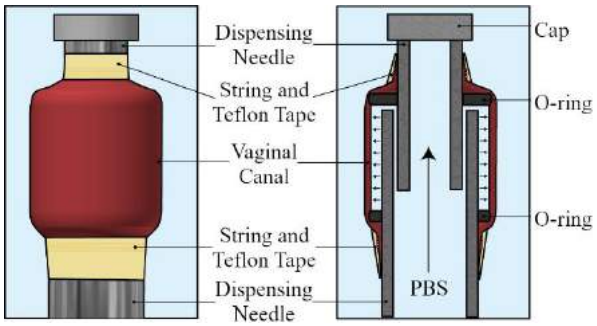

**Figure 1: Vaginal tissue clamped between two concentric needles as described in [5].**

Using these images, 3D DIC software (Vic-3D, version 8, Correlated Solutions, Columbia, SC) was used to calculate the normal axial Lagrangian strains in the longitudinal direction (LD) and circumferential direction (CD) of the vagina. Nominal normal stresses in the LD and CD were calculated assuming the specimens behave as a cylindrical pressure vessel, using the collected pressure data and measured dimensions. A map of the local normal Lagrangian strains in the LD and CD for a representative specimen is shown in Figure 2. As these strains varied across the surface of each specimen, a small circular region with a diameter <1 mm was selected, and the average (across this region) were computed.

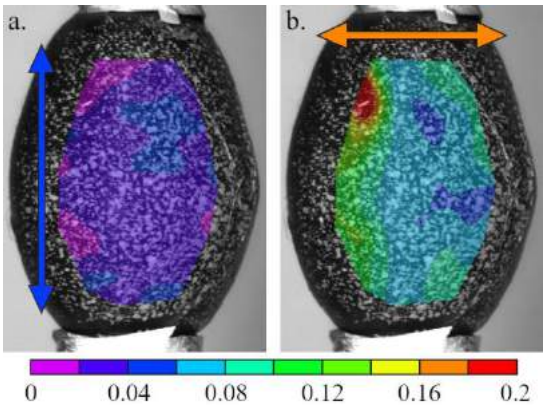

**Figure 2: Maps of axial strains in the LD (a) and CD (b) for a representative vaginal specimen. Blue and orange arrows indicate the orientation of the LD and CD respectively.**

## RESULTS

The average increase in strains over time in the LD and CD from the beginning to the end of each creep test is shown in Figure 3 (n=13).

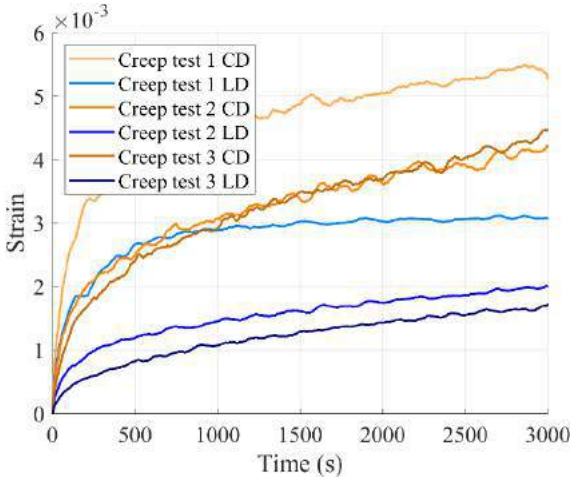

**Figure 3: Average increase in strain over time throughout creep tests 1, 2, and 3 in the CD and LD (n=13).**

The mean increase in strains in the LD and CD at 3000 s into each creep test are reported in Table 1 (n=13). Under paired t-test, the change in strain at 3000 s into each creep test was significantly higher in the CD than in the LD ($p < 0.05$). In the LD, the increase in strain during creep test 1 was significantly higher than the increase in strain during creep test 2 or 3. In the CD, the increase in strain during creep test 1 was significantly higher than the increase in strain during creep test 2. Other comparisons were not statistically significant under paired t-test.

**Table 1: Average (mean ± s.e.m.) increase in strain in the LD and CD at 3000 s into each creep test (n=13).**

| | LD | CD |
|---|---|---|
| Creep test 1 | 0.00309 ± 0.00045 | 0.00534 ± 0.00090 |
| Creep test 2 | 0.00188 ± 0.00021 | 0.00411 ± 0.00045 |
| Creep test 3 | 0.00167 ± 0.00016 | 0.00438 ± 0.00045 |

## DISCUSSION

This study presents the first biaxial study of the creep behavior of rat vaginal tissue at multiple and consecutive levels of pressure/stress. The vaginal specimens were found to strain consistently more in the CD than the LD. The increase in strain was higher during creep test 1 than during creep test 2 or 3. It is likely that the organization and architecture of the collagen fibers, which dictate the mechanical behavior of vaginal tissue, play an important role in reducing the strain experienced by the tissue during creep in the LD and at subsequent pressures/stresses.

In agreement with Clark-Patterson et al. [6], our experimental data showed that increasing pressure/stress does not lead to a proportional increase in strain during creep. Although the results are not included in this data set, several specimens ruptured during creep at 12 psi (creep test 3). This could indicate that the structural mechanism which acts to decrease the amount of strain from the first to second creep test fails at higher pressure/stress, possibly due to tissue damage.

This work represents a crucial first step in understanding the complex mechanical behavior of vaginal tissue. Investigations which pair further viscoelastic mechanical studies with microstructural investigations will provide critical key insights into why and how the behaviors observed in this study occur. Furthermore, future studies will investigate how the mechanical properties investigated here change throughout pregnancy to anticipate childbirth. This in turn will provide information for setting universal criteria for the recommendation and administration of Cesarean procedures.

# CHARACTER IMPEDANCE WITH EXERCISE TESTING CORRELATES WITH RIGHT VENTRICULAR-PULMONARY ARTERIAL COUPLING IN ISOLATED POSTCAPILLARY PULMONARY HYPERTENSION

## INTRODUCTION

Pulmonary hypertension (PH) is present in ~70 million people globally and almost always leads to a mismatched right ventricular (RV)-pulmonary arterial (PA) relationship (RV:PA uncoupling), resulting in right heart failure (RHF) [1]. The gold standard method of PH diagnosis involves right heart catheterization (RHC) to measure mean pulmonary arterial pressure (mPAP), pulmonary arterial wedge pressure (PAWP), and pulmonary vascular resistance (PVR) [2]. However, during early disease stages at rest, the pulmonary vasculature can compensate, leading to misdiagnosis and an average three-year diagnosis/treatment delay [3]. Recently, exercise testing has been shown to detect and diagnose at these early stages of PH, improving clinical intervention and prognosis [3].

Even when PH assessment incorporates exercise testing, however, diagnosis relies on PVR, which is primarily based on steady pulmonary hemodynamics, ignoring the innate pulsatile component in pulmonary vasculature [4]. By contrast, pulmonary vascular impedance (PVZ) captures the relationship between pulsatile pressure and flow, which depends on arterial stiffness and lung compliance [5, 6]. To date, only a few studies have quantified PVZ during exercise [7, 8] and none have investigated correlation with RV:PA uncoupling.

Therefore, our goal was to measure and analyze the relationship between metrics of PVZ, including characteristic impedance ($Z_C$), and RV:PA coupling during exercise in subjects with PH. We hypothesize that increases in $Z_C$ with exercise will correlate with RV:PA uncoupling.

## METHODS

**Subject Population.** 10 adult subjects (5 female, 5 male) referred for invasive cardiopulmonary exercise testing (iCPET) were enrolled in a multi-step, rest-to-exercise-to-recovery study protocol. Enrolled subjects were in WHO Group I (pulmonary arterial hypertension; PAH, n = 3), II (PH due to left heart disease; PH-LHD, including both Ipc-PH and Cpc-PH, n = 5), and IV (PH due to chronic thromboembolism; PH-CTEPH, n = 1) or did not have PH (n = 1). The study protocol was described to all subjects, who provided informed consent (IRB ID: 2019-1184).

**Invasive CPET & Echocardiogram.** All subjects underwent iCPET in the semi-recumbent position utilizing a cycle ergometer [9]. This assessment included simultaneous RHC at rest and exercise, with simultaneous pulsed-wave Doppler (PWD) echocardiography of the right ventricular outflow tract (RVOT). Then, subjects performed exercise with 2-minutes of unloaded peddling, followed by an incremental ramp protocol at 10 Watts/min (60 RPM on ergometer at all times). At every 25 Watts, the incremental protocol was held at that stage, and simultaneous PAP (via Millar catheter) and RVOT PWD were acquired. After peak symptom-limited exercise, simultaneous PAP and echocardiographic doppler data were acquired 5-minutes into recovery.

**Real-Time Pressure-Volume Loop Acquisition.** Simultaneous pressure-volume (PV) data were obtained with a high-fidelity conductance catheter (CD Leycom, Zoetermeer, Netherlands) inserted and advanced into the RV cavity near the apex [10].

**Pulmonary Vascular Impedance Analysis.** From the continuously obtained, time-dependent, PA pressure (P) and flow (Q) waveforms, the time domain characteristic impedance ($Z_C$) at rest, exercise, and recovery was estimated by the "up-slope" method of the P-Q relationship during early systole for varying threshold percentages of the maximum flow rate ($Q_{max}$), which was based on an iterative linear fit and sum of squares process [5]. $Q_{max}$ threshold percentages ranged from 40-80%, with a mean threshold of 56%.

**Right Ventricular, Pulmonary Arterial Coupling Analysis.** RV:PA coupling was determined by the ratio of end-systolic to arterial elastances ($E_{es}/E_a$), which were derived from RV PV loops and pressure waveforms, for each subject at all stages of protocol following the second derivative single beat method [11, 12].

**Statistical Analysis.** Linear regression and two-tailed Pearson's correlation coefficient analyses were used to assess the relationship and significance between $Z_C$ and RV:PA coupling during exercise. p-value $\leq 0.05$ was considered significant. $R^2 \leq 0.40$ was considered a weak linear relationship, $0.40 \leq R^2 \leq 0.70$ was considered a moderate linear relationship, and $R^2 \geq 0.70$ was considered a strong linear relationship.

## RESULTS

**Association Between $Z_C$, RV:PA Coupling, and Exercise.** The small sample sizes for Cpc-PH (n = 1) and No PH (n = 1) prevented statistical analysis and drawing conclusions for these groups. There was a significant negative relationship between RV:PA coupling and $Z_C$ in the Ipc-PH group during exercise (**Fig. 1A;** slope = -28.94, $R^2 = 0.48$, $p \leq 0.05$), which was absent in the pre-capillary PH group (**Fig. 1B**). Moreover, in the pre-capillary PH group, $E_{es}/E_a$ was weakly positively correlated with $Z_C$ during exercise (slope = 13.03, $R^2 = 0.08$). When only focusing on the exercise segments of the protocol (i.e., excluding rest and recovery stages), RV:PA coupling correlated even more strongly with $Z_C$ in the Ipc-PH group ($R^2 = 0.73$, $p \leq 0.05$) but remained non-significantly correlated with $Z_C$ in the precapillary PH group ($R^2 = 0.08$, $p > 0.05$).

## DISCUSSION

The current study confirms that measuring impedance and ventricular pressure-volume loops during exercise provide a comprehensive assessment of cardiopulmonary disease that can be used to better understand the pathophysiology of disease. Our main finding is that $E_{es}/E_a$ and $Z_C$ exhibit a significant, strong inverse correlation in Ipc-PH, but not pre-capillary PH (**Fig. 1**). The lack of relationship between $E_{es}/E_a$ and $Z_C$ in pre-capillary PH is supported by recent findings from Ravallette, which investigated 47 PAH subjects that were grouped based on disease severity [13]. However, these findings were limited to analyses at rest. Further interpretation of our results reveals that in Ipc-PH there may be a threshold (~0.016 mmHg*s/mL), above which $Z_C$ negatively correlates with $E_{es}/E_a$. In our data, below this threshold, the correlation is weaker, the data are more spread out, and all Ipc-PH subjects were at rest or in recovery. Alternatively, exercise may generate a unique relationship between $Z_C$ and RV:PA coupling in Ipc-PH, further supporting exercise's diagnostic impact.

Furthermore, in the Ipc-PH subjects, it appears that as exertion increases, the change in pulsatile hemodynamics deteriorates the RV:PA relationship, which is intact at rest. Recently, two unrelated studies had similar findings, where $Z_C$ increased with exercise in PAH and RV:PA coupling decreased with exercise in PH-LHD [8, 14]. Thus, our study marries these two concepts and reveals a unique uncoupling trend in Ipc-PH with $Z_C$ during exercise. Moreover, our study provides novel correlative information. Finally, in the event that invasive PV data cannot be collected either at rest or exercise, our findings suggest that Ipc-PH subjects whose $Z_C$ increases with exercise experience RV:PA uncoupling with exercise, and thus warrant closer monitoring.

The current study has two main limitations: 1) small sample size for all groups and 2) not all subjects achieved all stages of exercise.

Overall, our findings suggest metrics of pulsatile hemodynamics with exercise reveal distinctive relationships within two PH subgroups, which may not be present at rest. The causal factors responsible for these correlations have yet to be determined.

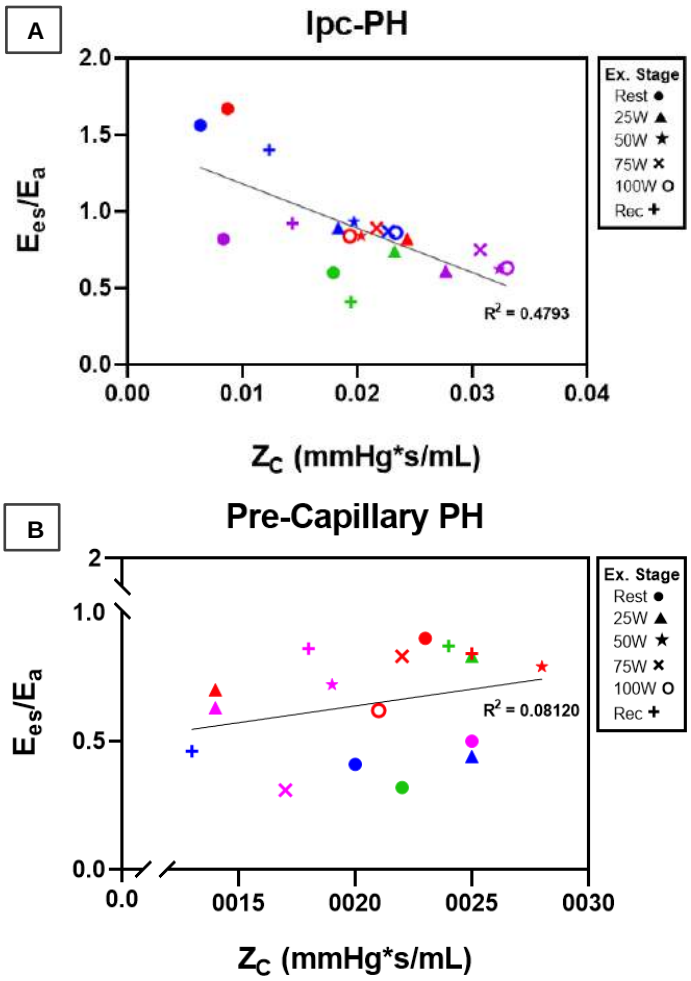

**Figure 1: Correlation comparison between RV:PA coupling ($E_{es}/E_a$) and characteristic impedance in the time domain ($Z_C$) for A. Ipc-PH (n = 4) and B. pre-capillary PH (n = 4). In each group, every subject is shown using a distinct color symbol.**

# A SMART-PIV APPROACH FOR IN VITRO EVALUATION OF CORONARY HEMODYNAMICS

**Elena Torta (1), Giuseppe C. A. Caridi (1), Claudio Chiastra (1), Diego Gallo (1), Umberto Morbiducci (1)**

(1) Polito$^{BIO}$Med Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy

## INTRODUCTION

In the last two decades, Particle Image Velocimetry (PIV) has become a reliable measurement technique for the in vitro characterization of the local fluid dynamics in presence of cardiovascular pathologies (e.g. atherosclerosis, aneurysms) or implantable medical devices (e.g. stent, aortic valve). PIV-based experimental measurements play a fundamental role in validating/verifying in silico models and/or in the design/optimization of cardiovascular devices, contributing to the minimization of safety and ethical issues associated with animal and human experiments [1,2,3]. The wide use of PIV in cardiovascular applications is hampered by the high costs of its components, i.e. high-power lasers, high speed cameras and synchronization units (order of magnitude of 100 k€). Recently, attempts have been made to use alternative test benches adopting e.g. video cameras embedded inside commercial smartphones [4]. A further strength point of turning to lower-cost PIV systems whenever possible is given by the possibility to adopt low-energy light sources requiring much less energy as well as less safety procedures and standards (EN 207 in EU; ANSI z136 in US) than pulsed lasers commonly used in standard PIV applications (the latter belonging to Class 4, IEC 60825-1 i.e. the highest and most dangerous class of laser). In this regard, the feasibility of adopting the combination of a smartphone camera and a continuous wave laser for reliable velocity measurements has been already demonstrated in air and water flows [4]. These alternative approaches, when applicable, have allowed a scaling down of the costs to an order of magnitude of 1 k€.

The present study explores the feasibility of adopting a test bench based on the use of smartphone cameras and low energy light source (referred to as smart-PIV approach in the following) for cardiovascular applications. In detail, (1) smart-PIV is adopted to analyze the flow field in realistic phantoms of healthy and stenotic coronary arteries, and (2) the hemodynamic results are compared with the ones obtained from standard PIV measurements.

## METHODS

The adopted smart-PIV experimental set up is presented in Figure 1. The study was conducted in realistic silicone phantoms of coronary arteries manufactured applying a molding technique by Elastrat (Geneva, Switzerland). One phantom consisted in a patient-specific replica of a healthy left circumflex coronary artery with a diameter of 3mm reconstructed from angiographic images (healthy case). The second phantom represented a diseased condition, through an artificially generated 67% diameter stenosis obtained by locally reshaping the healthy model (stenotic case).

Measurements were carried out under steady state flow conditions, spanning flow rates within a range of 80-100 mL/min for the healthy model and of 10-80 mL/min for the stenotic one, according to in vivo measurements [5]. An ultrasonic flow meter (Transonic, Ithaca, NY, USA) was used to monitor the flow rate. A 60/40 water to glycerin mixture was used as a working fluid in order to match the kinematic viscosity and density of blood. Polyamide particles (density 1030 kg/m$^3$, diameter 60 μm) were used as tracers. In the smart-PIV set-up, a smartphone camera and a low-power continuous laser (30mW) were used. Specifically, the camera of a Samsung Galaxy S9+ (12800x720 pixels, 960 Hz) smartphone was adopted for the time-resolved, high frame rate image acquisition, resulting in an image resolution of 34 μm/pixel (healthy case) and of 26 μm/pixel (stenotic case) and a temporal resolution of 1040 μs. In the standard PIV set-up (Dantec Dynamics A/S, Denmark), one HiSense Zyla camera (CMOS, 2560x2160 pixels) and the Bernoulli 200-15 Dual Pulsed Nd:YAG laser (nominal pulse energy of 200 mJ at 15 Hz) were adopted. The image pair interval Δt ranged between 90-900 μs, while the image resolution was of 20 μm/pixel (healthy case) and of 16 μm/pixel (stenotic case). The MATLAB® (MathWorks, Natick, MA, USA) toolbox PIVlab was adopted to postprocess the acquired images using the ensemble-correlation method [5].

SB³C2022-031

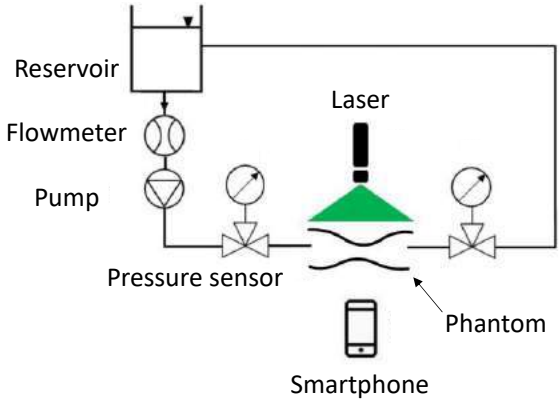

**Figure 1: Experimental smart-PIV set-up. The same hydraulic circuit is maintained for the standard PIV measurements.**

## RESULTS

The comparison between smart-PIV and standard PIV measured 2D velocity vector fields in the healthy and stenosed coronary artery phantoms is shown in Figure 2. In detail, the smart-PIV approach is capable to capture the main flow features identified by the conventional PIV approach, in particular those acceleration regions (one in proximal segment and one in the distal segment) locally dictated by the irregular shape of the healthy vessel phantom (Figure 2-a). The agreement between measurements, which is satisfactory in the central region of the vessel, is moderate in the near wall region. The two PIV-based approaches catch the flow features of the stenotic vessel with a very good agreement (Figure 2-b), in particular (1) the increase in fluid velocity caused by the area reduction in the stenotic region, where the classical jet-like flow configuration is properly detected, and (2) the typical post-stenotic recirculation region. The capability of the smart-PIV approach in identifying local flow features in the stenotic vessel is testified by the results displayed in Figure 3, where the expected expansion/stretching of a stable recirculation region distal to the stenosis in consequence of an increasing flow rate is properly measured.

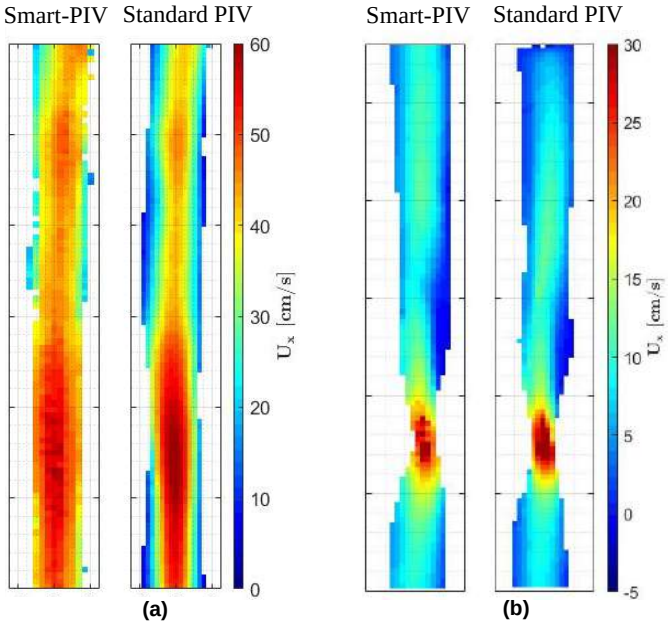

**Figure 2: Axial velocity maps in (a) healthy LCX phantom ($Q_{inlet}$= 80mL/min), and (b) stenotic LCX phantom ($Q_{inlet}$= 30mL/min).**

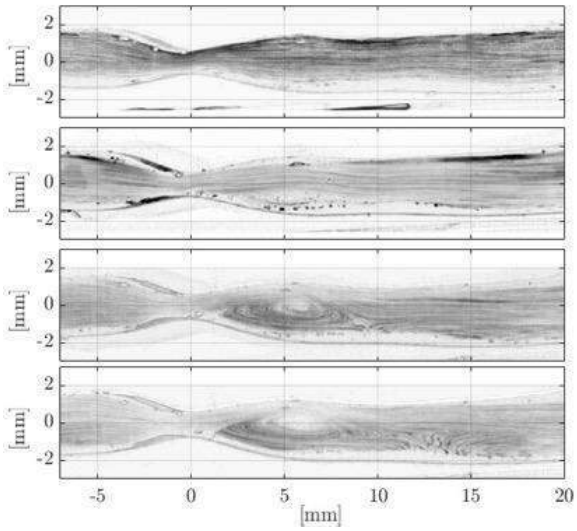

**Figure 3: Flow patterns visualization in the stenotic LCX phantom at (from top to the bottom): 10-30-50-80 mL/min.**

## DISCUSSION

In this study the feasibility of using a smart-PIV approach for the in vitro characterization of healthy and stenosed coronary flows in patient-specific phantoms is explored. Corroborated by standard PIV measurements, the findings of this work support the possibility of employing a low-cost, low-energy consumption, easily maneuverable acquisition system for the characterization of cardiovascular flows [4]. In the very next years, the expected speed up of smartphone-based technologies could allow to use the experimental test bench proposed here for e.g. the rapid and economic characterization of more complex flow fields such as the ones observed in the presence of implantable devices. At this stage of the investigation, the limited smartphone camera image acquisition frame-rate still hampers the wide application of the proposed set-up to the in vitro characterization of e.g. prosthetic heart valves. In relation to the presented coronary artery flow characterization, the limitation in the smartphone camera acquisition frame-rate explains the strong reported agreement between smart-PIV and standard PIV at low-to-moderate flow regimes in the stenotic phantom, while it underwent measurement degradation in the stenosis region at the highest flow regimes, where blur particles generated by continuous illumination and intense spatial gradients might affect the quality of the measured flow field (data not shown).

In conclusion, an easily reproducible and maneuverable, secure, low-cost and low-energy consumption set-up for the in vitro characterization of cardiovascular flow is proposed. Thanks to the decrease in terms of costs and the increase in terms of security, the smart-PIV system can be used for educational and research purposes for low-cost practical investigations, thus expanding the use of PIV in biomedical applications.

## INTRODUCTION

Pelvic organ prolapse is a common condition requiring surgery in 1 of 7 women. High operative failure rates of 25% occur because of a limited understanding of its pathophysiology. Important progress in identifying causal mechanisms has come from 3D analysis of magnetic resonance (MR) images as well as finite element analysis of prolapse, but obtaining a geometric model is an essential but time-consuming step that mainly depends on the image segmentation process. Deep learning methods such as convolutional neural networks (CNNs) have shown advantages in improving the accuracy and efficiency of biomedical image segmentation. Training data are crucial for model performance, but large datasets are difficult to collect and the annotation of biomedical images is expensive, tedious, and time-consuming, further limiting the number of labeled images used for training. Therefore, there is a need to find an approach to reduce the annotation burden for CNN training in biomedical applications.

Since there are usually more images that are not annotated, some researchers have investigated how to utilize unlabeled data through unsupervised learning methods[1-4]. Self-supervised learning (Self-SL) is one of the unsupervised learning methods that uses only unlabeled data to learn general knowledge by creating proxy tasks. But if a few labeled training data are available, these can be used as a reference to guide the CNN training and to evaluate the model performance. So the present method utilizes both labeled and unlabeled data making it a semi-supervised learning (semi-SL) method. The semi-SL method not only reduces the need for labeled data, but also ensures that the model can learn knowledge from manual annotations[5], which is promising for biomedical applications[6].

In this work, we aimed to investigate a semi-supervised algorithm for 3D geometric model reconstruction of pelvic organs using MR images. More details are elaborated below.

## METHODS

To take advantage of both labeled data and unlabeled data, a semi-SL framework was designed (Fig. 1). The training framework had two stages. In the first stage, CNN 1 was trained using the unlabeled MR images for the image restoration task. Next, CNN 2 was trained using the pre-trained weights of CNN 1 to segment using labeled MR images to end the first stage. In the second stage, CNN 2 was used to perform pseudo-label prediction on the unlabeled images. In this stage, the training process of CNN 3 utilized both unlabeled data and labeled data. CNN 3 was also initialized with weights of CNN 1 at the beginning of training. During the forward propagation, CNN 3 was used for the prediction of labeled and unlabeled data. During the backward propagation, the total loss included both the supervised loss and the unsupervised loss, and the CNN 3 weights were updated according to the total loss. These steps are described in detail below.

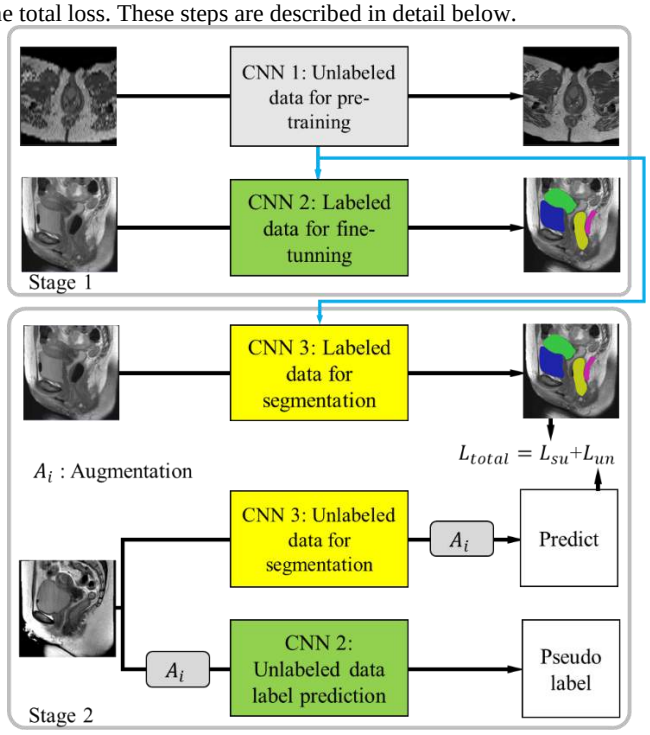

Figure 1: The semi-SL framework for pelvic organ segmentation. Notes: CNNs 1-3 share the same model structure but different weights. $A_i$: Augmentation of rotation and scaling.

In the self-SL step, the image restoration task was used as a proxy task. The image degradation equation was expressed as follows:

$$I^{d}_{\downarrow r_x S_y}(x,y) = I(x \cdot r_x, S(y)) \quad (1)$$

where $I^d$ is the degraded image and $I$ is the original high-resolution image. $r_x$ represents the downsampling ratio and $S(\cdot)$ is the shuffle operator. During downsampling, the downsampling ratio was set to 1:4, 1:6, and 1:8, respectively. The loss function, L1 loss, was defined as:

$$Loss_{CNN1} = \frac{1}{MN}\sum_{m,n}^{M,N} |g_{mn} - r_{mn}| i \quad (2)$$

where $M$ and $N$ are the length and width, respectively. $g_{mn}i$ and $\dot{r}_{mn}$ are the pixel values of the high-resolution image and the predicted image of CNN 1, respectively.

Then CNN 2 was trained using the labeled segmentation data. The loss function is the cross entropy (CE), which was defined as:

$$\text{CE} = \sum_{l=1}^{L}\sum_{n} -t_{ln}\, log(m_{ln}) \quad (3)$$

where $L$ is the total segmentation classes. $t_{ln}$ represents the pixel values of the ground truth and $m_{ln}$ represents the segmentation mask of the $l^{th}$ class at the $n^{th}$ position. CNN 1 trained in the previous step was used for the model initialization of CNN 2.

Next, the weights of CNN 1 weights were used for the initialization of CNN 3. In the semi-supervised training, there are two branches, namely the labeled branch and the unlabeled branch. The total loss was represented as follows:

$$L_{total} = L_{su} + L_{un} \quad (4)$$

where $L_{total}$ represents the total loss, $L_{su}$ represents the supervised loss, and $L_{un}$ represents the unsupervised loss. $L_{su}$ is computed by evaluating the difference between the prediction and the manual annotation. $L_{un}$ was calculated by evaluating the difference between the prediction and the pseudo label predicted by CNN 2. The unsupervised branch was trained using the mean square error (MSE) loss defined as follows:

$$MSE = \frac{1}{L*N}\sum_{l=1}^{L}\sum_{n}(t_{ln} - m_{ln})^2 \quad (5)$$

where $N$ represents the number of pixels for output.

Finally, the segmentation performance was evaluated using the Dice similarity score (DSC), defined as follows:

$$DSC = 2\frac{\sum_{l=1}^{N}\sum_{n} t_{ln} m_{ln}}{\sum_{l=1}^{N}\sum_{n}(t_{ln}+m_{ln})} \times 100 \quad (6)$$

An Adam optimizer was used for training on an NVIDIA TITAN RTX graphics card with 24 GB of computational memory. The CNN was trained for 800 epochs with a learning rate of 0.0002.

To explore the effectiveness of the semi-SL, we used a dataset that included 48 MR series (4103 images), from the Michigan Pelvic Floor Research Collection with ethical approval, scanned in the axial, coronal, and sagittal planes. From the total, 16 MR series (1442 images) were selected for uterus and urinary bladder annotation, and 32 MR series (2661 images) remained unsegmented for self-SL. The labeled MR images were divided into model training (902 images) and testing (540 images) sets. In the testing dataset, 180 images were used for the optimal model validation. Besides, the segmentation performance of vanilla UNet-based baseline[7], self-SL, and semi-SL were compared using different numbers of training images (182, 362, 542, and 722 images).

## RESULTS

A comparison of segmentation performance is shown in Fig. 2. It shows that the segmentation results of semi-SL were consistently better than those of baseline and self-SL when the same number of images were used for training. It also shows that when semi-SL was performed using data from six subjects, the performance was close to the segmentation results of the baseline using data from ten subjects. Similarly, when using the same number of images, self-SL always had better segmentation performance than the baseline. This also shows that the segmentation performances of all three methods improve as training images increases.

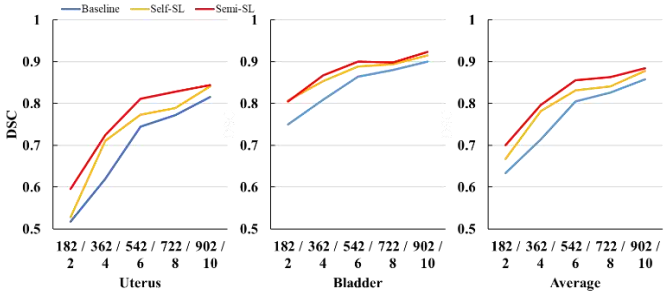

Figure 2: Segmentation performance using U-Net with a different number of training images. 902/10 refers to 902 images from 10 subjects.

For individual organs, the DSCs of the bladder were always better than those of the uterus with the same number of training images. However, the DSC of the uterus improved significantly with the number of images.

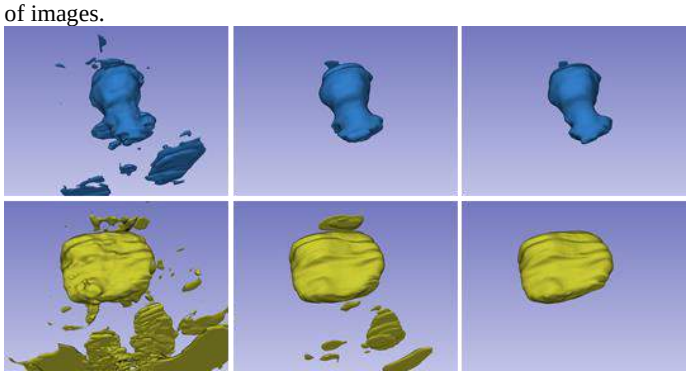

Figure 3: Comparison of the results of the 3D geometric model reconstruction of the uterus (Blue) and urinary bladder (Yellow). The first column shows the baseline results with 542 images. The second and third columns are the results of semi-SL with 542 images and 902 images, respectively.

Fig. 3 shows the results of the 3D geometric model reconstruction for three different configurations. When training with 542 images, the semi-SL (second column) clearly reduced artifacts compared to baseline (first column). The results in the second column are similar to those in the third column, which also demonstrates the effectiveness of the proposed method for reconstruction with less training data. Besides, the average segmentation time for a single MR image is 0.022 seconds.

## DISCUSSION

A semi-SL algorithm was designed to improve the segmentation performance of pelvic organs by utilizing both labeled and unlabeled data. This algorithm proved efficient and accurate for the segmentation and 3D geometric model reconstruction of pelvic organs. In the future, we plan to evaluate the effectiveness of its extension in clinical settings.

## INTRODUCTION

Restenosis is a frequent complication of percutaneous transluminal angioplasty (PTA) in the femoral arteries, which is responsible for the low primary patency rate at 1-year follow-up (~60%) [1]. The PTA-induced injury (i.e., endothelial denudation and arterial wall damage) has been recognized to trigger the inflammatory-driven arterial wall response, characterized by vascular cell activation leading to abnormal tissue re-growth [2]. Moreover, altered hemodynamics after the intervention modulates vascular cell activity, contributing to the overall remodeling of the arterial wall [3]. Besides the biomechanical factors, different systemic and biological events are involved in the complex multifactorial and multiscale process that determines the arterial wall response to PTA, whose complete understanding is lacking. Multiscale computational modeling, integrating continuum- with agent-based methods, has the potential to improve the current knowledge of the underlying pathological pathways by simulating the interrelated mechanobiological events [4]. Accordingly, the present work proposes a fully-automated multiscale agent-based modeling framework that replicates arterial wall remodeling after PTA by integrating the effects of the PTA-induced wall damage and post-intervention hemodynamics on cellular activities.

## METHODS

Figure 1 shows schematically the developed multiscale framework of restenosis following PTA. The framework was applied to an idealized model of a diseased femoral artery and consists of three modules, namely: (i) a PTA module, in which a finite element (FE) analysis of PTA was performed and the post-PTA arterial configuration and wall damage were determined; (ii) a hemodynamics module, in which the wall shear stress (WSS) of the deformed arterial configurations was computed using computational fluid dynamics (CFD) simulations; (iii) a tissue remodeling module, in which a 2D agent-based model (ABM) first replicates arterial wall remodeling of several cross-sections by simulating cellular and extracellular matrix (ECM) dynamics in response to the computed arterial wall damage and WSS, and in a second step reconstructs the 3D arterial lumen geometry from the ABM outputs.

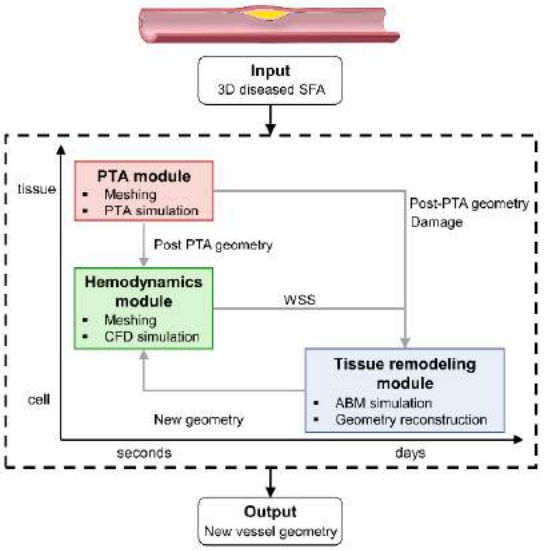

**Figure 1: Multiscale framework of restenosis after PTA.**

The framework was applied for a follow-up time of 3 months. At each simulated post-operative month, the hemodynamics and tissue remodeling modules are coupled, so that the hemodynamics is calculated in the current remodeled arterial geometry and the WSS input to the cellular activities is updated.

For the PTA module, hyperelasticity was considered to model the arterial wall tissues. The material properties were derived from experimental data of human femoral arteries [5],[6]. The ductile damage model available in Abaqus (Dassault Systèmes Simulia Corp.) was adopted to compute the amount of damage of each intima element. Regarding the hemodynamics module, steady-state CFD simulations were performed in the deformed artery models using Fluent (Ansys Inc.) to compute the WSS profile along the luminal wall. A parabolic velocity profile (flow-rate of 200 mL/min [7]) was applied at the inlet, while a reference pressure was applied at the outlet. An ABM for 19 evenly-spaced arterial cross-sections was created using Matlab (MathWorks) by adapting our previously developed ABM of atherosclerosis to the restenosis scenario [8]. Specifically, a three-layered arterial wall ABM structure was created by importing the nodal coordinates of the 19 cross-sections from the FE model. Each layer was populated with cells, ECM and plaque (in the intima of the diseased portion) agents. Probabilistic rules were defined to control the behavior of cells and ECM according to their local damage and WSS inputs. As for the damage-related input (*Dinput*), the FE-computed damage was considered as a weight of a generic post-operative inflammatory curve [9], according to the hypothesis that regions exposed to higher trauma (i.e., higher damage) lead to a more intense inflammatory response. Regarding the WSS-related input (*WSSinput*), luminal regions exposed to low WSS were associated to a high *WSSinput*, which promotes increased cellular activity.

After 1 simulated month, the ABM simulations were stopped, a new 3D arterial geometry was reconstructed from the ABM outputs and the hemodynamics – tissue remodeling modules sequence was repeated until the desired follow-up time (3 months).

## RESULTS

The virtual PTA resulted in an increase in lumen area of ~25% in the treated vessel portion and caused a mild damage (up to ~0.35), with the largest values localized at the plaque side in the intima layer. The hemodynamics in the post-operative arterial configuration presented three regions, namely (i) the healthy extremities were characterized by WSS ~ 0.5 Pa, (ii) the central atherosclerotic portion with a WSS > 1 Pa, and (iii) the region downstream of the plaque with a WSS < 0.05 Pa. Both the PTA-induced damage and the WSS were used to initialize the ABM, simulating the monthly post-operative remodeling of the arterial wall. Figure 2 shows details of the ABM evolution of 2 explanatory arterial cross-sections and the remodeled arterial geometry obtained at month 3. The most important intimal growth was observed at the most vulnerable regions (i.e., those with elevated damage levels and low WSS), with a lumen area reduction of ~25% at plane 10 (plane with the highest damage) and of ~50% at plane 15 (plane exposed to very low WSS). Overall, a median restenosis of 27% was obtained at 3 months, with the greatest reduction in lumen area occurring during the first post-operative month. Moreover, a heterogeneous lumen area reduction was found along the artery, due to the development of a focal restenosis pattern, in particular at month 3 (Figure 2).

## DISCUSSION

A novel multiscale framework of restenosis at the cell-tissue scale was developed to mimic the 3-month arterial wall remodeling following PTA procedure in an idealized, diseased SFA model. The framework captured the early inflammatory-driven cellular activation due to the PTA-induced wall damage and the long-lasting hemodynamic-driven arterial wall remodeling. In particular, the combination of the 2 biomechanical factors allowed us to detect relevant features of the vascular adaptation process to PTA, namely: (i) localization of the greatest intimal growth in the regions exposed to high damage and low WSS; (ii) a 3-month lumen area restenosis of 27%, in accordance with clinical observations in femoral arteries [10]; and (iii) temporal dynamics of the lumen area characterized by 3 phases (early severe reduction of the lumen area, followed by stabilization and late focal narrowing), as observed in stented femoral arteries [11].

Based on these promising results, the application of the framework to patient-specific cases of SFAs treated with PTA is ongoing, as shown in Figure 3 for an explanatory patient-specific arterial cross-section. Accordingly, the present study lays the foundation for an in-silico model of restenosis that can be used to predict the remodeling of the entire lumen area following endovascular interventions in patient-specific scenarios.

# A COMBINED MECHANICAL AND BIOLOGICAL APPROACH TO QUANTIFY FAILURE IN HUMAN SKIN

**J. Hayes (1), C. Higgins (2), M. Masen (1)**

## INTRODUCTION

Lower limb prosthetics have proven to be an extremely successful intervention, providing mobility to people with congenital limb deficiencies and traumatic amputations. However, retention rates among lower limb amputees are very low, with 22% of amputees abandoning their prosthesis within 1 year and 29% of amputees using their prosthetic only indoors after 1 year [1]. It is generally accepted that device abandonment associated with high levels of injuries from usage, with 63% of amputees reporting one or more skin problems [1]. Injury of the residuum skin at the socket interface is a commonly reported issue among prosthesis users [2]. Prosthesis wear time 4 months after amputation is reported as less than 8 hours per day and mean time walking on the device is 3.4 hours a day [3], this low wear time is consistent with high reports of skin injuries in lower limb amputees [4]. Current prosthetics research puts heavy emphasis on manufactured components, i.e., socket and joint articulation, not much work has been undertaken to understand how the skin interacts in the coupling with the prosthetic device. To achieve adequate function, a lower limb prosthetic requires extreme resilience from the skin on the limb stump. During use, all loads are transferred through the socket-skin interface, meaning the skin is subjected to significant loading through shear stresses. These increased demands on the skin may result in a variety of injuries, as non-plantar skin is not specialised for loading. In this study we look to find tissue tolerance levels by quantifying the response to mechanical loading through cellular mechanisms like apoptosis.

## METHODS

In this study we look at how loading type and duration affect tissue viability, as quantified by cleaved caspase-3 expressed in the compressed and the uncompressed case. We use 8 mm punches of human abdominal skin sampled from tissue discarded after abdominoplasty.. The samples are then transferred to the top of a 0.45 µm nylon membrane placed on a nonwoven gauze in a 35 mm dish. William's E media (1.5 ml) supplemented with 1% Penicillin/Streptomycin 2 mM L-glutamine, 10 µg/ml insulin and 10 ng/ml hydrocortisone is added to the nonwoven gauze in each well.[5]

Prepared samples are subjected to loading through biomomentum indentation and use of a novel nanotribometer [6] for shear loading. Specimens are embedded in optimal cutting temperature compound (OCT compound) and sectioned at 14 µm and mounted onto microscope slides. Analysis of caspase expression is achieved with immunofluorescent microscopy techniques using a confocal microscope for image acquisition and Icy for post processing image analysis.

We aim to determine the difference in cell death compared to a control specimen; cell death is quantified with use of cleaved caspase-3 (a protein used to execute programmed cell death in response to increasing cell damage).

## RESULTS

Figures 1 and 2 show fluorescent microscopy images of fixed human abdominal skin sections, with figure 1 showing the unloaded sample and figure 2 the sample after mechanical loading. The composite fluorescent microscopy images presented show intact nuclei (Blue), Collagen VII (Green) and Cleaved Caspase-3 (Red).

Structural changes can be observed between the compressed and uncompressed case. The dermal-epidermal junction is ruptured (arrow), as shown by the basement membrane (green line) in figure 2, indicating that the barrier function of the skin would be compromised, and the tissue may become necrotic.

In both results caspase-3 expression overlaps with the nuclear stain. This is consistent with caspase-3 being translocated to the nucleus during apoptosis, in order to cleave nuclear substrates [7].

In figure 1 (uncompressed case) caspase-3 induced apoptosis is localised close to the dermal-epidermal junction but the remainder of the cells do not express caspase-3. In contrast in figure 2 (compressed

case) caspase-3 expression is found most cells throughout the depth of the tissue section, suggesting a global commitment to apoptosis in the skin as a result of being compressed.

.

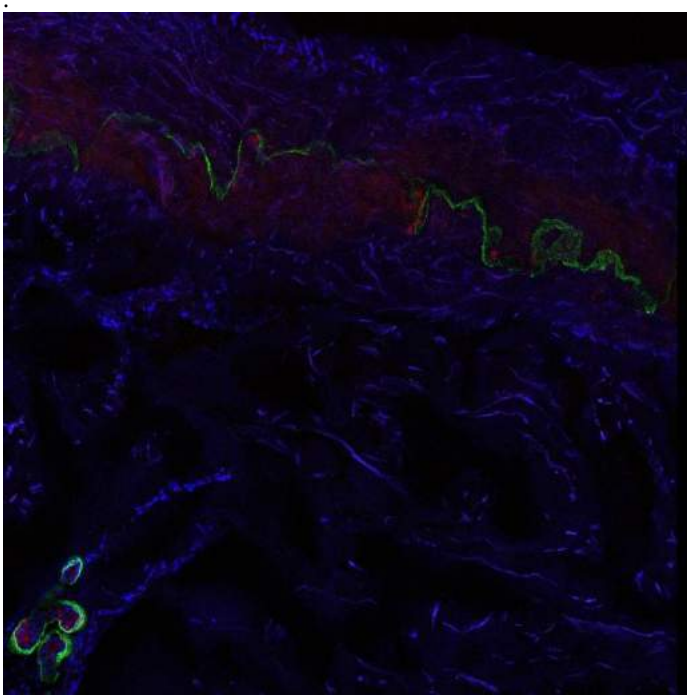

**Figure 1: Uncompressed control immunofluorescent confocal image on 14 µm section of abdominal human skin. Section stained for Nuclei (blue), Collagen 7 (green) and Cleaved Caspase-3 (red)**

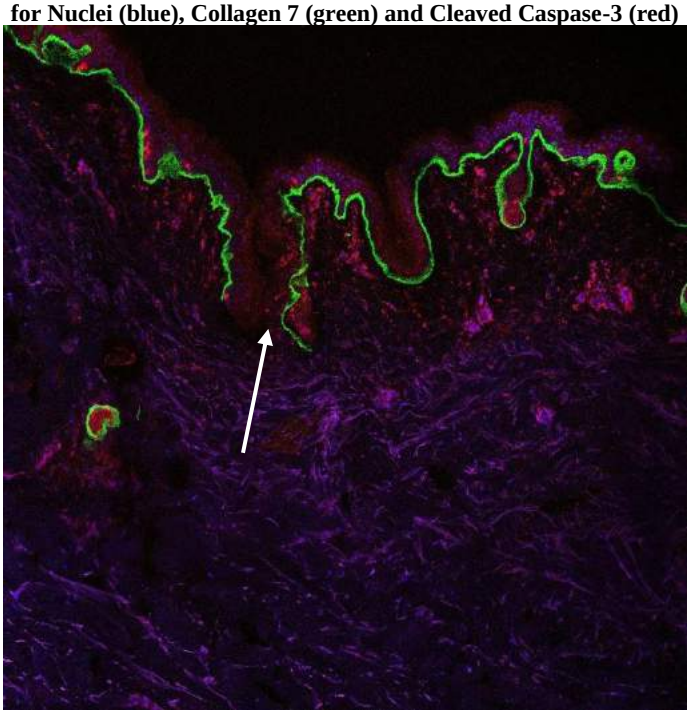

**Figure 2: Compressed control immunofluorescent confocal image on 14 µm section of abdominal human skin. Section stained for Nuclei (blue), Collagen 7 (green) and Cleaved Caspase-3 (red)**

The first set of results indicate that compressive stress has resulted in an upregulation of nuclear caspase-3, indicating an increase in apoptosis. that would suggest that a stress related mechanism of regulated cell death must exist.

## DISCUSSION

The results presented highlight the effects of 6 hours of loading onto human skin and may help explain the high injury prevalence in prosthesis users. We found that loading causes an increase in apoptosis in cells across the tissue, when compared to an uncompressed baseline. In this study we looked at entire tissues in contrast to previous studies on skin load ability, which were performed on single cell layers, thus distorting the stress field for the cells. Therefore, the results presented have more relevance to in vivo applications and provide a meaningful conclusion on how to quantify failure in skin from mechanical insults. A limitation of the study is the small sample size of skin tested, and the unique setup of the experiment prevents direct comparison to the literature. A methodology for assessing cell viability is important and needs to utilise engineering testing procedures with biological failure mechanisms. This study will outline how different loading and time domains effects using the method discussed.

In conclusion increasing the mechanical stimuli causes an upregulation of apoptotic genes and commitment to cell-death by individual cells within the tissue. There is, however, a lack of critical understanding on whether a critical stress level exists, and if so, what this critical stress level would be. Current work focuses on how duration of mechanical insults affect tissue viability and how the presence of shear affects cell death, as these are two factors of great importance in current prosthesis technology. Better understanding on how stress-initiated apoptosis occurs is pivotal to improving regenerative medicine and prosthesis technology to prevent skin failure from prosthesis wear.

# NOVEL BIOMECHANICAL APPROACH TO IMPROVE CONTROLLED CORTICAL IMPACT TESTING FOR STUDYING RODENT CLOSED-HEAD TRAUMATIC BRAIN INJURY

**Emilie A. Potts (1), Lihong Lu (2), Xiaoyun Xu (3), Arthur Brown (3), and Haojie Mao (1, 2)**

## INTRODUCTION

Researchers have relied on animal studies for decades, particularly for traumatic brain injury (TBI) studies. These types of studies have aided researchers in obtaining a better understanding of the after-effects and repercussions of the brain following a TBI [1]. Numerous testing methods have been utilized in the past, which can be broken into two categories, open- and closed-head impact systems. Closed-head impact (CHI) systems use either a mechanical force or gravity to conduct an impact on the skull, not penetrating the brain directly, while open-head impact models directly impact the brain. Controlled cortical impact (CCI) and fluid percussion injury (FPI) are popular open-head impact models for rodent studies [2].

Further growth of the CHI model has developed neurotrauma models that report both head kinematics and brain pathology, such as the one called CHIMERA (Closed-Head Impact Model of Engineered Rotational Acceleration) [2]. This model was created to address the gap in knowledge between the translation of animal studies and human cases [2]. Other types include an improved weight drop model to deliver a weight to an animal placed on a foam [3]. With these improved testing methods, researchers can yield a variety of brain-related deficits found in human cases in an animal application. These brain-related deficits can include memory impairment, diffuse axonal injury (DAI), inflammation, and tau accumulation [2], which all can account for life-altering effects.

The CCI testing method has been deeply developed over the past 40 years and is now used to gather a better understanding of the biomechanical properties surrounding brain injuries[1][3][4], specifically investigating the relationship between engineering parameters and biological damage [6]. This testing tool utilizes a mechanical force onto the exposed surface of the brain creating repeatable injuries such as axonal damage, contusions, and neuronal death [4][6]. CCI is chosen over other testing methods as it has a high rate of repeatability, scalability, and user adaptability and control [5]. This device offers the researcher to select different parameters such are depth, velocity, and site of impact [5], allowing the researchers to simulate the severity of TBI that they desire. Although CCI testing has been proven to be a reliable method over the decades, there is always room for improvement for closed-head TBI, and that is where this study comes into play.

In our previous closed-head mild TBI model using the CCI device, mouse heads were placed on a plate, restricting large rotations [7]. Repeated impacts to the head were found to induce mild TBI such as altered levels of synaptic proteins and behavioural deficits in attention and spatial memory [7]. In this study, a new CCI-based model is developed, primarily focused on the rotational properties, as it has been proven that the angular motion of the brain has worsened biological repercussions. When comparing the repercussions of linear motion to angular motion, angular motion significantly outweighs linear motion. In addition, large head rotations were observed in real-world human head impacts and hence were mimicked in this study.

## METHODS

### *Experimental setup*

Similar to traditional CCI tests, a pneumatic CCI impactor machine was utilized to impact the mice head at the bregma, where the coronal suture bisects the midline. Each impact was then recorded with the aid of two highspeed cameras, each camera obtaining a different angle, from lateral and frontal views. To ensure optimal filming conditions, two floodlights were used to illuminate the testing field. The height of the camera and floodlights were adjusted to be the same height as the testing surface. The cameras were placed directly in front of the desired view, while the floodlights were off to the side, with the light beam directed at the subject. A schematic diagram is depicted below in Figure 1. Before testing, the camera settings were adjusted accordingly, and the camera view was zoomed in to eliminate unneeded background to ensure easy tracking of the mouse movement in later steps.

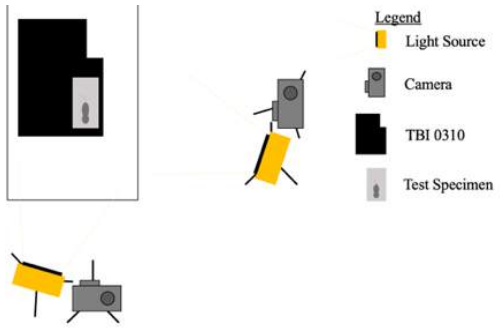

**Figure 1: Schematic diagram of experimental setup**

***Testing Specimen Preparation***

Each mouse was anesthetized with ketamine (80mg/kg)/xylazine (10mg/kg) and was placed in a custom-designed head cover with trackable dots. The mouse was then placed on a transparent plastic film that was secured to a transparent container and moved into the testing field.

***Data Collection***

Before each impact, the cortical impactor (Traumatic Brain Injury Device (TBI) 0310) was calibrated and centered over the intended impact site. Each impact was recorded by two observers to eliminate movement between cameras, as excessive movement would introduce vibrations to the video. After each impact, the recorded video was trimmed to the impact event to limit the amount of memory being used.

Once the impact occurred, the plastic film supporting the mouse would break due to the force of the impact, and the mouse would freefall on to a cushion at the bottom of the container. An example of the movement can be seen in Figure 2. The container and supporting film were transparent to ensure tracking of the mouse movement was not obscured during the recording.

For initial 5 m/s, single-impact tests, four small female and two large male mice were tested. For 3.5 m/s, triple-impact tests four small female and 16 small male mice were tested, and each mouse was impacted three times; the three impacts were done in consecutive days (one hit per day for 3 days), resulting in all three hits being conducted within 48 hours. One video recording was lost due to human error (Mouse 0210907-5).

**Figure 2: Example of the tracking of the mice in the lateral (left) and frontal (right) views.**

The set of X and Y values for each point tracker was exported from Tracker and imported into Microsoft Excel (Redmond, Washington: Microsoft Corporation), and later imported into MATLAB (Natick, Massachusetts: The MathWorks Inc.) for further analysis. With the use of MATLAB codes, the angular and linear properties of the mouse head were calculated for 10 ms following impact. The linear data will be presented elsewhere.

## RESULTS & DISCUSSION

A total of 66 laboratory impacts were recorded and preliminary data were analyzed. High-speed videos confirmed large head rotations (>60 degrees) for all impacts. The average angular velocity was determined for three studies. The 5 m/s impact speed study resulted in a 316 rad/s velocity. While the two 3.5 m/s impact speed studies resulted in 287 rad/s for the female mouse study, and 343 rad/s for the male mouse study.

The most significant difference between the described CCI setup and other CCI setups reported in the literature lies in the break-away transparent platform used to support the mouse at impact. In traditional setups, the mouse is rested on a fixed platform, such as a desktop, while the setup herein described has the mouse supported on a tear-away plastic film. The break-away platform promotes more realistic post-impact head movements.

Simulating more organic head movements allows for more clinically relevant data. As seen in Figure 3, this method allows for peak acceleration and velocity at the time of impact to be calculated. However, with this realistic model of concussive injuries, there are factors to be taken into consideration such as impact distance and speed. In traditional CCI testing, impact distance varies between 0.5 to 2 mm as the testing specimen is on a fixed surface and the brain cannot exceed the confines of the skull cavity [3][6]. This present method has an impact distance of 8 mm as the unfixed platform allows the testing specimen to move away from the impactor to prevent serious damage to the brain. Also, regarding impact speed, both 5 and 3.5m/s were tested. However, it was found that 5m/s was too forceful and included lots of axonal staining after single impacts. Despite setting the machines to a specific speed, deviation in speed during the impacts was also noted and needs to be considered in future subject-specific injury analysis.

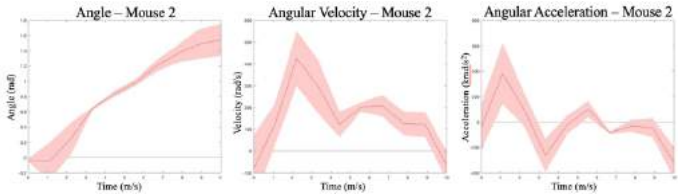

**Figure 3: Standard deviation graphs for Mouse 2, angle (left), angular velocity (center) and angular acceleration (right)**

Having numerous views of the impact is ideal as it allows for verification that the head is rotating along desired axis. The frontal view confirms that the head is moving in a linear downwards motion in the majority of cases. As buckling of the head or moving on a diagonal may introduce more axes of rotation, they are not accounted for in our calculations.

This proposed method shows promise to simulate more realistic head movements following experimental TBI. The unfixed break-away platform allows natural head movements and rotations post-impact, which generates more realistic after-effects when compared to standard CCI testing. Our method has the potential to improve the clinical relevance of CCI small animal (rodent) testing using CCI devices by using popular CCI devices to induce closed-head, large-rotation TBIs.

## INTRODUCTION

Elastography is a non-invasive imaging approach that is commonly used to quantify the average and spatially-resolved stiffness of soft tissues of the body. Quantification of material stiffness can provide a powerful approach to understanding structure-function relationships in soft tissues, including load-bearing tissues such as cartilage. In cartilage, softening and decreased stiffness is a functional hallmark of osteoarthritis (OA) pathogenesis due to structural changes to the collagen network and depletion of proteoglycans [1]. Moreover, OA is a degenerative joint disease that is a leading cause of joint pain, disability, and health care costs worldwide. However, diagnosing early-stage OA can be difficult due to a lack of validated outcome measures for individuals with early knee OA [2]. As post-traumatic OA may progress from an initial injury in the superficial zone of cartilage to more widespread biochemical and mechanical changes throughout the zonal tissue cartilage, quantifying changes to cartilage material properties non-invasively *in vivo* is of substantial interest. While elastography seems like an ideal approach to accomplish this, current conventional elastography methods, most commonly using ultrasound, lack the ability to penetrate stiff musculoskeletal tissues such as cartilage due to the dissipation of high frequency shear waves [3].

MRI is unique among imaging tools as it can characterize tissues with high spatial detail, has a deep penetration depth, and can assess tissues non-invasively [4]. Recently, spiral displacement encoded stimulated echo MRI (spiral DENSE) has been used to calculate pixel level full field displacement maps of soft tissues under repetitive motion [5]. In this work, we coupled spiral DENSE MRI to displacement under applied loading MRI (dualMRI) to capture *in vivo* full field displacement and mechanical strain maps of the human knee during varus loading. Material property characterization leveraging full-field information was accomplished by combining both the virtual fields method (VFM) and a constrained FEBio-based optimization method [6, 7]. In summary, we present a proof of concept for one human subject of a combined MRI experimental method and processing pipeline to acquire *in vivo* full field cartilage displacements, and non-invasively quantify cartilage stiffness and Poisson's ratio.

## METHODS

*Varus Loading of Human Knee:* 1 adult female subject, age 25, with a healthy left knee was recruited. An MRI-compatible loading apparatus that provides a varus-valgus load to the tibiofemoral cartilage of the knee was manufactured and validated, leading to compression of the medial femoral condyle (**Fig 1A**). Momentum conservation was used to calculate the load applied on the foot to be equivalent to one-half body weight of load applied at the knee. Following validation, the subject was imaged in a clinical MRI system (3T; Siemens Prisma$^{fit}$) using a cyclic loading regime (pneumatic, 25N load at foot, 1s load,1s unload) to mimic a walking cadence.

*Spiral DENSE MRI:* Spiral displacement-encoded MRI was collected following preconditioning to a quasi-steady-state load-displacement response (**Fig 1B**). A steady-state response was achieved by applying 8 minutes of cyclic loading to minimize the viscoelastic response of articular cartilage. 27 time-sequenced coronal plane DENSE MR images were collected using 8 averages, 10 spiral interleaves, and a temporal resolution of 40ms. Echo time (TE) was 2.5ms and relaxation time (TR) was 20ms. Field of view, slice thickness, and displacement encoding gradient were 125×125μm$^2$, 1.7mm and 0.64cycles/mm, respectively. Total imaging time was 13.6 minutes.

*Displacement and Strain Calculation:* Cartilage and bone regions of interests (ROIs) were manually segmented and binary masks were created to represent the articular cartilage/menisci regions and bone. MRI phase data was unwrapped using a custom Goldstein branch-cut phase unwrapping algorithm [8]. Displacements for each pixel within the cartilage ROIs were determined from unwrapped phase data [9] and

smoothed (**Fig 1C**) using a locally weighted Gaussian filter with a kernel size of 3. A nearest neighbor transform was used to minimize bias at the ROI edges during smoothing [10]. In-plane Green-Lagrange strains were calculated from the smoothed displacements.

*Inverse Modeling to Derive Material Properties:* The virtual fields method (VFM) was applied to determine the Poisson's ratio of the medial femoral cartilage region. To apply the VFM, the main orientations of the cartilage were defined, and a kinematically admissible virtual displacement field and the associated virtual strain field were determined [6]. Assuming both plane strain and Hooke's law, Poisson's ratio was calculated using the principle of virtual work. To determine Young's modulus, cartilage and bone material elements from the segmented MRI image were mapped to a pseudo 2D hexahedral finite element mesh. The tibia was modeled at full length based upon the experimentally measured leg length of each participant. Linear elastic springs were incorporated into the models to represent the collateral ligaments. MRI-derived displacements were prescribed to nodes within the medial and lateral cartilage (**Fig 1D**). Boundary conditions were assigned to the FE model to mimic the varus-valgus load. An inverse parameter optimization on the medial cartilage Young's modulus was performed (FEBio) using the experimentally known force at the base of the tibia (25N) as the optimization function.

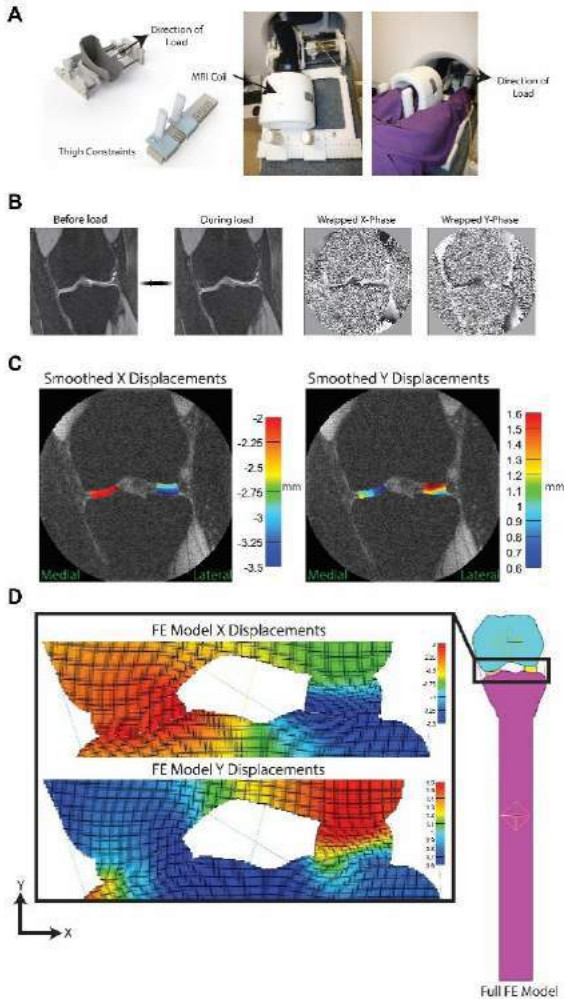

**Figure 1: (A) Varus-valgus MRI compatible loading device. (B) Magnitude and phase images of the knee undergoing varus load. (C) Smoothed displacements obtained by DENSE MRI. (D) FE Model used for inverse parameter optimization of medial cartilage**

## RESULTS

The knee joint translated gradually both in *x* and *y* (**Fig 1B**) due to varus loading applied at the foot. In the medial cartilage, displacement in *x* was spatially uniform while *y* displayed higher values near the medial side and lower near the lateral side. Optimization required approximately 5 minutes of solution time on a 240 GB computing cluster. Final converged material properties in the medial cartilage were a Young's modules of 0.62 MPa and a Poisson's ratio of 0.48.

## DISCUSSION

This work provides a single-subject proof of concept of a MRI framework to non-invasively determine cartilage stiffness and Poisson's ratio. While other work has determined cartilage material properties *ex vivo*, we believe this is the first work to do so *in vivo* using standard clinical 3T MRI. Additionally, while previous work has calculated relative stiffness within cartilage [3], our method allows us to calculate an absolute stiffness value. To further investigate this method, additional subjects with both healthy and pathological knees will be added to this study. Future work will also include further validation and sensitivity studies. Ultimately, we plan to expand this work to identify heterogeneous distributions of the Young's modulus within cartilage [6]. We hypothesize based upon *ex vivo* cartilage mechanical studies that changes in stiffness to the medial cartilage middle and deep zones are potential biomarkers for osteoarthritis pathogenesis [8]. Ultimately, we hope this framework can provide a way forward to measure cartilage material properties in a clinical MRI setting and could potentially be extended to other load-bearing musculoskeletal tissues, including ligament and intervertebral disc.

# PATIENT SPECIFIC MODELING OF OBSTRUCTED VENTRICULOPERITONEAL SHUNT PERFORMANCE

**Sung Min Kwon (1), Stephanie C. TerMaath (1)**

(1) Mechanical, Aerospace and Biomedical Engineering, University of Tennessee, Knoxville, TN, USA

## INTRODUCTION

Hydrocephalus is a condition in which an excessive amount of cerebrospinal fluid (CSF) is accumulated in the ventricular system, resulting in elevation of intracranial pressure (ICP). Elevated ICP can damage brain tissue and cause many serious symptoms including headaches, nausea, papilledema, cognitive difficulties, motor skills impairment, incontinence, and even death if left untreated. Approximately 1 of every 500 infants is born with hydrocephalus making it the most common reason for neurosurgery in children in the US [1]. While there is no cure, the most common treatment for hydrocephalus is insertion of a device called a ventriculoperitoneal (VP) shunt. This shunt drains excess CSF from the ventricular system and directs the fluid to the abdomen where it can be absorbed. While essential to patient treatment, this implantable medical device has a high failure rate. Most of the patients who receive shunt insertion require additional neurosurgeries to revise or replace the VP shunt within 10 years.

VP shunts have been used for over 50 years, yet there is no notable solution to prevent shunt failure. One of the most common reasons for shunt malfunction is obstruction of the ventricular catheter (VC) that transports CSF from the lateral ventricle (LV) to the valve. Reducing the obstruction rate of the VC requires understanding a complex CSF dynamics scenario characterized by patient specific anatomy and physiological conditions. In addition to the high dimensional parameter space needed to characterize shunt performance, it is also challenging to mimic the in-vivo environment experimentally. Computational fluid dynamics (CFD) using validated models is a method to rapidly model and investigate the effects of the large number of parameters on CSF behavior and shunt performance. The objective of this research is to model patient specific in-vivo conditions and characterize CSF transport through obstructed VC from an obstructed LV to the valve. In addition to the model, a physically realistic apparatus has been created to collect validation data. This research studies the interacting effects of VC insertion location, lateral ventricle (LV) and choroid plexus (CP) geometry, boundary conditions (BC), obstructions, and in-vivo operating conditions on CSF dynamics through an obstructed VC. The results provide essential information to characterize CSF transport using a patient specific 3D computational model to inform VC optimization studies to reduce failure rates.

## METHODS

The computational simulation, parameter studies, and sensitivity analysis follows the approach shown in Figure 1 and described below.

**Patient Specific LV model:** The open-source 3D printing software, Slicer, and Computer Aided Design (CAD), Solidworks, are utilized to model patient specific LVs. A total of five different LV CAD models are constructed from CT scans. The choroid plexus is a unique shaped tissue within the brain that produces the majority of CSF, and its location can vary for all patients. The shape and size of the CP implemented in the LV model are based on Madhukar et al [2].

**VC model:** The baseline VC has 4 rows and 4 holes on each row with each drainage hole measuring 3 mm apart. The side holes appear in a zigzag pattern. The length of the catheter is 200 mm and the inner and outer diameters are 1.2 mm and 2.5 mm respectively. Each drainage hole is tapered.

**Modeling and Simulating CSF Flow:** The open-source CFD software OpenFOAM® is utilized for the computational simulations. Several assumptions included incompressible flow, Newtonian fluid, and steady-state. A range of intracranial pressure (ICP) and intra-abdominal values for both normal and hydrocephalus patients are applied as the inlet and outlet BCs. Wall shear stress is capturing using extra grid layers near the drainage holes. Postprocessing was conducted using the open-source multiple-platform application, Paraview to obtain quantified data, particularly streamlines, outflow from the VC, and wall shear stresses.

SB³C2022-037

**Experimental validation:** A test apparatus is constructed to collect data to validate the computational model. Patient specific pediatric LV and skull models are extracted from CT scans and fabricated using a mold and 3D printing respectively. Water is used to represent the CSF. The skull is filled with aloe vera gel to replicate fluid structure interaction. The experiment is conducted under steady-state conditions with a constant water pressure.

**Parameter studies and sensitivity analysis:** The effects of LV shape, BCs, and VC locations (Fraizer's and Kocher's point) on CSF flow are investigated. Shunt performance is measured relative to outflow and wall shear stress (WSS) (known to correlate to obstruction propensity). Sensitivity analysis to determine the relative influence of model parameters is performed using a surrogate model created with machine learning to calculate Sobol Indices.

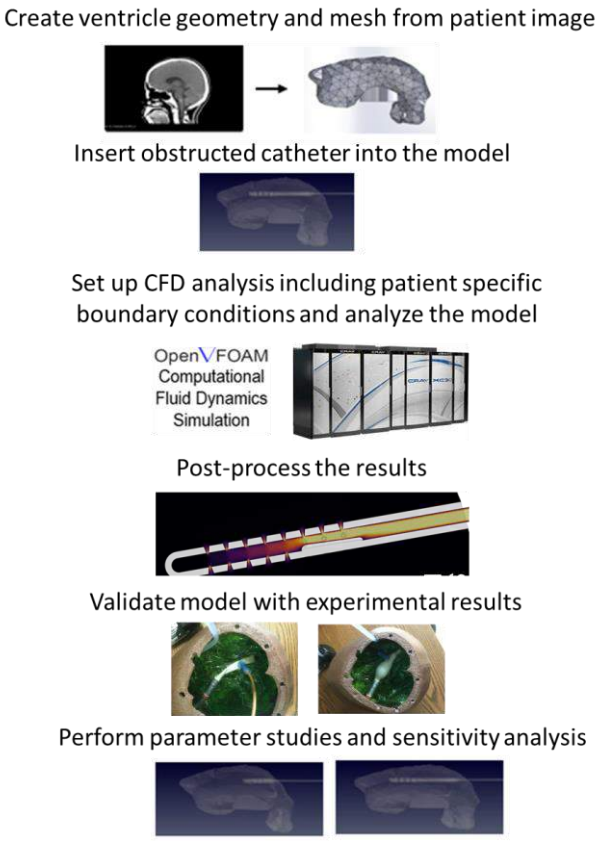

**Figure 1: Patient Specific modeling and CSF analysis process**

## RESULTS

Pressure and flow rate values were obtained experimentally and compared to the 3D computational model results. Varying catheter locations and BC for five different LV models were simulated. Some primary results include the following. No significant change in WSS and outflow was identified relative to LV shape and catheter location for constant BC. The detail results of WSS for varying VC will be shared during the presentation. However, the streamlines of CSF flow from the CP to the catheter exhibit significant differences due to LV shape and catheter location (Fig. 2 and 3). As typically observed in the literature, more than 50 percent of CSF flow passes through the proximal drainage hole (Fig. 4). The effects of VC obstruction are highly correlated to obstruction size, porosity, and location (Fig 5). Detailed results of this study including sensitivity analysis will be provided in the presentation.

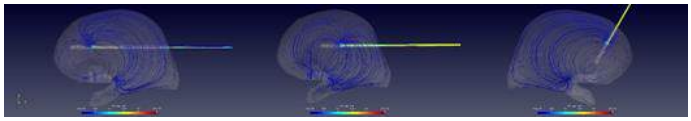

**Figure 2: Representative comparison of streamline for varying VC locations in an enlarged LV**

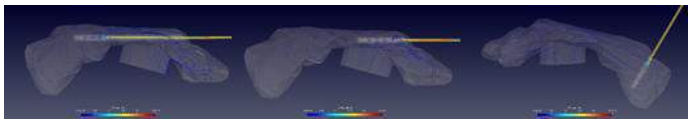

**Figure 3: Representative comparison of streamline for varying VC locations in a slit LV**

**Figure 4: The majority of CSF flows through the proximal holes**

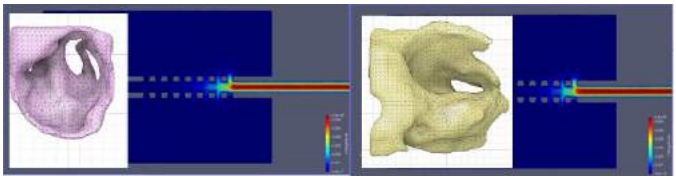

**Figure 5: Representative comparison of obstruction porosity and size effects**

## DISCUSSION

CFD application has been widely and successfully used as an analytical tool in the biomedical field to model biofluid flow phenomena. This paper investigates the effects of patient specific geometric, in-vivo BC, and VC obstruction on shunt performance as measured by outflow and wall shear stresses using parameter studies and sensitivity analysis. It should be noted that this study was based on steady state flow. In the future, physically realistic in-vivo operating conditions will be added to the computational model including pulsatile effects, transient effects due to valve opening and closing, turbulence effects in the CP, and fluid structure interaction to characterize more realistic in-vivo CSF dynamics.

# THREE-DIMENSIONAL DEFORMATIONS OF SWINE APICAL VAGINAL SUPPORT

**K. Donaldson (1), J. Thomas (2), S. Clark-Deener (3), Y. Zhu (2), and R. De Vita (1)**

(1) Department of Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, USA

## INTRODUCTION

Pelvic floor disorders, including pelvic organ prolapse which involves the descent of the pelvic organs into the vagina, affect up to 50% of U.S. adults with female pelvic anatomy, sometimes causing severe physical and psychological symptoms [1,2]. The uterosacral ligaments (USLs), often targeted as native tissue supports in pelvic surgeries, are the most important support structures of the apical vagina, cervix, and uterus. Despite their mechanical importance to normal pelvic organ support and their role in correcting prolapse, the USLs remain understudied from a mechanistic perspective. In particular, the viscoelastic mechanical properties of the USLs must be elucidated in order to understand how these disorders occur as well as how they may be treated. The objective of this study is to characterize the three-dimensional deformations of the USLs under equibiaxial loading.

## METHODS

USLs were excised from 5 healthy gilts (virgin swine) immediately post sacrifice. Since the USLs *in vivo* are membrane-like in nature, the main loading axes were defined in the direction from the distal attachment at the cervix to the proximal attachment at the sacrum (the main *in vivo* loading direction, or MD) and the direction perpendicular to it (the perpendicular direction, or PD). Specimens of 1.5 cm by 1.5 cm were isolated, suspended with hooks, and loaded into a custom-built biaxial testing apparatus equipped with two 8.9 N-capacity load cells. Specimens were immersed in PBS and preloaded to 5 mN along the MD and PD. They were then equibiaxially preconditioned between 0.01 N and an upper value of 1, 1.5 or 2 N at a rate of 10 μm/sec for 10 cycles. Following preconditioning, specimens were loaded quasi-statically to their upper load at 5 μm/s and then held at a constant load and allowed to creep for 40 minutes. During this time, images were taken at a rate of 1 Hz for digital image correlation calculation of the (Lagrangian and normal) strain fields in both the MD and PD. Optical coherence tomography (OCT) was used to collect through-thickness images at discrete time points throughout the tests. Deformation data were compared between the MD and PD using paired Student's t-tests. Creep strains in the MD and PD were fit to the exponential equation:

$$\varepsilon = \alpha t^n. \quad (1)$$

where ε is strain, α is a material constant and *n* is the rate of creep.

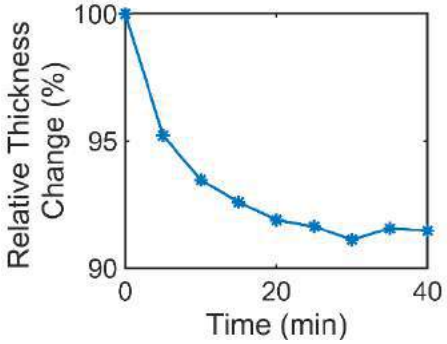

**Figure 1: Average relative thickness change for one representative USL specimen during creep.**

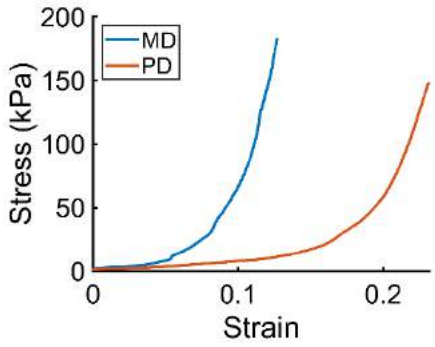

**Figure 2: Stress-strain curves in the MD (blue) and PD (orange) for a representative specimen during quasi-static testing.**

## RESULTS

Thickness data were successfully computed using OCT for a subset of 8 specimens out of the total 15 tested, which were used to calculate the (nominal and normal) stresses both in the MD and PD for each of these specimens during the pre-creep and creep loading phase of the testing protocol. These specimens were found to be significantly stiffer in the MD than in the PD when strains were compared at equivalent values of stress in each loading direction: 50 kPa ($p$=0.036), 100 kPa ($p$=0.025), and 150 kPa ($p$=0.025). The OCT images showed that the specimens consistently got thinner during quasi-static loading, but during creep, some specimens got thinner while others increased in thickness or stayed the same. The creep behavior of the 15 total specimens was not different between the two loading directions. The specimens did not strain much in either direction during creep, and the rates of creep in the MD and PD were very similar ($p$=0.71)

## DISCUSSION

The gilt USLs demonstrated some anisotropy during quasi-static testing with the specimens straining less in the MD than in the PD at equivalent values of stress. However, we found that the

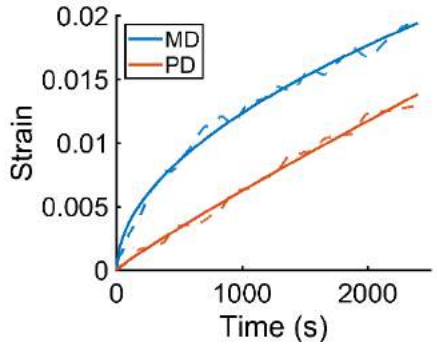

**Figure 3: Moving average (dashed lines) and curve fitting (continuous lines) of (normal, Lagrangian) strain over time during creep testing in the MD (blue) and PD (orange) for one representative specimen.**

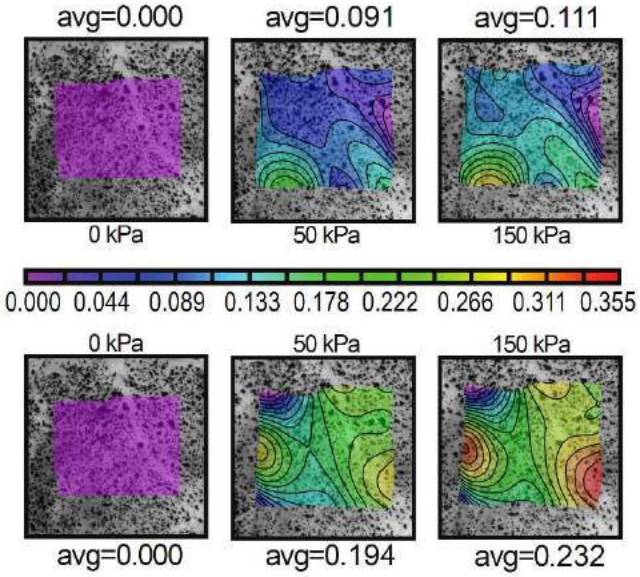

**Figure 4: Map of (normal, Lagrangian) strains and average strains in the MD (top) and PD (bottom) at (nominal) stress levels of 0 kPa, 50 kPa, and 150 kPa in each respective direction during quasi-static testing.**

creep properties were not different between the two loading directions. The gilt USLs experienced less creep than the swine USLs which were previously tested by our lab (Baah-Dwomoh et al. 2018) [3]. This is potentially due to increased damage of the swine USLs during pregnancy when they must support the increased weight of the uterus. The OCT images showed variability in specimen thickness change over the course of creep, with some specimens getting thinner and some thicker over time. This likely reflects competing effects of tensile forces and swelling. Collectively, these data could allow us to better understand the *in vivo* behavior of the USLs and ultimately inform surgeries for prolapse correction which use the USLs to restore pelvic organ support.

# HOW CARTILAGE TRIBOMECHANICS IS COMPROMISED BY ELEVATED CONTACT STRESSES AND INACTIVITY

**Shamimur R. Akanda (1), Jamie M. Benson (2), Arnab Bhattacharjee (1), David L. Burris (1), Christopher Price (1,2)**

## INTRODUCTION

Articular cartilage, the tissue that lines our diarthrodial joints, sustains, near frictionless lubrication over millions of articulations annually. This phenomenal behavior derives from the tissue's biphasic properties. When initially loaded, cartilage generates high interstitial fluid pressures and fluid load support that limit tissue compression and interfacial frictions. However, static loading drives time-dependent fluid exudation from cartilage, compromising its fluid load support, allowing substantial tissue compression and loss of lubricity.

Thus, cartilage can, on the one hand, withstand transient contact pressures (~10-20 MPa during walking and running) that far exceed its compressive modulus (~0.5-1 MPa) without compromising lubricity.[1-3] On the other hand, cartilage is habitually exposed to non-zero quasi-static average contact stresses (~0.2-2 MPa)[4] that cannot be overlooked as a primary influencer of tissue function. Indeed, how habitual average stresses influence fluid exudation, tissue compression, and loss of fluid load support, and how the joint compensates for their detrimental consequences provides key insights into joint lubrication and how modifiable human factors could impact joint health/longevity.

Habitual non-zero joint contact stresses invariably lead to time dependent cartilage compressions and loss of fluid load support. To maintain cartilage's critical fluid pressure-dependent functions our joints must counteract these losses, by recovering interstitial fluid. Fortunately, *in vivo* and intact joint studies demonstrate joint articulation to be a strong modulator of fluid recovery.[5] Such recovery has been thought to occur solely through 'passive' mechanisms, during cartilage unloading and 'bath exposure'.[6] Recently, we've identified an alternative mechanism by which articulation promotes active interstitial fluid recovery. Using the convergent stationary contact area (cSCA) benchtop testing configuration, we've shown that interfacial sliding, by generating hydrodynamic pressures within sliding contact interfaces, drives robust fluid recovery.[7-9] Importantly, this 'tribological rehydration', which rescues tissue compression and lubricity, is governed by a competition between load-induced fluid exudation and sliding speed-mediated rehydration.

Subsequently, we've established, for physiologically relevant sliding speeds (80mm/s), that optimal tribological rehydration occurs at contact stresses of ~0.5MPa in healthy cartilage; above ~1.0MPa, tribological rehydration is significantly compromised, if not abolished.[10] Furthermore, we've shown how '*daily*' sliding activity patterns influence '*diurnal*' interstitial fluid exudation and recovery, tissue compression, and frictional behaviors. Sliding patterns mimicking frequent daily activity promote significantly reduced tissue compressions and friction exposures under modest compressive stresses (~0.25MPa) than more sedentary patterns.[11] These results suggest that elevated joint contact stresses and increasing levels of inactivity, which are associated with obesity and rapidly increasing in prevalence, could serve to significantly, and synergistically compromise activity mediated fluid recovery within cartilage, and thus tissue functionality/health.

The objective of the present work was to investigate the influence of both elevated cartilage contact stresses and sedentary activity patterns, both modifiable osteoarthritis risk factors, on sliding-mediated tribological rehydration using the cSCA testing configuration. OwHo

## METHODS

In *study 1* (**Fig. 1A**), ovine femoral condyle cSCA explants (Φ = 12 mm) were subjected to tribological characterization under different activity patterns simulating a human '*day*' of fixed activity volume.[11] Each day contained a 22 min '*awake*' period, comprising 15 '*sedentary*' min (static loading) and 7 '*active*' min (80mm/s sliding), and a 13 min '*sleep*' period of nominal contact unloading. These times were scaled, based upon contact size, to match the exudative dynamics of the human knee.[11] Different loads (2 & 7N) and three activity patterns (1, 3-, or 15-equally distributed bouts) were investigated in each explant (n = 6).

In *study 2* (**Fig. 1B**), *daily* sliding volume was reduced (3.5 min) or increased (10.5 min), with *sedentary* time adjusted accordingly, to

determine the effect of *daily* activity volume on *tribological rehydration* under elevated applied loads (7N, n = 6).

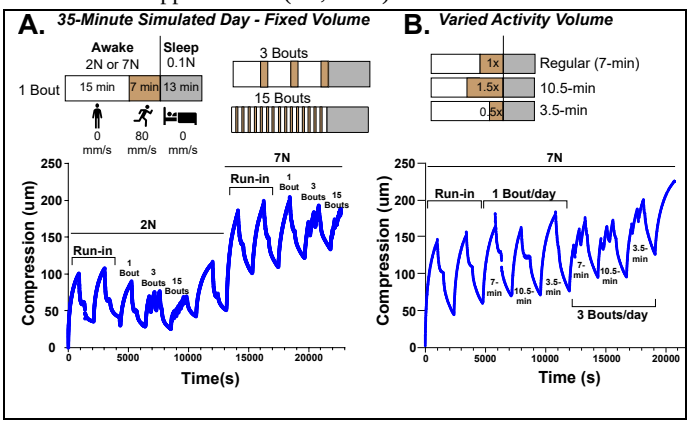

**Fig. 1: Experimental design to investigate the effects of A) activity patterning (w/ fixed activity volume) and applied load, and B) activity volume at elevated loads on tribological rehydration.**

## RESULTS

In study 1, the effects of daily activity patterning and contact stress (~0.25 vs. 0.5 MPa) on tribological rehydration and tissue compression were clear (**Fig. 2**). For a fixed sliding volume (7.5 min), all activity patterns and loads supported tribological rehydration to some degree (**Fig. 2A, B**). However, activity patterns having less-frequent sliding exhibited significantly elevated compressions at the start- and end-of-sliding and when averaged across each *day* (**Fig. 2C, D**); 1x > 3x > 15x.

Modest increases in contact stresses compromise tribological rehydration. [10] Here, we show that they also greatly exacerbate activity pattern-influenced compression accumulation. When thrice daily activity was simulated for five 'days', an ~2-fold increase in contact stress caused an ~2-fold increase in tissue compression (**Fig. 2E**), suggesting that increased activity frequency alone might not fully restore rehydration under elevated contact stresses.

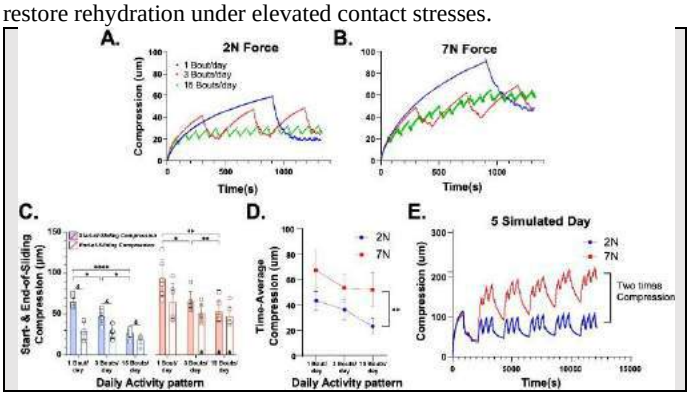

**Fig. 2: Representative compression traces for a cSCA explant subjected to three different '*activity*' patterns at A) 2 vs. B) 7N. Summary of C) start- & end-of-sliding, and D) time-averaged cSCA compression outcomes for different loads and activity patterns. E) Compression response of a cSCA explant across 5-days of simulated thrice daily activity at 2 vs. 7N.**

Indeed, while we found, in study 2, that a 50% increase in activity volume (to 10.5 min) could improve activity-mediated compression recovery in the presence of elevated loads (7N, or 0.5-0.6MPa; **Fig 3**), these gains were modest. Increasing the prescribed activity ratio from ~33 to 50% of the '*awake*' day resulted in only a 10% suppression of compression accumulation under elevated contact stresses compared to '*normal*' activity (**Fig. 3C, D**). The effect of halving *daily activity volume* (to 3.5 min) resulted in predictable increases in compression accumulation due to reduced sliding-mediated tribological rehydration.

For the sake of brevity, only tribological rehydration/compression outcomes have been shown; frictional responses were far less sensitive to the applied stresses and activity patterns explored here (not shown).

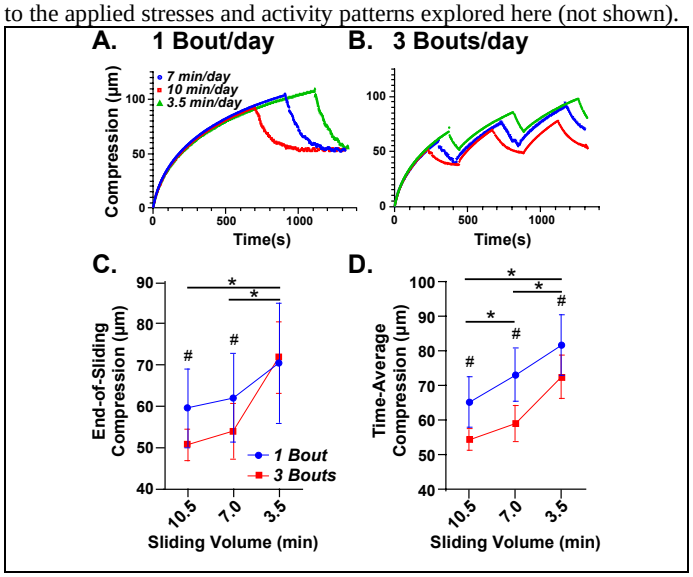

**Fig. 3: Representative explant compression under different volumes of A) once vs. B) thrice '*daily*' sliding activity at elevated (~0.5MPa) contact stresses. C) End-of-sliding and D) time-averaged compression outcomes (* p<0.05 for indicated comparisons, # p<0.05 between 1 vs 3 bouts/day).**

## DISCUSSION

Recently, osteoarthritis (OA), has been discussed as an evolutionary mismatch disease, rooted in our joints being poorly adapted to the environment we now live in. Obesity and inactivity, prevalent yet modifiable risk factors associated with OA, have been suggested as prime 'mismatch' candidates. Yet, how they contribute to elevated OA risk/prevalence is unclear. Through our benchtop activity studies, a plausible mechanism by which obesity and inactivity might directly and physically compromise articular cartilage function can be found.

Cartilage function depends upon maintaining high levels of interstitial fluid load support. Joint activity, it appears, supports cartilage function by providing robust mechanisms to passively (e.g., bath exposure) and actively (i.e., tribological rehydration) recover interstitial hydration. It also appears that the elevated contact stresses and reduced activity levels experienced by joints in obese and sedentary individuals likely compromise the balance between fluid exudation (increased) and imbibition (decreased) needed to maintain optimal interstitial hydration, tissue strains, and tribomechanical functions.

Future work is needed to establish the links between obesity and inactivity-linked tribomechanical behaviors and disease etiology, both *in vitro* and *in vivo*. However, the present work does suggest, that beyond the established biochemical effects of obesity and sedentariness on cartilage health, these easily modifiable risk factors of might also have more simply understood, and possibly more detrimental, effects on basic cartilage function.

# A STRUCTURAL BIO-CHEMO-MECHANICAL MODEL FOR TRACTION FORCE MICROSCOPY OF VASCULAR SMOOTH MUSCLE CELLS

**Shannon M. Flanary, MSE (1), Victor H. Barocas, PhD (2)**

(1) Department of Chemical Engineering & Materials Science, University of Minnesota – Twin Cities, Minneapolis, MN, USA
(2) Department of Biomedical Engineering, University of Minnesota – Twin Cities, Minneapolis, MN, USA

## INTRODUCTION

Traction force microscopy (TFM) is a vital tool to quantify the contractility of many cell types, including vascular smooth muscle cells (VSMCs). Although seeming simple and easily qualified, TFM involves a complex interplay among biological, chemical, and mechanical processes. To interpret and apply TFM data, we require computational models informed by the real-life complexity.

Previous simulations of TFM experiments were continuous and treated the cell as a black box.[1–3] These attempts did not consider how a contractile signal is generated, how actomyosin stress fibers interact, nor how the elastic substrate deforms. A realistic model of TFM cannot be formulated without consideration of how these phenomena interact.

Therefore, we developed a comprehensive model that builds upon previous studies within and beyond biomedical engineering to simulate TFM (Figure 1). This simulation utilizes previous advances in systems biology to model ECM deposition and phenotype switching to predict actomyosin activation.[4–6] Additionally, a result from tribology was used to model substrate displacement due to focal adhesion forces.[7] This new model is intended to predict the two-dimensional contractile behavior of VSMCs under various experimental conditions.

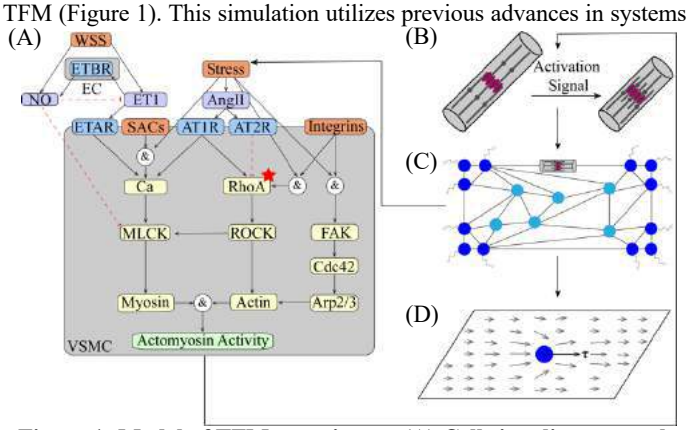

**Figure 1: Model of TFM experiment. (A) Cell signaling network. Star denotes node manipulated in case study. (B) Stress fiber contraction. (C) Cytoskeletal network of stress fibers. (D) Displacement of elastic substrate.**

## METHODS

The model consists of four components: *cell signaling* (Fig. 1A) drives *stress fiber contraction* (Fig. 1B), and the stress fibers interact with one another via a *cytoskeletal network* (Fig. 1C). Focal adhesions transmit cytoskeletal forces to the substrate, inducing *substrate deformation* (Fig. 1D). The model also includes feedback between cytoskeletal stress and biochemical signaling.

*Cell Signaling Network*: A VSMC signaling network was constructed by isolating nodes of interest from a published model.[4] The relationships between nodes were modeled as ordinary differential equations based on a normalized (0-1) Hill function for activation of each species in the network.[8] The calculated steady-state actomyosin activity set the maximum fiber activation level in the fiber-level model.

*Stress Fiber Contraction:* Actomyosin bundle contraction and stress were modeled following Deshpande et al.[1], with fiber bundle activation ($\eta$) described by a first-order kinetic equation:

$$\frac{d\eta}{dt} = (1-\eta)\frac{k_f C_{max}}{\theta}\exp\left(\frac{-t}{\theta}\right) - \left(1-\frac{\sigma}{\sigma_0}\right)\frac{k_b}{\theta}\eta \qquad (1)$$

where $C_{max}$ is the maximum actomyosin activity based on the signaling network results, $\sigma/\sigma_0$ is the normalized fiber stress, $k_f$ and $k_b$ are rate parameters for formation and dissociation of fibers, and $\theta$ the activation signal decay time. The normalized active fiber stress was described[1] as:

$$\frac{\sigma}{\sigma_0} = \left(1+\exp\left(-5.301\left(\frac{k_v\dot{\lambda}}{\eta}-\frac{\eta}{2k_v}\right)\right)\right)^{-1} \qquad (2)$$

where $k_v$ describes the reduction in fiber stress with increased shortening rate $\dot{\lambda}$ and $\sigma_0$ is the product of the fiber activation level and maximum stress allowed by biochemistry. The passive fiber stress was given by:

$$\sigma_p = \frac{E}{B}\left(\exp\left(B\frac{\lambda^2-1}{2}\right)-1\right) \quad (3)$$

where $\lambda$ is the stretch, and $E$ and $B$ are material constants.

*Cytoskeletal Network:* A Delaunay network of 50 randomly seeded interior nodes and 7 uniformly spaced boundary nodes in each corner of the 127 $\mu$m x 32 $\mu$m region was constructed to simulate an actomyosin stress fiber network. Boundary nodes were designated as focal adhesions, linking the VSMC to the substrate. Equilibrium positions of the fiber network nodes were determined by setting the sum of all fiber forces and the spring force due to substrate displacement (for focal adhesions) to zero (i.e., mechanical equilibrium for each node).

*Substrate Displacement:* Each focal adhesion was modeled as a circular contact displacing tangentially on a linear elastic half-space.[7] The superposition of all focal adhesion forces and displacements determined the overall substrate deformation.

## RESULTS

The bio-chemo-mechanical model operates by combining inputs from biochemical signaling and mechanical stress generation. The model captures dynamic contraction of the stress fiber network following a single activation signal. To capture steady-state behavior, the model can be modified to respond to recursive signaling. Without additional activation signals, the fiber stress peaks uniformly after a delay associated with penetration of the activation signal into the network (Figure 2). Fiber stress is approximately uniform due to biochemical signaling being modeled as uniform throughout the cell. Additionally, the substrate displacement is concentrated near focal adhesions.

The integration of biochemical signaling into the model allows the comparison to experimental results from genetically-modified VSMCs. Work completed by Porter et al.[9] has demonstrated that a knockdown of SUN1 results in a decrease in traction force through a reduction in RhoA, a positive regulator of ROCK-mediated contraction, activity.[10] When the maximum activation level of the RhoA node in the signaling network (starred in Fig. 1A for reference) was reduced, the model recapitulated the 40-50% reduction in VSMC traction stress demonstrated by Porter et al. (Figure 3A).[9]

In addition to direct biochemical modulation, VSMCs are also mechanosensitive and adapt their contractility in response to changes in substrate stiffness. In work examining circular dorsal ruffle formation, Huynh et al.[11] illustrated that traction force is positively correlated with substrate stiffness in VSMCs. When only the shear modulus of the substrate was changed in the model, the traction force rose as seen experimentally, but the stiffness-dependence was much less pronounced (Figure 3B). VSMCs also respond to increased substrate stiffness by increasing focal adhesion size and number.[12] When the number of

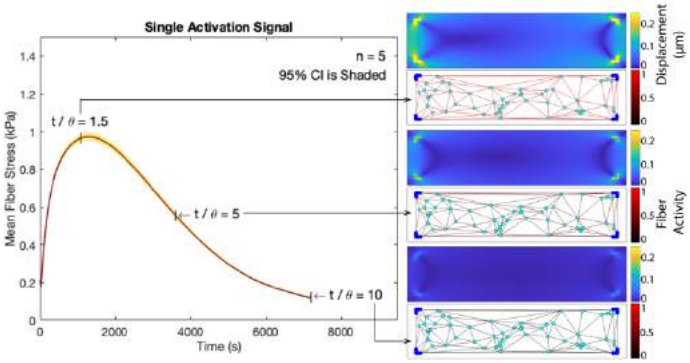

**Figure 2: Dynamics of (left) actomyosin fiber stress after a single activation signal and (right) resulting substrate displacement (top) and fiber network (bottom) of a simulated VSMC on 12 kPa substrate over time.**

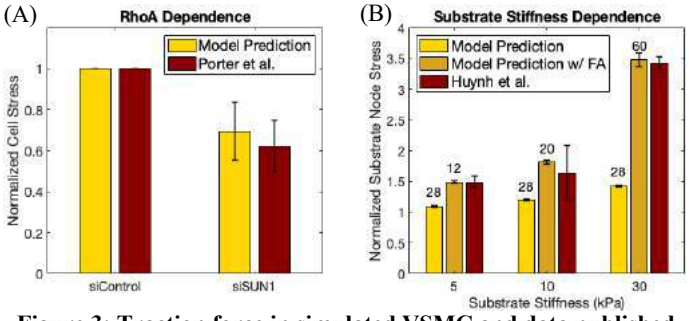

**Figure 3: Traction force in simulated VSMC and data published by (A) Porter et al.[9] and (B) Huynh et al.[11] Cases are normalized to siControl and 2.5 kPa substrate. Text above is focal adhesion number and error is 95% confidence interval.**

simulated focal adhesions was scaled with substrate stiffness, the computational model matched the experimentally-observed changes in cell traction with no other adjusted parameters.

## DISCUSSION

This new model of traction force microscopy recapitulates data from published VSMC experiments. The level of biochemical node activation in the cell signaling network component does not map directly to experimental measures of expression due to the use of normalized values, and therefore the model responds to changes in a qualitative, but not necessarily quantitatively similar, manner.[4–6] The solution to rectify this discrepancy would sacrifice the benefit of not defining large numbers of rate constants and biochemical binding parameters. Thus, for more complex signaling networks, it is not beneficial to quantitatively match the reaction weights directly.

When the number of simulated focal adhesions was not modulated to respond to substrate stiffness, the model did not match experimental data published by Huynh et al.[11] However, it is well established that cells on stiff substrates increase the size and number of focal adhesions.[12] When the number of substrate nodes was modeled to respond to substrate stiffness, the simulated response matched experimental data. The distinct advantage of the model relying on feedback from focal adhesions allows the number and distribution of focal adhesions to respond dynamically over time in future applications.

This simulation of a TFM experiment benefits from its ability to draw upon feedback from both chemical and mechanical signals. Unlike previous models that do not consider the biochemical signal cascades, this version can capture the behavior of VSMCs from a variety of genetic sources and biochemical treatments. A discrete approach also provides the possibility of matching fiber anisotropy seen in VSMC micropatterning.[13] Additionally, the discrete fiber formulation allows an accurate representation of the substrate displacement resulting from focal adhesion point forces. The presented bio-chemo-mechanical model offers a powerful tool for predicting the dynamic contractile behavior of VSMCs *in vitro*.

# ELASTIC STRENGTH AND ITS RELATION TO MINERAL DENSITY IN JUVENILE EQUINE BONES OF THE LOWER LIMB

**Sara G. Moshage (1), Annette M. McCoy (2), Mariana E. Kersh (1,3,4)**

## INTRODUCTION

Most fatal musculoskeletal injuries in racing horses occur in the lower limb, particularly the third metacarpal/tarsal (MC3/T3) and proximal phalanx (P1) bones, and are a significant welfare issue for racehorses [1,2]. Mechanical loading via exercise has proven to be a viable means for inducing bone adaptation to mitigate fractures [3] but determining the amount and type of exercise remains a challenge [3,4]. Computational models allow for pre-clinical, non-invasive predictions of the mechanical loads of bone in vivo [5] under different exercise modes. Critical to these predictions is accurate material properties, such as the Young's modulus, which can be assessed empirically from computed tomography based apparent mineral density [6,7]. Currently, no such relationship has been reported for juvenile equine bone.

While the growth plates in the distal MC3 and proximal P1 close at nearly the same time [8] and these regions form a congruous joint, whether their mineralization rates and therefore properties are the same is not known. Further, density-modulus relationships vary by anatomical location and are known to be anisotropic [6,7]. Therefore, the objectives of this study were to (1) determine whether the longitudinal and transverse Young's modulus in the P1 and MC3 are different and (2) develop a density-modulus relationship for juvenile equine bone.

## METHODS

**Specimens** – Intact bones (P1:8, MC3:3, MT3:1) were collected from young horses (age: 3-day (n=1), 4-weeks (n=6)) euthanized for reasons unrelated to this study. The bones were wrapped in PBS soaked gauze and stored in plastic bags at -20°C.

**Intact Sample Imaging** – Bones were cleaned of soft tissue and imaged with overlapping microCT (μCT) scans (isotropic resolution = 144 μm, 90 kVp, 177 μV, Rigaku CTLab GX130) acquired along the bone length and merged (Fig. 1A, Amira 2020.1). The bones and mineral density phantoms (range: 25-750 mg HA/cm$^3$, CIRS) were then scanned in a clinical CT scanner (LightSpeed16, GE Medical Systems) with the same protocols used for live horses (resolution=0.875 x 0.875 x 0.625 mm, 120 kVp, 200 mA).

**Bone Core Preparation** – Bone sections perpendicular to the longitudinal axis were cut using a water-irrigated diamond band saw. Trabecular cores were removed in the longitudinal (n=81, Fig. 1B) and dorsal-palmar transverse (n=53) directions using a water-irrigated diamond sintered coring bit (diameter = 5mm) mounted on a drill press. Bone marrow was left intact [9] and the cores were fixed in custom Delrin endcaps using 2-part epoxy (exposed length =12.29±1.57 mm). Samples were wrapped in PBS-soaked gauze and refrigerated at ~2°C for 18 hours before testing.

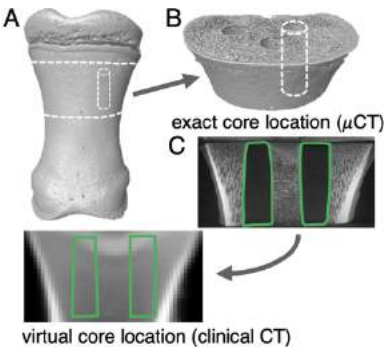

**Figure 1: (A) P1 showing cut lines. (B) Longitudinal core. (C) Bone cores in the intact image stack.**

**Bone Core Imaging** – Importantly, the CT density of intact bone is known to be different from cut samples [10]; therefore, we developed a method to identify virtual cores. The bone sections that remained following core extraction were μCT scanned and aligned to the intact CT data to locate each core within the clinical CT data set (Fig. 1C, Amira 2020.1).

**Compression Testing** – Cores were brought to room temperature and hydrated with PBS. Compression tests were performed on a tabletop test frame (Instron 5967) using a fixed lower platen and a self-aligning, spherical seated upper platen. Embedded cores were pre-loaded to 5N, pre-conditioned for 5 cycles by loading to 0.001 strain at 0.01 strain/s, and loaded till failure at 0.01 strain/s. Force and crosshead displacement

were recorded after adjusting for machine compliance using the direct technique [11]. Data were sampled at 100 Hz.

**Young's Modulus Calculation** – Stress was calculated by dividing force by each sample's cross-sectional area and strain by dividing displacement by exposed length for each sample. Young's modulus was calculated as the slope of the linear regression of all data between two points on the elastic portion of the stress-strain curve.

**Density Calculation** – The clinical CT scan and phantoms were used to calculate average CT density ($\rho_{CT}$) for each core. Ash density (g/cm$^3$) was calculated using Eq. 1 [12].

$$\rho_{ash} = (\rho_{CT} + 0.09)/1.14 \quad (1)$$

**Statistical Analysis** – MT3 and MC3 samples were combined (herein referred to as MC3). Normality of Young's modulus and ash density was tested using a Shapiro-Wilks test. Distributions of Young's modulus between groups were compared using a Mann-Whitney-Wilcoxon test. For each bone, Young's modulus and ash density were log transformed and their relationship was examined using linear regressions. The slope and intercept were used to define the exponential and leading coefficient terms, respectively, in the function relating modulus to ash density. The interaction effect of sample orientation with ash density on experimental modulus was evaluated using an analysis of variance. All analyses were performed in R (v3.5.2).

## RESULTS

The MC3 group had 48 longitudinal and 27 transverse samples, while the P1 group had 33 longitudinal and 26 transverse samples. The transverse modulus of MC3 samples was lower (Mdn=197 MPa) than samples from the P1 (Mdn=250 MPa, Fig. 2) and these distributions differed significantly (p=0.04). In contrast, there was no significant difference between longitudinal samples from the MC3 and P1 (Mdn E=458 MPa and 394 MPa, respectively). The median longitudinal modulus was 132% higher than the median transverse modulus in the MC3 (Fig. 2A) and 57% higher in the P1 (Fig. 2B); these distributions differed significantly (p<0.001 and p=0.0015, respectively).

Bone type (MC3 vs P1) significantly affected the leading coefficient (p<0.001) but not the exponent (p=0.07) of the density-modulus relationships. Both the leading coefficient and exponent (p<0.001) were sensitive to sample orientation for the MC3. In contrast, orientation only affected the leading coefficient (p<0.001) for the P1.

Overall, longitudinal modulus is better predicted in the P1 than the MC3 by a factor of ~4 ($R^2$ of 0.64 and 0.14, respectively, Fig. 3 orange lines). However, our predictions of modulus in the transverse direction are more robust, with density predicting 84% of the variability in the P1 and 75% of the variability in the MC3 (Fig. 3 blue lines).

## DISCUSSION

We found that the longitudinal modulus in the MC3 and P1 was not significantly different, while the transverse modulus in the P1 was higher than the MC3 reflecting a tendency towards more isotropic material properties in the P1. These differences may be because the loading modes of the MC3 and P1 are different. It's likely the MC3 undergoes bending due to its long slender structure, whereas the cuboidal P1 would be more resistant to bending. Variation in surface strain modes between the distal MC3 (compression) and the P1 (shear) has been reported [13]. The density-modulus relationship derived in our study, combined with computational models of musculoskeletal loading, provides the groundwork for testing our hypotheses regarding the nature of bone loading during movement.

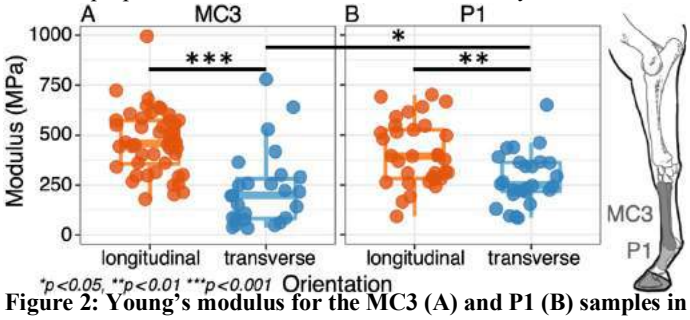

**Figure 2: Young's modulus for the MC3 (A) and P1 (B) samples in the longitudinal (orange) and transverse (blue) directions.**

In terms of predicting modulus from ash density, bone type influenced the leading coefficient but not the exponent and is consistent with differences in density-modulus relationships between anatomic locations for human trabecular bone [7]. The prediction of elastic modulus using density alone was stronger in the P1 compared to the MC3. Further work is needed to confirm whether mineralization rates are different between the two bones as well as the influence of microstructure and non-mineral composition on the elastic modulus.

When the density-modulus relationship derived from mature horses [14] was applied to our longitudinal MC3 samples, the Young's modulus root mean squared error (RMSE) was nearly double the RMSE in this study (RMSE=269 vs 147 MPa). However, over 80% of the samples tested by Les et al. were cortical bone though they reported no difference in the density-modulus relationship between cortical and trabecular bone. Our samples are trabecular and may explain some of the differences between $E_{Les1994}$ and $E_{long}$ (Fig. 3A). Current work involves testing cortical bone samples.

Our data highlight the sensitivity of elastic modulus to bone type and orientation. The incorporation of these data into computational models will allow for more rigorous predictions of the mechanical environment of bone and therefore the potential for bone adaptation.

# MULTISCALE MODELING OF CARDIAC VALVE DISEASE USING CELL-LEVEL SIGNALS TO DRIVE MYOCARDIAL GROWTH

**Hossein Sharifi (1), Austin G. Wellette-Hunsucker (2), Charles K. Mann (1), Kenneth S. Campbell (2), Jonathan F. Wenk (1,3)**

## INTRODUCTION

Multiscale models of the cardiovascular system are emerging as effective tools for investigating the mechanisms that drive ventricular growth and biological remodeling. Such models can be used to evaluate the effects of molecular-level mechanisms on organ-level function, which could provide new insights for improving patient care. PyMyoVent is a multi-scale computer model that simulates a left ventricle (LV) pumping blood around a systemic circulation by bridging from molecular to organ-level mechanisms. In previous work, we implemented baroreflex control of arterial pressure by using feedback to regulate heart rate, intracellular $Ca^{2+}$ dynamics, the molecular-level function of both the thick and the thin myofilaments, and vascular tone.

Davis et al. [1] have suggested that cardiac growth correlates with the magnitude of tension developed by myofilaments over time, which reflects the work done by the heart. Therefore, cellular level mechanisms that are associated with altered work demand in the heart could be potential driving signals for concentric growth. In this study, we hypothesize that the energy used by cells, to perform the work required by the heart, could be an alternative signal in driving concentric growth.

Valvular diseases, such as mitral insufficiency, lead to overstretching of the sarcomeres and thus increasing of the passive stress within a cell. The alteration in the intracellular passive stress can be sensed by proteins located near the end of sarcomeres. In particular, titin, which spans from the Z disk to the M line, contains an elastic structure within the I band that interacts with other proteins on the Z disk. This provides the passive stiffness of the sarcomeres by storing strain energy during diastole [2]. Therefore, in the current framework, the intracellular passive stress, which reflects the stress within titin, is assumed to drive the serial deposition of sarcomeres and eccentric growth of the LV.

## METHODS

In this work, we extend PyMyoVent with concentric growth (wall thickening / thinning) and eccentric growth (chamber dilation / constriction) driven by cell and molecular-level signals (Figure 1). Specifically, concentric growth is controlled by the energy used by cells during contraction (expressed as myosin ATPase normalized to myofibrillar volume), while eccentric growth responds to intracellular passive stress. The new framework's ability to predict LV growth was tested by simulating two types of valvular disease, namely aortic stenosis and mitral insufficiency.

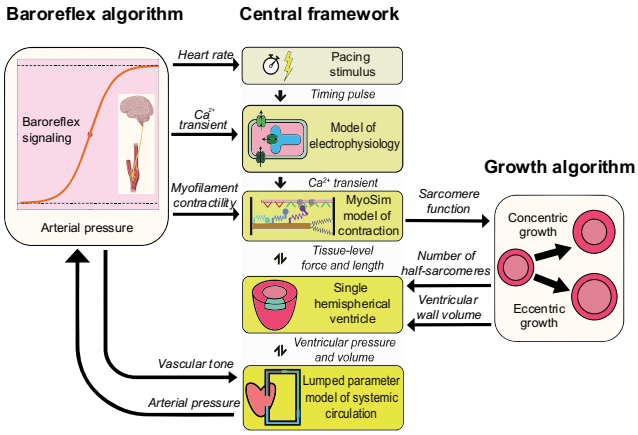

**Figure 1. Overview of the PyMyoVent framework.** Adapted from Campbell et al. [3].

The growth module algorithm was inspired by the underlying biology. In vivo, growth stimuli signals trigger a complex pathological downstream signaling pathway that promotes cell growth and

ventricular enlargement. In the current model, a growth stimulus signal ($S_i$) transduces into a normalized growth signal $G_{a,i}$ that represents the net result of triggered upstream signals within the cell. The rate of change in $G_{a,i}$ is defined as

$$\frac{dG_{a,i}(t)}{dt} = \begin{cases} k_{a,i}\dfrac{\left(S_i - S_{i,set}\right)}{S_{i,set}}\left(1 - G_{a,i}(t)\right) & S_i \geq S_{i,set} \\ k_{a,i}\dfrac{\left(S_i - S_{i,set}\right)}{S_{i,set}}\left(G_{a,i}(t)\right) & S_i < S_{i,set} \end{cases} \quad (1)$$

where i represents the growth type (i.e. concentric or eccentric), $k_{a,i}$ is a rate constant and sets the speed at which $G_{a,i}$ responds to a change in $S_i$. $S_{i,set}$ is the homeostatic setpoint for the stimulus signal $S_i$. During positive feedback, $G_{a,i}$ tends towards one when $S_i$ is greater than $S_{i,set}$ and towards zero when $S_i$ is less than $S_{i,set}$. In vivo, these bounds mimic the saturated levels of phosphorylation and dephosphorylation of underlying proteins by protein kinase.

The control signal $G_{c,i}$ reflects the net result of downstream signals and governs how the effector parameters (i.e. wall volume or the number of half-sarcomeres) should respond to the normalized growth signal $G_{a,i}$. The rate of change in $G_{c,i}$ is defined as

$$\frac{dG_{c,i}(t)}{dt} = \begin{cases} \gamma_{growth,i}\dfrac{\left(G_{a,i}(t) - 0.5\right)}{0.5} & G_{a,i} \geq 0.5 \\ \gamma_{anti\ growth,i}\dfrac{\left(0.5 - G_{a,i}(t)\right)}{0.5} & G_{a,i} < 0.5 \end{cases} \quad (2)$$

where $\gamma_{growth,i}$ and $\gamma_{anti\ growth,i}$ are rate constants that set the speed at which the effector parameters would grow or shrink according to $G_{a,i}$. Finally, eccentric growth was implemented by changing the number of serial half-sarcomeres around the circumference of the left ventricle. Concentric growth was modeled by changing the left ventricular wall volume to mimic the parallel deposition of half-sarcomeres.

## RESULTS

Figure 2 summarizes the simulated response to two types of valvular dysfunction wherein each column represents one case. All simulations started with model parameters set to default values that mimic the LV function of an adult human with no valvular disease.

Aortic stenosis (left-hand column) was modeled by increasing the aortic resistance parameter. In response to such a perturbation, LV wall volume increased by ~30%, end-diastolic LV cavity volume decreased by ~8%, but end-systolic LV cavity volume remained nearly unchanged. These changes led to thickening of the LV wall by ~21% and ~29% at end-systole and end-diastole, respectively, suggesting the occurrence of concentric growth.

Mitral insufficiency (right-hand column) was modeled by allowing retrograde blood flow through the mitral valve during systole. A ~60 ml regurgitant volume resulted in the LV wall volume increasing by ~50% and dilation of the LV cavity (~57% at end-diastole and ~68% at end-systole). Due to these changes, the LV wall hypertrophied by ~12% at end-diastole and 10% at end-systole. Furthermore, simulations for each valvular disorder regained LV size and function (reversal of growth) once the disease-mimicking perturbation was removed.

## DISCUSSION

The new framework simulated concentric growth (wall thickening / thinning) and eccentric growth (chamber dilation / constriction) in response to two types of valvular disorder. The results were consistent with changes in LV dimension reported in the literature for patients with aortic stenosis and mitral insufficiency. In conclusion, the simulations suggest that myosin ATPase normalized to myofibrillar volume and intercellular passive stress can be used to drive concentric and eccentric growth in simulations of valve disease.

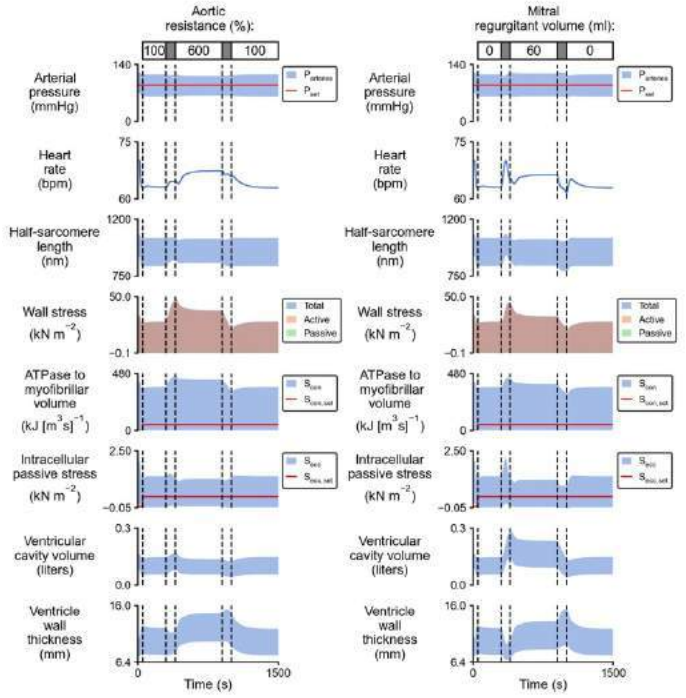

**Figure 2. Predicted LV growth in response to two types of valvular disorders.** Each column summarizes the simulated response to a valvular disease (left, aortic stenosis; right, mitral insufficiency). In each column, $P_{arteries}$ is arterial pressure, $P_{set}$ is the baroreflex setpoint which is set to 90 mmHg, $S_{con}$ and $S_{con,set}$ refer to the driving signal and setpoint for concentric growth, respectively, $S_{ecc}$ and $S_{ecc,set}$ refer to the driving signal and setpoint for eccentric growth, respectively. The growth module was activated at 50 s (first vertical line from left on all panels) when the system was at steady state using default parameters. The disease-mimicking perturbations were gradually applied (between second and third vertical lines) by altering the relevant model parameters. Once the growth simulations were at steady state, the underlying perturbations were removed (between fourth and fifth vertical lines) to capture the reversal of growth. Variables that are pulsatile during a cardiac cycle are shown by an envelope containing the extreme values.

# EVALUATING THE CAPABILITIES OF A NOVEL DEVICE DESIGNED TO PRESERVE WHOLE PANCREASES VIA OXYGENATED PERFUSION

**Daniel J. Portillo (1), Jose Gonzalez (1), Carorina Villareal (1), Sophia Salazar (1), R. Lyle Hood (1,2)**

(1) Department of Mechanical Engineering, The University of Texas at San Antonio, San Antonio, TX, USA
(2) Department of Biomedical Engineering, The University of Texas at San Antonio, San Antonio, TX, USA

## INTRODUCTION

Although there are over 1,000 pancreas transplants performed in the US every year, that number is slowly declining as more donors are presenting higher-risk organs for transplantation [1]. Recent research focused on preserving pancreases using machine perfusion (MP), as opposed to static cold storage (the current gold standard), has shown that MP offers significantly improved preservation outcomes [1]. The benefits of MP for pancreas preservation include nutrient delivery, toxic waste removal, and reduced rates of ischemic reperfusion injury [1]. Leemkuil *et al.* also demonstrated that supplying oxygen to the perfusion solution is feasible and can further increase pancreatic tissue viability [2]. Despite those benefits, there are currently no devices on the market that are designed to preserve pancreases via MP.

Fortunately, a cost-effective, versatile oxygenating perfusion system (VOPS) has been previously designed by our group [3]. The novel design of the VOPS incorporates the oxygenator and perfusion pump into one embodiment. That embodiment contains small silicone tubes, which are cyclically inflated/deflated with compressed oxygen. The expanding and contracting tubes act as a diaphragm-style pump that displaces and circulates the perfusion solution throughout the device. Since oxygen permeates through silicone, the tubes also supply oxygen to the circulating perfusion solution. Thus far, our group has successfully demonstrated that the VOPS is capable of supplying perfusion pressures, flow rates, and oxygenation rates used in previous kidney, liver, and heart preservation studies [3].

The focus of this work was to evaluate the VOPS's ability to supply perfusion parameters used by previous groups to preserve pancreases. Since perfusion pressure is the most reported perfusion parameter in pancreas preservation [4], we hypothesized that the VOPS could achieve perfusion pressures between 15 – 60 mmHg while pumping against a phantom element that mimicked the vascular resistance of a pancreas.

## METHODS

Preliminary tests were conducted to measure the rate that each silicone tube length expanded and contracted, which determined the rate that they were pulsed. Three different lengths of silicone tubing (Silastic® Laboratory Tubing, DuPont de Nemours, Inc.) were evaluated in the VOPS; they had a constant inner diameter of 0.058 in. and lengths of 10, 30, or 50 ft. Various compressed oxygen pressures were used to inflate and deflate the tubes, ranging from 2 – 12 psi (increments of 2 psi). In total, 90 trials were conducted (three silicone tubes, 6 oxygen pressures, n=5). Phosphate-buffered saline (PBS, Sigma-Aldrich) was used as the perfusion solution and a flexible polyvinyl chloride (PVC) tube was installed in the perfusion loop to mimic the vascular resistance of a pancreas (0.76 mmHg/mL/min) [5].

The perfusion pressures were measured with pressure transducers (PX309-030G5V, Omega Engineering, Inc.) and the flow rate was measured with an ultrasonic flow sensor (2PXL-TS410, Transonic Systems Inc.). All sensors were read simultaneously using a custom LabVIEW virtual interface (NI 9221 and NI USB-9162, LabVIEW 2019 SP1, National Instruments). The oxygenation rate ($\dot{O}_2$) was calculated using Equation 1 (Van 't Hoff equation) and relied on an oxygen solubility constant ($H_c$), the volume of solution in the VOPS

($V_{sol}$), and the pressure increase in the device ($P_{dev}$) over the time of the trial ($t_{trial}$).

$$\dot{O}_2 = H_c V_{sol} \left(\frac{\Delta P_{dev}}{t_{trial}}\right) \quad (1)$$

## RESULTS

Figure 1 illustrates the peak perfusion pressures attained by different silicone tube lengths across the range of oxygen supply pressures. The peak perfusion was linearly correlated to the oxygen supply pressure and inversely proportional to the length of silicone tubing. All three lengths of silicone tubing achieved adequate perfusion pressures when operating with oxygen pressures between 4 – 10 psi. Figures 2 and 3 illustrate the mean flow rates (7.1 – 20.6 mL/min) and mean oxygenation rates (5.5 – 90.2 µmol/min), respectively, that were achieved while the VOPS was operating within ideal perfusion pressures [4].

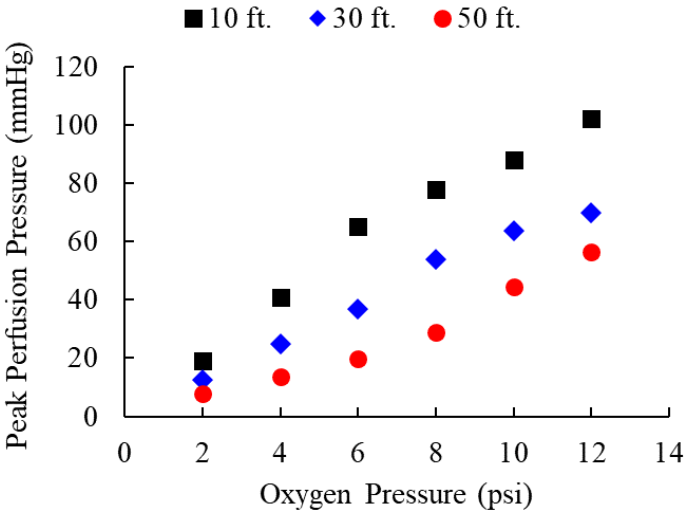

**Figure 1. Peak perfusion pressures produced by different lengths of tubing at various oxygen pressures.**

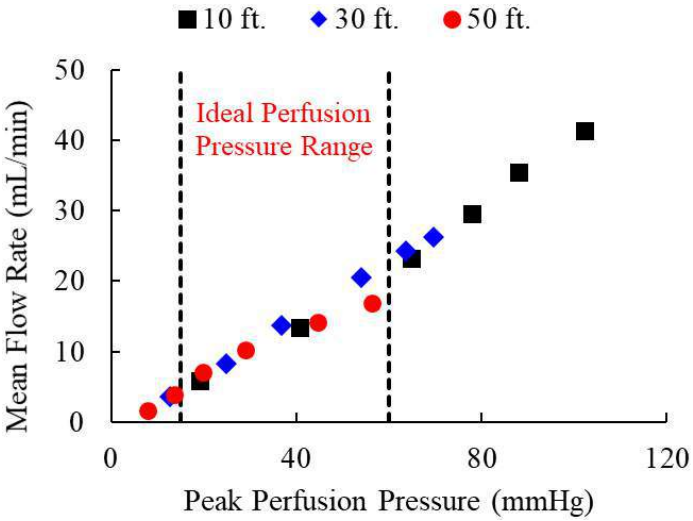

**Figure 2. Mean flow rates and peak perfusion pressures produced by the VOPS for various silicone tubes.**

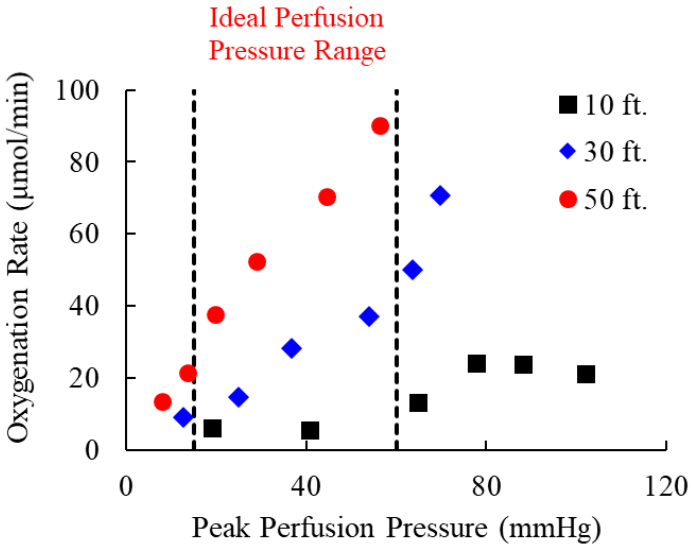

**Figure 3. Oxygenation rates and peak perfusion pressures produced by the VOPS for various silicone tubes.**

## DISCUSSION

The results confirmed our hypothesis by demonstrating that the VOPS produced a wide range of flow rates and oxygenation rates when performing at ideal perfusion pressures (15 – 60 mmHg) [4]. Although all tube lengths produced equivalent flow rates, the shorter tube lengths produced higher perfusion pressures and lower oxygenation rates. This study strengthens the notion that *versatile* oxygenating perfusion systems could exist and would facilitate wider use compared to the current organ-specific preservation devices. Future work will focus on characterizing the VOPS across different viscosities of common perfusion solutions, creating computational models to simulate the VOPS performance, and *ex vivo* studies to evaluate the preservation efficacy of the VOPS.

## INTRODUCTION

Cardiovascular disease is the leading cause of death in the United States, and the estimated annual cost associated with heart diseases in the U.S. alone is over $200B [1]. The current paradigms for in vivo cardiovascular diagnosis and research is imaging and catheterization, but imaging can be expensive, catheterization is invasive, and both are inadequate with respect to capturing certain measurements, such as local stresses within the myocardium [2].

Computational modeling can assist researchers and clinicians by providing insight into data inaccessible to imaging modalities [3]. The heart lends itself to macro-scale, whole organ computational modeling because the myocardium can be described as a continuum, and the blood acts as an incompressible fluid at the organ scale [4]. Fluid-structure interaction (FSI) methods, in which the fluid dynamics inform the structural deformations and the stresses from the structures impact the fluid velocity, have the potential to provide the most accurate and predictive description of the blood-organ relationship as neither the structure motions nor fluid dynamics are prescribed [4].

We are only aware of two previous FSI models of the entire heart, but these models either lack physiologic valves [5] or model the myocardium in a way non-conducive to extracting meaningful data about stresses and strains [6]. The immersed finite element (IFE) method [7] is an FSI method that enables modeling studies of biological tissues, including cardiac chambers coupled with valves [8, 9]. This study employs the IFE method to construct a comprehensive model of the entire heart, including physiologic valves. This model of the heart will ultimately be used as a platform for valve replacement and repair studies that cannot be conducted using prior models because of the capabilities of the FSI methods used.

## METHODS

Our IFE method relies on a finite element (FE) mesh for all of the structures fully inscribed within a cuboid computational fluid domain. The myocardial structure in our model was generated using computed tomography (CT) data from a male in his 30s. The segmentation process results in surface representations of most of the cardiac structures that must be thickened to physiologic values. For the ventricles, however, the myocardium is thick enough to capture the inner and outer surfaces which can be attached to capture the in vivo wall thickness. In contrast the valves are difficult to capture using CT data [2]. Consequently, the structures of all four valves and the valve complexes were constructed using measurements from previous studies on valve anatomies [10, 11]. Fig. 1 shows the resulting FE geometry.

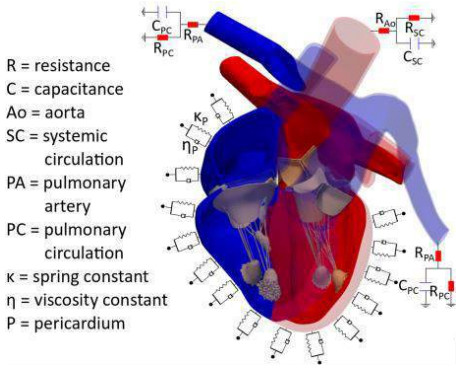

**Figure 1: The structure of the model includes all of the chambers and valve complexes. The pericardium, modeled by a spring-dashpot model, acts to tether the structure, and the Windkessel model informs the outflow boundary conditions.**

The passive mechanics of the structures are generally anisotropic because of the myosin and actin fibers within the myocardium and the collagen fibers within the valves [12]. To capture this anisotropy within our model, we defined three orthogonal fiber fields within the

FE mesh [12]. We identified constitutive equations that relied on fiber orientations for the structures based on studies that used human tissue for parameter estimation via stress-strain experiments [13-15]. The contraction of the heart is generated using an active strain model [16] using waveforms based on chamber pressure plots. The effects of the pericardium are modeled using a spring and dashpot in parallel tethered to the epicardial surface [17], as seen in Fig. 1.

The fluid in the IFE method is modeled using the incompressible Navier-Stokes equations. The boundary of the fluid domain is defined with traction free boundary conditions (BCs) except where the outflow vessels of the structure meet the edge of the domain. The outflow pressure BC is controlled by a three-element Windkessel (WK) model [18], shown in Fig. 1, that uses the flux through the outflow boundary of the fluid domain to inform the pressure. The left and right heart fluid flows and pressures are not currently connected, so during atrial filling we rely on a fluid source within the atria to generate fluid. The entire model was built using the IBAMR software platform [19].

## RESULTS

We ran full simulations of the model over consecutive cycles to test the efficacy of our methods. Fig. 2 shows snapshots of one of the model iterations at key points within the cardiac cycle, which helps to verify that the valves are working and the fluid is being pumped as anticipated during each phase of the cycle.

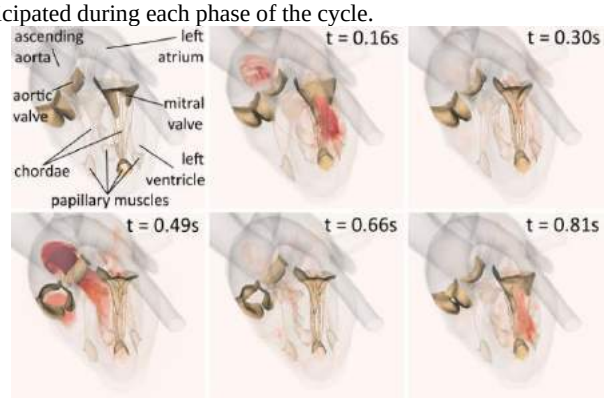

**Figure 2: Heat map of the velocity magnitude (0-120 cm/s) during different phases of the cardiac cycle.**

A particularly useful diagnostic tool is the pressure-volume (P-V) relation in the left ventricle (LV) throughout the entire cycle (Fig. 3). LV is the focus of our results as the most data exists for the LV, and the LV is subject to the highest stresses and strains. Plotting the P-V relationship over successive cycles can also show if the model is converging to a steady-state with regards to the LV performance. From the P-V relation we can also extract general data about the cardiac cycle to assess performance including the end diastolic volume (EDV), end systolic volume (ESV), and stroke volume (SV) (Fig. 3).

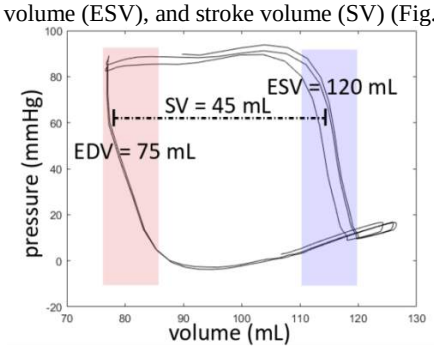

**Figure 3: Pressure-volume loop over 3 consecutive cycles with labelled isovolumetric contraction (blue) and relaxation (red) phases. Loops are formed counter-clockwise in time. End diastolic volume (EDV), end systolic volume (ESV), and stroke volume (SV), have been labelled for clarity.**

## DISCUSSION

The results demonstrate that the IFE method can be used to model whole-heart fluid and structural dynamics across full cardiac cycles. Our model intrinsically captures the isovolumetric contraction and relaxation phases of the cardiac cycle, and it reaches a steady state with respect to the LV P-V relationship within two-to-three cardiac cycles (Fig. 3). This is significant in that no prescriptive motion is defined and the fluid is only externally influenced by the WK model at the boundary and a fluid source in the atria during atrial filling.

The flow dynamics also capture the important posterior-to-anterior washout jet of fluid during the ventricular filling phase after contraction (Fig. 2). Our model is unique in that it captures these features while also using a physiologic description of the valves. The SV is 45 mL (Fig. 3), which leads to a cardiac output (CO) of 2.7 L/min given that the simulation was running at 60 bpm. This is significantly lower, however, than a healthy cardiac output of 5 L/min, where the SV should be closer to 80 mL [20].

In its current condition the model can be improved with respect to SV and CO. However, results from previous iterations show that changing the contraction magnitude, tuning the WK parameters, and adjusting the contraction waveforms significantly affects the P-V relationship in a predictable way. We are confident that we can use these features to replicate a fully physiologic cycle of a healthy human heart.

With these results we have also shown that the model has potential, after tuning, to be used in valve replacement and repair studies where FSI is needed in addition to physiologic valves. Specifically we plan to use this model to conduct the first FSI studies of edge-to-edge repair devices and transcatheter mitral valve replacement devices used as interventions for mitral regurgitation. With this model we can query the stresses these devices place on the heart and the valve leaflets, as well as identify any changes in flow patterns these devices cause.

# ROBUST ARTICULATION-INDUCED CARTILAGE REHYDRATION IS SUSTAINED FOLLOWING PROTEOGLYCAN LOSS

## INTRODUCTION

Articular cartilage is a highly-hydrated connective tissue that facilitates load dissipation and nearly frictionless motion at diarthrodial joints. Nonetheless, cartilage is susceptible to osteoarthritis (OA), a progressive, irreversible disease that is a leading cause of disability among U.S. adults.[1] Healthy cartilage consists primarily of interstitial fluid (68-85% by weight). The remainder is comprised of a deformable matrix of anionic proteoglycans (PG) and fibrillar collagen (5-10% and 10-20% wet weight, respectively).[2] Degradation of these matrix constituents is a hallmark of OA that increases tissue compliance and permeability. Indeed, biochemical approaches, such as enzymatic digestion of proteoglycans and/or collagen, stimulate OA-like changes *ex vivo,* including decreased modulus and elevated permeability.[3-5]

Benchtop tribological studies suggest that ECM degradation impairs cartilage's lubrication behaviors, including friction coefficients and fluid load support (FLS).[4-5] However, such studies have been confined to sliding environments interrogating only a portion of the lubrication modes accessible to cartilage, namely boundary (sliding speeds ≤1 mm/s) and mixed mode lubrication (~10 mm/s). Recently, we found that sliding at higher—and more physiological—speeds (≥40 mm/s) promotes interstitial fluid recovery. Under these conditions, interstitial lubrication is sustained through a hydrodynamically-mediated mechanism termed *tribological rehydration*.[6] In the context of tribological rehydration, our findings suggest cartilage's exceptional *in vivo* frictional behaviors ($\mu$<0.01) depend on the maintenance of high FLS via articulation-driven fluid recovery. Furthermore, we recently discovered that healthy cartilage's ability to support tribological rehydration at speeds ≥40 mm/s is largely insensitive to tissue property variations across five model species.[7] Here, we extended our studies of articulation-mediated interstitial fluid recovery to compromised tissues using controlled digestion of articular cartilage via chondroitinase-ABC (chABC). Using this model, we assess whether moderate levels of PG removal (consistent with OA progression in humans) have adverse effects on articulation-induced tribological rehydration.

## METHODS

Osteochondral explants (∅19mm) were harvested from the femoral condyles of mature bovine stifle joints. Biphasic tissue properties were measured by microindentation with a ∅4mm spherical probe under creep relaxation. Hertz biphasic theory[8] was used to calculate the effective contact modulus ($E_c$), tensile modulus ($E_t$), and equilibrium contact modulus ($E_{c0}$). Tribological characterization consisted of 30 minutes of static compression at 0.25 MPa followed by 15 minutes of reciprocal sliding at 80 mm/s under the same stress. Compression magnitudes ($\delta$) and friction coefficients ($\mu$) were recorded in LABVIEW and analyzed via MATLAB.

Indentation and tribological characterization were repeated following enzymatic digestion with 0.1 units/mL chondroitinase ABC (chABC) in 50 mM Tris-HCl, 60 mM sodium acetate, and 0.02% bovine serum albumin.[4] Explants were digested for 40 min, washed, indented, and tribologically characterized. Explants then were digested for an additional 3 hr and 20 min (for total enzyme exposure time of 4 hr) and characterized a third time. These incubation times were chosen based on preliminary studies that aimed to generate modulus and permeability values consistent with, and then exceeding those of arthritic human cartilage.[9] Differences among groups were assessed via two-way ANOVA with significance at multiple comparison-adjusted $p < 0.05$.

## RESULTS

Biphasic tissue properties were characterized via Hertzian indentation. As evidenced in **Fig. 1A**, 40 minutes of chABC digestion had little influence on deformation relative to naïve samples under equivalent normal loads (~160mN; $p = 0.71$). In contrast, a sharp

increase in deformation was observed following 4 hours of digestion ($p < 0.0001$). As expected, equilibrium contact moduli ($E_{c0}$), which describes the compressive stiffness of the ECM at steady state, decreased significantly with each digestion period (**Fig. 1B, left**). Average equilibrium contact moduli decreased by 24% and 60.5% (from 0.56 ± 0.24 MPa for naïve tissue to 0.44 ± 0.18 and 0.30 ± 0.13 MPa) following 40 minutes and 4 hours of chondroitinase digestion, respectively ($p < 0.0001$). Chondroitinase digestion had no significant impact on $E_c$ (**Fig. 1B, right**), which depends upon contributions of both fluid load support and solid matrix integrity, or on $E_t$ ($p > 0.20$).

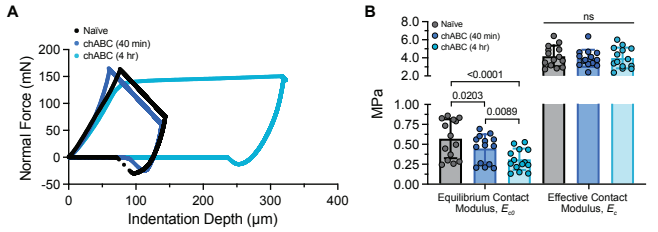

**Fig. 1. Mechanical characterization. (A) Force vs. deformation response of a representative sample before and after digestion. (B) Digestion led to decreases in equilibrium contact moduli (left) but no differences in effective contact moduli (right).**

The tribological rehydration of a representative sample prior to and following 40 minutes and 4 hours of enzymatic digestion via chondroitinase are shown in **Fig. 2**. Data summarizing the strain recovery and friction behaviors of n = 7 longitudinally digested cSCA explants are shown in **Fig. 3**. While strain at the start- and end-of-sliding were significantly elevated following 4 hours of enzymatic degradation ($p = 0.0001$ and 0.024 vs. naïve tissue for start- and end-of-sliding, respectively), no differences in strain recovery among groups were observed ($p = 0.20$). This indicated sustained capacity for tribological rehydration even following 4 hours of PG digestion (**Fig. 2A**). Similarly, friction coefficients did not differ significantly among groups, despite exhibiting a modest rise with longitudinal chABC digestion (**Fig. 2B**).

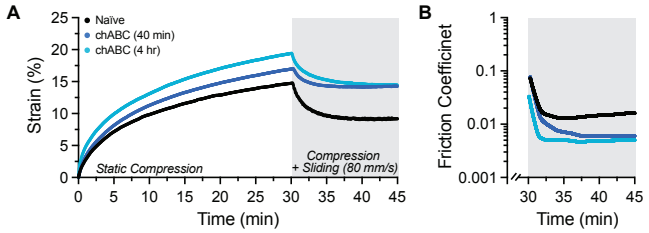

**Fig. 2. Tribological rehydration behavior of a representative before and after proteoglycan digestion.**

## DISCUSSION

Our findings demonstrate that cartilage can retain rather remarkable tribological rehydration and lubrication capacity following proteoglycan digestion. Consistent with prior work,[4] chABC digestion led to substantial loss of compressive stiffness (>50%) and increases in permeability (18%, not shown), but had little effect on collagen network integrity (as assessed by tensile modulus). Despite substantial reductions in compressive modulus, chABC-digested cartilage exhibited marked strain recovery and concomitant decreases in friction coefficients (to ~0.01) during high-speed sliding. In contrast, preliminary assessments of tribological rehydration following collagenase degradation indicate deleterious effects of compromised tensile stiffness on tissue function, namely reduced strain recovery and

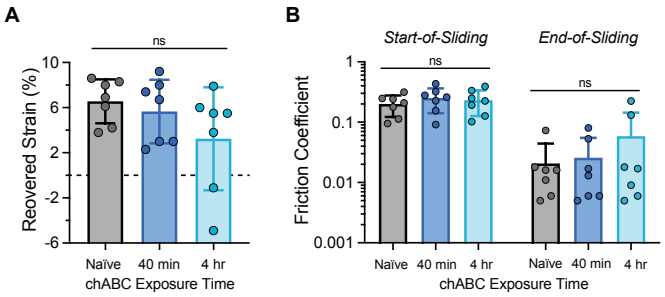

**Fig. 3. Chondroitinase digested explants retained the capacity for robust tribological rehydration, as indicated by the strain recovery (A) and friction behavior (B). Tribological rehydration produced significant decreases in friction coefficients between start- and end-of-sliding in all conditions ($p < 0.002$, paired t-test).**

elevated equilibrium friction coefficients (≥0.1). These findings suggest that the collagen network's ability to resist lateral expansion under compressive load plays a crucial role in tribological rehydration. This mirrors work from Soltz and Ateshian, who found that high tension-compression nonlinearity is required to sustain high FLS in cartilage.[10] However, our results also hint at a compressive property floor below which interstitial lubrication is significantly impacted. **Fig. 3A** shows two explants failed to exhibit interstitial fluid recovery following the second chABC digestion. Interestingly, these samples had the lowest equilibrium contact moduli both initially (~0.25 MPa, vs. ~0.4-0.9 MPa for the remaining samples) and after the second digestion (~0.1 MPa).

Broadly, this study provides important insights regarding OA etiology and treatment strategies. That cartilage can support tribological rehydration in the face of significant proteoglycan loss and compromised compressive resistance might inform the natural timeline of OA progression. While PG loss is considered an early sign of OA onset, the disease can remain asymptomatic for many years following such identification. This may be, at least in part, because cartilage appears capable of supporting robust hydration recovery and interstitial lubrication well after PG loss is initiated. Furthermore, PG loss is thought to precede collagen loss in the OA cascade. It has been suggested that interactions of aggrecan and other PGs with collagen create a macromolecular coating that protects collagen from proteolytic degradation.[11] Thus, only once extensive PG loss has occurred might the collagen network become vulnerable to physical and/or biological degradation. Together with our present findings, this suggests that PG repair/reinforcement, such as by a PG-mimetic interpenetrating network (IPN)[12] may be a promising strategy to slow OA-associated degradation of both PG and collagen. Our ongoing work will investigate whether PG-based reinforcement can restore FLS and tribological rehydration in digested cartilage.

# IDENTIFYING MICRO-INDENTATION TESTING PARAMETERS SUITABLE FOR BRAIN TISSUE TESTING

**Xuesong Zhang (1), Johannes Weickenmeier (1)**

(1) Department of Mechanical Engineering
Stevens Institute of Technology
Hoboken, NJ, United States

## INTRODUCTION

Mechanical properties of soft tissues play an important role in maintaining their physical and biological function. It is well understood that the mechanical environment of cerebral tissues influences everything from neuronal development to neurodegeneration [1,2]. For example, Goriely et al. have summarized and concluded the importance of mechanical factors, including deformation, stretch, strain, strain rate, pressure, and stress on regulating both brain geometry and functions [3].

Brain tissue is considered as extremely soft and most complex organ in the body, which can be divided into gray matter and white matter. Specifically, gray matter consists of neurons, some axons. While white matter is made up of glial cells and bundles of myelinated axons. Also, both white matter and gray matter have remarkable water content. The microstructural nature of brain tissue leads brain to be a nonlinear, anisotropic, poroviscoelastic, and spatially heterogeneous material [4].

Indentation is one of the most popular experimental techniques to determine the mechanical properties of a wide array of soft biological tissues. Despite its frequent use, however, some experimental design factors must be determined for each application including variations from repeated measurements in the same location, indentation speeds, indentation depths, bead size, testing conditions such as dry or submerged, and the model use to analyze the force-displacement data. In the present study, we investigated the impact of these indentation parameters on stiffness and report indentation results for fresh mouse brain experiments.

## METHODS

**Sample Preparation.** We used fresh mouse brain tissue (with a focus on the corpus callosum, cortex, cingulum, and hippocampus) and the brain-mimicking material gelatin methacrylate (GelMA) hydrogel. Specifically, 5% (weight/volume) GelMa was cured by UV light for 2 minutes, which has been widely used in biomedical applications, including 3D bioprinting brain-like constructs [5]. Fresh mouse brains were harvested from 6-week-old female mice from Jackson Laboratory. We cut 1000 um thick slices, glued them into a Petri dish, and submerged our samples in three different fluids to test their impact on the indenter-tissue interaction: deionized (DI) water, phosphate-buffered saline (PBS) solution, and contact lens (CL) solution. GelMA bioink was prepared from ready lyophilized GelMA foam (Allevi Inc., PA, USA). 0.5% Lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP, Allevi Inc., PA, USA) and 5% GelMA foam were mixed thoroughly with PBS at 60°C for over an hour in the dark. When the final GelMA bioink solution is well homogenized and dissolved, it is stored overnight in the dark at 4°C. When needed, GelMA is melted down in a warm water bath (37 °C) and crosslinked after use under 365nm UV light.

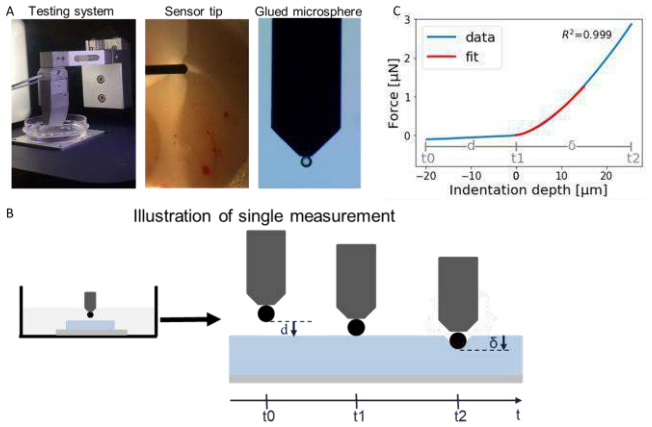

**Fig.1. Illustration of the machine setup, testing protocol, and the resulting force-depth data. (A) Machine setup. (B) Testing method. (C) The resulting force-indentation depth data and the model fitted curve.**

**Indentation Measurement and Data Analysis.** We performed a sensitivity analysis with 5% GelMa and a fresh mouse brain slice and varied six parameters: number of measurements in the same location (1 to 9), indentation speed (5, 10, 15, 20μm/s), indentation depth (4 to

20µm), bead diameter (50 and 100µm), tissue surfactant (PBS, DI water, and CL solution), and fitting model (Hertzian contact model, Neo-Hookean, and Ogden). We used our FT-MTA03 testing device (FemtoTools AG) equipped with a FT-S200 sensing probe (Fig.1A). Our testing protocol, as shown in Fig.1B, is as follows: we position the tip over the sample 20µm and further indent the sample until it reaches the mentioned indentation depths at the proposed speeds. We fit our force-displacement data to three previously mentioned material models and report resulting stiffness parameters. We subsequently performed Student T-tests to analyze statistical significance between individual groups (* indicates $p < 0.05$, ** indicates $p<0.01$, and *** indicates $p<0.001$).

## RESULTS

We summarize the results of our sensitivity analysis with 5% GelMa in Figure 2. Averaged GelMa stiffness is 1.3±0.07 kPa and is independent of the number of measurements in the same location (Fig.2A). Due to the nonlinearity of the sample, stiffness increases with indentation depth (Fig.2B). Average stiffness is higher at an indention speed of 20µm/s (1.37±0.08 kPa) in comparison to 5µm/s (1.26±0.09 kPa) due to the viscosity of the material (Fig.2C). Average stiffness decreases with bead size because of the nonlinearity of the material (Fig.2D). The strain is smaller when we use a larger bead diameter according to equation $\varepsilon i = i0.2 * i\sqrt{d/R}$, with strain ε, indentation depth d, and bead radius R [6]. Furthermore, the different fitting models (Fig.2E) result in young's moduli of 1.3±0.09 kPa for the Hertzian contact model, 1.03±0.08 kPa for the Neo-Hookean material model, and 1.06±0.12 kPa for the Ogden model; goodness of fit, measured by the $R^2$ value (>0.998), was similar for all three models (Fig.2F). Lastly, the surfactant has a great influence on indentation testing; contact lens solution gives the least resistance (Fig.2F) for the indenter when compared to PBS and DI water due to the decreased surface tension of CL solution [7].

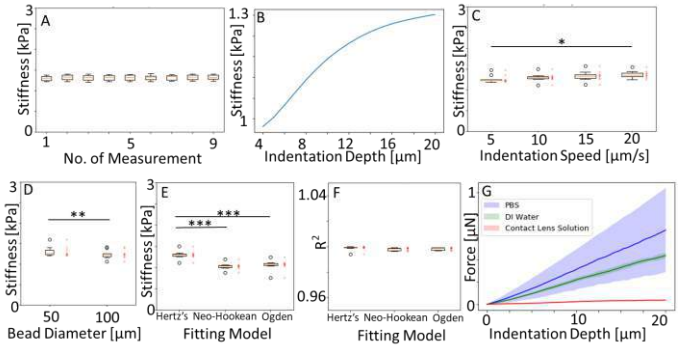

**Fig.2. The sensitivity analysis of parameters in indentation testing for 5% GelMa. (A) The number of measurements at the same location. (B) Indention depths. (C) Bead sizes. (D) Indentation speeds. (E) Fitting models. (F) The $R^2$ values of the fitting models. (G) The mean and standard deviation curve for different surfactants.**

For fresh mouse brain, stiffness of cortex is decreasing from 4.02±0.52 kPa to 3.4±0.59 kPa when we compare the first measurement and the fourth measurement in the same location (Fig.3A). This might be caused by surface damage resulting from repeated measurements and the poro-viscoelastic property of brain tissue. The stiffness continuously increases with indentation depth (Fig.3B). Moreover, the cortex is stiffer when we used a larger diameter bead (Fig.3C), the reason is might because the smaller bead we used, the less water was confined under the bead during testing. Averaged stiffness increases from 3.73±0.7 kPa to 5.06±0.91 kPa with increasing indentation speed from 5µm/s to 20µm/s (Fig.3D), suggesting highly viscous tissue properties. Like 5% GelMa, different fitting models result in different young's modulus (Fig.3E), however, the non-linear models (Neo-Hookean and Ogden) show better $R^2$ values (Fig.3F) than Hertz's linear contact model.

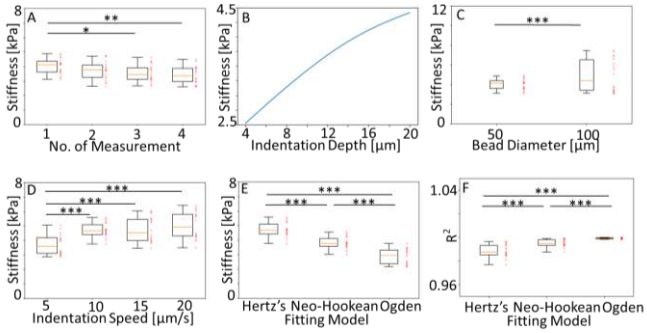

**Fig.3. The sensitivity analysis of parameters in indentation testing for fresh brain cortex. (A) The number of measurements at the same location. (B) Indention depths. (C) Bead sizes. (D) Indentation speeds. (E) Fitting models. (F) The $R^2$ values of the fitting models.**

## DISCUSSION

The influence of testing parameters in indentation experiments was investigated and resulted in a testing protocol suitable for fresh mouse brain tissue. Our results also confirmed that fresh tissue is more heterogeneous, viscous, and behaves more nonlinearly than 5% GelMa.

We already successfully applied our protocol to fresh hippocampal mouse tissue and are able to create localized stiffness maps that align with anatomical subregions as shown in Fig.4. Going forward, we will use our testing protocol to determine the impact of individual microstructural brain constituents on tissue-level mechanical behavior.

## INTRODUCTION

Traumatic brain injury (TBI) is widespread and associated with the possibility of debilitating emotional and cognitive deficits. TBIs are caused by rapid brain deformations that arise from skull acceleration. The mechanics of TBI are incompletely understood; improved insight and ability to simulate injury could help reduce, diagnose, and treat TBI.

The mechanical behavior of the human brain is difficult to characterize *in vivo*; previous studies have relied on computational and animal models to study brain biomechanics [1, 2, e.g.]. However it is challenging for computer models to capture the nonlinear, viscoelastic, and anisotropic response of the brain, and animal models cannot completely recapitulate human brain behavior due to differences in structure and size. Recently, experimental techniques such as tagged MRI (tMRI) and MR elastography (MRE) have emerged as tools to study low-amplitude, dynamic deformation in the human brain *in vivo*. These imaging methods provide high-resolution data complementing animal and cadaver studies of brain biomechanics.

In previous work we analyzed tMRI images using dynamic mode decomposition (DMD) [3] and identified dominant low frequency modes of oscillation (~7-11 Hz) in which the brain may be vulnerable to injury. MRE is used in our lab [4] to harmonically excite motion in the human brain. The objective of this research is to compare (i) the low frequency modes found by tMRI of impulsive skull motion to (ii) deformation modes excited by harmonic skull motion using MRE.

## METHODS

3D displacement (Fig 1a) and strain data were acquired by tMRI (18 ms/frame 1.5×1.5×5 mm voxels) in two subjects (S1, M 32 yrs; S2, F 37 yrs) undergoing mild impulsive, rotational deceleration in the axial plane (neck rotation). To produce the impulsive loading, the subject voluntarily rotates their head towards the left shoulder until arrested by a soft impact. tMRI images are acquired by a custom sequence synchronized with motion. Displacement and strain were estimated from the motion of tag planes [5]. These data are also on the Brain Biomechanics Imaging Repository on the NeuroImaging Tools and Resources Collaboratory (NITRC) site [6]. Strain fields were analyzed by DMD [3] to find the dominant oscillatory mode of 3D deformation, defined by a complex 3D strain tensor at each voxel. (Fig 1b).

MR elastography was used to image brain deformation in two different human subjects (S3, F 57 yrs; S4, M 55 yrs) undergoing harmonic skull motion at 10 Hz and 50 Hz. Skull motion was driven by an inflatable silicone actuator pre-loaded against the side of a subject's head. A pneumatic driver (Resoundant, Rochester, MN for 50 Hz or customized PL-300 sub-woofer, BIC America, Anaheim CA for 10 Hz) was used to deliver harmonic pressure waves to the actuator. A custom MRE sequence [6] was used to obtain all components of 3D harmonic displacement (3×3×3 mm voxels, Fig 1a), which were numerically differentiated to estimate 3D strain tensors at each voxel (Fig 1b).

To compare strains in dominant modes from tMRI of impulsive motion to harmonic strains from MRE in different subjects, we performed a series of spatial transformations (Fig 1). Anatomical T1-weighted images (Fig 1c) were used to rigidly register each subject's brain to a standard structural template (MNI152 T1-weighted 0.8 mm brain atlas) using Advanced Normalization Tools (ANTS) [7] (Fig 1d) T1- and T2-weighted images were rigidly registered to the MNI-152 space [8] using the Advanced Normalization Toolkit (ANTs) v2.2 [9], resampled to 0.8 mm isotropic resolution.

Strain tensor components were re-computed in the rigidly registered space based on the rotation matrix associated with the rigid registration. The radial-circumferential ($\varepsilon_{r\theta}$) strain component was computed in the rigidly registered space using the centroid of the brain volume as the origin (Fig 1d). This strain component was chosen because radial-circumferential shear is the dominant mode of deformation in neck rotation [5].

The nonlinear transform from each subject's T1 volume to the MNI152 template was calculated using the cross-correlation standard

SB³C2022-047

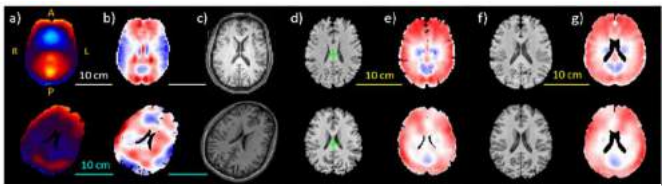

**Figure 1. Comparison of oscillatory strain fields in the brain from MRE during harmonic skull motion (top row) and from DMD of tMRI during impulsive skull motion (bottom row). (a) Displacement $u_x$ (x=LR, y=AP). (b) Cartesian ($\varepsilon_{xy}$) strain fields. (c) T1 images in their respective "native" spaces. (d) Rigidly registered T1 images (centroids in green). (e) Strain ($\varepsilon_{r\theta}$) fields after rigid registration. (f) T1 images registered to MNI atlas. (g) $\varepsilon_{r\theta}$ strain fields after nonlinear registration to MNI atlas. Scale bars 10 cm: white (MRE), cyan (tMRI), yellow (MNI).**

symmetric normalization (SyN) transformation model in ANTS (Fig 1f). The SyN transformation matrix was applied to the $\varepsilon_{r\theta}$ strain (Fig 1g) for each set of tMRI or MRE data. A mask was applied to each set of strain data to remove voxels in the ventricles.

Comparisons between data sets were performed either over the entire brain volume or slice-by-slice. In the whole volume comparison, strain fields are normalized using the $L_2$ norm as shown in Eq. (1a). A dot product is then taken between each normalized strain field ($\hat{\varepsilon}_{r\theta}$), giving a correlation value between 0 and 1 (Eq. (1b)). A correlation magnitude of 1 indicates identical strain fields. The slice-by-slice comparison is analogous; but performed in each slice independently.

$$\hat{\varepsilon}_{r\theta,i} = \frac{\varepsilon_{r\theta,i}}{\sqrt{\sum_n |\varepsilon_{r\theta,n}|^2}} \quad (1a) \qquad CV = \hat{\varepsilon}^{(1)}_{r\theta} \cdot \hat{\varepsilon}^{(2)}_{r\theta}. \quad (1b)$$

## RESULTS

Transformed $\varepsilon_{r\theta}$ strain fields in the MNI atlas space are shown in Fig 2, for the dominant modes of oscillation from DMD of impulsive motion (Fig 2ab), MRE of harmonic motion at 10 Hz (Fig 2cd), and MRE of harmonic motion at 50 Hz (Fig 2ef). Slice-by-slice comparisons between (i) the dominant DMD mode from tMRI of impulsive motion and (ii) a strain field from MRE of 10 Hz harmonic motion show a large region of high similarity throughout the cerebrum (Fig 3a) as well as lower similarity in the cerebellum. In whole-volume comparisons (Fig 3c) relatively high correlation scores (>0.60) are found between DMD modes of impulsive motion and strain fields from MRE of 10 Hz harmonic motion. Relatively low correlation values (<0.50) were found between DMD modes from impulsive motion and MRE of harmonic motion at 50 Hz. Notably, similar low values were found between strain fields from MRE of harmonic motion at 10 Hz and 50 Hz.

## DISCUSSION

Dominant modes of oscillatory, 3D deformation in the human brain induced by impulsive motion of the skull are similar to the patterns of deformation induced by low-frequency (10 Hz) harmonic excitation of the skull. In contrast, both the dominant modes of oscillation caused by impulsive excitation, and the patterns of deformation due to low-frequency (10 Hz) skull motion, differ from the deformation patterns induced by high-frequency (50 Hz) harmonic skull motion.

To perform comparisons between strain fields obtained by different imaging methods (tMRI and MRE), caused by different motion types (impulsive or harmonic), in different subjects, we leveraged the ANTS registration suite to transform fields into a common MNI atlas space. Once in this space, quantitative comparison is straightforward. The approach used here to find correlations between scalar fields can be readily extended to vector or tensor fields.

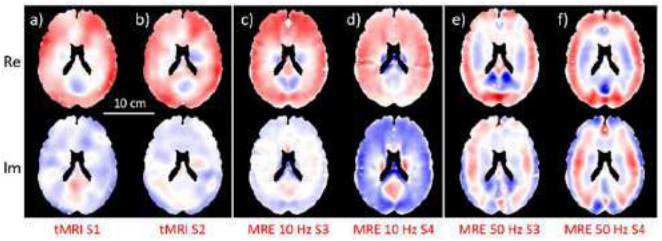

**Figure 2. Dominant oscillatory modes of brain deformation induced by impulsive and harmonic skull motion. Strain fields ($\varepsilon_{r\theta}$) are shown on a representative axial slice after registration to the MNI atlas (slice location is denoted by the dashed blue line in Fig 3b). (c) Whole-volume correlation magnitudes computed between oscillatory modes shown in Fig 2.**

We acknowledge some limitations. Data from only 4 subjects were used, and the subject ages in tMRI and MRE differed substantially. With age, the human brain shrinks and ventricle size increases. The MNI-152 atlas is not ideal, as it was constructed using subjects aged 18-44 yrs. In future studies we plan to compare brain deformation patterns in groups of subjects of similar age and sex. Nevertheless, this study shows the importance of low-frequency modes in the response of the brain to impulsive loading, and that these modes are uncovered by MRE.

## INTRODUCTION

Symptomatic intervertebral disc (IVD) herniations cause debilitating numbness and pain. While resection of the herniated tissue can alleviate these symptoms, the remaining compromised annulus fibrosus (AF) is left unrepaired, providing an uninterrupted path for aberrant scar infiltration, nociceptive nerve ingrowth, and recurrent herniation [1]. The low AF cellularity, high density, and avascularity prevent endogenous healing and predispose the disc to degeneration.

Numerous approaches have attempted to seal the AF injury or deliver biologics to enhance repair [2-3]. Although some of these approaches have partially restored IVD biomechanics, the inflammation-mediated loss of extracellular matrix (ECM), that exacerbates degeneration, has not yet been addressed. Therefore, there is a need for an annular repair device that provides both physical reinforcement and closure of the AF tear while simultaneously mitigating inflammation to prevent the degenerative loss of ECM.

Upon herniation of the disc, local expression of the proinflammatory cytokine interleukin-1β (IL-1β) increases, contributing to the acute loss of ECM post-injury. Elevated IL-1β also causes an increase in nerve growth factor (NGF) - a chemotactic signal that increases the infiltration of nociceptive neurites into the disc [4-5]. Thus, blocking IL-1β signaling may prevent the inflammation-mediated loss of ECM and prevent recurrent pain.

Mechanically-activated microcapsules (MAMCs) are drug-encapsulating depots that have tunable mechano-activation and degradation properties, thus representing an ideal localized drug delivery system for the load-bearing IVD [6]. The goals of this study were to (1) develop and optimize a mechano-responsive annular repair scaffold and (2) assess the delivery, retention, and performance of the AF repair device in a goat cervical spine herniation model. We hypothesized that repairing the torn AF post-herniation and blocking local IL-1β signaling would prevent the loss of AF ECM, decrease neurite and scar infiltration, and improve IVD biomechanics.

## METHOD

MAMC Fabrication: MAMCs were fabricated to encapsulate a model drug (bovine serum albumin, BSA) or the IL-1 receptor antagonist, Anakinra (Sobi) [6].

Drug Bioactivity Assessments: To test the effects of increasing Anakinra concentrations on cell viability, Alamar Blue cell viability assay was performed on AF cells from healthy human donors (Articular Eng.) after 3 days of culture with soluble Anakinra. To assess drug bioactivity after encapsulation in MAMCs, the contents of Anakinra-loaded MAMCs or soluble Anakinra was added to human AF cells ± IL-1β (10ng/mL) for 3 days. qPCR was performed after treatment to assess changes in catabolic gene expression.

Patch Fabrication: Aligned polycaprolactone (PCL) – polyethylene oxide (PEO) nanofibrous scaffolds were fabricated via electrospinning [7]. Annular repair devices were fabricated by heating up 3D-printed metal stamps to 80ºC and melt-stamping MAMCs between two scaffold sheets. Metal stamps with varied lengths of the longest rhombus diagonal (δ: 3-5 mm) were tested.

Scaffold Tensile Loading: Dynamic uniaxial tension cycles (6% strain, 1Hz) were applied to MAMC-laden scaffolds along the fiber direction using a custom-built bioreactor, after which MAMC imaging was performed to quantify MAMC mechano-activation. To determine scaffold mechanical properties, scaffolds were subjected to uniaxial tension to failure with optical strain tracking of local deformation [8].

In Vivo Annular Repair: With IACUC approval, 8 goats underwent annular injury and/or patch repair at C2-3 and C3-4, with the C4-5 level used as a healthy control. Annular injury consisting of a partial-thickness AF laceration followed by full thickness needle puncture was performed. Scaffold groups received either a BSA-MAMC control patch (repair) (l:10 mm, w: 3.5 mm, δ=4) or an Anakinra-loaded patch (Anakinra) that was sutured over the injury. Animals were euthanized at 4 weeks. Cervical spines were subjected to MRI at 3T for quantitative T2 mapping. Following MRI, motion segments were subjected to

SB³C2022-048

compressive testing (0 to -100 N, 0.24MPa) to determine biomechanical properties. Motion segments were then fixed, decalcified, and processed for paraffin histology. Mallory-Heindenhain staining was performed, and collagenous infiltration was quantified using ImageJ.

Statistical Analyses: Significant differences were assessed via parametric or non-parametric one- or two-way ANOVA ( * $p \leq 0.05$, ** $\leq 0.01$, ***$\leq 0.001$, ****$\leq 0.0001$).

## RESULTS

Anakinra-loaded MAMCs were effectively fabricated (**Fig. 1a-b**). Anakinra concentrations of up to 1000 ng/mL did not have a detrimental effect on AF cell viability (**Fig. 1c**) and caused a concentration-dependent decrease in the expression of MMP3 and LCN2. Furthermore, the contents retrieved from Anakinra-loaded MAMCs demonstrated a comparable effect to that of soluble Anakinra (**Fig. 1d**).

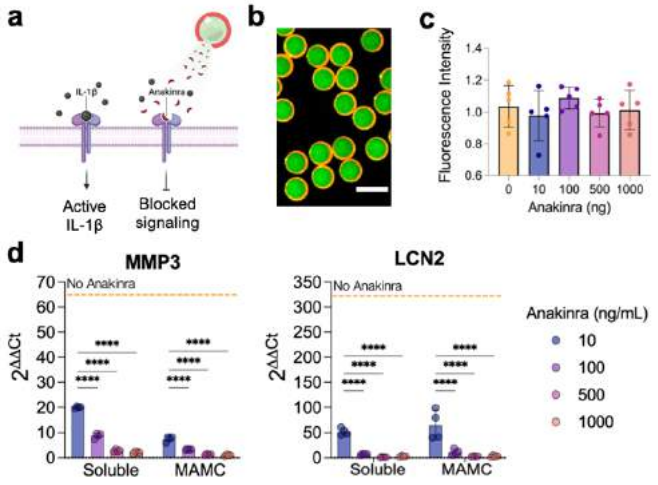

**Figure 1: (a) Anakinra delivery blocks IL-1$\beta$ signaling. (b) Anakinra-loaded MAMCs (scale: 50$\mu$m). (c) Alamar Blue viability assay for cells treated with Anakinra. (d) MMP3 and LCN2 expression after treatment with soluble Anakinra or Anakinra extracted from crushed MAMCs in the presence of IL-1β.**

Annular repair scaffolds were formed by melt-stamping MAMCs between two fibrous scaffold layers (**Fig. 2a**). Dynamic tensile loading of scaffolds resulted in increasing mechano-activation of MAMCs with increasing number of loading cycles (**Fig. 2b**). $\delta$=4 and 5 mm stamp patterns created comparable MAMC mechano-activation profiles while the $\delta$=3 pattern resulted in less activation with loading. Melt stamping increased the tensile modulus of the scaffolds compared to an unstamped scaffold of comparable thickness (**Fig. 2c**).

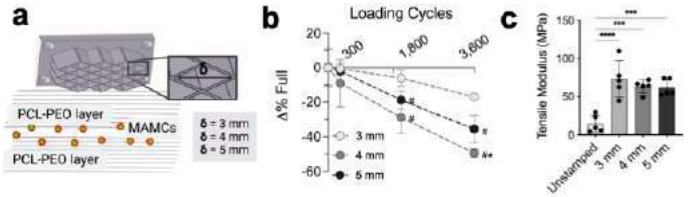

**Figure 2. (a) Schematic of melt-stamped scaffolds. (b) MAMC mechano-activation with tensile loading (# vs. 0 cycles, * vs 3 mm) and (c) scaffold tensile modulus.**

After 4 weeks *in vivo*, annular repair patches remained secured at the injury site. Average T2 maps showed greater signal in the AF for injury and repair (empty scaffold) groups compared to uninjured controls and the Anakinra scaffold group (**Fig. 3a-b**). Repair with an empty patch maintained the disc linear modulus at uninjured levels, while stiffening occurred in the injury group (**Fig. 3b-c**). Empty patch delivery also reduced the collagenous infiltration observed on the anterior and posterior AF of injured discs (**Fig. 3d-f**). Disc biomechanical testing and histology (including immunohistochemistry for neurites and catabolic factors) for animals treated with Anakinra-loaded scaffolds is currently in progress.

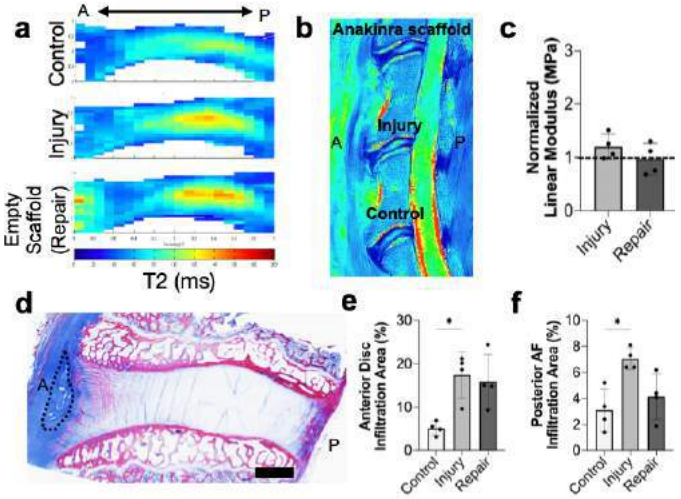

**Figure 3: (a) Average MRI T2 (A: anterior, P: posterior). (b) Representative T2 for Anakinra scaffold, injury, and control. (c) Linear modulus normalized to healthy control (dashed line). (d) Mallory Heindenhain-stained section for empty scaffold repair (dashed line) (scale: 1mm). Fibrous tissue infiltration area in the (e) anterior and (f) posterior AF.**

## DISCUSSION

Anakinra potently blocked IL-1β signaling, attenuating the upregulation of catabolic genes in human AF cells in a dose-dependent manner. Therefore, the localized delivery of MAMCs with bioactive Anakinra may be used to provide therapeutically effective concentrations at the target injury site. MAMCs could be integrated into annular repair patches and mechano-activated in response to dynamic loading. The repair patches remained in place after 4 weeks *in vivo*. Interestingly, empty patch delivery prevented the stiffening of injury-only groups, potentially by decreasing the robust scar infiltration and collagenous remodeling observed after injury. While further analysis of Anakinra-loaded patch groups is in progress, the effects of Anakinra treatment *in vitro* and the T2 signal observed for the Anakinra patch group indicate that the simultaneous provision of structural reinforcement and anti-inflammatory molecules may potentially prevent catabolic remodeling and loss of disc function post-herniation.

## INTRODUCTION

Primary open-angle glaucoma (POAG) is a leading cause of irreversible vision loss worldwide, and elevated intraocular pressure (IOP) is the primary modifiable risk factor [1-5]. Elevated IOP results from increased resistance to aqueous humor (AH) outflow in the juxtacanalicular region of the conventional outflow pathway where the trabecular meshwork (TM) and Schlemm's canal (SC) inner wall cells interact [6]. Extracellular matrix (ECM) stiffening and increased transforming growth factor beta2 (TGFβ2) in the AH are strongly associated with outflow tissue dysfunction [7]. Yes-associated protein (YAP), a central player in mechanotransduction, has emerged as key contributor to glaucoma pathogenesis [8,9]; a recent genome-wide study identified *YAP1* among novel glaucoma risk loci [10]. However, the precise role of SC cell YAP signaling in response to known glaucomatous stressors is poorly understood. Here, we investigate how ECM stiffness/composition and TGFβ2 regulate YAP activity in human SC cells using biomimetic hydrogels [11] with tunable stiffness, and whether pharmacologic YAP inhibition increases *ex vivo* outflow facility.

## METHODS

ECM hydrogels were fabricated by photocrosslinking functionalized collagen type I (3.6 mg/ml [all final concentrations]), elastin-like polypeptide (2.5 mg/ml), and hyaluronic acid (0.5 mg/ml, 0.025% (w/v) photoinitiator Irgacure® 2959) [11]. Bioinert alginate (4 mg/ml) was added to facilitate $Ca^{2+}$ (100 mM)-mediated hydrogel stiffening and alginate lyase (50 μg/ml)-mediated softening (**Fig. 1A**). Fibronectin (FN) was used to coat ECM hydrogels (10 $\mu g/cm^2$). Human Schlemm's canal (HSC) cells were isolated from surgical discard corneal rims and validated according to accepted standards in the field. Four HSC cell strains were used for the experiments in this study. Donor demographics were as follows: Male/33-years-old; M/46; F/46; F/68. HSC cells were plated on hydrogels and stimulated with TGFβ2 (2.5 ng/ml), ROCK inhibitor (Y27632; 10 μM), or latrunculin B (Lat B; 2 μM). YAP signaling in SC cells cultured on hydrogels was inhibited with verteporfin (VP; 0.5 μM). YAP transcriptional activity, cytoskeletal organization, fibrotic marker levels, and ECM remodeling were quantified. Outflow facility with ocular perfusion of VP (10 μM) was measured in enucleated eyes from 3-6-month-old C57BL/6J mice using *iPerfusion* [12].

## RESULTS

ECM-alginate hydrogel stiffness was increased ~3-fold upon $Ca^{2+}$ crosslinking ($p<0.001$); alginate lyase treatment restored soft baseline levels (**Fig. 1B**). ECM stiffening increased YAP activity and F-actin levels in HSC cells ($p<0.001$), which was fully restored by matrix softening (**Fig. 1D-G**). Nuclear YAP completely translocated to the cytoplasm within 3 h after ECM softening; F-actin levels reached baseline after 24 h ($p<0.0001$). FN coating enhanced HSC cell YAP activity and actin cytoskeleton/ECM remodeling. TGFβ2 increased nuclear YAP and its downstream effectors transglutaminase-2 (TGM2) and connective tissue growth factor ($p<0.001$). This was found to be dependent on cytoskeletal integrity; Y27632 or Lat B co-treatment potently interrupted aberrant YAP signaling. VP treatment fully blocked TGFβ2-driven YAP activation in HSC cells ($p<0.0001$) and largely restored FN, TGM2, F-actin, α-smooth muscle actin, and phospho-myosin light chain levels ($p<0.001$) – all implicated in POAG pathogenesis. Importantly, 6/10 mouse eyes displayed ~15-80% increased outflow facility with VP perfusion.

## DISCUSSION

The mechanosensitive transcriptional coactivator YAP plays important roles in mechanotransduction, a process through which cells translate external biophysical cues into internal biochemical signals. YAP modulates target gene expression profiles across many cell and tissue types [8,9]. Through this mechanism, YAP signaling regulates critical cellular functions and normal tissue homeostasis; imbalance or failure of this process is at the core of various diseases [13]. A recent genome-wide meta-analysis identified *YAP1* among 44 previously unknown POAG risk loci [11]; this observation provides strong new evidence that YAP may play a prominent role in glaucoma pathogenesis. However, the detailed mechanisms underlying YAP modulation in HSC cells under glaucomatous conditions (i.e., elevated ECM stiffness/composition and increased growth factors in AH) remain to be elucidated. To model this, we used ECM-alginate hydrogels with tunable stiffness to study the roles of YAP in HSC cells in response to stiffened matrix, FN deposition and TGFβ2. As summarized in **Fig. 2**, our data support that YAP is a critical regulator of HSC cellular responses to ECM stiffening/composition and elevated TGFβ2 seen in POAG; we propose that increased YAP activity may drive further HSC cell contractility and actin/ECM remodeling to exacerbate disease pathology conditions. This conclusion is supported by the findings that (i) ECM stiffening elevates YAP activity and F-actin, which is completely reversed by matrix softening; (ii) TGFβ2 induces YAP transcriptional activity; F-actin relaxation/depolymerization abolishes TGFβ2-induced aberrant YAP signaling. (iii) YAP inhibition with verteporfin increases actin cytoskeletal/ECM remodeling and cell contractile properties; and (iv) ocular perfusion of verteporfin increases outflow facility.

Our data suggest that YAP modulates HSC cell dysfunction in response to known glaucomatous stressors, and that pharmacologic YAP inhibition has promising potential to improve outflow tissue dysfunction.

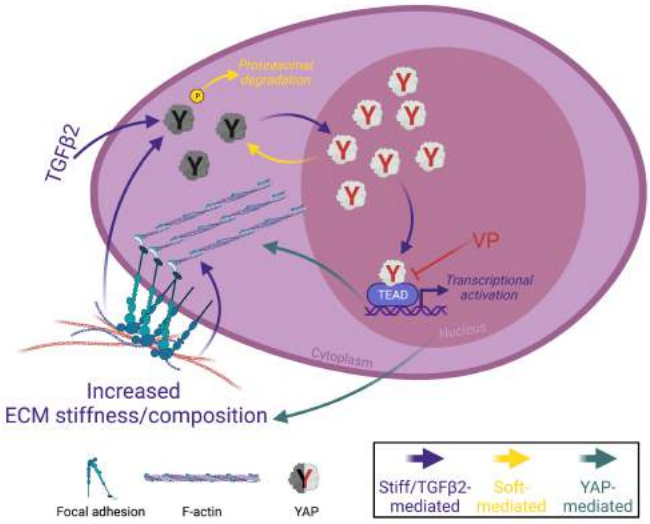

**Fig. 2. Schematic illustration of the effects elicited by ECM stiffness/composition and TGFβ2 that modulate YAP activity in HSC cells.** Stiffened matrix elevates YAP activity (purple arrows = stiff/TGFβ2-mediated), which can be reversed by matrix softening (yellow arrows = soft-mediated). TGFβ2 increases nuclear YAP contingent on cytoskeletal integrity; actin cytoskeleton relaxation/depolymerization decrease nuclear YAP. YAP activation induces HSC cell contractility and actin/ECM remodeling (green arrows = YAP-mediated), which together may induce ocular hypertension in POAG. Created with BioRender.com.

# A CONTINUUM MODEL FOR TRANSITION BETWEEN CELL-DENSE AND CELL-SPARSE TISSUES: APPLICATION TO CEREBRAL ANEURYSMS

**Elizabeth D. Shih (1), Ryan M. Mahutga (1), Victor H. Barocas (1), Patrick W. Alford (1)**

## INTRODUCTION

During initial cerebral aneurysm (CA) formation, the tissue is cell dense, but as the CA progresses, vascular smooth muscle cells (VSMCs) undergo apoptosis and the tissue becomes cell sparse (1) (**Fig. 1A**). VSMCs are primarily responsible for maintaining tissue integrity through cellular contraction and structural regulation of its surrounding extracellular matrix. Understanding the role of VSMCs in aneurysms is integral to examining CA mechanics during growth and remodeling (G&R) to determine rupture risk. In our models of G&R, we assume G&R to be a function of VSMC stress (3). The most common continuum method for modeling G&R is using the constrained mixture (CM) theory, which assumes that all constituents strain equally (4) (**Fig. 1B**). There have been other models that consider cell-sparse tissues, in which the cell does not strain equally with its matrix, but these models assume an infinite matrix volume (5). We hypothesize that in intermediate cell density conditions, neither of these models accurately represents the stress state of the cells in the tissue. Here, we study tissue models with intermediate cell density and determine how much error is introduced by the existing models and what characteristics introduce the most error (**Fig. 1C-D**). Based on these studies, we propose a new modified strain factor model for intermediate-cell-density tissues and evaluate its efficacy against our simulated data.

## METHODS

**Finite Element Model (FEM).** A cube was created in FEBio with a cell modeled in the center of a box, representative of matrix (6) (**Fig. 1C**). Different cell volume fractions ($\phi_{cell}$), morphologies, material properties, and matrix material properties were assigned to the model. Cauchy stresses of the system ($\boldsymbol{\sigma_{tot}}$), cell ($\boldsymbol{\sigma_{cell}}$), and matrix ($\boldsymbol{\sigma_{mat}}$) were calculated at each time step during an unconstrained uniaxial stretch in the 1-direction. A total of 160 simulations were examined.

**Constrained Mixture (CM) Analysis.** CM models assume that all constituents comprising a tissue strain equally, and that the stresses of the constituents can be weighted against their respective volume fractions and summed together to determine the total stress of the tissue (**Fig. 1D**). In our analysis, we simplify the tissue into two components: the cell and the matrix.

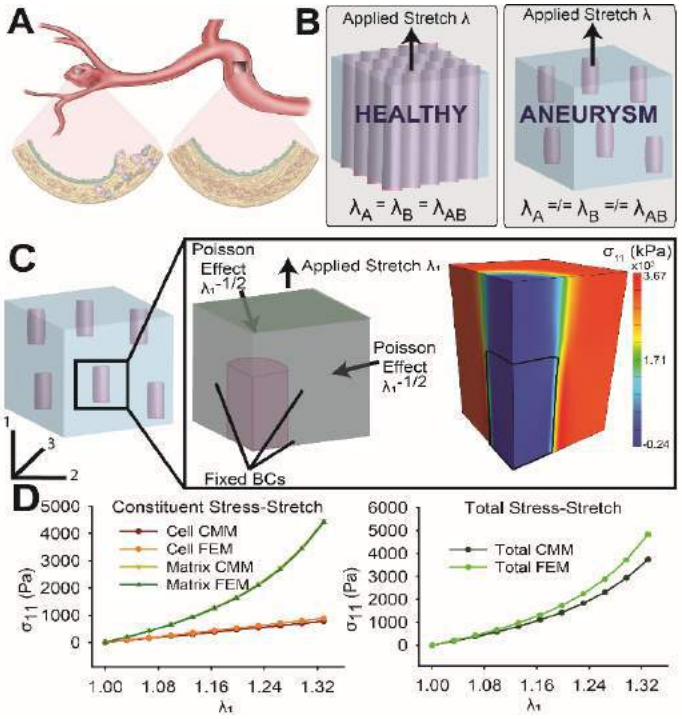

**Figure 1. A. Illustration of CA versus healthy arterial structure (2). B. Deformations of VSMCs in healthy arteries and CAs. C. Schematic of FEM, with example simulated. D. Example FEM and CM stress-stretch curves.**

$$\boldsymbol{\sigma_{tot}} = \phi_{cell}\boldsymbol{\sigma_{cell}} + [1 - \phi_{cell}]\boldsymbol{\sigma_{mat}} \quad (1)$$

where $\boldsymbol{\sigma_{cell}}$ and $\boldsymbol{\sigma_{mat}}$ are both functions of the applied strain ($\boldsymbol{\varepsilon_{app}}$). We derived stresses for the components and the total mixture for comparison against the FEM results.

**Marquez Strain Factor (SF) Analysis.** Marquez *et. al*. evaluated the relationship between cell and matrix strain and derived a strain factor (SF) from Eshelby's theory, which solves for a strain field of an inclusion of some geometry in an infinite matrix (5, 7)

$$\boldsymbol{A^{Marquez}} = [\boldsymbol{I} + \boldsymbol{E}(\boldsymbol{C^m})^{-1}(\boldsymbol{C^c} - \boldsymbol{C^m})]^{-1} \quad (2)$$

where $\boldsymbol{I}$ is the identity tensor, $\boldsymbol{E}$ is the Eshelby tensor, which describes the geometry of the inclusion, and $\boldsymbol{C^c}$ and $\boldsymbol{C^m}$ are the stiffness tensors of the cell and the matrix, respectively. Under uniaxial strain, $\boldsymbol{A^{Marquez}}$ is simplified into a scalar term $SF^{Marquez}$, which acts as a coefficient to the applied strain $\varepsilon_{app}$ to solve for the cell strain $\varepsilon_{cell}$

$$\varepsilon_{cell} = SF^{Marquez}\varepsilon_{app} \quad (3)$$

For each of our simulations, we calculated $\boldsymbol{E}$ given the cell geometry, derived the $SF^{Marquez}$, and found the subsequent $\varepsilon_{cell}$. We re-calculated the Cauchy stress of the cell in Eq. 1 using $\varepsilon_{cell}$ and compared the values against the simulated results. Additionally, we fit a 'true' SF to each simulation to evaluate the Marquez value against a true value.

**Modified SF Model.** $SF^{Marquez}$ incorporates the effects of cell geometry ($\boldsymbol{E}$) and cell ($\boldsymbol{C^m}$) and matrix ($\boldsymbol{C^{im}}$) stiffnesses but not the effects of cell volume fraction ($\phi_{cell}$). We fixed the listed variables to evaluate how $\phi_{cell}$ influences $\varepsilon_{cell}$. As $\phi_{cell}$ increases, the true SF approaches 1, reflective of a dense system where a SF is unnecessary. To account for this, we incorporated a weighting term on the SF that is nonlinearly dependent on $\phi_{cell}$:

$$SF^{modified} = \left(e^{-a\phi_{cell}}\right)SF^{Marquez} + (1 - e^{-a\phi_{cell}}) \quad (4)$$

where $a$ was fit to a value of 5.38. The weighting term pulls the SF towards 1 as density increases, where SF=1 indicates equal strain between constituents. Like the above analyses, we compared our new model against FEM data.

## RESULTS

**Sparsity influences cell stress.** Cell stresses predicted by the FEM and the CM model were compared for varying cell geometries (**Fig. 2Ai**) and cell/matrix stiffnesses (**Fig. 2Aii**) at different $\phi_{cell}$'s. The error between CM and our FEM data is minimized as the aspect ratio approaches 1, where the cell percolates through the matrix, deforming similarly with the matrix. As stiffness ratios deviate from 1, where both constituents have the same material properties, errors are observed to increase. Notably, errors consistently increase as $\phi_{cell}$ decreases, indicative of decreasing cell density. This supports our hypothesis that sparse systems require a modified CM law.

**Sparse-cell models do not replicate cell stresses at intermediate cell density.** We applied Marquez's SF to the total strain to find the cell strain, and the resulting stress was compared against FEM data (**Fig. 2Bi-ii**). Contrary to the CM model, the Marquez model showed high accuracy at low volume fractions but was less accurate as cell density increased. These data show that the Marquez SF does not fully capture the effects of semi-sparse tissues. An $R^2$ of 0.79 was obtained from linear regression of the true SFs against the Marquez SFs (**Fig. 2Dii**).

**Modified SF improves stress calculations.** We modified the SF to adjust for the nonlinear effects of $\phi_{cell}$ and compared the results against our FEM data. A substantial decrease in error was observed across the board for all simulations (**Fig. 2Ci-ii**), and an $R^2$ of 0.92 demonstrated the improved goodness of fit (**Fig. 2Diii**).

## DISCUSSION

Here, we demonstrate that neither the CM model nor the Marquez SF application capture cell stress at intermediate cell densities. We modify the SF to account for these conditions and find that the model is substantially improved when compared to simulated data.

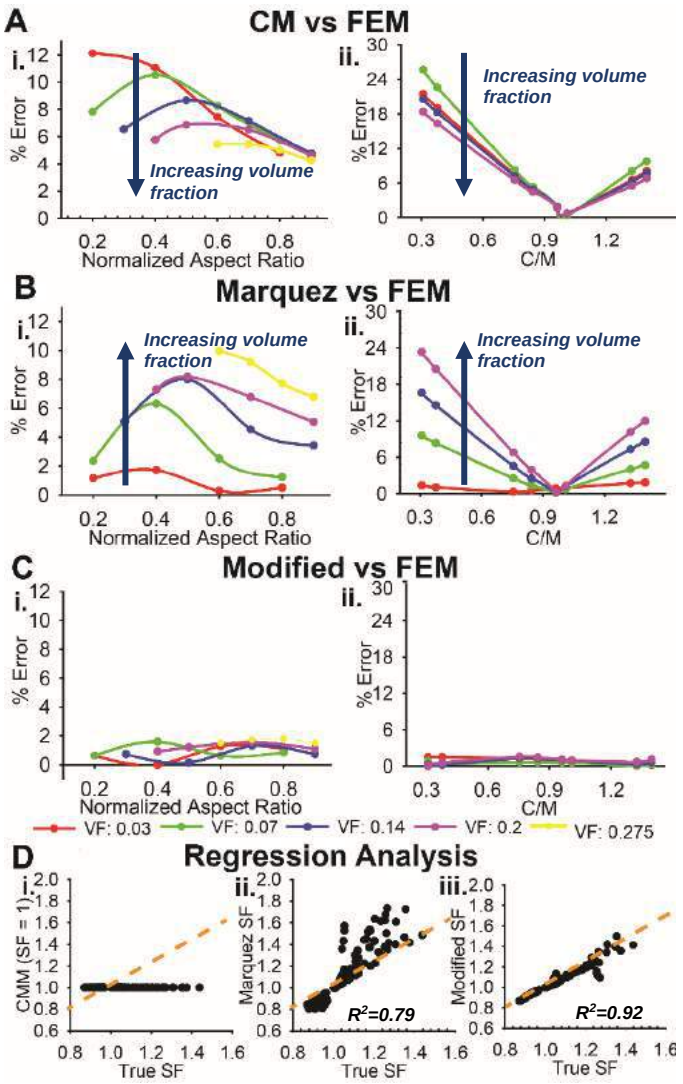

**Figure 2. A: Error plots of CM model against FEM results when (i) C/M is fixed at 0.75 and when (ii) CH is fixed at 0.6. Bi-ii.: Corresponding plots with Marquez SF. Ci-ii.: Corresponding plots with modified SF. D. Regression analyses for each model.**

This modification has significant implications to the determination of cell stress we believe to drive G&R (3). This is particularly relevant for CAs which have a lower cell density than that of healthy arteries (1-2). We will continue to investigate how our model for intermediate cell density systems describe how mechanical stimuli drive VSMC mechanoadaptation of its surrounding matrix, and how that influences stress at the tissue-scale. This will help us elucidate how heterogeneous and multiscale mechanics in diseased arteries evolve aneurysm stability under load.

# SIMPLE ANALYTIC MODEL FOR PERISTALTIC FLOW AND MIXING

**R. Ibanez (1), M. Shokrian (1), J.-H. Nam (1), D. H. Kelley (1),**

(1) Mechanical Engineering, University of Rochester, Rochester, New York, USA

## INTRODUCTION

Peristaltic flows occur when a fluid channel is subjected to periodic, traveling deformations at its boundaries. This type of flow is found in numerous biological systems [1-3]. One area of particular interest is the inner ear, where the fluid homeostasis plays an important role for healthy hearing [1].

We present an analytic approach to modeling peristaltic flow and mixing properties, with particular interest toward biophysical peristalsis. We show that experimental and computational results validate our analytic approach. We demonstrate that the assumptions we made are valid for the parameter regime of the inner ear, and that peristalsis should play a role in enhancing the rate of chemical diffusion in the inner ear.

## METHODS

To analytically model the problem, we consider a simplified two-dimensional system seen in figure 1. The simplified domain is an infinite two-dimensional channel of mean width $L$. It is periodic in the x-direction, with a spatial period $\lambda$. Fluid flows because one boundary is deformed in a periodic shape $\eta(x,t)$ moving with constant speed c in the x-direction and characteristic amplitude $A$. The viscosity of the fluid is given by $\nu$.

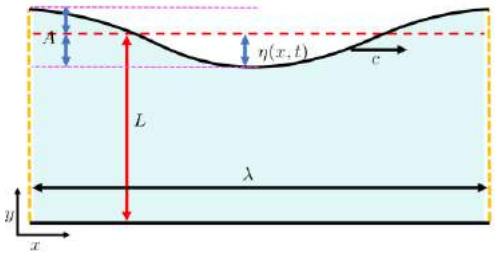

**Figure 1: Sketch of the analytic model's domain.**

We find an analytic solution to the problem for high Reynolds flows (where $Re = cL^2/\nu\lambda \gg 1$), amplitude is small $\epsilon = A/Li \approx 0$ and the wavelength is long $\lambda/Li \gg 0$.Then we apply a viscous correction.

The inviscid approach consists of defining a stream function $\psi$ where the x velocity is $\partial\psi/i\partial x = -u$ and y velocity is $\partial\psi/i\partial x = v$. Then, solving equation (1) using separation of variables and applying the boundary conditions of the problem.

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} = 0 \qquad (1)$$

The viscous correction is implemented by solving Stokes' second problem. Where we solve equation (2) near $y = 0$ and $y = \mathrm{L}$ using the boundary conditions derived from the inviscid solution.

$$\frac{\partial \mathrm{u}}{\partial \mathrm{t}} = \nu \frac{\partial^2 \mathrm{u}}{\partial y^2} \qquad (2)$$

A solution is obtained that can be used to determine a generalized Lagrangian mean flow, which describes the material transport properties of the flow. This is useful for determining the mixing properties of peristalsis.

For validation we use numerical simulations using a finite element method in the COMSOL Multiphysics software. We also use experimental measurements to validate the analytic model. The experiment consists of a transparent long square channel (2.54cm x 2.54cm x 91.4 cm), where one of the walls is flexible. The flexible wall is actuated using an array of stepper motors. Figure 2 shows a diagram of the experimental setup. To measure the induced flow, we use particle imaging velocimetry (PIV) processed via PIVlab [4] and particle tracking velocimetry via a MATLAB based predictive tracking algorithm [5]. PIV is used to obtain velocity fields and Eulerian data form the flow. PTV is used to obtain Lagrangian measurements of the flow to determine mass transport properties of the flow.

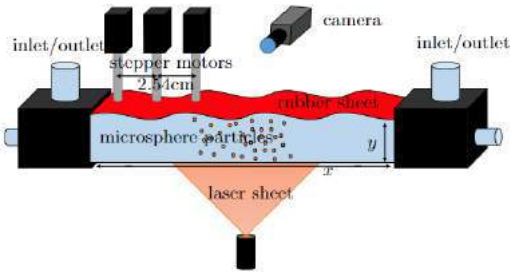

**Figure 2: Sketch of the experimental apparatus. Flow is driven via the actuation of the stepper motors, which deform the rubber sheet to produce a shape that closely approximates a periodic wave traveling with constant speed in the x-direction.**

Finally, we compare the analytic model and numerical results when applied to microfluidics in the context of the inner ear. We show using a combination of our analytic results and numerical diffusion simulations that peristalsis enhances mixing in a channel.

## RESULTS

We show validation results in figures 3 and 4. Figure 3 compares the root mean squared velocity for different parameters between different methods, results agree between methods suggesting our analytic model is accurate. Figure 4 compares Lagrangian drift velocities, the agreement suggests that the analytic model accurately captures the Lagrangian properties of the flow. Having validated the analytic model, we show using the Lagrangian measurements and modeling that peristalsis can enhance mixing. Figure 5 demonstrates the effects on chemical concentration during peristalsis in the parameter range of the inner ear. Our validated model suggests that the effects of peristalsis enhance the rate of mixing significantly due to the Lagrangian properties of the flow when compared to pure diffusion.

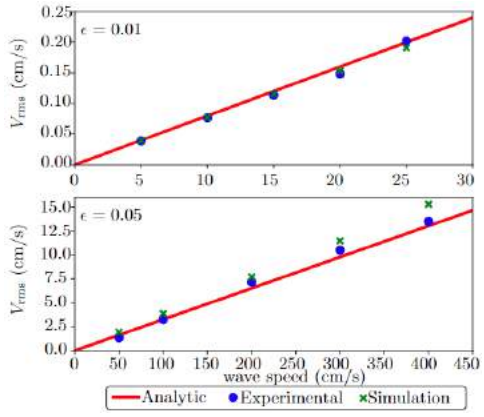

**Figure 3: Comparison of the root-mean-square velocity in the bulk flow region in experiments, modeling, and simulations. The wavelength was held constant at λ = 30 cm.**

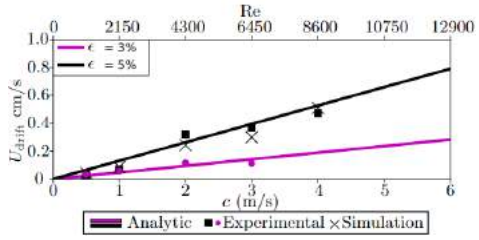

**Figure 4: Variation of the mean drift velocity $U_{drift}$. The wavelength was held constant at λ = 30 cm.**

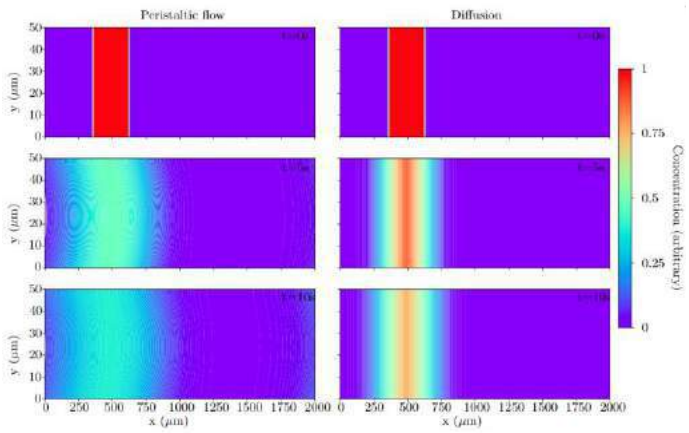

**Figure 5: Change of the concentration of a passive scalar subjected to both diffusion and the modeled Lagrangian mean flow, or subjected to diffusion alone.**

## DISCUSSION

The simplicity of our analytic model and range of parameters makes it a useful tool to be employed in a diverse set of biophysical problems. The simplicity of the analytic model makes it a useful tool for understanding the role of peristalsis in biophysical flows, particularly where mixing effects are of interest.

# CORTICAL THICKNESS CORRELATES WITH CORTICAL MORPHOLOGY AMONG HUMAN AND NON-HUMAN PRIMATE BRAINS

**Nagehan Demirci (1,2), Maria A. Holland (1,2)**

## INTRODUCTION

The typical human brain has a highly folded superficial layer, i.e. the cerebral cortex, with gyral ridges and sulcal valleys. Although each brain is unique, one morphological feature of the cortex is common for each individual; gyri are universally thicker than sulci [1]. This characteristic thickness distribution has been partially explained by biological and mechanical factors. Cellular processes and mechanical forces generated during growth have been shown to lead to these consistent variations in cortical thickness between gyri and sulci [2]. In our recent study, we found a strong correlation between cortical thickness and shape by analyzing 501 typical human brains [3]. We showed that cortical thickness varies in a gyral-sulcal spectrum, with the cortex consistently thickest for convex shapes, thinnest for concave shapes and in the middle for saddle shapes. In this study, we investigate this pattern of the cortex among non-human primate brains with varying shapes and sizes and compare with the human data. We hypothesize that the mechanical forces that emerge during the development of the brain might lead to this systematic morphological trait of the cortex, therefore, we expect to observe a similar outcome. We used our open-source computational pipeline [4] to investigate cortical thickness variations both globally and locally among 12 different primate species ranging from the Senegal Galago to humans. The pipeline takes in cortical surface meshes as an input and outputs many quantitative measures including curvature (mean curvature, Gaussian curvature, and shape index), thickness, depth, and area at each vertex.

## METHODS

We used publicly available neuroimaging resources in this study (Table 1).

Many automated pipelines that perform tissue classification (gray and white matter) and surface reconstruction (pial and white surfaces) are optimized for humans, and struggle to process non-human brains due to their varying shapes and sizes. Therefore, we have used a variety of different tools to find an optimal solution for segmentation and surface reconstruction for each species (Table 1).

**Table 1: Primate species used in this study along with their total number of subjects, sources, and processing tools.**

| Species | Subject # | Source | Processing Tool(s) |
|---|---|---|---|
| Human | 501 | ABIDE [5, 6] | Freesurfer [7] |
| Chimpanzee | 54 | NCBR [8] | CAT12 in SPM12 with Juna-Chimp Template [9] |
| Rhesus Macaque | 26 | INDI-PRIME [10] | AFNI and ANTs with NMT Template [11] |
| Bonobo | 1 | NCBR [8] | BrainVisa Morphologist [12] |
| Gorilla | 1 | NCBR [8] | BrainVisa Morphologist [12] |
| Others | 1 per species | [13] | Freesurfer [7] |

Then, by using our open-source computational pipeline [4], we analyzed the pattern of cortical thickness variations in each species with respect to local topology (concave, saddle, and convex shaped local points). Additionally, we developed an open-source pipeline to reduce manual interventions on reconstructed surfaces after tissue segmentation, automate topology corrections, and smoothen the initial surface generated. This pipeline will be shared in the near future for use by other researchers.

SB³C2022-052

## RESULTS

We present the cortical thickness variations throughout the cortex as a Gaussian kernel density distribution. To determine the shape at each point of the surface mesh we used a non-dimensional surface measure, i.e. shape index [14], which has a value between -1 and 1 that corresponds to a perfect cup and a perfect cap respectively. We found a strong correlation between cortical thickness and cortical topology not only for humans but also for non-human primate species, which might be suggesting a universal physical law (Fig. 1).

Additionally, we calculated the total area of the pial surface for each species. We plotted mean cortical thickness in the order of increasing surface area (Fig. 2). We observe that there is a significant correlation between surface area and cortical thickness. The most noticeable outcomes are: 1) general increase of cortical thickness with surface area, in line with previous findings; 2) excellent correlation of cortical thickness with local shape; 3) relatively larger cortical thickness of the Rhesus Macaque compared to its neighbors; and 4) increased difference of average cortical thickness between convex, concave, and saddle shape with increases in surface area.

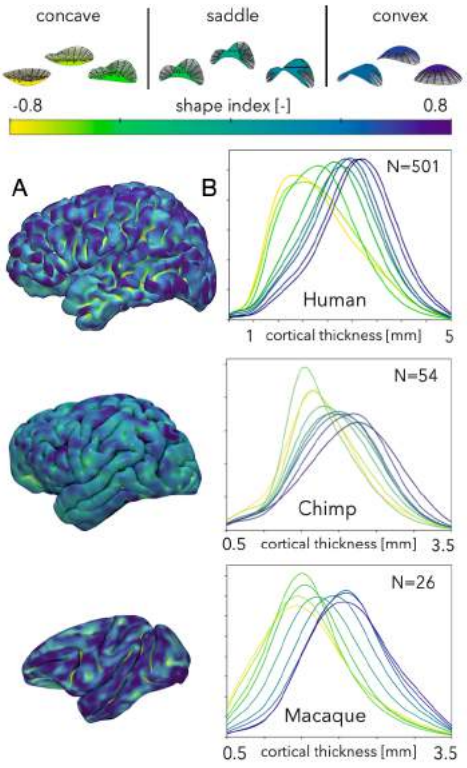

**Fig. 1: Correlation of cortical thickness with cortical topology. (a) Shape index overlaid on pial surface (b) Cortical thickness kernel density distribution profile with respect to local shape.**

## DISCUSSION

In this study we comprehensively investigated the correlation between cortical thickness and cortical morphology among human and non-human primate brains with varying shapes and sizes. The main conclusion of this study is the well-organized variation of cortical thickness in a gyral-sulcal spectrum for all species; convex shape is thickest, concave shape is thinnest, and saddle shape is in the middle consistently. This result might be suggesting a universal physical law of cortical folding. The physical forces generated during growth and development of the cortex might strongly be affecting the final cortical morphology and its relationship with cortical thickness. As a secondary note, cortical thickness noticeably correlates with the size of the cortex, increasing with surface area. Interestingly, we found a relatively thicker cortex on a global scale for Rhesus Macaque compared to other species with comparable sizes, which requires further consideration.

As part of our future work, we will thoroughly compare our results with the data in the literature and expand our dataset by including more species. Next, we will explore the correlations of cortical thickness with sulcal depth and folding index, as these quantitative measures might also vary significantly among different species. Finally, considering the current challenges of analyzing non-human primate MRI datasets, we will enhance our computational pipeline and develop algorithms to effectively process multiple brains with varying shapes and sizes.

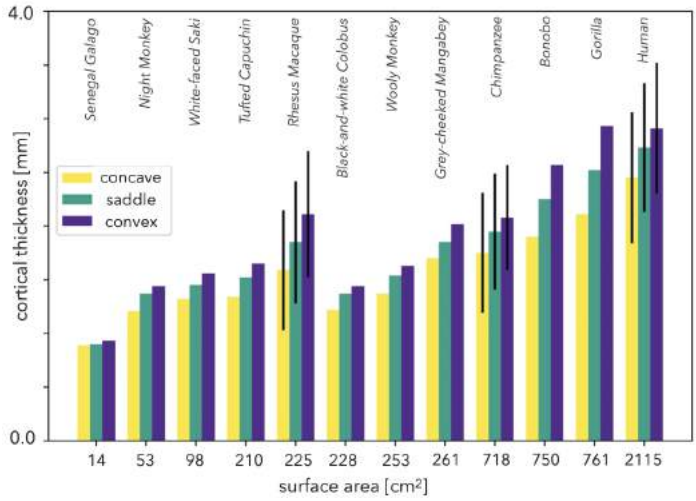

**Fig. 2: Mean cortical thickness of all concave, saddle, and convex shaped points with respect to total pial surface area. Note that, subject size is greater than one for rhesus macaque (N=24), chimpanzee (N=56), and human (N=501) species.**

## INTRODUCTION

Photopolymerization has emerged as a key fabrication technique in biomedical engineering, with applications ranging from drug delivery, tissue engineering, bioprinting, microfluidics, and more. Many of these applications leverage photopolymerization's precise spatial and temporal control to construct highly detailed and consistent polymer structures. However, recent studies have demonstrated that commonly used, synthetic photoinitiators, coupled with UV light exposure, may have toxic effects on cells and can disrupt cell signaling. [1-3] Bio-sourced photoinitiators may be more biocompatible, nontoxic, and biodegradable than their synthetic counterparts. [4-6] In this work, we determined the effectiveness of several bio-sourced initiator systems using light-based photo-rheology. Our results help to advance the use of bio-sourced initiators for biomedical applications and establish a procedure for using rheology to determine photoinitiator effectiveness.

## METHODS

*Prepolymer Formulations*

Bio-sourced initiators (curcumin, Curc; riboflavin, Ribo; and β-carotene, Bcar) were added to poly(ethylene) glycol dimethacrylate 750 (PEGDMA) at a final concentration of 0.2 wt%. Groups containing potential amine synergists (histidine, Hist; adenosine, Adeno; or 2-(diethylamino)ethyl methacrylate, DEA) were added at 0.2 wt%. The synthetic photoinitiator I369 was included as a positive control; I369 was dissolved in acetone at 100 mg/mL and used at a final concentration of 0.1 wt%.

*Photo-rheology*

Photo-rheology was performed using a Kinexus Ultra+ (Netzsch, Selb, Germany) coupled with a violet ($\lambda$ = 410 nm) LED light source (3-Watt High Intensity LED Spotlight, Oznium). This wavelength was chosen as it is close to the wavelength used in many bioprinters. For all solutions, a single-frequency strain controlled oscillatory sequence was performed using an 8 mm upper geometry, a gap height of 0.05 mm, a frequency of 1 Hz, and a strain rate of 1%. Data points were collected every 5 seconds over a 30-minute run.

For each sample, shear storage modulus data were collected over time to evaluate the polymerization kinetics and properties. This approach leverages the dependence of modulus on extent of reaction (crosslinking). Two primary metrics were extracted from storage modulus profiles: 1) rise time, defined as the time at which the modulus increased from baseline, and 2) final modulus, calculated as the average storage modulus at the end of the light exposure window (29 min).

## RESULTS AND DISCUSSION

To determine bio-sourced initiator systems with the greatest photopolymerization potential, we used a model polymer (PEGDMA) and real-time photo-rheology. As the samples polymerized under violet light, rheological behavior was recorded, and the extent of the reaction was observed via the evolution of the storage modulus (**Fig. 1A-B**). In these experiments, the photoinitiation efficiency of four groups (control – no initiator, curcumin, riboflavin, and β-carotene) with four additional additives (Hist, Adeno, DEA, and I369) were evaluated. Of the three initiator candidates, curcumin had the shortest rise time as well as a comparable final modulus to the positive control (**Table 1**). The modulus profiles of the riboflavin formulation do not appear to be substantially different than the negative control, in which some spontaneous crosslinking occurs. Meanwhile, B-carotene seems to hinder PEGDMA crosslinking by violet light. These results indicate that curcumin may be an appropriate photoinitiator for crosslinking using the violet range, while riboflavin and B-carotene are not efficient photoinitiators on their own in this system.

SB³C2022-053

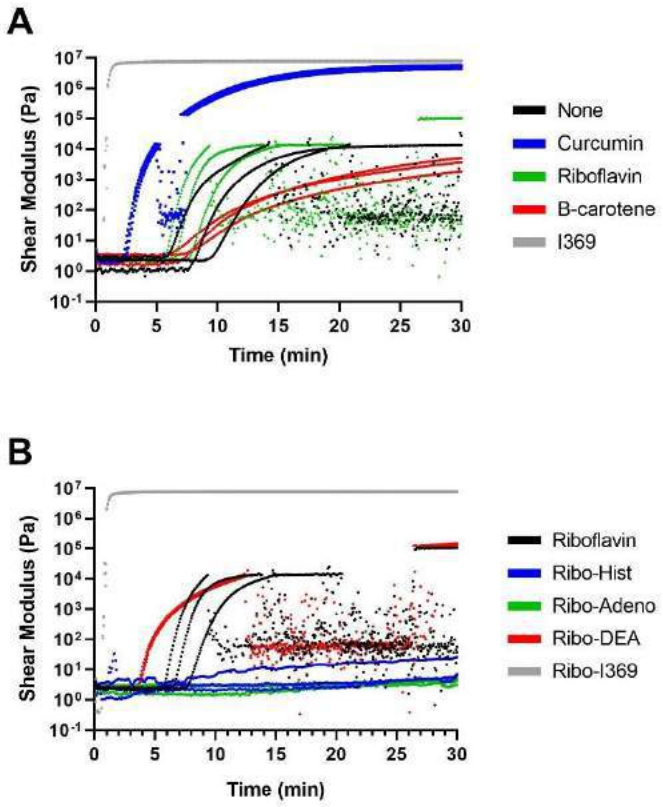

**Figure 1.** Graphs of the shear modulus evolution upon violet light exposure for the bio-sourced initiator systems. A) Comparison of the bio-sourced initiator samples with positive (I369) and negative (no initiator) controls. B) Riboflavin initiator group with potential synergist additives, similar trends were observed across all initiator groups. In all runs, the violet light was on for 29 minutes, with a thirty second delay at the start of the run. N=3 for all samples.

**Table 1.** Rise times of the various bio-sourced initiators and controls as well as the rise times of the potential synergists added to the riboflavin group. Note: DNR stands for 'Did Not Rise', and a rise time of 0 seconds indicates the sample's modulus increased within 5 seconds of the light being turned on. Data is shown as mean ± standard deviation.

| | None | Curc | Ribo | Bcar | I369 |
|---|---|---|---|---|---|
| Rise Time (s) | 520 ± 130 | 130 ± 10 | 400 ± 70 | 810 ± 150 | 0 ± 0 |
| | | | | | |
| | Ribo | Ribo - Hist | Ribo-Adeno | Ribo-DEA | Ribo-I369 |
| Rise Time (s) | 400 ± 70 | DNR | DNR | 220 ± 5 | 0 ± 0 |

When comparing the polymerization effectiveness of the bio-sourced initiators with potential amine synergists, the addition of the synergists actually decreased the extent of reaction in most cases (**Fig 1B**). Like the initiators, the synergists in this experiment were chosen as an evaluation of potential bio-sourced synergists. Here, histidine is an amino acid and adenosine in a sugar-attached nucleic acid, both with tertiary amines groups (most synthetic synergists are molecules with tertiary amines). The synthetic synergist (DEA) included in the groups proved the exception; the addition of DEA seemed to slightly improve the polymerization reaction across the samples. We hypothesize that the bio-sourced synergists are instead acting as inhibitors to the reaction, possibly through less defined side-reactions which use up many of the free-radicals generated upon light exposure and decrease the overall extent of crosslinking. Moving forward, we plan to evaluate other possible bio-sourced synergists to potentially improve the polymerization effectiveness of the bio-sourced initiators.

In most samples throughout this study, we observed a region during the reaction where the storage modulus profile exhibited a sudden and drastic inconsistency: storage modulus appeared to drop, and the signal became noisy before returning to an expected profile. This phenomenon seems to have occurred in approximately the same range of modulus values (while not necessarily the same timepoint in the run) for different samples. The phenomenon is also correlated with extremely high harmonic distortions (data not shown), which could indicate the data are not an accurate representation of the sample's modulus. While sample slipping is a possible explanation, consistent resumption of the modulus profile would be unlikely in this case. As an alternative explanation, we hypothesize that the sample is undergoes a structural phase separation event as pockets of crosslinked material grow and become immiscible in the unpolymerized phase. [7] Our future work will focus on testing this hypothesis using atomic force microscopy and dynamic scanning calorimetry.

Overall, the results presented here describe the use of photo-rheology to evaluate the polymerization effectiveness of bio-sourced initiator systems. Our findings indicate that curcumin alone is the most promising bio-sourced initiator under violet light, based on both rise time and final polymerized storage modulus. Current work is now moving forward to use curcumin-initiated systems in 3D bioprinting applications. Namely, while curcumin was the most effective bio-sourced initiator, photopolymerization parameters such as exposure time and light intensity must still be tuned for structural design fidelity to be achieved, and curcumin's cytocompatibility in this context needs rigorous evaluation. However, the use of photo-rheology as a method to first test the effectiveness of initiator systems provides a more precise starting point for selecting printing parameters. In the long run we anticipate that our findings will be translatable to many biomedical applications that leverage light-based 3D printing to fabricate cellular, tissue, and medical devices and products.

## INTRODUCTION

Neonatal brachial plexus palsy (NBPP) occurs during the birthing process in approximately 1.5/1,000 total births[1]. When the injury persists past 12 months of age, continuing outcomes may include joint subluxation, muscle weakness, and sensory dysfunction[2]. Until the early 1990's, it was thought that NBPP solely occurred due to trauma induced by lateral neck traction caused by the birthing attendant (exogenous force). Since then, clinical evidence has demonstrated that NBPP may occur due to other mechanisms of injury. Factors affecting the mechanism of injury may include bending of the neck, fetal malpositioning, labor induction, labor abnormalities, operative vaginal delivery, and shoulder dystocia[1].

NBPP injuries are difficult to research clinically due to ethical issues that surround the venerable subject group - infants. Finite element models (FEM) present an opportunity to investigate different aspects of NBPP. Currently, there is no FEM model in the literature of a neonatal brachial plexus and spinal cord. The objective of this study was to create a two-dimensional model of the neonatal brachial plexus that could be used to investigate how the stress and strain develop in the various roots of the brachial plexus when loads and displacements are applied. This first phase of the project focuses on development and validation of the model.

## METHODS

ABAQUS software was used to design, mesh, and analyze the brachial plexus and spinal cord model of a neonate. The brachial plexus is divided into five sections – roots, trunks, divisions, cords, and terminal nerves. Our 2D model was constructed solely of the roots and trunks due to the 3D anatomical complexity that occurs within the division section.

The model was based on dimensions measured during primary reconstructive surgery. These dimensions are provided in Table 1 and include the length of the sections as well as both the transverse and cranial-caudal dimensions of each nerve root. The cranial caudal dimensions were used to depict the thickness of the nerves in this 2D model, as that dimension falls within the plane of analysis.

**Table 1: Average Dimensions (mm) for Infant Brachial Plexus**

| Dimensions | C5 | C6 | C7 | C8 | T1 |
|---|---|---|---|---|---|
| **Cranial Caudal** | 3 | 3.1 | 3.8 | 2.7 | 2.5 |
| **Transverse** | 1.1 | 1.3 | 1.6 | 1.4 | 1.4 |
| **Spinal root to dorsal root ganglion** | 7.5 | 7.5 | 7.5 | 7.5 | 7.5 |
| **Dorsal root ganglion to end of bony foramen** | 9 | 8 | 7 | 5.5 | - |
| **Foramen to formation of trunk** | 14 | 15.5 | 19 | 7 | 6 |

Two cases were developed to analyze the difference between quasistatic stretch (0.01 mm/second) and dynamic stretch (10 mm/second) of the nerves, as seen in Table 2. Within ABAQUS software boundary conditions and loads were established. The boundary conditions were the same for both cases, including an encastré condition to the midline of the spinal cord and XYSMM condition to the superior and inferior portions of the five nerves. The encastré boundary condition constrains all active structural degrees of freedom within the edge selected and the XYSMM boundary condition allows the nerve to stretch in the plane of the model when loads were applied.

To date, there has been no assessment of the mechanical properties of neonatal brachial plexus. The Young's modulus and Poisson's ratio were taken from neonatal piglets, as seen in Table 2[3,4]. Due to lack of clinical research on neonatal spinal cord and brachial plexus mechanical properties, in our 2D model, the same Young's modulus was used for both the brachial plexus and spinal cord.

Two different loading conditions were examined with the model, as summarized in Table 2. Both simulated a pulling force applied to the

nerves at the distal end of the trunk, as would occur with the depression of the shoulder while the head and neck remained aligned with the axis of the spine. Two different loading rates were used, to match experimentally available data for validation – and these affected both the Young's modulus and the maximum load applied, which increase at higher loading rates due to the viscoelastic nature of nerves.

Loading was modeled as an applied stress at the distal end of each nerve trunk – at the junction with the division. The tensile stress was calculated based on the maximum load (Table 2) normalized by the estimated cross-sectional area of the nerve root. This cross-sectional area was calculated based on an ellipse with the major and minor axes equal to the cranial-caudal and transverse dimensions (Table 1). The force used to calculate the applied stress to the C5/C6 and C8/T1 trunks was twice as high as that applied to C7, due to the fact that the latter structure includes the axons of only the single nerve root.

**Table 2: Mechanical Properties of the Neonatal Brachial Plexus and Spinal Cord – Measured in Piglets at Two Loading Rates[3,4]**

| Case | Loading Rate (mm/second) | Maximum Load (N) | Young's Modulus (MPa) | Poisson's Ratio |
|---|---|---|---|---|
| 1 | 0.01 | 1.08 | 1.48 | 0.4 |
| 2 | 10 | 2.12 | 2.02 | 0.4 |

## RESULTS

Tables 3 and 4 provide the values of each type of stress and displacement predicted by the model for both loading cases, with all measurements taken at the proximal end of the nerve root, where it intersects with the spinal cord.

Our model was validated through comparison with the results of Dr. Anita Singh[3]. Dr. Singh calculated a stress in the piglet brachial plexus corresponding to the failure load. For Case 1, the maximum stress found experimentally was 0.20 MPa, and for Case 2 it was 0.45 MPa. In our model, the maximum Von Mises stress for Case 1 was 0.255 MPa, and for Case 2 it was 0.444 MPa.

**Table 3: Results of Case 1 Model (Low Loading Rate Properties)**

| | Von Mises Stress (MPa) | Max Principal Stress (MPa) | Tresca Stress (MPa) | Displacement Magnitude at end of trunk (mm) |
|---|---|---|---|---|
| **C5** | 0.173 | 0.174 | 0.177 | 8.764 |
| **C6** | 0.255 | 0.254 | 0.225 | |
| **C7** | 0.077 | 0.086 | 0.110 | 4.382 |
| **C8** | 0.157 | 0.151 | 0.157 | 8.764 |
| **T1** | 0.155 | 0.159 | 0.169 | |

**Table 4: Results of Case 2 Model (High Loading Rate Properties)**

| | Von Mises Stress (MPa) | Max Principal Stress (MPa) | Tresca Stress (MPa) | Displacement Magnitude at end of trunk (mm) |
|---|---|---|---|---|
| **C5** | 0.329 | 0.324 | 0.350 | 5.609 |
| **C6** | 0.444 | 0.442 | 0.461 | |
| **C7** | 0.199 | 0.161 | 0.161 | 3.569 |
| **C8** | 0.277 | 0.295 | 0.295 | 5.609 |
| **T1** | 0.315 | 0.310 | 0.310 | |

The results are presented visually for Case 2 in Figure 1. The pattern of stresses was the same for Case 1 and Case 2, as the nerve roots were modeled as homogeneous, linear elastic materials.

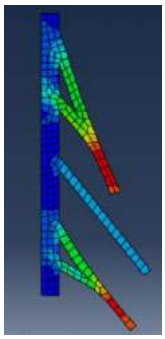

**Figure 1: Case 1 results for Von Mises stresses**

## DISCUSSION

Clinical patterns of injury and some experimental work demonstrates that C5 and C6 experience higher stress under initial loading of the brachial plexus than do the lower roots[5]. Our study also demonstrates that pattern of injury, as seen in Table 3 and 4. Our goal of this study was to validate the model against previous literature and replicate the findings and similar stress values.

When it comes to any finite element analysis, limitations exist and must inform the application of the results. In our model, the first limitation stems from the fact there are no neonatal mechanical property values of the human infant brachial plexus and spinal cord, thus the needed use of neonatal piglets. The second limitation is the inability to model the complete brachial plexus in two dimensions. The need to stop at the division level limits our ability to study the entirety of the brachial plexus model.

While this model is not a complete model of the brachial plexus, it does provide opportunity to investigate how normal variations in nerve anatomy (e.g., root diameter and angle) affect the stress developed at the nerve roots. This 2D model is the first step towards developing a complete 3D model of the neonatal brachial plexus. This will provide the opportunity to more accurately assess the effect of the birth process and biological variation's structure and properties on the risk of NBPP.

## ACKNOWLEDGEMENTS

We thank our colleagues from Lynda Yang's neurosurgery team at the University of Michigan, who provided insight and expertise that assisted the research – including the infant nerve dimensions. This project was supported through NSF Award CBET 2028474.

# COMPUTATIONAL MODELING OF CRYOBALLOON ABLATION FOR PULMONARY VEIN ISOLATION

## INTRODUCTION

Cryoballoon Ablation (CBA) is a promising treatment for atrial fibrillation (AF). Since the release of CB2 (second-generation Arctic Front Advance Pro cryoballoon) by Medtronic [1] in 2020, the efficiency of CBA surgery has increased drastically. During CBA, a cryoballoon (CB) is first positioned at the pulmonary vein (PV) ostium that connects the left atrium (LA). Liquid nitrous oxide is then injected into the CB, and a phase change gradually absorbs heat and freezes the targeted region in the LA. When the temperature in the targeted region falls below $-20^0$C, lesion formation is initiated at the balloon-tissue contact region. Isolation is confirmed by the loss of PV potentials, and the time taken to achieve this isolation is called time to isolation (TTI). After TTI the CB is held in place as per recommended dosing protocols for about 2 to 4 minutes per freeze.

The effectiveness and safety of CBA, however, depend on multiple factors, such as the cooling rate, leakages, minimal temperature, and the isotherm distribution. Some of the underlying issues with CBA include the possibility of phrenic nerve injury as well as determining the optimal CB position and dosing time to get a contiguous lesion. In addition, the presence of leakage also reduces the efficacy of CBA, which necessitate further lowering of the CB temperatures and increase hold times.

Given these issues, there is a need to investigate factors affecting the temperature (and flow) field in the area surrounding the PV ostium to help optimize the treatment. On the other hand, only a few highly idealized numerical models [1,2] have been developed to simulate CBA. As such, the goal here is to develop a patient-specific computational modeling framework to investigate blood flow and temperature field during CBA surgery in a realistic LA geometry. Specifically, we seek to investigate how the presence of a CB affects hemodynamics in the LA, and how the presence of leakage affects temperature distribution at the PV ostium, which directly affects the lesion formation.

## METHODS

Hemodynamics and heat transfer in the LA are described by solving the continuity, incompressible Navier-Stokes and energy conservation equations. Non-dimensional numbers governing the physics are the Reynolds number $Re = \frac{V_{sc} L_{sc}}{\upsilon}$ and Prandtl number $Pr = \frac{\upsilon}{\alpha}$, where $\upsilon$ is the kinematic viscosity and $\alpha$ is the thermal diffusivity of blood. Laminar flow is assumed here and the complete non-dimensional boundary value problem in the LA fluid domain, is given as follows:

$$\frac{\partial \boldsymbol{u}}{\partial \tau} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} - \nabla \cdot \boldsymbol{\sigma} - \boldsymbol{f} = \boldsymbol{0}, \tag{1}$$

$$\nabla \cdot \boldsymbol{u} = \boldsymbol{0}, \tag{2}$$

$$\frac{\partial \mathrm{T}}{\partial \tau} + \boldsymbol{u} \cdot \nabla \mathrm{T} - \frac{\nabla^2 \mathrm{T}}{Pe} - Q = 0. \tag{3}$$

In the above equations, $\boldsymbol{u}, p, \mathrm{T}$ are the velocity, pressure, and temperature fields, respectively, whereas $\boldsymbol{\sigma}(\boldsymbol{u}, p) = -p\boldsymbol{I} + \frac{1}{Re}(\nabla \boldsymbol{u} + (\nabla \boldsymbol{u})^T)$ is the stress tensor for a Newtonian fluid and $Pe = Re \cdot Pr$ is the Peclet number.

The finite element (FE) method is used for spatial discretization of Eqs. (1) – (3). A closer look at the physical properties of blood and the velocity at the PV ostium reveals that the flow is advection dominated. Numerical stability to capture sharp spatial gradients is achieved by applying Streamline-Upwinding (SUPG) and crosswind stabilization[3] schemes to the weak form. To further increase stability and accuracy, we include two additional stabilization terms, namely a Least-Squares on Incompressibility Constraint (LSIC) and a penalty-based backflow stabilization term[4]. The latter confines the flow to be in the normal direction and helps to avoid numerical

instabilities arising from flow reversal at the mitral valve (MV). Lastly, we also employ the Pressure-Stabilizing Petrov Galerkin (PSPG) stabilization to suppress the node-to-node pressure oscillations.

The standard first order forward Euler scheme is used for time-discretization of the inertia term in Eq. (1) and (3) along with the unconditionally stable crank Nicolson scheme for the advection, temperature diffusion and viscous terms. We employ the Taylor-Hood elements for velocity/pressure and quadratic elements for temperature. The Incremental Pressure Correction Scheme is used to decouple the equations and the resultant time-discretized weak form of the governing equations (with $\boldsymbol{v}$ , $q$, $w$ as test functions) is given below:

$$\left\langle \frac{\boldsymbol{u}^{*}-\boldsymbol{u}^{\theta}}{\Delta\tau}, \boldsymbol{v} \right\rangle + \left\langle \boldsymbol{u}^{\theta}\cdot\boldsymbol{\nabla}\boldsymbol{u}_{\boldsymbol{ck}}^{*}, \boldsymbol{v} \right\rangle + \left\langle \boldsymbol{\sigma}\left(\boldsymbol{u}_{\boldsymbol{ck}}^{*}, p^{\theta}\right), \boldsymbol{\nabla}\boldsymbol{v} \right\rangle - \left\langle \boldsymbol{\sigma}\left(\boldsymbol{u}_{\boldsymbol{ck}}^{*}, p^{\theta}\right)\cdot \boldsymbol{n}, \boldsymbol{v} \right\rangle_{\partial\boldsymbol{\Omega}} - \langle \boldsymbol{f}, \boldsymbol{v} \rangle + \int_{\Omega} \gamma_{SUPG}\left(\boldsymbol{u}^{\theta}\right) i P\left(\boldsymbol{u}^{\theta}, \boldsymbol{v}\right)\cdot\left(\frac{\boldsymbol{u}^{*}-\boldsymbol{u}^{\theta}}{\Delta\tau} + \boldsymbol{u}^{\theta}\cdot\boldsymbol{\nabla}\boldsymbol{u}_{\boldsymbol{ck}}^{*} - i\overline{\boldsymbol{\nabla}}\cdot\boldsymbol{\sigma}\left(\boldsymbol{u}_{\boldsymbol{ck}}^{*}, p^{\theta}\right) - \boldsymbol{f}\right) dx + \int_{\Omega} \left(\gamma_{CW}\left(\boldsymbol{u}^{\theta}\right) i\Lambda\left(\boldsymbol{u}^{\theta}, \boldsymbol{u}^{*}\right)\right) : \boldsymbol{\nabla}\boldsymbol{v}\, dx + \int_{\Omega} \gamma_{LSIC}\, i(\boldsymbol{\nabla}\cdot\boldsymbol{u}^{*}) i(\boldsymbol{\nabla}\cdot\boldsymbol{v})\, dx + \langle 10^{4} i(\boldsymbol{I}-\boldsymbol{n}\otimes\boldsymbol{n}) i\boldsymbol{u}^{*}, \boldsymbol{v} \rangle_{\partial\Omega_{D}^{p}} = \boldsymbol{0} \quad (4)$$

$$\left\langle \nabla\left(p^{\theta+1}-p^{\theta}\right), \nabla q \right\rangle + \frac{1}{\Delta\tau}\langle \boldsymbol{\nabla}\cdot\boldsymbol{u}^{*}, q \rangle + \int_{\Omega} \gamma_{PSPG}(\boldsymbol{u}^{*}) i\overline{\nabla} q \cdot \left(\frac{\boldsymbol{u}^{\theta}-\boldsymbol{u}^{\theta-1}}{\Delta\tau} + \boldsymbol{u}^{\theta}\cdot\boldsymbol{\nabla}\boldsymbol{u}_{\boldsymbol{ck}}^{\theta} - \boldsymbol{\nabla}\cdot\boldsymbol{\sigma}\left(\boldsymbol{u}_{\boldsymbol{ck}}^{\theta}, p^{\theta}\right) - \boldsymbol{f}\right) dx = 0 \quad (5)$$

$$\left\langle \frac{\boldsymbol{u}^{\boldsymbol{\theta+1}}-\boldsymbol{u}^{*}}{\Delta\tau}, \boldsymbol{v} \right\rangle + \left\langle \nabla\left(p^{\theta+1}-p^{\theta}\right), \boldsymbol{v} i \right\rangle = 0 \quad (6)$$

$$\left\langle \frac{\mathrm{T}^{\theta+1}-\mathrm{T}^{\theta}}{\Delta\tau}, w \right\rangle + \left\langle \boldsymbol{u}^{\boldsymbol{\theta+1}}\cdot\nabla \mathrm{T}_{ck}, w \right\rangle + \frac{1}{Pe}\left[\langle \nabla \mathrm{T}_{ck}, \nabla w \rangle - \langle \overline{\mathrm{T}}_{\omega} i, w \rangle_{\partial\Omega_{N}^{\mathrm{T}}}\right] - \langle Q, w \rangle + \int_{\Omega} \gamma_{SUPG}\left(\boldsymbol{u}^{\boldsymbol{\theta+1}}\right) i P\left(\boldsymbol{u}^{\boldsymbol{\theta+1}}, w\right)\cdot\left(\frac{\partial \mathrm{T}^{\theta+1}}{\partial\tau} + \boldsymbol{u}^{\boldsymbol{\theta+1}}\cdot\nabla \mathrm{T}_{ck} - \frac{\nabla^{2}\mathrm{T}_{ck}}{Pe} - Q\right) dx + \int_{\Omega} \left(\gamma_{CW}\left(\mathrm{T}^{\theta}\right) i\Lambda\left(\boldsymbol{u}^{\boldsymbol{\theta+1}}, \mathrm{T}^{\theta+1}\right)\right) : \nabla w\, dx = 0 \quad (7)$$

In the above, $P(\boldsymbol{u}, \boldsymbol{m}) = \boldsymbol{u}\cdot\boldsymbol{\nabla}\boldsymbol{m}$ and $i\Lambda(\boldsymbol{u}, \boldsymbol{\phi}) = \boldsymbol{\Gamma}(\boldsymbol{u})\cdot\boldsymbol{\nabla}\boldsymbol{\phi}$ are the SUPG and crosswind operators and $\gamma$ is the stabilization constant.

We use the open-source FE library FEniCS [5] to solve the weak forms in Eqs. (4) – (7). Simulations are performed on a patient specific LA geometry with an oblate CB with a major diameter of 23 mm that occludes the right-inferior PV (RIPV) inlet (**Fig. 1**). Model dimensions [6] are listed in Table 1. PV isolation is simulated by applying a temperature of -70ºC on the CB. Patient specific PV flow rate measurements[7] and blood perfusion rate in the LA wall are imposed as boundary conditions in the model. At the LA wall, Eq. (3) reduces to the Pennes Heat conduction equation. Initial blood temperature is set as 37ºC and the problem is solved for 40 heart cycles on a FE mesh consisting of a total of 1.86 mi DOF's with a Courant number < 0.25.

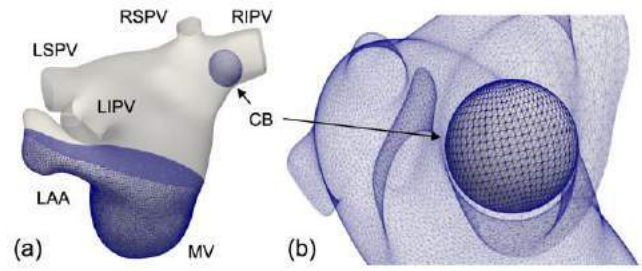

**Figure 1: (a) A schematic of patient specific LA with an oblate CB at the RIPV (b) Fine uniform mesh at CB.**

**Table 1: Areas and diameters of PV's extracted from MRI data**

| | LSPV | LIPV | RSPV | RIPV |
|---|---|---|---|---|
| Area ($mm^{2)}$ | 322.5 | 209.9 | 188.35 | 437.6 |
| Av. Dia. (mm) | 20.26 | 16.34 | 15.48 | 23.6 |

## RESULTS

**Fig. 2a** shows the temperature distribution at the RIPV ostium after a periodic steady state is reached. This occurs in less than 30 seconds. Once, the lesion thickness remains unchanged with time, we stop the simulation. **Fig. 2b** shows the region at the RIPV ostium where the temperature is less than $-20^{0}$C (i.e., threshold at which the lesion is formed). The maximum lesion thickness at the PV ostium is found out to be 6.8 mm. The heat transfer rate across the CB also flattens out once a steady state is reached, and the average value is about -2150W. **Fig. 2c** shows the gap measured at various points between the CB to the RIPV ostium and the corresponding temperature at the RIPV ostium. Next, we simulate different positions of the CB. We observe that no lesion is formed if there is considerable leakage around the gap (defined by a threshold value of 2mm), which causes advection of the cold energy from the CB downstream. Hence, a contiguous balloon-tissue contact area with minimum leakage throughout is highly important for optimum lesion formation.

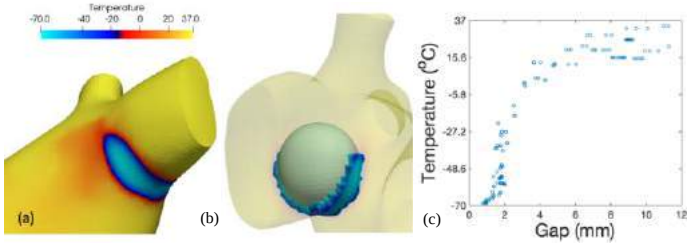

**Figure 2: (a) Periodic steady state temperature at the RIPV ostium. (b) Mesh cells at the lesion where temperature is $< -20^{0}$C (c) Temperature vs gap (between the CB and RIPV ostium).**

## DISCUSSION

Here, we have developed a novel computational framework to simulate CBA. Our model is used to predict lesion formation at the PV ostium. For CBA, we show that the LA wall temperature (and effectiveness of PV isolation) is sensitive to the leakage at the PV ostium. We also found that a minimum gap of 2mm is necessary for lesion to form on the LA wall. The developed computer framework will be applied in future studies for understanding and patient-specific optimization of the CBA. The framework will be used also to determine the conditions (e.g., at different PV velocities) at which lesions will form. At present, there are some limitations associated with this study. First, motion of the LA wall is not considered here. Second, we do not account for a closed MV. In future, we intend to improve on our framework by incorporating a fluid-structure interaction model.

## INTRODUCTION

Respiratory diseases, known to be one of the leading causes of death worldwide, are primarily characterized by compromised lung constituents. Specifically, the connective tissues of elastin and collagen are responsible for the recoil and structural integrity of the lung [1,2]. Studies have shown that the cause for chronic obstructive pulmonary disease (COPD) is attributable to the damage of elastin fibers [3,4]; moreover, excessive collagen deposition leads to tissue stiffening diseases, such as cystic fibrosis and asthma [5]. Investigations characterizing the imbalance of these constituents have previously been done on guinea pig and dog lung [6,7] but are limited to parenchymal strips, not isolating pulmonary airways, which are a major site of lung function compromise and occlusion in disease.

Here we introduce the first biaxial tensile tests on lung airways to compare the degenerative effects of collagen and elastin. This study directly compares the mechanics of treated and untreated specimens, examining these effects through the lens of tissue anisotropy by analyzing both circumferential and axial material properties, and additionally assessing heterogeneity by comparing proximal to distal airways via the comparative material behaviors of the trachea, large bronchi, and small bronchi. This experiment provides airway tissue mechanical insights in diseased states and furthers our understanding of the role of these structural constituents.

## METHODS

Airway tissue samples from four pigs obtained from an abattoir and cut into squares with an effective testing size of 5.1 +/-0.2mm. Since the cartilage layer is significantly stiffer than the soft tissue, it was removed to assess solely the behavior of the connective tissue, similar to methods described in past studies [8]. The dissected samples were comprised of three regions based on their extra- or intra-parenchymal location and inner diameter [9]: the trachea (>16mm), the large bronchi (>7mm), and the small bronchi (>3mm). A mark made on the corner of the tissue designated the circumferential orientation. Samples were placed in a 1X phosphate-buffered saline (PBS) bath and refrigerated until the day of testing.

Elastase and collagenase (Worthington Biochemical Corp.) solutions were prepared: the elastase solution consisted of 0.001mg/ml Trypsin inhibitor and deionized water to obtain a concentration of 0.1units/ml, while the collagenase solution had a concentration of 96units/ml [10]. Both solutions were mixed using a thermal shaker at 100RPM. Each untreated sample was placed in PBS at ambient room temperature for 30min [11], then tested and subsequently treated for direct comparison with either a 1ml bath of elastase for 1 hour or collagenase for 30 min [12]. Biaxial tensile testing was conducted using 1.5N load cells, cycling each specimen to 60% strain in both loading directions at a rate of 1%/s. The protocol consisted of five preconditioning cycles and a final test cycle which was analyzed.

The engineering stress-strain loading curve for each bronchial region, treated and untreated, was analyzed. Due to the curve's bilinear transition between small and large strains, the slopes were calculated based on the initial modulus ($E_I$) and ultimate modulus ($E_U$) as in prior studies using a linear fit with $R^2 > 0.90$ [13]. From four pigs, 36 untreated specimens (12 per trachea, large bronchi, and small bronchi regions) were tested; of those, half of each region's samples were subsequently collagenase or elastase treated groups, designating six samples per region per un/treated categories for equal group statistical comparisons. A two-way ANOVA with post-hoc Bonferroni was used to compare the effects of tissue treatment with a defined significance of $p<0.05$, where *$p<0.05$, **$p<0.01$, ***$p<0.001$, and ****$p<0.0001$.

## RESULTS

The circumferential and axial stress-strain loading curves (average +/- standard deviation) of the untreated and treated regions of the lung are shown in Figure 1. Overall, the untreated small and large bronchi regions were most similar to each other: the untreated trachea response

was statistically disparate, stiffer than other regions both axially and circumferentially. Once treated, the small and large bronchi regions continued to exhibit comparable behaviors to one other. The trachea samples became most similar to its bronchial counterparts after collagenase treatment in the circumferential direction only, but remained distinct otherwise.

For all three airway regions, collagenase and elastase tissue treatment resulted in lower stresses for the same induced strains compared to untreated counterparts. This degenerated response was noted to be statistically significant for collagenase treatments in all regions. In fact, collagenase treated samples experienced a 64-89% reduction of maximum stress from its pre-treated state, whereas elastase treated samples experienced a 44-63% stress reduction compared its untreated state.

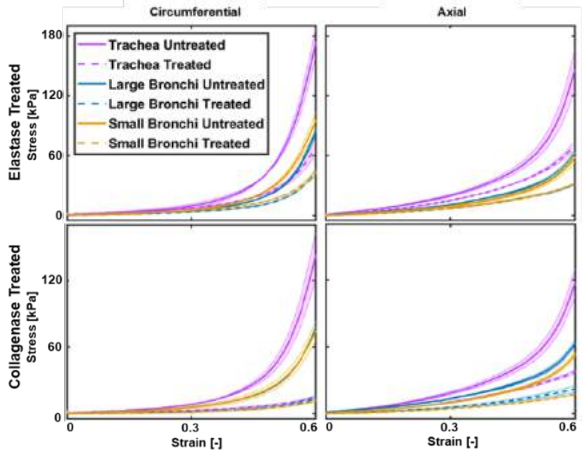

**Figure 1: Average +/- standard deviation of the stress-strain loading profiles of untreated versus elastase and collagenase treated lung regions in the circumferential and axial directions.**

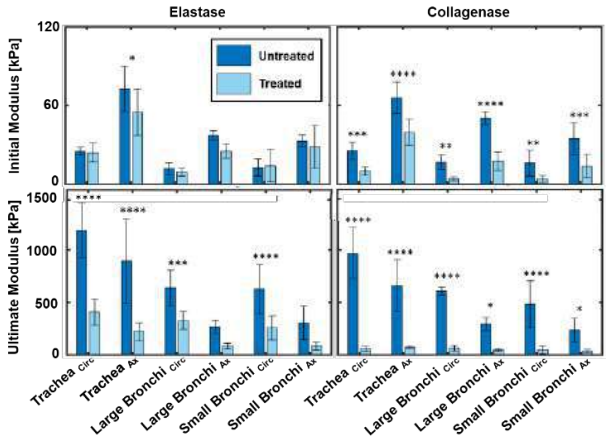

**Figure 2: Average +/- standard deviations of the initial ($E_I$) and ultimate ($E_U$) moduli of each airway region, and circumferential or axial orientation.**

Airway tissue stiffness, observed via the initial and ultimate moduli values displayed in Figure 2, decreased significantly over all regions and directions of the collagenase treated samples compared to the untreated states. The elastase treated samples collected from the trachea demonstrated a significant decrease in the axial direction for both moduli, but other regions did not exhibit this significant axial degeneration; however, the circumferential response of all regions did significantly decrease with elastase treatment for the ultimate modulus. Tissue compliance tended to increase in most treated samples, however the change due to elastase was not as substantial as the collagenase treated tissues: the initial modulus of the collagenase treated tissues experienced a 40-76% decrease, whereas the elastase treated samples exhibited only a 4-33% reduction. The elastase treatment also had less effect on the ultimate modulus as well compared to the collagenase treatment, with a 49-74% reduction compared to an 84-94% decrease respectively.

## DISCUSSION

Our findings observe an overall increase in tissue compliance after the degeneration of airway constitutive collagen and elastin fibers. Albeit the degree of induced damage remains to be quantified via planned upcoming histological assessments, this study provides the first mechanical characterization of degenerated airways as observed in pulmonary disease. When elastin and collagen are damaged in COPD [14], lung tissue softens and exhibits reduced recoil, aligning with our findings. The converse, where increased collagen deposition in the airways as a result of disease causes tissue stiffening [5,15], also supports our findings.

An interesting outcome within the collagenase treated samples in the circumferential direction is how bronchial regions nearly converged to the same stress-strain curve. This could possibly be due to the structure of the lung constituents, where the weave of the trachea's axially aligned fibers differ from that of the large and small bronchi [16], and thus, upon degeneration, the underlying matrix in the circumferential direction behaves similarly across all regions.

Higher instances of degeneration in the collagenase treated group compared to the elastase group may be attributable to our utilization of a 1000-fold greater treatment concentration in order to be able to measurably degrade collagen, since collagen fibers have a greater elastic modulus than elastin and are present in greater abundance in the airway network [16,17]. Our preliminary studies found that if elastase treatment activation levels used for the aorta [10] or parenchyma [18] were employed, the resulting elastase treated stress-strain curve would be completely flat and insensitive to loading between the physiological 0-60% strain regime, whereas the collagenase treated specimens were responsive. Future work will utilize confocal imaging to measure the damage imposed upon the elastin and collagen network to yield insights regarding the comparative pulmonary mechanical role for each constituent.

## INTRODUCTION

Chronic liver conditions resulting from prolonged hepatic inflammation and fibrosis have been indicted as the cause of 2 million deaths each year [1]. Liver fibrosis is a dynamic process characterized by the scarring and accumulation of extracellular matrix (ECM) components resulting from chronic liver injury, including choleostatic and metabolic diseases. Activation of hepatic stellate cells (HSCs) has been shown to be the primary driver of hepatic fibrosis in both experimental and clinical models of liver injury, and therefore a key target for anti-fibrotic therapy. Extracellular signals from the ECM (e.g., stiffness) and adjacent hepatic cells including hepatocytes and liver sinusoidal endothelial cells (LSECs) and have been sown to modulate HSC activation and play a role in the progression of hepatic fibrosis. The increasingly stiff ECM and upregulation of integrins increases the formation of focal adhesions, triggering intracellular signaling that further sustain the fibrotic state, such as p21-activated kinases (PAK), focal adhesion kinase (FAK), and yes-associated protein (YAP) - mediated upregulation of genes associated with ECM deposition and inflammation.

It is well known that the dietary intake of omega-3 (n-3) polyunsaturated fatty acids (PUFAs) exerts strong anti-inflammatory and anti-oxidative stress effects and has been beneficial within the context of cardiac, kidney and pulmonary fibrosis and non-alcoholic hepatic steatosis. Less is known if n-3 PUFAs could be used to treat non-lipid associated hepatic fibrosis. Studies by Zhang et al. suggest that n-3 PUFAs can reduce HSC proliferation and activation by upregulating YAP/TAZ degradation [2]. As YAP/TAZ nucleation has been linked to cell-ECM signaling, we aim to harness a 3D tissue engineered hepatic model to evaluate the influence of both ECM and PUFAs on FAK activation and ultimately its effect on modulating HSC activation. We hypothesize that hepatic constructs formed in hydrogels functionalized with RGD peptides will exhibit improved viability, function and phenotype compared to malHA only, due to increased FAK activation. Furthermore, feeding of dietary PUFAs will attenuate HSC activation and we aim to show that this is at least partially dependent upon the degree of FAK activation.

## METHODS

Hepatic constructs were formed by suspending a 3:1 ratio of HepG2s (hepatocyte-like cell line) (ATCC) to LX-2s (hepatic stellate cell-like cell line) (ATCC), in un-crosslinked maleimide-modified hyaluronic acid (malHA) hydrogel, as previously reported [3-4]. The addition of 5 kDa dithiol PEG crosslinked the gels around the cells, resulting in 25 µL constructs that were prepared in a 48-well plate. All hepatic constructs were maintained for 14 days and supplemented with Dulbecco's Modified Eagle Medium. All assays were performed in triplicate.

Viability was assessed using ATP quantification (Promega CellTiter Glo 3D). Cell viability and organization was visualized using calcein-ethidium homodimer staining and imaging on a macro-confocal microscope. RNA was isolated using TRIzol reagent and utilized in qPCR to quantify the expression of CYP1A1, FAK, YAP, TAZ, and connective tissue growth factor (CTGF). Immunofluorescence (IF) was used to visualize hepatocyte polarization, by staining for zonula occludin-1 (ZO-1), a tight junction protein, and multidrug resistance protein 2 (MRP2), which is expressed on the apical domain of hepatocytes.

The capacity of the constructs to generate lipids de novo was quantified through feeding of [$C^{14}$]-acetate at 1 µCi/mL, extracting the total lipids with hexane:isopropanol, sorting them into classes through thin-layer chromatography, and quantifying the amount of [$C^{14}$] in each class using a scintillation counter. Results were normalized to total DNA. The PUFA-processing capacity was demonstrated by feeding the constructs with the essential dietary n-6 PUFA linoleic acid (LA), extracting lipids from the constructs out to 8 hours post-feed, and

SB³C2022-057

quantifying the production of long-chain PUFAs through the formation of fatty acid methyl esters and gas chromatography.

To test the effect of PUFAs on HSC activation and the FAK pathway, hepatic constructs were stimulated with 10 ng/mL TGF-β, and then supplemented with n-6 PUFA (GLA) or n-3 PUFA (EPA) in the media with and without the presence of a FAK inhibitor (25 uM, FAK inhibitor 14, Fisher Scientific) was applied to the hepatic constructs in conjugation with media changes. The activation state of the LX-2s were quantified through staining of α-smooth muscle actin and qPCR quantification of *Col1A1* expression. Statistical analysis was performed using 2-way ANOVA with post-hoc Tukey tests in GraphPad.

## RESULTS

Inclusion of RGD peptides in the malHA hydrogel increased cell viability, while the inhibition of FAK resulted in significantly reduced viability as quantified through the production of ATP ($p = 0.0082$) (Fig1). Cellular aggregates were shown to develop within the constructs containing RGD as the culture time progressed (constructs were imaged out to 14 days) (Fig1). This effect was lessened in constructs formed without RGD peptides or treated with the FAK inhibitor.

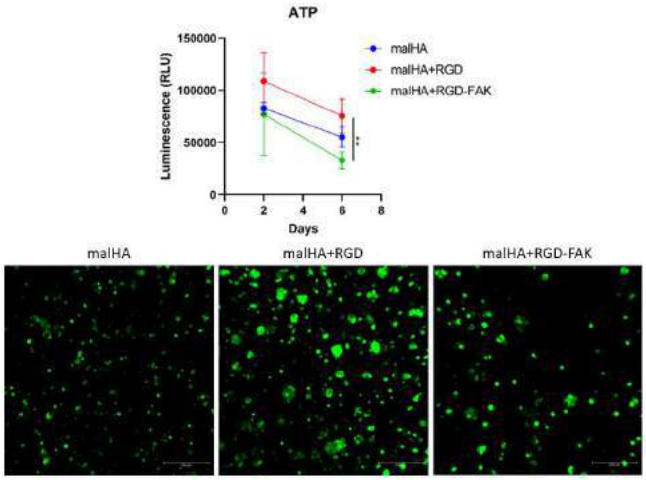

**Figure 1. Construct viability as demonstrated by ATP output through 6 days and live-dead imaging after 14 days of culture.**

CYP1A1 expression levels were also impacted by the inhibition of FAK. Expression levels increased between days 2 and 6 regardless of the presence of RGD peptides, though in a non-significant manner. The inhibition of FAK resulted in a trend toward decreased CYP1A1 expression. The production of albumin was increased significantly on day 6 of culture when RGD peptides were present in the scaffolds compared to no RGD present ($p=0.014$).

Successful conversion of [$C^{14}$]-acetate into the complex lipid species phospholipids, free cholesterol, triglycerides, and cholesterol esters indicate that the constructs could perform *de novo* lipogenesis (**Fig. 2A**). We also successfully demonstrated that upon feeding of LA, the constructs not only contained increased levels of LA (**Fig. 2B**) compared to those fed with only the human serum albumin vehicle control, but also increased levels of the product long-chain PUFAs dihomo-gamma linolenic acid (DGLA) (**Fig. 2C**) and arachidonic acid (ARA) (**Fig. 2D**). In our preliminary assays (n=3/group), we observe an increasing trend that requires further study. ($p=0.162$, $p=0.134$, and $p=0.1137$ for the diet effects of LA, DGLA, and ARA respectively). This is consistent with the dietary effects we demonstrated in a similar model of monocultured primary human hepatocytes [5].

When hepatic constructs were stimulated with TGF-β, we observed decreased viability and function (albumin and urea) compared to those that were not stimulated [4]. We further anticipate increased expression of *Col1A1* and α-SMA. We expect that in constructs exposed, then treated with the n-3 PUFA EPA, there will be a decrease in this inflamed phenotype. Additional experiments are needed.

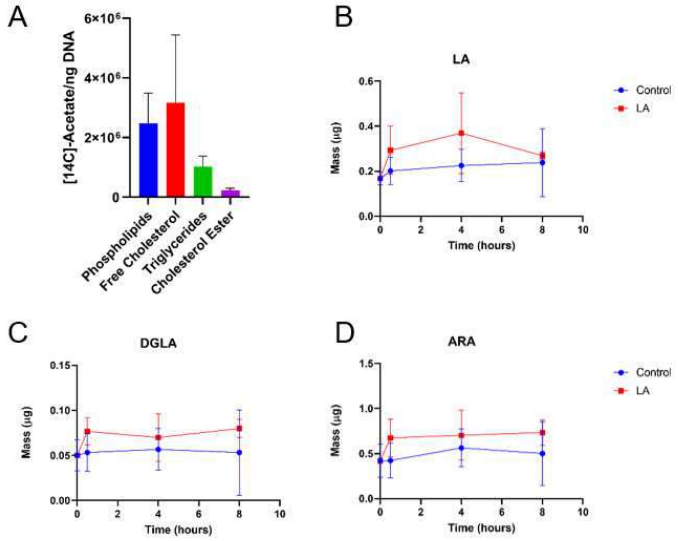

**Figure 2. De novo lipogenic and PUFA processing capacity of the hepatic constructs as demonstrated through feeding experiments.**

## DISCUSSION

Preliminary findings confirm our hypothesis that viability and hepatic functional markers were enhanced in the presence of RGD peptides, and that this effect was negated when FAK phosphorylation was inhibited. Furthermore, we successfully demonstrated that 3D hepatic models were capable of processing acetate into complex lipid species, as is done in the liver during states of energy excess. Upon supplementation with the n-6 PUFA LA under normal conditions, n-6 PUFAs DGLA and ARA increased, as expected. This is an indication that LA was successfully metabolized into the long chain PUFAs. When hepatic constructs were stimulated with TGF-β we observed activation of LX-2s and this was exacerbated in the presence of n-6 PUFAs. This study reveals some interesting insights about how dietary PUFAs can affect early HSC activation and fibrotic pathways. Further studies are needed with primary cells (rather than cell lines). We anticipate that this tissue engineered platform will enable exploration into more mechanistic effects of PUFA and lipid diets on HSC activation and involvement in hepatic fibrosis progression.

## ACKNOWLEDGEMENTS

Funding for this study was provided by Dr. Rahbar's laboratory start-up funds, NIH K25 HL133611 and HL13361-04S1 and NSF REU Award #1950281. We would like to acknowledge the assistance of Dr. Susan Sergeant and Matt Davis with the fatty acid methyl extraction. HepG2 and LX-2 cell lines were provided by Dr. Shay Soker.

## INTRODUCTION

Atrial fibrillation (AF) is the most common arrythmia affecting 3-6 million individuals in the USA alone[1]. AF is associated with numerous adverse outcomes including heart failure, stroke and reduced survival. Catheter ablation has gained increased popularity given its improved efficacy and acceptable safety profile. The effect of ablation on the left atrial flow dynamics has not been studied extensively. It has been proposed that tissue remodeling and clinical outcomes of various cardiovascular procedures are mediated by the impact of these procedures on cardiac fluid dynamics[2]. Some studies reported hemodynamic deterioration, worsening of mitral regurgitation and impaired diastolic function after radiofrequency ablation. Conversely, positive effects on hemodynamics have been reported with restoration and maintenance of sinus rhythm after radiofrequency ablation and improvement of outcomes with some variability depending on AF duration, comorbidities, extent of ablation, and ablation energy. To address these knowledge gaps, we performed an exploratory study with full geometric and flow dynamics assessment of 10 patients who underwent AF ablation.

## METHODS

Contrast-enhanced computed tomography (CT) and echocardiographic images of 10 patients (labeled patient 1 to 10) pre- and post-ablation were obtained from Mayo Clinic, Rochester, MN. The 10 datasets included full cardiac cycles (20 subsets), and echocardiographic studies. The overall workflow adopted in this study is shown in **Figure 1**. The CT images were imported into Mimics Research 23.0 (Materialise, Belgium) and segmented to generate the 3D digital models. All the phases of the 20 subsets were segmented. In order to determine the inflow boundary conditions (BC) and the phase that corresponds to the E-wave with minimal approximations and in order to account for the specific shape of the atrium during that phase (as the atrium contracts), we extracted and plotted versus time the ventricular volumes, depending on each heart rate (HR) of each patient. After that, the derivative of the volume with respect to time was performed to obtain the flow variations. The mitral valve saddle shape was segmented using a different threshold limit in Mimics Research 23.0 and the area was calculated using a spline function in Mimics. The area obtained from the saddle shape was conserved during the extraction of the LA geometry. The LV flow waveform variation with time was converted to velocity versus time by dividing by the MV area. The first peak obtained after the LV volume starts increasing (as it is filling) was chosen to be the phase that corresponds to the E-wave. This process was used to select the appropriate **geometry** of the LA at the E-wave. Echocardiographic waveforms were used to extract the appropriate boundary conditions (BC) at the MV outlet corresponding to the E wave. A constant pressure equal to 0 was imposed at the PVs. Rigid walls and no slip BCs were imposed on the LA surface. The segmented geometry was imported into Ansys Workbench 2020 R1, where extensions equivalent to 10 times the vessel diameters were applied to overcome entrance effects and to have an appropriate velocity profile. The LA models were then meshed with polyhedral meshes after mesh independent results were performed and an element size of 1.2mm was selected (~2,700,000 elements). The computational fluid dynamic (CFD) simulations were performed using Ansys Fluent.

Blood was simulated as an incompressible Newtonian fluid with a density of 1060 kg/m$^3$ and a dynamic viscosity of 0.0035 Pa.s. As the Reynolds number, estimated from peak MV at the E-wave and the MV diameter, was for all cases always below 2000, a laminar model was chosen. Three transient simulations were carried out to ensure stability and overcome transition effects. For data analysis, the final cycle was used for stability. We compared the results obtained from the CFD with available PV echo data showing velocity waveforms. We found close agreement with the values obtained from CFD and from echocardiography. Our study documented several flow dynamic characteristics before and after AF ablation: (1) blood velocities and

SB³C2022-058

velocity streamlines, (2) wall shear stress (WSS), and (3) vorticity. Where vorticity is further defined by the q-criterion and circulation.

## RESULTS

Velocity: In 6 patients (1, 2, 3, 5, 6, and 9), an increase in velocity post-ablation was noted whereas in the other 4 (4, 7, 8 and 10), a decrease in velocity magnitude was noted. **Figure 2** shows velocity streamlines pre- and post-ablation for each patient. The average velocity pre-ablation was 0.82±0.45 m/s and 1.01±0.53 m/s (p = 0.39) post-ablation.

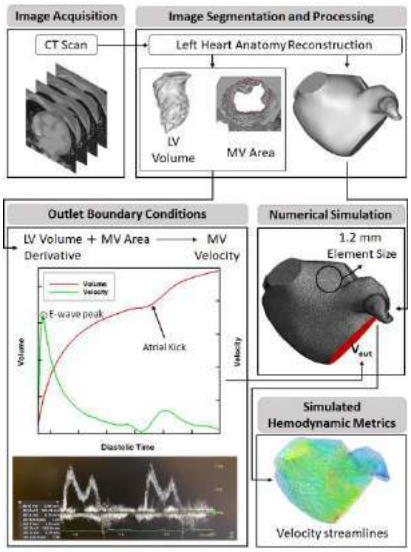

**Figure 1. Overall project workflow.**

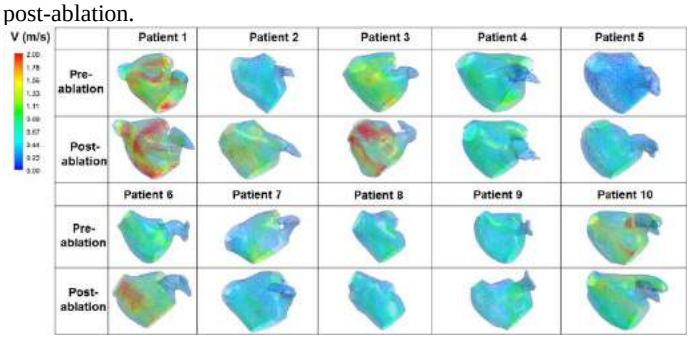

**Figure 3. Velocity streamlines in the left atrium pre- and post-ablation for the 10 patients.**

Vorticity: To visualize and appreciate the 3-dimensional structures of the simulated flow that grow and evolve, we used the q-criterion. Regions with q>0 are dominated by rotation and are occupied by vortex structures. From pre- to post-ablation, different vortex tubes, and different vortex locations are noted in all patient cases, but there was no unique vortex pattern that unified the LA flow dynamics after ablation. To visualize the effect of ablation on the hemodynamic structures, we showed vorticity, and vortex structures on a plane right below the four pulmonary veins and right above the left atrial appendage (LAA). **Figure 3** shows the velocity streamlines in the plane, highlighting the formed vortices. The plane pre-ablation is characterized, in each patient case by clear vortices rotating clockwise and counterclockwise. After ablation in some cases, these vortices get divided into smaller and multiple ones of different rotational directions such as the case with 5 patients (1, 5, 7, 8 and 9). In 3 other cases, several vortices pre-ablation get reduced to one vortex (patients 2, 4 and 6). Patient 3 shows a clear vortex before ablation and no discernable vortex structure after ablation. In same plane, the circulation (Γ) was also calculated (**Table 1**).

| Γ (m²/s) | Pt 1 | Pt 2 | Pt 3 | Pt 4 | Pt 5 | Pt 6 | Pt 7 | Pt 8 | Pt 9 | Pt 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| Pre-ablation | 0.978 | 0.226 | 0.516 | 0.524 | 0.201 | 0.421 | 0.31 | 0.243 | 0.342 | 0.716 |
| Post-ablation | 0.895 | 0.558 | 0.638 | 0.442 | 0.357 | 0.576 | 0.246 | 0.212 | 0.374 | 0.455 |
| %Change | -8.49 | 146.90 | 23.64 | -15.65 | 77.61 | 36.82 | -20.65 | -12.76 | 9.36 | -36.45 |

**Table 1. Circulation calculated in the plane under the pulmonary veins (PV) and above the left atrial appendage (LAA).**

Circulation was found to increase post-ablation in 5 patient cases and decrease in the other 5.

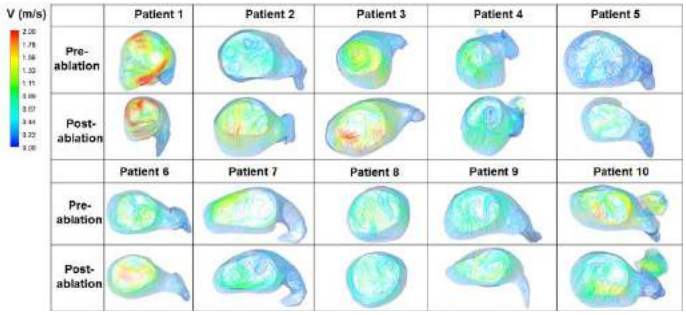

**Figure 2. Velocity streamlines in a plane above the LAA and below the pulmonary veins pre- and post-ablation for the 10 patients.**

Geometrical variations: From a geometrical perspective, there were considerable differences in pre and post ablation LA volumes and PV. Post-ablation, the LA volumes were found to decrease in all but one patient. The percentage of increase differed among the patients and ranged from 5.96% (lowest with patient 8) to 28.83% (highest with patient 9). There was an average decrease in LA volume (11.58±15.17%), after ablation.

## DISCUSSION

In this exploratory study, with heterogeneity in the population and small size, there were no uniform trends in the change in hemodynamics and geometries after the ablation procedure. However, a few general themes were notable and warrant further research. LA volumes decreased after AF ablation. Catheter ablation has been repeatedly shown to reduce LA size without necessarily affecting LA systolic function[3]. The mechanism underlying this change remains poorly understood. The impact on overall LA velocity distribution was not uniform amongst the patients, as 4 patients showed a decrease and 6 showed an increase in overall velocity distribution. In some studies, a decrease in the E-wave velocity of the MV was observed after ablation[4], whereas an increase was observed in others[5]. There was more flow unsteadiness and distinctive vortex patterns after ablation as evidenced in **Figure 2**. These observations were evident in the streamlines and the q-criterion results that demonstrated a prevalence in rotational structures in the atrium in addition to multiple division and coupling of vortices. In some studies, it was demonstrated that vortices are slow in propagating in less compliant geometries compared to more compliant ones[6]. The slow motion may lead to more mixing and disintegration of the vortex structure with the surrounding flow, leading to the resulting unsteadiness. Incoherent, broken, and unstable vortices are the result of either impaired flow or stiffening of the surrounding walls[7]. The calculated circulation (Γ) in the plane located between PVs and above LAA consistently decreased when the velocities decreased. This was expected as geometrical changes occurred on the PV ostia influencing flow mixing and entrainment into the atrium and on the overall LA volume, affecting therefore the rotational aspects of the blood flow and the entrainment of the vortices. Further exploration of the impact of catheter ablation on intracardiac flow dynamics is warranted to discern general and uniform patterns that may correlate with clinical outcomes.

## INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital cardiovascular defect (1-2% of all live births) and is characterized by the abnormal formation of two rather than three cusps.[1] Approximately 50% of young adults with BAV develop premature calcification leading to aortic stenosis by age 35, and this is particularly prominent with fusion of the right and noncoronary (R/NC) cusps.[2] The mechanistic etiology of premature calcification in BAV is poorly understood, but studies, primarily on adult cohorts after the onset of calcification, have used computational models, cardiac imaging, and bench-top methods to speculate that BAV-associated alterations in mechanical stimuli contribute to calcification (Fig 1).

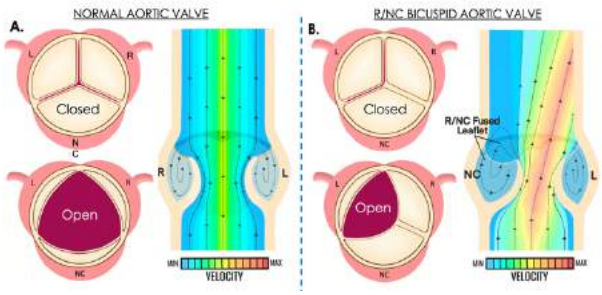

**Figure 1. Aortic Valve Flow Patterns. Compared to the TAV (A), cusp fusion in R/NC BAV (B) leads to a smaller, elliptical opening that results in a high velocity jet skewed to the ascending aorta and creating asymmetrical flow patterns in the sinus. L, left coronary; R, right coronary; NC, noncoronary.**

However, contributions to the field lack evidence supporting a link between the valvular biomechanical environment and molecular changes that promote premature calcification in the setting of R/NC BAV in the pediatric population. Therefore, our objective is to create fluid-structure interaction (FSI) simulations of young BAV patients to elucidate BAV-induced mechanical stimuli prior to calcification. In addition, we use a murine model of R/NC BAV to correlate mechanical stimuli with temporal and spatial transcriptomic changes indicative of calcification processes in valve cell populations during early stages of the disease.[3]

## METHODS

Magnetic resonance imaging (MRI) of 23 y/o patients with R/NC BAV and a healthy tri-cuspid aortic valve (TAV) were conducted after IRB approval. Aortic and coronary artery morphology were extracted using SimVascular (simvascular.github.io). Valve cusps were constructed in SolidWorks (Dassault Systems) using dimensions made patient-specific by scaling to sinus geometry.[4] Physiologic boundary conditions (BCs) were implemented including measured pressure at the aortic inlet, a lumped-parameter model of downstream physiology at the aortic outlet, and flow imposed at coronary artery outlets (Fig 2A). Hyperelastic anisotropic properties based on Gasser-Ogden-Holzapfel's model were applied using biaxial tensile results of human valve cusps from a 20 y/o.[5,6] FSI simulations were performed by coupling

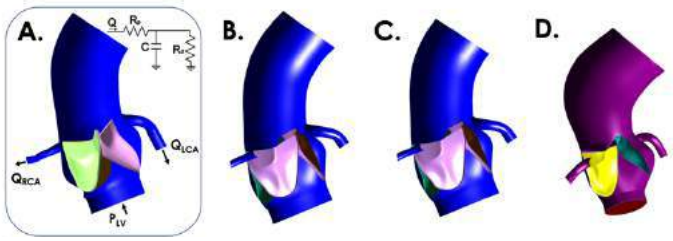

**Figure 2. FSI Simulation Test Cases. TAV and BC setup (A), Virtual R/NC BAV w/ same BCs (B), Virtual R/NC & tuned BCs (C), and patient-specific R/NC BAV (D)**

FlowVision (Capvidia) with Abaqus/Explicit (Dassault Systems). Three cases were conducted from the TAV patient including (1) TAV, (2) virtual R/NC fusion with the same BCs to elucidate the impact of BAV alone, and (3) R/NC fusion with tuned BCs mimicking physiologic compensation to BAV (Fig 2). A validation case (4) included fusion from the R/NC BAV patient. Quantification of mechanical stimuli such as wall shear stress (WSS) and von Mises stress were then extracted.

Endocardial-specific heterozygous deletion of *exocyst 5 (Exoc5)* (*NfatC1$^{cre(+)}$/Exoc5$^{f/+}$*) is reported to lead to aortic valve degeneration in 100% of mice, which includes R/NC in ~45% with secondary calcification present by ~5-6 weeks.[3] Aortic valve function and anatomical dimensions are currently being determined in experimental and genotype controls (*NfatC1$^{cre-}$/Exoc5$^{f/+}$*) using echocardiography and 4D Flow MRI. This is assessed during early (~4 weeks) and later (10-12 weeks) stages of the calcification process. In parallel, aortic valve tissue is being collected and prepared for spatial gene expression studies to determine differential mRNA differences between genotypes correlative to biomechanical profiles.

## RESULTS

Preliminary FSI results from virtual fusion of the R/NC cusps in case 2 revealed reduced systemic pressure requiring tuning of BCs in case 3 to match clinical values. Both R/NC BAV cases showed similar alterations in mechanical stimuli, with differences due to tuning of BCs. Compared to TAV, the fused BAV cusp in case 2 experienced overall higher WSS throughout the fibrosa/aortic surface during systole while WSS was mostly isolated to the tip region on the nonfused cusp (Fig 3).

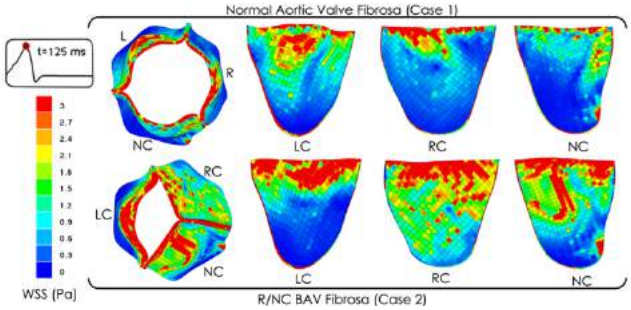

**Figure 3. Wall Shear Stress (WSS). Virtual fusion of R/NC cusps imposes higher WSS magnitude (red) on the aortic/fibrosa surface of BAV cusps. LC, left coronary; RC, right coronary; NC, noncoronary.**

Compared to TAV, the R/NC BAV in case 2 also features regions of high von Mises stress concentrated to the fusion site, which are not present on TAV cusps (Fig 4).

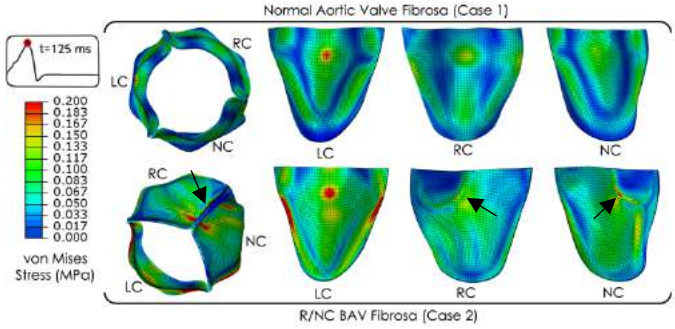

**Figure 4. von Mises Stress. Virtual R/NC fusion leads to high von Mises stress at the cusp fusion site (black arrows) not present in TAV. LC, left coronary; RC, right coronary; NC, noncoronary.**

Out of n=15 *NfatC1$^{cre(+)}$/Exoc5$^{f/+}$* mice that are genetically predisposed to developing R/NC BAV, 3 have demonstrated increased mean velocity gradients (>1000 mm/s) across the aortic valve as well as increased mean pressure gradients (> 4 mmHg) via echocardiography. Development of an optimized protocol for 4D Flow MRI of the aortic valve in mice is currently underway to confirm our echocardiographic findings and serve as a tool for FSI model construction. Figure 4 shows a four-chamber view of a wild-type heart obtained using a 9.4T Bruker MRI scanner with a cardiac and respiratory gradient-echo sequence.

**Figure 5. Magnetic resonance imaging (MRI) of murine heart. Preliminary images of *NfatC1$^{cre+}$/Exoc5$^{f/+}$* mice in a four-chamber view.**

## DISCUSSION

To our knowledge these are the first FSI simulations to characterize the mechanical stimuli for a young adult with R/NC BAV prior to calcification. Our models are *technically* innovative with the implementation of realistic material properties and inclusion of coronary artery flow, which are known to affect flow in the cusp sinuses.[8] Therefore, these methods allow for robust assessment of mechanical stimuli on the valve cusps and thus may ultimately allow us to further characterize the spatiotemporal mechanical changes in both human pediatric and murine BAV subjects leading up to calcification. By examining molecular gene expression changes of the aortic valve over time in the mouse model, which is not possible in humans, we will be able to correlate spatial transcriptomics studies in response to BAV-induced mechanical stimuli leading up to calcification. Additionally, these findings may complement and validate other computational studies using calcification progression models.[7]

## INTRODUCTION

TissueMend (TEI Biosciences and Stryker Corporation) is a Class II FDA-approved surgical patch intended to reinforce damaged soft tissues (Figure 1). The patch is composed of non-denatured, non-crosslinked collagen derived from fetal bovine skin, exhibits good biocompatibility, and is most commonly used in rotator cuff, patellar, and Achilles tendon repair surgeries [1]. Groups have studied the uniaxial mechanical behavior of TissueMend and compared it to other surgical patches and tendons. Aurora et al. [2] and Derwin et al. [3] reported TissueMend to have a Young's modulus of approximately 15.2 ± 3.5 MPa and 20 – 30 MPa, respectively. Despite having a higher hydroxyproline content than its competitors [3], these moduli are lower than but still comparable to those of similar products; however, they fall short of the 1 – 2 GPa modulus range generally associated with tendons [4–6].

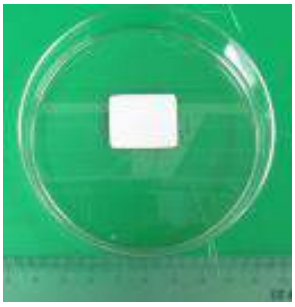

**Figure 1. The uncut, unhydrated TissueMend sample.**

Quantifying the directional mechanical behavior of surgical products, such as TissueMend, intended to reinforce and repair damaged tendons is of the utmost importance since tendons exhibit pronounced anisotropy due to strong collagen fiber alignment [6,7]. There have been no reported biaxial mechanical characterizations of TissueMend, however, or other attempts to quantify its mechanical anisotropy. We have developed a Generalized Anisotropic Inverse Mechanics (GAIM) method capable of quantifying regional variations in stiffness and anisotropy of soft tissues [8–11]. In this study, we used biaxial testing and GAIM to improve the understanding of TissueMend's anisotropic mechanical behavior.

## METHODS

**Sample Preparation.** Prior to testing, the TissueMend sample was covered in phosphate buffered saline (PBS) for ~10 minutes to hydrate. The sample was then trimmed into a cruciform shape (~15x15 mm) and scanned by a LJ-V7080 laser micrometer (Keyence) at 20 Hz to obtain a 3D thickness profile. To determine full-field displacement, we speckled the sample with India ink (Speedball Arts) using an airbrush at an air pressure of 40 psi and a sample-to-nozzle distance of about six inches. The sample was placed in a custom gripping system and secured to the biaxial testing machine (574E2, TestResources). For this experiment, a combination of axial (WF12S; TestResources) and six degree of freedom (Nano 17; ATI) load cells were used to record in-plane normal and shear forces. The sample was immersed in PBS throughout mechanical testing and images of the sample's surface were acquired at a frequency of approximately 7 Hz.

**Mechanical Testing.** The TissueMend sample was cut so that the long-axis (Figure 1) aligned with the horizontal testing axis. Preload (~0.24 N) was added to each arm of the sample and it was preconditioned with 10 equibiaxial stretches of ~15% strain at a strain rate of 1%/s [12,13]. Subsequent biaxial testing consisted of a series of extensions designed to generate shear stresses in the sample and included equibiaxial, two-arm, three-arm, and strip biaxial tests [9]. Testing concluded with one final equibiaxial extension used to confirm no damage was inflicted during the atypical extensions and that the sample's state of pseudoelasticity was unchanged.

**Data Analysis.** The GAIM method directly solves the stress balance using the measured boundary forces and full-field

displacements determined by digital image correlation. The components of the fourth-order neo-Hookean generalization of the linear elasticity tensor, $K_{ijkl}$, are fit for a state of static equilibrium as shown in Equations 1 and 2:

$$S_{ij} = K_{ijkl}E_{kl} \quad (1)$$

$$\left(F_{mi}K_{ijkl}E_{kl},\right)_j = 0 \quad (2)$$

where $S_{ij}$ is the second Piola-Kirchhoff stress, $E_{kl}$ is the Green strain, and $F_{mi}$ is the deformation gradient [13]. The Galerkin finite element method relates nodal forces to the stiffness constants for each individual element (Equation 3) as follows:

$$\boldsymbol{G = MK} \quad (3)$$

where $\boldsymbol{G}$ is a vector of nodal forces, $\boldsymbol{K}$ is a vector of elastic constants, and $\boldsymbol{M}$ is a collection of leftover terms from the discretized form of Equation 2. By assuming the sample domain is comprised of homogeneous partitions, Equation 3 becomes an overdetermined linear system solvable with a least-squares approach. For a state of plane stress, solution of the inverse problem results in six stiffness tensor constants for each partition. The eigentensors of $\boldsymbol{K}$ represent principal states of stress and strain [14]. The first Kelvin modulus corresponds to the largest eigenvalue and represents stiffness in the sample's stiffest direction. The associated eigenvectors enable estimation of relative mechanical anisotropy ($r$) and preferred stiffness directions ($\theta$) [9]. Relative mechanical anisotropy ranges from 0 for a totally isotropic material to 1 for a totally anisotropic material and is comparable to the retardation metric produced by polarized light microscopy [12].

## RESULTS

Table 1 includes mechanical characterizations from GAIM for the TissueMend sample with increasing numbers of partitions. In all cases, the first Kelvin modulus, relative mechanical anisotropy, and the preferred stiffness direction were similar. The TissueMend sample exhibited roughly uniform stiffness with an average Kelvin modulus of about 11 MPa across the sample surface and a low spatial standard deviation ranging from 5.1 to 6.2 MPa. It exhibited marked, uniform anisotropy with an average relative anisotropy of about 0.8 (indicating the sample was roughly nine times stiffer in the preferred direction) and a spatial standard deviation of 0.16 to 0.19. The average preferred stiffness direction was about $\theta$ = -13º relative to the horizontal axis, with a spatial standard deviation of about 16º. This average roughly corresponds with the horizontal. This was consistent with gross inspection of the TissueMend sample, which suggested collagen fibers were predominately oriented along the long-axis. Low spatial variability of mechanical properties suggested homogeneity and is apparent in Figure 2, which illustrates the similar relative anisotropy and preferred stiffness direction for 1 partition and 64 partitions throughout the bulk of the sample.

## DISCUSSION

TissueMend is a commercial product intended to support weak or damaged tendons and while it has been shown to perform similarly to its competitors in uniaxial tests, few efforts have been made to quantify its biaxial mechanical properties. The sample tested here had a Kelvin modulus of approximately 11 MPa, which agrees reasonably well with reported values from uniaxial tests [2,3]. We found that TissueMend had pronounced anisotropy and was approximately nine times stiffer in the horizontal direction than the vertical direction. This level of mechanical anisotropy is similar to the physiological levels of anisotropy in tendons tested by Hoffmeister [6], and is, to our knowledge, the first attempt to quantify homogeneity and anisotropy in TissueMend samples.

**Table 1. GAIM results for a TissueMend sample using a varying number of partitions.**

| Partitions | Kelvin Modulus (MPa) | $r$ | $\theta$ (degrees) |
|---|---|---|---|
| **1** | 13.2 | 0.83 | -12.5 |
| **16** | 11.5 ± 5.1 | 0.78 ± 0.17 | -14.5 ± 15.5 |
| **32** | 11.3 ± 5.3 | 0.81 ± 0.19 | -13.5 ± 16.0 |
| **52** | 11.1 ± 5.8 | 0.79 ± 0.16 | -12.4 ± 15.6 |
| **64** | 10.7 ± 6.2 | 0.78 ± 0.18 | -12.6 ± 16.4 |

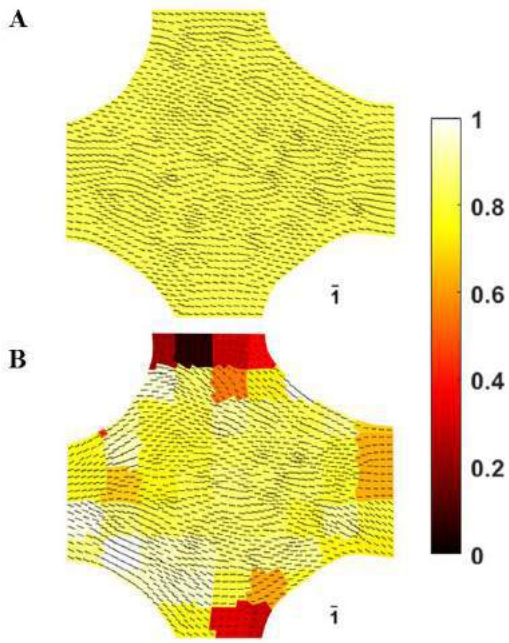

**Figure 2. Relative mechanical anisotropy and preferred stiffness direction computed for a TissueMend sample with A.) one partition and B.) 64 partitions.**

## INTRODUCTION

A leading cause of cardiovascular disease is atherosclerosis, a chronic inflammatory disease characterized by the progressive thickening and hardening of arterial walls. Early in the atherogenic process, endothelial dysfunction is induced by disturbed fluid shear stress (FSS) acting on the vessel wall. In these regions, endothelial cells (ECs) maintain a rounded morphology with an unaligned cytoskeleton. ECs exposed to disturbed FSS express an athero-prone and inflammatory phenotype that promotes monocyte adhesion and translocation. Conversely, athero-protective regions of the vasculature where laminar FSS is persistent contain ECs with an anti-inflammatory phenotype that are elongated and aligned with the direction of blood flow. The complex molecular basis for these distinct endothelial phenotypes *in vivo* remains unclear. One regulatory candidate is the transcription factor Yes-associated protein (YAP), which functions as a mechano-transducer that regulates endothelial phenotype and gene expression in response to the mechanical environment. In cells exposed to laminar FSS, YAP becomes inactivated through phosphorylation by the Hippo signaling pathway and is retained within the cytoplasm. However, oscillatory FSS activates YAP via dephosphorylation and subsequent nuclear translocation. The induction of activated YAP is associated with upregulated inflammatory EC target genes which are all highly expressed within atherosclerotic plaques [1].

The differential response of ECs and YAP activation to various flow regimes has been extensively studied within literature, but it is still largely unclear exactly how ECs convert mechanical stimuli into biochemical responses. Previous studies have correlated endothelial morphology and cytoskeletal alignment, independent of FSS, to the regulation of EC function and phenotype [2,3]. However, the in-depth transcriptional signature of an elongated and aligned endothelial monolayer within static culture has yet to be investigated and is needed in order to further understand endothelial mechanotransduction.

## METHODS

Micropattern Fabrication: Topographical micropatterned and planar substrates were fabricated as previously described [2,4]. Briefly, micropatterned PDMS submasters with ridge and groove widths of 3 µm were fabricated by soft lithography. Planar PDMS submasters were fabricated using petri dishes as a master. Polyurethane was then dispensed on top of the submasters and covered by a glass coverslip. The culture substrates were cured by using 2 J of long-wave UV light. Substrates were demolded and sterilized prior to cell culture.

Cell Culture: Baboon carotid artery endothelial cells (BaCaECs) at passage 3 were cultured in complete endothelial growth medium and seeded on substrates for 24 hrs for RNA-sequencing (RNA-seq) experiments. For subsequent experiments, BaCaECs (passage 4) were seeded for 48 hrs.

RNA Isolation and Sequencing: After 24 hr of static culture on substrates, BaCaECs were lysed and total RNA was purified using a Qiagen RNeasy Mini Kit following the manufacturer's protocol. RNA quality assessment and sequencing was performed by OHSU's MPSSR core. Briefly, quality and quantity of total RNA were assessed with an Agilent 2100 Bioanalyzer with all samples having a RIN $\geq$ 9.9. RNA-seq fastq files were aligned with STAR (v2.7.9a) to the Ensembl baboon reference genome Panu_3.0.104 by OHSU's Epigenetics core. Differential analysis was performed with edgeR (v3.28.0). P-values were adjusted by the Benjamini-Hochberg procedure. Enrichr was used to identify pathways regulated by micropatterning.

Image Analysis: BaCaECs were stained for YAP, VE-cadherin, and nuclei. Samples were imaged on a Zeiss LSM 880 scanning confocal microscope (20X, NA = 0.8). Three images per pattern per

SB³C2022-062

sample were collected for quantitative image analysis. Cells were randomly traced using a 4x4 grid overlaying the VE-cadherin color channel. Whole cell morphology was determined by calculating shape index, where 0 equals a perfect line and 1 equals a perfect circle. The nuclear/cytoplasmic YAP intensity ratio was determined by manually drawing ROIs for the cellular nucleus and VE-cadherin border. The YAP intensity ratios were calculated as previously described [1].

Statistical Analysis: Data are presented as mean ± standard deviation. Statistical significance was determined using a Student's t-test between substrate types. Results were considered statistically significant with a *p*-value < 0.05.

## RESULTS

**Identification of mechano-sensitive genes in BaCaECs due to micropatterning.** We investigated the transcriptional profile of BaCaECs on micropatterned surfaces using RNA-seq global gene expression analysis of ECs cultured on either micropatterned or planar substrates. We find 1302 differentially expressed genes in micropatterned BaCaECs with 888 genes were significantly up-regulated and 914 genes were significantly downregulated relative to planar substrate cells (**Fig. 1**). Notably, YAP transcriptional targets (ANKRD1, VCAM1, ICAM1, CTGF, CYR61, and IL-6) that are associated with atherosclerotic plaques were significantly down-regulated for micropatterned BaCaECs. Enrichr pathways analyses were next performed using the significantly downregulated gene set. This algorithm identified multiple pathways significantly downregulated by micropatterned substrates including: NF-κB, lipid and atherosclerosis, TNF, and IL-17 inflammatory signaling pathways (**Fig. 2**, p < 0.00001).

**Micropatterning modulates endothelial morphology and phenotype**. We also observe significant elongation for micropatterned cells induced by topographical micropatterning. Micropatterned cells exhibit shape indices of 0.51 ± 0.01 compared to planar cells with shape indices of 0.61 ± 0.03 (data not shown, p < 0.05). YAP activation was significantly downregulated for micropatterned cells compared to planar cells with nuclear/cytoplasmic as determined YAP nuclear localization with intensity ratios of 2.01 ± 0.13 and 3.04 ± 0.35 (p < 0.05), respectively (**Fig. 3**), consistent with previous studies and our transcriptional analysis.

## DISCUSSION

Topographical micropatterning is an effective technique to align and elongate endothelial monolayers in the absence of fluid shear stress but FSS-independent, mechano-sensitive athero-protection has yet to be fully investigated. Our current study used bulk RNA-seq to reveal the transcriptional difference produced by micropatterning that modulates endothelial mechanotransduction pathways to induce an anti-inflammatory phenotype. We find a subset of YAP target genes significantly downregulated in micropatterned ECs. We also find that micropatterning regulates YAP activation by downregulating nuclear translocation using single-cell image analysis techniques. Taken together, our data supports micropatterning as a potential cardiovascular device surface modification to improve biocompatibility via modulating endothelial morphology and genetically altering inflammation transduction mechanisms.

## INTRODUCTION

Combinations of loads that the knee experiences during different levels of activity can place an individual at greater risk for ligament injury. This is especially evident in adolescents, as high impact sports such as football and soccer have all been associated with Anterior Cruciate Ligament (ACL) ruptures. These are due to high impact loads caused from side cutting maneuvers, even in non-contact scenarios.

Advancements in finite element technology have made it possible to develop patient-specific models that can accurately predict the *in vivo* environment of the knee. Despite adolescents making up the majority of ACL reconstructions, never has this methodology been applied to this core demographic. The goal of this research project was to determine how different loading conditions experienced through high and low impact sports influence the biomechanics of the ACL and Medial Collateral Ligament (MCL) in adolescents.

## METHODS

A total of 22 CT images of juvenile knees were utilized (ages: 9-18, m: n=16, f: n=6). 3D Slicer was used to convert the CT images into a three-dimensional representation of the bony anatomy. FEBio was used to construct each tibiofemoral joint and perform the finite element analyses (Figure 1).

The developed knee models were validated through simulations replicating the anterior drawer and pivot shift test. The predicted anterior tibial displacement determined by the finite element models were shown to accurately represent what has been established experimentally with these clinical tests [1-2].

Front knee baseball hitting [3] (low impact) and side cutting [4] (high impact) kinetic adolescent experimental data was used to replicate the two different loading scenarios (Table 1).

Since anterior force and internal rotation torques were not reported in the adolescent side cutting experimental data, one of the assumptions made for this study is that adolescent side cutting kinetics are proportional to those experienced in adults [5].

A 95% confidence interval (CI) was taken to determine statistical significance.

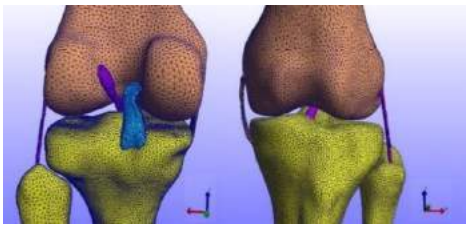

**Figure 1: Frontal plane views of the adolescent model.**

**Table 1: Kinetic experimental loading conditions used in the high and low impact simulations.**

| | Baseball Hitting Kinetics [3] | Side Cutting Kinetics [4] |
|---|---|---|
| *Internal Rotation (Nm)* | 6.3 | 43.4 |
| *Valgus Torque (Nm)* | 11 | 63.5 |
| *Anterior Force (N)* | 86.2 | 395.5 |

## RESULTS

The high impact side cutting maneuver resulted in greater ligament displacement compared to the low impact baseball swing simulation for both the ACL and MCL (Table 2).

**Table 2: Descriptive statistics for ACL and MCL displacement.**

| | ACL Displacement | | MCL Displacement | |
|---|---|---|---|---|
| | *Baseball Hitting* | *Side Cutting* | *Baseball Hitting* | *Side Cutting* |
| N | 22 | 22 | 22 | 22 |
| Mean | 4.7 | 9.5 | 4.1 | 6.0 |
| SD | 2.1 | 4.5 | 1.8 | 2.3 |

A 95% confidence interval on the predicted ligament displacements was performed (Table 3). It can be observed that there is no overlap of the confidence intervals between the baseball hitting and side cutting displacements for both ligaments.

**Table 3: 95% CI for ACL and MCL baseball hitting and side cutting loading scenarios.**

| ACL Displacement | MCL Displacement |
|---|---|
| *Baseball Hitting 95% CI (mm)* | *Baseball Hitting 95% CI (mm)* |
| 3.85 - 5.56 | 3.29 - 4.82 |
| *Side Cutting 95% CI (mm)* | *Side Cutting 95% CI (mm)* |
| 7.65 - 11.42 | 5.0 - 6.94 |

As expected, the peak first principal stress of the ACL and MCL increased significantly when subject to higher loading conditions. When analyzing ratios of peak stress increases, both ligaments experienced over a two-fold increase when undergoing the side cutting maneuver compared to the baseball hitting simulation (Table 4).

**Table 4: Ratio of peak 1st principal stress for the ACL and MCL.**

| Ratio of Peak 1st Prinicpal Stress (Side Cutting : Baseball Hitting) | |
|---|---|
| *ACL* | *MCL* |
| 2.14 : 1 | 2.5 : 1 |

## DISCUSSION

Ligament displacements increased significantly when the input parameters replicated a high impact loading environment for both the ACL and MCL. This follows trends that have been established experimentally, as knee ligaments have been shown to experience greater displacement when subject to increasing force levels [3-4].

Furthermore, the 95% confidence intervals between the low and high impact loading scenarios did not overlap for ACL and MCL displacement demonstrating that the difference between sporting maneuvers is statistically significant. This shows that knee loading experienced in high impact sports places more strain on the ligaments ultimately increasing the likelihood of ruptures.

One limitation of the proposed models is the inability to directly quantify the predicted stress against known literature values. This is in part due to the differences in experimental and computer simulated methodologies in calculating ligament biomechanical properties. Many experimental tensile testing methods rely on calculating nominal stress values over a simplified, uniform geometry [6]. In contrast, however, the finite element models calculate the stress of each individual tetrahedron within the mesh of a specific ligament resulting in non-uniform stress/strain distributions which are more representative of the *in vivo* biomechanics.

Notwithstanding the discrepancies between the finite element modeling and experimental methodologies, the predicted peak stress values of the models provide valuable insight into the effect that various loading conditions have on the knee ligament biomechanics. In particular, ratios of stress increases can be extracted from the data revealing the consequence of high impact loading on the ligaments. Both the ACL and MCL experienced over a two-fold increase in peak first principal stress when undergoing the side cutting maneuver compared to the baseball swing. This demonstrates that participating in higher intensity activities places greater stress on the ligaments thus increasing the chance of the athlete developing an injury in the future.

Although the ACL is the most commonly injured ligament in the knee, MCL injuries are often experienced during ACL ruptures. In adolescent populations, isolated ACL injuries occur at a rate of 78% where as two-ligament injuries (ACL and MCL) occur at a rate of 17% [7]. ACL injuries are predominately due to anterior forces being combined with valgus and internal rotation torques resulting in a pivot shift movement [8]. Pivot shift mechanisms are found in baseball hitting and side cutting activities and this combination of loading is primarily resisted by the ACL [9]. The ACL's resistance to these motions is evident in the modeling as higher loading parameters resulted in increases in ACL displacement and stress.

The MCL is also impacted by these movements because the axis of the pivot shift mechanism is located about the MCL [9]. When the forces are applied to the knee, movements at the medial side of the tibia are restricted by the tension in the MCL [9]. This rise in MCL tension is depicted in the FEBio models such that both displacement and peak principal stress increase when subject to higher impact loading. Both the ACL and MCL experienced comparable displacement in the lower impact simulation. However, it is during the side cutting maneuver that the displacements between the ACL and MCL are found to be statistically significant. This is consistent with the findings in the literature that conclude that pivot shift movements are predominantly resisted by the ACL as overall, it experienced the greatest average displacement.

It is interesting to note that the MCL had a greater ratio increase in peak stress than the ACL despite having a lower average displacement. This suggests that high impact forces place *both* ligaments in a vulnerable position for injury. In doing so, this further supports clinical findings that higher external valgus moments such as those experienced during side cutting maneuvers are predictive of ACL injury as higher loading resulted in higher predicted ligament displacement and stress [8]. Thus, it can be concluded from the models that side cutting increases the likelihood of a coupled ACL/MCL injury compared to lower impact activities such as hitting a baseball.

Despite limitations of the study, the proposed models were able to demonstrate how increasing loads experienced in high impact sports can lead to ruptures of the ACL and MCL – the two ligaments that are often affected during knee injuries [10]. This provides a solid foundation by which to assess and understand the biomechanical consequences of various sporting maneuvers.

Developing models that quantify the changes in the biomechanics of the knee ligaments during different sporting activities can be utilized by orthopaedic surgeons in justifying alterative activities for patients who have had a prior ACL reconstruction or may be prone to ACL injury given their bony anatomy risk factors.

## INTRODUCTION

Brain development involves precisely orchestrated genetic, biochemical, and mechanical events. At the cellular level, neuronal proliferation in the innermost zone of the brain followed by migration towards the outermost layer results in a rapid increase in brain surface area, outpacing the volumetric growth of the brain, and forming the highly folded cortex. Atypical neurodevelopment and cortical malformation are associated with neurological disorders such as autism spectrum disorder [1], schizophrenia [2], and epilepsy [3]. Hence, a deeper understanding of neurodevelopment is of great interest and could prove essential for increased knowledge, improved diagnostics, and effective treatments of developmental disorders.

Here we aim to provide mechanistic insights into the process of brain development and cortical folding using a biomechanical model that couples cell division and migration with volumetric growth. Unlike phenomenological growth models, our model tracks the spatio-temporal development of cohorts of neurons born at different times. Each cohort is modeled separately as an advection-diffusion process, and the total cell density determines the extent of volume growth. We numerically implement our model in Abaqus/Standard (2020) [4] by writing user-defined element (UEL) subroutines. On the experimental side, we apply *in utero* electroporation (IUE) to ferret brains to visualize and track cohorts of neurons born at different stages of embryonic development, which is used to calibrate our model. The calibrated simulations of cortical folding align qualitatively with the experiments.

## METHODS

***In utero* electroporation** We conducted our well-established IUE procedure on ferret brains to visualize the distribution of migrating neurons over time [5,6]. We consider N=8 ferret brain sections, covering different imaging dates and different IUE dates, corresponding to distinct cohorts of neurons (Fig 1). We select a consistent rectangular region from each brain section as the region of interest (ROI), in which the cell migration dominates in the vertical direction. The cell counting of each ROI is done via ImageJ [7] and is used later for model calibration (Fig 2, circles).

**Mathematical modeling** Unlike previous models [8,9,10], we track the cell density of *i*th cohort of neurons, $c_i$. The advection-diffusion process governs the neuronal cell density,

$$\dot{c}_i + c_i \frac{\dot{J}}{J} = f_i^c + \mathrm{div}\mathbf{q}_i \,, \tag{1}$$

where $J$ is the volumetric change, $f_i^c$ is the rate of neurogenesis, and $\mathbf{q}_i$ describes how neurons migrate along with the velocity field $\mathbf{v}$ and spread out in space via diffusion.

Next, to take the growth-related growth into account, our total deformation could be decomposed into elastic and growth counterparts,

$$\mathbf{F} = \mathbf{F}^e\mathbf{F}^g. \tag{3}$$

According to the literature [11,12], the neurons that migrate along glial fibers at the early stage contribute to radial expansion. In contrast, the tangential expansion dominates when neurons reach their destinations in the cortical plate. Thus, we take the growth deformation tensor as a linear combination of the two modes,

$$\mathbf{F}^g = \vartheta^{\parallel}(c)\mathbf{N}\otimes\mathbf{N} + \vartheta^{\perp}(c)(\mathbf{1} - \mathbf{N}\otimes\mathbf{N}), \tag{4}$$

where $\vartheta^{\parallel}(c)$ and $\vartheta^{\perp}(c)$ are functions that relate to the cell density, and $\mathbf{N}$ is a unit vector that indicates the direction of glial fiber at the reference state. The ferret brain is modeled as standard neo-Hookean material,

$$\psi_R(\boldsymbol{C}^e, J^e) = \frac{\mu}{2}[\mathrm{tr}(\boldsymbol{C}^e) - 3 - 2\ln(J^e)] + \frac{L}{2}\ln^2(J^e), \tag{5}$$

where $\mu$ and $L$ are Lamé constants. Note that only elastic deformation ($\boldsymbol{C}^e = \boldsymbol{F}^{eT}\boldsymbol{F}^e$, $J^e = \det(\boldsymbol{F}^e)$) contributes to the stress.

## RESULTS

We calibrate our model to a 1-D cell density profile from N=8 ferret brains via a genetic algorithm, and the results show a good agreement between simulations and experiments. Some material parameters are constrained within the reasonable range reported by the literature. Note that only calibration results of cohort 2 are shown here (Fig 2).

We then simulate cortical folding with the parameters obtained from the model calibration. Our simulation with both 2-D and 3-D settings -- we only show 2-D case here -- are qualitatively in line with our experiments (Fig 3). As expected, cohorts of neurons generated at E31, E33-34, and E36-37 gradually reside at the cortex's lower, medium, and upper layers, respectively.

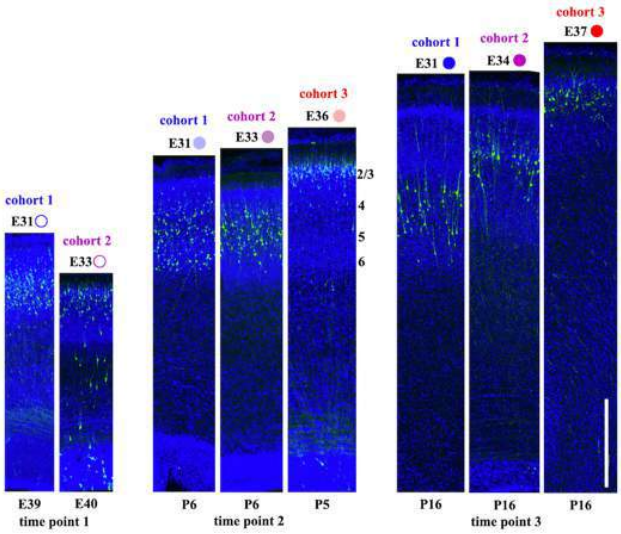

**Fig 1: Regions of interest taken at consistent locations of N=8 typically developing ferret brains, grouped based on IUE and imaging times. Neurons are labeled with EGFP (bright green). Scale bar: 500 µm.**

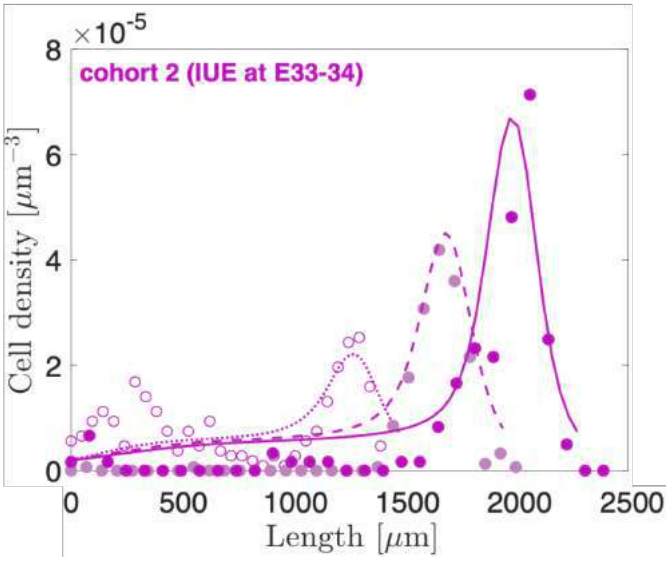

**Fig 2: Comparison between experiments (circles) and model (lines) of cohort 2 at three different imaging dates.**

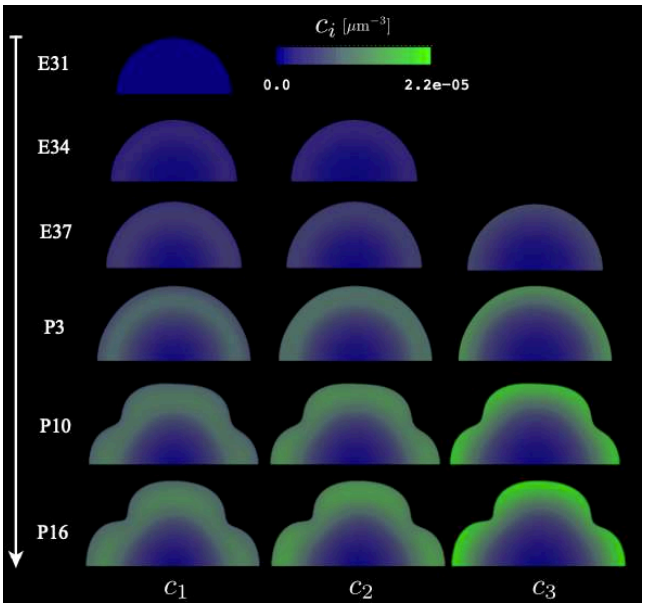

**Fig 3: Simulations of cortical folding with contour denoted as cell density $c_i$.**

## DISCUSSION

In this work, we have developed a biomechanical model for numerical simulations of brain development. The model extends the earlier works to account for the spatial-temporal development of multiple cohorts of neurons, each modeled as an advection-diffusion process. The model was implemented numerically by writing customized finite elements in the commercial finite-element program Abaqus/Standard (2020) [4]. We also conducted novel experiments on ferret brains via IUE, used for model calibration. Our simulations qualitatively agree with the experiments on ferret brains.

Our results suggest significant opportunities for further extensions and improvements in future work. First, the current work accounts for only three cohorts of neurons for simplicity. Secondly, we assumed constant mechanical properties throughout the brain. Finally, our work could potentially be used to study atypical-developing brains.

# MULTISCALE MODEL OF PREGNANCY–INDUCED HEART GROWTH APPLIED TO POSTPARTUM RECOVERY

**Molly S. Kaissar (1), Kyoko Yoshida (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

Pregnancy stands at the interface of mechanics and biology – continuous loading from the growing fetus combined with drastic shifts in circulating hormones induce rapid soft tissue remodeling. The adaptations of a pregnant patient's cardiovascular system include an expanding blood volume, rising cardiac output, and decreasing vascular resistance [1, 2]. These changes coupled with an increase in circulating hormone concentrations culminate in the patient's heart growing approximately 30% in both mass and cavity volume by term pregnancy [3]. Following delivery, the patient's heart then regresses to its pre-pregnant size within 3–6 months [3].

Cardiovascular disease accounts for 35% of pregnancy-related mortality, with pregnancy-associated heart failure causing 32% of deaths between 43 days to one year postpartum [4]. Heart growth is driven by a combination of mechanical and hormonal cues, yet the mechanisms that cause this remodeling during pregnancy and postpartum are not well characterized. Uncovering these remodeling mechanisms is necessary to understand how pregnancy-induced physiological changes can lead to heart failure during postpartum recovery. Thus, our aim is to investigate the interactions of the hormonal and mechanical cues that drive left ventricular (LV) remodeling during the postpartum period.

Towards this objective, we applied our existing multiscale model of LV growth during pregnancy to normal postpartum remodeling [5]. We simulated 21 days of normal rat pregnancy followed by 21 days of postpartum-induced changes in hemodynamics and hormones and compared our predictions to the available data. We then manipulated the activity of different signaling network model inputs to determine their influence on cardiac remodeling during postpartum recovery. Our analysis suggests that hemodynamic changes are important drivers of postpartum LV remodeling.

## METHODS

*Multiscale Model of Cardiac Growth*

To simulate pregnancy-mediated cell-level growth, we used an intracellular signaling network model that predicts cardiomyocyte hypertrophy in response to key reproductive (*Progesterone, P4; Estrogen, E2*) and cardiovascular *(Angiotensin II, AngII*) hormones and a generalized stretch term (*Stretch*) (Fig. 1a). The activity level of each species was represented as a value between 0 and 1, where 0 indicates no signaling activity and 1 represents maximal activation. At each time step, the network model simulated 5 hours of growth to predict changes in cardiomyocyte size (*CellArea*).

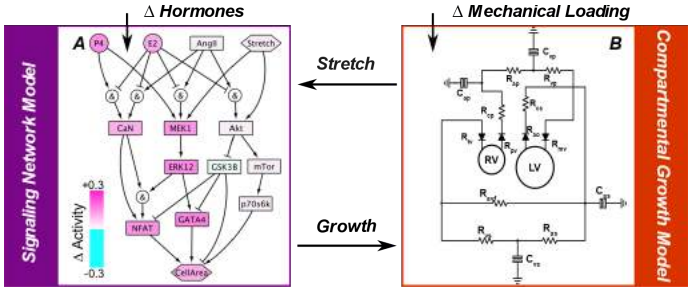

**Figure 1: Multiscale cardiac growth model for pregnancy.** A schematic of the cell-level intracellular signaling network model (*A*) coupled to the organ-level compartmental growth model (*B*).

To simulate organ-level growth, we used a mechanical compartmental model of the rat heart and circulation that predicts cardiac hypertrophy in response to hemodynamic changes (Fig. 1b). This model uses a kinematic growth framework that calculates the total stretch experienced by the heart ($F_{tot}$) as a product of the growth stretch ($F_g$) and the elastic stretch ($F_e$), $F_{tot} = F_g \times F_e$. $F_g$ is related to the

network model output *CellArea* through $J_g = 2 \times CellArea$, where $J_g = \det(F_g)$. The maximum elastic fiber stretch, $\max(F_{e,f})$, is calculated by the compartmental model and fed back into the signaling network model input, *Stretch*, to complete the loop between the two models. We previously calibrated the multiscale model parameters by matching the individual effects of volume overload (VO) and hormonal infusions of AngII, E2, and P4 on LV growth and demonstrated this model's ability to correctly predict LV growth during pregnancy [5].

*Simulating Postpartum Remodeling*

To simulate postpartum remodeling, we extended the growth simulation to include the postpartum period. To capture hemodynamic changes, we optimized the stressed blood volume input in the compartmental model to match the reported mean arterial pressure. We simulated cardiac remodeling in non-lactating and lactating rats since non-lactating rats return to pre-pregnant cardiac output and hormones within days of weaning, whereas lactating rats exhibit elevated cardiac output and P4 with suppressed E2 while nursing [6, 7].

*Contributions of Mechanics vs. Hormones on Postpartum Remodeling*

As our previous modeling work identified P4 and hemodynamics as the primary drivers of growth during pregnancy [5], we investigated their influence on postpartum remodeling. To understand the relative contributions of each parameter on postpartum remodeling, we re-ran the simulated the 21 days of postpartum-induced changes while maintaining either *P4* or *Stretch* at the activity level it reached at the end of pregnancy.

## RESULTS

During the 21-day postpartum period in rats, our model predicted a decrease in LV mass in the non-lactating group, but an increase in LV mass in the lactating group (Fig. 2). These results suggest that the elevated cardiac output and circulating P4 concentration induce additional heart growth as rats nurse their pups.

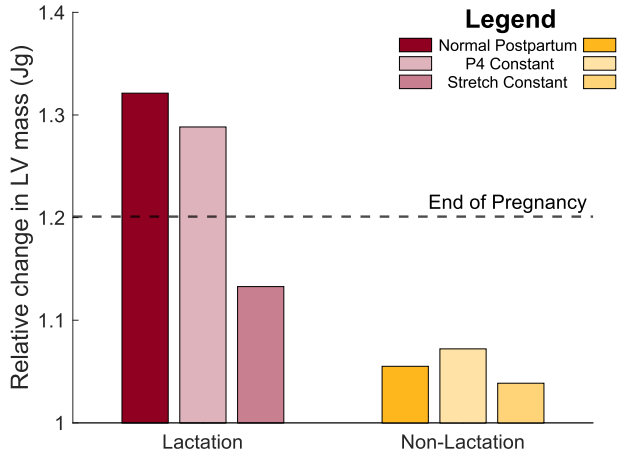

**Figure 2: Predicted changes in left ventricular (LV) mass in the non-lactating and lactating groups.** Bars represent changes in LV mass with respect to the pre-pregnant LV mass.

To assess the relative contributions of P4 and hemodynamic changes on postpartum cardiac remodeling, we repeated the postpartum simulations with either the *P4* or *Stretch* network model inputs maintained at the activity levels reached at the end of pregnancy. Maintaining either *P4* or *Stretch* at these constant levels underpredicted growth. In both the non-lactation and lactation groups, maintaining *Stretch* at a constant activity had a greater impact on the predicted LV mass (Fig. 2, rightmost bar in each group) and cardiomyocyte size (Fig. 3, *CellArea*) compared to maintaining *P4*. These results suggest that hemodynamic changes play a bigger role during postpartum remodeling in our model compared to changes in circulating P4 concentration.

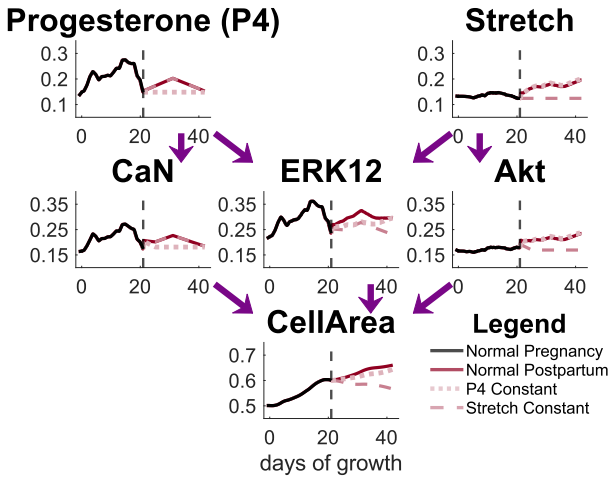

**Figure 3: Signaling network model predictions for the lactation group during pregnancy and postpartum recovery.** Arrows represent interactions between species, where intermediate species are influenced by *P4*, *Stretch*, or *P4* + *Stretch*.

## DISCUSSION

The objective of this work was to determine how hormonal and mechanical cues influence LV remodeling during postpartum recovery. The elevated cardiac output and progesterone in the lactation group led to increased LV mass in our multiscale model of cardiac growth. We further demonstrated that the mechanical signal *Stretch* played a larger role compared to hormonal signal *P4* during postpartum-mediated cardiac remodeling. Together, our results indicate hemodynamics as a primary driver of growth during postpartum recovery in our model.

During postpartum recovery, human patients, regardless of breastfeeding status, experience similar decreases in cardiac output to non-lactating rats [8] – likely due to the differences in the typical number of offspring per pregnancy (1-2 babies in humans vs. 8-12 pups in rats) and the resulting demand on the mammary glands [6, 9]. Therefore, the non-lactating simulation presented here is likely a better representation of human postpartum cardiac remodeling.

Future work will focus on applying this model to understand normal and abnormal postpartum-induced cardiac remodeling. Towards this goal, we will simulate postpartum remodeling in hypertensive pregnant rats and genetically modified mice that experience postpartum heart failure, better known as peripartum cardiomyopathy.

# HYALURONAN, PRG4, AND CYTOKINE PRODUCTION IN SYNOVIOCYTES IS SENSITIVE TO CYCLIC STRAIN MAGNTIUDE

**Meghana Pendyala (1), Paige Woods (2), Douglas K Brubaker (3), Elizabeth A Blaber (1), Tannin Schmidt (2), Deva D Chan (1,3)**

## INTRODUCTION

Synovial fluid works to lubricate the surfaces and maintain the macroenvironment of the joint [1]. Hyaluronan (HA) and PRG4 (proteoglycan-4) are major components of synovial fluid and are produced by fibroblast-like synoviocytes in the synovial membrane [2]. In healthy joints, synovial fluid contains high molecular weight HA and PRG4 [1], but in osteoarthritis (OA), HA concentration, HA molecular weight, and PRG4 concentration decreases [3,4]. Changes to cytokine concentrations in the synovial fluid have also been used as biomarkers to determine disease state [5]. Despite our knowledge on changes to proteoglycan and cytokine content within the joint, the effect of mechanics on these changes has not been thoroughly assessed.

HA is produced by three isoenzymes, hyaluronan synthase 1, 2, and 3 (HAS1, -2, -3) [6]. Hyaluronidases, which have been shown to increase activity during OA, break down HA chains into fragments [7]. Promoting *HAS2* expression has been shown to increase HA concentration [8], making synthase activity an ideal target for improving HA content. PRG4 is a vital component of synovial fluid, working to maintain its viscosity and to modulate cellular function [9], highlighting the need to improve PRG4 concentration within an OA joint.

Synoviocytes also modulate the inflammatory state within the synovial fluid. Chronic synovial inflammation is typically found in osteoarthritic joints, along with increased concentrations of pro-inflammatory cytokines, such as TNF-alpha, IL-6, IL-8, and IL-12, within the synovial fluid [10].

Mechanical stimulation, from exercise [11] to applied loading to cells [12], has been shown to alleviate OA symptoms, improve overall production of HA and other proteoglycans, and alter the expression of inflammatory molecules. The goal of our study is to determine the extent to which cyclic loading affects HA, PRG4, and cytokine content from synoviocytes. Our hypothesis is that high strain magnitudes will promote HA and PRG4 production and decrease pro-inflammatory cytokine secretion.

## METHODS

Human synovial sarcoma fibroblasts (SW982, ATCC) were cultured and seeded onto silicone membrane well-plates at a density of 3-4 x $10^4$ cells/cm$^2$. After 24h, cells were subjected to 0%, 5%, 10%, and 20% peak strain magnitude at a frequency of 1 Hz (sinusoidal waveform) for 3 hours using the Flexcell FX6000T Tension System (Figure 1). Cells were also plated on tissue culture plastic (TCP) as a control.

Four hours after the end of loading, media was removed and cell layers were lysed for RNA isolation. TaqMan®-based qRT-PCR was used to measure expression of *HAS1*, *HAS2*, *HAS3*, *HYAL1* (hyaluronidase 1), *HYAL2* (hyaluronidase 2), *CEMIP* (cell migration inducing hyaluronidase), *TMEM* (cell surface hyaluronidase), relative to *GAPDH*.

From separate wells, 24 hours after the end of loading, media was removed for HA and PRG4 concentration quantification using ELISA and cytokine concentration using a multiplex panel. Cell layers were fixed and stained for HA (HA binding protein with Alexa Fluor-488) and counterstained with DAPI.

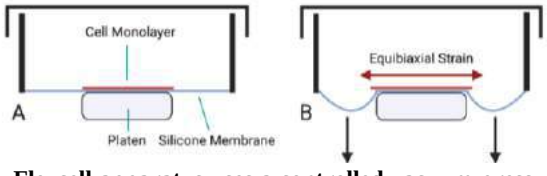

**Figure 1. Flexcell apparatus uses a controlled vacuum pressure to apply strain.** A) Cells are seeded onto a silicone membrane, B) which is stretched when subjected to a controlled loading parameter.

## RESULTS

Synoviocytes cultured on the silicone membranes had significantly lower *HYAL1* and *TMEM* expression when compared to cells cultured on TCP. Hyaluronan synthase gene expression was not significantly affected by substrate stiffness, and only *HAS3* expression was significantly different among the loaded groups (Figure 2). Cells strained to 20% strain showed higher *HAS3* ($p = 0.043$). 5% strain and 20% strain had significantly lower abundance of *HYAL1* and *HYAL2*. Cells strained to 10% strain had lower *HYAL2*, *TMEM* expression than 5% ($p = 0.01$) and 20% strain ($p = 0.003$).

All cyclic loading groups had lower HA concentration than the unloaded group, with the 5% strain group having the highest concentration among loaded groups (Table 1). Immunofluorescence imaging revealed that all stained HA was localized intracellularly. When comparing PRG4 concentrations of loaded groups, 5% strain resulted in a significant percent increase from the unloaded group (Table 1), while 10% and 20% strain decreased the amount of PRG4 in the conditioned media.

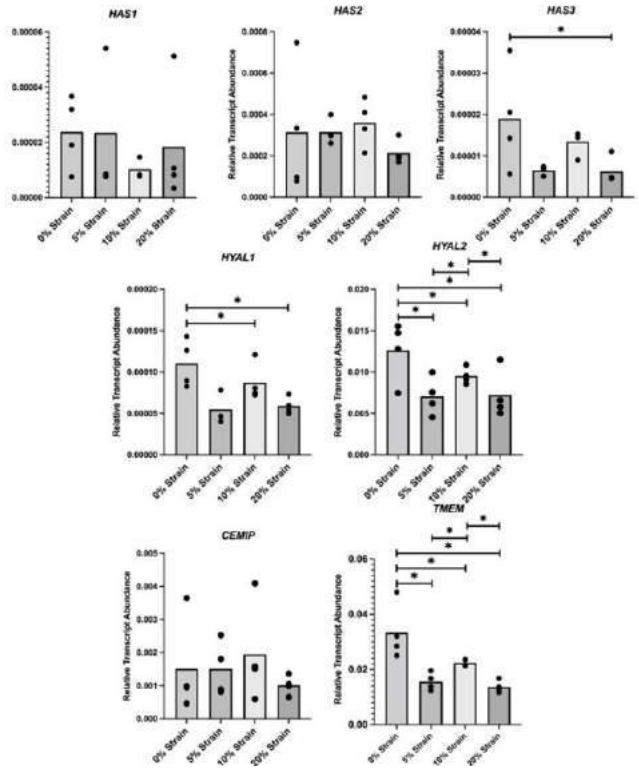

**Figure 2. Gene expression of hyaluronan turnover genes**. Relative transcript abundance measured as $2^{-\Delta Cq}$, where $\Delta Cq$ is the difference in quantification cycle from the gene of interest to *GAPDH*. Black circles represent replicates and significant difference (*, $p < 0.05$) between groups are shown with brackets.

**Table 1. Percent change concentrations of hyaluronan (HA) and PRG4 calculated against the 0% strain group**. Shown as mean ± standard deviation. Significance between groups shown by an asterisk ($p < 0.05$).

| | *HA Concentration* | *PRG4 Concentration* |
|---|---|---|
| **5% Strain** | -32.4% ± 0.09 | 26.3% ± 0.37 * |
| **10% Strain** | -11.1% ± 0.31 | -64.3% ± 0.20 * |
| **20% Strain** | -18.2% ± 0.15 | -38.2% ± 0.10 * |

Media from synoviocytes cultured on silicone membranes had significantly higher cytokine concentrations when compared to media from the TCP group. 5% strain had lower IL-5 concentration than 10% strain ($p = 0.035$), lower IP-10 concentrations than 0% ($p = 0.035$), 10% ($p = 0.030$) and 20% strain ($p = 0.005$) and RANTES concentrations than 10% ($p = 0.029$) and 20% strain ($p = 0.017$).

## DISCUSSION

Cyclic loading impacted HA turnover gene expression, decreasing *HAS3* and hyaluronidase expression. The softer silicone substrate stiffness also resulted in a hyaluronidase expression., and hyaluronidase expression was affected by substrate stiffness. However, strain magnitude did not demonstrate a consistent effect on HA turnover gene expression.

Previous studies have shown that static stretch of synoviocytes result in minimal changes to synthase expression [13], highlighting that cyclic loading impacts synoviocyte response differently that static stretch. However, changes to the expression of HA degrading enzymes have not been measured in previous mechanical stimulation studies. In this study, *HYAL1*, *HYAL2*, and *TMEM* expression was upregulated in a magnitude-dependent manner. This coincides with the reduction in overall HA concentration from the media and the presence of intracellular HA, which is indicative of HA reuptake and breakdown [14]. Cyclic tensile strain has been shown to depolymerize HA from chondrocytes, which supports the idea that cyclic strain may be increasing HA breakdown. 5% cyclic strain also increased PRG4 concentration in the media, consistent with studies that show cyclic compression increases PRG4 secretion in chondrocytes [15].

Cytokine concentration was sensitive to strain magnitude, with 5% strain reducing the concentration of pro-inflammatory markers, such as IL-5, IP-10, and RANTES, while 10% and 20% strain increased concentrations of these cytokines, compared to the unloaded group. Previous studies have shown that the effect of cyclic tensile strain affect cytokine production in synoviocytes is dependent on loading parameters, i.e. short-term or long-term exposure to stimulation [16, 17]. This variability suggests that cytokine production from synoviocytes is highly sensitive to changes in the mechanical environment, shown here by the significant increase in all cytokine concentration from culture on a silicone membrane and the sensitivity to strain magnitude.

Our data reveal that hyaluronidase expression and concentrations of HA, PRG4, and cytokines were sensitive to cyclic strain. Taken together, these results underscore the importance of mechanical stimulus of the synovium in regulating the joint environment.

## INTRODUCTION

Thoracic aortic aneurysms (TAAs) are bulging enlargements of the aorta. They affect approximately 15,000 people in the US per year and can be fatal in 80% of the cases when ruptured [1]. Studies have suggested genetic connective tissue disorders that affect extracellular matrix (ECM) proteins [2] as well as blood flow dynamics features, such as altered luminal pressure, wall shear stress, and intramural stress, are linked to the disease [3].

Blood fluid dynamics features have been correlated with aneurysm outcome[4]. However, computational models aortic growth and remodeling often simplify the hemodynamically-driven stress along the aorta [5]. This simplification can lead to inaccuracy in longitudinal and axial growth, since it doesn't account for inhomogeneous growth of the tissue resulting from inhomogeneous fluid stress fields.

We studied hemodynamically-driven heterogeneous growth in the aortic wall of *FBLN4*$^{SMKO}$ mice. To perform the study, we use a combination of subject-specific fluid-solid-interaction (FSI) models, longitudinal data obtained from medical scans during the mouse lifetime, and a local stress-driven growth model.

## METHODS

**Mouse models:** Mouse models with TAA caused by deletion of the ECM fibulin-4 gene in smooth muscle cells (*Fbln4$^{SMKO}$*) were used in the study. TAA growth in each animal was monitored throughout the early disease stages by magnetic resonance angiography (MRA). The scans were collected at two-, four- and six-months of age. After the mice died naturally or were sacrificed at roughly 24 months of age, biaxial tests were used to obtain material properties of the aortic tissues.

**FSI simulations:** MRA scans of mice at age 2 months were used to generate mouse-specific models via the SimVascular image processing features. The wall thickness was considered to be constant and based on experimental measurement. The aortic wall was described using the Holzapfel-Gasser-Ogden (HGO) model to account for anisotropic tissue mechanics; HGO parameters were specified for each mouse based on postmortem measurements. A Newtonian model (viscosity 3.5 cP) was used for the blood. A waveform from an earlier mouse study was used as inlet boundary condition [6] and was assumed to be the same for all mice. For the brachiocephalic, left common carotid, and left subclavian arteries, as well as for the outlet at the distal end of the aorta, windkessel models with values based on literature were used as boundary conditions [6]; the same windkessel parameters were used for all mice. Simulations were performed for ten cardiac cycles using SimVascular [7] at the Minnesota Supercomputer Institute (MSI).

**Local stress-driven growth model:** The local stress-driven growth was solved for each element in the finite element mesh. The growth model is based on that of Alford and Tabor [8]

$$\frac{\dot{\lambda_r}}{\lambda_r} = \frac{1}{T_r}\left(\frac{\sigma_r}{\widehat{\sigma_r}} - 1\right); i\frac{\dot{\lambda_\theta}}{\lambda_\theta} = \frac{1}{T_\theta}\left(\frac{\sigma_\theta}{\widehat{\sigma_\theta}} - 1\right) + \frac{1}{T_\tau}\left(\frac{\tau_w}{\widehat{\tau_w}}\right); i\frac{\dot{\lambda_a}}{\lambda_a} = \frac{1}{T_a}\left(\frac{\sigma_a}{\widehat{\sigma_a}} - 1\right) \quad (1)$$

where $\dot{\lambda}_i i\text{and}i\dot{\lambda}_i$ are the growth stretch rate and the stretch ratio respectively.$i\hat{\tau}_w$ is the target wall shear stress, $\tau_w$ is the hemodynamics-driven wall shear stress, $\widehat{\sigma_i}$ is the target stress, $\sigma_i$ is the hemodynamics-driven stress and $T_i$ is a time constant for i-direction (r, θ, z).

**Finite Element Growth:** Kinematic growth of the aorta was defined locally by a growth tensor $\mathbf{G}$=diag$(\lambda_r, \lambda_\theta, \lambda_z)$ at time relative to the reference state, t=T$_0$. For this study, T$_0$ was taken to be at 2 months and the geometry was prestressed during the FSI simulation to account for the residual stress from the initial growth. The macroscale change in the geometry is solved using *Prestrain* plugin [9] of *FEBio Studio* 3.5 [10].

**Model tuning and validation:** Time constants were based on longitudinal measurement of aortic diameter. Fig. 1 on the next page shows the validation and tuning scheme. The ascending aortic geometry (Fig. 1b) was extracted from MRA scans of 2 month-old mice (Fig. 1a). FSI simulation were performed on the extracted geometry, and von Mises stress distributions were calculated (Fig. 1c). A ring around the maximum diameter region was extracted from the full geometry (Fig. 1d), and the G&R model was solved (Fig 1e) by adjusting the time constants so radial growth matched the experimental trends (Fig 1f).

SB³C2022-068

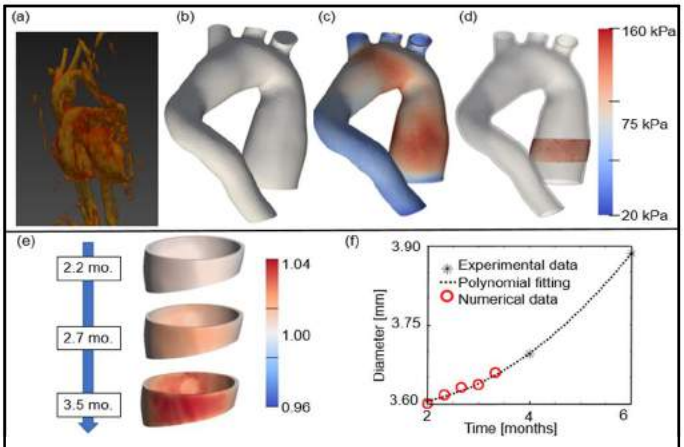

**Figure 1: (a)** MRA scans of *FBLN*$^{SMKO}$ mice taken at 2 month old**. (b)** 3D model generated from the scans. **(c)** von Mises stress distribution from the FSI simulations**. (d)** Aortic ring around the largest diameter region used to solve the **(e)** local growth or the aortic tissue and **(f)** validate the model based on the change in diameter over time.

## RESULTS

Five *FBLN4*$^{SMKO}$ mice were used for this study. Figure 2a below shows the *in vivo* change in the aortic diameter observed across 16 weeks. The data were fitted to a polynomial curve to obtain the growth trend between experimental data points. The inset of Figure 2a shows the changes in aortic diameter for the first few weeks obtained from the G&R model and compared against the experimental observations. The G&R model describes the initial radial growth process (from of 8 to 12 weeks) reasonably well for all the five models. Fig 2c shows the adjusted time constants for all five mice. As expected, smaller values of the radial and tangential time constants were observed for geometries with a larger growth in the first weeks.

Using the fitted time constants, the stress-driven G&R model was solved for full aortic geometry of two mice. The Von Mises stress was obtained from the mouse-specific FSI simulation, as shown on Fig. 3a and 3e. Figures 3b-3d and 3f to 3h display the computed growth along the aorta due to the inhomogeneous stress distribution. The growth process presents longitudinal and axial heterogeneity. As expected, more growth occurs in the ascending aorta.

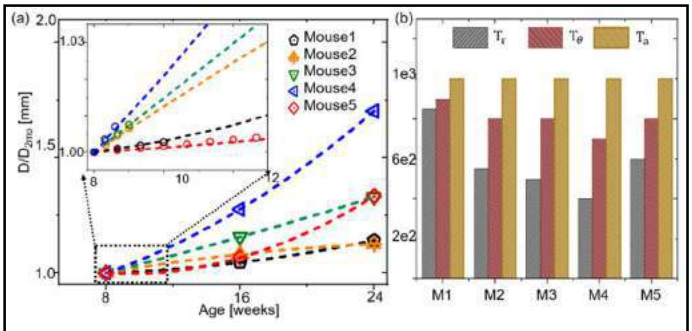

**Figure 2: (a)** Change in maximum aortic diameter for 5 *FBLN*$^{SMKO}$ mice models**.** Markers are measurements obtained from MRA scan and dashed lines are the polynomial fitting of the experimental. The inset figure shows the change in the diameter obtained from the G&R model (open circles) compared against the trend observed experimentally (dashed lines)**.** 3D model generated from the scans. **(b)** Time constants obtained from tuning the G&R model for each mouse model.

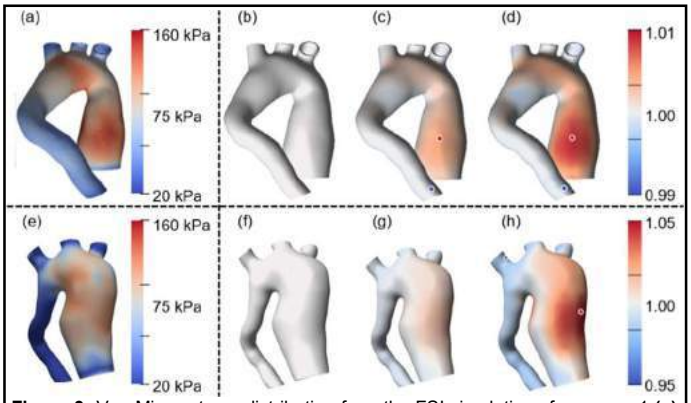

**Figure 3:** Von Mises stress distribution from the FSI simulations for mouse 1 **(a)** and mouse 4 **(e).** Total aortic growth driven by the stress distribution at **(a/f)** 1 weeks**, (b/g**) 2 weeks and **(d/h**) 4 weeks relative to the reference state.

## DISCUSSION

Five aortic models for Fbln4$^{SMKO}$ mice at the age of two months were created based on MRA. Mouse-specific material properties and wall thickness were combined with generic boundary conditions for blood flow in the FSI simulations. Results for von Mises stress were used as input to solve the local stress-driven G&R model. The G&R was compared to the trend of the change in diameter measured *in vivo*. The model qualitatively matched the experimentally observed radial growth for the first 3-12 weeks relative to the initial state.

Results for full aortic growth show substantial heterogeneity of the growth process along the length of the aorta, as a direct consequence of the inhomogeneous stress distribution along the aortic wall. Those results reinforce the importance of using anatomically realistic models, rather than simplified models, when a complex geometry such as the aorta is being considered.

The study is performed with only five mice and involved only two mouse model. Further analysis is necessary to determine additional limitations of the subject-specific growth model, and its translatability to human subject. Nevertheless, as it becomes more and more possible to acquire geometric and mechanical data from patients [11] and to do complex, detailed computer simulations, multi-physics models will provide new insight into growth and development of aneurysms.

# EFFECTS OF FISETIN ON TRIPLE NEGATIVE BREAST CANCER INVASION

**Jacob Heiss (1), Nina Treacher (1), Hossein Tavana (1)**

(1) Biomedical Engineering, The University of Akron, Akron, OH, USA

## INTRODUCTION

Triple negative breast cancer (TNBC) is a highly aggressive disease that often metastasizes to other organs [1]. Metastasis involves local invasion of cancer cells into the adjacent tissue to access circulation [2]. Although targeted therapies of cancers have increased the efficacy of treatments while reducing systemic toxicity, a lack of hormone receptors and HER2 amplification on TNBC cells significantly limits targeted therapies for this disease. Currently, chemotherapy is the mainstay treatment for TNBC. However, because chemotherapeutics are toxic to normal cells and do not prevent invasion of cancer cells, other treatment options are being explored. We report that fisetin, a naturally occurring plant flavanol, has anti-invasion properties blocks the extracellular matrix invasion of TNBC cells in a three-dimensional in vitro tumor model.

## METHODS

Four TNBC cell lines were used in this study: MDA-MB-231, SUM159, MDA-MB-157, and BT-549. Tumor spheroids were created from each cell line using an aqueous two-phase system cell patterning technology [3]. Each spheroid was encapsulated in 2.7 mg/ml human-derived type I collagen to simulate the extracellular matrix. Incubation resulted in the formation of a collagen hydrogel containing the spheroid. The spheroids were treated dose-dependently with fisetin in a concentration range of 0-200 μM. After sufficient invasion of cells under no treatment (three days for MDA-MB-231, SUM159, and MDA-MB-157, and six for SUM159), confocal microscopy was used to image cell invasion. For each dose and cell line combination, five spheroids were imaged in replicate. In order to see the cells with confocal microscopy, the MDA-MB-231 and SUM159 cell lines were transfected to stably produce a green fluorescent protein and the MDA-MB-157 and BT-549 cells were stained with a Calcein AM dye. Matrix invasion of cells was quantified by measuring the total pixel area of the invading cells from the collapsed z-stack image for each spheroid. The invading areas were used to create a dose-response curve and find the 50% inhibitory concentration (IC50) for each cell line.

## RESULTS

We selected a 2.7 mg/ml collagen concentration to give a stiffness of ~2.5 kPa to reproduce stiffness of human breast tumors [4]. While all four TNBC cell lines effectively invaded the collagen matrix under no treatment, fisetin significantly decreased the invasiveness of all four cell lines (Fig 1). Fisetin showed a maximum inhibition of TNBC invasiveness by 98%, 100%, 93%, and 100% for MDA-MB-231, SUM159, MDA-MB-157, and BT-549 cell lines, respectively. In addition, we found the IC50 value for each cell line to be 11.23 μM for MDA-MB-231, 40.57 μM for SUM159, 51.57 μM for MDA-MB-157, and 26.29 μM for BT-549 (Fig 2).

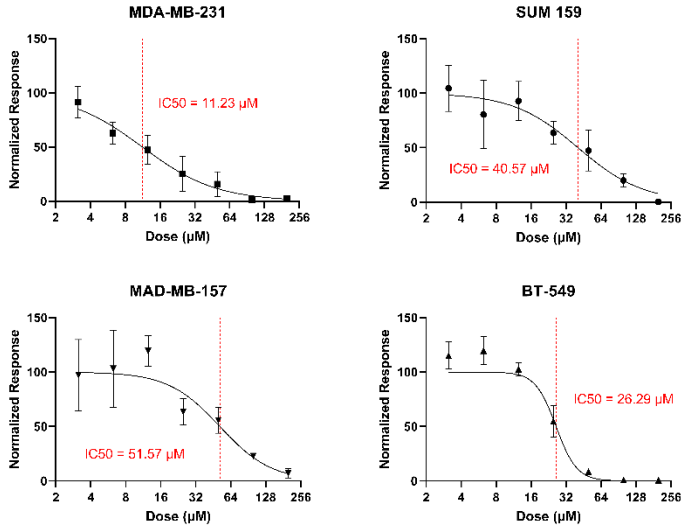

**Figure 2: Dose-response curves of fisetin treatment for each cell line. IC50 values marked in red.**

## DISCUSSION

We demonstrated that fisetin effectively reduces the matrix invasion of TNBC cells. This finding is consistent with a previous study from our group that fisetin interferes with signaling of PI3K/Akt and MAPK/ERK pathways, which are highly active in TNBC cells [5]. Our finding suggests that fisetin may provide additional benefits in treating TNBC. To further establish this finding, we plan to test this effectiveness of fisetin in more complex tumor models that contain other components of tumor stroma, such as cancer associated fibroblasts and critical matrix proteins in TNBC tumors such as hyaluronan and fibronectin, as well as in animal models.

## INTRODUCTION

3D tissue-engineered *in vitro* models, particularly multicellular tumor spheroids (MCTSs), are being increasingly used to explore disease progression and novel therapeutic strategies, especially for oncological applications. Once grown to 0.03-0.5mm$^3$ in volume, these avascular constructs begin mimicking several key aspects of *in vivo* tumors, such as 3D structure and pathophysiological gradients [1,2]. However, a lack of standardization of MCTS fabrication has led to a large variety of "spheroid" or "organoid" models, many of which are unable to achieve the necessary morphology (i.e., size, sphericity) for physiologically-representative behavior. This poses a particular challenge for drug-screening MCTS applications, where inaccurate models may overestimate the efficacy of a given drug. Indeed, improper screening models have already been implicated in the high percentage of investigated drugs that later fail in clinical trials [3].

Previously, our lab has used Optical Coherence Tomography (OCT), a non-destructive structural imaging modality, to assess 3D morphologies of MDA-MB-231 breast cancer MCTSs formed via liquid overlay, the current gold standard method of fabrication [4]. We demonstrated that in liquid overlay cultures the addition of Matrigel (solubilized basement membrane derived from mouse sarcoma) was required for the formation of 3D spheroids, even for cells that have an innate ability to self-aggregate [4]. In other work, we demonstrated the ability to form highly spherical aggregates, without requiring Matrigel, by growing these same cells in microcapsules [5,6]. Lastly, we have shown that the OCT-based technique used to assess model morphology can also accurately estimate cell density within these 3D aggregates, and provide a systematic and non-destructive measure of cell viability throughout aggregate growth, and in response to drug [4].

Herein, we non-destructively assess the differences in drug response between HER2+ tumor aggregate models created in microcapsules and those created via liquid overlay, highlighting the influence of morphology on model behavior and the importance of model selection for *in vitro* drug-screening applications.

## METHODS

Following established methods, cell-loaded microcapsules were prepared using electrostatic bead generation [7,8]. Briefly, AU565 HER2+ breast cancer cells (5e6 cells/mL) were suspended in 1.5% alginate (Sigma, #9005-38-3) and extruded into a 2% CaCl2 bath using an electrostatic droplet generator to form calcium alginate gel beads. The gel beads were incubated with 0.16% w/v chitosan (Spectrum MFG, C1569) to form alginate-chitosan membranes around each bead, and subsequently incubated with sodium citrate to chelate the alginate bead cores. This produced cell-loaded core-shelled capsules 300-350 µm in diameter. Cells began to aggregate after 14 days in culture, and formed spheroids matching the capsule diameter by 27 days. On day 27, matured spheroids were drugged with 50ug/mL Trastuzumab, a clinically-used chemotherapeutic, and cultured for 5 days.

Control aggregates were formed via liquid overlay (L.O.), the current gold standard method for aggregate production. Cells were seeded (2.5 x10$^4$ cells/well) in non-adherent U-shaped 96-well plates and cultured for 4 days either with or without the addition of 2.5% Matrigel [9]. On day 4, matured aggregates were drugged with 50ug/mL Trastuzumab and cultured for 5 days.

Following our previously published technique [4], 3D volume scans of full tumor aggregates were collected via OCT at key timepoints of 0h, 24h, and 120h (5d) post-drug addition. Imaris image analysis software was used to count the number of cell-sized objects present in each scan, which when normalized to the measured aggregate volume, provides a systematic estimation of cell density at each timepoint, ***within each aggregate*** throughout the drug timecourse. Statistical comparisons were made using Student's t-test, and data are shown as means ± SD, with $p < 0.05$ used as significance cutoff.

## RESULTS

Morphologically, aggregates grown with liquid overlay were quite flat, while those grown with the addition of Matrigel became thicker and more disk-like (**Figure 1A+B**). Sphericities for these samples were 0.34 ± 0.01 and 0.57 ± 0.03, respectively, (with 0 representing a plane and 1.0 a perfect sphere). Neither of these L.O. fabricated aggregates met the 0.8 cutoff characteristic of good tumor spheroid models [10]. However, those grown via microcapsule grew to be quite round (**Figure 1C**) with an average sphericity of 0.79 ± 0.09, ranging approximately at the cutoff value. Thus, spheroid shape for this cell line was rescued by growing these cells within capsules, which boast better size and shape control than liquid overlay, even in AU565 cells that have been reported to have little to no innate ability to self-aggregate.

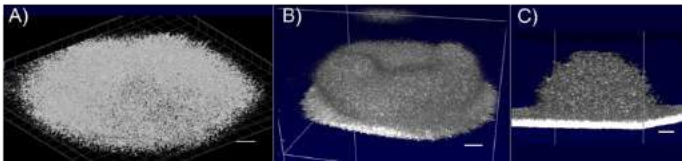

**Figure 1: Representative OCT volume scans of matured AU565 tumor aggregates fabricated via A) liquid overlay, B) liquid overlay with Matrigel, or C) microcapsule, highlighting differences in morphology. Scale bars = 100 µm.**

Cell aggregates exhibited increased drug resistance with greater model dimensionality; with more cell death observed in flatter aggregates than in the 3D spheroids (**Figure 2**). When treated with drug for 5 days, aggregates grown via liquid overlay saw a severe drop in the number of viable cells throughout the timecourse. The addition of Matrigel imparted a significant increase in drug resistance at both timepoints assessed, possibly due to the Matrigel itself or the increase in aggregate thickness. Of the models tested, capsule-based spheroids were most resistant to the drug, which was particularly evident at the final timepoint.

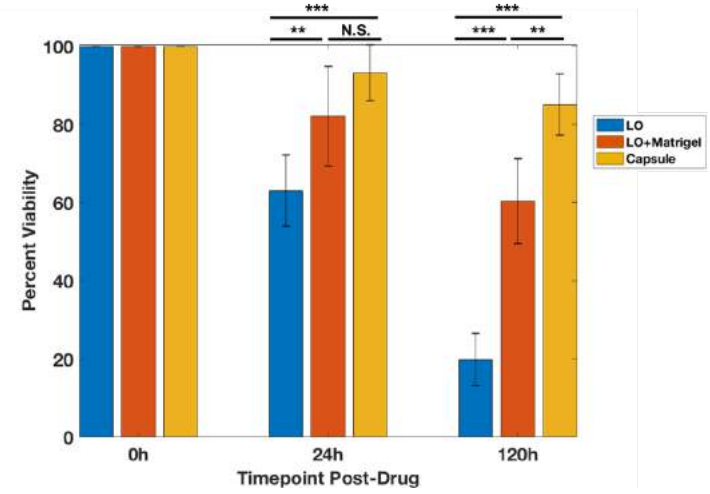

**Figure 2: Longitudinal quantification of tumor aggregate percent cell viability in response to anti-cancer drug indicates increased drug resistance in more spherical aggregates (L.O. n=6, capsule group n=3)(** = p < 0.001, *** = p < 0.0001).**

## DISCUSSION

Our goal was to quantify the drug response of a known chemo-therapeutic on HER2+ *in vitro* tumor aggregate models fabricated in core-shelled microcapsules and via liquid overlay with and without Matrigel, using our non-destructive, OCT-based approach to assess viability. Our data show that these different approaches produced AU565 aggregates of different dimensionality (2D, 2.5D, and 3D), and that cells grown to tumor spheroids within capsules (3D) are significantly more resistant to drug than those grown via the gold standard L.O. method, with (2.5D) or without (2D) Matrigel. Within the liquid overlay models, Matrigel addition increases aggregate thickness, which is expected to create larger diffusion gradients and thus limit the penetration of the drug into the aggregate, which may explain why these models were more resistant than those grown without Matrigel. This same reasoning could explain the even greater drug resistance observed in 3D capsule-based spheroids. Future work should also investigate possible shielding effects from the capsule wall, which may be further protecting the cells from the drug.

Given that *in vivo*-like gradient formation and drug response are functions of spheroid morphology, it is likely that 3D aggregates with high sphericities will provide much more accurate surrogates for drug discovery than their low-sphericity counterparts. Taken together, these findings emphasize the importance of using 3D models in drug-screening applications and demonstrate the utility of electrostatic bead generation for engineering 3D tumor spheroids, even in a cell line with little to no known ability to self-aggregate.

# A STUDY ON THE TRIAXIAL MECHANICAL PROPERTIES OF SILICONE ELASTOMERS FOR POTENTIAL USE AS A BRAIN TISSUE SURROGATE

**Ahsanul Torza (1), Johannes Weickenmeier (1)**

(1) Department of Mechanical Engineering
Stevens Institute of Technology
Hoboken, NJ, United States

## INTRODUCTION

Freshly isolated human tissue samples are difficult to obtain for several logistical and regulatory reasons [1]. Thus, researchers use animal models and elastomers to measure the mechanical response in various applications including traumatic brain injury, neurosurgical procedures, and mechanobiology experiments [2]. To ensure bio-fidelity in predicting behavior in either finite element or physical surrogate brain models, accurate material properties of the brain are necessary. Measurements of human and animal brain tissue properties have been recorded using various ex vivo methods. There is a significant discrepancy in reported property values due to differences in experimental parameters such as postmortem time, temperature sensitivity, and brain region [3].

The human brain is a nonlinearly elastic porous material and shows rate-dependent characteristics. This behavior can be attributed to interaction between interstitial fluid and the solid matrix of the tissue. As a result, brain deformations during trauma (fast rate), palpation (medium rate), and brain shift (slow rate) differ [4]. Hyperelastic constitutive models are currently used to express the mechanical behavior of brain materials under strain and are typically calibrated using data from a single deformation mode (compression, tension, or shear). It has been shown, however, that this approach is insufficient for materials whose strain-stress response varies significantly between deformation modes [5]. Therefore, constitutive models of brain behavior should include multiple deformation modes for optimal parameter calculation.

A wide range of artificial brain tissue simulants has been proposed in literature, including agarose, gelatin, hydrogels, and silicone elastomers. In recent years, Polydimethylsiloxane (PDMS Sylgard 184) has been proposed as the preferred surrogate brain material [4,6]. The stiffness of PDMS can be altered by adjusting the ratio of the base to the curing agent. However, it is unknown what is the optimal ratio to produce PDMS comparable to fresh human brains. Previous work aiming at determining a suitable mixing ratio is limited because their constitutive model parameters were calibrated based on only a single mode of deformation [4].

The purpose of this study is to assess and contrast mechanical properties of fixed bovine brains with silicone elastomers using the same experimental device and testing in 4 different deformation modes without altering the sample, enabling a direct comparison of the materials.

## METHODS

In soft materials such as the brain and PDMS, loads higher than a few hundred kilopascals (kPa) will cause irreversible damage [7]. To account for this, we developed a custom-built triaxial testing device (Fig. 1a) to measure forces experienced by soft materials. Three orthogonally arranged translational stages can displace the 2N load cell attached to a pin containing the test sample. To create the control and acquisition system, LabView was used. This system allows the number of cycles, distance traveled by each stage, and strain rate on each axis to be controlled independently.

It has been shown that PDMS at a ratio of 1:80 shows similar compression properties as fresh porcine brains [4]. On that account, we created PDMS in a custom-built aluminum mold with a varying ratio of 1:80, 1:100, and 1:120. Every PDMS ratio was prepared as follows: 30 minutes of mixing followed by one hour in a vacuum chamber to remove air bubbles, then two hours to cure in an incubating chamber at 100 degrees °C, and finally 24 hours of cooling before extraction.

7 cubic samples for each PDMS ratio and 7 bovine brain samples from different locations were prepared. Sample size was set to 5x5x5 mm and 1 loading-unloading cycle at 0.03 mm/s in compression, tension, and two shear directions were performed. Since brain tissue exhibits a different behavior during loading and unloading, both curves were averaged for each test (Fig 1b).

SB³C2022-071

The behavior of brain tissue is frequently modeled using Ogden model-based-hyperelastic constitutive equations [7]. In this case, the shear modulus μ and nonlinearity parameter α are material dependent parameters that were determined via a customized inverse finite element scheme (iFEM) implemented in ABAQUS and python, that simultaneously fitted all four deformation modes, see Fig 3a.

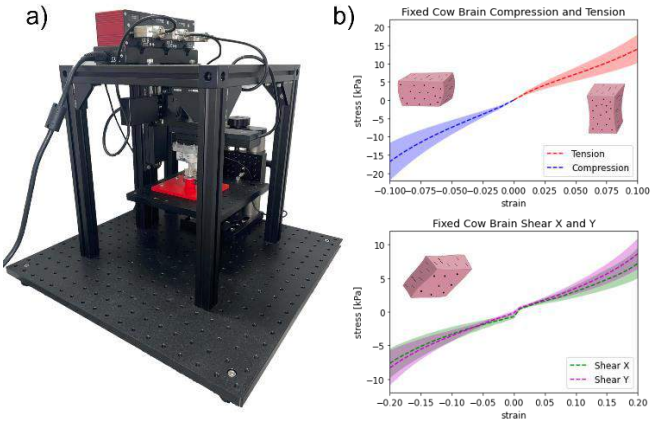

**Figure 1. a) Triaxial testing device. b) Standard deviation and mean of the average curves for 7 bovine brain samples under 4 deformation modes (compression, tension, shear x, and shear y)**

## RESULTS

For all three PDMS ratios, mean and standard deviation of the stress-strain curves were calculated for each mode of deformation (Fig. 2). The results show that the PDMS with a mixture ratio of 1:80 falls within the standard deviation of fixed cow brain behavior in all 4 modes of deformation. For increasing PDMS ratio, stiffness decreases, indicating a softer elastomer more closely representative of fresh brain stiffness. When tension is applied, both materials reach a lower stress level compared to compression. In addition, the shear stress values for both materials were similar in each respective strain directions.

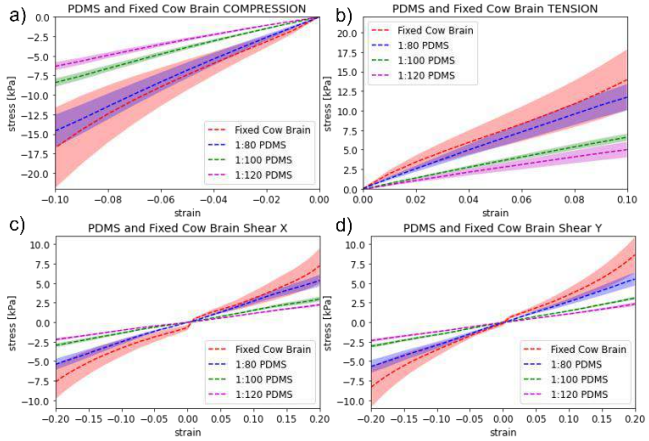

**Figure 2. Mean and standard deviation of seven PDMS with varying ratio and fixed bovine cubes in a) compression, b) tension, c) shear x, and d) shear y.**

Using the iFEM approach, model parameters were obtained by fitting against fixed brain data, see Fig 3b. Shear modulus and nonlinearity parameters describing the 4 deformation modes of the 1:80 PDMS and fixed bovine brain simulations differed by 4.86 kPa and 1.07, respectively.

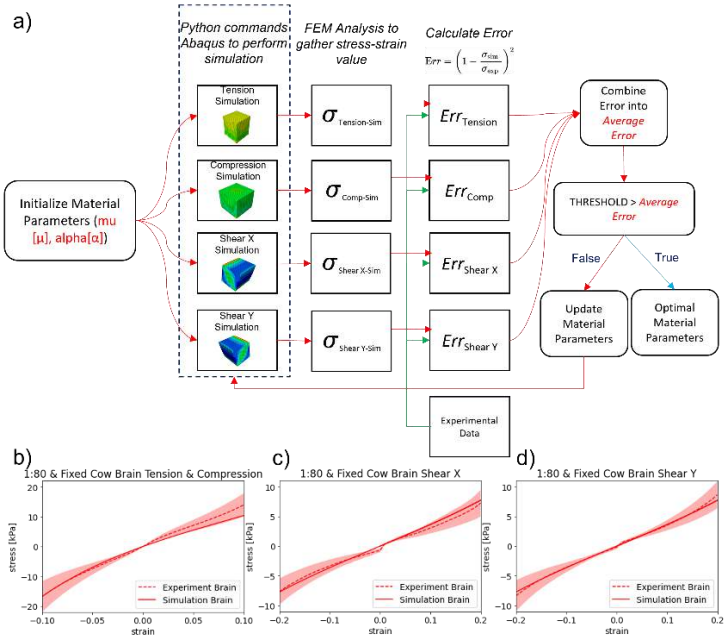

**Figure 3. a) Overview of inverse finite element model and b) plot of simulation and experiment of fixed bovine brain in compression and tension, c) shear x, d) shear y**

## DISCUSSION

Our triaxial testing device and iFEM results show that PDMS with a 1:80 mixture ratio has a similar stiffness to fixed bovine brain tissue. Furthermore, the iFEM provided a way to characterize the behavior of PDMS and fixed bovine brain in tension, compression, and shear with one set of parameters.

Our results for PDMS with ratio 1:80 differed from data reported in literature as they left their mold inside the over for 2 days, and they used 0.083 mm/s to test their material under compression [4]. A speed of 0.03 mm/s was used in our work to achieve a quasi-static process [7]. In an additional test, after curing PDMS 1:80 for 2 days, a significantly stiffer behavior was observed compared to fixed bovine brain tissue.

In this study, we demonstrate that the curing time, mixing ratio, and strain rate affect the mechanical response of PDMS, and that the Ogden model successfully reproduces the mechanical response of four different deformation modes with a single parameter set.

# APOE ε4 GENOTYPE DECREASES BARRIER FUNCTION AND GLUCOSE UPTAKE IN INDUCED PLURIPOTENT STEM CELL-DERIVED BRAIN MICROVASCULAR ENDOTHELIAL CELLS

## INTRODUCTION

5.8 million Americans have Alzheimer's disease (AD), and with the aging population, that number is predicted to triple by 2050. With no effective treatments to prevent or slow AD, it is currently the seventh leading cause of death in the United States [1]. The cause of AD is unknown, but people homozygous for the apolipoprotein E (APOE) ε4 allele have a more than 25 times higher odds ratio for AD compared to those with the ε3 or ε2 allele [2]. It is therefore essential to understand how the APOE ε4 allele contributes to AD development.

One of the first detectable AD biomarkers is brain glucose hypometabolism [3]. Glucose entry into the brain is modulated through the selective transporter GLUT-1 in brain microvascular endothelial cells (BMEC) [4]. BMEC GLUT-1 density is directly correlated with glucose uptake into the brain [5]. Isolated BMEC from transgenic APOE ε4 mice demonstrated decreased glucose flux through glycolysis compared to APOE ε3 cells [6]. However, BMEC from mice and humans are demonstrably different in their barrier function [7], [8], indicating that animal cells do not accurately recapitulate human cell function. The goal of this study was to determine how the APOE ε4 genotype affects barrier function and glucose uptake in a human BMEC model. We hypothesized that BMEC homozygous for the APOE ε4 genotype would demonstrate decreased glucose uptake and barrier function compared to APOE ε3 cells.

## METHODS

**CRISPR/Cas9:** IMR90 human induced pluripotent stem cells (iPSC) homozygous for the APOE ε3 genotype were dissociated from Matrigel-coated plates into a single cell suspension and combined with Cas9, sgRNA, ssODN, and a homology-directed repair enhancer. Cells were electroporated using a Neon system. Cells were replated, and CRISPR efficiency was evaluated using Sanger sequencing. Individual cell colonies were produced, and colonies determined to have the APOE ε4 genotype were expanded, along with unedited isogenic controls.

**Cell Culture:** APOE ε3 and APOE ε4 iPSC were maintained in mTESR-plus medium. Cells were differentiated into iPSC-BMEC following previously established protocols [8]. Briefly, cells were cultured in E6 medium for 4 days, then switched to human endothelial serum free medium (hESFM) supplemented with 50x B27, basic fibroblast growth factor (bFGF), and retinoic acid (RA) for 48 hours. Cells were then dissociated into single cells and replated on 6-well plates or glass coverslips coated with collagen IV and fibronectin in hESFM with B27, bFGF, and RA for another 24 hours. Finally, cells were switched to hESFM with B27 for experiments.

**Immunocytochemistry:** Tight junction proteins in iPSC-BMEC seeded on glass coverslips were analyzed by labeling with a primary antibody for the tight junction protein zonula occludin-1 (ZO-1) and Hoechst (nuclei). Cells were then imaged using a spinning disk confocal microscope (Nikon). Images were analyzed for continuous junctions, indicating barrier fidelity, using a junction analyzer program (JAnaP) [9]. GLUT1, the primary BMEC glucose transporter, was also labeled with a primary antibody and imaged by confocal microscopy. GLUT1 was quantified by analyzing fluorescent intensity using ImageJ and normalizing to the number of nuclei.

**Metabolic Analysis:** Following differentiation, iPSC-BMEC were seeded in 6-well plates and cultured for 2 days. At 0- and 24-hours following a medium change, 200 µL media aliquots were collected and analyzed for glucose and lactate concentration on a YSI 2950 Bioanalyzer. Glucose uptake, lactate production, and lactate-to-glucose ratio were then calculated.

**Statistical Analysis:** Statistical analyses were completed in GraphPad using a Mann-Whitney test, with $p < 0.05$ being significant.

## RESULTS

We first determined how the APOE genotype impacted iPSC-BMEC barrier function. Tight junction continuity, as measured by JAnaP analysis of ZO-1, was nearly 85% lower in iPSC-BMEC with the APOE ε4 genotype as compared to iPSC-BMEC with the APOE ε3

SB³C2022-073

genotype. GLUT1 fluorescence intensity also decreased by 22% in the APOE ε4 compared to APOE ε3 iPSC-BMEC (Fig. 1B).

To determine if decreased GLUT-1 correlated with reduced glucose uptake in APOE ε4 iPSC-BMEC, we analyzed media glucose and lactate concentrations with a YSI Bioanalyzer. Glucose uptake significantly decreased by 28% in APOE ε4 iPSC-BMEC compared to those with the APOE ε3 genotype (Fig. 2A). Interestingly, lactate production was similar between the cells regardless of genotype (Fig. 2A). The lactate:glucose ratio, which should be two if every glucose is metabolized to lactate via glycolysis, was slightly below two for the APOE ε3 iPSC-BMEC. However, the lactate:glucose ratio was above two for the APOE ε4 iPSC-BMEC (Fig. 2B).

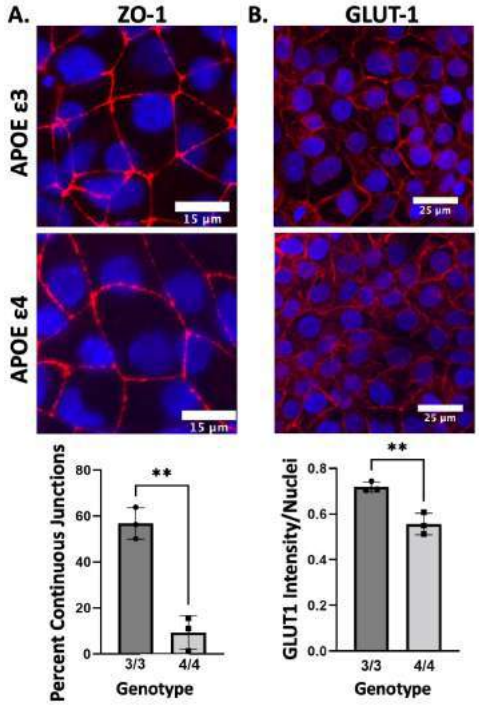

**Figure 1. APOE ε4 genotype decreased iPSC-BMEC tight junction continuity and GLUT1 compared to APOE ε3 genotype.** A. Representative confocal microscopy images of ZO-1 (red) and nuclei (blue) in APOE ε4 and APOE ε3 iPSC-BMEC. Quantification of continuous junctions by JAnaP. B. Representative confocal microscopy images of GLUT1 (red) and nuclei (blue) in APOE ε4 and APOE ε3. Fluorescent intensity analyzed using ImageJ. ** $p < 0.001$.

## DISCUSSION

We now show that the APOE ε4 allele decreases tight junction continuity and glucose uptake in iPSC-BMEC. Decreased ZO-1 continuity in APOE ε4 compared to APOE ε3 iPSC-BMEC likely contributes to decreased barrier function, which has also been observed via decreased trans-endothelial resistance (TEER) in immortalized BMEC from transgenic mice [6]. However, the effect of APOE ε4 had not yet been demonstrated in a human BMEC model, which has higher barrier strength than mouse BMEC. We will use JAnaP to further quantify barrier continuity of other BMEC tight junction proteins, including occludin and VE-cadherin [9]. We will also assess barrier function using TEER and a dextran permeability assay.

APOE ε4 iPSC-BMEC had decreased GLUT1 compared to APOE ε3 iPSC-BMEC, which correlated with decreased glucose uptake. This is congruent with research in immortalized BMEC from transgenic mice, in which APOE ε4 BMEC produced less ATP from glycolysis than APOE ε3 BMEC [6]. Interestingly, APOE ε4 iPSC-BMEC had similar levels of lactate production as APOE ε3 cells, despite their decreased glucose uptake. This could indicate that APOE ε3 iPSC-BMEC shunt more glucose into branch pathways of glycolysis such as the hexosamine biosynthesis pathway (HBP), thereby producing less lactate per glucose molecule. Since APOE ε4 iPSC-BMEC produce more than two lactate per glucose molecule, there must be another lactate source. This could indicate that APOE ε4 cells undergo increased rates of reductive carboxylation of glutamine, in which glutamine enters the TCA cycle and goes backwards through the TCA cycle to produce lactate (Fig. 2C). Alternatively, APOE ε4 cells may mobilize glucose stores such as glycogen to produce more lactate. In future experiments, we will investigate the fate of glucose and other metabolites in iPSC-BMEC by metabolic mass spectrometry. We will also measure metabolite transport by culturing iPSC-BMEC on Transwell filters to demonstrate how APOE genotype alters glucose transport.

Overall, these experiments give novel insight into how the APOE ε4 genotype decreases BMEC tight junction continuity and glucose uptake in a human derived BMEC model, which could inform how the APOE allele contributes to AD development via cerebral glucose hypometabolism.

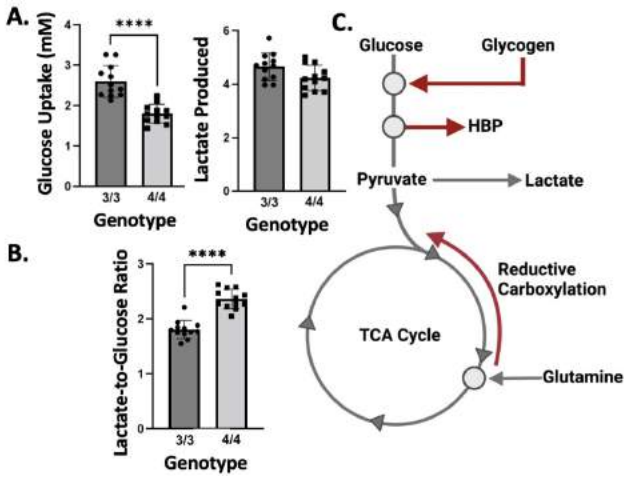

**Figure 2. APOE ε4 iPSC-BMEC took up less glucose but produced similar amounts of lactate compared to APOE ε3 iPSC-BMEC.** A. Glucose and lactate concentrations were measured in the cell culture media at 0 and 24 hours by YSI bioanalyzer. B. Lactate-to-glucose ratio calculated from glucose and lactate concentrations. C. Metabolic pathways that may contribute to altered lactate:glucose ratios. **** $p < 0.00001$.

## INTRODUCTION

Excessive deposition of fibrillar collagens is associated with a wide range of diseases including cancer[1] and fibrosis, cardiovascular[2], lung[3], eye[4] and age-related diseases. In all these diseases, it is becoming increasingly apparent that collagen deposition is not merely a byproduct of disease progression, but an important factor that drives disease progression[5]. Thus far attempts to restore collagen homeostasis have focused on genetic and molecular signaling pathways that regulate collagen synthesis[6]. However, in addition to these, there are *mechanical* factors that can play a crucial role in driving fibrosis. One such factor that has not received much attention is the force-dependent inhibition of the collagenase enzymes that degrade collagen[7,8].

In healthy tissue, collagen is maintained in a homeostatic balance between processes that regulate production and organization of collagen and the activity of collagenase enzymes and their inhibitors that regulate collagen degradation. This homeostatic balance can be disrupted in disease, especially in inflammatory environments. The resulting changes in the composition and mechanics of the local extracellular environment are sensed by cells, causing them to switch their physical connections from cell-cell contacts to integrin-based cell-matrix contacts[9,10]. This switch in connectivity increases the strain on the collagen fibers within the extracellular matrix, slowing down the rate of collagen degradation. Collagen deposition also causes an increase in matrix stiffness which can increase the force that cells exert on the collagen fibers, leading to a further decrease in the rate of collagen degradation. Thus, the force-dependent inhibition of collagenase is a critical factor that can create a detrimental, self-sustaining feedback loop that promotes more collagen deposition and disease progression.

Here we report that the force-dependence of collagen fiber degradation can be overcome using macrophages and a milk fat protein Mfge8. We show that in contrast to collagenase, tensile strain on collagen fibers accelerates the degradation of fibrillar collagen by macrophages and Mfge8.

## METHODS

Collagen degradation was quantified as the normalized change in the stiffness of collagen gels over time. To measure stiffness, gels were mounted on a dual-mode lever arm force transducer system capable of stretching gels uniaxially. First, gels were preconditioned using five triangular displacement stretch-relaxation cycles with a maximum displacement of 2.2mm to eliminate viscoelastic effects, then baseline force-length measurements were collected (t=0 min). Stress-strain curves were generated by dividing force output during stretch by the cross-sectional area of each gel to obtain stress and dividing the displacement of the gel by the initial gel length to obtain strain. Stiffness was reported as the Young's modulus of gels measured at 6% strain. For collagenase experiments, collagen gels were held at either 0% strain or 7.5% strain during 45 minutes of treatment with bacterial collagenase (*Clostridium histolyticum*, 34 μg/ml, pH = 7.4). Stiffness was measured every 15 minutes and normalized by the stiffness of each gel at baseline prior to the addition of collagenase.

To measure collagen degradation by macrophages, MH-S murine alveolar macrophages were treated with 0.25 μg/ml lipopolysaccharide (LPS) and 10 μg/ml recombinant human Mfge8 protein and incubated with collagen gels at a density of 200,000 cells/gel for up to 1 hour. Experiments were performed within custom 3D-printed collagen stretcher devices that were designed to hold collagen gels stretched during incubation with macrophages. After incubation, gels were removed from the devices and stiffness measurements were collected. At each time point, degradation was quantified as the stiffness of gels incubated with macrophages normalized by the stiffness of control gels incubated under the same conditions without any macrophages present. To inhibit force in macrophages, cells were pretreated with the Rho-associated kinase (ROCK) inhibitor Y-27632 at 100 μM for 1 hour. After 1 hour of pretreatment, macrophages were incubated with collagen gels for 1 hour in the stretcher devices in the presence of Mfge8, LPS, and 100 μM Y-27632.

SB³C2022-075

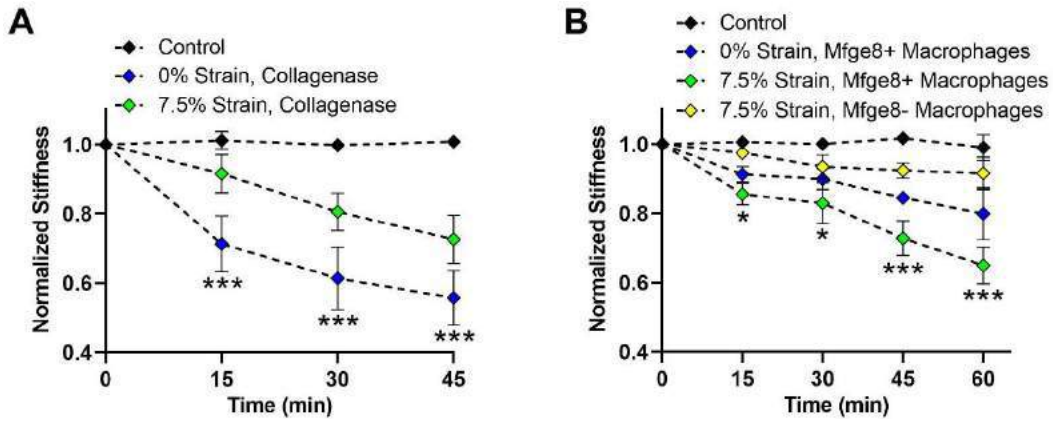

**Fig. 1 - (A) Normalized stiffness over time for untreated control gels (black, N=5), gels held at 0% strain during collagenase treatment (blue, N=6), and gels held at 7.5% strain during collagenase treatment (green, N=6). (B) Normalized stiffness over time for untreated control gels (black diamonds, N≥3), gels held at 0% strain during incubation with Mfge8-treated macrophages (green, N≥5), gels held at 7.5% strain during incubation with untreated macrophages (yellow, N≥4), and gels held at 7.5% strain during incubation with Mfge8-treated macrophages (blue, N≥5). Statistical significance is represented by (*) for P<0.05, (**) for P<0.01, and (***) for P<0.001.**

## RESULTS

***Tensile strain on collagen fibers inhibits degradation by collagenase enzymes, but accelerates degradation by macrophages and Mfge8:***

**Figure 1A** shows the change in normalized stiffness over time for untreated control gels (black), gels held at 0% strain (blue), and gels held at 7.5% strain (green) during collagenase treatment. A two-way ANOVA test with time and strain as the independent factors confirmed that time and strain both had a significant effect on normalized gel stiffness (time: P<0.001, strain: P<0.001), and the effect of time was dependent on whether strain was present (P<0.001). Unstrained gels experienced a significantly larger decrease in normalized stiffness compared to gels held at 7.5% strain during collagenase treatment at every time point (Tukey test, 15 min: P<0.001, 30 min: P<0.001, 45 min: P<0.001, **Fig. 1A**). This was an expected result, since evidence demonstrating the strain-dependence of collagenase activity has been previously demonstrated[7,8]. Although the strain-dependence of collagenase activity has been previously reported, the effect of strain on the degradation of fibrillar collagen by macrophages has not been explored. Here, we applied strain to collagen gels during incubation with macrophages treated with Mfge8 and measured the change in gel stiffness over the course of 1 hour. **Figure 1B** displays the results from these experiments, where the normalized stiffness of gels from each treatment group are displayed as a function of time. A two-way ANOVA analysis with time and strain as the independent factors revealed that time and strain both significantly affected normalized gel stiffness (time: P<0.001, strain: P<0.001), and the effect of time was dependent on whether strain was present (P = 0.002). At every time point, collagen gels held under tension experienced a larger decrease in gel stiffness after incubation with Mfge8-treated macrophages (Tukey test, 15 min: P=0.034, 30 min: P=0.015, 45 min: P<0.001, 60 min: P<0.001, **Fig. 1B**).

***Cytoskeletal tension is necessary for macrophages to degrade strained collagen fibers:***

Our experiments using Mfge8-treated macrophages to degrade collagen fibers under tension revealed that strain within collagen networks led to a higher degree of degradation by macrophages, which directly contrasts the results of our experiments using collagenase. Based on this finding, we hypothesized that if the degradation of fibrillar collagen by Mfge8-treated macrophages is enhanced when force is applied to collagen fibers, then eliminating the ability of macrophages to generate force should diminish the effect of strain on collagen degradation. To test this hypothesis, we incubated Mfge8-treated macrophages with strained collagen gels for 1 hour in the presence of 100μM of the ROCK inhibitor Y-27632. Y-27632 reduces force generation in cells by inhibiting myosin light chain phosphorylation and removing ROCK-mediated inhibition of myosin light chain phosphatase[11]. The results from this experiment revealed that incubating Mfge8-treated macrophages with Y-27632 diminished the effect of strain on gel stiffness after 1 hour (Mann-Whitney Rank Sum test, P=0.005, N=8).

## DISCUSSION

Degrading excess collagen deposited in fibrotic tissue is challenging due to the strain-dependent inhibition of collagenase enzymes that degrade fibrillar collagen. In this study, we show that macrophages can degrade strained collagen fibers in the presence of the milk fat protein Mfge8. Further, we demonstrate that the force-dependence of collagen fiber degradation is reversed in the case of Mfge8 and macrophages, with strain accelerating the degradation of fibrillar collagen. We conclude that if macrophage degradation of collagen is enhanced by the presence of force, the combination of Mfge8 and macrophages could serve as a potential therapy to counteract pathological collagen remodeling in fibrosis.

## INTRODUCTION

Myocardial infarction (MI) is one of the most common cardiovascular diseases and results in damaged cardiac tissue. The limited healing capacity, specific fibrillar structure and the electrical conduction of the adult cardiac tissue make the damaged myocardium regeneration one of the most challenging topics in regenerative medicine. Tissue-engineered cardiac patches have great potential as a therapeutic treatment for MI. However, heart regeneration through patches is still limited, due to electromechanical coupling and resemblance with the heart tissue, and high durability of the patch.

Many studies have focused on assessing the effect of the patches on the damaged tissue by evaluating the promotion of angiomyogenesis, through reduction of the scar tissue size, and improvement of cardiac functions [1]. Yet, the mutual interaction of cardiac patches with the healthy tissues has not been completely explored, which is crucial to understand in order to enhance the therapeutic effect of cardiac patches.

Here, we investigated the impact of the cell-free or cellular patch on the healthy beating tissue underneath, as well as the effect of this beating tissue on the cells encapsulated in the patch. As the cell source, we used human induced pluripotent stem cells (hiPSCs)-derived cardiomyocytes (iCMs), which have recently become an attractive therapeutic solution to replace the lost cardiac tissue [2]. In this study our aim is to 1) investigate the effect of placing the cell-free patch on the beating and phenotypical characteristics of the underlying iCMs (the beating tissue), 2) encapsulate iCMs in the patch and observe their effect on the beating tissue, 3) create a numerical model to understand the effect of cyclic contraction and relaxation (cardiac cycle) of the beating tissue on the patch, and 4) investigate the consequences of this cardiac cycle on the encapsulated iCMs in the cardiac patch.

## METHODS

hiPSCs were differentiated to iCMs following a well-established protocol [3]. iCMs seeded on 12 mm glass coverslips were used as the underlying healthy beating tissue. Gel patches were prepared from a solution containing gelatin methacryloyl (GelMA) (10%) and visible light photoinitiators, ruthenium, and sodium persulfate (2%) in PBS. To test the effect of cell-free patch on the beating tissue, a 7 mm ring-shaped polydimethylsiloxane (PDMS) mold was placed on the healthy tissue and GelMA solution (17 µL) was placed in the mold, crosslinked using visible light (3s), and further crosslinked enzymatically using microbial transglutaminase (8 % *w/v* in cell culture media, 30 mins at 37 °C). To observe the effect of the cellular patch on the healthy tissue, iCMs were mixed with GelMA solution (40 mil/mL) prior to placing on top of the beating tissue and crosslinking the gel. To test the effect of the beating healthy tissue on the encapsulated iCMs, a dynamic cell culture model was created by placing the cellular patch on the beating tissue. To prepare the static cell culture model, cellular patches, were placed on non-beating iCMs on 12 mm glass coverslips. The samples were kept for 7 days or 21 days in culture before doing any experiments with media changes every 3 days. Immunostaining was performed by following the manufacturer's instructions and the samples were stained for sarcomeric alpha-actinin. Sarcomere length was then quantified using ImageJ. For beating characterization, brightfield videos were taken and analyzed using an in-house MATLAB code adapting a block-matching algorithm to identify the beating velocity and frequency. To study the effect of the contraction of the beating tissue on the gel deflection, a simple numerical model was created using COMSOL Multiphysics. The force applied by the beating tissue on the gel when contracted was measured using a nano-indenter through dwell experiments.

For the synchronization analysis of the patch and the healthy tissue, the $Ca^{2+}$ flux staining was performed, and videos were taken at the boundary of underlying beating iCMs and cellular patch on top while keeping the focus on the underlying beating cells. The videos were then analyzed using a custom-made MATLAB code. The mean ± standard deviation was reported. The student's t-test was used to find any

SB³C2022-076

statistically significant differences and $p<0.05$ was considered statistically significant.

## RESULTS

When the cell-free patch was placed on the beating tissue, the sarcomere length of the underlying iCMs increased significantly ($p = 0.0014$), while the beating velocity and frequency decreased ($p = 0.0010053$ and non-significant respectively) (**Figure 1**). On the other hand, when iCMs were encapsulated in the patch, the beating velocity and the frequency of the underlying healthy tissue increased to a healthy beating velocity (8 µm/s) and frequency (0.67 Hz) level of iCMs which has been previously reported [4] (**Figure 2**). A numerical model was used to understand the deformation exerted by the contraction of the healthy beating tissue on the cell-free gel placed on top as a patch. When the underlying iCMs contracted, the total displacement of the patch was 850 µm on the bottom surface of the gel, and 94.6 µm on the top surface (data not shown). The maximum total displacement measured at the bottom surface corresponds to an approximately 12% strain. Experimentally, using a video showing the deflection of the patch, the difference between the contracted and the relaxed gel was measured, and the strain was calculated as 12.5%, validating the numerical model. When the cellular patches were placed on the healthy beating tissue, the beating velocity and the frequency of the encapsulated cells improved compared to patches in static condition on both day 7 and day 21 ($p < 0.01$ for day 21 frequency result) (**Figure 3**). The $Ca^{+2}$ transient profiles revealed synchronized beating of the iCMs encapsulated in the patch and the healthy beating tissue underneath, which is crucial for gel-healthy tissue integration (**Figure 4**).

(A) A representative snapshot from calcium flux time-lapse recording (the image was divided into 16 groups and each group was represented with a different color), (B) $Ca^{2+}$ transient profile of each designated group as extracted from these time-lapse recordings.

## DISCUSSION

Although, placing the cell-free patch on the healthy tissue had an adverse effect on the beating characteristics of the underlying healthy tissue, encapsulating iCMs in the patch improved these characteristics. This observation is in parallel with the findings from the literature [5] and most likely resulting from the released secretion and the beating of the encapsulated iCMs. We hypothesized that the cyclic deformation caused by the healthy beating tissue on the patch would result in the maturation of the encapsulated iCMs. We observed some improvement in the beating characteristics; however, the change was not significant. The strength of this paper is to evaluate each aspect of the patch and healthy tissue separately while also investigating the patch-tissue integration. One limitation of this paper may be focusing only on the relation of the patch with beating heart tissue and not having scar tissue.

## INTRODUCTION

Neck pain is a leading cause of activity limitation and years lived with disabilities [1]. Many sources for neck pain have been recognized, including the highly innervated facet capsular ligament (FCL) [2]. To understand the FCL's role in neck pain, the interactions between the FCL and other spinal components must be examined. One approach is to develop a finite element (FE) model of the cervical spine segment, simulating the motion segment and its components' behaviors under physiological loading conditions. This approach can be particularly attractive when patient anatomical and kinematic data are available.

The goal of this study was to develop and demonstrate a method to create 3D subject-specific models of the lower cervical spine (C4-C7), with focus on FCL biomechanics. This model incorporates spine geometry and replicates individual vertebral kinematics.

## METHODS

In this study, a kinematically-driven, subject-specific model of a healthy 23-year-old female's cervical FCL was developed and simulated in FEBio Studio [3]. The geometries of C4–C7 vertebrae were created by segmenting the skeletal surfaces out from the Computed Tomography (CT) scans (0.22x0.22x0.6 mm; 1.8 mSv; Siemens AG, Munich, Germany) of the participant's cervical spine. The FCL geometries were generated by morphing an existing FCL model [4] to the extracted facet joint geometry following [5].

The fiber structures and material characteristics of the tissue were extracted from available cervical FCL data [6–8] and were incorporated in a hybrid multiscale model [9] to generate fiber characteristics that are subsequently used in FEBio to define tissue material.

To generate kinematic data for the FE model, the participant performed flexion-extension, axial rotation, and lateral bending (three trials each) during biplane videoradiography acquisition (160mA, 70kV, 30Hz, 0.32mSv/trial). Undistortion (DSX Suite, C-Motion Inc., USA) and calibration [10] were completed, and volumetric shape-matching was performed for levels C4-C7 [11]. Data were filtered with a moving average filter and relative kinematics were extracted (Kinematics Toolbox v4.0, Becky Lawrence, PT, PhD).

### *3D volumetric mesh of vertebral bodies*

The CT image stack was imported into an image processing software (Materialise Mimics, v23, Materialise NV, Belgian) and the 3D vertebral shells of C4-C7 were segmented out using an automatic threshold mask based on pixel intensity, followed by manual refinement. The resulting 3D surface meshes (triangle with 3 nodes – tri3) were created and exported in the stereolithography (STL) format using a custom MATLAB program which ensures retaining the same coordinate system between the extracted geometries and the shape-matching images. The 3D surface meshes were then re-meshed (4 nodes tetrahedral – tet4) in Materialise 3-Matic (v15, Materialise NV, Belgian) to construct volumetric geometries of the cervical vertebrae. The 3D volumetric meshes of vertebral bodies were imported into the FEBio Studio software as rigid bodies (Fig.1 on next page).

### *3D geometry of FCLs*

Extraction of FCL geometry from participants *in vivo* is not feasible. Therefore, we used Zarei et al.'s method [5] to morph an existing L3-L4 FCL geometry [4] (Fig. 1a) onto the facet joint areas of our model. Briefly, the area that FCL attaches to the joint's bones on the new model (Fig. 1b) were picked such that they match the corresponding insertion regions on the available micro-CT geometry. Then a set of linear equations was solved to map every point on the reference geometry (micro-CT) to its corresponding node on the target geometry (new geometry) (Fig. 1c-i). The insertion points on the bones were used as known boundary conditions to solve these equations. Then, a re-meshing technique [12] was used to generate high quality 4-node quadrilateral (quad4) elements (Fig. 1j). Finally, the new surface mesh was extruded to an average thickness of $0.42 \pm 0.07$ mm (mean $\pm$ std) for cervical FCL [8] to generate a volumetric 8-node hexahedron (hex8) mesh for each FCL (Fig. 1k).

***Fiber structures and material properties for FCLs***

The cervical FCL is a collagenous tissue with high spatial heterogeneity in its collagen organization [8]. To incorporate fiber heterogeneity into our continuum FE model, we used a hybrid method [9]. First, a set of previously inferred fiber structures from quantitative polarized light imaging (Fig. 2a) [6,7] was used to generate fiber alignment maps and morph them onto the FCL surface mesh (Fig. 2c) [5,13]. Next, structural information for each finite element was used to generate a 3D Delaunay network in MATLAB (R2019a, MathWorks, Natick, MA) to serve as a representative volume element (RVE). Additional details on network generation and its governing equations are available in [14]. Each RVE network then underwent the network-to-continuum scheme that was described in [9] to calculate the fiber parameters for a three-orthogonal-fiber-family strain energy density function for that network. This fiber-based strain energy density function was combined with a neo-Hookean ground matrix in FEBio to form a coupled solid mixture material for each element (Fig. 2d).

***Loading and boundary conditions***

Prescribed displacements were applied to the bone geometries to mimic the kinematics extracted from biplane videoradiography. To simulate each motion in FEBio, the C7 vertebra was held fixed and the relative motions of C4-C6 vertebrae were calculated with respect to it. Since FEBio defines the rotation of a rigid body in terms of quaternion angles, the relative Euler angles measured for each vertebral body were converted to their corresponding quaternion angles and imported into FEBio as load curves. The FCL-bone attachment areas were defined as tied connections controlled by the bone motion.

## RESULTS

We demonstrated a successful implementation of this method to generate nine 3D, subject-specific FE models of a healthy 23-year-old female's cervical spine and simulated them in axial rotation, flexion-extension, and lateral bending motions to calculate the stress field over the FCLs. Fig. 3a, b shows the average of von Mises stress and the average of the top one percent von Mises stress over the FCLs when the head is in its ultimate position in these motions. Error bars in this figure represent the range of von Mises stresses across three trials for each motion. Fig 3c is a representative image of the von Mises stress distribution in left FCLs and vertebrae position for extension.

As can be seen in Fig. 3a, b, the results were, as expected, roughly symmetric between the right and left sides (e.g., the stresses in the C4-C5 and C5-C6 FCLs were high in ipsilateral axial rotation), but some differences were also observed (the von Mises stress was higher on the left C4-C5 FCL for both left and right lateral bending), and there was an asymmetry in the flexion-extension response, with larger stresses on the left side.

## DISCUSSION

The primary limitations of the proposed approach stem from the fact that FCL fiber organization and geometry cannot be captured accurately with available imaging technologies. To address these limitations, we rely on *ex vivo* structural data from literature along with the fact that the FCL encapsulates the facet joint and must conform to joint geometry, which is reliably derived from CT. Nevertheless, it is clear that there are significant individual differences that cannot be measured *in vivo* at present.

Despite these limitations, the current study provides a methodology to create a subject-specific model of the cervical FCLs (C4-C7) and can investigate various clinical questions by coupling experimental kinematics with multiscale computational models.

## INTRODUCTION

Many painful and physically debilitating conditions involve sub-failure mechanical damage to seemingly intact connective tissues such as tendons and ligaments. We found that the amount of denatured collagen in rat tail tendon (RTT) fascicles increased over experiments of cyclic loading to a constant load level (creep cyclic fatigue) with fluorescently tagged collagen hybridizing peptides (CHPs) that bind to denatured collagen (Fig. 1A). The results for collagen denaturation during the cyclic loading of tendons combined with CHP staining provides us with valuable information to formulate constitutive models that predict sub-failure damage in tendons through the mechanism of collagen molecular damage.

Therefore, the objective of this study was to develop, implement, and test the ability of a new CDM that produces the sub-failure damage behavior seen in our RTT fascicle creep cyclic fatigue loading data. The damage model was designed to predict the specific damage mechanisms seen in our experimental creep cyclic fatigue stress-strain data collected by Zitnay et al. (Fig. 1B) [1]. It encompasses a modified version of the combination discontinuous and continuous damage model presented originally by Balzani et al. [2], convolved with the elastic undamaged material used to describe a tendon material. The damage formulation was accurately able to capture the sub-failure damage accumulation seen in the creep cyclic fatigue and provide predictions for other loading scenarios.

## METHODS

The constitutive model in the present study was created to describe the two softening mechanisms seen in our stress-strain creep cyclic fatigue experimental data (Fig. 1B) conducted by Zitnay et al. [1]. During the experiment, 6 month old rat tail tendon (RTT) fascicles were fatigue loaded to 40% of their UTS at 0.4, 4, or 40% $s^{-1}$ until failure (Fig. 1A) [1]. We plotted and analyzed the stress-strain data from the 0.4% $s^{-1}$ experiments and characterized the damage behavior through two mechanisms. The first mechanism during this experiment was defined as the preconditioning effect in which the fibers in the RTT fascicle completely straightened out from their crimped formation (Fig. 1B, 1). The second mechanism was characterized as collagen damage (Fig. 1B, 2). The collagen damage is thought to have occurred over the entire experiment, however, it has a small contribution up until the fibers become un-crimped and are able sustain their maximum load.

In our finite element (FE) models, the RTT fascicle undamaged elastic constitutive material was composed of a matrix and fibers described by the Coupled Veronda-Westmann and exponential-linear materials within our finite element program, FEBio. This undamaged elastic material was convolved with a modified CDM model adapted from Balzani et al. [2]. Specifically, the internal damage variable $D$ scaled the initial strain energy of the fibers $\Psi_f^0$, while the stress free configuration $c$ was subtracted off to shift the stress strain curve to the right for increasing cycles:

$$\Psi_f = (1-D)\Psi_f^0 - c \text{ with } c = \Psi_f^0\left(\boldsymbol{C} = \boldsymbol{I}\right), \quad (1)$$

where $\boldsymbol{C}$ is the right Cauchy Green deformation tensor (a function of the deformation gradient $\boldsymbol{F}$).

The novelty of the Balzani damage model is the inclusion of two interrelated mechanisms described as continuous and discontinuous damage. The continuous damage formulation accumulated damage in the loading and reloading portion of each cycle. It was mathematically described as the change in the undamaged effective strain energy of the fibers over time:

$$\beta = \left\langle \tilde{\beta} - \tilde{\beta}^{ini} \right\rangle, \quad \tilde{\beta} = \int_0^t \left\langle \dot{\Psi}_f^0(s) \right\rangle ds \cdot \quad (2)$$

Here the internal variable $\beta$ is the measure of the continuous damage function and $\tilde{\beta}_{ini}$ is the value of $\tilde{\beta}$ at the initial damage state to ensure the damage evolution only begins to accumulate when the strain energy

increases above its initial state. The variable $t$ is the time associated with the current loading situation, while the variable $s$ is the time associated with the loading history, where $t \in \mathbb{R}^+$ and $s \in \mathbb{R}^+$. On the other hand, the discontinuous damage function accumulated damage based on the maximum strain energy achieved in the loading history up to the current state:

$$\gamma = \max_{s\in[0,t]} \left\langle \Psi_f^0 - \Psi_{f,ini}^0 \right\rangle \cdot \tag{3}$$

Here, $\Psi_{f,ini}^0$ is the strain energy density of the fibrils at their initial state [13]. We modified the Balzani damage model formulations to represent increases in damage by the addition of the preconditioning effect $D_1$ and collagen damage $D_2$ mechanisms seen in RTT fascicles through:

$$D(\beta,\gamma) = D_1(\beta,\gamma) + D_2(\beta,\gamma) \cdot \tag{4}$$

We then optimized our material parameters to the creep cyclic fatigue experimental data and used this model to predict other common tendon loading scenarios.

## RESULTS

All models were able to predict the creep cyclic fatigue damage over the number of cycles with a small standard deviation amongst models (Fig. 2A, grey shading). The continuous damage function for all models linearly increased until it began to incline near the failure point (Fig. 2B, purple line). The discontinuous damage function increased slowly in a sigmoid fashion up to failure (Fig. 2B, green line). The standard deviation for the continuous damage grew from minimal to marginal over the number of cycles (Fig. 2B, purple shading), while the discontinuous damage standard deviation remained fairly large through the entire test (Fig. 2B, green shading). When comparing to experimental stress-strain data, the models were able to closely reproduce the experimental creep cyclic fatigue experimental stress-strain curve by Zitnay et al. (Fig. 2C & 2D).

## DISCUSSION

The model validation for the creep cyclic fatigue loading provides us with confidence in our experimental and computational methodologies. To our knowledge, there are no comparable studies in the literature that model creep cyclic fatigue sub-failure damage accumulation in tendons with the combined continuous and discontinuous damage formulations. This new CDM provided the ability to more closely inspect the different mechanisms present during cyclic fatigue damage accumulation by mathematically separating the preconditioning effect and collagen damage mechanisms.

The novelty of this CDM formulation came from adapting the mathematics from the Balzani damage model to simulate tendon sub-failure damage, while also providing the ability to convolve the damage model with other undamaged constitutive materials in FEBio. The Balzani damage model equipped us with the means to capture continuous and discontinuous damage. However, unlike the Balzani damage model and other common models in the literature [2-4], the total damage function scaled the strain energy of the fibers, instead of being more intricately inserted in the calculation of the strain energy density function, allowing different material models to be used. This allows the total damage function to be separate from the undamaged constitutive model, providing flexibility in the FEBio implementation to use any undamaged constitutive material that has a fiber term.

We have created a new continuum damage mechanics model that accurately reproduces and predicts the damage accumulation in tendons over cyclic fatigue loading conditions. The verification models, formulations, user manual, and finite element software are open to the public on the FEBio website, allowing others to expand this damage model to their specific tendon or ligament modeling needs. Thus, this project is advancing our capabilities to model damage accumulation which will increase our understanding of damage mechanisms, prevention strategies, and treatments for tendon-related pathologies.

## INTRODUCTION

In recent years, the development of wearable sensors has emerged as a useful alternative to camera-based laboratory motion capture methods for gait analysis and rehabilitation research (Arif and Kattan). One type of wearable sensor, an inertial measurement unit (IMU), consisting of orthogonal accelerometers, rate gyroscopes and magnetometers allows for the direct measurement of a body segment's linear acceleration, angular velocity, and environmental magnetic field strength. Within the context of sports, for example, the development and application of post-collection equations are required if IMUs are to be used for the direct assessment of the forces or torques causing injuries like ACL ruptures. Several studies have reported upon the correlation between linear acceleration and ground reaction force (GRF) and have then attempted to develop models relating IMU linear acceleration to GRF (Elvin et al.; Meyer et al.). However, these studies have employed linear models. It may be that the relationship between IMU linear acceleration and GRF is not purely linear and is instead more complex and affected by multiple variables either directly or indirectly. So, the purpose of this study was to develop a mathematical model that can be applied to an IMU's data to obtain more accurate and reliable GRF estimates.

## METHODS

Cadaveric knee specimens were used for this experiment. An in-depth explanation of how specimens were prepared can be found in a previous study (Ajdaroski et al.). Specimens were rigidly fixed in a custom-built testing rig designed to apply different magnitudes of simulated one-legged jump landing GRF in multiples of body weight (xBW); this rig included simulated trans-knee muscle forces and has been validated in previous studies (Ajdaroski et al.; Lipps et al.). Pairs of knee specimens were used, with one knee being randomly selected to be tested under lower (nominally 1-2xBW) GRF, and the other knee tested under higher (nominally 3-4xBW) GRF conditions.

Two, 6-axis load cells (MC3A-1000, AMTI, Watertown, MA) were used to record 3D forces, one at the end of the mid-tibia and the other at the end of the mid-femur. The sampling rate for each load cell was 2 kHz. Using two IMU sensors (APDM Wearable Technologies, Portland, OR), one sensor was rigidly attached to the medial aspect of the mid-tibia stripped of soft tissue, and likewise the other directly to the lateral aspect of the mid femur using Co-flex bands and elastic ties to mitigate potential motion between IMU and bone. IMU sampling rate was 200 Hz. The IMUs were calibrated through the predefined calibration conditions recommended for use with the Moveo Mobility software from APDM. An in-depth overview of the testing procedure can be found in a previous study (Ajdaroski et al.). A fourth order, zero-lag, low pass Butterworth filter was applied to all accelerometer and gyroscope data. Based on the findings of previous studies. which show there is a strong correlation between linear acceleration and GRF, it was assumed that peak vertical linear acceleration (pVLA) occurred at the same time as peak vertical force (pVF) (Elvin et al.).

Because testing resulted in a clustered data set, development of a mathematical model relating values as measured by the IMUs to the GRF was accomplished through the implementation of mixed effect modeling (MEM). A grouping based on specimen was used to account for inter-specimen differences which may arise from body muscle-to-fat ratio, age, sex, weight, and height. Furthermore, because of the lack of usefulness of the random effects in terms of contributing to a useable model, only fixed effects terms were utilized in the construction. The pVF was assumed to be the outcome variable with potential predictor variables assumed to be the 6-axis linear and angular acceleration data from both upper and lower IMUs, as well as body mass. Various combinations, as well as potential interactions between one or more predictor variables were considered. The efficacy of the MEM was determined based on how accurate and how reliable the MEM's predicted values were compared to the measured values. This was assessed through mean absolute percent error (MAPE) values and associated limits of agreements from Bland-Altman plots (LoAs).

SB³C2022-079

## RESULTS

Of the constructed MEMs observed, the best model (Equation 1), consisted of the vertical linear acceleration of the lower leg ($x$), rotational angular acceleration of the lower leg ($y$), the flexural angular acceleration of the lower leg ($w$), and the linear acceleration of the upper leg ($z$) along with a random intercept term.

$$62.5x - \frac{y}{100}(30.5 + 0.539x) + \frac{z}{100}(1.83y + 3w + 0.068yw) - 340 \quad \textbf{(1)}$$

**Table 1: The absolute difference ("ABS. xBW") and the mean absolute percent error (MAPE) between predicted and measured GRF (in units of body weights, xBW) for each xBW range. N denotes the number of observed trials in each xBW range, and SD the standard deviation.**

| xBW Range | N | ABS. xBW ± SD | MAPE ± SD |
|---|---|---|---|
| **0-1** | 162 | 0.07 ± 0.06 | 7.8 ± 5.8% |
| **1-2** | 235 | 0.15 ± 0.10 | 9.9 ± 6.5% |
| **2-3** | 443 | 0.15 ± 0.11 | 6.0 ± 4.5% |
| **3+** | 20 | 0.22 ± 0.12 | 7.4 ± 4.2% |
| **Mean** | | 0.14 ± 0.11 | 7.5 ± 5.6% |

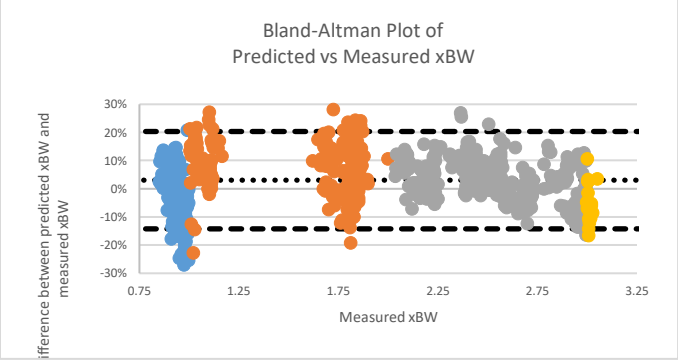

**Figure 1: Bland-Altman plot of the % difference between the predicted and measured xBW (y-axis) and the measured GRF (in units of xBW (x-axis)). Colors represent xBW range**

## DISCUSSION

The purpose of our study was to develop a mathematical model that could accurately and reliably predict GRF using wearable sensors. The results show there was a MAPE of 7.5% between the predicted and measured ground impact force in xBW, indicating our model shows potential in accurately estimating xBW based on IMU data. However, the Bland-Altman LoA (LoA: Lower Limit, -14.2%; Upper Limit, 20.4%) show that the model may not be reliable in its predictive capabilities under all conditions. Importantly, as the landing force was increased in magnitude, the % difference range between predicted and measured decreased. This indicates that model reliability was better for large GRFs than small GRFs (Figure 1). It should be noted that because we removed the soft tissue between the bone and each IMU, these results were not affected by the usual soft tissue artefacts that complicate IMU measurements in living individuals (when IMUs are placed over skin and muscle overlying bone).

A model has been developed to estimate peak GRF (pGRF) via accelerometer data from an IMU during youth gait (Neugebauer et al.). pVGRF was modeled using both a MEM in which a subject-specific random effect was used, as well as a generalized regression model. They reported that the MEM resulted in a MAPE between actual and predicted pGRF of 5.2 ± 1.6% which is lower than that observed in our study. This may be due to the inclusion of speed of action (i.e., running vs walking) as a fixed effect. However, in on-field studies, quantification of speed of an action may not be possible. Alcantara et al. examined the accuracy of a linear regression model to predict pGRF via sacral-mounted accelerometer data across multiple running speeds (Alcantara et al.). Construction of the linear regression model was accomplished using linear acceleration obtained from the IMU, the subject's body mass, step frequency, and running speed as the predictor variables. They reported a MAPE of 4.04 ± 2.57%, lower than that observed by either Neugebauer et al. or in our study. However, like the Neugebauer et al. study, the use of subject's step frequency and running pose on-field difficulties in quantification. Furthermore, neither study reported the reliability of their models, either through the determination of LoAs or by some other means. Reporting the reliability of a model's predictive capability may be essential, because even if the model demonstrates a high level of accuracy (low MAPE), the reliability may be such that predictive values can range from ± 20% of measured value.

Overall, the low MAPE value in our model using only IMU derived data shows the potential for predicting GRF from an IMU, particularly in sports involving large landing forces. However, the large LoA shows the model's reliability needs improvement. Future research might include factors like sex and height to help develop a more robust model.

# STIMULATING THE HEDGEHOG SIGNALING PATHWAY TO IMPROVE ZONAL TENDON-TO-BONE INTEGRATION

**Timur B. Kamalitdinov (1), Keitaro Fujino (1,2), Xi Jiang (1), Sinaia Keith Lang (1), Mary K. Evans (1), Miltiadis H. Zgonis (1), Andrew F. Kuntz (1), Nathaniel A. Dyment (1)**

## INTRODUCTION

Zonal enthesis formation involves anchoring collagen fibers, creating proteoglycan-rich fibrocartilage, and mineralizing part of this fibrocartilage. During development, Hedgehog (Hh) signaling promotes fibrocartilage production and maturation, leading to these distinct zones [1]. Despite this important developmental role, it is not known whether the Hh pathway plays a similar function in adult tendon-to-bone repair. To address this gap in knowledge, we modulated the Hh pathway in a murine anterior cruciate ligament reconstruction (ACLR) model [2,3] to assess its role in tendon-to-bone integration between the implanted tendon graft and adjacent bone. Our objective is to genetically and pharmacologically stimulate the Hh pathway in α-smooth muscle actin (αSMA)-expressing bone marrow stromal cells (bMSCs), which give rise to zonal fibrocartilaginous attachments [2], to promote tunnel integration. Our central hypothesis is that the Hh pathway promotes zonal fibrocartilage formation in the adult, similarly to its role in growth and development.

## METHODS

All animals and procedures were approved by UPenn's IACUC. Experimental Design. ACL reconstructions were performed on 60 transgenic mice. *Genetic Hh Activation Study*. αSMACreERT2 mice [4] were crossed with constitutively active SmoM2 mice [5] (Gt(ROSA)26Sor$^{tm1(Smo/EYFP)Amc}$/J) to yield SMACre;SmoM2 (SmoCA) mice with increased Hh signaling and Cre-negative controls. Mice were sacrificed at 28 days post-surgery and assigned to cryohistology (n = 7-13/group) or biomechanics (n = 5-7/group). Tamoxifen injections (80 mg/kg) were given on the day of surgery and every other day thereafter for a total of five injections to constitutively activate Smo in αSMA-expressing cells. *Pharmacologic Hh Activation Study*. Mice received either Hh agonist (20mg/kg Hh-Ag1.5 [6]) or PBS injections 5X per week. Mice were sacrificed at 28 days post-surgery and assigned to cryohistology (n = 6-8/group) and biomechanics (n = 7/group). Calcein was given 7 days before sacrifice and Demeclocycline was given 1 day before sacrifice to help define the mineralized fibrocartilage (MFC) zones of attachments. ACL Reconstruction. The ACL was excised near the femoral insertion. Bone tunnels were drilled with 27G needles. A tail tendon autograft was passed through the tunnels and anchored to the femoral and tibial outer cortices with stainless steel washers [2,3]. Mineralized Cryohistology. Knees were fixed in formalin, embedded, sectioned undecalcified with cryofilm, and imaged on the Zeiss Axio Scan.Z1. Tunnel Pullout Test. Femurs were potted in PMMA and gripped such that the tunnel was parallel to the linear actuator. A suture was passed through the washer and loaded to failure. Image Quantification. MFC area/total length, percentage of tunnel length containing MFC, and percentage of MFC produced in the last week were measured to assess the extent and timing of zonal integration at day 28. Bone area fraction (BAF), mineral apposition rate (MAR), mineralizing surface/bone surface (MS/BS), and alkaline phosphatase+ surface/bone surface (AP/BS) were measured in the newly formed bone 400μm from the tunnel interface at day 28 using OsteoMeasure. Statistics. Treated and control groups were compared via Student's t-tests ($p < 0.05$). Data presented as mean ± SD.

## RESULTS

SmoCA and Hh agonist-treated groups did not display any adverse systemic effects throughout the duration of the study. Hh Pathway Positively Regulated Tunnel Integration and Strength. When targeting the αSMA-expressing amplifying progenitor pool, SmoCA mice had 45% greater MFC compared to controls at day 28 (Fig. 1F, $p < 0.01$) resulting in 58% greater pullout strength (Fig. 2B, $p = 0.25$). Mice that received Hh agonist for four weeks had 25% more MFC (Fig. 1G, $p = 0.15$) resulting in 48% greater pullout strength (Fig. 2C, $p = 0.03$). Hh Pathway Activation Increased Attachment Sites and Area in the Last Week. Since Hh-stimulated mice showed greater MFC formation at 28 days, we next sought to identify the mechanism that led to this improved integration: increased number of attachments along the tunnel length or increased mineral apposition within each attachment. We found that

16% more of the tunnel length contained MFC in the SmoCA mice (Fig. 3B, p = 0.01) and 17% more in Hh agonist-treated mice (Fig. 3C, p = 0.04) compared to respective controls after 28 days. Additionally, there was 37% greater MFC produced in the last week in SmoCA mice compared to controls (Fig. 3E, p < 0.01) while Hh agonist-treated mice had comparable levels of MFC produced in the last week with controls (Fig. 3F, p = 0.45). Both SmoCA and Hh agonist-treated mice had comparable BAF, MS/BS, and AP/BS with their respective controls at 28 days after surgery in the newly formed bone surrounding the tunnels (n = 5-13 for each measure, p > 0.1). SmoCA mice had 11% lower MAR compared to controls (n = 4-13, p = 0.03) while Hh agonist-treated mice had comparable MAR compared to controls after 28 days (n = 3-4, p > 0.1)

Pol – polarized light, Dem – demeclocycline.**

## DISCUSSION

Following ACL reconstruction, bMSCs must expand and infiltrate the periphery of the tendon graft, then assemble collagen and zonal fibrocartilage to properly anchor the tendon to adjacent bone. Similar to enthesis development, we demonstrated that Hh signaling promoted mineralized fibrocartilage formation (Fig. 1) leading to greater pullout strength (Fig. 2). While Hh signaling improves fracture repair via improved osteogenesis and angiogenesis [6], we found in this study that Hh promoted fibrocartilage formation with minimal effects on adjacent bone at day 28. Since a higher percentage of the tunnel length contained MFC in the treated vs. control groups (Fig. 3A-C), Hh may promote the initiation of attachment sites along the length of the tunnel. The SmoCA mice continued to mineralize more than controls in the later stages of healing (Fig. 3D-F), unlike the agonist treated group, which may indicate that the agonist treatment lost its effectiveness with time. Therefore, our results indicate that the increased MFC formation may, at least partially, be due to increased commitment of the bMSC progeny to initiate the attachments and if the cells maintain elevated levels of Hh signaling (i.e., SmoCA) during later stages, they will continue to produce elevated levels of MFC.

An improved understanding of the signaling pathways that regulate zonal insertion formation in the adult will be crucial to developing new therapies to improve repair outcome. If the Hh pathway is harnessed therapeutically, it could result in a paradigm shift in the treatment of these debilitating injuries, especially in more challenging scenarios that require reformation of the enthesis, such as rotator cuff repair.

## INTRODUCTION

Alzheimer's Disease (AD) is a neurodegenerative disease and the most prevalent cause of dementia[1]. Brain atrophy due to AD leads to gradual cognitive decline, personality changes, and eventually inability to sustain one's daily activities independently. Previous studies have shown that cerebrovascular changes are common neuropathologic findings in aged subjects with dementia[2]. Despite the importance of cerebrovasculature in brain function, compared with studies on the degeneration and alteration of neurons, cerebrovascular remodeling during the progression of AD and the neurovascular relationships in the brain are less delineated. To establish an understanding of the changes in structure and function of cerebrovascular arteries with AD progression, biaxial inflation-extension tests were performed on anterior cerebral arteries (ACAs) from normal control and pathologically diagnosed AD groups, from which the stress-stretch relationships in circumferential and longitudinal directions were obtained. Additionally, histology studies, multiphoton imaging, and polarized light microscopy were carried out to examine structural integrity of the ACAs.

## METHODS

**Biomechanical Characterization.** A total of 28 human ACAs were obtained from NIH NeuroBioBank. Based on pathological Braak stage, samples were divided into early AD (Braak I-II), intermediate AD (Braak III-IV), and advanced AD group (Braak V-VI). Biaxial inflation-extension tests were performed using a pressure Myograph (DMT 110P XL, Denmark). Samples from the 2nd segment of ACA were canulated at both ends, stretched axially to *in vivo* stretch ratio, and then inflated. After preconditioning, biaxial inflation-extension tests were performed from 0 - 80mmHg, the mean arterial pressure of ACA[3], at 10 mmHg increments. The inlet and outlet pressure P, axial force $f_T$, and the outer radius $r_o$ of the artery during the procedures were recorded. ACA rings were cut from the arteries after the biaxial inflation test to measure the undeformed inner radius $R_i$ and outer radius $R_o$. Assuming incompressibility and using a thin wall model, the circumferential and longitudinal stress, $\sigma_\theta$ and $\sigma_z$, respectively, can be calculated as:

$$\sigma_\theta = \frac{Pr_i}{r_o - r_i}, \text{ and } \sigma_z = \frac{f_T + P\pi r_i^2}{\pi(r_o - r_i)(r_i + r_o)} \quad (1)$$

where $r_i = \sqrt{r_o^2 - (R_o^2 - R_i^2)/\lambda_z}$ is the inner radius, and $\lambda_z$ is the axial stretch.

**Structural Characterization.** After biomechanical characterization, rings about 1mm in length were cut from the ACAs and fixed with paraformaldehyde, embedded in paraffin, cut into 5 μm slices, and collected on slides. Half of the slides were stained with Movat's stain for histological analysis and the other half were deparaffined for label-free imaging with quantitative birefringence microscopy (qBRM). For qBRM, the unstained sections were imaged with a monochromatic red LED source. First, A cross-circular polarized setup with a 20× objective lens (Olympus UPLFLN20XP) was used to acquire full-sample images. A horizontally-aligned region of the arterial wall was then selected and imaged with the same objective to generate quantitative images with the rotating linear polarizer and circular analyzer method[4]. A set of six images were taken during stepwise rotation of the linear polarizer at 30° increments. In the resulting image sets, the intensity variation of each pixel can be analyzed as a function of the angle of the rotating polarizer[5], providing quantitative birefringence parameter maps of relative retardance and in-plane optic-axis orientation.

For multiphoton imaging, the circumferential cross-sections of ACA rings were imaged using a Zeiss LSM 710 NLO Microscope with a 20× water immersion objective lens. An 810nm Ti:sapphire laser was used to generate second harmonic generation from collagen (417/80 nm) and two-photon-excited fluorescence from elastin (525/45 nm). Images were taken at 1 μm intervals to a depth of approximately 50 μm.

## RESULTS

As AD develops, the mechanical response of ACAs changes progressively. Compared to the control, the axial force in the early AD stage doubled, and nearly tripled in the intermediate and advanced stages (Fig. 1a). The longitudinal stress in the AD groups showed similar extent of increase in the AD groups (Fig. 1c). AD progression also leads to a left shift of the pressure-diameter curves (Fig. 1b). The toe region of the circumferential stress-stretch curves shortened, and the curves become steeper at a lower stretch (Fig. 1d). The left-shift of the stress-stretch curve demonstrates a continuous reduction in compliance of ACAs with AD progression, which becomes more

pronounced in the intermediate and advanced stages.

Progressive structural changes were also observed in ACAs. Presented in Figure 2 are ACAs from a 72-year-old control, a 66-year-old with early AD pathology (Braak I-II), a 69-year-old with intermediate AD pathology (Braak IV), and a 62-year-old with advanced AD pathology (Braak VI). Movat's stain revealed that ACAs exhibit decreased medial layer thickness and loss of smooth muscle cells (Figs. 2b-d). Medial layer thickness reduced by nearly half for ACA with advanced AD pathology (Fig. 2d). As a result of smooth muscle cell atrophy, an empty band appeared between the medial and adventitial layer, indicating compromised structural integrity of the arterial wall with the loss of elastic fibers and smooth muscles cells.

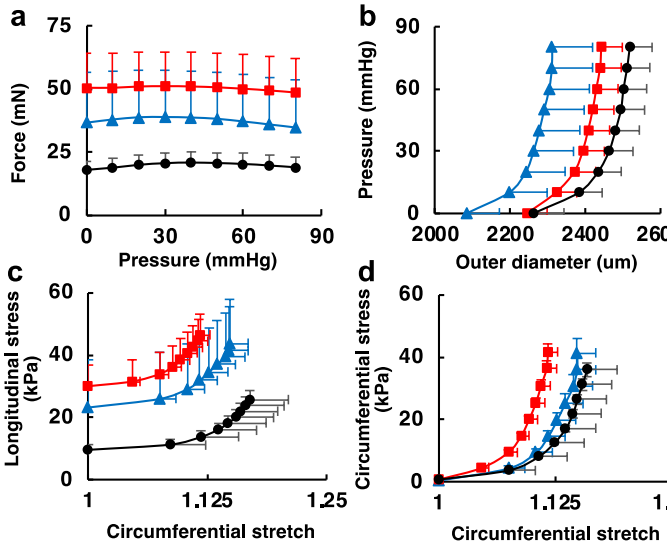

**Figure 2. Mechanical response of ACAs from biaxial inflation-extension tests at in vivo axial stretch. (a) Axial force – pressure; (b) pressure – diameter; (c, d) longitudinal and circumferential stress vs. circumferential stretch, respectively. Control (●), early AD (▲), and intermediate & advanced AD groups (■).**

Structural degeneration in elastin was further revealed from the multiphoton images (Figs. 2e-h) taken at different stages of AD progression. The loss of elastic fibers becomes evident with an empty band appearing at the media-adventitia interface. Additional observation can be made in the qBRM images (Figs. i-l). In the normal control (Figure 2i), the structural integrity of the arterial wall is evident from the compaction of the layers and the relatively uniform color of the orientation map. The corresponding images of the AD cases (Figures 2j-l), on the other hand, exhibit clear signs of structural breakdown and delamination. In the medial layer, this can be seen by a steady decline in the quantity of birefringent elastin fibers and smooth muscle cells as AD progresses. Moreover, in the adventitial layer, the collagen fibers become progressively more disorganized in AD arteries, as evidenced by the colorful orientation map (Figure 2l).

## DISSCUSSION

Current understanding of cerebrovascular remodeling in AD is limited. Smooth muscle atrophy in posterior cerebral artery has been reported[6], however, changes in human cerebrovascular function and extracellular matrix in AD have not been studied. Our study shows that with pathological progression of AD, human ACAs undergo progressive stiffening, elastin and collagen structural breakdown, and smooth muscle cell atrophy.

The ACAs become stiffer as AD develops (Fig. 1). Arterial stiffening has been reported in AD and other dementia cases using noninvasive measurements such as pulse wave velocity method, but the reason remains unclear [7][8]. The collagen disorganization in AD, which can be clearly seen in our birefringence images (Figures 2j-l), can potentially cause early collagen recruitment and contribute to cerebral artery stiffening. The elastin degradation, accompanied by smooth muscle cell deprivation, leads to the overall media atrophy and this progresses with pathological AD stages (Figs. 2f-h).

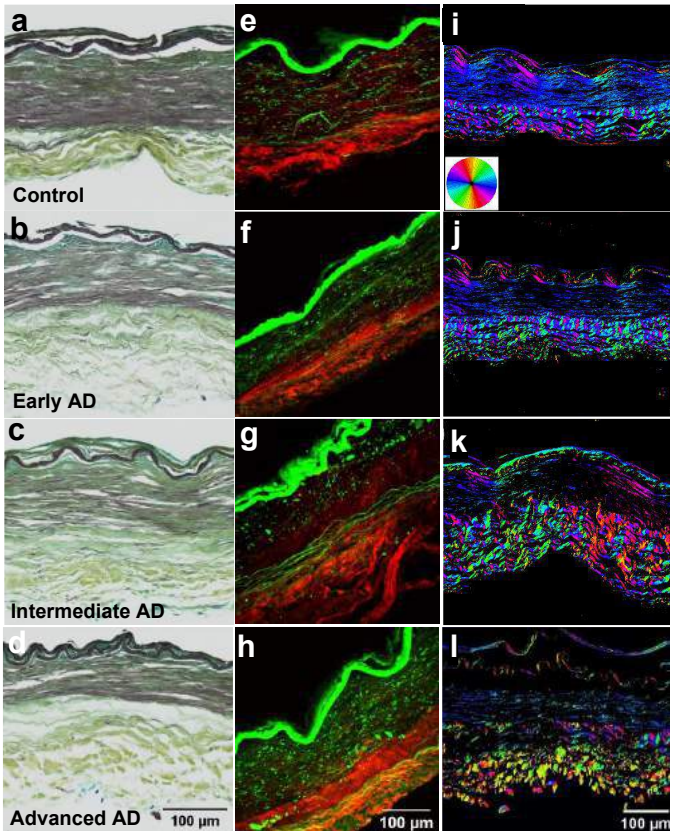

**Figure 1. Circumferential cross section of ACAs from a control, early AD, intermediate AD, and advanced AD subject. (a-d) Histological images with Movat's stain which stains nuclei and elastin black, GAGs blue, and collagen yellow. (e-h) multiphoton images showing elastin green and collagen red. (i-l) Birefringence images showing the optic-axis orientation maps obtained with qBRM. The inset in *i* shows the color coding for the orientation of the optic axis. Scale bars, 100 µm. Intimal layer is facing up in all images.**

Cerebrovascular dysfunction can render the brain more susceptible to pulse pressure and lead to blood brain barrier (BBB) breakdown[9]. With an impaired BBB and vascular contractibility, Amyloid-β is more likely to deposite in brain tissues and the cerebrovascular system[10], resulting in smooth muscle cells atrophy, causing further decrease of vascular contractability and cerebral blood flow.

In summary, our study demonstrated, for the first time, progressive structural changes in human ACAs during the development of AD, including elastin degradation, smooth muscle cell atrophy and collagen disorganization. These structural changes compromise arterial wall integrity and lead to cerebrovascular stiffening as AD progresses. Future studies are underway to quantify these structural changes and their correlations with AD progression.

# COLLAGEN WAVINES REGULATES THE DAMAGE OF VEIN TISSUE

**XH. He, J. Lu**

Department of Mechanical Engineering
The University of Iowa
Iowa City, Iowa, United States

## INTRODUCTION

Coronary artery disease (CAD) is a prevalent cause of morbidity and mortality worldwide. Human saphenous vein (SV) is routinely used as a coronary arterial bypass graft (CABG) in treating CAD. SV segment harvested for graft often undergoes a distension procedure in which the segment is pressurized beyond the venous pressure. Many saphenous vein CABGs were found to fail in service. The failure has been attributed to factors including elevated pressure in the service condition, and structural remodeling caused by damage during distension [1]. The present study aims to investigate the role of collagen fiber waviness in regulating the damage of vein tissue. To this end, a constitutive model considering collagen waviness and damage, with layer-specific properties, is proposed. The descriptive capability of the model is evaluated against reported experimental data. The model is then applied to examine the change of tissue properties induced by distension. Eventually, the uniaxial properties of the SV and the human abdominal aortic(AA) tissue are characterized using this model, and further compared through performing statistical analysis.

## METHODS

### *Modelling recruitment and dispersion*

Although much thinner walled than arteries, the vein also consists of three layers: intima, media and adventitia. The media and adventitia layers can be regarded as a fibrous composites with wavy collagen fibers embedded in isotropic ground substance. In our previous studies [2], a two-layer version microstructurally-motivated constitutive model is proposed to consider different waviness, direction distribution and stiffness characteristics of the media and adventitia layer for the vascular tissue. The strain energy density function (SEDF) consists of contribution from the lumped ground matrix and collagen fibers ($W_f$) in both layers:

$$W = \frac{\mu_1}{2}(\mathrm{I}_1 - 3) + \sum_{j=M,A} W_{f,j} \qquad (1)$$

For each layer, the fibers are assumed to be dispersed and the directional density follows von Mises distribution. After applying a four-point integration scheme to discrete the continuous distribution, we obtain an expression for fiber energy in each layer

$$W_f = \mu_{2i}[\kappa^2 w_b(\theta_0^1) + \kappa(1-i\kappa)\big(w_b(\theta_0^1) + w_b(\theta_0^3)\big) + (1-\kappa)^2 w_b(\theta_0^4)] \qquad (2)$$

where $w_b\big(\theta_0^i\big)$ is the strain energy of a fiber bundle oriented in the quadrature directions $\theta_0^i$. At the fiber-level, the undulation of a single wavy fiber is quantified by a straightness parameter $p$. Beta distribution function $\psi(p)$ is employed to describe the random distribution of the fiber straightness within the fiber bundle. The beta distribution is parameterized by a mean straightness parameter $e$ and a concentration parameter $s$. Cauchy stress at the fiber bundle level then follows as

$$\sigma_b = \lambda\frac{dw_b}{d\lambda} = \mu_{2i}\lambda\int_{\lambda^{-1}}^{1}(\lambda\rho - 1)\psi(p; ie, s)\,d\mathrm{p} = i\mu_{2i}\lambda(\bar{\lambda} - 1) \qquad (3)$$

Here $\bar{\lambda}$ is a kinematic average variable "*effective stretch*" introduced by the authors in [3] to account for the true stretch of the fiber bundle after factoring out the uncrimping effect.

### *Modelling damage*

We introduce a damage variable $D_f$ for the fiber energy function such that the fiber bundle strain energy $w_b$ in (2) is updated as $(1 - D_f)w_b$. $D_f$ is assumed to be a function of the effective stretch $\bar{\lambda}$. This is motivated by a recent study [4] which found that the rupture stretches of human ascending aortic aneurysms tissue are closely clustered $\bar{\lambda}$ =1.1, suggesting that the inelastic behavior of fiber

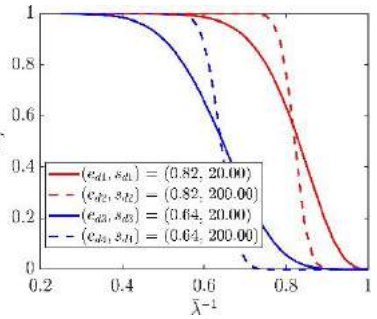

**Figure 1: Influence of $(e_d, s_d)$ on $D_f$**

SB³C2022-082

bundles may be intrinsically described by the effective stretch. Further, we assume that $D_f$ is given by beta distribution of $1/\bar{\lambda}$:

$$D_f = \int_{\bar{\lambda}^{-1}}^{1} \psi(\eta; e_d, s_d)\, d\eta \qquad (7)$$

where $e_d$ and $s_d$ are two damage parameters. As illustrated in Fig. 1, $ie_d$ controls the position of the damage evolution curve while $s_d$ affects the local damage rate.

***Constitutive fitting***

This model is applied to fit the uniaxial tensile test data (with damage) of four SV samples harvested along the circumferential and longitudinal directions [5]. The uniaxial data obtained in each direction is treated as a biaxial case by assuming the stretch in the transverse direction as $\lambda_t\ i = i1/\sqrt{\lambda_{exp}}$.

***Change of waviness after distention***

We hypothesis that the manual pressure distension mainly changes the collagen waviness. A partially joint fitting (PJF) is then conducted over the biaxial response data (without damage) of SV with and without manual pressure distension [6]. PJF employs two groups of waviness and ground stiffness parameters and one group of other parameters to fit both specimens jointly.

***Difference of uniaxial properties between vein and artery***

The stress function (3) is fitted to uniaxial response data (up to yield) from 30 human SV samples published in [5,7] and 93 human abdominal aortic (AA) samples published in [8]. Statistical analyses are performed to investigate the differences of fitted constitutive parameters as well as the ultimate stress $\sigma_u$, ultimate stretch $\lambda_u$ and ultimate effective stretch $\overline{\lambda_u}$ in two data groups. A primary normality test finds that the data do not follow the normal distribution. Hence, a nonparametric test, namely Mann Whitney U test, is performed to determine whether significant differences exists between the parameters in these two groups. Parameters with p-value less than 0.05 are deemed to be significantly different.

## RESULTS

The response of four SVs with damage are accurately captured using the proposed model with $R^2$ reaches 0.998 (Fig. 2a).

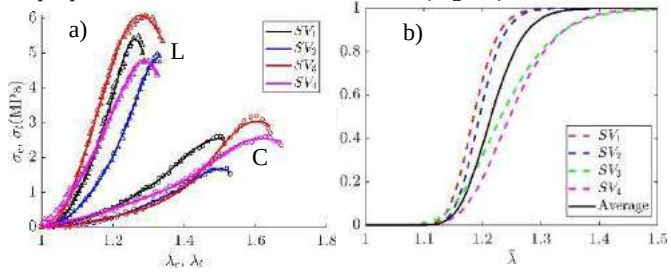

**Figure 2: a) Fitted response. b) damage evolution versus $\bar{\lambda}$**

The damage evolutions using fitted damage parameters and the calculated mean values with respect to the effectives stretch are illustrated in Fig. 2b. Despite the damage rates are varied, nonnegligible damage value $D_f$ occurs in all SV samples when effective stretch reaches around 1.1.

The PJF approach yields an excellent fitting of the biaxial response data for both the normal and distended SV (Fig. 3). The fitted waviness parameters are presented in Table 1. As expected, evident reduction of waviness is observed in both layers in the distended case. At the same time, the stiffness parameter of the ground substance reduced. The change of waviness could be partially caused by the breakage of collagen fibers, or disruption of the elastin network.

**Table 1: Fitted parameters**

| Parameter | Normal | Distend |
|---|---|---|
| $e_A$ | 0.678 | 0.804 |
| $e_M$ | 0.849 | 0.918 |
| $s_A = s_M$ | 21.048 | 110.889 |
| $\mu_1(MPa)$ | 0.013 | 0.009 |

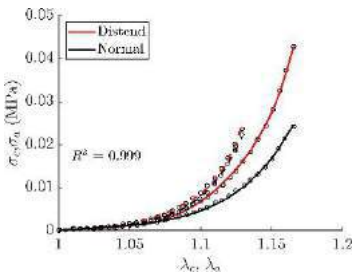

**Figure 3: Fitted biaxial response**

Statistical results of variables obtained from the SV and the AA are presented in Table 2. Compared to the ultimate stress and stretch which are much higher in SV, the ultimate effective stretches are centered around 1.11 within a small interquartile range in both SV and AA. This result is consistent with the observed clustering of damage initiation effective stretch. Among the fitted parameters, there are significant differences in collagen waviness $(e, s)$ and collagen stiffness $(\mu_2)$ between SV and AA. The SV is associated with higher $e$ and $\mu_2$, indicating much wavier and higher content of collagen.

**Table 2: Fitted parameters in median [interquartile range]**

| | SV (n =30) | AA (n = 93) | p-value |
|---|---|---|---|
| $e$ | 0.60 [0.54, 0.70] | 0.84 [0.73, 0.89] | **2.46e-08** |
| $s$ | 43.68[7.22, 86.13] | 73.17 [ 40.28, 136.94] | **1.12e-03** |
| $\mu_1$ | 0.079[0.06, 0.08] | 0.070 [ 0.045, 0.099] | 0.247 |
| $\mu_2$ | 33.52[11.74,90.89] | 4.43[ 2.59, 7.65] | **3.27e-12** |
| $\overline{\lambda_u}$ | 1.11[ 1.07, 1.14] | 1.11 [ 1.08, 1.14] | 0.411 |
| $\lambda_u$ | 1.80[1.48, 1.93] | 1.33 [ 1.25, 1.52] | **5.90e-07** |
| $\sigma_u$ | 4.48[ 3.09, 8.40] | 0.67 [ 0.41, 1.09] | **1.78e-15** |

## DISCUSSION

The constitutive model proposed in current study accurately capture the stress response and damage in SV tissue under tensile loading. The observed similar $\bar{\lambda}$ at damage initiation suggests that the collage waviness plays a significant role in regulating vein damage. It is found that the change of response characteristics induced by manual distension could be attributed to the reduction of fiber waviness. The SV is found to have much wavier collagen fibers than the AA tissue. The adventitia layer has been reported to have much higher content and undulation of collagen fibers than the media layer. Therefore, waviness of fibers in the adventitia layer could dominate the distensibility of the entire wall. Thus the SV collagen tissues are much wavier than AA may shed light on understanding the failure of the CABG when the SV is exposed to arterial pressure.

The current study embodies some limitations. Firstly, response data with damage from only four samples are used in the constitutive fitting. There is a need to accumulate more data to validate our model. Secondly, the predicted waviness parameters should be validated experimentally. This could be accomplished using the optical imaging methods. Although limitations exist, current study reveals the importance of collagen waviness in regulating the damage of venous tissue.

## INTRODUCTION

Coronary Artery Disease (CAD) is the most frequently reported cardiovascular disease (CVD) and is one the primary causes of death today. CAD involves myocardial ischemia due to atherosclerotic build-up, which narrows the arterial lumen. There is an estimate by the Indian Heart Association that approx. 60% of the world and CVD load will happen in the South Asian countries in spite of accounting for only 20% of the entire world population. However, early prognosis and diagnosis of CAD could reduce this high morbidity rate and thus decrease the mortality rate. In recent times, for computing cardiovascular hemodynamics, some assessment tools have been developed. These cardiovascular assessment tools provide awareness to physicians to assist CVD diagnosis by allowing them to use the CFD based computational indicators/markers to CVD. In the patients with questionable CVD conditions these tools help in identifying the coronary lumen plaque and shape property during their initial clinical visits [1,2]. Currently, to evaluate the intensity of coronary stenosis from (CAD-RADS) database, the fractional flow reserve (FFR) is extensively used, with the target of verifying the impact of the stricture (stenosis) on the myocardial ischemia [3]. In CAD patients, hemodynamics plays a vital role in the progression, evaluation, and treatment of cardiovascular disease. For personalized treatment planning, suitable blood flow-based markers like shear stress of wall, deformation of the vessel wall, blood pressure, streamlines, and velocity are used to explore the impact of mechanical stimuli in CVD. Standardized person-specific and region-specific reporting will be helpful to reduce the variability of CADs among practitioners for maximizing the clinical impact of coronary computed tomography angiogram (CCTA). Therefore, it is crucial to know the hemodynamics characteristics of patients having chest pain in the initial visit. This study performed a detailed blood flow analysis of suspected coronary artery diseases using CFD and an open-loop system. This study will provide the medical practitioner with some theoretical support for diagnoses and treatments of CADs.

## METHODS

In this study, a CCTA scanning examination was done for one of the hospitalized patients of age 51 yrs. having chest pain for diagnosis of coronary artery disease (CAD) at a 128 slice CT scan center, SSH, Institute of Medical Sciences BHU, Varanasi, India

The study was supervised in conformity with the principles of the declaration of medical ethics requirements. The ethical review committee of the Institute of Medical Sciences, BHU, Varanasi, India. To generate a patient-specific anatomic model based on CT angiography image data, the geometry of coronary arteries and aorta was first reconstructed from the patient image data using open-source [5]. The design details of the model are depicted in Figure 1.

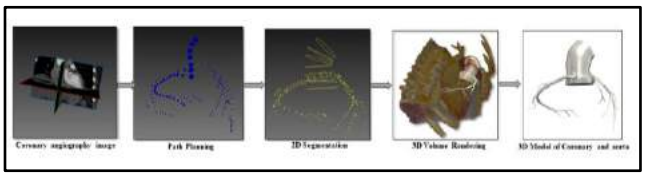

**Figure 1: - (a) Complete step by step process for coronary arteries modelling using CT-image data**

To analyze the various hemodynamic parameters like Pressure Drop, Velocity Profile, WSS, TASSS, OSI, FFR and streamline a three-dimensional (3D) finite element model of the coronary arteries from CCTA, was used as shown in Fig 1(b). In the study, blood was assumed to be a Newtonian fluid with a density of (1.06 g/mL) and dynamic viscosity of (0.04 dyne. s/cm$^2$) for all simulations. Blood vessel walls were assumed to be rigid in all cases. A time-step size of 0.001 ms was chosen to satisfy the stability condition. Simulations were run for 3 cardiac cycles until the pressure fields at the inlet and outlet did not change more than 1% from the previous cycle. Blood flow was modelled using the incompressible Navier–Stokes equations NSEs and the corresponding governing equations for NSEs given below:

$$\rho\vec{v},ti+i\rho\vec{v}i.\nabla\vec{v}\,i=i-\nabla p+div(\tau)+i\vec{f} \quad (1)$$

$$divi(\vec{v})=0\ddot{u}fori(\vec{x},t)\,i\in\Omega i\times i(0,T) \quad (2)$$

$$\text{Where}\quad \tau=\mu(\nabla\vec{v}+i(\nabla\vec{v})^T) \quad (3)$$

To assess the wall shear stress acting on the lumen wall under pulsating flow in human heart circulation, Time Average Wall Shear Stress

(TAWSS), Oscillatory Shear Index (OSI) and Relative Residence Time (RRT) were considered.

## RESULTS & DISCUSSION

In this study all the numerical simulations pertaining to the patient with chest pain have been carried out using CFD methods. The various hemodynamic parameters were investigated after three cardiac simulations and validated with the previous work [6]. The critical regions of TAWSS, OSI and RRT as shown in Figure 2 are also analyzed. Velocity contour and streamlines of blood flow in the coronary model are shown in Figs 2 and 3. Astoundingly, the patient classified as (CAD-RADS0) had abnormal hemodynamic characteristics that could not be ascertained from the CCTA directly. The results recommended that this patient should also have been treated well at the time of their initial visit to avoid future adverse effects. Also, patient-specific hemodynamic characteristics may play as vital a role as changes in coronary artery morphology in the prognosis of patients with coronary stenosis.

The present work was focused on single-patient data. However, based on this preliminary study, our future research will emphasize the following: (1) Does the degree of coronary stenosis have a strong effect on coronary blood supply and less of an effect on the blood flow disorder? and (2) Does the location of stenosis have a strong effect on intra-luminal blood flow disorder?

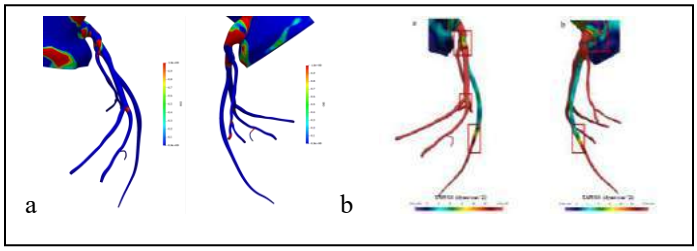

**Figure 2:(a) Oscillatory Shear index (OSI) distribution contour map on vessel wall 3D model including LCA & RCA (b) Time average wall shear stress (TAWSS) a) 3D model including LCA & RCA**

## INTRODUCTION

Exercise is a major stimulus that drives structural and metabolic changes to skeletal muscle as well as systemic changes in cardiovascular health. The response of muscle to exercise depends on the type of stimulus [1] and understanding muscle adaptation in response to exercise is challenging due to the coupled effect of both local (e.g., muscle fiber) and systemic (e.g., metabolism) adaptation. We have recently developed a novel exercise model using optogenetic stimulation (opto stim) of the skeletal muscle to elicit isometric muscle contraction in transgenic mice without the simultaneous effect of systemic metabolic changes associated with aerobic or resistance exercise. In this study, we first measured in vivo ankle torque produced by opto stim of the triceps surae muscle in young mice daily for two weeks using our established protocol [2]. We then identified if and how transcriptional profiles of muscle change after 5 and 12 days of daily opto stim using RNA sequencing (RNAseq).

## METHODS

The Unit for Laboratory Animal Medicine at the University of Michigan approved all animal procedures.

*Ankle torque measurements*: Right triceps surae muscles of doxycycline-treated 4-week-old Acta1-Cre; Ai32 (AA) homozygous male mice (n = 8) were subjected to daily bouts of *in vivo* opto stim (455 nm light) at 10 Hz (70 msec on; 30 msec off) for two weeks (20 min/day; 5 days/week; 10 bouts total). The hindlimb was stabilized via knee clamp and the foot was positioned on a pedal to measure isometric ankle joint torque (Aurora Scientific) (2). The maximum ankle torque over the 20 min-period was normalized to body weight (nMAT). nMATs were averaged for each sample per week, repeated measure ANOVA was performed between days, and students t-test was performed to compare nMATs between weeks using GraphPad Prism ($p < 0.05$).

*RNAseq experiment*: In a separate experiment, we repeated daily bouts of opto stim of the right triceps surae muscles on a cohort of 3-week-old AA male mice (n = 6) using the same stimulation protocol without the force measurement system. Daily bouts were repeated for 5 days (5 bouts) or 12 days (10 daily bouts) (n = 3/time point; contralateral limb was unstimulated control). Mice were euthanized three hours after the last bout and triceps surae muscles were dissected, snap-frozen, and stored at -80 ºC. Muscles were pulverized using steel beads in Trizol and total RNA was isolated with on-column DNA digestion (PureLink RNA Mini Kit, Invitrogen). RNA integrity was > 9.0 for all samples. Poly-A mRNA library preparations and next-generation sequencing were performed using Illumina NovaSeq Shared platform followed by Snakemake pipeline analysis [3] for quality control and sequence alignment. Differential expression (DE) of genes was determined from the count matrix with paired design in DESeq2 in R/Bioconductor [4]. A 1.25-fold change threshold was applied with Wald tests of significance and p-values were corrected for multiple testing using the Benjamini and Hochberg method, with significance set at p-adjusted < 0.05. For pathway analyses and identifying upstream regulators, two gene lists (5 days and 12 days) were input separately using Ingenuity Pathway Analysis (Qiagen). A cut-off of p-adjusted < 0.1 was applied and significance was set at enrichment $|z| \geq 2$ with Fisher's exact $p < 0.05$ and $< 0.01$ for pathways and regulators, respectively.

## RESULTS

nMAT generated by opto stim did not change significantly during the experiment (Fig. 1). After 5 bouts of daily isometric contraction, 326 genes were upregulated, and 110 were downregulated in the stimulated muscle compared to contralateral controls (Fig. 2A). After 12 days, 56 genes were downregulated, and 116 genes were upregulated (Fig. 2B). We identified 99 DE genes conserved between both time points. Five days of stimulation led to enriched pathways related to immune response, cellular development, nuclear receptors, metabolism, and inhibition of matrix metalloproteases (Fig. 3). Pathway enrichment was reduced after 12 days with only 6 significantly enriched pathways relating to cellular development, nuclear receptor signaling, and immunological response (Fig. 3B). Numerous transcription regulators

SB³C2022-084

were identified as upstream regulators at the 5-day time point, but only two were found to be activated after 12 days of stimulation (Fig. 3A).

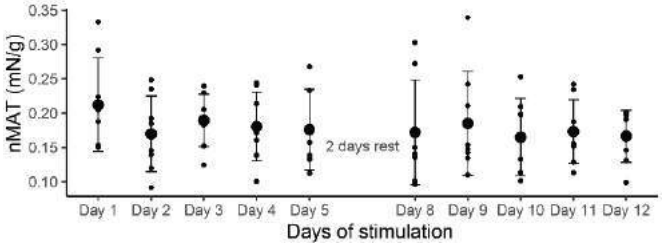

**Figure 1: nMAT for each 20 min bout of daily opto stim. Average nMAT did not change throughout the experiment. Data shown are biological replicates (small dots), average (large dots) with standard deviation (bars).**

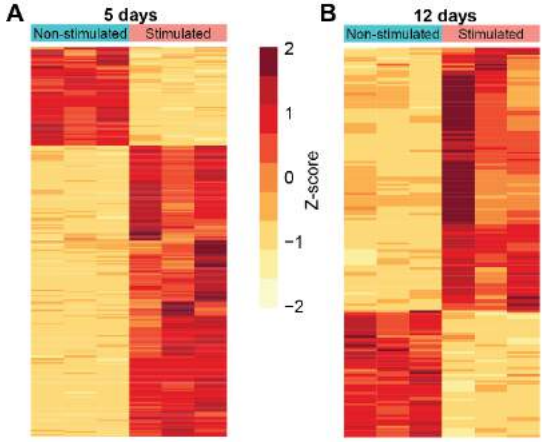

**Figure 2. RNAseq revealed consistent changes in DE genes within groups after (A) 5 and (B) 12 days following opto stim of muscle compared to unstimulated controls.**

## DISCUSSION

This study explored 1) the repeatability of opto stim induced torque production and 2) the transcriptional changes in skeletal muscle following daily bouts of opto stim in young mice. Opto stim has the following advantages over traditional exercise methods, e.g., treadmill running or electrical stimulation: opto stim is non-invasive and locally contracts skeletal muscle independent of nerve activation; opto stim minimizes systemic/organism-scale metabolic adaptation; and opto stim provides a controlled experimental approach for paired (intra-animal) comparisons. Myogenic (*Ankdr2, Cspr3, MyoD1*), anti-myogenic (*Tead4, Tnfrsf12a*), adipogenic (*Adipoq, Cebpa, Lpl*, etc.), inflammatory (*Il1r1*), and fibrotic (*Lox*) genes were DE over the stimulation period. *Runx1*, a transcription factor active during muscle regeneration, was identified as an upstream regulator following opto stim at 5-days [5]. *Nfkbia* was also activated, which may explain the reduced immune response at the transcriptional level at 12 days [6]. *Myod1,* which is responsible for muscle cell proliferation, differentiation, and transformation, was activated only after 12 days of stimulation. Besides inflammatory responses, opto stim activated p38 MAPK, PKA, and FAK signaling, which are active during the differentiation of myogenic cell lines in response to exercise stimuli [7, 8], and also activated CREB, VDR/ RXR, and GM-CSF signaling which may indicate muscle regeneration [9-11]. Opto stim also led to HIF1a signaling enrichment, which plays a critical role in exercise-induced muscle metabolism [12]. Surprisingly, PPAR signaling, a pathway related to mitochondrial biogenesis and often elevated by exercise [13], was inhibited by opto stim, suggesting the volume and intensity of muscle contraction may not be adequate to induce or maintain structural changes [14]. A decreased number of DE genes, upstream regulators, and enriched pathways after 12 days also indicate transcriptional adaptation to our opto stim protocol [1, 14].

These findings support our hypothesis that opto stim of skeletal muscle is a repeatable and effective exercise protocol that elicits differential transcriptional responses and activates known pathways associated with inflammation, muscle regeneration, and differentiation. Future studies should focus on the transcriptional profile in aged mice following opto stim, the structural changes to muscle following acute and repeated opto stim, as well as comparing our transcriptional findings to that of "gold standard" exercise regimens (e.g., treadmill running) and injury (e.g., denervation).

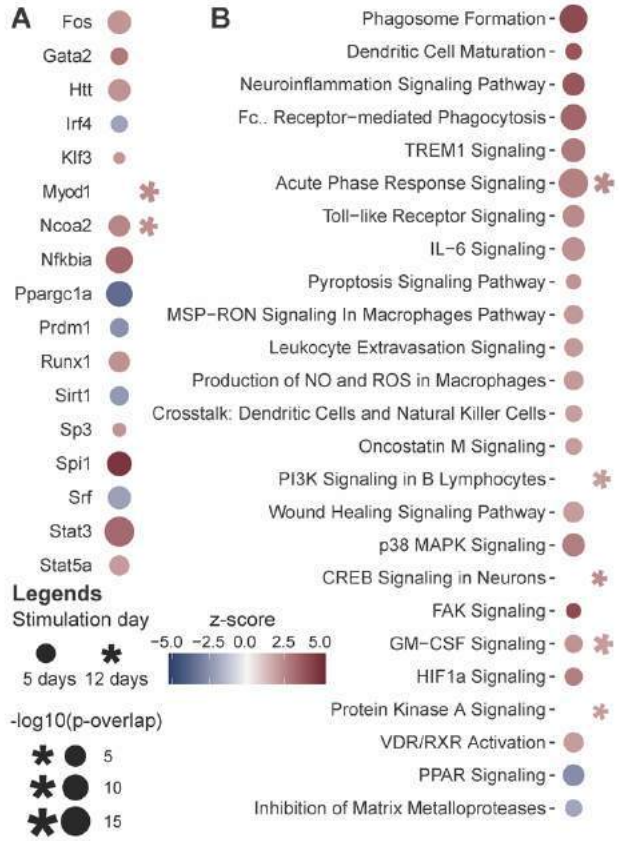

**Figure 3. (A) Upstream transcription regulators and (B) canonical pathways, identified using Ingenuity Pathway Analysis, which were enriched by opto stim. Positive & negative z-scores = activated and inhibited pathways, respectively.**

# MODELLING INDENTATION OF SKIN USING A THIN-LAYER NONLINEAR HYPERELASTIC MODEL

**L. Li (1), M. Masen (1)**

(1) Department of Mechanical Engineering, Imperial College London, London, United Kingdom

## INTRODUCTION

A full understanding of the mechanical properties of skin tissue is crucial for exploring the tissue behaviors and tolerance in all kinds of activities, as well as designing improved medical and clinical devices. Hertz' theory, as the classical contact mechanics theory, is commonly used to define the mechanical parameters from indentation tests on a range of soft tissues, by assuming the tissue follows linear elastic behavior, with small deformation. However, most soft tissues express nonlinear properties during indentation tests. This nonlinear behavior does not only depend on the intrinsic hyperelastic properties of the tissue, but also originates from geometric confinement, for instance most tissue specimens used in mechanical tests only have a small thickness and are supported by a hard or rigid specimen holder. Hayes' model provides a numerical solution to describe such substrate effects during indentation tests but is still based on the linear elastic field equations, meaning it cannot be used to describe the behavior for soft tissues with hyperelastic properties and at large deformations. Ogden's model has been proven to provide a good description for hyperelastic behavior of soft tissues, including skin.

In this study, a computational model based on Ogden's material model was established to describe thin skin tissue with nonlinear hyperelastic properties during spherical indentation. Following a similar procedure as the Hayes model, two correction functions were introduced to account for the effect of geometric confinement due to both the substrate and indenter geometry. The correction functions are defined based on the radius of the spherical indenter, the thickness of the indented sample and the depth of indentation into the tissue. Additionally, a parameter defining the relationship between the contact radius and indentation conditions, as quantified the indenter size and the sample thickness, was defined to consider the nonlinear behavior of the soft tissue under large deformation. The numerical simulations obtained were compared with experimental data, providing a good match.

## METHODS

Hayes model as shown in Eq. (1) is commonly used to describe the contact force $P$ during indentation of thin layered homogeneous isotropic soft materials on a solid substrate. It was established based on a representation of the underlaying boundary value problem in terms of potential functions [1].

$$P = \frac{2\kappa\sqrt{\chi}ER^{\frac{1}{2}}\omega_0^{\frac{3}{2}}}{1-\nu^2} \tag{1}$$

where $P$ is contact force, $E$ is the elastic modulus, $\nu$ is the Poisson's ratio and $\omega_0$ is the indentation depth. $\kappa$ and $\chi$ are correction parameters used to account for the geometric confinement due to the boundary condition and indenter geometry, respectively. They were determined by the explicit solution of the Fredholm integral equation $\omega$, as Eq (2) and (3).

$$\kappa = \frac{P(1-\nu)}{4aG\omega_0} = \int_0^1 \omega(\tau)\mathrm{d}\tau \tag{2}$$

$$\chi = \frac{a^2}{\omega_0 R} = \frac{-\omega_1(1)}{\omega_2(1)} \tag{3}$$

in which $\omega$ could be obtained as follows:

$$\begin{aligned}
&\xi = \frac{x}{a}, \quad \tau = \frac{t}{a} \\
&\omega(\xi) = \omega_1(\xi) + \frac{a^2}{\omega_0 R}\omega_2(\xi) \\
&\omega_1(\xi) = 1 - \frac{1}{\pi}\int_0^1 \omega_1(\tau)\left[K(\tau+\xi) + K(\tau-\xi)\right]\mathrm{d}\tau \\
&\omega_2(\xi) = -\xi^2 + \frac{1}{\pi}\int_0^1 \omega_2(\tau)\left[K(\tau+\xi) + K(\tau-\xi)\right]\mathrm{d}\tau
\end{aligned} \tag{4}$$

From Eq. (2), two correction parameters $\kappa$ and $\chi$ are related to the contact radius $a$,the indentation depth $\omega_0$ and the indenter radius $R$. In

classical Hertz' model, there is $\kappa = 3/2$ and $\chi = 1$. Therefore, the contact radius $a$ could be written as Eq. (5).

$$a = \omega_0^{\frac{1}{2}} R^{\frac{1}{2}} \tag{5}$$

Extending this to hyperelastic material and following the approach followed by Lin [2], we assume a similar relationship using the Hayes correction parameter $\chi$.

$$a = \sqrt{\chi}\,\omega_0^{\,m} R^{1-m} \tag{6}$$

In Ogden's model, the stress σ relates to the strain, quantified in terms of the stretch ratio λ, as defined in Eq. (7), following an exponential relationship with an exponent of $\alpha$-1 [2]. For hyperelastic materials these expressions can be combined to derive a relationship between force and indentation depth for small deformations. To accommodate large deformation, the contact force was further modified following Fessel's [3] method, to finally provide Eq. (9), describing the relationship between force and indentation for a hyperelastic material under large deformation.

$$\sigma = \frac{2\mu}{\alpha}\left(\lambda^{\alpha-1} - \lambda^{-\alpha/2-1}\right) \tag{7}$$

$$\lambda = 1-\varepsilon, \quad \varepsilon = u_z + \frac{1}{2}u_z^{\,2}, \quad u_z = \omega_0 - \psi(r) \tag{8}$$

$$P = \frac{2\kappa\sqrt{\chi}ER^{1-m}\omega_0^{\,(\alpha-1+m)}}{\left(1-\nu^2\right)\left(1-\omega_0/h\right)^n} \tag{9}$$

In these equations, $\mu$ *and* $\alpha$ are the Ogden material parameters, $\lambda$ is the stretch ratio, $\varepsilon$ the strain, *u the* displacement and *h* the sample thickness. The correction factors $\kappa$, $\chi$, *m* and *n* relate to the indenter radius *R*, the indentation depth $\omega_0$ and the sample thickness *h*.

## RESULTS

The FEA model is shown in Figure 1, where both the substrate and the indenter were defined as steel.

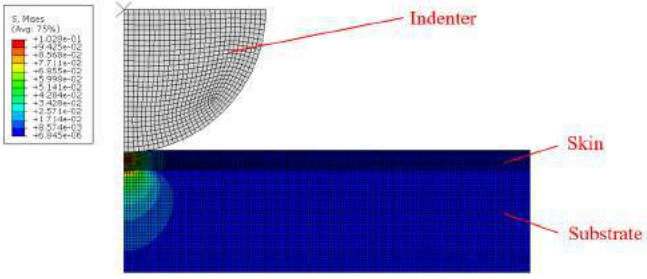

**Figure 1: Overview of the Finite Element Model, showing the stress distribution in the tissue and the substrate during indentation**

An initial estimate of the Ogden material parameters ($\mu$ = 0.2566 and $\alpha$ = 1.9942) was obtained from literature [2]. Subsequently, a series of numerical simulations was conducted with these material properties in which the indenter radius was varied between 4 mm and 8 mm in intervals of 0.5 mm. From these simulations, curves describing the relationship between contact radius *a* and indentation depth $\omega_0$ were extracted as shown as the blue circles in Figure 2. From this data, the parameters $\chi$ and *m* were obtained, curve fitting Eq. (6) shown as the red curves in Figure 2. The obtained values are listed in Table 1. For reference, the green curves in Figure 2 represent the assumed material behaviour for $m = n = 0.5$, representing the Hertz solution of Eq. (5).

**Table 1: The parameters *m* and $\chi$ obtained from simulations**

| ***R* [mm]** | 4.0 | 4.5 | 5.0 | 5.5 | 6.0 | 6.5 | 7.0 | 7.5 | 8.0 |
|---|---|---|---|---|---|---|---|---|---|
| ***m*** | 0.6067 | 0.6054 | 0.6054 | 0.6038 | 0.6054 | 0.6044 | 0.5888 | 0.6044 | 0.6027 |
| **$\chi$** | 7.7494 | 7.0541 | 6.4912 | 5.9983 | 5.6212 | 5.4150 | 4.9974 | 4.8354 | 4.7214 |
| **$\kappa$** | 0.5763 | 0.6337 | 0.6981 | 0.7614 | 0.8284 | 0.8885 | 0.9016 | 1.0221 | 1.0545 |
| ***n*** | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 | 1.5 |

Whilst *m* takes a fairly constant value of 0.6 irrespective of indenter radius *R*, $\chi$ reduces substantially with increasing value of *R*. Substituting this into Eq. (5) provides the following relation between contact radius, indenter size and indentation depth, $a = \sqrt{\chi}\,\omega_0^{\,0.6} R^{0.4}$, where $\chi$ follows Table 1. With $\chi$ and *m* known, values for $\kappa$ and *n* can be obtained from curve fitting eq. (8) through the numerically determined relationship between contact force *F* and indentation depth $\omega_0$.

Finally, the skin Ogden modulus $\mu$ and material parameter $\alpha$ were updated by curve fitting Eq. (9) through physical experimental results obtained on skin tissue using the Biomomentum soft tissue indenter, resulting in $\mu = 0.37 \pm 0.24$ MPa and $\alpha = 1.98 \pm 0.09$.

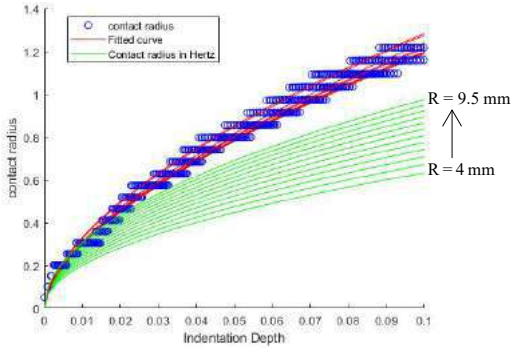

**Figure 2: Relationship between a and $\omega_0$ for different indenter radii.**

## DISCUSSION

To accurately describe the indentation behaviour of thin soft tissue, we employ two correction functions $\kappa$ and $\chi$ to account for the limited thickness of the specimens, in combination with two hyperelastic correction parameters *n* and *m.* The result is a semi-analytical model describing the hyperelastic behavior of thin specimens of soft tissue in indentation tests. The relationship between force and indentation as obtained using this model provides a more accurate description of experimental results. The material parameters extracted from experimental results, at present show a relatively large variation.

# CONTRIBUTION OF ELASTIN AND COLLAGEN TO THE MECHANICAL BEHAVIOR OF BOVINE NUCHAL LIGAMENT

**S. Halvorsen (1), R. Wang (1), Y. Zhang (1,2,3)**

## INTRODUCTION

Bovine nuchal ligament, or *ligamentum nuchae*, is a highly elastic structure often used in tissue research for its abundance of the structural protein elastin. Located in the dorsal cervical region, the *ligamentum nuchae* stabilizes the head and neck. The ligament comprises two distinct regions – a lamellar portion and a paired funiculus, which extend from the external occipital protuberance of the skull and gradually unite to form the stiffer supraspinous ligament that runs along the spine [1]. The funiculus has an organized structure of closely interwoven elastic fibers and collagen fibrils, the two most abundant structural proteins in the body. These fibers are almost entirely oriented along the direction of the spine [2].

Elastic fibers provide elasticity and resilience while collagen provides strength and stiffness, and a balance between these proteins is necessary for physiological functions of *ligamentum nuchae*. Elastic fibers make up approximately 70% of the ligament [3], while collagen content is split between types I and III collagen with small amounts of types IV, V, and VI [2]. Understanding bovine *ligamentum nuchae* structure and mechanics is necessary to consider tissue grafting. Previous studies demonstrate the effectiveness of autografting equine *ligamentum nuchae* for digital flexor tendon healing in donkeys [4].

To better understand the structure and mechanical behavior of *ligamentum nuchae*, this study combines imaging and mechanical testing to quantitatively examine the elastin and collagen microstructure and their individual contribution to the nonlinear stress-strain behavior of the tissue. Additionally, a transversely isotropic structure-based constitutive model that considers the structural organization of elastic and collagen fibers is presented.

## METHODS

*Sample Preparation*

Bovine nuchal ligaments excised from male Holstein calves aged 2-14 days old were frozen in a -20°C freezer before experiments. Rectangular samples ($n = 5$) approximately 30×8×3 mm in size were cut from the ligaments and sandpaper tabs were glued at the ends. For purified elastin network, ligament samples were treated with cyanogen bromide (CNBr) in 70% formic acid to remove all constituents apart from the elastin network [5]. Sandpaper tabs were then re-attached for further mechanical testing.

*Uniaxial Tensile Testing*

Samples were tested before and after CNBr treatment in uniaxial strain-control at 0.5 mm/s up to 1.35 stretch for 12 cycles using an Instron testing device equipped with a 10 N load cell. Force and displacement were recorded. Assuming incompressibility, Cauchy stress $\sigma$ was calculated using Eq. 1:

$$\sigma = F\lambda/A_o \quad (1)$$

where $A_o$ is the undeformed cross-sectional area and $\lambda$ is the stretch. Tangent modulus was calculated as the slope of the unloading stress-stretch curve using *gradient* function in MATLAB.

*Histological Study*

Intact and elastin network samples oriented in both longitudinal and transverse directions ($n = 4$) were stained with Movat's Pentachrome for histological study. Histological slides were imaged under an Olympus VS120 Slide scanner at 40× magnification.

*Multiphoton Imaging*

Multiphoton imaging was performed to study the structure of elastic and collagen fibers in *ligamentum nuchae* using a Carl Zeiss LSM 710 NLO microscope with a 20× water immersion objective. Samples were immersed in 1× PBS for imaging. The femtosecond infrared 810 nm pulse laser generated two-photon excited fluorescence from elastin (525/45 nm) and second harmonic generation from collagen (417/80 nm) [5]. Z-stack images were acquired with an interval of 1 μm with total depths ranging from 50 to 100 μm.

SB³C2022-086

*Constitutive Modeling*

Structure-based constitutive models that consider the organization of elastic and collagen fibers were developed and used to describe the mechanical behavior of intact *ligamentum nuchae* and purified elastin network that was assumed to be transversely isotropic. Modified from Holzapfel et al. [6], the elastin network is modeled using a single-fiber family model, with the strain energy function shown below in Eq. 2:

$$W_E = C_{10}(\bar{I}_1 - 3) + \frac{k_{1E}}{2k_{2E}} \exp[k_{2E}\langle \bar{I}_4 - 1\rangle^2] - 1 \quad (2)$$

The model contains three parameters: $C_{10}$, $k_{1E}$, and $k_{2E}$, which represent the ground substance response, a stress-like parameter, and a unitless parameter, respectfully. $\bar{I}_1$ and $\bar{I}_4$ are the first and fourth invariants, respectively. The strain energy function for the intact *ligamentum nuchae* tissue considers the contribution from both elastic and collagen fibers by incorporating a second fiber family for collagen, described by two new parameters: $k_{1C}$ and $k_{2C}$, and is shown in Eq. 3 as:

$$W_C = W_E + \frac{k_{1C}}{2k_{2C}} \exp[k_{2C}\langle \bar{I}_4 - 1\rangle^2] - 1 \quad (3)$$

Cauchy stress is derived from the strain energy function as:

$$\sigma_m = -pI + 2F * \frac{\partial W}{\partial C} * F^T \quad (4)$$

where $I$ is the identity tensor and $p$ the Lagrange multiplier. Both models were fitted simultaneously to the stress-stretch responses of elastin network and intact tissue using the *fminsearch* function in MATLAB to minimize an objective function. Goodness of fit was measured by the root mean square error [7].

## RESULTS

Figure 1a shows averaged stress-stretch response for intact *ligamentum nuchae* and elastin network under uniaxial tension. The stress-stretch responses of the two groups of samples are similar prior to 1.25 stretch, at which point the intact tissue stiffens. A similar trend was observed in the tangent modulus in Fig. 1b, increasing from 0.5 MPa to nearly 8 MPa between 1.25 and 1.35 stretch for the intact tissue.

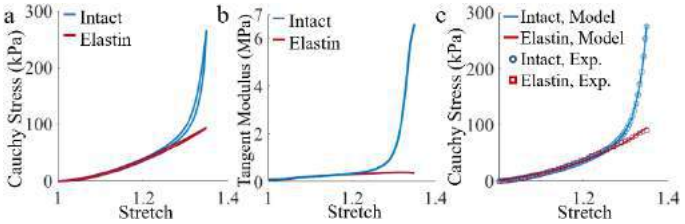

**Figure 1. (a) Averaged stress-stretch responses and (b) averaged tangent modulus for *ligamentum nuchae* and elastic network samples. (c) Representative results showing the fitting of the stress-stretch response of elastin network and *ligamentum nuchae* using the constitutive models in Eqs. 2 and 3.**

Figure 1c contains a representative plot demonstrating the fitting capability of the constitutive models. Material parameters for the hyperelastic behavior of *ligamentum nuchae* and elastin network are $C_{10}$=0 kPa, $k_{1E}$=26.277 kPa, $k_{2E}$=0.269, $k_{1C}$=0.0715 kPa, and $k_{2C}$=9.965. The model RMS error of the sample is 0.0371 with an $R^2$ value of 0.98.

Histological stains of intact tissue and elastin network shown in Figures 2a and 2b depict the longitudinal cross-sections of the tissue samples, respectively. Figure 2a shows longitudinally oriented wavy elastin and collagen fibers with the presence of ground substance, while only elastin fibers are shown in Figure 2b due to the removal of other constituents, as evidenced by the white empty spaces.

Figures 2c and 2d contain a multiphoton image and Z-stack image, respectively, of the transverse cross-section view of *ligamentum nuchae*. The dotted pattern seen in Figure 2c is due to the elastic fibers coming out of the page. Collagen is generally sparse in comparison to elastin fibers, with few visible in Figure 2c. Localized collagen-rich

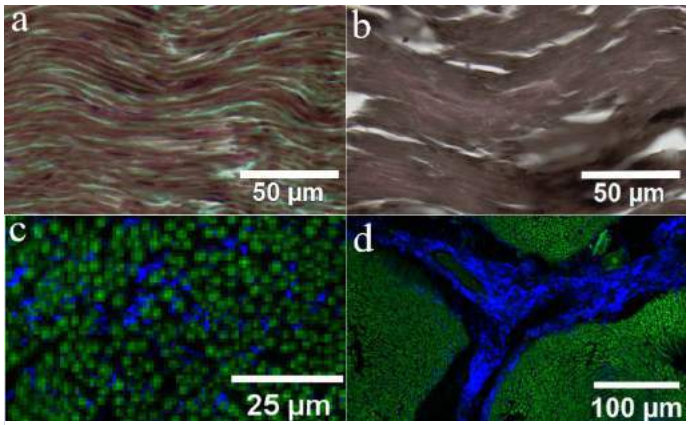

**Figure 2. (a,b): Histological images of *ligamentum nuchae*. Movat's Pentachrome stains elastin grey, collagen yellow, and ground substance blue-green. (c,d) Multiphoton images of *ligamentum nuchae*, with elastin shown in green and collagen in blue.**

regions exist throughout the ligament, as shown in a maximum intensity projection of a 75 μm deep Z-stack in Figure 2d.

## DISCUSSION

In this study, we examined the contributions of elastic and collagen fibers of *ligamentum nuchae* by combining uniaxial tension data with multiphoton imaging and histological studies. Our study demonstrates elastic fibers are responsible for undertaking the mechanical loading under 1.25 stretch, after which the engagement of collagen fibers results in significant stiffening behavior (Fig. 1). Removal of collagen inhibits sample stiffening. The delay in stiffening implies an elastic extension of the ligament in physiological range with lower resistance. Collagen recruitment acts as a protection point to prevent overextension of cattle neck, possibly leading to tissue damage. Purified elastin uniaxial stress-stretch data is comparable with that from Green et al. [8]. Age- and disease-induced reorganization and degradation of the elastic and collagen fibers may affect both the contribution of elastin to deformation of *ligamentum nuchae* and the collagen recruitment process due to their closely interwoven structure.

The transversely isotropic constitutive models developed in this study (Eqs. 1 and 2) effectively capture the mechanical behavior of purified elastin network and intact tissue. The contribution of strain energy due to ground substance is much smaller compared to the fiber families, suggesting that the elastin and collagen are the main contributors to sustain the mechanical loading.

In conclusion, our study reveals the sequential roles of elastin and collagen fibers in contributing to the mechanical response of *ligamentum nuchae*. The mechanical behavior of *ligamentum nuchae* was well captured by a transversely isotropic structure-based constitutive model that considers the contribution of elastic and collagen fiber families.

## INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of mortality in the U.S. and globally (1). Atherosclerosis is a form of CVD that is characterized by the formation of a fatty plaque inside the artery. In this disease, the fatty plaque blocks the blood flow and can potentially cause myocardial infarction and stroke. The availability of autologous blood vessels such as saphenous vein and radial artery is limited for bypass surgery. Synthetic grafts like expanded polytetrafluoroethylene (ePTFE) and Dacron have high failure rates specifically in small-diameter applications. Thrombosis and Intimal Hyperplasia (IH) are two main failure mechanisms of vascular grafts. The onset of thrombus formation is linked to deviation from homeostatic hemodynamic condition where activated platelets and polymerized fibrin create a thrombosis that can ultimately lead to arterial occlusion (2). During IH, different factors including compliance mismatch between the graft and native tissue cause smooth muscle cell migration toward the lumen which thickens the vascular wall and causes stenosis (3). A variety of methods have been researched to prevent stenosis, however, it has yet remained a clinical problem. In porous vascular grafts, blood can penetrate through the structure during systole and can be reversed during diastole. We hypothesized that a large luminal reversal fluid velocity (LRFV) carries a momentum that can repel the platelets and reduce the incidence of thrombosis and matching the compliance reduces the likelihood of IH. In this study, we determined the material, geometrical, and transport properties of a bilayered vascular graft that maximize the LRFV while simultaneously matching the compliance to a target artery. A multi-objective function was minimized using a particle swarm optimization algorithm to find the optimized graft properties.

## METHODS

We developed a porohyperelastic (PHE) finite element framework to model a bilayered and porous vascular graft. We used ABAQUS solver to run the simulations. In this solver, transport in a deformable porous media is governed by Darcy's law (4).

$$v_i{}^{fr} = -\frac{k_A}{\gamma_f}\frac{\partial p^f}{\partial x_i} \quad (1)$$

$v_i{}^{fr}$ is the relative fluid velocity, $k_A$ is the apparent permeability, $\gamma_f$ is the specific weight of the permeating fluid (water), and $p^f$ is the pore fluid pressure. A compressible Neo-Hookean model was utilized to model the material behavior.

$$U^{eff} = C_{10}(\bar{I}_1 - 3) + \frac{1}{D_1}(J-1)^2 \quad (2)$$

$U^{eff}$ is the effective drained strain energy potential per unit of reference volume, $J$ is the total volume ratio, $I_1$ is the first deviatoric strain invariant. $C_{10}$ and $D_1$ are material parameters. $C_{10}$ and Poisson's ratio $(v)$ were defined as open-fit parameters and the relationship between $C_{10}$ , $D_1$ and $v$ was used to calculate $D_1$ in each simulation.

$$D_1 = \frac{3(1-2v)}{2C_{10}(v+1)} \quad (3)$$

A 2D axisymmetric model was developed in this study (Figure 1) and the dimensions were matched to rat aorta (internal diameter of 1.2mm, thickness of 100µm and a cardiac cycle duration of 0.15s). There were three steps in our simulations: 1) internal ramping pressure from zero to 100mmHg 2) consolidation 3) cyclic pressure between 80 and 120mmHg. A mesh convergence study was implemented with a criterion of less than 1% difference in the luminal reversal flow. The results revealed that a 0.5-micron element size in the radial direction is appropriate. All rotational degrees of freedom, displacements in the axial direction and pore pressure at the outer surface of the graft wall were set to zero.

SB³C2022-087

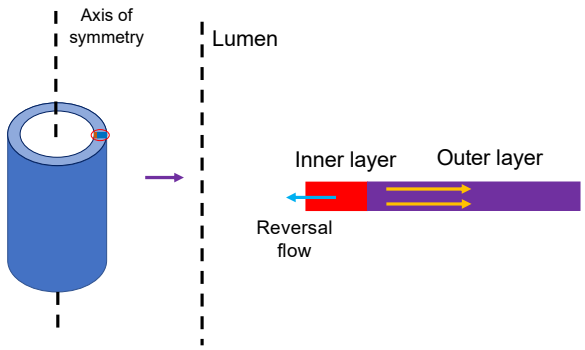

**Figure 1. Geometry of the vascular graft in the 2D Axisymmetric model**

A two-step particle swarm optimization algorithm (MATLAB) was utilized to minimize the objective functions (5). The results of the first step of the optimization were used as the initial guess for the second step. In single-objective optimization, we focused on maximizing the luminal reversal flow using the following function.

$$f_{so} = e^{v^{fr}} \tag{4}$$

For multi-objective optimization, we simultaneously maximized the LRFV and matched the compliance to rat aorta (C=0.0014) using the following function.

$$f_{mo} = \sqrt{s_1\left(\frac{e^{v^{fr}} - {f_{so}}^{opt}}{{f_{so}}^{opt}}\right)^2 + s_2\left(\frac{f_c - C_{ratiaorta}}{C_{ratiaorta}}\right)^2} \tag{5}$$

$s_1$ and $s_2$ are scaling factors, ${f_{so}}^{opt}$ is the minimized single-objective function and $f_c$ is the graft compliance in each simulation. $C_{10}$, $v$, $k_A$ and t for each layer were the open-fit parameters except for the outer layer thickness which was calculated based on the overall thickness and the thickness of the inner layer. Table 1 summarizes the optimization constraints.

**Table 1. Optimization constraints**

| | $C_{10} i(kpa)$ | $v$ | $k_A(m/s)$ | t (μm) |
|---|---|---|---|---|
| Lower bound | 80 | 0.3 | $1e^{-3}$ | 10 |
| Upper bound | 1000000 | 0.49 | $1e^{-12}$ | 90 |

## RESULTS

Figure 2 represents the LRFV and compliance of the vascular graft in both optimizations. In single-objective optimization, we achieved a maximum LRFV of 168 μm/s. In this optimization, the graft compliance was approximately 5 times larger than that of rat aorta. In multi-objective optimization, imposing mechanical constraints to match the compliance resulted in a lower LRFV of 49 μm/s. The graft compliance was precisely matched to the target artery. Table 2 summarizes the optimized parameters for both optimizations. These results indicate the significance of increasing the thickness of a highly permeable inner layer and a low-permeability outer layer in a compressible soft vascular graft to increase the LRFV. $C_{10}$ value of the outer layer in the multi-objective optimization was optimized to match the compliance to rat aorta. Poisson's ratio values are all at the bounds indicating the effect of high compressibility on the LRFV.

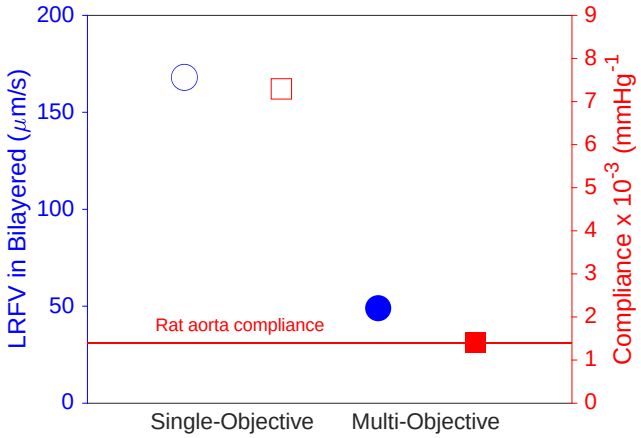

**Figure 2. LRFV and compliance in single and multi-objective optimizations**

**Table 2. Optimized parameters in both optimizations. ($C_{10}$ is in $kpa$, $k_A$ is in $m/s$ and thickness is in μm)**

| | Inner layer | | | | Outer layer | | | |
|---|---|---|---|---|---|---|---|---|
| | $C_{10}$ | $v$ | $k_A$ | t | $C_{10}$ | $v$ | $k_A$ | t |
| SO | 80 | 0.3 | $7.6e^{-4}$ | 90 | 80 | 0.3 | $\mathbf{1.5e^{-11}}$ | 10 |
| MO | 80 | 0.3 | $1e^{-3}$ | 90 | $\mathbf{1.1e^{-3}}$ | 0.3 | $1e^{-12}$ | 10 |

## DISCUSSION

In this research, we optimized the material, geometrical, and transport properties of a porohyperelastic bilayered vascular graft to maximize the LRFV which can potentially repel the platelets. We achieved an LRFV of 168 μm/s and 49 μm/s in the single-objective and multi-objective optimization, respectively. In multi-objective optimization, we accurately matched the graft compliance to rat aorta. Soldani et. al., have shown that a highly permeable inner layer and a highly impermeable outer layer can reduce thrombus formation in-vivo (6), which is consistent with our optimization results. Ayyalasomayajula et. al, have also captured luminal reversal flow in an abdominal aortic aneurysm computational model (7). We used a compressible Neo-Hookean material to perform this study. More complex constitutive models and incorporation of anisotropy into our model can potentially alter the optimization results. Thrombosis in both acute and chronic form has long been a major clinical problem. Although we require in-vitro and in-vivo data to support our hypothesis, our computational findings open a new avenue to address this clinical need.

## INTRODUCTION

Despite a high short-term success rate of thoracic endovascular aortic repair (TEVAR) for type B aortic dissections, the desired mid- and long-term outcome, i.e. the formation of a fully thrombosed false lumen, is often not obtained. Instead, for 30% of the patients aortic expansion within the first year is observed [1]. Up to now, it has not been elucidated how to predict which patients will benefit from TEVAR on the long-term. Consequently, more insight into the effect of TEVAR on the dissected aortic wall may be required to further optimize the current treatment on a patient-specific level. In order to fully understand the effect of this treatment, it is needed to accurately capture the biomechanical response of the stent graft deployment on the blood flow and the dissected aortic wall. Such insight may be acquired from computational biomechanical studies, but dissected wall models are currently fairly limited and, to the best of our knowledge, do not include anisotropy combined with constituent-specific residual stretches in the soft tissue [2]. Besides, the influence of both geometrical, e.g. wall thickness, and material modeling parameters on the resulting wall displacement remains largely unknown. With the long-term goal to predict the patient-specific outcome of TEVAR, it is essential to know the influence of variations in these parameters, especially for those parameters that cannot be retrieved from clinical CT scans.

Therefore, this study aims to develop a computational framework of an idealized dissected aortic wall, including anisotropy and residual stresses, which is used to estimate the uncertainty on the predicted wall displacements.

## METHODS

The finite element model framework for the idealized dissected aortic wall was developed in Abaqus\Standard (Dassault Systèmes, France). The model was generated, starting from a cylinder, with a diameter of 27.3 mm and length of 60 mm, that contained a false lumen, with a length of 40 mm, and tears in the dissected membrane (DM), both with a predefined size and location [3]. The wall consisted of a medial and an adventitial layer, both modelled as an anisotropic hyperelastic material according to the Gasser-Ogden-Holzapfel (GOH) model [4]. The deposition stretches of elastin and collagen were included using a Matlab (The MathWorks Inc., Natick, MA, USA) implementation of the algorithm presented by Famaey et al. for an intact thick-walled cylinder without false lumen or tears [5]. Firstly, these deposition stretches were applied and the true and false lumen were subsequently loaded to diastolic (80 mmHg) and systolic (120 mmHg) pressure. A mesh sensitivity study was performed to ensure a mesh independent outcome and resulted in a model with 36 000 hexahedral elements.

The uncertainty related to the unknown total wall (1.3-2.5 mm), medial (65-85% of total wall thickness) and DM (50-90% of medial thickness) thickness and material properties ($c_{10}$ = 0.005-0.025 MPa , $k_1$ = 0.0002-1.0 MPa, $k_2$ = 4.0-35.0, $\alpha$ = 0-90°, $\kappa$ = 0-1/3) was estimated, using a Latin hypercube with 40 samples and input ranges based on a literature study. The conventional material properties of the GOH model were converted into a single clinically tangible functional stiffness parameter, i.e. the pulse wave velocity (PWV), which was assessed for a reference tube with the same material parameters. PWV at 80 mmHg was limited to the physiological range of 4 to 12 m/s. As the dissected wall deformation is of interest, the maximal displacements of the remaining wall (RW) and DM, relative to the intact configuration, at diastolic and systolic pressure were taken as output parameters.

## RESULTS

From the 40 samples of the Latin hypercube, 39 fulfilled Abaqus's convergence criteria. Each of the converged cases resulted in a typical dissected configuration with a narrowed true lumen and a false lumen that is bulging out, as shown in figure 1. The box plots, based on these 39 cases, of the maximal displacements of RW and DM at diastolic and systolic pressure are presented in figure 2, as well as the corresponding absolute difference in maximal displacement between diastole and

systole. For RW, median maximal displacement values of 2.21 mm and 2.78 mm were found at diastolic and systolic pressure, respectively. For DM, median maximal displacements of 5.76 mm in diastole and 6.10 mm in systole were observed. Considering the absolute difference of the maximal displacements at diastolic and systolic pressure, median values of, respectively, 0.62 mm and 0.23 mm were observed for RW and DM.

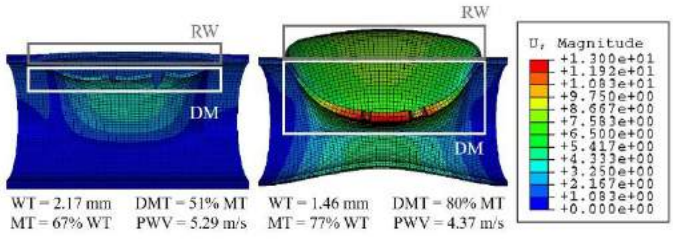

**Figure 1: Deformed systolic configurations for two samples that represent the extent to which the bulging in and out of the dissected membrane (DM) and remaining wall (RW) varies. The applied input parameters – wall thickness (WT), media thickness (MT), dissected membrane thickness (DMT) and pulse wave velocity (PWV) – for both samples are indicated too. The displacement magnitude (U) is given in mm.**

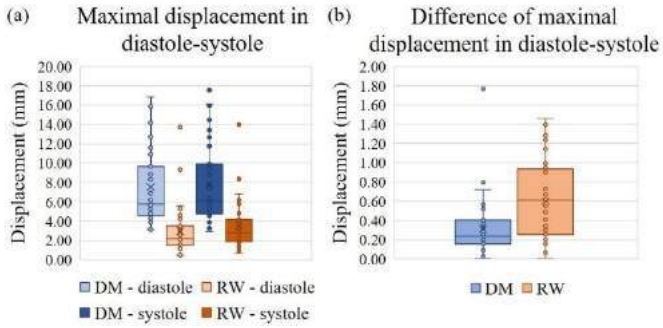

**Figure 2: Boxplots of (a) the maximal displacements of the dissected membrane (DM) and remaining wall (RW) at diastolic and systolic pressure and (b) the absolute difference between these displacements of DM and RW, based on the 39 converged samples.**

Based on the minimal and maximal results, uncertainty ranges of [-79; 524]% and [-75; 417]% of the corresponding median value were found for the maximal displacement of RW in diastole and systole. Similarly, variations of [-45; 195]% and [-51; 190]% were found for DM at diastolic and systolic pressure, respectively. By using the interquartile range, the following variations w.r.t. the corresponding median value were found in diastole and systole, respectively: [-33; 56]% and [-33; 49]% for RW; [-20; 62]% and [-21; +58]% for DM.

## DISCUSSION

From the 40 simulated Latin hypercube samples, based on large though physiologically relevant ranges for the considered input parameters, only one case with a total wall thickness of 1.35 mm diverged. This points out that a robust model framework was developed for an idealized dissected aortic wall.

The median maximal displacement is larger for DM compared to RW, both in diastole and systole. By considering the differences between diastole and systole, an estimation is made for the expected displacement throughout the cardiac cycle, although no pressure waves are taken into account and the locations of the maxima might differ. The simulations with this idealized model yielded a median DM displacement of 0.23 mm from diastolic to systolic pressure, with values ranging from 0.01 mm to 1.77 mm. Baumler et al. observed a maximal DM displacement of 0.6 mm in the cardiac cycle based on 4D MRI data for a patient-specific case, while Ganten et al. observed a median maximal DM displacement of 1.3 mm [2,6]. There is, thus, still a discrepancy between the model results and the experimental data, which is suggested to be mainly caused by the difference in dissection length. Indeed, the dissection extended from the thoracic to the abdominal aorta in the experimental data whereas the dissection length in the idealized model was only 40 mm. However, a similar order of magnitude was obtained, especially when comparing to the data of Baumler et al. [2].

Although the median maximal RW displacement has a lower magnitude, it seems to result in higher variations between systolic and diastolic pressure, i.e. a median difference of 0.62 mm, compared to DM. Taking into account that the same pressure load is applied to the true and false lumen, it is intuitive that RW displacement is more susceptible to variations in pressure.

The full uncertainty ranges based on the minimal and maximal displacement results, over all cases, show large variations, in particular for RW. The uncertainty based on the interquartile ranges is remarkably smaller, with a total variation of 80-90% of the corresponding median maximal displacement for RW and DM. Although a smaller range is expected, the large differences in upper boundary might indicate that the full uncertainty ranges overestimate the uncertainty for the majority of the cases. However, it is important to keep in mind that these extreme cases can, although rarely, occur as well.

For both types of uncertainty ranges, no large differences were observed between systole and diastole, suggesting that the applied pressure load will influence the uncertainty results only up to a limited extend. It might, therefore, be sufficient to consider one loading state when looking into the uncertainty imposed by unknown wall thicknesses and material parameters.

This study presented a robust model framework of the soft tissue behavior in an idealized aortic dissection. Although the geometry was idealized, an advanced material model including constituent-specific residual stresses was applied. This framework was used to quantify the uncertainty on the biomechanical response of the aortic dissection to inflation, taking into account the physiological variability of geometrical and constitutive material parameters that cannot be determined from clinical CT scans. It was shown that this variability strongly influences the predicted maximal displacements of DM and RW. It is, therefore, essential to report and further investigate the outcome uncertainty when developing dissected wall models. Given that the resulting uncertainty in wall displacement strongly depended on the exact uncertainty metric, a more advanced technique might be required to provide a more accurate estimate. It is, therefore, envisaged to combine the obtained result with a Gaussian process.

# CALIBRATING MECHANOREGULATORY MODELS OF FRACTURE REPAIR AND REMODELING USING IMAGING DATA FROM SHEEP

**Tianyi Ren, MS (1) and Hannah L. Dailey, PhD (1)**

(1) Department of Mechanical Engineering and Mechanics, Lehigh University Bethlehem, PA, USA

## INTRODUCTION

One of the most common misconceptions about bone repair pertains to remodeling. Traditionally, fracture healing is described as a sequence of four phases starting with an inflammation phase, followed by two repair phases consisting of soft callus formation and hard callus formation, and completed via a remodeling phase. Most numerical models assume that remodeling occurs after bridging and can therefore be neglected in favor of capturing the process of woven bone deposition in the callus. The potential drawback of this four-phase model is that it does not consider the often-significant temporal overlap between the different phases. The key barrier to developing new mechanoregulatory models that can consider coupled repair and remodeling is the lack of available *in vivo* validation data. Therefore, the objectives of this study were to: 1) measure remodeling activity during fracture healing using micro-computed tomography (μCT) scans of osteotomized ovine tibiae, and 2) use this *in vivo* data to calibrate a mechanoregulatory simulation of fracture repair with coupled remodeling. To achieve this, we developed an image-processing technique to noninvasively quantify structural remodeling adaptations at the bone-callus boundary and adapted an established strain-based numerical simulation framework to predict fracture repair with remodeling.

## METHODS

### *Image-Based Measurement of Remodeling During Fracture Healing*

Twenty-six adult female Swiss alpine sheep (average body weight 68 kg, range 63-76 kg) were part of previously completed research studies with tibial osteotomies stabilized by two different medial plates. Group 1 consisted of a 3-mm gap tibia osteotomy stabilized with a 12-hole stainless steel plate. Group 2 consisted of data from animals with a 17 mm gap tibia defect stabilized with a 12-hole stainless steel plate and augmented with autografts. After sacrifice at nine (Group 1) or twelve (Group 2) weeks, both tibiae (operated and intact) from each animal were excised and stripped of soft tissue. The stabilizing plate and screws were carefully removed from the operated tibia. Both tibiae were wrapped in saline-soaked gauze and μCT was scanned at 60.7 μm isotropic resolution.

The radiodensity data across the cortical-callus boundary was sampled from the images using our recently published method [1]. In brief, radial arrays of profile lines were created from the medullary canal through the callus. This process was repeated for sets of transverse planes containing 20 sequential slices each. Data points were sampled from the underlying pixels using bicubic interpolation, resulting in at least 170,000 data points in each region of interest (ROI). For this study, one ROI was sampled at the midshaft of each intact contralateral limb. Two ROIs were sampled for osteotomies, one just distal to the osteotomy line and one at the distal extent of the callus. Data from each profile line was registered to set its local linear coordinate system to zero at the bone-callus boundary (if osteotomized) or at the pericortical surface (if intact). Negative linear coordinates were normalized to the local cortex thickness; positive linear coordinates were normalized to the doubled local callus thickness. Radiodensity was normalized to the median cortical bone density in the untreated limb for each sheep. Multi-objective optimization in MATLAB was used to fit the parameters of a piecewise generalized sigmoid function describing the gradients in mineralization from cortical bone to callus. Fit parameters obtained for all 26 animals were then compared between the three ROIs. Two-tailed paired-samples t-tests was used to analyze if the fitting function constants and the evaluated slope of the fitting function at the pericortical boundary ($x$=0) were significantly different between the operated and contralateral limbs and between the central and peripheral callus. All statistical analyses were performed using SPSS Statistics 27 (IBM Corp; Armonk, New York, USA).

SB³C2022-089

### *Mechanoregulation Simulations with Coupled Repair & Remodeling*

Iterative simulations of bone healing with coupled remodeling were carried out in ANSYS with the mechanoregulation model controlled in MATLAB (R2021A; Mathworks, Inc.) using the Fuzzy Logic Toolbox (v. 2.3.1). Model parameters without remodeling activity were established in our previous studies [2,3]. Healing simulations were run with a fuzzy engine comprising 16 linguistic rules to control tissue differentiation based on dilatational and distortional strains, the volume fractions of connective tissue, cartilage, and bone at the previous iteration, and proximity to the fracture line. For this new work, remodeling was incorporated into our fuzzy logic framework by introducing a new tissue type (cortical bone, $E_{cb}\,i{=}\,i12.5iGPa$) with remodeling rules that activate only for cortical bone and woven bone elements, which were allowed to have density-dependent properties. The new regulatory remodeling model describes three levels of strain stimuli: resorption, quiescence, and formation. To capture the coupled remodeling of both cortical bone and callus, we adapted a published strain energy density-based description of the remodeling stimulus [4].

## RESULTS

### *Remodeling Occurs in Tandem with Early Fracture Healing*

The radiodensity sampling data clearly showed evidence of remodeling activity in the cortical wall bounded by callus (Fig. 1D). At the proximal and distal ends, there was an average decrease in density of 1-2% in the operated limbs compared to the intact contralateral limbs. At the midshaft, the preexisting increase in radiodensity toward the pericortical boundary seen in the intact bones (Fig. 1C) disappeared in the osteotomized bones (Fig. 1C/D). Comparing intact versus operated limbs, there were statistically significant differences in all obtained radiodensity profile fitting function parameters that describe the extent of remodeling ($p \leq 0.001$). At the pericortical boundary bounded by callus, these changes corresponded to a 23.4% drop on average from the peak density of the native cortical wall.

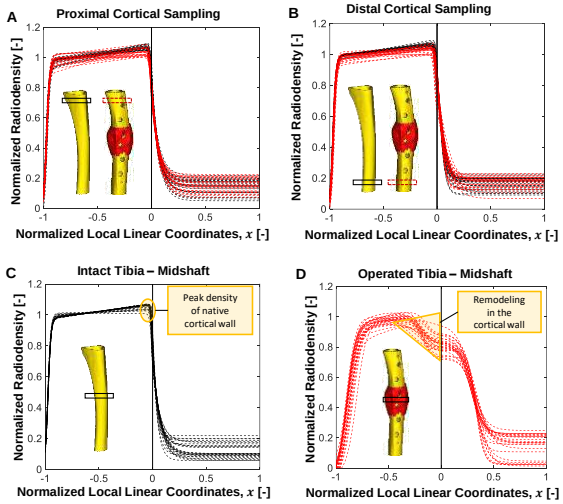

**Figure 1: Profilometry curves were fitted from data sampled at the proximal end (A) or distal end (B) of intact tibiae (black curves) and operated tibiae (red curves). Data was also sampled at the midshaft of intact tibiae (C, black curves) and operated tibiae (D, red curves). Early remodeling caused a 23% average reduction in density in the cortical wall bounded by callus.**

### *Calibration of Mechanoregulatory Healing Models with Remodeling*

Without remodeling, the fracture healing simulation produced bridging with no changes in density in the cortical wall and achieved a steady-state callus size and material distribution. With remodeling, both increasing callus mineralization and loss of cortical wall density were observed in the models. The remodeling rate constants and strain energy density thresholds were systematically varied to study the sensitivity of the model results to these parameters. When the remodeling rate constants were set too high, extreme non-physical remodeling occurred, resulting in a total erosion of the cortical wall in consistent with the experimental observations. However, with calibration, the results achieved a qualitatively good match of callus shape, callus propagation, and remodeling extent when compared with the animal data (Fig. 2).

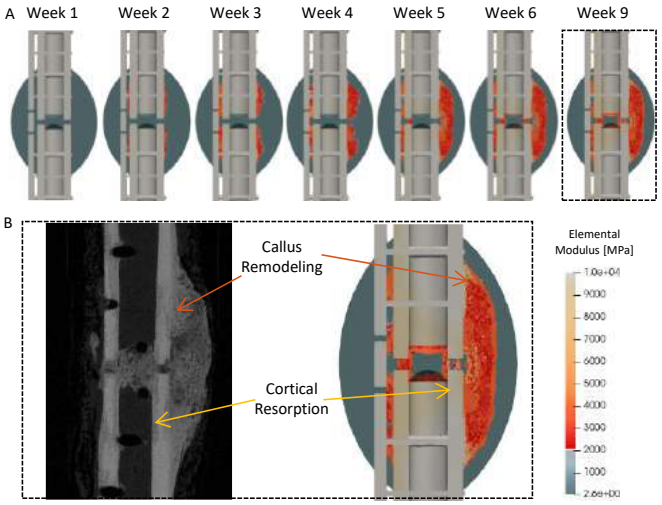

**Figure 2: A) Elastic modulus contour plots at selected timepoints for the mechanoregulation model with remodeling. B) Model prediction compared to coronal slice view from a µCT scan of an ovine tibial osteotomy at 9 weeks post-op.**

## DISCUSSION

The results of this study showed that remodeling occurs in the cortical tissue adjacent to the repair zone early in the healing process, in tandem with bridging. The image analysis methods were successful in quantifying the extent of these changes. The *in vivo* data also provided a framework for incorporating and calibrating remodeling terms in a mechanoregulatory simulation of fracture healing. These methods are unique in their use of *in vivo* datasets for numerical model development. The results suggested that incorporating remodeling activity is critical for the development of numerical simulations that match the physiologic patterns of callus development *in vivo*. The work also provided a basis for future investigations that will explore the mechanical and biological stimuli that drive late-stage callus resorption.

## INTRODUCTION

Endothelial activation characterized by the increased production of reactive oxygen species (ROS) and a shift towards a pro-inflammatory state is associated with numerous cardiovascular diseases including atherosclerosis[1,2]. Endothelial phenotype, and thus activation, is regulated by the application of shear stress, an example of endothelial mechanotransduction. The endothelial glycocalyx (GCX), a glycoprotein-proteoglycan layer extending from the endothelial membrane, is a known mechanotransducer that promotes proper function of endothelial cells[4]. Major GCX components implicated in mechanotransduction include its core proteins, mainly syndecan and glypican, the protein receptor CD44, and the attached glycosaminoglycans heparan sulfate (HS), hyaluronic acid, and chondroitin sulfate. Elucidating the role of a healthy GCX and normal shear stress in deterring endothelial activation remains critical to combatting a wide range of cardiovascular diseases.

Interestingly, it was previously reported that GCX degradation, particularly of the HS and sialic acid components, leads to increased ROS production[5]. Yet, these findings have not been further validated and the molecular mechanism behind the relationship remain unknown. While GCX degradation is associated with classical markers of pro-inflammatory EC activation (e.g., increased adhesion molecule expression), high-throughput analyses on the impact of HS degradation on endothelial phenotype have not been performed but would provide a deeper understanding of the full impacts of the GCX in regulating endothelial function. Furthermore, studies investigating the impact of shear stress on ROS production have generated contradicting results and the full extent to which flow regulates endothelial inflammation is unclear. Thus, the goal of this research was to identify the roles of both shear stress application and HS expression on endothelial activation with specific regards to ROS production and the expression of inflammatory genes.

## METHODS

To analyze the effects of HS and shear stress on endothelial activation, Human aortic endothelial cells were exposed to shear stress in a parallel-plate flow chamber (adapted from previous work)[6] with either intact or enzymatically degraded glycocalyx layers. For all shear stress experiments, cells were exposed to flow for 24 hours at an eventual 14 dynes/cm$^2$, administered using a peristaltic pump. The HS component of the endothelial glycocalyx was enzymatically degraded using 250 μIU/mL (micro international units) of heparinase III (Ibex; Montreal, Canada) for 24 hours in either static or flow conditions. Optimal HepIII concentration was determined through a dose response and subsequent immunocytochemistry (ICC) of HS.

Once the cells were conditioned, a variety of biological assays were performed to determine the effects of HS degradation and shear stress, including ROS probes, RNA sequencing (RNA-seq), western blotting, and ICC. For all assays, four groups of samples were analyzed: (i) static conditioned, (ii) flow exposed, (iii) Hep III-treated and static conditioned, and (iv) Hep III-treated and flow exposed. Two ROS assays, dihydroethidium, to identify mainly superoxide, and 6-chloromethyl-2', 7'-dichlorodihydrofluorescein diacetate (H2DCFDA), a more general indicator of ROS including hydrogen peroxide (H2O2), were performed to identify ROS production. RNA-seq was applied to assess the presence, quantity, and dynamic expression of genes associated with either the endothelial redox state or endothelial inflammatory response. Finally, western blotting and/or ICC was performed on a variety of anti/pro-oxidant and anti/pro-inflammatory proteins including HS, Nrf2, Nf-κB-p65, Nox2/4, ICAM-1, E-selectin, and KLF2.

Data pertaining to fluorescent imaging and western blotting was analyzed using one-way ANOVAs with post hoc Tukey's multiple comparison tests with an alpha value of 0.05. Additionally, with the exception of RNA-seq data, data was normalized to control groups in each experiment to eliminate any bias introduced by inter-experiment

SB³C2022-090

differences such as cell passage number. For RNA-seq data, differential expression was assessed using the Wald test implemented in the DESeq2 R package. Correction for multiple hypothesis testing was accomplished using the Benjamini-Hochberg false discovery rate (FDR). To identify changes in expression of entire gene sets, Gene Set Enrichment Analysis (version 2.2.1) was used.

## RESULTS

To initially evaluate the impact of uniform flow on EC redox state, a combination of fluorescent ROS probes, ICC, and western blotting was utilized. Using the fluorescent ROS indicator $H_2$DCFDA, we found that the application of 24 hours of uniform flow reduced total ROS levels by approximately 30% compared to static controls. Furthermore, the reduction in total ROS was accompanied by a significant 2.5-fold increase in the activation of the antioxidant transcription factor Nrf2 as determined by ICC. Increased Nrf2 activation and decreased total ROS also correlated with significant reductions in the oxidant enzymes Nox2 and Nox4 to approximately 10% and 54% of their static expression, respectively, as indicated by western blots. Regarding the GCX's role in the redox state, we found that HS degradation had no significant effect on overall ROS production or anti/pro-oxidant protein expression.

RNA-seq was utilized to further investigate the impact of uniform flow and the endothelial glycocalyx, particularly its HS component, on endothelial redox state while also identifying key genes implicated in these relationships. Out of 41 antioxidant genes with significant expression (>1000 counts) that had previously been implicated in endothelial redox regulation, we observed increased expression in 23 of these genes after exposure to uniform flow in non-enzyme (non-Hep III) conditions. Specifically, significant increases in the expression of antioxidant genes including GSTO-1, HMOX-1, NQO1, NRF2, PRDX1, SELENOS, TXN, and TXNRD1 were observed to increase after flow exposure. With regard to oxidant genes, uniform flow exposure reduced the expression of the oxidant genes CYBA, a Nox protein subunit, and MAOA while simultaneously increasing NOX4 expression. Additionally, RNA-seq supported our fluorescent and western blot redox analysis, finding no impact of HS degradation on redox gene regulation.

Increased production of ROS, such as hydrogen peroxide and superoxide, occurs during pro-inflammatory endothelial activation associated with cardiovascular diseases such as atherosclerosis[7]. Thus, we utilized RNA-seq, ICC, and western blot data to identify relationships between uniform flow or heparan sulfate degradation and inflammation related to endothelial activation. Uniform flow exposure led to a significant upregulation of anti-inflammatory genes. Specifically, flow led to increased expression of 15 out of 22 investigated anti-inflammatory genes. These included genes associated with Nf-kb inhibition such as CHUK, IKBKG, NFKBIA, and NFKBIE as well as the KLF transcription factor family, of which KLF2 and KLF4 have been strongly implicated in anti-inflammatory endothelial function. Additionally, out of 60 pro-inflammatory genes associated with activation, 30 of these genes had significantly decreased expression after uniform flow exposure, including the adhesion molecules ICAM-2 and VCAM-1; the transcription factor HIF1A; the cytokines IL1A, IL1B, and IL33; the immune receptor TLR3; the glycoprotein VWF; and the endopeptidase MMP14.

HS was also found to regulate gene expression related to pro-inflammatory EC activation. Specifically, the RNA-seq results demonstrated upregulation in pro-inflammatory genes after HS degradation, correlating with the increased expression of 42 out of the 60 investigated genes. These included the adhesion molecules ICAM-1, SELE, and VCAM-1; the cytokines IL1A and IL1B; MMP14; and the Nf-kb subunits NFKB2 (p52/100) and RELB. The observed increase in pro-inflammatory gene expression after HS degradation occurred in both static (untreated static vs. Hep III-treated static) and flow (untreated flow vs. Hep III-treated flow) conditions. These increases were also interestingly accompanied by a significant increase in anti-inflammatory gene expression, suggesting a complex relationship between HS degradation and inflammatory state.

To support findings from RNA-seq data, protein-level analysis was performed on a known inflammatory (ICAM-1) and anti-inflammatory (KLF2) marker. Western blotting identified a significant 86.6% increase in total ICAM-1 protein expression when comparing static and Hep III treated static conditions. Furthermore, ICC imaging identified a significant 63.0% increase in Hep III uniform flow ICAM-1 expression, compared to static conditions. Altogether, protein-level analysis supports RNA-seq findings of enzymatic degradation of HS increasing inflammation. On the other hand, uniform flow led to a significant 22.3% and 21.1% upregulation in KLF2 expression via ICC between Hep III flow and static conditions as well as Hep III flow and Hep III static respectively. Additionally, uniform flow exhibited an 11.8% (although statistically insignificant) increase in KLF2 mean fluorescence intensity, compared to static conditions.

## DISCUSSION

Collectively, findings from this study implicate the beneficial roles of shear stress exposure on endothelial activation via a shift towards anti-oxidant and anti-inflammatory gene expression while identifying a pro-inflammatory response induced by HS degradation, in agreement with previous research[8,9]. However, to our knowledge, no previous study has utilized RNA-seq or similar high-throughput modalities to study the role of HS degradation on activation. RNA-seq paired with more traditional protein-level analysis illustrates the complexity of the endothelial redox response that involves not several but dozens of genes, suggesting that future studies investigating endothelial redox state may require high-throughput analysis to accurately identify the complete effects. Ultimately, data from this study may be used to develop therapeutics combating ROS production, inflammation, and other modes of endothelial activation associated with several cardiovascular diseases such as atherosclerosis.

# PARTIAL ACL INJURY LOCATION IMPACTS BIOMECHANICS AND TISSUE REMODELING IN A SKELETALLY IMMATURE PORCINE MODEL

**Danielle Howe (1), Jacob D. Thompson (1), Andre Bautista (1), Lauren V. Schnabel (2), Jeffrey T. Spang (3), Matthew B. Fisher (1,3)**

## INTRODUCTION

Approximately 25% of diagnosed ACL injuries are partial tears, which can be concentrated in either the anteromedial (AM) or posterolateral (PL) bundle of the ACL [1]. While full-thickness ACL tears typically lead to two-fold greater anterior knee joint laxity, partial tears lead to more subtle increases [2]. For this reason, there is not a consensus regarding treatment of partial tears, particularly in pediatric patients [3]. Some advocate for non-operative management to avoid the risk of disrupting growth plates as well as any further trauma to the joint. Others argue that surgical reconstruction is needed to restore joint stability and avoid subsequent injury to the menisci and cartilage. Furthermore, some opt for single-bundle surgical augmentation while conserving the intact bundle. To improve clinical decision-making, it is important to determine whether partial ACL injury leads to degenerative changes to the joint, and particularly to cartilage. Additionally, it would be valuable to determine whether these changes differ between injuries concentrated in the AM or PL bundle. Large exploratory studies with pediatric patients are difficult and rare. As such, the pig has been established as a model of the human ACL since the AM and PL bundles function similarly in mature humans and pigs [4]. Additionally, porcine ACL size and bundle function throughout skeletal growth have been well characterized [5,6]. Furthermore, the porcine model can be paired with clinically translatable tools to non-invasively study joint health and remodeling, such as T2* (indicative of collagen organization) and T1rho (indicative of proteoglycan content) mapping via MRI. Therefore, the objective of this study was to evaluate the effect of partial injury location in a juvenile porcine model on joint function as well as remodeling of the remaining ACL bundle and cartilage.

## METHODS

All experimental protocols were approved by the NC State University IACUC. A total of 16 juvenile (3 month old) Yorkshire cross-breed pigs underwent unilateral arthroscopic transection of the AM bundle (n=4 female, n=4 male) or the PL bundle (n=4 female, n=4 male) and a sham operation in the contralateral joint. After 24 weeks, animals were euthanized, and hind limbs were collected for analysis. T1rho mapping (FLASH, FA:10°, TR:8.74ms, TE:4.6 ms, ST: 1.5 mm, TSL: 2, 10, 20, 30, 40 ms) and T2* mapping (T2 SWI, FA:12°, TR:31ms, TE: 3.3, 7.01, 11.35, 15.68, 20, 24.4 ms, ST: 0.8mm) were performed on all stifle (knee) joints at full extension using a Siemens PRISMA 3T MRI system. Relaxation maps were created by fitting mono-exponential curves on a voxel-by-voxel basis using MATLAB. Articular cartilage was manually segmented from T1rho images to calculate the median T1rho value for the medial and lateral femoral and tibial compartments. The bundles of the ACL were segmented from T2* images to calculate the median T2* value of each bundle. ACL models segmented from T2* images were also analyzed using MATLAB to calculate the cross-sectional area (CSA) of each bundle [5,6].

Next, joints were biomechanically tested using a universal force-sensing robotic testing system (Kuka, SimVitro) [5,6]. 100 N of anterior-posterior (AP) drawer was applied to stifle joints at 60° of flexion while recording translations. The kinematics were then replayed while recording forces. Kinematics were repeated while recording forces after removing the capsule followed by the AM, then PL bundle (or only the remaining bundle in injured joints). Joint laxity was calculated as the AP tibial translation (APTT) under AP drawer. The force contributions of each bundle under maximum anterior translation were calculated using the principle of superposition [7].

Joint laxity, bundle contribution, bundle CSA, and bundle T2* values were compared between injured and contralateral joints using paired t-tests with Holm-Sidak correction for multiple comparisons ($\alpha$=0.05). The difference in median T1rho values between paired injured and contralateral joints was compared between injury types using unpaired t-tests ($\alpha$=0.05) and compared to zero using one-sample t-tests ($\alpha$=0.025). Data presented as mean overlaid with individual data points.

SB³C2022-091

## RESULTS

At 24 weeks post-surgery, mean force-translation curves were nearly indistinguishable between intact and PL-deficient (PL-) joints, while curves from AM-deficient (AM-) joints extended substantially further, with a shallower appearance (Fig. 1B). APTT was 50% greater in AM- joints compared to contralateral controls (adjusted [adj.] p=0.001), but within 9% (not significant) for PL- joints (Fig. 1C).

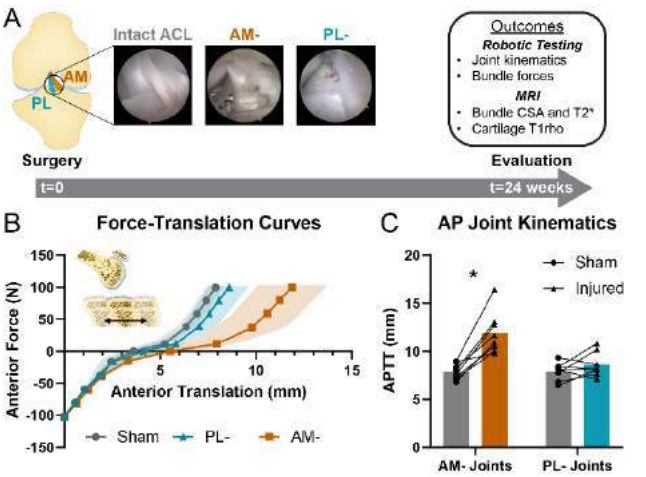

**Figure 1: (A) Joints were evaluated at 24 weeks after arthroscopic AM or PL bundle transection. (B) Average anterior-posterior (AP) force-translation curves. Shading represents 95% CI. (C) AP tibial translation (APTT). Lines connect data points from paired joints. *statistical significance from paired t-test.**

The force contribution of the remaining bundle to anterior drawer restraint was greater in AM- joints (166%↑, adj. p=0.004) and PL- joints (53%↑, adj. p=0.011) compared to the corresponding bundle in contralateral joints. (Fig. 2A). Correspondingly, the remaining bundle remodeled such that the CSA of the remaining bundle was larger compared to the healthy contralateral bundle for both AM- joints (28%↑, adj. p=0.005) and PL- joints (25%↑, adj. p=0.001) (Fig. 2B). T2* values of the remaining bundle in injured limbs did not significantly differ (<3ms) from the contralateral pair for either injury case (Fig. 2C).

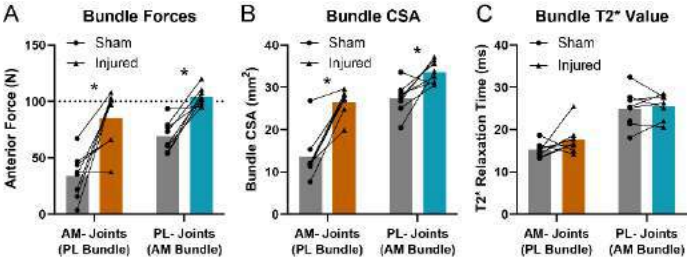

**Figure 2: Remaining bundle (A) force contributions under maximum anterior translation (dotted line represents applied load), (B) cross-sectional area, and (C) T2* value compared to contralateral joints. *statistical significance from paired t-test.**

The difference in T1rho value between paired injured and contralateral joints averaged larger for AM- joints than PL- joints, although not significantly different, for lateral femoral (2.7ms, p=0.27), medial femoral (4.6ms, p=0.06), lateral tibial (3.9ms, p=0.12), and medial tibial (0.8ms, p=0.84) cartilage, respectively (Fig. 3). Additionally, means were not statistically different from zero (control) for PL- joints (p=0.3-0.9) or AM- joints (p=0.04-0.6).

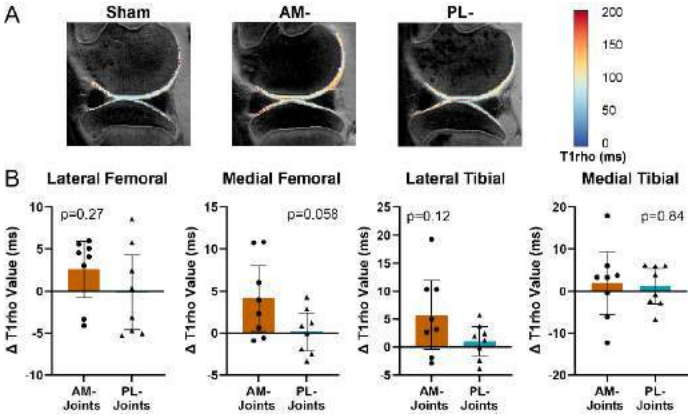

**Figure 3: (A) Representative T1rho maps of medial cartilage for each case. (B) Difference in median T1rho values between paired injured and contralateral joints for the medial and lateral femoral and tibial articular cartilage. Error bars represent 95% CI. P-values from t-test between injury types shown in graph.**

## DISCUSSION

In this study, functional outcomes varied by injury location at 24 weeks after partial ACL injury. The remaining bundle remodeled for both injuries, but AM- joints had increased joint laxity while PL- joints had similar laxity to intact joints. Additionally, cartilage T1rho was elevated in AM- joints but not PL- joints, though differences were not statistically significant for the current sample size. Ongoing work will increase the sample size. Joint function and bundle data from intact legs in the present study are consistent with values reported in mid- to late-adolescent (6-18 month) pigs [5,6]. These results point to potential clinical challenges in diagnosing PL- injuries but indicate that AM- injuries may be detectable via anterior drawer or Lachman tests. In PL- joints, near-intact levels of joint laxity, the ability of the remaining bundle to remodel by increasing in size, and little evidence of abnormal cartilage remodeling suggest that conservative treatment may be adequate for partial injuries concentrated in the PL bundle in young patients. However, AM- joints showed measurably increased joint laxity and the potential for abnormal cartilage remodeling, suggesting reconstruction or single-bundle augmentation may be necessary to restore stability and prevent cartilage degeneration. Although clinical data from pediatric partial tears are rare, one study with 45 patients found PL-concentrated tears were more likely to experience re-injury than AM-concentrated tears [8], contrary to the present study. However, it is not clear whether factors such as injury severity or joint laxity differed between groups at the onset of the study. Additionally, the study excluded patients with a Lachman test showing >5mm side-side difference. From our data, it is possible that more AM tears were excluded and that the results suffer from survivor bias. Ongoing and future work will compare between ages and sexes.

# ACTIVE/PASSIVE MECHANICAL PROPERTIES OF AORTA EXPLANTS FROM A MOUSE MODEL OF DIET-INDUCED MEDIAL ARTERIAL CALCIFICATION

**Breanna Pederson (1), Mengistu G. Gebere (2), Mohamad Azhar (2), Narendra R. Vyavahare (3), Susan M. Lessner (1,2), John F. Eberth (1,2)**

## INTRODUCTION

Arterial calcification occurs in most individuals above 60 years of age and is a well-known clinical predictor of all-cause mortality.[1,2] Unlike atherogenesis that originates in the intima, medial arterial calcification (MAC) is the mineralization of the musculo-elastic middle layer of large arteries leading to progressive stiffening, increased pulse pressure, and eventual heart and kidney damage. MAC is particularly prominent in patients with chronic kidney disease and diabetes due to dysregulated metabolic processes.[3] In MAC, vascular smooth muscle cells (VSMC) undergo a phenotypic switch into osteoblast-like cells, losing smooth muscle-specific markers.[4] A high-adenine and high-phosphate diet (adenine-diet) was previously shown to induce chronic kidney disease and MAC in rats. Still, this model has had limited translatability to other species thus far.[5] With several genetic mouse models available to researchers to study aortopathic conditions, extension of the adenine-diet to mice could provide a tool to understand the human condition better and to test potential therapeutic strategies. Distinguishing the role of extra-cellular-matrix stiffening in MAC from the reduced contractile capacity of the VSMCs is a crucial step in model characterization. Thus, in this study, we confirm the effectiveness of the adenine-diet to produce MAC in mice and test the active and passive mechanical properties to quantify the biomechanical consequences this diet has on extra-cellular-matrix remodeling and altered VSMC tone.

## METHODS

Explanted mouse abdominal aortas, taken from five-month-old C57BL6 male mice fed an adenine (n=3-4) or standard chow (n=7, control) diet, were biaxially tested in our lab. Due to limited tissue availability, qualitative histology was performed on females of the same age and diet groups as their male counterparts. Inflation-extension testing was performed over a pressure range of 10-160 mmHg and an axial stretch ratio of ±10% of the *in vivo* axial stretch ratio, defined as the ratio at which axial force is pressure-invariant. Two contractile states were investigated: first with VSMCs maximally contracted using phenylephrine ($10^{-5}$ M), next with the cells fully relaxed through the addition of sodium nitroprusside ($10^{-4}$ M). Both tests were performed in a 37 deg-C temperature-controlled and oxygenated medium. Isometric decomposition delineated the active stress from the total (contracted) and passive (relaxed) stress state of arteries at a common biaxial stretch ratio (details provided in Zhou et al. 2018). Using two-tailed t-tests, differences between discrete data were considered at $p<0.10$ and $p<0.05$ as indicated in the figures by * and **, respectively.

## RESULTS

The active-passive biaxial inflation-extension properties (**Figure 1**) of aortic explants were successfully tested using our custom-designed Mouse Aortic Active Response Tester (MAARTy). The adenine-diet group was found to have a lower *in vivo* axial stretch ratio (Ad = 1.49 ± 0.11, Ct = 1.65 ± 0.06; p=0.05), decreased passive outer diameter (Ad = 0.70 ± 0.01, Ct = 0.78 ± 0.08, $p<0.05$), and decreased passive area compliance (Ad = 0.002 ± 0.0002, Ct = 0.003 ± 0.0009 $mm^2$/mmHg; $p<0.10$) compared to controls (**Figure 2**). Moreover, the active stress

generation revealed adenine-diet hypo-contractility (Ad = 33.54 ± 9.72, Ct=63.26 ± 29.00 kPa; $p<0.10$) compared to controls (**Figure 3**). Although trending towards a lower value in the adenine-diet group, passive circumferential stretch was not statistically different between the two groups.

Histological composition analysis using Alizarin Red revealed a heterogeneous distribution of calcific nodules (deep red) in the media that lacked circumferential and axial uniformity. A representative sample of this heterogeneity can be seen in **Figure 4**. Additionally, each mouse demonstrated considerable specimen-to-specimen variation despite identical diets.

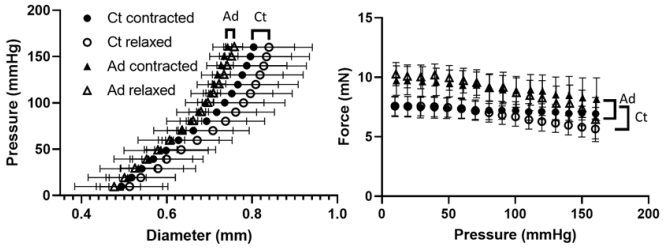

**Figure 1: Continuous A) pressure-diameter and B) force-pressure for fully contracted and fully relaxed VSMC tone in control (Ct) and adenine diet (Ad) mice. All data at *in vivo* axial stretch ratio.**

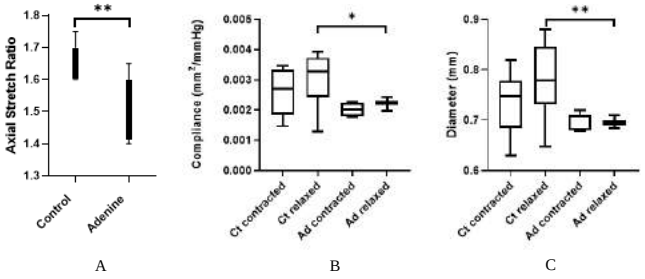

**Figure 2: A) In vivo axial stretch ratio, B) area compliance, and C) diameter for control and adenine diet mice. Panels B-C at 100 mmHg using fully contracted and fully relaxed VSMCs.**

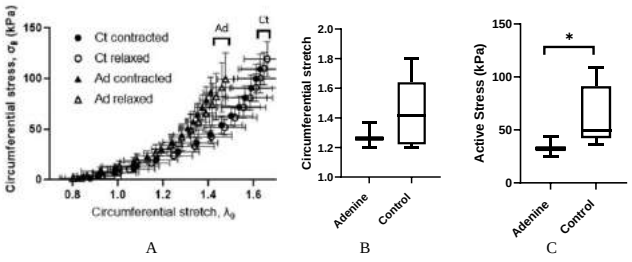

**Figure 3: A) Continuous stress-stretch relationships for fully contracted and fully relaxed VSMCs using control (Ct) and adenine diet (Ad) mice. B) Circumferential stretch ratio at 100 mmHg in the fully contracted configuration and C) active stress generation at the average stretch ratios described in B using isometric decomposition.**

**Figure 4: Alizarin-Red staining of aortas taken from two female adenine-diet mice illustrate considerable spatial heterogeneity and sample-to-sample variation, especially in female mice. Calcific nodules are indicated by the deep red staining areas.**

## DISCUSSION

Through histomechanical characterization of explanted mouse aortas we have confirmed the presence of calcific nodules in our diet-induced mouse model of MAC and preliminarily characterized the biomechanical phenotype of these mice. Our results indicate significant regional and animal-to-animal variations in calcification, thus highlighting the need to correlate specimen-specific calcium scoring with an individual vessel's mechanical properties. In terms of passive properties, biaxial mechanical testing indicated a reduction in caliber and extra-cellular-matrix stiffening in the adenine-diet explants. These tissues also demonstrated hypo-contractility with decreased VSMC vasoreactivity compared to controls. Thus, the extra-cellular-matrix properties and the contractile capacity of aortas were pathologically altered in adenine-diet mice. Overall, our findings suggest that the adenine-diet mouse model of MAC is successful, but with significant variability.

# A 3D COMPUTATIONAL MODEL OF AORTIC VALVE INTERSTITIAL CELL CONTRACTILE BEHAVIOR WITHIN A PEG HYDOGEL MEDIUM

**Alex Khang (1), John Steinman (1), Xinzeng Feng (1), Michael S. Sacks (1)**

(1) James T. Willerson Center for Cardiovascular Modeling and Simulation, The Oden Institute and Department of Biomedical Engineering, The University of Texas at Austin, Austin, Texas, United States of America

## INTRODUCTION

Aortic valve interstitial cells (AVICs) oversee extracellular matrix (ECM) maintenance and turnover in the aortic valve (AV) and take on an activated phenotype in diseases such as bicuspid AV (BAV) disease, in which the AV has two instead of the normal three leaflet tissues. AVIC activation is characterized by increases in ECM production, remodeling, and contractility via expression of alpha-smooth muscle actin stress fibers (SFs). Currently, we have a limited understanding of the intrinsic differences between AVICs from structurally normal AVs and BAVs and how these differences contribute toward an increased rate of disease progression in the BAV population. Moreover, we have a limited understanding of AVIC contractile behaviors, which play a critical role in mechanosensing and ECM remodeling and reflect AVIC activation levels and biophysical state. This is partly because individual SF forces and their orientation are difficult to measure directly due to their small feature size (~7 nm). Previous studies of AVIC mechanics have heavily utilized 2D culture environments out of convenience and ability to visualize the AVICs directly. However, these environments do not recapitulate the 3D nature of the AV, resulting in unrealistic SF structures. Herein, we used experimental and computational methods to estimate AVIC SF architecture and contractile forces in tissue-emulating 3D hydrogels. Ultimately these techniques will be used to study differences in AVICs from normal AVs and BAVs.

## METHODS

**3D traction force microscopy (3DTFM)**. Porcine AVICs and fluorescent microbeads were seeded in peptide-modified, poly (ethylene glycol) hydrogels for 72 hours before experimentation. The sample was incubated in Tyrode's Salt before obtaining an image stack of a single AVIC and surrounding fluorescent microbeads. Afterwards, Cytochalasin D was added to elicit cell relaxation through actin depolymerization and a second z-stack of the same FOV was obtained. The images were analyzed with our software, FM-track [1], which outputted an AVIC surface mesh and field displacements (Fig. 1). The displacements were interpolated onto the AVIC surface mesh, resulting in a 1:1 mapping between the initial and final AVIC shapes.

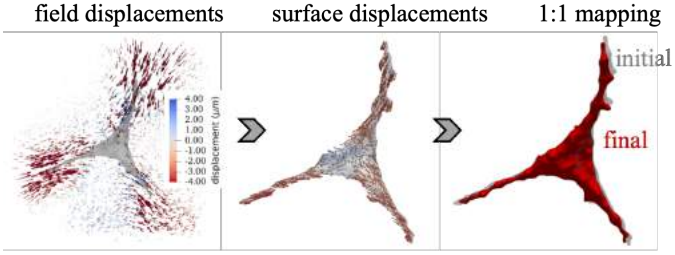

**Figure 1: 3DTFM experimental data. Field displacements and AVIC surface meshes are generated by our software FM-track [1]. Field displacements are interpolated onto the AVIC surface mesh to establish a 1:1 mapping to the final configuration.**

**Finite element mesh**. The hydrogel, AVIC cytoplasm, and AVIC nucleus were modeled (Fig. 2). AVIC geometry and spatial position was informed by 3DTFM data. Average nuclear geometry and spatial position was informed by immunostaining images from prior studies. The mesh consisted of ~50,000 linear tetrahedral elements.

**Modeling the mechanical behavior of the hydrogel**. The hydrogel domain was modeled as a Neo-Hookean solid with the following strain energy density function:

$$\psi = \frac{\mu}{2}(I_1 - 3 - 2\ln J) + \frac{\kappa}{2}(J-1)^2\,, \qquad (1)$$

where $\mu$ is the shear modulus, $I_1$ is the first invariant of the right Cauchy-Green deformation tensor, $J$ is the determinant of the deformation gradient tensor, and $\kappa$ is the bulk modulus. To account for cell-induced degradation [2] or strengthening of the gel, $\mu$ was allowed to vary spatially from the experimentally measured value of 108 Pa.

SB³C2022-093

**Modeling AVIC SF contraction**. The cytoplasm and nuclear domains were modeled as Neo-Hookean using eq. 1 with shear moduli of 750 and 7500 Pa, respectively, as informed by literature values [3,4]. SFs were modeled in the cytoplasm with total Cauchy stress given as:

$$\boldsymbol{T}^{sf} = \mathrm{H}(I_4 - 1)\left(2\frac{I_4}{J}\frac{\partial \psi_p^{sf}}{\partial I_4}\boldsymbol{m}\otimes\boldsymbol{m}\right) + \mathrm{f}\bar{\phi}_{sf}\frac{I_4}{J}\boldsymbol{m}\otimes\boldsymbol{m}, \quad (2)$$

where the first and second terms account for the passive and active stress produced by the SFs, respectively, $H()$ is a Heaviside step function that ensures SF passive stress arises only in tension ($I_4 > 1$), $I_4$ is the SF stretch, $\psi_p^{sf}$ is the SF strain energy density function:

$$\psi_p^{sf} = \frac{\mu_{sf}\bar{\phi}_{sf}}{2}(I_4 - 1)^2, \quad (3)$$

where $\mu_{sf}$ and $\bar{\phi}_{sf}$ are the SF modulus and expression level, respectively, $\boldsymbol{m}$ is the SF orientation, and $f$ is the contractile strength per unit SF. Parameters $\mu_{sf}$ and $f$ are set to 390 and 1590 Pa, respectively [3,4]. We backed out $\boldsymbol{m}$ and $\bar{\phi}_{sf}$ by minimizing the error between the simulated and experimental hydrogel displacements.

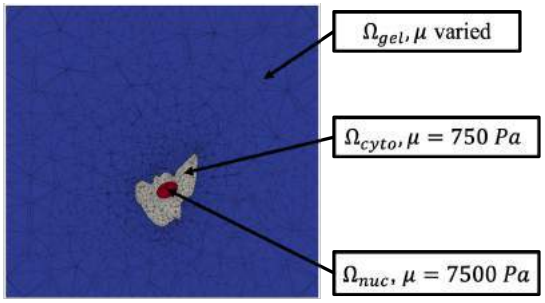

**Figure 2: A cross section of the 3D finite element mesh containing the hydrogel matrix, the AVIC cytoplasm, and the AVIC nucleus.**

## RESULTS

**Gel-model predicts hydrogel stiffening by AVICs.** Stiffening the hydrogel material near the AVIC surface resulted in better qualitative agreement in displacement magnitude with experiment than a homogenous model (Fig. 3A). The model estimated a non-linear stiffness profile in relation to distance from the AVIC surface (Fig. 3B). Stiffening also resulted in better quantitative agreement in displacement and principal stretch profiles with experimentation (Fig. 3C&D). Measurements were made along the arrows shown in Fig. 3A.

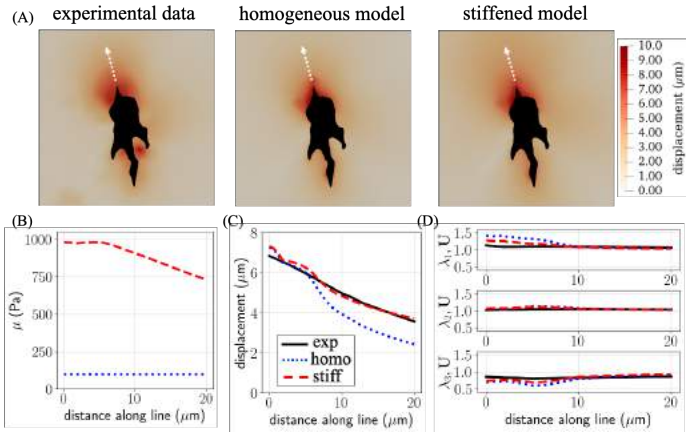

**Figure 3: (A) Plane slices depicting displacement magnitude for the experiment and both the homogeneous and stiffened simulations. (B,C,D) The shear modulus, displacement, and principal stretch profiles measured along the arrows shown in panel (A).**

**AVIC model predicts SF orientation.** The model successfully predicted SF orientations ($\boldsymbol{m}$) within the AVIC cytoplasm (Fig. 4). In addition, the model successfully predicted SF expression levels ($\bar{\phi}_{sf}$) and total stress ($\boldsymbol{T}^{sf}$), which showed that the highest SF expression level, and therefore total stress, was localized at the AVIC protrusions (Fig. 4A&B). The simulated AVIC shape in the final configuration (red) showed good agreement with experiment (green) (Fig. 4C).

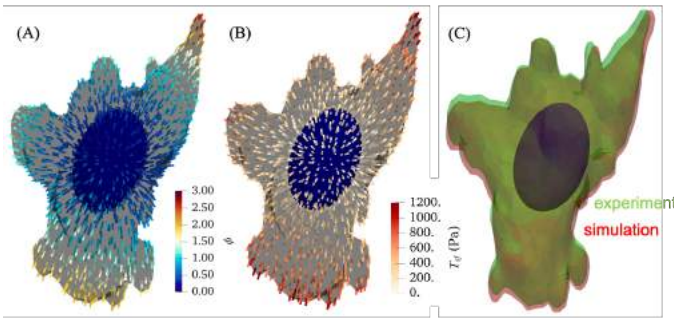

**Figure 4: SF orientation depicted by lines. (A) SF expression level. (B) Total SF stress. (C) The simulated (red) and experimental (green) AVIC shapes in the final configuration.**

## DISCUSSION

To our knowledge, we present for the first time the ability to predict 3D SF architecture and contractile strength in AVICs embedded within a 3D medium. This novel experimental and computational approach allows for unprecedented insight into AVIC SF structure, expression levels, and contractile forces in full 3D, which reflect AVIC biophysical state and phenotypic activation level. Moreover, our simulation was able to predict that AVICs strengthen and do not meaningfully degrade the hydrogel, contrary to previous reports in the literature [2]. This is likely a result of the AVICs excreting nascent ECM components that reinforce the PEG hydrogel material and lead to an increase in local moduli.

Looking forward, these approaches are currently being extended to study intrinsic differences between human AVICs derived from patients with structurally normal AVs and BAVs. Specifically, this model will enable us to quantify differences in AVIC biophysical state and activation levels between the two groups. This will provide key insight into cell-level differences that may lead to increased disease progression in BAV patients, which is critical toward identifying cell-level targets for therapy.

# PATIENT-SPECIFIC FINITE ELEMENT MODELING TO PREDICT CLINICAL RISKS OF PERCUTANEOUS PULMONARY VALVE IMPLANTATION

**Carly L. Donahue (1), Varun Aggarwal, MD (2), Victor H. Barocas, PhD (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA
(2) Department of Pediatrics, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

Almost 20% of congenital heart disease patients have right ventricular outflow tract (RVOT, Fig. 1a) dysfunction [1], which can be treated non-surgically by percutaneous pulmonary valve implantation (PPVI). During PPVI, a replacement valve is delivered via catheter and anchored by a stent. Stent oversizing may cause distortion of a nearby vessel, a risk currently assessed via balloon angioplasty prior to stent deployment. Aortic valve insufficiency (AVI) due to aortic root (AR) distortion is seen in up to 10% of patients during balloon angioplasty [2]. Additionally, around 5% of PPVI patients experience coronary artery compression [3,4] which can result in myocardial ischemia. Both of these potential outcomes can be disastrous.

Imaging [5,6] and 3D printing vessel anatomy [7] have been explored to assess the feasibility of stent placement but are unable to evaluate the effects of stent expansion. Finite element (FE) analysis of patient-specific PPVI models has been used to evaluate coronary compression risk in two studies [8,9], with one group reporting run times of 300hr on 16 CPUs [8]. The time-consuming nature of complex FE models makes them impractical for the clinical setting. To this end, we created a simpler, faster FE model to assess the risks of PPVI, aid in procedural planning, and potentially prevent unsuitable candidates from undergoing unnecessary procedures.

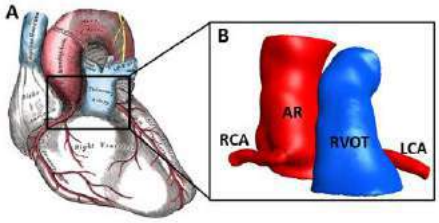

**Figure 1: A) Human Heart Illustration showing the proximity of the RVOT to the AR and coronary arteries [10]. B) 3D model of a patient's vascular anatomy constructed from a CT scan.**

## METHODS

**3D Model Generation:** Patient-specific models (e.g., Fig. 1b) were constructed from segmented CT scans of the RVOT, AR, and coronary arteries. Vessel wall thicknesses were set to 1.5 mm, 1.8 mm, and 0.7 mm. The space between vessels was filled with a compressible solid representing adipose tissue. Element volumes for vessels and adipose tissue were 0.06-0.20 $mm^3$ and 0.91-2.83 $mm^3$, respectively.

**Material Models:** Material models for each anatomical component were based on available data for healthy, human tissue [11–14]. The RVOT was modeled as an incompressible, anisotropic Holzapfel-Gasser-Ogden material [15] with strain energy $W$ given by

$$W = i\frac{c}{2}i(I_1\, i - i3)\, i + i\frac{k_1}{2k_2}\sum_{\alpha=1}^{2}(\exp(k_2\langle E_\alpha\rangle^2)\, i - i1) \quad (1)$$

where $E_\alpha = i\kappa(I_1 - i3)\, i + i(1i - i3\kappa)(I_{4\alpha} - i1)$, $C$ is the right Cauchy-Green deformation tensor, $I_1 = itr(C)$, $I_4 = ia_{\alpha r} \cdot C \cdot a_{\alpha r}$, and $\alpha = 1, 2$. There are two fiber families along vectors $a_{\alpha r}$ in the local $\{e_1, e_2\}$ plane making an angle $\pm i\gamma$ with the circumferential direction $e_1$. The model constants are $c$, $k_1$, and $k_2$. The AR and coronaries were modeled using an incompressible, isotropic Ogden model [16] with strain energy $W$ given by eqn. (2). Adipose tissue was modeled as neo-Hookean, equivalent to eqn. (2) with $m_1=2$.

$$W = i\frac{c_1}{m_1^2}i\left(\lambda_1^{m_1}\, i + i\lambda_2^{m_1}\, i + i\lambda_3^{m_1}\, i - i3\right)i \quad (2)$$

**FE Simulation of PPVI:** Simulation was performed using the FE solver FEBio [17]. Based on the RVOT geometry, a custom MATLAB code identified a 2 cm long RVOT segment with the smallest luminal diameter as the target for stenting. Lumen surface nodes in the stented region were displaced radially to achieve 30% oversize relative to the vessel diameter. Following stent expansion, the interaction between the RVOT and the surrounding vessels was analyzed for potential complications.

**Retrospective Analysis of PPVI:** Nine PPVI cases from the catheterization lab were analyzed using the FE code, and the model predictions were compared to clinical observation. To prevent bias, the engineering analysis for each case was blinded to the clinical outcome.

## RESULTS

Model results agreed with the retrospective clinical outcomes. In patients that experienced AVI and/or coronary compression in the catheterization lab, the affected vessels showed increased displacement, stress, and strain as a result of PPVI in the model. The change in the cross-sectional inscribed circle diameter is the most clinically relevant output due to its direct implication in AVI and reduced coronary blood flow (Fig. 2).

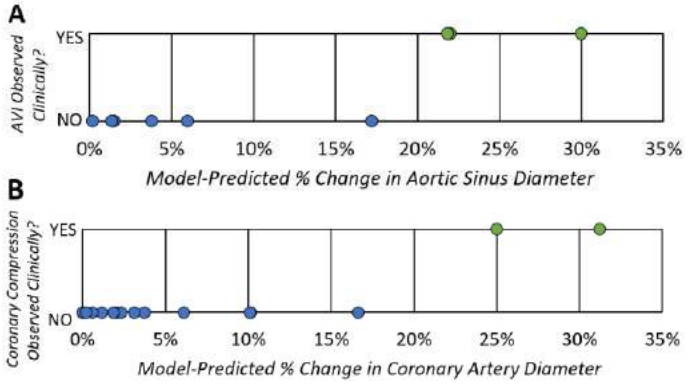

**Figure 2: A) Correlation between the FE-calculated change in aortic sinus inscribed circle diameter and clinically observed AVI. B) Correlation between the FE-calculated change in coronary inscribed circle diameter and clinically observed compression.**

In the three patients that experienced AVI in the catheterization lab, the FE model of PPVI showed that the aortic sinus diameter decreased by at least 21%. Five of the six models from patients that did not experience AVI clinically had diameter changes less than 6%. An example of AVI observed in a FE simulation is shown in Fig. 3.

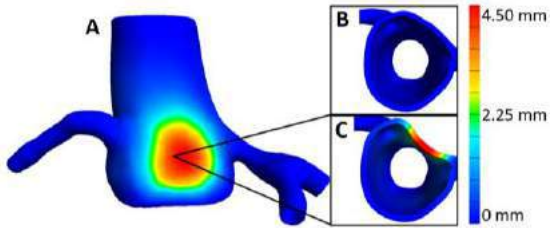

**Figure 3: A) Color map showing displacement as a result of stent oversizing in the aortic sinus. B) Cross-sectional view of the aortic sinus before stent expansion. C) Cross-sectional view showing the distorted aortic sinus after PPVI.**

In the two patients that experienced left coronary artery compression clinically, the model showed the coronary lumen diameter decreased at least 26%. In both simulations, the 30% stent oversizing created conflicting boundary conditions between the stent and the fixed boundary condition under the coronary artery where it is embedded in the heart tissue. This error indicated coronary compression, but to achieve model convergence, the stent oversize condition was lowered to 20%. In 14 of 15 coronary arteries (left and right) that were not compressed in the catheterization lab, the FE model showed diameter changes of less than 11%. An example of modeled coronary artery experiencing compression resulting from PPVI is shown in Fig. 4.

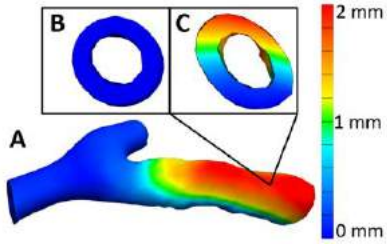

**Figure 4: A) Color map showing compression of the left coronary artery as a result of stent oversizing. B) Cross-sectional view of the coronary artery before stent expansion. C) Cross-sectional view showing the distorted artery after PPVI.**

## DISCUSSION

These results demonstrate the ability of our workflow to identify risks of AVI and coronary compression during PPVI in a computationally efficient manner. To our knowledge, this is the largest study using FE analysis to predict PPVI risks, and our model is the first to predict the occurrence of AVI in addition to coronary compression. Our simulations have run times of less than 5 minutes on a desktop computer, making them much faster than previous models and eliminating the need for a supercomputer. This improvement in efficiency creates the potential for the clinical implementation of pre-procedural FE analysis for PPVI risk evaluation.

Two limitations should be considered while interpreting results. First, the materials used in the model are inherently not patient-specific. As a result, the model is unable to predict the asymmetric expansion of the RVOT due to inhomogeneity, calcification, or scarring. Additionally, varying stiffness in the AR and/or coronaries would also impact how the vessels resist deformation. Second, while the run times of our FE analysis are significantly faster than previous studies, image segmentation and model generation are still relatively slow processes. Combining the proposed FE workflow with an automatic image segmentation technique would result in an improved clinical tool for assessing the risks of PPVI.

# ASSESSING ARTERIAL STIFFNESS IN HUMAN BLOOD PRESSURE WAVEFORM USING HARMONIC DISTORTION

**Nicholas M. Milkovich (1), Gary F. Mitchell (2), Béla Suki (3), Yanhang Zhang (1,3)**

(1) Department of Mechanical Engineering, Boston University, Boston, Massachusetts, USA

## INTRODUCTION

Blood pressure (BP) is routinely used as a measure of cardiovascular function. BP is also a key indicator of hypertension (HT), which is closely associated with stiffening of arteries[1]. Stiffening of central elastic vessels, such as the aorta and the carotid arteries, results in a pressure augmentation from the propagating and reflected waves, components of the BP waveform (BPW)[2]. Therefore, the BPW is also associated with arterial stiffness. Commonly used indexes to assess arterial function includes augmentation index (AI) and pulse wave velocity (PWV). Interestingly, AI and PWV have proven to not be strongly correlated with one another[3]. This could imply that not all BP information responsible for distorting the BPW via wave reflection is being considered in these calculations. Recently we have developed a new index from the BPW, harmonic distortion (HD), that showed promise in assessing arterial stiffness in a mouse model[4]. We hypothesize that this index can be used to further characterize arterial stiffness in human BPWs collected clinically. In this study, BPWs from the Framingham Heart Study (FHS) participants were analyzed for HD and compared with existing indexes.

## METHODS

*Human BPWs:* BPWs of 10-20 sec in length collected via over-skin carotid artery tonometry from 400 male and female participants (≥18 years of age), enrolled at the FHS, were used in this study with approval from the FHS Executive Committee and Boston University's Institutional Review Board. De-identified data such as age, sex, height, weight, BPs, carotid-femoral PWV, AI, prior cardiovascular disease (CVD), and HT were also collected for these patients.

*Harmonic distortion:* To quantify the shape of BPW, we calculated HD, defined as[4]:

$$HD = \sum_{k=2}^{8} \frac{|A_k|^2}{|A_1|^2} \quad (1)$$

where $|A_k|^2$ are the Fourier coefficients of a single BPW multiplied by their complex conjugates. Thus, HD is essentially the ratio of energy above the fundamental frequency to that at the fundamental frequency of the waveform. Fourier coefficients higher than the 8th were found to be negligible and do not contribute significantly to HD. For an ideal sinusoidal wave, the HD is 0. To obtain HD, individual heartbeat cycles isolated from the 10-20 sec BPW recordings (Fig. 1a) were processed using custom MATLAB code according to Equation (1). As an illustration, the normalized power spectrum (PS), $|A_k|^2/|A_1|^2$, were obtained for the BPW and plotted in Figure 1b. The HD value and the corresponding BPW's systolic BP (SBP) were recorded.

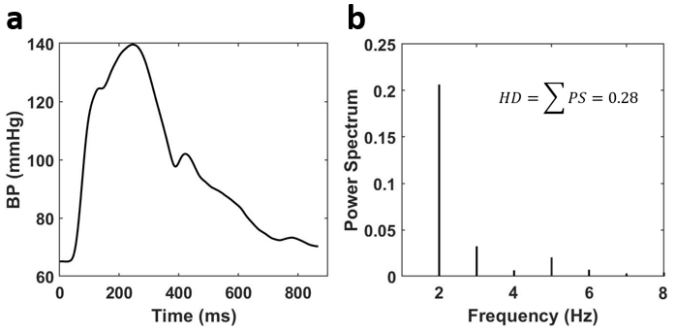

**Figure 1: (a) A single human BPW from carotid artery tonometry and (b) normalized power spectrum of the BPW.**

HD values from all patients were then pooled for further analysis. HD data was further processed by generating evenly sized BP bins and HD values outside two standard deviations of the average were removed from that bin. The average HD and SBP for each bin were then plotted for age groups (≥ 50 and < 50 years) and with and without HT. Linear regressions were then performed on the HD-SBP data separately according to HT diagnosis and age being above or below 50 years.

SB³C2022-095

*Statistical analysis*: HD-SBP data was confirmed non-Gaussian via the Kolmogorov-Smirnov test. A Wilcoxon Rank Sum test was performed on HD data between 90-160 mmHg for participants by HT and age groups. This BP range was chosen for the overlapping range of SBP value in all groups. Regression statistics (estimate, variance, degrees of freedom) were used to find significance between regression coefficients. Backward stepwise regressions were performed on HD, PWV, and AI, recursively eliminating non-significant variables, including age, height, weight, mean arterial pressure (MAP), SBP, diastolic BP (DBP), sex, and prior cardiovascular disease (CVD). The indexes were then introduced as independent factors to the linear model to determine any correlation with one another ($^{*}P < 0.05$).

## RESULTS

Figure 2 shows the HD vs. SBP relations obtained from BPWs by HT and age groups. HD shows a negative linear relationship with SBP. This trend varies distinctly according to HT and age. Further, regression slopes are significantly different by HT and age (HT: $p = 0.038$, Age: 0.009). In the HT groups (Fig 2a.) the hypertensive patients appear to have higher HD values from 100-150 mmHg, though the HD values between both groups are not statically significant ($p = 0.083$). The young group (< 50 yrs) has significantly higher HD values (Fig. 2b), regardless of SBP ($p < 0.001$). Both the HT group and old group (≥ 50) contain the highest observed SBPs (~150-175 mmHg) and lowest measured HD values (~0.3-0.2).

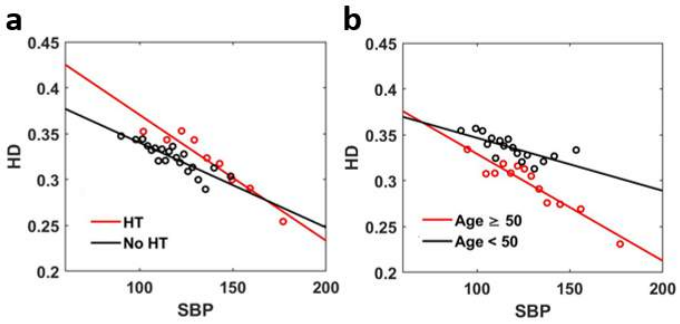

**Figure 2: Linear regressions between average HD and average SBP for participants by HT diagnosis (a) and by age (b).**

Table 1 shows the results of stepwise regressions for select *in vivo* indexes with respect to independent variables. These indexes include PWV and AI, as well as the new index HD. All variables were highly significant to the index calculations ($p \leq 0.007$) if not eliminated by the recursive regression. AI is the only index that differs by sex and PWV by height. When introducing the indexes in to each regression, PWV and AI were found to be significant with HD with $p = 0.021$ and $p < 0.001$, respectively, however PWV and AI were found to not be significant with one another ($p = 0.058$).

**Table 1: p Values from Backward Stepwise Regression showing Stiffness Index Significance to Patient Data**

| | HD | PWV | AI |
|---|---|---|---|
| Age (yr) | <0.001 | <0.001 | <0.001 |
| Height (m) | - | 0.007 | - |
| Weight (kg) | <0.001 | - | - |
| Sex (M/F) | - | - | <0.001 |
| MAP (mmHg) | <0.001 | - | - |
| SBP (mmHg) | <0.001 | <0.001 | <0.001 |
| DBP (mmHg) | <0.001 | - | - |
| prior CVD (Y/N) | - | <0.001 | 0.002 |
| R Value | 0.521 | 0.782 | 0.660 |

## DISCUSSION

BPWs contain information from the coupled interactions between forward and reflected waves, and arterial wall mechanics. With increased arterial stiffness, the BPW peak is augmented due to the overlapping of the forward and reflected waves[2]. At higher BPs, there is an increase in arterial stiffness due to the gradual recruitment of collagen fibers in the adventitia[5]. The inverse linear *relationship* between HD and SBP (Fig. 2) suggests that HD is sensitive to changes in arterial stiffness. Further, our study consistently show that HD decreases with age (Fig. 2b), as increase in arterial stiffness with aging is well documented[2,5]. Also, the significant difference in HD slope (Fig. 2) illustrates a marked change in HD's SBP dependence with HT and aging. The reason that the HD values between HT arteries and the non-HT ones are not significantly different is not clear and requires further investigation.

Addressing the efficacy of the three *in vivo* indexes begins with the R values, a metric of correlation, from the backwards stepwise regressions. PWV has proven to have the highest correlation ($R = 0.782$) suggesting it is the best fit for this model and database. The large variance of HD data observed during our analysis could be responsible for its lower R value (Table 1). However, the HD index is still highly significant with its independent factors showing sensitivity to age, weight, and BPs. Interestingly, only HD is significant with all BP information and weight (Table 1). This is unexpected due to PWV and AI having previously established correlation with cardiovascular risk factors such as BP and weight[6,7]. However this could due to the relatively small number of participants in this study.

Our study further highlights that PWV and AI are not correlated. However, HD is strongly correlated with both AI and PWV, implying its sensitivity to a combination of factors measured independently in PWV and AI. Study shows that PWV and AI are both sensitive to aging, but PWV is primarily sensitive to arterial stiffening risk in older individuals (> 50) while AI is sensitive to risk in younger individuals (< 50)[3]. Our results suggest HD has greater sensitivity to older individuals (Fig. 2b) but can also effectively differentiate between age groups. AI is the only index showing high significance with sex (Table 1), which supports the finding that higher AI values in females compared to males of the same age[7]. Taken together, our study suggests that HD provide a more comprehensive analysis of the BPW.

## CONCLUSION

In this study we studied the effectiveness of HD in assessing arterial stiffness using human BPWs. HD's sensitivity to BP measures, age and HT suggests that HD provides a comprehensive assessment of the BPWs. HD is also shown to be correlated with both PWV and AI. BPWs obtained using tonometry is readily available clinically. Hence, our results demonstrate that HD can potentially be used to clinically assess arterial function in patients with various diseases.

## INTRODUCTION

Type B Aortic dissection (TBAD) is the most frequent acute descending thoracic aortic pathology [1]. A tear occurs in the aortic wall, resulting in a sudden split of the vessel into a true lumen (TL) and a false lumen (FL). TBAD are characterized by a significant rate of aneurysm formation and high 10-year mortality rates [2]. Several computational studies have explored the factors determining the long-term fate of TBAD, including size and number of entry and exit tears, FL thrombosis, and hypertension [3-5].

A serious complication in TBAD is dynamic occlusion (DO) of the TL due to motion of the intimal flap, resulting in blockage of blood supply toward a vital organ, i.e. kidney, inducing malperfusion, which is the second most fatal complication of aortic dissection after rupture [6]. In a large fraction of patients in our clinical experience, global blood pressure (BP) changes are associated with DO. Global increases in BP have been shown to trigger DO, whereas pharmacologically induced reductions in BP restored the patency of the TL (Figure 1). The mechanisms by which the dynamic motion of the flap results in DO remain poorly understood and unexplored.

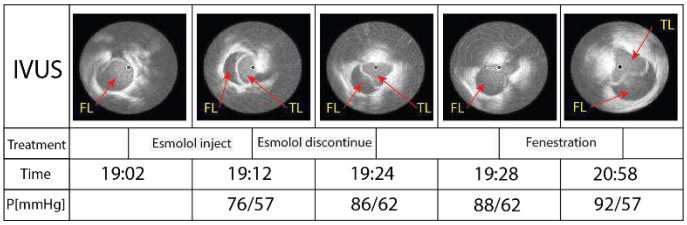

**Figure 1: Timeline of DO with drug and fenestration treatments. IVUS: intravascular ultrasound. P: global blood pressure.**

In this work, we aim the explore the biomechanical and hemodynamical factors driving DO. We hypothesize that relatively small pressure differentials between TL and FL experienced during global changes in BP in DO are sufficient to displace the flap to induce occlusion or to restore TL patency. To test this hypothesis, we developed a Fluid-structure interaction (FSI) model of aortic DO.

## METHODS

An idealized 3D model of a TBAD was constructed by assuming uniform aortic diameter (30 mm), a single entry tear (20 mm diameter), and an intimal flap (100 mm length) with uniform thickness (1 mm), resulting in TL and FL areas of 100 and 580 mm$^2$, respectively (see Figure 2 (a)). There was no re-entry tear on the intimal flap.

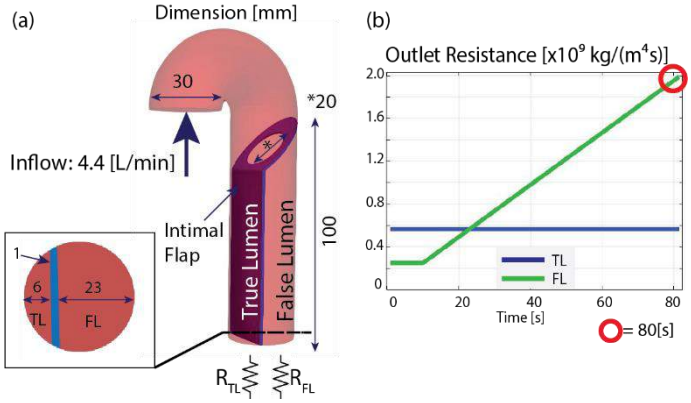

**Figure 2: (a) Idealized 3D TBAD geometry and (b) Imposed histories of outlet resistance in TL and FL over the course of 80 s.**

A Neo-Hookean constitutive model was used for the intimal flap with stiffness parameter of 180 kPa. This value is more compliant than typical stiffness values of the whole aortic wall [7] due to its correspondence with the intima and inner-most media segments of the aorta. The remaining (outer) aortic walls were modeled as rigid. Given that DO occurs over the course of several minutes, hemodynamic simulations were run under mean flow conditions. Outflow boundary

conditions for TL and FL were set by imposing dynamic changes in zero-dimensional resistors ($R_{TL}$ and $R_{FL}$) which trigger global changes in BP. FSI simulations were run using COMSOL Multiphysics.

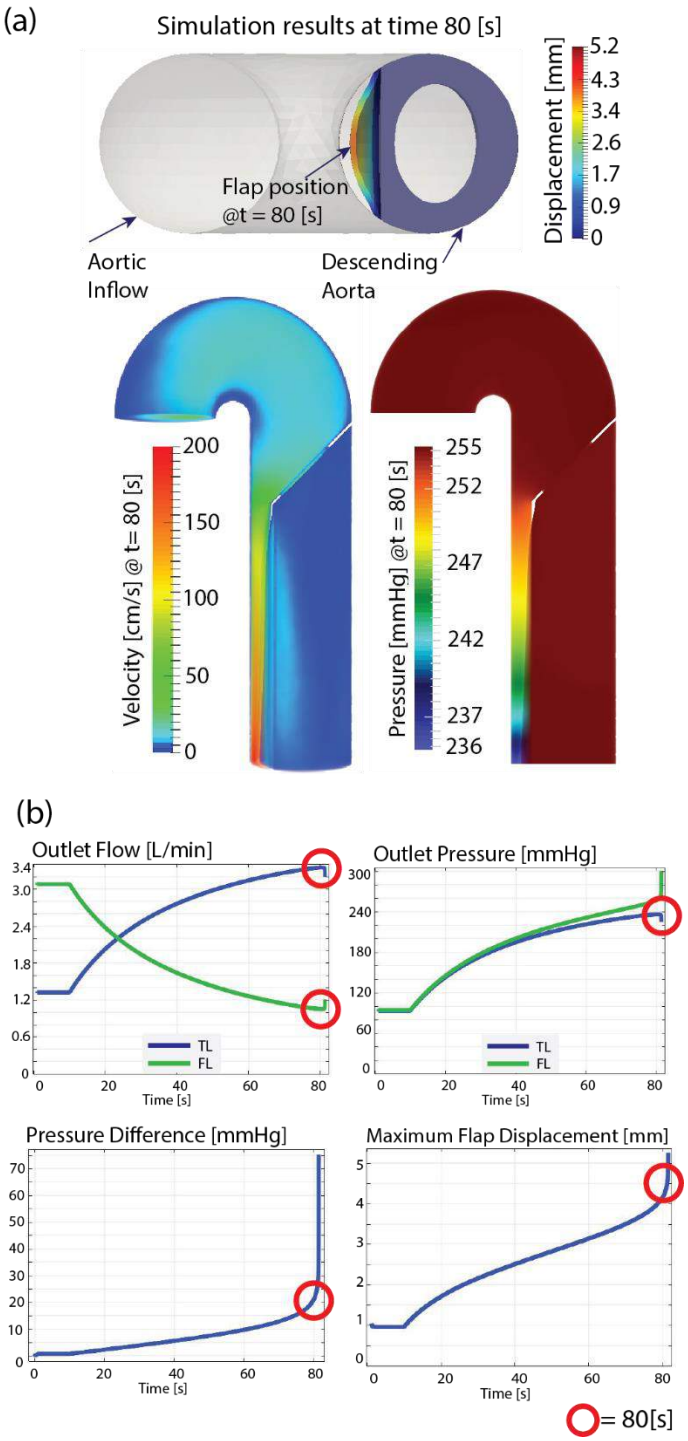

**Figure 3: (a) Flap displacement, pressure, and velocity simulation results at t = 80 seconds and (b) Time histories of Outlet flow, outlet pressure, pressure difference between TL and FL, and maximum flap displacement**

## RESULTS

TL resistance was kept constant, and FL resistance was increased over 80 seconds (Figure 2 (b)). These resistance changes resulted in an overall increased in BP, as well as motion of the flap towards the TL wall, ultimately resulting in DO (Figure 3 (a)), consistent with clinical findings (Figure 1). Blood flow decreased in the FL and increased in the TL, resulting in high TL velocities (Figure 3 (a)). Both TL and FL pressures were increased during the simulation. However, there was a relatively small (<20 mmHg) pressure differential between TL and FL during most of the simulation (Figure 3 (b)). As this pressure differential increased, flap displacement towards the TL aortic wall also increased. Maximum flap displacement was located at the distal part of the model due to the pressure difference between TL and FL. TL pressure and flow dropped suddenly once the flap almost got in contact with the TL wall, at time = 81seconds (Figure 3 (b)).

## DISCUSSION

A simplified FSI model of TBAD was used to study DO. With increased FL resistance, dynamic increases in global BP resulted in flap motion and TL collapse, as reported in our clinical data. Our results demonstrated our hypothesis that relatively small differences in TL and FL pressures are enough to induce the flap motion.

The simulation was stopped right before contact between the flap and TL aortic wall occurred. This would have required using a contact model in the analysis. However, despite this limitation, sudden drops in TL pressure and flow were observed as the TL area got closer and closer to zero. At this point (t>80 s.), most of the blood flowed through the FL.

Further limitations of this model include the lack of re-entry tears in the flap, which have been shown to induce significant changes in hemodynamics [8], the rigid wall assumption for the outer aortic walls, and the lack of side branches. Despite these limitations, this simple FSI model has enabled us to successfully test the hypothesis that relatively small pressure differentials between TL and FL are enough to drive flap motion in DO.

## INTRODUCTION

The vascular endothelium is lined by a mechano-sensitive glycocalyx (GCX) layer comprising of glycosaminoglycans (GAGs), glycoproteins and proteo-glycan complexes. The main components of the GCX are hyaluronic acid (HA), syndecan-1 (SDC-1), heparan sulfate and chondroitin sulfate. Under normal physiologic conditions, the GCX is intact and maintains a homeostatic balance. However, when physiologic flow is altered (e.g., high flow, high shear environment), there is a disruption in the GCX [1,2]. The shedding of the endothelial GCX after injury results in an increase in vascular permeability, platelet adhesion, and in worse cases endothelial dysfunction. In particular, shock-induced endotheliopathy (SHINE) is a growing concern as increasing levels of circulating GCX components (e.g., HA and SDC-1) are associated with hypercoagulability, in-hospital complications, and poor patient outcomes [3,4].

The phenomenon of shear-dependent changes in the endothelial GCX is emerging to play an important role in endovascular medical interventions. For example, Resuscitative Endovascular Balloon Occlusion of the Aorta (REBOA) is an emerging technique aimed to minimize internal bleeding by creating a temporary aortic occlusion. This lifesaving intervention prolongs survival until definitive surgical hemostasis can be achieved [5]. However, one of the greatest limitations to REBOA is the ischemia-reperfusion (I/R) injury and subsequent renal failure that manifests after imposing a full aortic occlusion. As a result, partial REBOA (p-REBOA) and other endovascular hemorrhage control (EHC) devices that allow for variable levels of occlusion have been developed [4]. While p-REBOA may attenuate the degree of ischemia imposed, there is still concern about the vascular endothelial damage and end-organ damage that may arise as a consequence of altered hemodynamics and prolonged periods of tissue hypoperfusion [6, 7].

We have previously shown with computational fluid dynamics (CFD) simulations that REBOA and p-REBOA results in significant hemodynamic alterations, including areas of high shear proximal and around the site of occlusion which could lead to potential GCX damage [Fig. 1, 8]. In this study, we aimed to quantify the degree of vascular endothelial GCX damage, *in vivo*, induced by full and partial REBOA. We hypothesize p-REBOA will cause more GCX damage than REBOA. We performed a pilot study that analyzes circulating blood biomarkers of shed GCX components and endothelial integrity from local tissue in a porcine hemorrhage model.

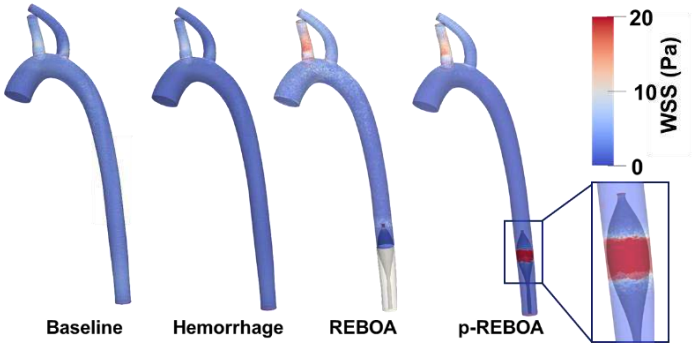

**Figure 1. Wall shear stress (WSS) distribution. Areas of high shear stress are identified in the brachiocephalic artery during full REBOA and around the p-REBOA balloon [8].**

## METHODS

**Porcine Hemorrhage Model:** 10 male and female Yorkshire swine were subjected to 20% hemorrhage (by blood volume) then randomized to either receive a full or partial aortic occlusion (i.e.,

REBOA vs. p-REBOA, n=5/group) for 20 minutes and subsequently resuscitated with a standardized critical care protocol for 4 hours.

To quantify the degree of GCX damage, we serially collected serum over the duration of the experiment and vascular tissue samples were collected after euthanasia. Specifically, we focused on 4 time points: baseline (T0), end of hemorrhage (T30), end of aortic occlusion (T60), and 10 minutes post-occlusion (T75). Enzyme-linked immunosorbent assays (ELISA) for pig serum were used to quantify circulating hyaluronic acid (HA, Echelon Biosciences) and syndecan-1 (SDC-1, Bluegene biotech) as the two key components of the GCX. We used a repeated measures two-way ANOVA to assess differences in GCX biomarkers over time and between groups; significance was set at 0.05 level.

To quantify any histological changes to the vascular endothelium, tissue samples were harvested at the end of each experiment. Specifically, we collected tissue from five key areas that were potentially affected by high shear or distal ischemia; 1) proximal to the REBOA placement, 2) at the site of REBOA, 3) distal to REBOA, 4) the brachiocephalic trunk, and 5) the left renal artery. All samples were fixed in paraformaldehyde. At the time of submission, the histological characterization of the tissue is ongoing with plans to perform H&E staining for morphology, and immunohistochemical (IHC) staining of CD138 (i.e. SDC-1), E-selectin, and thrombomodulin, to quantify local changes in the integrity of the endothelium and GCX.

## RESULTS

We observed significant changes in circulating levels of HA (Fig. 2) over time, consistent with prior reports of SHINE. Maximal levels of shed HA were observed after full REBOA intervention. Animals receiving p-REBOA tended to exhibit lower HA levels in comparison to REBOA at the end of aortic occlusion (T60, 943.8 ng/ml vs. 747.7 ng/ml) and 10 minutes post occlusion (T75, 1238 ng/ml vs. 655.1 ng/ml), though not statistically significant. Additionally, at T75 minutes HA levels in REBOA trended up in contrast to p-REBOA which trended downwards. Further experiments are needed to confirm these trends.

Unlike HA, circulating levels of SDC-1 were relatively constant over time (Fig. 3). The highest levels were actually detected at baseline in the REBOA pigs, suggesting that instrumentation of the pigs may influence the level of SDC-1. Overall, these circulating biomarkers suggests that there is less systemic shedding of the endothelial GCX damage imposed by p-REBOA.

While the vascular tissue processing is ongoing at this time, we aim to quantify the local variations in GCX and endothelial integrity. We expect that vascular areas of high shear will exhibit the most GCX damage.

## DISCUSSION

Our preliminary findings reveal higher trends of systemic shedding of HA with full REBOA compared to p-REBOA. We did not detect any differences in circulating SDC-1 levels between REBOA and p-REBOA. These preliminary findings suggest that there may be other factors influencing GCX shedding in full REBOA compared to p-REBOA. For example, an increase in oscillatory flow and pulsatility within the supraaortic region may affect GCX integrity. Alternatively, higher levels of ischemia in full REBOA compared to p-REBOA [9,10] can be contributing to the increase in HA shedding.

Furthermore, it is important to note that these systemic biomarkers may not be concordant with local markers of GCX shedding or damage. Our histological analysis of tissue damage may offer insight on why these differences occur as well as the direct impact of the balloon itself on the endothelial GCX layer. While preliminary findings indicate full. REBOA results in more circulating HA than p-REBOA, further studies are needed to confirm this phenomenon.

Ultimately, this pilot study offers interesting insight on the impact of an aortic occlusion during hemorrhagic shock on the vascular endothelium and poses interesting questions for future studies. We anticipate to build on these findings and leverage GCX integrity as a metric to better characterize the use of REBOA and p-REBOA as a clinical intervention, as well as to guide resuscitation strategies post-REBOA to accelerate the restoration of the GCX.

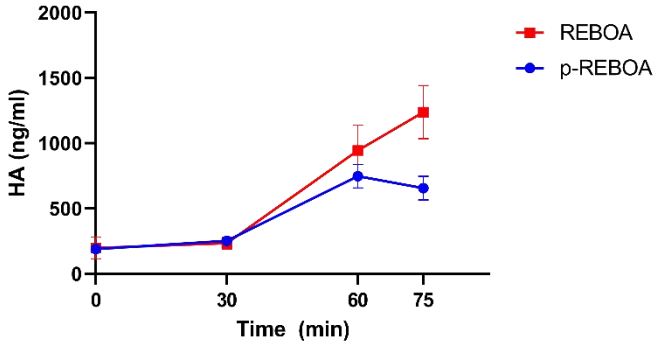

**Figure 2. Preliminary serum HA levels are trending higher after full aortic occlusion (REBOA) compared to a partial occlusion (p-REBOA), 15 minutes after occlusion is imposed (i.e. T75 min).**

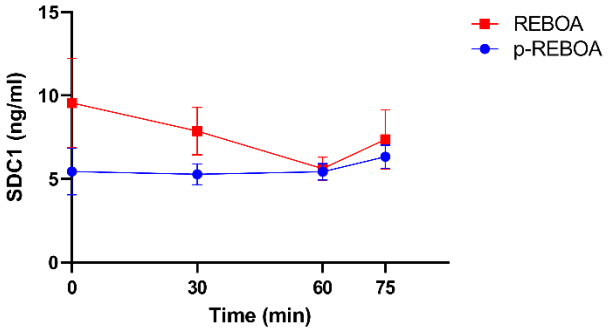

**Figure 3. Preliminary serum SDC-1 levels are similar between REBOA and p-REBOA.**

# MECHANOTHERAPEUTICS TO MODULATE THE FOREIGN BODY RESPONSE

**Niamh A. Ward (1), William Whyte (2), Debkalpa Goswami (2), Ruth E. Levey (3), Garry P. Duffy (3), Ellen T. Roche (2), Eimear B. Dolan (1)**

## INTRODUCTION

The long-term performance of implanted medical devices is hindered by the foreign body response (FBR). This is a complex cascade of events that is initiated upon implantation of a foreign object, such as a medical device, to protect the body from this foreign object. The FBR is initiated by the adsorption of proteins to the surface of the implant. The presence of protein receptors enables the adhesion of monocytes which secrete pro-inflammatory cytokines and chemokines, stimulating further inflammatory cell infiltration [1, 2]. Inflammatory cytokines also initiate the differentiation of fibroblast cells to collagen-producing myofibroblasts, which deposit a hypopermeable, collagen-rich fibrotic capsule (FC) around the implant [3]. In many instances, this is an advantageous response, as the FC forms a protective barrier between the body and a potentially harmful foreign object. However, this is detrimental to medical devices that rely on molecular exchange, such as devices that encapsulate cells or include biosensing components, as the FC impedes diffusion of essential molecules between the device and surrounding tissue [4].

Our group previously demonstrated that mechanical actuation of an implanted reservoir for 14 days in a rat model caused a significant reduction in thickness of the formed FC ($p = 0.0005$). Additionally, there was a significant reduction ($p = 0.0036$) in myofibroblast cells at the implant site, suggesting that mechanical loading may affect cell differentiation and/or proliferation. In this study, implanted devices were actuated at a frequency of 1 Hz for 5 minutes every 12 hours at a pressure of 6.9 – 13.8 kPa, and FC thickness was compared to non-actuated controls [5].

For this mechanotherapeutic platform to reach its full potential, we must explore the reproducibility of these promising results in a different animal model and with a different device geometry, as varying applications of this technology will necessitate a wide range of device design requirements. One potential application of this platform is to serve as a cell encapsulation device for the treatment of type 1 diabetes (T1D). Cell therapies have shown promise in restoring glucose responsiveness in T1D patients [6], but currently necessitate lifelong immunosuppression to overcome rejection by the host immune system. In this instance, the device must provide immunoprotection, and a large surface area to volume ratio to reduce the diffusion distance of essential nutrients to the encapsulated cells [7]. Alternatively, arrays of smaller, interconnected actuatable reservoirs may be preferred for reducing FC formation around implantable pacemaker leads [5]. We must also identify the precise cellular interactions that modulate the FBR when actuation is applied. Whilst it is widely understood that mechanical loading can affect cell differentiation and signaling, there is no clear consensus on how applied forces can influence cell behavior in relation to the FBR. For example, mechanical stretch has been attributed to both up- and down- regulation of markers of fibrosis [4,5]. This work uses a combined approach of analytical modelling and *in vitro* and *in vivo* studies to demonstrate reproducibility of this FBR modulating technology and improve our understanding of actuation mediated FBR modulation at the cellular level.

## METHODS

Analytical models of the tissue-interfacing membrane of actuatable devices were designed based on Von Kármán plate theory and analytical approximations for clamped circular and rectangular plates proposed by Timoshenko and Woinowsky-Krieger [10] and Zhang *et al*. [11]. These models predict the surface strain of different configurations of thermoplastic polyurethane (TPU) membranes during actuation. In this study we explored the use of devices with both hemispherical and rectangular geometries.

Actuatable devices were manufactured using TPU sheets (HTM-8001-M and HTM-1001 polyether TPU film, American Polyfilm, Inc). Vacuum thermal forming was used to form sheets of 0.3 mm thickness, which were sealed with TPU sheets of 0.076 or 0.15 mm thickness using a heat-press. A Micro-Renathane® catheter was inserted between the

SB³C2022-098

sheets, creating an actuatable reservoir (hemispherical configuration shown in Figure 1).

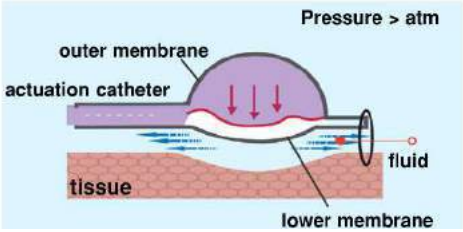

**Figure 1** Hemispherical actuatable device, adapted from Dolan *et al.* 2019 [5]

In the previous *in vivo* study we investigated hemispherical devices in a rat model for 14 days [5]. Here, rectangular actuatable devices were implanted in C57BL/6 mice and actuated using the above regime at a pressure of 13.8 kPa. After 14 days, actuation was ceased, and devices remained implanted for a further 8 days. After 23 days, devices were explanted *en bloc* and stained with phosphomolybdic acid before imaging using Scanco Medical MicroCT 100. FC thickness was quantified using Materialise MIMICS and 3-matic Research software. The thickness of the FC was compared to non-actuated controls using an unpaired, one-tailed, two-sample t-test (OriginLab Corp.).

To explore these responses at a cellular level and investigate the effect of actuation on collagen production, myofibroblast cell line WPMY1 were seeded on lower membrane (actuating membrane) of hemispherical devices (see Figure 1) and cultured for 14 days *in vitro.* Devices were connected to a pressurized air supply and actuated using the previously described actuation regime at an increased pressure of 27.5 kPa. Collagen production was measured using a Sircol Soluble Collagen Assay (Biocolor Ltd.), and collagen production by cells in the actuated group were compared to non-actuated controls using an unpaired, two-tailed, two sample t-test with Welch's correction (GraphPad Software, Inc.).

## RESULTS

Our models predict actuation of a clamped rectangular TPU plate (12 mm x 6 mm) induces a maximum in plane principal strain ($\varepsilon_p$) of 9.7% (mean $\varepsilon_p$ =2.07%) when a uniform pressure of 13.8 kPa is applied (Figure 2A). Following 14 days actuation of a device with the above dimensions in a mouse model, there was a significant reduction ($p<0.0001$) in FC thickness surrounding the device on day 15 when compared to non-actuated controls. This effect was sustained, although attenuated, at day 23 ($p=0.02453$) despite ceasing actuation (Figure 2B).

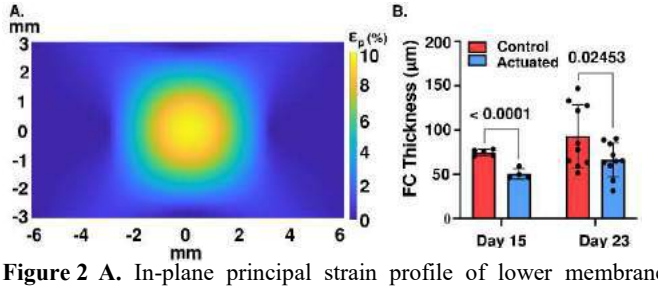

**Figure 2 A.** In-plane principal strain profile of lower membrane during actuation at 13.8 kPa **B.** FC thickness (μm) surrounding implanted devices after 14 days actuation *in vivo*. Data is presented as mean ± standard error of the mean.

Modeling predicts that actuation of a clamped circular TPU plate (Ø = 7.2 mm) induces maximum surface strains of 3.9% in the radial ($\varepsilon_r$) and tangential directions when pressurized to 27.5 kPa (Figure 3A). At the same applied pressure (27.5 kPa), there was a significant reduction in collagen production by WPMY-1 (myofibroblast cell line) cells after 9 ($p = 0.01409$) and 14 ($p = 0.02729$) days actuation *in vitro* when compared to non-actuated controls (Figure 3B).

## DISCUSSION

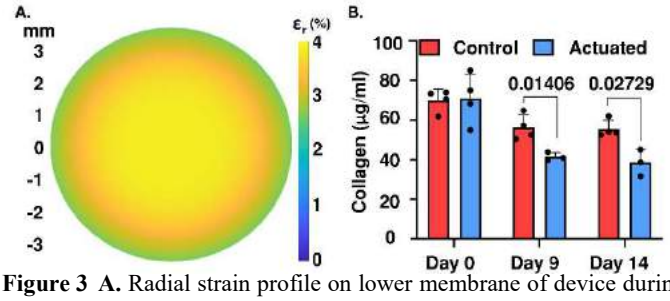

**Figure 3 A.** Radial strain profile on lower membrane of device during actuation at 27.5 kPa **B.** Collagen production (μg/ml) by WPMY-1 cells *in vitro*. Data is presented as mean ± standard deviation.

Here, we show that periodic cyclical loading at a low membrane strain magnitude *in vivo* for a 14 day period can significantly reduce FC formation in a mouse model. This builds upon our previous work where we demonstrated a significant reduction in FC thickness in a rat model using the same actuation regime. Importantly, we show reproducibility of actuation mediated FBR modulation in different animal models and with multiple device geometries. This mechanotherapeutic platform holds great promise for a range of applications, including improving targeted drug delivery, and extending the longevity of biosensors.

However, we must first improve our understanding of how mechanical actuation modulates the FBR at the cellular level. Whilst it is difficult to recapitulate the highly complex immune response using an individual cell type *in vitro*, our work suggests that mechanical actuation can modulate the host FBR through a reduction in myofibroblast presence at the implant site, and a reduction in collagen production by these cells. We hypothesize that this effect is driven by mechanical strain applied at the device interface, or by inducing extracellular fluid flow around the device during actuation. Strain has been shown to reduce myofibroblast differentiation [9], which may lead to a reduction in collagen-producing cells around an implant. It is also understood that fluid flow can aid clearance of inflammatory cells [12], curtailing recruitment of fibroblasts to the implant site. Future work will aim to identify the specific signaling pathways that are disrupted by actuation. Whilst strain and fluid flow are inherently linked, we aim to fully decouple these to identify the mechanism driving this response.

# SPECTRAL ANALYSIS OF KINETIC ENERGY IN A HEALTHY AORTA

**David Büchner (1), Emily L. Manchester (2), Xiao Y. Xu (2)**

(1) University of Stuttgart, Stuttgart, Germany
(2) Imperial College London, London, United Kingdom

## INTRODUCTION

Detailed analysis of turbulence and transition in blood flow has become more relevant, as advanced experimental and numerical resources have enabled us to quantify turbulence parameters and link them with different cardiovascular diseases. Nevertheless, physiological blood flow in vessels, such as the aorta, has been assumed to be predominantly laminar. It is surprising that this assumption is still widely accepted and rarely questioned even though the presence of disturbed flow and flow instabilities in the aorta is well known [1,2,3]. While the discussion on the actual state of flow in healthy human aortas and other blood vessels is ongoing, relatively little effort has been spent on the development of a holistic understanding of it. A recently reported study seeks to provide further clarification by employing powerful tools from general fluid dynamics [4]. Using Womersley's analytical solution of the Navier-Stokes equations as well as Doppler ultrasound measurements of healthy carotid arteries they demonstrate that the flow is sensitive to initial conditions, globally unstable, and exhibits a kinetic energy cascade; all three being major characteristics of turbulence. However, their study remains limited to the carotid arteries and thus calls for similar investigations also in other vessels, especially the aorta. The present work takes on this motivation and conducts a spectral analysis of kinetic energy (KES) for the flow field obtained by an extensive Large Eddy Simulation (LES) of an anatomically realistic aorta under normal physiological conditions.

## METHODS

The aorta, as the vessel of interest in this study, has complex geometric features. To fully capture the true state of flow it is necessary to perform investigations using anatomically realistic models. For this reason, following the workflow described in [5], a subject-specific aorta model was reconstructed from MRI scans of a healthy volunteer. The modelled geometry includes the ascending and descending aorta, aortic arch, and the main branching arteries as shown in Figure 1.

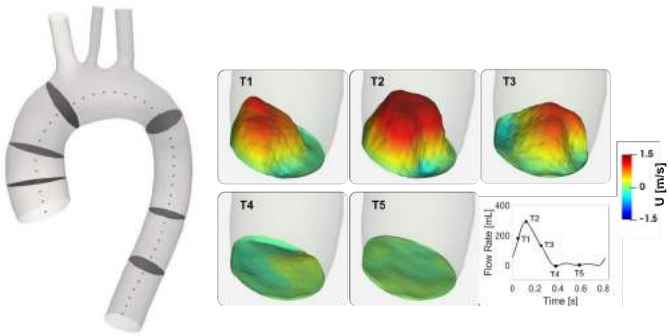

**Figure 1: Reconstructed 3D geometry of the aorta and locations of the selected cross-sections (left) and 3D time-resolved inlet velocity profiles (right).**

As described in [5], the LES model was implemented in OpenFOAM with blood being assumed to be Newtonian and the aortic walls rigid. At the inlet 3D time-resolved velocity profiles, reconstructed from 4D-flow MRI (Figure 1), were applied while a three-element Windkessel model was used for all outlet boundary conditions. Following mesh and time-step sensitivity studies, the simulation was run for 23 cardiac cycles and the resolved velocity field was validated against 4D-flow MRI data.

From the computed flow field in the modelled aorta, velocities at six cross-sections (defined in Figure 1) were extracted; proximal- and mid-ascending aorta, entry to the arch, proximal- and mid-descending aorta, and entry to the distal-descending aorta. At every grid point within the cross-sections, the velocity components were transformed

from the global Cartesian coordinate system to a point-wise local coordinate system in the axial, circumferential, and radial directions. Fourier decomposition was then conducted and the KES was calculated for every point and direction, both for the entire time-trace as well as for every cardiac cycle individually, following the method proposed in [6]. Moreover, for every harmonic the energy was integrated over the cross-sections, allowing a more holistic qualitative assessment of the spectral distribution of the kinetic energy at the selected locations.

## RESULTS

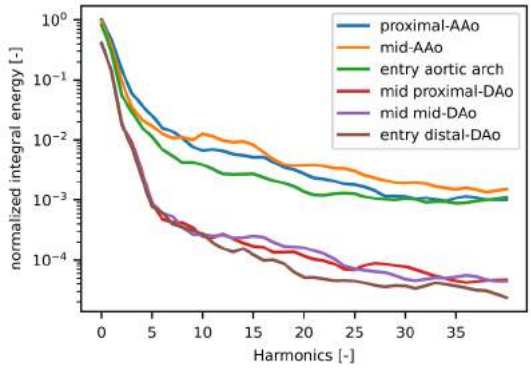

**Figure 2: Energy amplitudes of the harmonics integrated over the respective cross-section for flow in the axial direction. Frequency of the fundamental harmonic is 1.23 Hz.**

The distribution of integrated kinetic energy over the first 40 harmonics resolves a distinctive reverse exponential course as depicted in Figure 2. The course is similar in shape for all locations; a steep decline of energy contained until around the 5th harmonic, followed by a gradual and less steep decrease towards higher harmonics. However, the steep decline is much less pronounced at locations in the ascending than in the descending aorta. As a result, the range of a more gradual decline is, although of a similar shape at all locations, almost two orders of magnitudes lower in the descending aorta. In other words, in the descending aorta considerably less energy is contained in high-frequency components, thus fluctuations, of the flow. Moreover, the contained energy is normalized also by the total area of the cross-sections thereby eliminating the effect of narrowing cross-sections and energy leaving the system through the arch branches. Consequently, the overall decrease of energy can be attributed to the transport and dissipation of turbulent kinetic energy.

In order to better understand this integral distribution, the kinetic energy amplitudes of the individual frequency ranges are plotted over the cross-sections. Figure 3 shows the results for the summed 8 highest harmonics evaluated. Evidently, the highest amplitudes are reached in the mid ascending aorta, also explaining the highest integral values in this frequency range, as observed in Figure 2. Similar plots of other frequency ranges and velocity magnitudes reveal the presence of larger coherent structures in this region. They form during systolic acceleration and break down during systolic deceleration and diastole, releasing turbulent kinetic energy into the system. With decreasing strength, this process continues towards the arch. Although most of the turbulent kinetic energy is dissipated when the descending aorta is reached, secondary effects, such as radial forces and flow separation, introduce new but weaker fluctuations mainly in the inner area of the aortic curvature. The turbulent kinetic energy introduced by this then slowly dissipates again, as can be seen by the lower amplitudes and less energy contained at the cross-section located at the entry to the distal aorta.

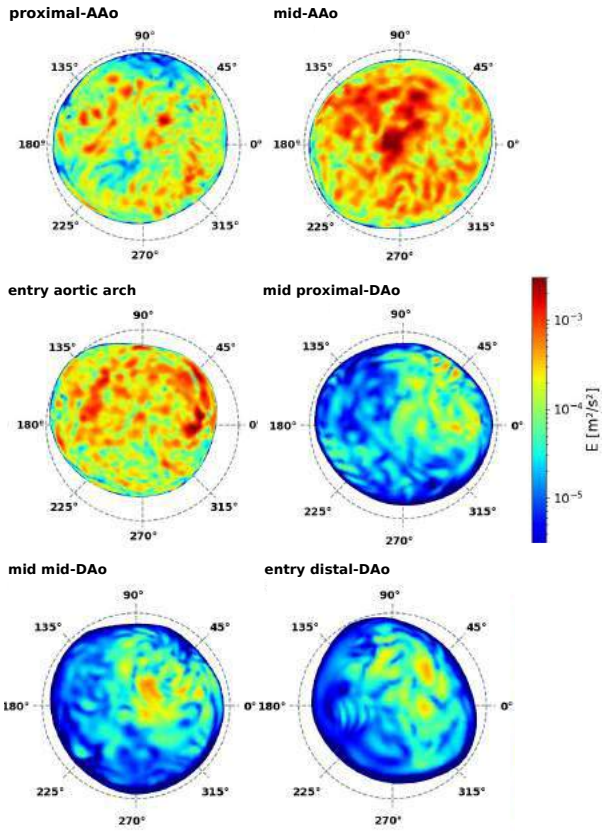

**Figure 3: Pseudocolormaps of the amplitude of the combined 8 highest harmonics considered, respectively 43.21 to 50.62 Hz.**

## DISCUSSION

The obtained results are in overall agreement with previous findings of flow instabilities in the aorta [1,2] and demonstrate that they cause high-frequency fluctuations thus turbulent like flow patterns along the entire aorta. Moreover, the spectral analysis performed shows that in the aorta, similar to in the carotid artery [4], transport of kinetic energy between different frequency components as well as dissipation takes place; this primary characteristic of turbulent flow is present in a healthy aorta under normal physiological conditions.

For now, this study is confined to flow in one individual aorta, and results, therefore, cannot be generalized to make universal statements. In addition, the non-Newtonian effect and wall compliance should be taken into account in future analysis.

## ACKNOWLEDGEMENTS

# MATERIAL PROPERTY CHANGES OF POLYMERIZED RED BLOOD CELLS IN SICKLE CELL DISEASE

**Dillon C. Williams (1), David K. Wood (2)**

(1) Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States
(2) Biomedical Engineering, University of Minnesota, Minneapolis, MN, United States

## INTRODUCTION

Sickle cell disease (SCD) is an autosomal recessive blood disorder that arises from a single nucleotide mutation in the β-globin gene; a GAG codon is switched to a GTG codon causing a glutamine to be replaced by a valine [1]. This leads to a mutated hemoglobin, known as HbS, which has lower oxygen affinity than healthy HbA and can bind to other HbS proteins under deoxygenated conditions. When HbS proteins bind they form polymer domains that can develop into long inflexible strands that deform the red cell and give it the characteristic sickle shape. Sickled red blood cells are the main driver of the adverse effects of SCD [2].

Sickle cell disease is an enormous global health burden. SCD affects roughly 13 million people worldwide; the polymerization of HbS under low oxygen tension leads to a multitude of adverse effects. The mechanical and morphological changes and decreased oxygen carrying capabilities of polymerized red cells disrupt bulk flow, create vascular occlusions, and increase inflammation and cell adhesion. Over time this can lead to thrombosis, stroke, ischemia, hemolytic anemia, and organ failure. In the United States, patients with SCD have an average life expectancy of 54 years versus the healthy average of 76 years [3].

Though the underlying mechanism of SCD has been well studied, the link between hemoglobin aggregation and altered red cell mechanical properties is not well understood. When polymer domains form in the deoxygenated red cells the cells undergoes drastic changes in material properties. In bulk flow SCD patient samples exhibit altered fluid proprieties due to these mechanical changes [4]. The work in this study aims to quantify specific material and chemical changes in the red blood cells as they undergo sickling. Novel microfluidic platforms and optical instruments have been developed to quantify single cell saturation, morphology, and mechanical properties. The advances from this study will fill in knowledge gaps connecting changes at the molecular scale to single cell changes that ultimately lead to the SCD pathologies. This information will provide the necessary foundation for more focused design and testing of treatments.

## METHODS

To measure single cell properties, SCD patient blood samples were analyzed using two assays. The first assay, Quantitative Absorption Cytometry (QAC), builds off previous work published by Di Caprio et al [5] to quantify the saturation and morphology of single RBCs in high throughput under variable oxygen tension. In this assay, a custom built optical set up utilizes a constant red LED to quantify cell thickness, and two alternating blue LEDs in the Soret Band to leverage the optical absorption proprieties of oxygenated and deoxygenated hemoglobin and quantify the ratio of the two species. Single cell images are recorded to calculate saturation from the ratio of oxy and dexoyhemoglobin, and the morphology of the cells is analyzed by a convolution neural net to determine if the cells are polymerized or soluble. The outputs of this assay are fractions of soluble and polymerized cells at each oxygen tensions and saturation curves for both species.

The second assay utilizes microfluidic techniques to perform a controlled stress relaxation test at the single cell level for RBCs in high throughput under variable oxygen tension. Red cells are forced through a 4x6μm capillary channel under controlled pressure. In the capillary section cells undergo consistent deformation and upon exit relax back to a steady state geometry. A high speed camera uses image based auto triggering to capture cells undergoing this process. A custom python image analysis tool kit tracks the cells to determine shape and location, and from this the relative changes in circularity, C, can be determined.

$$C = \frac{2\sqrt{\pi(area)}}{perimeter} \quad (1)$$

The distribution of relative circularity changes in a sample gives a qualitative measure of the distribution of cell stiffness values.

## RESULTS

Results from one sample show the heterogeneous nature of red blood cells in SCD. The saturation measurements in the QAC assay show polymerized RBCs display a lower saturation at a given oxygen tension compared to soluble cells (fig. 1).

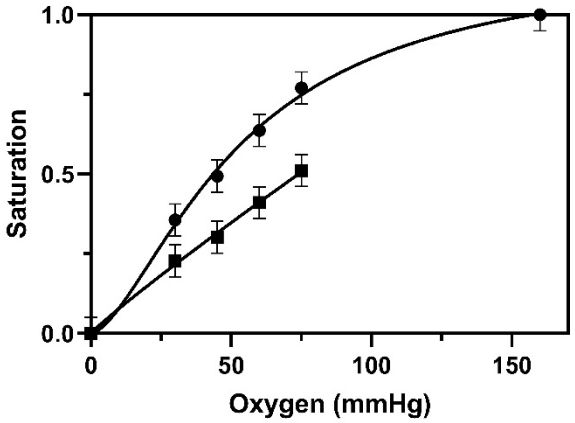

**Figure 1: Saturation curves of soluble population (circles) and polymerized population (squares). Soluble hemoglobin has a higher oxygen affinity resulting is high saturation for a given oxygen tension. There are no polymerized cells at 160mmHg**

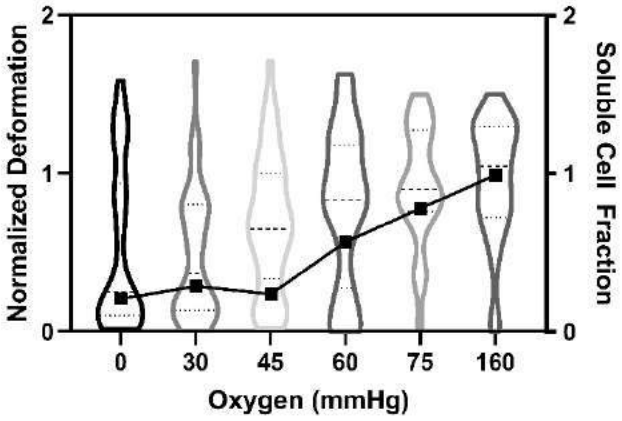
QAC also measures the fraction of soluble cells at a given oxygen tension. This is shown in figure 2 (right y-axis). The fraction of soluble cells increases with increasing oxygen content as polymer melts in the cells. Figure 2 also shows the distribution of normalized deformation from the Single Cell Deformation assay (left y-axis).



The soluble cell fraction has been overlaid on the distribution of normalized deformation to highlight the relationship between the two. At low oxygen tensions the fraction of soluble cells is low as a large portion of the cells are polymerized. Similarly, the deformation distribution is shifted towards zero at low oxygen tensions suggesting a higher fraction of stiff cells. As oxygen tension increases the soluble cell fraction increases, and the deformation distribution shifts towards one suggesting a higher fraction of pliant cells. These two independent assays, QAC and Single Cell Deformation, have been compared with a Paired T-Test and give a p value of 0.04.

## DISCUSSION

Many studies have presented data on the increased stiffness of sickle red blood cells. The data in this project so far agrees with the current understanding of SCD physiology. As oxygen decreases hemoglobin in sickle RBCs will polymerize, and as a result oxygen carrying capacity will decrease and cell stiffness will increase [6]. This study adds a measure of granularity to the data. Previous work has quantified cells as either polymerized or soluble with binary measures of material properties. However, at intermediate oxygen tensions it is unknown if polymerized RBCs act the same as those under fully deoxygenated conditions. A higher saturation of a polymerized cell could lead to less aggregation of hemoglobin and a more intermediate stiffness. These cells would not align with material properties of fully polymerized cells at 0mmHg or fully soluble cells at 160mmHg, and would suggest that the stiffness of polymerized RBCs exist on a continuum.

The preliminary data in this study suggests that this is a possibility. In figure 2 the comparison of soluble fraction to distribution of deformation shows strong agreement at both ends of the oxygen spectrum, but less so in the intermediate oxygen tensions. At 45 and 60 mmHg the soluble fraction is considerably less than the median of the normalized deformations, which suggests that some of the polymerized cells are not as stiff as those found in deoxygenated conditions.

The relative changes in mechanical properties are an important biomarker for SCD. As it is hypothesized that stiff, polymerized cells are responsible for vascular occlusion and endothelial damage [2], this biomarker is an excellent target for measuring efficacy of treatment.

## INTRODUCTION

Computational fluid dynamics (CFD) modeling is a widely used predictive tool in the design and assessment of medical devices. However, to be relied upon to inform regulatory decision making, the credibility of computational predictions must be demonstrated by performing verification and validation [1,2]. Toward this end, the U.S. Food and Drug Administration (FDA) collaborated with academic researchers to establish a benchmark centrifugal blood pump model for CFD validation. An open interlaboratory study was conducted in which participants from around the world submitted CFD simulation results of the benchmark blood pump for comparison with experimental data [3,4]. A total of 24 CFD simulations were submitted. In this study, we report the complete results of the interlaboratory study including comparisons of the CFD predictions in the pump with experimental velocity and hemolysis measurements at several different pump operating conditions.

## METHODS

The centrifugal blood pump (Figure 1) was designed with simple geometric features and could operate across a wide range of flow and pressure conditions. Details of the pump geometry are available at: https://nciphub.org/wiki/FDA_CFD/ComputationalRoundRobin2Pump. Interlaboratory experiments were conducted to provide an experimental benchmark dataset for CFD validation. Specifically, inlet and outlet pressure values were acquired and the velocity field was measured using particle image velocimetry (PIV) at six pump conditions with flow rates ranging from 2.5–7.0 L/min and rotational speeds of 2500–3500 rpm (Figure 2). The PIV methodology and results obtained from three independent labs are detailed in Hariharan *et al* [4]. The hemolytic potential of the blood pump was determined through *in vitro* tests using porcine blood at one lab [3].

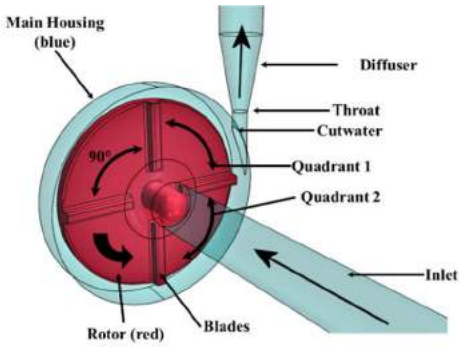

**Figure 1: Schematic illustration of the FDA benchmark blood pump.**

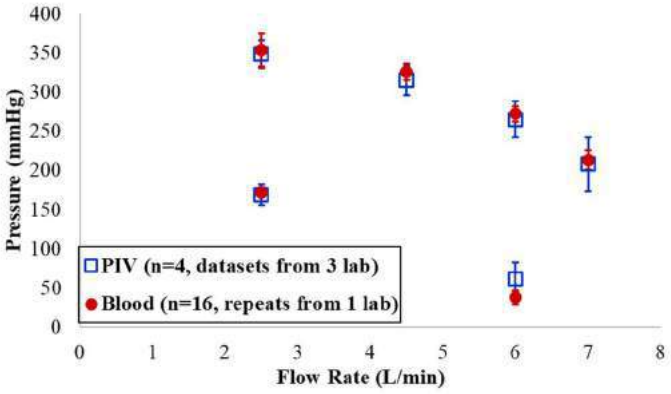

**Figure 2: Experimental measurements of pump pressure head versus flow rate for the FDA benchmark blood pump. The PIV data are from interlaboratory measurements in three labs and the blood data were acquired in one lab with 16 repeats.**

The interlaboratory CFD study was conducted by participants in a blinded fashion prior to the publication of the experimental data. The participants were only provided the geometry of the pump, the fluid properties, and the measured inlet velocity profiles and turbulence intensities, and they were asked to simulate six pump operating conditions. Beyond this, the participants were free to choose the specific CFD solver, mesh resolution, boundary conditions, turbulence model, and other simulation choices.

Here, we performed detailed analyses of the interlaboratory CFD results for three test conditions: (i) 2.5 L/min at 3500 rpm, (ii) 6.0 L/min at 2500 rpm, and (iii) 6.0 L/min at 3500 rpm. To prevent bias, the participant data were anonymized for the analyses. In particular, we compared the CFD predictions to the experimental results to assess computational performance in terms of the pump pressure head, velocity distributions throughout the pump and the outlet diffuser, and hemolysis. For scalar quantities, a percent error was calculated for the CFD predictions of pressure and hemolysis. As each of the individual modelers used different computational meshes, to evaluate the velocity field, we interpolated the simulation results and the PIV data onto a common high-resolution mesh using Kriging interpolation (Figure 3). To quantify the overall error in the velocity field predictions compared with the PIV measurements, we calculated a relative comparison error ($\varepsilon$) in different pump regions (Figure 1: Quadrants 1 and 2, and the diffuser region), defined as

$$\varepsilon = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(\frac{u_{CFD,i}-u_{exp,i}}{u_{exp,max}}\right)^2} \qquad (1)$$

where $u_{CFD,i}$ is the local CFD velocity magnitude at each spatial location, $u_{exp,i}$ is the corresponding experimental value at the same location, and $u_{exp,max}$ is the maximum experimental value in the entire region of interest.

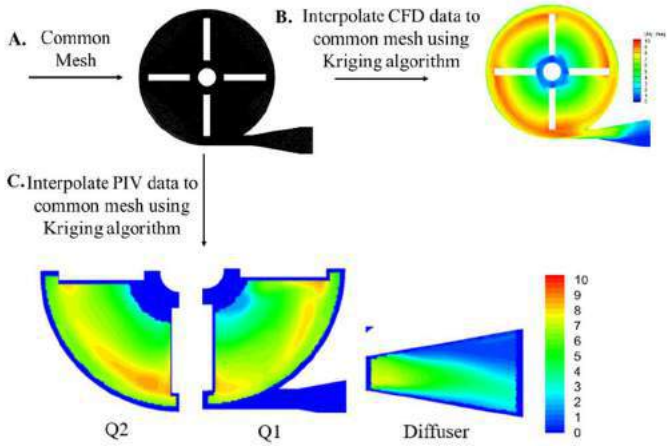

**Figure 3: Data analysis pipeline including A. the common interpolation mesh, B. interpolation of participant CFD submissions, and C. interpolation of PIV results.**

## RESULTS

The interlaboratory study participants submitted results from 14 steady-state and 10 transient simulations using a wide range of CFD solvers, reference frame formulations, mesh resolutions, and turbulence models. In general, there was not a strong correlation between mesh resolution or turbulence model with CFD accuracy compared to the experimental pressure and velocity measurements. Most CFD predictions of the pump pressure head were within two standard deviations of the mean experimental data, except at the 6.0 L/min, 2500 rpm condition for which only 16 of 23 submissions were within this range (Figure 4). The unsteady simulations of the velocity field agreed more closely with the experiments within the rotor region of the pump, but showed little advantage over the steady simulations in the outlet diffuser region. Predictions of hemolysis varied widely for the eight participants who submitted results.

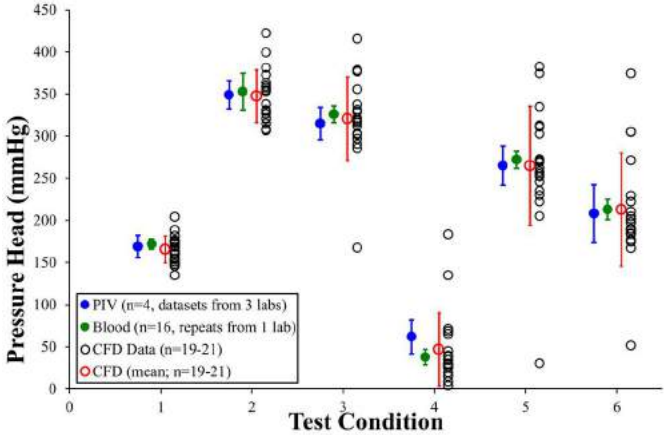

**Figure 4: Summary of pressure head from PIV experiments, blood experiments, and the interlaboratory CFD study simulations.**

## DISCUSSION

This study provides insight into the accuracy of CFD simulations of the FDA benchmark blood pump from a wide range of users in the medical device community. While the number of participants using different options and approaches was insufficient to determine definitive trends, there were some valuable observations. Most notably:

- CFD accuracy was not strongly correlated with the choice of turbulence model
- Transient simulations were more accurate than steady simulations in the rotor region of the pump
- Flow field predictions in the outlet diffuser were generally much less accurate than in the rotor region

We also note that, while a number of CFD submissions accurately predicted a single operating condition, few of the participants in the study were able to accurately predict the pump performance at all three conditions analyzed. This highlights the need to validate CFD modeling of mechanical circulatory support devices across a range of operating conditions, especially at off-design conditions that are more challenging to accurately predict.

## ACKNOWLEDGEMENTS

We thank Steven Day of the Rochester Institute of Technology who led the design and fabrication of the pump model in collaboration with RAM. This study was funded by the FDA CDRH Critical Path program and, in part, by a National Science Foundation INTERN supplement through NSF CMMI-2017805.

## INTRODUCTION

Lumped Parameter Network (LPN) models have provided a powerful tool for modelling the cardiovascular system, and have been used for medical device design, surgical planning, as well as education and training[1]. However, the determination of appropriate LPN component values has traditionally required extensive manual tuning and presents a practical barrier to using this tool. Several studies have attempted to address this practical barrier by developing automated tuning procedures, but a majority of these automated tuning procedures apply to highly simplified models of the cardiovascular system[2], [3]. Several studies provide automated tuning protocols for more sophisticated LPN models but apply to patients with congenital heart defects or only determine a limited set of cardiovascular parameters such as the elastance, end diastolic volume of the left ventricle, and systemic vascular resistance[4], [5].

To the best of our knowledge, there exists no protocol that can automatically provide a full set of component values for a sophisticated closed-loop model of the healthy cardiovascular system at rest, such that the hemodynamics simulated match a target set of multiple hemodynamic quantities. To address this, we develop a protocol which can automatically generate the full set of component values for an LPN model according to the desired set of hemodynamic parameters to be simulated. This desired (target) set of hemodynamics includes the mean aortic pressure, systolic and diastolic aortic pressures, cardiac output, as well as the systolic and diastolic ventricular volumes for both ventricles. In addition, the protocol also ensures that the resulting simulated mean pulmonary artery pressure and the mean atrial pressures are realistic for a typical healthy subject at rest.

## METHODS

Our protocol determines all LPN component values needed to obtain a set of target hemodynamic parameters (THP) in an LPN model derived from previous work (Figure 1). We divide all the LPN component values into three categories based on the procedure used to determine them. The first category of LPN component values includes LPN components governing the ventricles, the capacitance of the aorta and are determined using a neural network with an architecture specifically designed for non-linear regression[6]. The data required for training the neural network was obtained by running the LPN with 300,000 combinations of the LPN component values in the first category and recording the corresponding hemodynamic outputs.

The second category includes all of the remaining LPN component values except for the ventricular reference volumes. The values for the second category are predicted by scaling a reference set of LPN component values. The reference set of LPN component values reflect clinically nominal hemodynamics and were obtained by manual tuning. From the THP and using clinically nominal values for mean atrial pressures, the systemic vascular resistance (SVR) and the pulmonary vascular resistance (PVR) can be calculated. All of the reference values for the systemic and pulmonary resistances are then scaled to match the target SVR and PVR. To adjust for body size, the capacitances are scaled according to equation 1, similar to previous work[5], [7].

$$\frac{C}{C_i} = \left(\frac{TVR}{TVR_i}\right)^{-\frac{4}{3}} \quad (1)$$

Where $C$ and $C_i$ represent the scaled capacitance and reference capacitance, respectively. Similarly, $TVR$ and $TVR_i$ represent the target and the reference LPN total vascular resistance, respectively.

Finally, the third category which includes the ventricular reference volumes, are calculated using equations 2 and 3 based on information in the THP. The end systolic pressures are estimated using equations 4 and 5[8].

$$Vlv_0 = LVESV - \frac{LVESP}{E_{maxLV}} \quad (2)$$

$$Vrv_0 = \left(RVESV - \frac{RVESP}{E_{maxRV}}\right) + 15 \quad (3)$$

$$LVESP = \frac{mean(P_{ao})}{0.8721} - SV * 0.051565 \quad (4)$$

$$RVESP = \frac{2}{3} * \left(mean(P_{pa}) + sPAP\right) \quad (5)$$

Where $Vlv_0$ and $Vrv_0$ are the left and right ventricular reference volumes respectively. $LVESV$ and $RVESV$ are the left and right ventricular end systolic volumes respectively. $LVESP$ and $RVESP$ represent the left and right ventricular end systolic pressures. $mean(P_{ao})$ refers to the mean pulmonary artery pressure, $mean(P_{pa})$ the mean PA pressure, and $sPAP$ the systolic pulmonary artery pressure. All pressures are in mmHg, and volumes in ml.

To test protocol performance, we used 500 realistic sets of THP generated from previous work reflecting resting physiology of healthy subjects and compared the protocol output to the THP [9]. We have used the normalized root mean square error (NRMSE) to quantify the difference between the target values and the simulated hemodynamics.

## RESULTS

Simulation results show that waveforms for critical hemodynamic parameters were physiologically realistic (one example shown in Figure 2A) and within clinically normal ranges. The NRMSE between the target and simulated hemodynamics ranged between 0.63% and 14.2%. The highest NRMSE corresponds to systolic left ventricular volume for which the maximum absolute difference between the target and simulation was 9.6 ml. The NRMSE for all other parameters was below 8.2% (Figure 2B). In all test cases, the mean pulmonary artery pressure, both the left and right mean atrial pressures also lie within clinically normal ranges (< 25, <15, and < 10 mmHg, respectively).

## DISCUSSION

Our automated protocol can significantly shorten the time-consuming and labor-intensive process of tuning LPN models. The simulated pressure and flow waveforms from our protocol are clinically realistic, and match very closely to the desired tuning targets. The ability of our protocol to automatically generate appropriate LPN component values lowers the barrier-to-entry for other researchers to adopt powerful LPN modelling tools for their work.

## INTRODUCTION

Abnormal cerebrospinal fluid (CSF) flow is associated with a variety of poorly understood neurological disorders such as Alzheimer's Disease[1, 2] and hydrocephalus[3]. The lack of comprehensive understanding of the fluid and solid mechanics of CSF flow remains a critical barrier in the development of diagnostic assessment and potential treatment options for these diseases. We have developed a whole brain, patient-specific computational fluid dynamics (CFD) simulation of CSF flow in the cranial cavity, incorporating patient specific pulsatile brain deformation as boundary conditions, as a step towards comprehensive understanding of CSF dynamics and how they relate to neurodegenerative diseases.

## METHODS

A patient-specific 3D geometry of the CSF filled spaces was segmented from structural MRI. Patient-specific flow boundary conditions were measured and calculated using phase contrast MRI and conservation of mass. Patient specific pulsatile deformation along the surface of the cerebrum and cerebral ventricles is measured using amplified MRI. A three-dimensional CFD simulation was conducted using only patient-specific waveforms as boundary conditions. Phase contrast MRI measurement of maximum velocity at the cerebral aqueduct was used to validate the simulation with excellent agreement.

## RESULTS

The CSF dynamics across the cardiac cycle are presented, (a preview shown in Figure 1) illustrating the relationship between arterial flow and CSF flow. Flow in and out of the ventricles was shown to have a slight phase delay (~20% of the cardiac cycle) from flow in the subarachnoid space. Intracranial pressure dynamics are presented, with pressure in the Lateral Ventricles demonstrating less significant transient effects than pressure in the subarachnoid space.

## DISCUSSION

This work presents a quantitatively validated whole-brain simulation of CSF flow for a single healthy subject. The computational methodology improves over the state of the art by eliminating non-physiological boundary conditions and unnecessary assumptions about the mechanical properties of brain tissue, providing an essential step towards clinically useful tools for assessing the development of neurodegenerative disorders.

## ACKNOWLEDGEMENTS

This work was made possible by the generous support of the Catchot Family.

# MEASUREMENT OF STENT RETRIEVER REMOVAL FORCES IN AN EXPERIMENTAL MODEL OF ACUTE ISCHEMIC STROKE

**Demitria A. Poulos (1), Bryan C. Good (1)**

(1) Mechanical, Aerospace, and Biomedical Engineering
University of Tennessee
Knoxville, TN, USA

## INTRODUCTION

Large vessel occlusions (LVOs) are the cause of approximately 40% of strokes worldwide, and acute ischemic stroke (AIS) due to LVO accounts for 90% of 6-month post-stroke mortality [1]. The standard treatment for an AIS due to LVO is a mechanical thrombectomy (MT), and when compared to therapeutic treatments indicates an improvement in patient outcomes [2]. Current MT procedures require the use of stent retrievers (SRs) or aspiration techniques to restore blood flow. Despite its clinical success, nearly 2 out of 3 patients who had an AIS experience adverse outcomes [3]. To improve the degree of revascularization, the interaction between a SR and thrombus, as well as the thrombus removal force needs to be understood. These findings can improve clinical training and inspire new SRs to further improve patient outcomes [3].

## METHODS

To determine the required removal forces of embolus analogs (EAs) in experimental models of AIS, two protocols were used. In the first, EAs were created *in situ* from bovine blood collected in CPDA-1 anticoagulated bags. The blood was centrifuged to separate red blood cells and platelet rich plasma, reconstituted to achieve a hematocrit of 50%, and $CaCl_2$ was introduced to promote coagulation. Two types of tubing (Tygon medical tubing and PVC tubing) were used in both bare and collagen-coated states to mimic a range of vascular surface interactions. Type-I bovine collagen was diluted with HCl and DI water and allowed to incubate within the tubes at room temperature. After the addition of $CaCl_2$, the blood was allowed to statically clot for 1.5 hours in one of the vascular models. A Solitaire2 Revascularization Device (Medtronic) was inserted and deployed in the tube across each EA to mimic SR MT. To measure clot removal force, the tubing and SR were attached to a Single Column Material Testing System (Instron), and the SR wire was pulled at a constant 2 mm/s until the crosshead displaced 20 mm and the SR and EA were removed from the tubing (**Fig. 1A**). The length of each EA was measured with digital calipers after each experiment. Additional tests were performed for each model without an EA, as a control test to determine the friction between the SR and each surface.

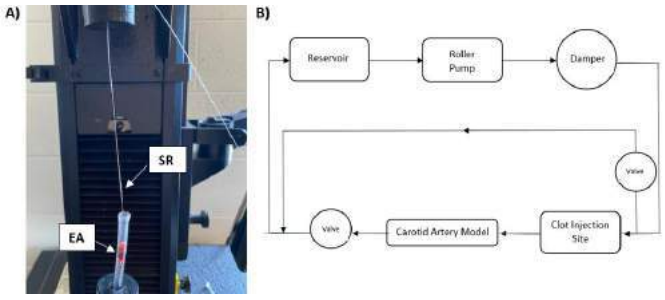

**Figure 1: Experimental setup of the A) Instron stent removal test and B) diagram of the benchtop circulatory flow loop.**

To more accurately represent how EAs originate and lodge in AIS patients, a benchtop circulatory flow loop was developed with a constricting cerebral artery model (**Fig. 1B**), which tapered from 5.5 to 3.3 mm in diameter. For this experiment, 6 mm diameter tubing and a Chandler loop were used to create EAs of 50% hematocrit under dynamic flow conditions for approximately 1.5 hours. The EAs were removed from the Chandler loop, cut to size, and inserted into the flow

loop upstream of the artery model. The EAs were allowed to lodge downstream within the carotid artery model for roughly 15 minutes under cerebral flow rate and pressure conditions. The model and lodged EA were removed from the flow loop and transferred to the Instron machine, the SR was deployed, and the Instron protocol from the previous experiments was followed to measure the EA removal forces.

## RESULTS

As displayed in **Fig. 2**, the measured force ramps up as the SR is pulled by the Instron machine until the EA eventually detaches from the tubing. The downward slope after detachment represents residual friction between the SR and tubing. Peak removal forces (**Table 1**) ranged between 0.1 to 0.5 N.

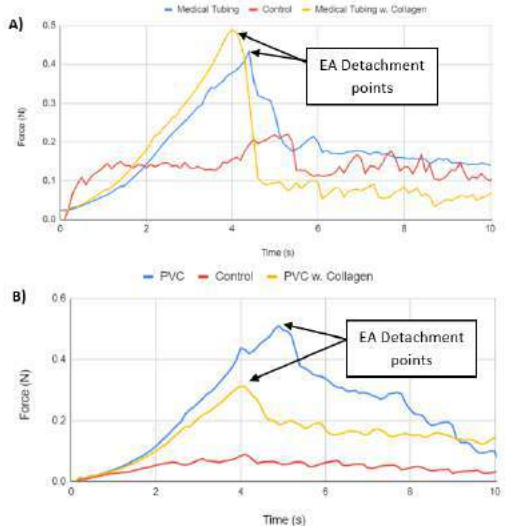

**Figure 2: Force vs. time data for EA removal in A) Tygon and B) PVC tubing with and without collagen compared to controls.**

From **Fig. 3** it can be observed that EA length correlated with lower removal forces. The average EA lengths for PVC bare and collagen coated tubes were approximately 27.1 and 25.4 mm and 22.9 and 24.1 mm for Tygon bare and collagen coated tubes. The introduction of collagen only had a minor effect on the EA removal forces shown in **Table 1**.

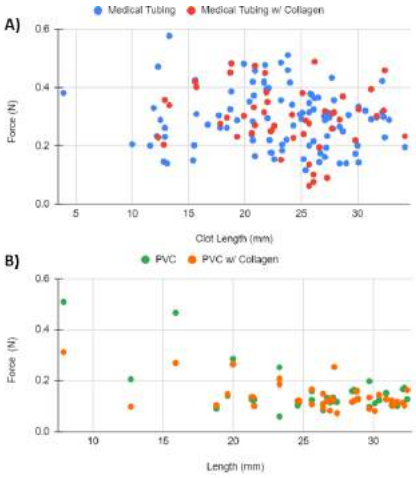

**Figure 3: Relationship between maximum removal force and EA length formed *in situ* in A) Tygon medical and B) PVC tubing.**

**Table 1: Sample size and removal forces for each test parameter**

| Test Parameter | Sample Size | Average Max. Force (N) |
|---|---|---|
| Tygon Medical Tubing | 102 | 0.295±0.1 |
| Tygon Medical Tubing with Collagen | 57 | 0.293±0.1 |
| PVC Tubing | 44 | 0.151±0.08 |
| PVC Tubing with Collagen | 51 | 0.132±0.05 |

A total of 5 EAs were tested in the circulatory flow loop, and the average removal force was 0.304±0.1 N. Similar trends were present in all 5 tests (example shown in **Fig 4**), the initial accumulation of force is a result of the SR pulling through the EA. Once the EA detaches it begins to curl on itself and the SR vacates the tube, pulling the EA accumulation with it.

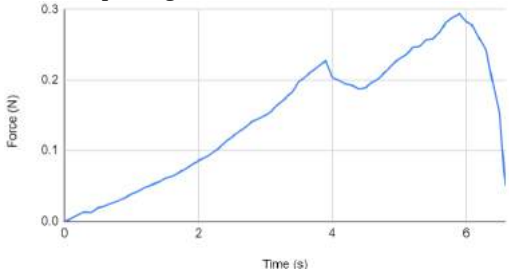

**Figure 4: Example of force (N) vs. time (s) data of an EA lodged in the circulatory flow loop cerebral artery model.**

## DISCUSSION

These results indicate that surface coating influences EA adhesion and can affect the maximum detachment forces. To accurately represent the formation and adhesion of EAs in AIS, further experiments will be performed with other concentrations of collagen and tubing surfaces. The simple vascular models, however, provided a basis for a more complex representation created by the constricting artery model and flow loop. When comparing the data across all experiments it is observed that the forces required to remove EAs from the circulatory flow loop model were greater than that of EAs formed statically in various vascular models. Since the flow loop was a more realistic representation of the formation of EAs, we can assume that data collected from this experiment can be compared to clinical settings. Further studies are needed to understand the complete range of thrombus removal forces. More data will be collected with the constricting carotid artery model, and other physiological cerebral models will also be introduced to the flow loop to observe the relationship between arterial geometry and SR removal forces.

## ACKNOWLEDGEMENTS

We thank Dr. Michael Froehler from the Vanderbilt University Medical Center for providing the SR used in this study.

# RADIOMICS FEATURES ON CONTRAST-ENHANCED AND NON-ENHANCED MRI ARE ASSOCIATED WITH INTRACRANIAL ANEURYSMAL RISK

**Sricharan S Veeturi (1,2), Nandor K Pinter (3), Adnan H Siddiqui (1, 3), Vincent M Tutino (1,2,4)**

## INTRODUCTION

Vessel wall enhancement (VWE) in intracranial aneurysms (IAs) is a phenomenon where a distinctly higher signal intensity is observed in T1-MRI image after injection of gadolinium-based contrast, as compared to the image before contrast injection. This is a potential imaging biomarker for risk stratification of IAs and has been associated with aneurysm instability. Clinical studies have associated VWE with growing/unstable aneurysms in the past and found that unstable aneurysms were more likely to exhibit VWE than stable aneurysms [1]. Currently, VWE assessment is done manually via visual inspection of non-enhanced MRI (NE-MRI) and contrast-enhanced MRI (CE-MRI) images and is characterized as focal/circumferential. To aid in more objective evaluation of enhancement, metrics have been developed in recent years to quantify the overall degree of enhancement. For example, $CR_{stalk}$ is the ratio of the maximal signal intensity on the aneurysm wall to the pituitary stalk intensity in the CE-MRI image. However, metrics like $CR_{stalk}$ are single values that are computed for each aneurysm case and may not consider the complex variations of intensity across the aneurysm sac that reflect differences in tissue behavior and biology.

Radiomics has emerged as a promising tool for analyzing and quantifying complex textural variations in signal intensities among different modalities of images [2]. This is a technique where images are converted into a mineable high dimensional space using automatically extracted data-characterization algorithms. In this study, we investigated if radiomics features (RFs) derived from NE-MRI and CE-MRI images could assist in better risk stratification of IAs. To do this, we performed radiomics analysis on NE-MRI and CE-MRI image pairs of aneurysms to extract 293 RFs and classified them as high or low-risk using their 5-year ISUIA scores as a risk surrogate. We built a multivariate regression model using the RFs that are significantly different between high and low risk aneurysms which could potentially help in better risk stratification of IAs.

## METHODS

Time of flight (TOF) MR angiography, NE-MRI and CE-MRI images from patients imaged between September 2019 and July 2020 were acquired. We excluded images which were at the cavernous segment of the ICA due to the presence of high intensity imaging artifact in the cavernous sinus region [2]. Additionally, we also excluded aneurysms that had a perpendicular height < 2 mm due to image resolution constrictions.

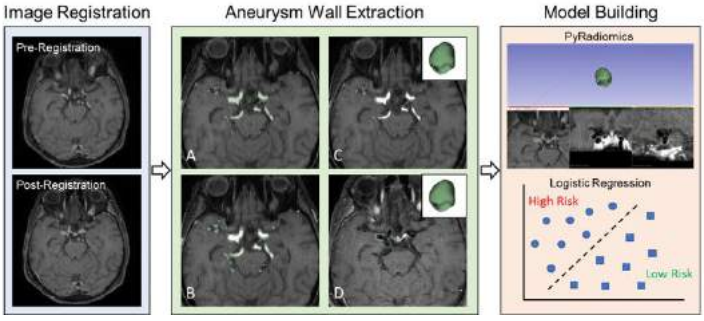

**Figure 1: Pipeline for extraction of radiomics features.** NE-MRI and CE-MRI images were registered in 3D slicer.

The pipeline for extracting RFs from the features shown in Figure 1. This was all performed in 3D slicer (www.slicer.org). We extracted RFs from the NE-MRI and CE-MRI using the masks as the region of interest, and also computed the difference in the RFs. An interactive PyRadiomics (https://radiomics.io) add-in was used in Slicer 3D to compute the RFs in all the images. The MRI images had an anisotropic

resolution (0.375 mm X 0.375 mm X 0.4 mm) hence, for more robust computation of RFs, the original images were resampled into an isotropic resolution of 0.5 mm X 0.5 mm X 0.5 mm [4]. We computed a total of 293 RFs for each aneurysm. The details are shown in table 1.

**Table 1: Radiomics Features computed for each aneurysm.**

| | Method | NE-MRI | CE-MRI | Diff. |
|---|---|---|---|---|
| Shape and Size | Aneurysm wall mask morphology | 14 | | |
| Intensity Distribution Metrics | Intensity Distribution Metrics | 18 | 18 | 18 |
| High level textural features | Gray-level co-occurrence matrix (GLCM) | 24 | 24 | 24 |
| | Gray-level size zone matrix (GLSZM) | 16 | 16 | 16 |
| | Gray-level run length matrix (GLRNM) | 16 | 16 | 16 |
| | Neighborhood gray-tone difference matrix (NGTDM) | 5 | 5 | 5 |
| | Gray level dependence matrix (GLDM) | 14 | 14 | 14 |
| | | | **Total: 293** | |

For risk categorization, we computed the 5-year ISUIA score for each case which were assumed to be representative of the risk [5]. Following feature extraction, we performed univariate analysis on all the RFs obtained. For normally distributed parameters, a two-tailed student t-test was used to assess statistical difference and from non-normally distributed parameters, we performed a non-parametric Mann-Whitney U test. A parameter was assumed to be significantly different if $p<0.05$ from the univariate analysis.

To evaluate the potential utility of RFs in risk stratification of aneurysmal lesions, we built a multivariate logistic regression model using the significant different RFs identified above. Aneurysms having a an ISUIA score>2.5 were considered high risk lesions. The co-linear RFs were first removed by performing a correlations analysis. Features having a correlation coefficient >0.8 were removed and a logistic regression model was trained using ISUIA scores as the independent variable. The logistic regression model was built using scikit-learn libraries in python. We implemented a leave-one-out cross validation due to small sample size. We compared the performance of the regression model with $CR_{stalk}$ alone as the metric for risk stratification.

## RESULTS

A total of 25 aneurysms from 23 patients were collected for this study. Using ISUIA as the clinical score, a total of 6 RFs were significantly different between high and low risk lesions of which 3 were RFs extracted from CE-MRI and 3 RFs from the difference. Correlation, Informational Measure of Correlation 2 (IMC2), and maximal correlation coefficient (MCC) were computed using the GLCM filter in the CE-MRI images. The coarseness computed using the difference in NGTDM values between NE-MRI and CE-MRI were significantly lower in high-risk aneurysms, whereas IMC1 computed using the GLCM filter and Busyness computed using the NGTDM filter in the CE-MRI were significantly higher in high risk aneurysmal lesions.

Using ISUIA as the clinical score, we ended up with 5 independent RFs which we used to train the logistic regression model. A heatmap of the correlation matrices is shown in figure 2. ROC analysis of the logistic regression model built using ISUIA scores showed a very good predictive value with ROC of 0.88. The model had an accuracy of 84%, a sensitivity of 75% and a specificity of 88%. Upon calculating the odds ratio, we found that the NGTDM busyness in the CE-MRI image had the highest odds ratio (1.05) followed closely by GLCM IMC1 (1.04). This shows that both the complexity of signal intensities as well as the gradients in signal intensities in CE-MRI images are higher in high-risk IAs. Gradients and complexity of signal are higher in aneurysms exhibiting VWE which is characteristic of high-risk aneurysms.

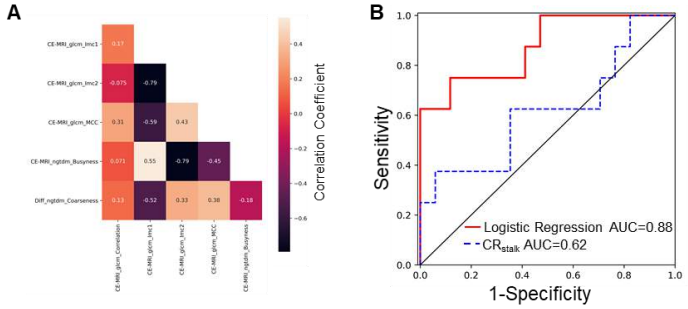

**Figure 1: Statistical models for predicting high risk lesions. A)** A heat map showing the final 5 independently associated RFs used to build the logistic regression model. **B)** Assessment of performance using of the logistic regression model and an existing metric $CR_{stalk}$ using ROC analysis.

## DISCUSSION

In this preliminary study we explored the feasibility of using radiomics features derived from NE-MRI and CE-MRI images in risk stratification of intracranial aneurysms. Over the years, it has been observed that ruptured and growing IAs demonstrate significantly higher contrast enhancement in the CE-MRI images as compared to stable IAs [1]. Indeed, our observations in the current study resonate with such previous studies. We observed that high-risk aneurysms were characterized by lower GLCM correlation, IMC2 and MCC in the CE-MRI image. In different ways, all these features quantify the complexity of the texture of the image. This suggests that high-risk aneurysms tend to have higher "complexity" or higher variations in in MRI signal intensity as compared to low-risk aneurysms in the CE-MRI image. This could potentially be due to the presence of vessel wall enhancement in certain parts of aneurysms. Additionally, we also observed that high-risk IAs had a lower difference in NGTDM Coarseness, which is a measure of the gradient of intensities of surrounding voxels from the center voxel, between NE and CE-MRI images. A potential explanation to the lower difference in high-risk IAs is that high-risk IAs tend to exhibit enhancement throughout the whole aneurysm which would lead to lower gradients and thus lower difference in coarseness values from NE-MRI images when compared to low risk aneurysms. Similarly, we also observed that the NGTDM busyness, which quantifies the rapidly changing signal intensities, was higher in case of high-risk IAs.

We also observed that statistical models built from RFs outperform current clinical metrics of assessing risk. Thus, RFs derived from NE and CE-MRI images could potentially be added as a quantitative tool for risk stratification in the current clinical pipeline.

## INTRODUCTION

To maintain a stable microenvironment for brain homeostasis, the blood-brain barrier (BBB) acts as a physical barrier to protect the brain parenchyma from the toxic effects of blood components but also poses a formidable challenge to the delivery of therapeutics[1]. Therefore, safe and effective approaches to open the BBB are essential to deliver therapeutics for CNS diseases. We have developed a novel method to reversibly open the BBB *in vivo* by picosecond-laser excitation of gold nanoparticles (AuNPs) modified by a antibody targeting JAM-A, one of the tight-juntion proteins along the BBB, and delivered human IgG, viral vector AAV and cargo-laden liposome successfully *in vivo*[2].

$Ca^{2+}$ influx and signaling have been shown to increase BBB permeability by several pathways including ERK1/2 phosphorylation to modulate the integrity of BBB. We investigated this hypothesis with an *in vitro* transwell BBB model (**Fig. 1**). We showed that picosecond-laser stimulation of targeted AuNPs causes a drop in the tranendothelial electrical resistance (TEER) and an increase in the permeability, both reversibly. We further observed $Ca^{2+}$ influx, propagation and recovery after laser stimulation. The phosphorylation of ERK1/2, one of the candidates on the $Ca^{2+}$ signaling pathway, maximized at 0.5 hr and recovered at 6 hr after laser tretament. These results suggest that the mechanism involves $Ca^{2+}$ influx and propagation.

## METHODS

*Nanoparticle synthesis and functionalization:* Gold nanoparticles (AuNPs) were synthesized and functionalized with BV16 (anti-human JAM-A) to target JAM-A or *lycopersicon esculentum* lectin (LEL) to target glycoprotein by previous reported method[2].

*In vitro experiments:* Human cerebral microvessel endothelial cell/D3 (hCMEC/D3) cells were seeded on collagen-coated transwell inserts and cultivated approximately 1 week to form cellular monolayer. The monolayers were incubated with AuNP-BV16 (0.5 nM) followed by laser treatment. To measure the permeability, the media with 1 mg/ml FITC-dextran was added to the upper chambers. At selective time points, 100 µl media were aspirated from the bottom chamber. The fluorescent intensity of FITC-dextran was detected with excitation at 490 nm and emission at 540 nm. The permeability (cm/sec) was calculated by rate of FITC-dextran quantity change over time (dQ/dt), divided by the initial concentration of dextran (C) and the membrane area (A) (Eq. 1). To detect $Ca^{2+}$, the monolayers were treated with 3 µM fluo-4 ($Ca^{2+}$ indicator) for 0.5 hr, followed by real-time imaging. The percentage change (%) of fluo-4 was calculated by the change in intensity, $\Delta I$ (the intensity at a time $t$, $I_t$, minus the baseline intensity, $I$), divided by the baseline intensity $I$ (Eq. 2). To detect phospharylation level of proteins, RIPA buffer was used to extract protein for western blot assay.

$$P_{app} = \frac{\frac{dQ}{dt} * 1}{A * C} \quad (1)$$

$$\text{Intensity change}(\%) = \frac{I_t - I}{I} = \frac{\Delta I}{I} \quad (2)$$

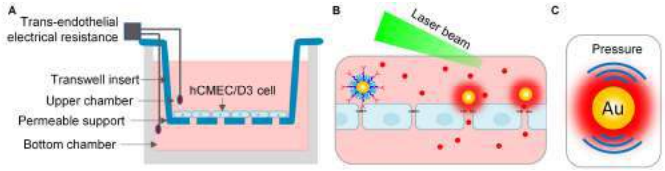

**Fig.1. Schematic of BBB opening *in vitro*.** (A) An *in vitro* transwell BBB model. (B) The targeting AuNPs on the cell membrane activated by picosecond laser. Red dots represent FITC-dextran molecules for permeability test. (C) Activated AuNP generates pressure variations.

## RESULTS

### Nanoparticle targeting and optical opening of the BBB

We examined the targeting of AuNP-BV16 using immunocytochemistry (ICC) staining. The results show similar distribution of free BV16 (positive control) and AuNP-BV16 on the cell boundaries, in contrast to control group (AuNP-PEG) (**Fig. 2A**), indicating that AuNP-BV16 targets JAM-A *in vitro*. Picosecond-laser excitation of AuNP-BV16 on monolayers temporarily decreases the TEER and increases the permeability (**Fig. 2B**). TEER drop suggests that the BBB opening involves the paracellular pathway to allow the passage of substances from top chamber to bottom chamber through intercellular clefts.

To improve the targeting efficiency, we modified the AuNPs with LEL for targeting glycoprotein. The results show that the targeting efficiency was improved by around 40-fold (**Fig. 2C**). AuNP-LEL (0.02 nM) resulted in the comparable TEER and permeability change when compared with 0.5 nM AuNP-BV16 (**Fig. 2D**).

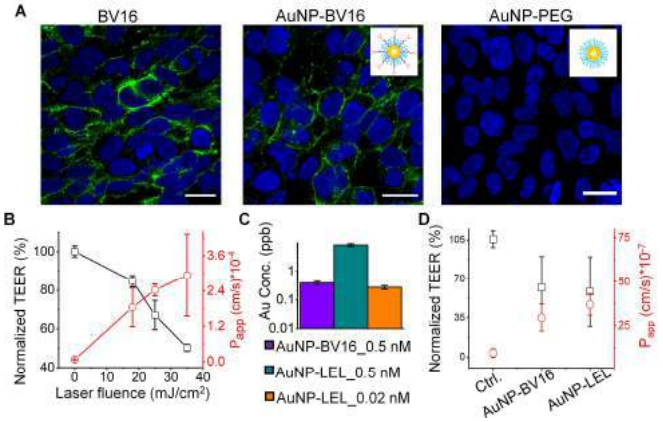

**Fig. 2. Picosecond-laser stimulation of cell-targeting nanoparticles opens the BBB reversibly.** (A) AuNP-BV16 distribution on the D3 monolayers by ICC staining. (B) Picosecond-laser stimulation of AuNP-BV16 on monolayers cause TEER drop and permeability increase (5 pulses). (C) Comparison of AuNP-BV16 and AuNP-LEL using Inductively Coupled Plasma Mass Spectrometry. (D) Comparison of TEER and permeability change between AuNP-BV16 (0.5 nM) and AuNP-LEL (0.02 nM). 35 mJ/cm$^2$, 5 pulses. Scale bar: 20 μm.

### Laser-induced $Ca^{2+}$ increase and propagation

Previous study reported that mechanical force can cause $Ca^{2+}$ increase in endothelial cells[4]. Picosecond-laser excitation of AuNPs leads to mechanical pressure variation, known as photoacoustic effect. To understand the mechanism of the BBB opening, we tested the $Ca^{2+}$ signal of the cells upon nanoparticle binding and laser irridiation. The result suggests that $Ca^{2+}$ were transiently increased after laser stimulation as indicated by the increase of fluo-4 intensity (**Fig. 3A**). More importantly, the analysis shows that $Ca^{2+}$ signal propagated after laser irradiation (**Fig. 3B and C**). When stimulating half area of the inserts, there is no significant difference of TEER drop compared with the full area irradiated by laser, indicating propagation (data not shown).

Taken together, these findings suggest the optical BBB opening (TEER drop) involves temporary $Ca^{2+}$ increase and propagation.

### Phosphorylation of ERK1/2

The influx of $Ca^{2+}$ into endothelial cell can activate second-messenger cascade and ultimately leads to the BBB opening[3]. Phosphorylation of ERK1/2 is one of the important activities in the $Ca^{2+}$-sensitive signaling cascades that causes cytoskeletal contraction to modulate the integrity of the BBB[3]. In our study, the western blot results show the phosphorylation of ERK1/2 can be detected at 5 min,

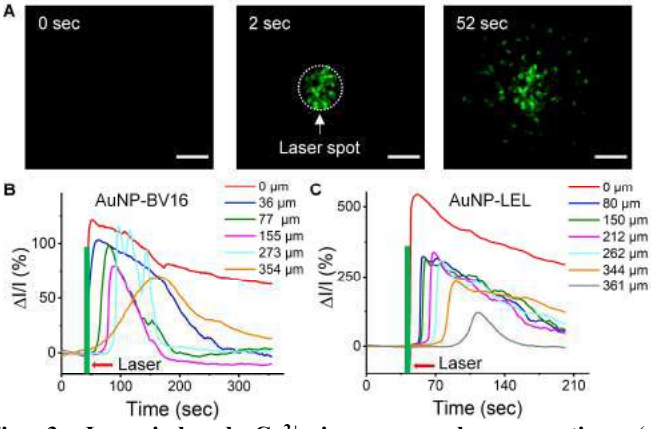

**Fig. 3. Laser-induced $Ca^{2+}$ increase and propagation.** (A) Represetive images of the intensity change of fluo-4 ($Ca^{2+}$ indicator ) after laser stimulation of AuNP-LEL. (B-C) Analysis of $Ca^{2+}$ increase and propagation after laser excitation of AuNP-BV16 (B) and AuNP-LEL (C). 35 mJ/cm$^2$, 1 pulse. Scale bar: 100 μ m.

maximized at 0.5hr and recovered at 6 hr after laser treatment (**Fig. 4**). Furthermore, the ERK1/2 inhibitor blocked the phosphorylation, further confirming that the $Ca^{2+}$ increase activated the phosphorylation of ERK1/2.

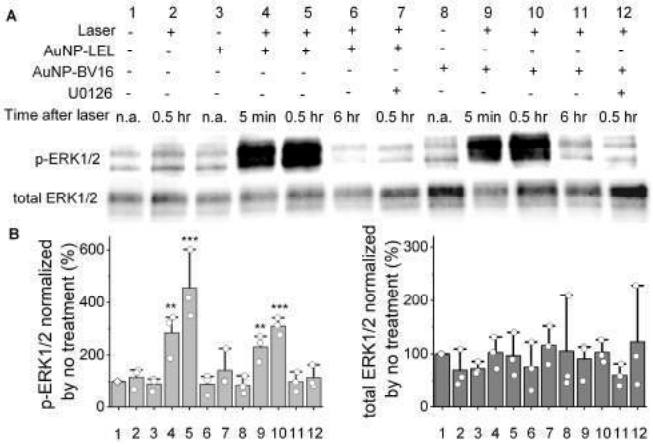

**Fig. 4. Phosphorylation of ERK1/2.** (A) The phosphorylated and total ERK1/2 detected by western blot. (B) The quantification analysis of (A). 35 mJ/cm$^2$, 5 pulses. One-way ANOVA. **: P<0.01, ***: P<0.001.

## DISCUSSION

In this study, we investigated the cellular signaling of the optical BBB opening. Our results suggest picosecond-laser stimulation of cell-targeting AuNPs triggers a $Ca^{2+}$ influx and propagation, which in turn causes temporary phosphorylation of second-messenger ERK1/2, ultimately leading to the reversible increase in the BBB permeability. Targeting glycoprotein by *lycopersicon esculentum* lectin advances this work with low concentration of AuNPs to reach comparable efficacy.

# SPATIOTEMPORAL DYNAMICS OF EPITHELIAL CELL PACKINGS AND TISSUE MECHANICS DURING MORPHOGENESIS

**Christian M. Cupo (1), Cole J. Allan (1), Andrew Pomposelli (1) Karen E. Kasza (1)**

(1) Department of Mechanical Engineering

## INTRODUCTION

The ability for epithelial tissues to remodel and flow during development is essential to generating functional tissue structure and shape. Coordinated cellular movements allow collections of cells to rearrange positions so that the tissue can remodel and flow as a fluid-like material during development (1-3). *Drosophila* body axis elongation is a dramatic example of a rapid tissue flow that drives embryo morphogenesis. This convergent and extension process doubles the length of the germband epithelial tissue in about 30 min and is driven by local cell rearrangements that require anisotropic myosin II activity (Fig. 1). Recent work from our group and others has revealed that the germband tissue becomes more fluid-like at the onset of body axis elongation, which is likely to help accommodate rapid cell rearrangements and tissue flow (4). However, it is not understood how local features of a tissue might control tissue mechanics and influence the likelihood for a cell rearrangement to occur at a particular location. Here, we develop a framework for analyzing local cell packings within the germband epithelium as a foundation for ultimately studying spatiotemporal tissue mechanics and the links to underlying protein activity and gene expression patterns in developing embryos.

## METHODS

**Fly Stocks.** Fly stocks were from the Bloomington Drosophila Stock Center (BDSC). The cell membrane was visualized with gap43-mCherry, and myosin II was visualized with sqh-GFP, a GFP-tagged myosin regulatory light chain.

**Time-Lapse Imaging.** Embryos were generated at 23ºC and collected for analysis at stage 6. Embryos were dechorionated for 2 min in 50% bleach and washed with distilled water for 2 min. Embryos were mounted between a glass slide and an oxygen-permeable membrane in a 50:50 mixture of halocarbon oil 27:700. Confocal imaging was performed on the ventrolateral region of the embryo at 0.7µm z-steps and 15 s time intervals using a Zeiss LSM880 laser-scanning confocal microscope.

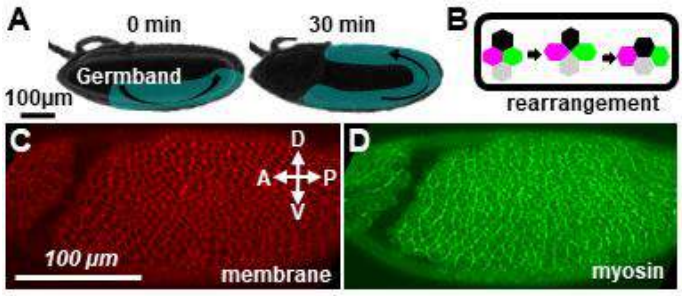

**Figure 1. During *Drosophila* body axis elongation, the germband epithelium extends to twice its initial length in 30 min via a rapid tissue flow.** Tissue flow (A) is driven by myosin-dependent oriented cell rearrangement events (B) that narrow and elongate the tissue. Images of cell outlines (C) and myosin II (D) during axis elongation.

**Image Processing and Quantification.** Analysis was performed on maximum intensity projections of 3 z-slices at the apical side of the tissue at the level of adherens junctions. Cell membrane networks were initially mapped by combining a watershed algorithm (5) with a mask in MATLAB and then resolving errors manually using the SEGGA tissue segmentation and analysis software (6). The cell shape index is defined as the cell perimeter ($P$) divided by the square root of the cell area ($A$):

$$p = P/\sqrt{A}$$

The corrected shape index $p_{\mathrm{corr}}$ accounts for packing disorder, as previously described (4). The cell shape alignment index $Q$ was

determined by triangulating the centers of all cells and finding the area-weighted average of the triangle alignment tensors, as previously described (7). Calculations were performed in MATLAB, unless otherwise noted. The time point $t = 0$ corresponds to the onset of tissue elongation.

## RESULTS

To explore how cell packings and tissue mechanics contribute to tissue flows at a local level, we determined the geometric configurations of cells in the germband and locally quantified these configurations. To visualize cell outlines, we used existing *Drosophila* lines expressing gap43-mcherry to tag cell membranes and then imaged the germband of developing embryos by confocal microscopy. To segment the tissue and extract the cell membranes network, we developed a custom MATLAB-based code to trace fluorescence intensity as described in Methods.

First, we analyzed the cell shape index $p$ and the cell shape alignment index $Q$, which have previously been reported to predict the solid-fluid behavior of the germband when analyzed at the tissue-level. To study these metrics at the local level, the cell shape index was calculated for each individual cell, and the shape alignment index was calculated for each cell and a corona of one cell neighbor outward. To visualize the local patterns of cell packings and inferred tissue mechanics, we color mapped the corrected shape index (Fig. 2A) and shape alignment index (Fig. 2B) for each cell. We find that both parameters vary spatially and temporally across the tissue, suggesting that spatially varying tissue mechanics might correlate with underlying protein localization or gene expression patterns.

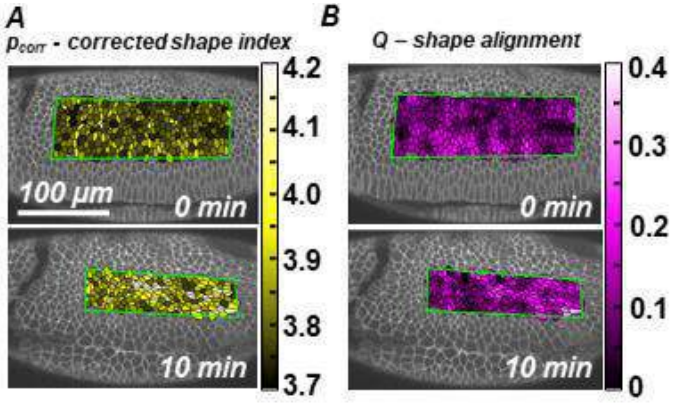

**Figure 2. Spatiotemporal variation of cell packings as a readout of local tissue mechanics in the germband.** To infer local tissue mechanics in the germband, we mapped the local corrected cell shape index $p_{corr}$ (A) and cell shape alignment $Q$ (B) in the ventrolateral region of the germband. Here, we show cell packings at 0 min and 10 min.

Next, we inferred the local solid-fluid tissue mechanical properties using a recently described anisotropic vertex model that predicts whether a tissue will behave as a solid (finite energy barriers to cell rearrangement) or a fluid (vanishing rearrangement energy barriers) (4). Within this framework, two metrics of cell packings in the tissue, $p$ and $Q$, predict the mechanical behavior of the tissue. This approach has been used successfully to predict the onset of rapid cell rearrangements and tissue flow in the germband (4). Above the predicted solid-fluid transition line in the $p$-$Q$ parameter space, there are vanishing energy barriers to cell rearrangement and fluid-like behavior, and below the transition line there are high energy barriers and solid-like behavior (Fig. 3A). We analyzed the trajectory of the germband in the $p$-$Q$ space over time, and found that at the whole tissue level, the germband becomes more fluid-like during axis elongation, consistent with previous reports (4). As a metric for local tissue mechanical behavior and rearrangement energy barriers, we measured the distance from the solid-fluid transition line in $p$-$Q$ space for each cell based on the local $p$ and $Q$ values at each time point. To visualize these data, we color-mapped at cell resolution the distance from the transition line (Fig. 3B). Notably, we observe spatial heterogeneities in this metric that also vary over time (Fig. 3B). This suggests that the mechanical properties of the tissue are spatially heterogeneous and that these spatial patterns of mechanics evolve over time as the germband transitions from solid-like to fluid-like during this developmental process.

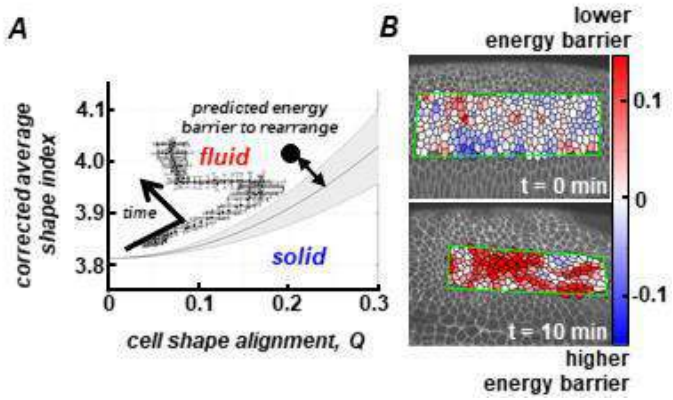

**Figure 3. Spatiotemporal patterns of predicted solid-fluid tissue mechanical properties and energy barriers to cell rearrangements.** As a metric for solid-fluid tissue mechanical behavior, we analyzed the distance from the predicted solid-fluid transition line in $p$-$Q$ space in the vertex model framework, with more fluid-like behavior associated with low energy barriers to rearrangement and more solid-like behavior associated with high energy barriers to rearrangement. (A) Tissue-scale behavior of the germband cell packings over time. (B) Local behavior of cell packings at t = 0 and 10 min reveals spatial and temporal patterns of tissue structure and predicted mechanical behavior.

## DISCUSSION

In this paper, we analyzed local cell packings in the germband epithelium and found that these packings are heterogeneous and evolve over time during axis elongation. In future work, we will connect these local cell packings to tissue mechanics and analyze how these spatial patterns evolve over time. Furthermore, we will correlate local tissue mechanics with cell rearrangement events and determine the influence of each packing parameter. Finally, we will connect spatiotemporal tissue mechanics to the underlying myosin II localization patterns and gene expression patterns in the developing embryo.

# MECHANO-ADAPTATION IN MICROPATTERNED MDCK TISSUES

**Bernard L. Cook (1), Patrick W. Alford (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

Many live tissues sense and respond to their mechanical state by changing form and function, or mechano-adapting. Mechano-adaptation may result in adaptive changes (e.g., an increase in muscle mass following routine weightlifting) or maladaptive changes (e.g., left ventricular hypertrophy following hypertension) in mature tissues. Further, mechano-adaptation helps sculpt embryonic tissues during morphogenesis. Because mechano-adaptation is prevalent in a variety of tissue remodeling contexts, it is important to develop experimental and computational tools to characterize this process.

Previously, we used our *in vitro* Cellular Microbiaxial Stretching (CμBS) assay to demonstrate that mechano-adaptation in an isolated cell depends on cellular architecture, which was captured by a continuum-based growth law [1]. However, mechano-adaptation in tissues is inherently a multicellular process. In addition to mechano-adaptive behaviors observed in a single cell, like cytoskeletal remodeling, mechano-adaptation in multicellular tissues can manifest through changes in proliferation and cell-cell contacts, among other behaviors. Here, we extend our work in single cells by using CμBS to experimentally characterize mechano-adaptation in 2D tissues comprised of micropatterned Madin Darby canine kidney (MDCK) cells and find that mechano-adaptation depends on cellular architecture and proliferation. Ultimately, this work will yield an experimental and computational framework that can be used to study mechano-adaptation *in vitro* in more specific contexts, such as embryonic heart looping.

## METHODS

**Stretching device.** The CμBS device [2] consists of a silicone membrane secured between metal clamps fastened to linear actuators. Bead-doped polyacrylamide gels are chemically bonded to the membrane, onto which cells are micropatterned. The device is fixed above an inverted microscope and housed within a chamber maintained at physiological conditions. The linear actuators are used to precisely stretch micropatterned cells, while the microscope is used to quantify cell-generated forces, architecture, and proliferation (Fig 1A, B).

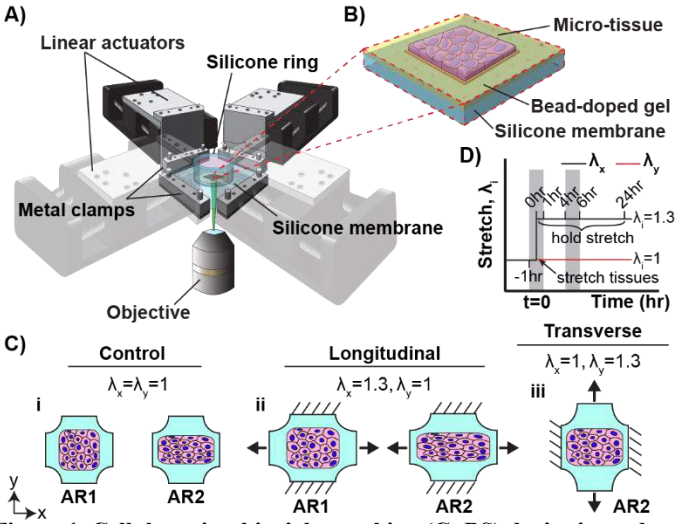

**Figure 1. Cellular microbiaxial stretching (CμBS) device is used to assess tissue mechano-adaptation. A) CμBS device. B) MDCK tissue patterned onto bead-doped gel bonded to the CμBS membrane. C) Stretching configurations. D) Stretching protocol. Data is collected between times highlighted by grey boxes.**

**Micropatterning.** For all experiments, MDCKs were micropatterned into aspect ratio 1 (AR1) or 2 (AR2) tissues (8000 $\mu m^2$) on CμBS substrates and cultured in cell growth medium.

**Stretching.** Tissues were uniaxially strained to 30% (applied stretch ratio $\lambda_i$=1.3) at 2%/s and held for 24 hrs (Fig 1C, D). To characterize tissue anisotropy, AR2 tissues were strained longitudinally

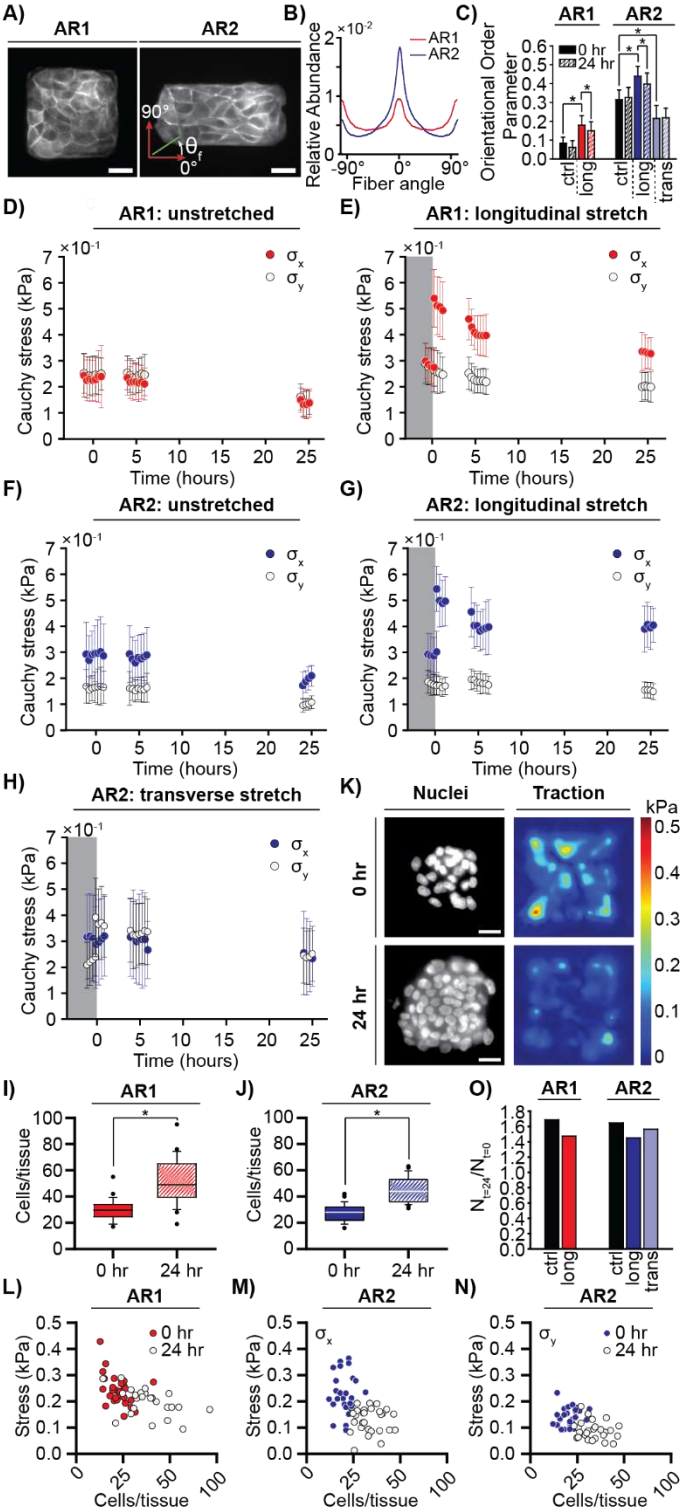

**Figure 2. Experimental measurements of mechano-adaptation. A) Tissues stained for F-actin. B) Probability density function of fiber alignment measured from tissues like those in (A). C) OOP of fiber alignment. D-H) Tissue stress behavior in mechano-adaptation experiment. In (E), (G), and (H), grey box highlights data taken before stretch. I-J) Cell density and tractions (K) over time in unstretched tissues. L-N) Tissue stress vs. cell density in unstretched tissues. O) Change in cell density. Scale: 40 μm.**

($\lambda_x$=1.3, $\lambda_y$=1) or transversely ($\lambda_x$=1, $\lambda_y$=1.3). Stresses in unstretched ($\lambda_x$=1, $\lambda_y$=1) tissues were assessed as a control (Fig 1C).

For stress experiments, fiducial bead images were captured to quantify tissue-induced bead displacements used to calculate tissue traction stress. For architecture experiments, MDCKs were stained with phalloidin (F-actin) and DAPI (nuclei) using immunocytochemistry.

**Cell stress and structure.** Midplane Cauchy stresses were calculated from tissue traction stresses and tissue geometry [1]. A ridge detection algorithm was applied to images of tissues stained for F-actin to quantify architecture alignment. Alignment was quantified with an orientational order parameter (OOP), which measurements relative alignment on a scale of 0 (unaligned) to 1 (perfectly aligned).

**Cell density.** Cell density was measured by counting nuclei in stained tissues using a custom MATLAB program. To characterize if cell density correlated with tissue stress, unstretched MDCKs were stained with Hoechst 33342 and traction stresses assessed simultaneously to measure nuclei per tissue and tissue stress, respectively. To characterize if changes in density depended on tissue shape or stretch, relative change in density for each stretch-shape condition was taken as $N|_{t=24}/N|_{t=0}$, where $N|_{t=24}$ and $N_{t=0}$ are mean cell densities at 24 and 0 hrs post-stretch for a given condition, respectively.

**Stats.** A one-way analysis of variance (ANOVA) was applied to OOP and cell density measurements to determine pairwise significance between groups. Significance was taken at $p < 0.05$.

## RESULTS

Without stretch, F-actin fibers in AR2 tissues were more aligned than in AR1 tissues (Fig 2A-B). Over time, this relationship was retained because the cytoskeleton did not significantly reorganize (Fig 2C). Following stretch, F-actin became more aligned and reorganized over time in tissues stretched longitudinally (Fig 2C). In AR2 tissues stretched transversely, F-actin became less aligned and did not reorganize, demonstrating an anisotropic mechanical response (Fig 2C).

In stretched tissues, stress increased in the direction of stretch and slowly decreased over time (Fig 2E, G, H), demonstrating an adaptation to stretch. However, it was not clear how tissues adapted to stretch. Stress patterns in unstretched tissues demonstrated that stress evolved without applied loading (Fig 2D, F), which was suspected to result from proliferation. We then sought to characterize tissue proliferation, its influence on stress behavior, and whether this was mechano-sensitive.

Without stretch, tissues experienced a significant increase in cell number that was consistent across tissue shapes (Fig 2I, J, O). Increase in cell number correlated with a decrease in tissue stress (Fig 2L-N). Interestingly, proliferation appeared to depend on applied loading inversely from what was expected: increased stress resulted in decreased proliferation in tissues of each shape (Fig 2O).

## DISCUSSION

Here, we used CμBS to demonstrate that mechano-adaptation in micropatterned tissues depends on architecture and proliferation. Interestingly, we found that the rate of proliferation decreases when tissues are stretched, which contradicts previous findings [3]. Further work will be performed to elucidate whether constraints from micropatterning or the timescale of the experiment yield these discrepancies. Moving forward, we seek to develop a continuum model that captures mechano-adaptation in these tissues. The experimental work here is a step towards developing this model. Together, these experiments and model will provide a framework for characterizing mechano-adaptation in specific contexts such as in the developing heart.

# THE MECHANICS OF NETWORKED, TYPE II COLLAGEN FIBERS FROM CARTILAGE

**Phoebe Szarek (1), David M. Pierce (1,2)**

(1) Department of Biomedical Engineering, University of Connecticut, Storrs, CT, USA
(2) Department of Mechanical Engineering, University of Connecticut, Storrs, CT, USA

## INTRODUCTION

Collagen, a key load-bearing molecule essential to the function of most soft tissues and load-bearing organs, is the most abundant protein in the mammalian world [1]. Understanding the mechanics of collagen is thus critical to understanding the biomechanics of soft tissues and organs. Type I collagen is the most abundant collagen in the human body (e.g. in dermis, tendons, and arteries), so researchers have extensively characterized the mechanics of type I collagen [2]. Type II collagen forms networks and is the second most abundant type in the human body (e.g. in hyaline cartilage and intervertebral discs), but *no data exist* on the tensile mechanical response of individual type II collagen fibers. Experimental testing of individual fibers of type II collagen poses many difficulties due to their small size (Ø 20-200 nm) and due to the complexity of *in vitro* fibrillogenesis [3,4].

We aim to quantify the mechanics of individual type II collagen fibers via inverse analyses of fiber networks with measurable bulk responses and fiber arrangements. Specifically, we aim to 1) identify an appropriate constitutive model for the stress-strain response of type II collagen fibers, 2) identify an appropriate failure model (criteria) for individual type II collagen fibers, and 3) determine the parameters for these models by leveraging our diverse experimental data.

## METHODS

*Specimen Preparation.* Following established protocol, we extracted 10×20 mm full-thickness specimens from bovine patella-femoral grooves (< 36 m old) [5]. We microtomed 140 or 160 µm slices from the superficial zones (SZ) and punched out dumbbell-shaped specimens (gauge width = 3 mm, length = 4 mm). We incubated these in phosphate buffered saline (PBS) with 0.5 mg/mL trypsin for 18 hrs at 37 °C to remove >95% of the proteoglycan (PG), then rinsed.

*Uniaxial Tension Testing.* We performed uniaxial tension tests using a custom microtensile device (20 N capacity with 0.3 mN resolution, 12.5 mm range with 2.5 µm resolution) at a displacement rate of 300 or 600 µm/min until failure in PBS at room temperature [5].

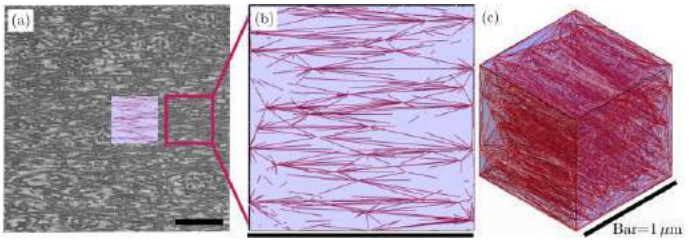

**Figure 1. Representative Statistically-Equivalent Representative Volume Element (SERVE) for modeling networks of collagen fibers. a) Transmission electron microscope image of collagen within the superficial zone of human cartilage. b) Cross section of a fiber-network SERVE model. c) RVE with statistically equivalent orientation, dispersion, and volume fraction of collagen fibers [7].**

*Statistically-Equivalent Representative Volume Elements.* We modeled a 1 µm$^3$ cube, i.e. a statistically-equivalent representative volume element (SERVE), at the center of the gauge region of the tensile specimen using FEBio (University of Utah) [6]. We used data on the orientation, diameter, and volume fraction of type II collagen fibers within the SZ (measured via Transmission Electron Microscope images [7]) to create statistically-equivalent networks of fibers within multiple SERVEs (Fig. 1). We modeled fibers as springs (selecting from five different constitutive models) and we modeled the PG-depleted interfibrillar space using a biphasic neo-Hookean model ($Gi = E_{\mathrm{iso}}/3$).

*Constitutive Models.* We used five different constitutive models for individual fibers: 1) linear, 2) exponential [8,9], 3) bilinear (i.e. toe and linear regions [10]), 4) exponential-linear, and 5) linear-exponential. We tested each of these models by fitting the stress-strain responses of networked collagen to data using inverse finite element modeling. Leveraging each of these constitutive models we fit the responses of the each SERVE to measured data. We assessed the model fits using both the coefficient of determination $R^2$ and number of parameters required.

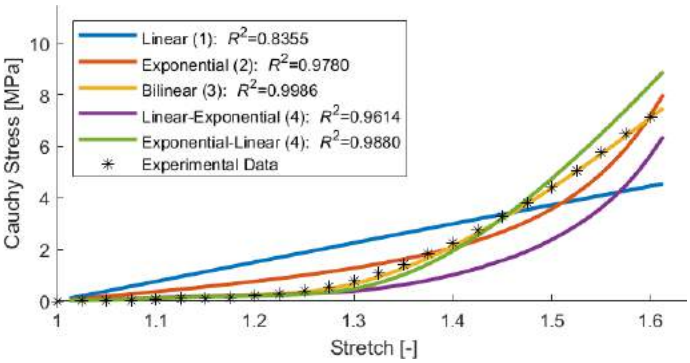

**Figure 2. Representative best fits of five constitutive models. The bilinear model provided the best fit to the experimental data even compared against models with more parameters (in parentheses).**

*Failure Models.* To model failure of individual type II collagen fibers we extended the constitutive models to include failure, and tested two failure criteria: 1) critical stress and 2) critical stretch. In the first failure criterion, e.g. if the stress exceeds a critical value the fiber is removed from the network. We rerun each time step of the simulation up to ten times to redistribute the total load, remove fibers, and stabilize the results. We assessed both failure models within SERVEs to establish which better predicted the network responses measured experimentally.

*Data Analyses.* We performed inverse fitting of the experimental data ($n$ = 10) using the parameter optimization module in FEBio. We fit the first 10% of the experimental data to establish the stiffness (shear modulus) of the isotropic matrix. We then fit the stress-strain data up to bulk softening (i.e. decrease in slope) using the different SERVEs with fibers ($n$ = 3) to fit the parameters of the individual fiber response. Finally, we fit the failure criteria using the complete data to rupture.

*Statistical Analyses.* Grouping all the data we used $t$-tests to discard SERVEs with responses significantly different from all others. We used two-way ANOVAs to assess the variance due to both experiments and network models (SERVEs). We used $p$ = 0.05 as our level of significance and reported median and interquartile range (M + IQR).

## RESULTS

*Constitutive Models.* Figure 2 shows a representative network response and the best-fits of the models. We found that a bilinear model

$$\sigma = \begin{cases} E_1(\lambda - 1) & \text{if } \lambda < \lambda_t \\ E_2(\lambda - \lambda_t) + E_1(\lambda_t - 1) & \text{if } \lambda \geq \lambda_t \end{cases}, \qquad (1)$$

where $E_1 < E_2$ are the slopes of the bilinear fiber model which transition at the stretch $\lambda_t$, provided the simplest and best-fit for the response of single fibers. Table 1 shows the resulting parameters after fitting all of the experimental data with the bilinear model. We found that responses from the SERVEs were statistically equivalent and had no effect on the model parameters. The fiber parameter most affected by the SERVEs, albeit not significantly, was the transition stretch.

**Table 1. Bi-linear Model Parameters for Type II Collagen Fibers.**

| | $E_{\text{iso}}$ [MPa] | $E_1$ [MPa] | $E_2$ [MPa] | $\lambda_t$ [-] |
|---|---|---|---|---|
| M | 1.015 | 0.9526 | 23.27 | 1.138 |
| IQR | 0.8100 | 0.9558 | 4.919 | 0.0649 |

*Failure Models.* Figure 3 shows the effects of adding mechanical criteria to model individual fiber failures within the networked collagen. Failure based on critical fiber stress more accurately captured the bulk network responses measured experimentally versus critical fiber stretch.

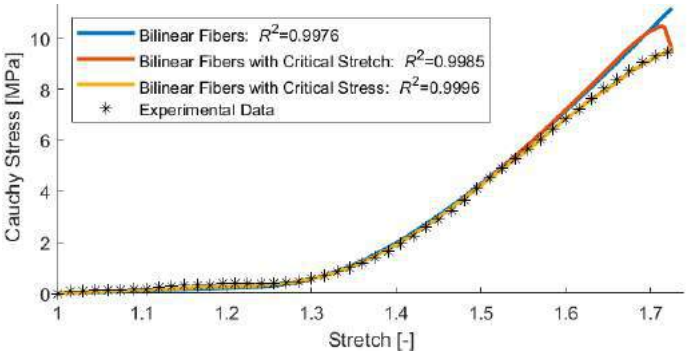

**Figure 3. Representative best fits including fiber failure. Maximum fiber stress more accurately captured the bulk network response measured experimentally versus maximum fiber stretch.**

## DISCUSSION

We propose a new fitted model for networked, type II collagen fibers within cartilage, and potentially within other soft tissues containing type II collagen. The bilinear model for a single fiber is comparable to the toe and linear regions seen in highly aligned collagenous structures. We model each fiber with zero-order continuity, but obtain a first-order continuous network response due to progressive recruitment of fibers. While we tested and modeled tension to rupture, physiological stretches are often less extreme, possibly explaining the usability of the common exponential model. Our model parameters also indicate that type II collagen may not be as stiff as type I collagen, cf. [2]; differences in testing methods may also explain the discrepancies.

Introducing fiber failure into our constitutive model allowed fitting of the complete experimental data and a better estimation of fiber and network responses at large strains. In our experimental data, we identified cases where networks abruptly failed making fitting of individual fiber failures difficult. Fiber failure with a stress-based criterion better represented network failure with softening but a stretch-based failure may better represent catastrophic network failure.

Limitations of this work include difficulty in decoupling the isotropic stiffness and the low-strain stiffness of the collagen fibers. Unfortunately, we are unable to run simulations with very low stiffness PG (e.g. the networks collapse) or past complete rupture (indeterminate solution). While it is primarily type II, collagen within cartilage is also heterotypic with small quantities of other types of collagen.

We introduce a new mechanical model for type II collagen fibers, a key load-bearing molecule in the human body. Our findings may serve to improve current modeling approaches and introduce opportunities for multiscale modeling. Including a failure criterion for individual fibers results in a better fit to experimental (data for networks tested to failure), a more accurate fiber response for physiological models, and the possibility to model softening under cyclic loading.

## INTRODUCTION

The increasing availability of large functional and structural brain connectivity datasets has led to a better understanding of the healthy and the diseased brain. One example is the attempt to correlate the propagation of toxic proteins with cerebral atrophy and cognitive decline associated with neurodegenerative diseases.

When treating the brain as a discrete network of nodes, which represent individual brain regions, and their connections, representing axonal white matter tracts, we obtain a simplified network model to simulate biomarker spread using graph theory. At the core of these models is the brain connectome, or the matrix representing the brain connectivity network, and a reaction-diffusion equation that describes the production and spreading of any respective biomarker [1,2]. Previous studies have shown that this connectome is organized according to a small-world topology [3], i.e., many specialized highly interconnected communities [4] and a highly effective level of integration of information between these communities throughout the brain. Some nodes are critical to this integration and segregation, which are called hubs. Hub nodes generally have a high number of connections (degree centrality) or a high level of betweenness centrality [5]. Meta-analysis on different brain disorders suggests grey matter lesions concentrate in brain network hubs regardless of the disorder [6]. It has also been shown that brain regions with strong anatomical connectivity are at increased risk of high toxic protein exposure [3]. Despite the good qualitative agreement between these models and data from pathology, however, the fact that each study uses a different approach to determine the adjacency matrix that represents their brain connectome is making direct comparisons between studies very challenging.

Here, we selected 100 subjects from the Human Connectome Project (HCP) [7] and quantify the differences between commonly used adjacency matrices by means of critical graph theory-based properties and results from biomarker progression simulations. We also proposed our anatomically corrected weighted streamline adjacency matrix, which is based on SIFT2 correction of diffusion MRI tractography [8], and compared it to the currently used connectomes. Streamlines are defined as pathways between two regions in the brain that assumes to follow the trajectory of biological axon fibers. SIFT2 is a widely used method in the structural connectomics community to reduce the biases caused by the reconstruction of the streamlines, which causes them not to accurately represent the density of underlying fiber bundles [8]. Using this method a cross-sectional area multiplier is applied to each streamline, which permits the use of the resulting weighted streamline count (S) as a more valid biological marker than the original non-weighted streamline count (N) of how strong each fiber bundle connects the two brain regions at its ends [8].

## METHODS

Prion-like diffusion of toxic protein within the brain network is well described by the following reaction-diffusion model:

$$\frac{dc_I}{dt} = \mathrm{k}\sum_{J=1}^{N} L_{IJ}c_J + \alpha c_I[1-c_I], \quad (1)$$

where $c_I$ is the nodal biomarker level, parameter k controls diffusivity, and parameter $\alpha$ characterizes the growth rate, i.e., the conversion rate of healthy into toxic protein. The graph Laplacian in (1) is defined as:

$$L_{IJ} = D_{IJ} - A_{IJ} \text{ with } D_{IJ} = \mathrm{diag}\sum_{J=1, I\neq J}^{N} A_{IJ}\,. \quad (2)$$

To determine adjacency matrix A, we used preprocessed connectome data from 100 healthy subjects in the HCP [7]. For each subject, we compute the four commonly used forms of the adjacency matrix and differentiate between matrices defined by (1) the number of streamlines between regions over the average length of streamlines (N/L), (2) weighted streamline count over the average length of streamlines (S/L) [8], as well as both number of streamlines and weighted streamlines count, divided by the average length of

streamlines squared ($N/L^2$ and $S/L^2$, respectively). Borrowing from basic graph theory, we calculated the following well-established graph measures to determine network differences for our four adjacency matrices: degree centrality, betweenness centrality [5], and global efficiency [9]. These measures quantify localized connectivity, between community connectivity, and efficiency of distant information transfer, respectively.

## RESULTS

Figure 1 shows the degree and betweenness centrality measures. Superior frontal, precentral, superior parietal, precuneus, postcentral brain regions appear to be critical hubs across all subjects. We also observe that hub location is mostly unaffected by the denominator of the adjacency matrices, i.e., division of N and S by L or $L^2$.

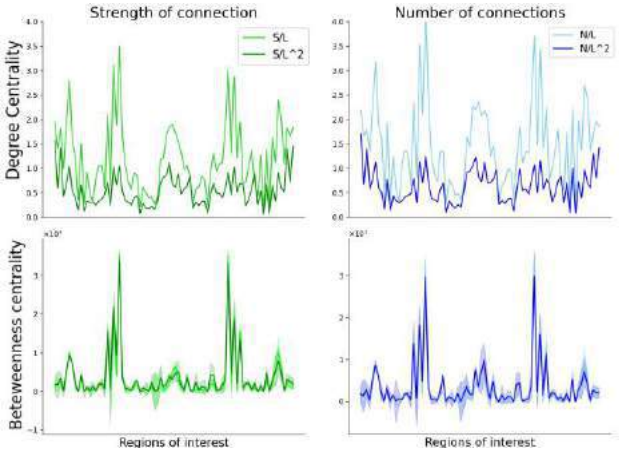

**Figure 1: Hubs of degree centrality (provincial hubs) and betweenness centrality (connector hubs) in our four connectomes.**

Figure 2 shows the global efficiency for our adjacency matrices. The value of global efficiency accounts for the network capacity for parallel information transfer. We observe that the values for the number of streamlines are larger than the values for the weighted number of streamlines and also by dividing both measures to the higher orders of length the value of the global efficiency reduces.

Figure 3 illustrates the change in the mean of one hundred biomarker curves with different graph construction methods in the A) precentral gyrus, one of the aforementioned brain hubs and a symptom node for loss of motor control in Alzheimer's disease and B) in all the other identified hubs of the brain network. For this simulation the misfolded proteins ($c_0$) were seeded of in the entorhinal cortex nodes of both hemispheres. The weighted number of streamlines-based simulations shifts the biomarker wavefront to the left in comparison to the number of streamline-based graphs. It can also be seen that the division by higher magnitudes of length shifts the curve to the right.

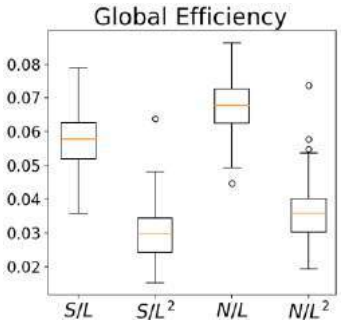

**Figure 2: Global efficiency of our four different adjacencies. This measure shows transmissibility between nodes.**

## DISCUSSION

Here we studied the location of brain hubs and the graph-theoretical measurements of two widely used brain connectomes and two proposed anatomically corrected connectomes. We saw that the hub regions were unaffected by the different methods of adjacency matrix definition that we used here. And the determined hub locations are consistent with previous works on studying structural brain hubs [5].

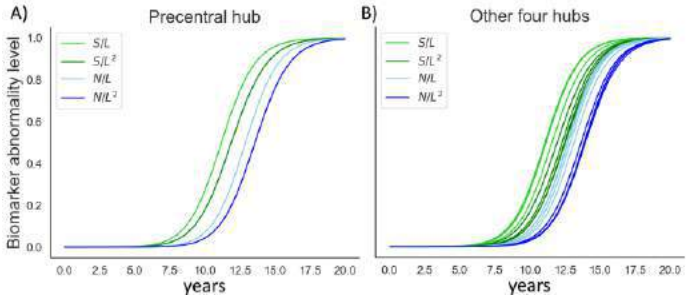

**Figure 3: Pattern of biomarker concentration change in A) precentral cortex and B) in Superior frontal, superior parietal, precuneus, postcentral in the different connectomes**

In Figure 2, we could see that using S/L results in lower global efficiency than N/L. This is due to the fact that the SIFT2 algorithm weighted down the streamlines that represent the major fiber bundles in the brain; these bundles are the main factor deciding global efficiency and are usually over-represented by tractography algorithms [10].

We could also see that the method of adjacency matrix calculation marginally impacted the biomarker progression pattern. The only major difference was that abnormality level curves are shifted horizontally. The slope of the curves and the time to reach the full toxicity are only marginally affected.

Also, according to Figure 2, based on the values of the global efficiency we would expect N/L to lead to quicker spread of toxic proteins than S/L, but the opposite is observed in Figure 3. This is due to the fact that global efficiency is not a direct representative of the efficiency in the neighborhood of a specific region, but rather a general representation of transmissibility of the whole connectome.

As a recommendation for future studies in the field, we suggest using the weighted number of streamlines. The correction for cross-sectional area used to define the weighted streamline count adds an additional step in our reconstruction process. It has been proven to be more anatomically informed, however, and therefore increases agreement between our disease progression simulations based on these connectomes and underlying pathology of the disease observed from patient data.

# A CONSTITUTIVE-BASED DEEP LEARNING MODEL FOR THE IDENTIFICATION OF ACTIVE CONTRACTION PROPERTIES IN THE VENTRICULAR MYOCARDIUM

**Igor A. P. Nobrega, Wenbin Mao**

Department of Mechanical Engineering
University of South Florida
Tampa, FL, USA

## INTRODUCTION

Cardiovascular disorders are the primary cause of death, comprising for more than 40% of all human fatalities [1]. Engineering, computer science, and data mining advancements have paved the way for new insights of soft tissue mechanical properties and their physiological responses. The examination of elastic properties of soft biological tissue [2] can uncover early indicators of illness or physiological complications [2] as these are entangled with its internal microstructure [3], which regulates its macroscopic behavior and mechanical functions. Moreover, to better comprehend the mechanical activities of the myocardial structure, accurate representations of myocardial structure utilizing constitutive models are essential.

Although various models have been constructed to depict both passive and active contraction of myocardial tissues, most of them are unsuitable outside the research setting; they often need substantial computing resources and time, limiting their use in clinical applications. Thus, the use of artificial intelligence and machine learning offers significant benefits over conventional techniques.

The primary goal of this study was to develop a constitutive-based deep learning method for evaluating and predicting the behavior of an active contraction model of the left ventricular myocardium during a cardiac cycle by autonomously selecting the best-fitting material parameters from patient-specific clinical conditions.

## METHODS

The active and passive reactions of myocardium are coupled as an additive decomposition of the Cauchy stress tensor $\sigma = i\sigma_p + \sigma_a$. In this definition, $\sigma_p$ identifies the passive stress component, which describes the myocardium's reaction when the muscle is not active. $\sigma_a$ defines the component of active stress that is induced by electrical stimulation of the myocardial tissue [4].

The passive model was based on Holzapfel-Ogden's extensively recognized depiction of the passive myocardial tissue [5]. Given that the ventricular wall is a multilayered structure with transmural variation in the direction of its myocytes, the modeling of fiber distribution throughout layers of the myocardium is a fundamental benefit of the chosen model. The passive stress function is composed of eight material parameters a, b, $a_f$, $a_s$, $b_f$, $b_s$, $a_{fs}$ and $b_{fs}$, and is given as follows:

$$\sigma_p\, i = \mathrm{a} e^{\mathrm{b}(\mathrm{I}_1 i - i3)}\mathbf{B} - i\rho \mathrm{I} + 2\mathrm{a}_f\left(\mathrm{I}_{4f} - 1\right)e^{\mathrm{b}_f\left(\mathrm{I}_{4f} i - i1\right)^2}\boldsymbol{f}\otimes\boldsymbol{f} + i2\mathrm{a}_s(\mathrm{I}_{4s} - 1)e^{\mathrm{b}_s(\mathrm{I}_{4s} i - i1)^2}\boldsymbol{s}\otimes\boldsymbol{s} + \mathrm{a}_{fs}\mathrm{I}_{8fs}e^{b_{fs}I_{8fs}^2}(\boldsymbol{f}\otimes\boldsymbol{s} + \boldsymbol{s}\otimes\boldsymbol{f}) \quad (1)$$

The active model adopted was proposed by Pezzuto et al. [4]. This model is advantageous due to its simple yet effective formulation. The active model considers the multiplicative decomposition of the deformation gradient by adding just one new parameter, $\gamma$, preserving the ellipticity of the stress tensor and yielding a "active strain" approach [4]. The model is defined by:

$$\sigma_a\, i = i(1-\gamma)i\boldsymbol{f}_0\otimes\boldsymbol{f}_0\, i + i\frac{1}{1-\gamma}(\mathbf{I}i - i\boldsymbol{f}_0\otimes\boldsymbol{f}_0) \quad (2)$$

, where $\boldsymbol{f}_0$ denotes the unit vector of fiber axis. The constitutive model was implemented in the open-source Finite Element (FE) solver FEBio [6], and was validated by comparing with the analytical solutions of a solid cube under simple shear and biaxial deformations [4][5]. In addition, we utilized two principal geometries of the left ventricle: an idealized truncated ellipsoid (Fig 1a) and a patient-specific one (Fig 1c). Mesh independence was performed for each geometry and the best configuration was used for all FEA simulations. Furthermore, to calculate the fiber orientation for each element, we adopted an rule-based reconstruction algorithm using Poisson interpolation proposed by Wong & Kuhl [7], which is commonly used in the field when clinical DT-MRI data is unavailable. As can be seen in figures 1b and 1d, the muscle fiber orientations properly change with position through the

wall: from a positive angle ($\alpha_{epi}$) in the sub-epicardial region to nearly 0◦ in the mid-wall to a negative angle ($\alpha_{endo}$) in the sub-endocardial region.

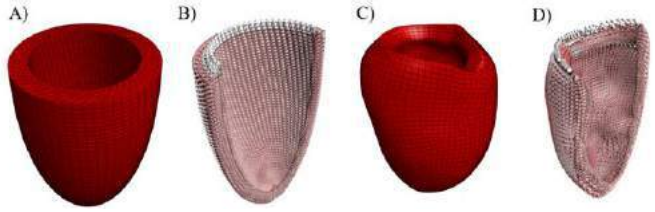

**Figure 1: Left ventricular myocardium meshes and fiber orientations: (a) and (b) idealized, and (c) and (d) patient specific.**

Our deep learning (DL) model (Fig. 2) consisted of two functional modules: (a) a convolution network (CNN) devoted to extracting features from a PV loop and clinical metrics to estimate the best set of fiber orientations (FO); and (b) a recurrent network (RNN) designed to estimate the γ waveform for an entire cardiac cycle. The inputs of the model are 5 clinical metrics: longitudinal and radial shortening, wall thickening, longitudinal and circumferential strains, and a PV loop; while the outputs are: $\alpha_{epi}$ and $\alpha_{endo}$ orientations and γ waveform.

How to generate adequate training data for the model? The pressure-volume (PV) loop data was obtained through a lumped-parameter simulator representing a wide spectrum of physiological and pathological waveforms. Other training data were generated by two pretrained neural network regressors: GR model and GC model to obtain the **γ** value and clinical metrics, respectively (dataset generator in Fig. 2). The training data for the regressors were obtained from FE simulations with variant γ value (0 ~ 0.3) and fiber orientations (from -40 to -80 degrees for $\alpha_{endo}$ and 40 to 80 degrees for $\alpha_{epi}$) using linearly increasing pressure loads from 0 to 20 kPa. We recorded the corresponding cavity volume and geometric characteristics from the deformed myocardium for each pressure value. Because the predictions of the regressors are very accurate, we treat the generated synthetic data from them as the gold standard for the final model.

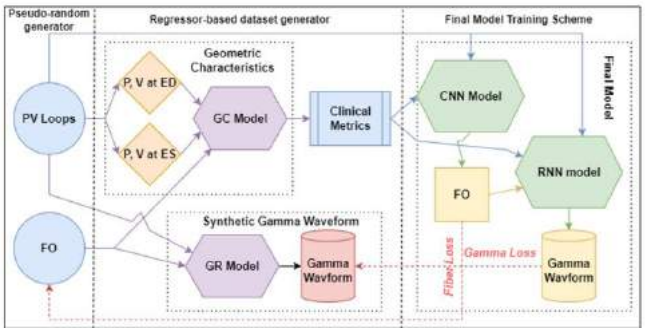

**Figure 2: Deep learning approach schematics.**

This procedure reduced the number of FE simulations required to obtain a suitable dataset for our final model. As such, our method used less than 1100 FE simulations to provide over 220,000 synthetic datasets. The traditional method of extracting training data straight from FE simulations would take significantly more time and memory.

## RESULTS

Each regressor was independently trained and evaluated to ensure high accuracy on their respective tasks. The final Mean Squared Error (MSE) for the GR and GC model was 1.38e-5 and 4.38e-6, respectively. Uniform accuracy distribution was observed for the entire testing dataset. Lastly, the final DL model reached an overall 1.583e-6 MSE and was observed to generate smooth **γ** waveforms.

To assess the final model's efficiency, we evaluated the accuracy of clinical metrics and volume waveforms obtained from the FE model with the predicted fiber orientation and gamma waveform parameters by the DL model. We first generated 50 sets of PV loops and fiber orientations. They were utilized to produce the clinical metrics by our GC regressor as input, along with the corresponding PV loop for the final DL model. With the predicted fiber orientation and gamma waveform, we conducted these FE simulations, and the simulation-obtained volumetric waveforms and clinical metrics were compared to the original inputs (Fig. 3). The predicted γ waveform is highest around peak systole, representing the strongest active contraction; followed by a gradual decrease to zero at the end of diastole. The volume waveform calculated from FE closely matches the input value. The relative error between these curves is less than 0.5%. Additionally, the mean absolute error for all clinical metrics was 0.7%.

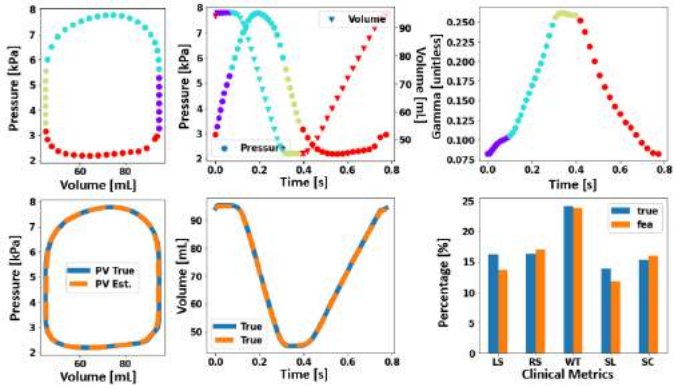

**Figure 3: A representative case for the comparison of FE simulation and the DL model prediction. First row: PV loop as inputs of the DL model and the predicted gamma waveform. Second row: Comparison of true (inputs of the DL model) and FE simulated volume waveforms and clinical metrics.**

## DISCUSSION

We were able to accurately capture the mechanical response of the left ventricular myocardium using a few clinically relevant measures and a predetermined pressure-volume curve by designing a constitutive-based machine learning model. Our model exhibits great accuracy for a variety of pressure-volume curves and is applicable to both idealized and patient-specific left ventricle geometries. The combination of artificial intelligence with constitutive-based models enables the autonomous selection of challenging model parameters facilities their usage for patient-specific geometries.

# MECHANICAL AND STRUCTURAL CHANGES DUE TO TENDON OVERLOAD IN A RAT MODEL OF SYNERGIST ABLATION

**Ellen T. Bloom (1), Lily M. Lin (1), Justin Parreno (2), Karin Grävare Silbernagel (3), Dawn M. Elliott (1)**

(1) Biomedical Engineering, University Delaware, Newark, DE, USA
(2) Biological Sciences, University of Delaware, Newark, DE, USA
(3) Physical Therapy, University of Delaware, Newark, DE, USA

## INTRODUCTION

Altered loading in tendon can lead to tendinosis and tendinopathy, however the mechanisms for clinical tendon disorders are not well understood and progressive changes following altered loading remain undetected until pain or rupture occur. Perhaps the most common animal model to overload tendons uses treadmill running to induce tendinopathy by increasing loading and frequency [1]. A rodent model of synergist ablation (SynAb), which overloads the plantaris tendon without altering loading frequency by ablating the synergist Achilles tendon, was recently evaluated for tendon remodeling via histology and gene expression up to 4 weeks [2,3]. However, the mechanical and structural changes and long-term effects remain unknown. The objective of this study was to quantify the progressive changes due to overload in plantaris tendon area (using *in vivo* MRI), fibril microstructure, and mechanical behavior in the rat SynAb model. For fibril microstructure, we utilized serial block face scanning electron microscopy (SBF-SEM) to obtain 3D image stacks [4] and developed a machine learning algorithm to evaluate several thousand collagen fibrils. We hypothesize that the tendon and collagen fibrils will show remodeling (increased tendon cross-sectional area) and will be more disorganized (larger fibril diameters and lower fibril density) after overload compared to sham and intact controls. We also hypothesize that overload from SynAb will induce a decrease in mechanical properties.

## METHODS

Bilateral plantaris tendons of 7-month-old Long-Evans female rats were studied according to three groups: SynAb (synergist ablation, where the Achilles was excised to overload the plantaris), Sham, and Intact controls. 3D T1-weighted MR images were acquired of rat hind limbs in vivo on a 9.4T Bruker Biospec scanner before surgery, at 4 weeks (Sham and SynAb only), and at sacrifice at 8 weeks (n=8/group) and 12 weeks (n=2/group). MR images were segmented, and the plantaris tendon cross-sectional area (CSA) median value was calculated across all slices. SEM images of one tendon from each group was acquired along 30 µm of tendon length with 200 nm section thickness, resulting in over 150 slices along the length (FEI Apreo VolumeScope SEM, Thermo Fisher Scientific). Auto-segmentation of collagen fibrils was performed using a deep convolutional neural network (U-Net) run on a GPU node of a high-performance computing cluster [5]. The average fibril diameter, circularity, and fibril % area for each slice were calculated across all slices. Differences between groups were evaluated with a two-way repeated measures (MRI) or one-way (SEM) ANOVA and means compared with Tukey HSD post hoc ($p < 0.05$).

A separate set of 4- to 8-month-old Long-Evans male rats were used to quantify mechanical behavior at 8 weeks (n=2) and 16 weeks (n=2) after SynAb. Sham and intact controls were pooled as no difference was observed with either treatment or time (n=4). Testing used an established protocol on a custom uniaxial device. At the reference length a 0.1 N preload was measured, and each sample was preconditioned with 5 cycles to 5% grip strain. After cyclic ramps to 10, 20, and 30%, a ramp to failure was applied and used for analysis. Parameters quantified included transition point (end of toe region), inflection point (yield), and linear region modulus [6].

## RESULTS

MRI images were able to clearly define tendon structures (Fig 1A-B) and the void was filled with granulation tissue after Achilles resection (Fig 1B). The SynAb CSA was significantly larger than intact and sham at 8 weeks post-surgery (Fig 1C). The SynAb had a 30% larger CSA at 8-weeks post-surgery, while intact and sham CSA did not change over time. The U-Net convolutional neural network prediction successfully segmented the collagen fibrils throughout the image stack (Fig 2A-B). In total, the analysis auto-segmented 5,000-7,000 fibrils in each image stack. Thus ~750,000 fibril diameters were identified for each sample (ongoing efforts are registering fibrils tracks along the tendon length). The average fibril diameter for SynAb was 3% and 19%

larger than Sham and Intact, with Sham also larger than Intact (Fig 2C). The average collagen fibril circularity (with 1.0 portraying a perfect circle) for SynAb was 14% and 25% higher than Sham and Intact, with also Sham higher than Intact (Fig 2D). The fibril % area (e.g., fibril density) for SynAb was 7% and 23% lower than Sham and Intact, with Sham also lower than Intact (Fig 2E).

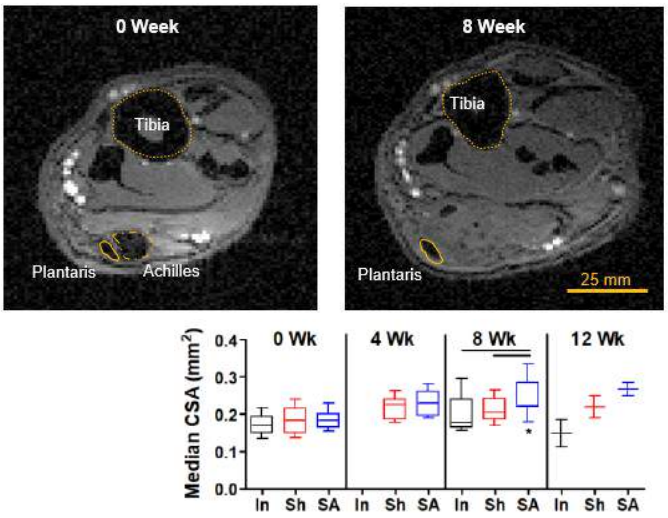

**Figure 1:** A-B) Representative MRI in SynAb at 0- and 8-weeks showing anatomy. C) Median (SD) CSA In=Intact, Sh=Sham, SA=SynAb. Line (between group) and * (over time) show p<0.05.

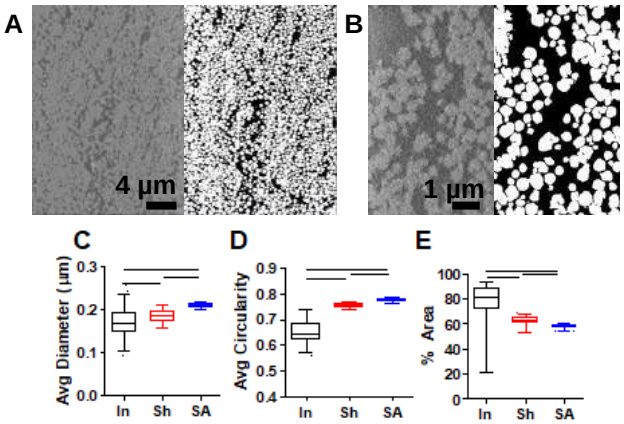

**Figure 2:** A-B) Representative SynAb SEM raw image and U-Net segmentations. C) Average diameter, D) average circularity, and E) fibril % area across image stacks. Lines show p<0.05.

Compared to control, SynAb modulus was lower at 8 weeks, but by 16 weeks returned toward control values (Fig 3A). The transition strain during the ramp to failure showed no differences between the groups (Fig 3B); however, the inflection point strain was higher for the SynAb 16-week samples (Fig 3C).

## DISCUSSION

This study demonstrated multiscale structural and mechanical changes in an animal model where the tendon was subjected to overload without increasing frequency. The SynAb model is a novel way to increase tendon loading to induce multiscale tendon remodeling without directly injuring the tendon. It is complementary to repetitive loading models that use treadmill running to alter tendon loading [1]. The geometry changes leading to larger diameters and more circular

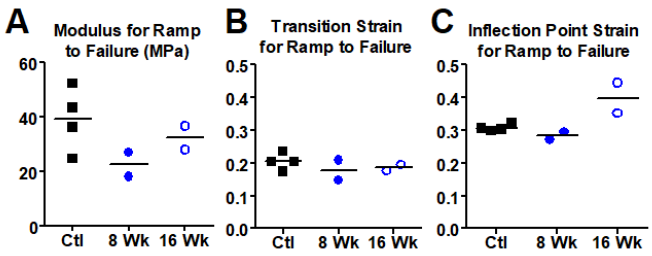

**Figure 3:** A) Modulus, B) transition strain, and C) inflection point strain from ramp to failure for control, 8-week, and 16-week SynAb.

collagen fibrils in the overloaded tendons suggests adaptation as the tendon attempts to increase its load-bearing capacity to meet the increased load demand. Decreased fibril density in the SynAb tendons may correspond to a degenerative response to the increased load. The SynAb tendons also showed a decrease in modulus compared to control, which indicates degeneration. However, the modulus for SynAb at 16 weeks was closer to control values, which may indicate positive adaptation by 16 weeks to meet the increased mechanical demand on the plantaris. Similarly, the high inflection point strain for the 16-week SynAb also suggests an adaptation to increase in load capacity for the tissue in the longer post-surgery time point. These possibly contradictory changes (increased CSA and fibril diameter vs. decreased fibril density and modulus) correspond to a transitory downturn in mechanical properties at 8 weeks followed by possible increase in tendon load capacity between 8 and 16 weeks, further illuminating the complex structural and mechanical changes that occur with altered tendon loading states.

This work shows machine learning can be successfully utilized to automatically segment large images sets of fibrils of dense collagenous tendon from SBF-SEM. The U-Net convolutional neural network was able to segment thousands of fibrils from the entire image stack spanning 30 µm. Following U-Net training, image stacks were fully segmented in ~15 minutes on a GPU node. Manual segmentation at a similar scale would take hundreds of hours. Further, the segmented diameters for the control fibrils are like those previously reported [7]. Previous investigations of tendon 3D volumes involved a much smaller number, ~50 fibrils [4]. In ongoing work, these comprehensive data of fibril geometry are being reconstructed along the length to investigate the 3D fibril structure. The success of these segmentations helps open a door to evaluating the complex 3D microstructure of collagen in tendon and other tissues.

Future work will add histological analyses, microscale mechanics, and increased sample numbers. In summary, the observed mix of changes following overload that includes possible early degeneration followed by later adaptation is intriguing and motivates next steps.

## INTRODUCTION

Upper limb loss is accompanied by loss of range of motion, loss of independence, financial burden, and other traumatic effects [1]. Smart prostheses, through the application of soft robotics, are devices that have the potential to fully restore function. They rely on the remaining, intact muscle groups to drive function. The ideal case is that they are capable of the range of motion of the extremities that they are replacing. At the very least, these devices must be able to restore the range of motion necessary for completing everyday tasks so that users can regain independence.

Unfortunately, current myoelectric smart devices have challenges that on average result in 30% of users abandoning them [2]. They are slow, uncomfortable, expensive ($60,000-$100,000), and rely heavily on a connection to the brain and body [3]. This dependence on connection accounts for long adjustment periods, malfunction, and the crossing of signals inputted to the device, which decreases their utility.

Therefore, there is a need for upper limb prostheses to be simpler, more intuitive, and function without complex input from the brain, while still providing necessary function to the user. To do this, inspiration can be drawn from an animal whose movements meet these criteria: the octopus.

The octopus is a muscular hydrostat which allows its arms to create unique movements and curvatures using nearly infinite degrees of freedom (DOFs). The octopus also has axial nerves in each of the arms that allow them to often move without the brain's input. They are even capable of completing some of the everyday activities that humans do, such as opening a jar or reaching and grasping for food. Existing motion data of octopus arms have been limited to largely 2D analysis. However, a smart prosthesis must be capable of 3D movements, which require more complex analysis.

Therefore, the goal of this work was to determine how to characterize 3D octopus movement data so that it can be used to influence an octopus arm-like prosthesis.

## METHODS

A four-camera underwater motion capture system was used to collect 3D movement data on amputated octopus arms, species *Octopus bimaculoides*. Five single retroreflective markers were attached to the skin of the amputated arm, and the arm was manually moved underwater to replicate octopus arm curvature (Figure 1). This involved moving the arm along a long, narrow elliptical path.

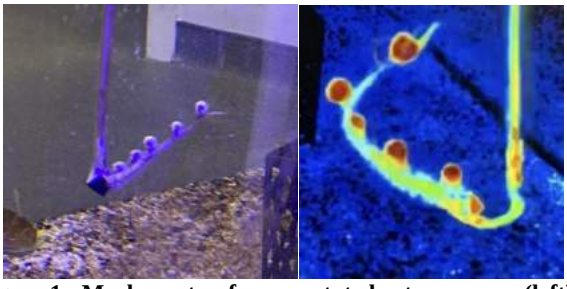

**Figure 1: Marker setup for amputated octopus arms (left) and motion capture display where the five dark red circles are the markers (right).**

The position data from the markers were used to calculate the overall curvature of the arm. The fields of robotics and biomechanics have different ways of computing curvature which makes relating the data to device design even more difficult. The robotics curvature, $(k_r)$ is

defined as $\frac{1}{R}$, where R is half the distance between the first and last marker. The biomechanical curvature (θ) is defined by the angle between the two vectors created by the first, middle, and last markers.

Finally, the planes of motion were investigated to understand the orientation of the octopus arm throughout these motions. A vector normal to the plane created by the first, middle, and last markers was calculated for three time points. These time points correspond to before curvature was initiated, during, and after (based on the path of motion).

## RESULTS

Figure 2 provides the results from the amputated arm for the robotic curvature analysis and for the biomechanical curvature analysis.

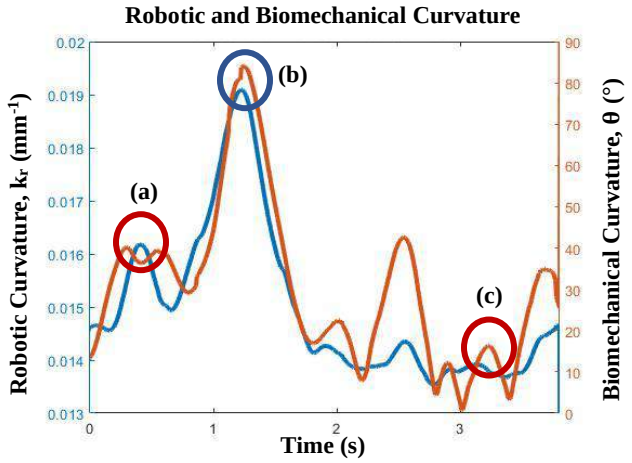

**Figure 2: Comparisons of two methods for curvurature calculation for the amputated octopus arm. Points a, b, and c will be used for analysis in Figure 3.**

Figure 3 shows the results of the planar analysis for three time points: before curvature was initiated, during, and after.

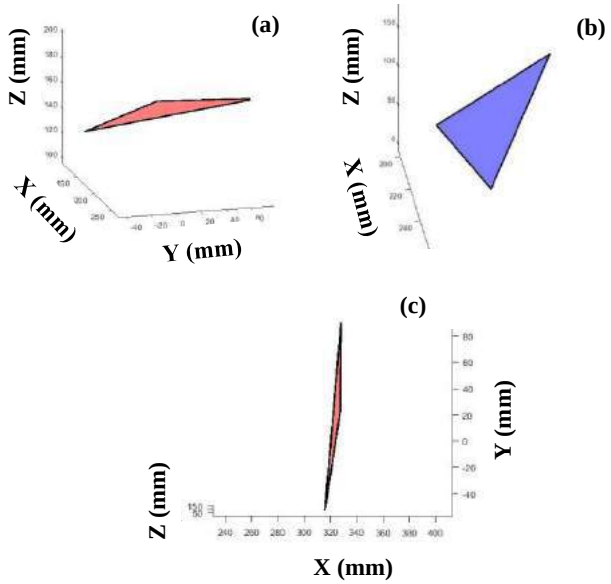

**Figure 3: Planes identify the orientation of the arm in space and correspond to three time points (a) before curvature was initiated, (b) during, and (c) the after.**

Based on Figure 2, in both analyses, straighter movements result in curvature values closer to 0 and more curved movements result in higher curvature values. The robotic curvature varies between 0.013 and 0.019 $mm^{-1}$ during the straight portions and the turning portions, respectively. Also, the biomechanical curvature reports ranges from 0 to 84° of movement during the straightaway and turning portions, respectively.

The planes of motion (Figure 3) were analyzed to determine the orientation of the curvature measurements in the octopus arm. The planes of motion move from Figure 3a to 3b to 3c. Note that together with the curvature, the plane orientation provides a complete description of arm movement. In addition to the overall leg orientation, larger curvature creates a larger planar area. The planes have areas of 843 $mm^2$, 1282 $mm^2$, and 341 $mm^2$, respectively.

## DISCUSSION

Methods used in soft robotics and biomechanics were applied to the curvature of the octopus leg to determine which one would be the most appropriate to describe it's movement. Since many soft robots only have one degree of freedom, the method to determine curvature is largely two dimensional. Although this analysis may be necessary to drive smart robotics, it is not intuitive or comprehensive enough to describe true human movements. The biomechanical analysis is better equipped to intuitively describe the magnitude of the curvature and it is more sensitive to movement. However, both analyses are unable to explain the orientation of the curvature in space.

The planar analysis describes the orientation of the octopus arms using planes. Current techniques for defining octopus movement have assumed that the curvature occurs in one plane. However, this analysis clearly demonstrates the multiple planes of movement. The straight portions of the movement actually have side-to-side curvature, which is shown by Figures 3a and 3c; and the turning portions have flexion-like curvature, shown in Figure 3b. Also, computation of the area component of the plane provides even more detail that may be beneficial to the description of movement.

The differences between movement definitions must be determined for advancement of biomechanics and soft robotics. Also, to be able to implement a multi-planar functioning octopus arm-like prosthesis, the added complexity of the planar movements must be better understood, as it has not been investigated or quantified. Future work will include a full planar analysis for all time points of octopus movement, and the best method for communicating curvature and orientation for the design of smarter and less expensive prostheses will be determined.

## INTRODUCTION

Digital immunoassays are capable of quantifying analytes in a calibration-free manner and detecting them at single-molecule level.[1] The major barriers to its widespread use are the time-consuming protocols (e.g., sample partition and signal amplification) and laboratory infrastructures.[2] Here we developed digital plasmonic nanobubble detection (DIAMOND) technique to overcome some of these bottlenecks. Specifically, we designed an optofluidic setup to flow the gold nanoparticle (AuNP)-based samples in a micro-capillary, where two aligned laser beams synchronically activate and detect the plasmonic nanobubbles (PNBs) generated from nanoscale heating of AuNPs (**Fig. 1a**). Since the PNBs are transient events and have no crosstalk between laser pulses, DIAMOND creates microscale "virtual detection zones" of about 16 pL and counts the "on" and "off" signals in a compartment-free manner (**Fig. 1b, c**). We demonstrated that DIAMOND can be implemented on a homogeneous immunoassay and does not require additional sample washing, separation, and signal amplification steps. On the other hand, DIAMOND does not require chip preparation or on-chip reaction and can be performed with less assay time (i.e., within 30 minutes) compared to other digital assays. Using antibody-modified gold nanoparticle (AuNP) probes with bovine serum albumin (BSA) backfilling, we demonstrated DIAMOND could specifically detect respiratory syncytial virus (RSV) in nasal swab samples and achieves a detection limit of ~100 PFU/mL or 1 RNA copy/μL equivalent. We also discussed several further improvements to this technology to bring it to a broad range of labs and practical applications in clinics.

## METHODS

*Preparation of antibody-coated AuNPs with BSA backfilling.* In brief, DTSSP as a crosslinker was first reacted with Synagis as detection antibody, followed by an overnight membrane dialysis at 4 ºC and incubation with AuNPs and 0.1% of DTSSP-BSA. The product was then washed and centrifuged before re-dispersed in 2 mM borate buffer.

*Detection of virus in complex sample matrix*. We used BD Universal Viral Transport Collection Kits to collect nasal swab samples from the nostrils of healthy adults following the manufacturer's instruction. The unpurified virus suspensions including respiratory syncytial virus (RSV), human metapneumovirus viruses (hMPV), parainfluenza viruses (PIV), and influenza virus type A (IVA) were then spiked into the as-prepared nasal swab healthy control samples and used as clinical samples. The use of human nasal swab samples was approved by Institutional Review Board (IRB) at University of Texas at Dallas (ID: 20MR0093).

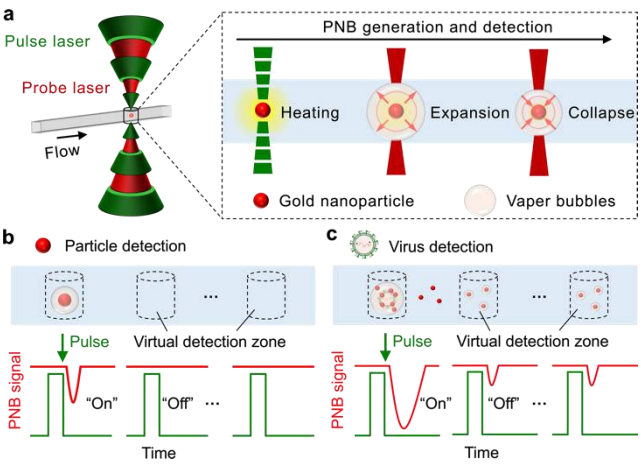

**Figure 1. Concept of digital plasmonic nanobubble detection (DIAMOND).** (a) The schematic illustration of the transient plasmonic nanobubble (PNB) events. Pump-probe laser configuration allows PNB

generation and detection simultaneously. (b, c) The principle of digital counting of "on" and "off" PNB signals for particle detection (b) and virus detection (c).

## RESULTS

We previously found that the antibody-modified AuNP probes had limited detection specificity for control viruses, including PIV, IVA, and hMPV (**Fig. 2a, b**). This is because those viruses were dispersed in culture fluids without purification and the impurities like cell debris involved in the medium could cause non-specific aggregation of AuNP probes. As a result, they led to positive counts and thereby false positive. To address this issue, we used bovine serum albumin (BSA) to backfill the AuNP probes. The BSA has been frequently used in immunoassays as block reagent and can prevent the non-specific binding for improved detection specificity.[3] To evaluate the performance of BSA-backfilled AuNP probes, we incubated them with respiratory viruses spiked in nasal swab samples and subjected the complete assay solution to the DIAMOND test. The viral transport medium (VTM), hMPV, PIV, and IVA were used as negative controls, and all viral titers were kept the same as $10^5$ PFU/mL. **Fig. 2c, d** show the virus detection results using BSA-backfilled probes, where the positive PNB signals from the control viruses were significantly reduced, while the PNB signals from RSV can be easily distinguished from the control samples, yielding $f_{on}$=100% that matches well with the theoretical probability. In contrast, the non-backfilled probes still cause non-specific aggregation upon detection. This result suggests that DIAMOND has a better detection specificity when utilizing BSA-backfilled probes. These probes also enabled sensitive detection of spiked RSV in nasal swab samples with a detection limit of 102 PFU/mL (**Fig. 2e, f**), equivalent to 1 RNA copy/μL as validated by digital isothermal amplification (data not shown). Taken together, these results demonstrated that implementing DIAMOND on a homogeneous immunoassay allows sensitive analysis of viral samples in the human specimen matrix and supports the potential clinical applications.

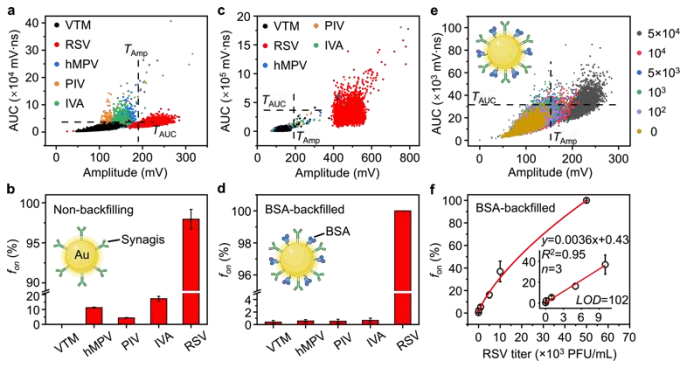

**Figure 2. Detection of RSV among closely related respiratory viruses by DIAMOND.** Detection and quantification results for (a, b) control viruses and RSV in culture fluids using non-backfilled AuNP probes; (c-f) control viruses and RSV spiked in *complex sample matrix* using BSA-backfilled AuNP probes.

## DISCUSSION

We envision several further improvements to this technology in order to bring it to a broad range of labs and practical applications. Current implementation of DIAMOND relies on a research-grade pump laser, which is too bulky to perform tests out of a lab. It is important to explore the feasibility of DIAMOND using a small benchtop device. As a first step, we used a portable nanosecond (ns) laser (Wedge-HB-532, RPMC) that can be integrated into a benchtop device (15×15×6 inches, **Fig. 3a**). Evaluation of PNB generation and detection by this ns laser shows robust results across a range of AuNP concentrations (**Fig. 3b-d**). More importantly, the ns laser provides a repetition rate up to 2,000 Hz and allows a much faster readout and thus more efficient event counting. Taking advantage of the high-throughput ns laser and a focusing flow, we expect to increase the event counting (e.g., 1 million readings within 10 minutes, similar to flow cytometer). This will improve the detection range and sensitivity of DIAMOND, because the digital counting performance essentially relies on the number of counted events.[4]

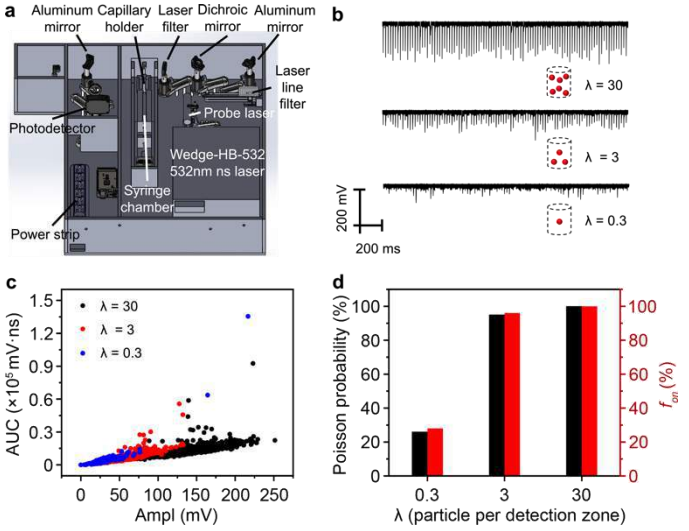

**Fig. 3. Detection of 75 nm AuNPs by DIAMOND using a nanosecond laser (Wedge-HB-532, RPMC).** (a) SOLIDWORKS model built for benchtop device. (b) PNB signal traces (100 pulses) generated from ns laser for 75 nm AuNP suspensions with different particle concentrations, where λ refers to the number of NPs per detection zone. (c) PNB signal analysis of amplitude and area under the curve (AUC) extracted from 3,000 pulses for the three samples in (b). (d) Bar plot of experimental frequencies ($f_{on}$) as determined in (c) and theoretical probability predicted by Poisson statistics for the given λ.

In summary, we have developed DIAMOND for virus detection via the AuNPs-based homogeneous immunoassay. DIAMOND allows digitizing a homogeneous assay without sample washing. Importantly, DIAMOND can specifically detect RSV among different respiratory viruses in complex matrix and achieve a detection limit of ~100 PFU/mL (or 1 RNA copy/μL). Compared with other digital assays, DIAMOND counts events in a compartment-free manner and utilizes a one-pot protocol for sample handling at room temperature. Our study provides a digital counting platform for rapid and ultrasensitive diagnostics of intact viruses at their early representation.

## INTRODUCTION

Nanoparticles (NPs) have found an essential role in various biomedical applications due to their capabilities to efficiently absorb external energy excitation and convert that energy to heat[1]. Heating generated by NPs broadly falls into one of two modes: nanoscale-confined heating (NCH) and macroscale-collective heating (MCH)[2]. Efforts had been made on revealing the transition between these heating modes[3-5]. Keblinski et al. highlighted the role of the duration of energy excitation in controlling the transition between NCH and MCH[3]. Baffou et al. systemically investigated how the geometry of an NP array affects the temperature confinement[4]. While these efforts advanced our understanding of nanoparticle heating, there is an important gap in understanding how single pulsed NP heating affects biological systems through protein denaturation or activation.

In this study, we developed a computational model to systematically investigate the single-pulsed heating of NP array and corresponding protein denaturation/activation. We found that NCH may lead to targeted protein denaturation, however, NCH does not lead to nanoscale selective TRPV1 channel activation. The excitation duration and NP concentration are primary factors that determine a window for targeted protein denaturation, and together with heating power, we defined quantified boundaries for targeted protein denaturation. Our results improve our understandings of NCH and MCH under realistic physical constraints and provide robust guidance to customize biomedical platforms with NP heating.

## METHODS

For NP array heating, we solve the problem by superposition of the analytical solution of single nanoparticle heating:

$$\Delta T_{multi}(\mathbf{r},t) = \sum_{i=1}^{N} \Delta T_{single}^{i}(\mathbf{r},t) \quad (1)$$

The single spherical particle heat conduction model in spherical system was analytically solved by Laplace transform[6].

The protein denaturation was treated as a first-order kinetic model, and the reaction rate was determined by the Arrhenius model[7]:

$$k = Ae^{\frac{-E_a}{RT_m}i} \quad (2)$$

where $T_m$ is the temperature of NP array heating.

For the TRPV1 channel, the activation can be determined by two-state model and the opening rate $k_{on}$ is estimated by[8]:

$$k_{on} = Ae^{\frac{-\Delta H - T_m \Delta S}{RT_m}i} \quad (3)$$

All solutions were calculated in Matlab 2019b software.

## RESULTS

We first constructed and validated the modeling framework for NP array heating and protein thermal denaturation: 10 μm ×10 μm 2D square arrays composed of 30 nm gold nanoparticles (AuNP) immersed in an aqueous solution(Fig. 1). To connect NP heating to the protein denaturation, we analyzed protein denaturation using α-chymotrypsin. Additionally, we analyzed NP heating-induced protein activation with the TRPV1 channel. Here we consider the NP-water interface ($P_1$) and the mid-point between NPs ($P_2$) as two representative locations. We will use $P_1$ and $P_2$ to indicate these locations, along with $\Delta T_1$, $\Delta T_2$ and $D_1$, $D_2$ and $O_1$, $O_2$ to indicate temperature increase ($\Delta T$), normalized protein denaturation ($D$), and normalized TRPV1 activation ($O$) at $P_1$ and $P_2$ respectively.

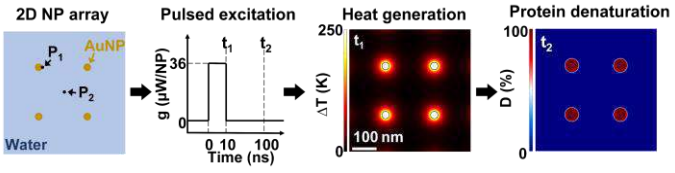

**Figure 1. Analysis framework for nanoparticle heating-induced protein denaturation.**

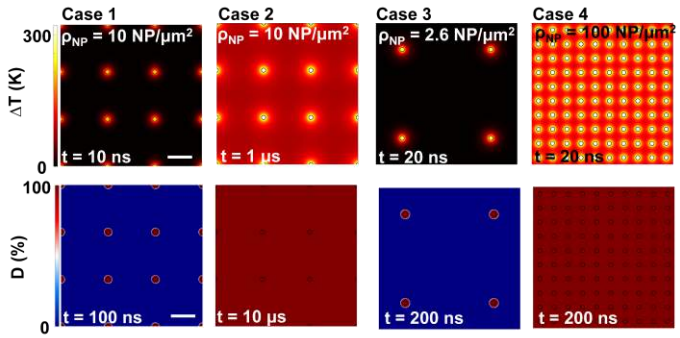

**Figure 2. Effects of excitation duration and NP area density on the heating and protein denaturation.** Heating power (g) = 36 μW/NP Scalebar represents 200 nm.

Secondly, we investigated the role of excitation duration and NP area density ($\rho_{NP}$) in transition from NCH to MCH, and from targeted to widespread denaturation respectively. Here we adopt $D_2/D_1$ to characterize the denaturation profile. High $D_2/D_1$ indicate uniform denaturation profiles, while low $D_2/D_1$ indicate heterogeneous profiles, which is necessary for selective denaturation. By comparing thermal responses and protein denaturation with NP array heating under different excitation durations (Fig. 2, case 1&2), and with NP arrays that have different $\rho_{NP}$ (Fig. 2, case 3&4), we found the excitation duration and $\rho_{NP}$ are key factors that driving transition from NCH to MCH, and from heterogeneous denaturation ($D_2/D_1 \sim 0$ % for case 1&3) to uniform denaturation ($D_2/D_1 \sim 100$ % for case 2&4).

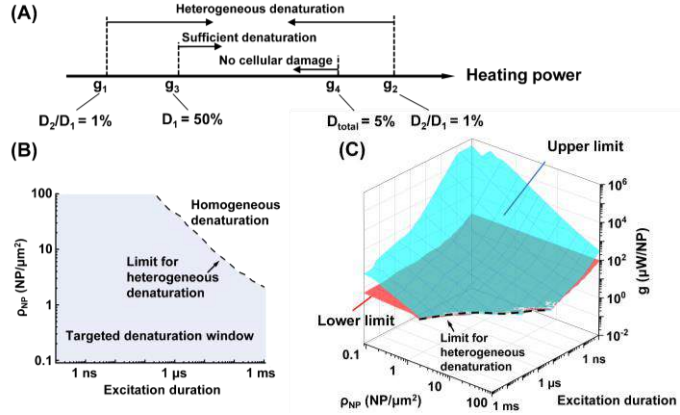

**Figure 3. Limits and window for targeted protein denaturation.** (A) Schematic of critical heating powers $g_1$, $g_2$, $g_3$ and $g_4$. (B) Excitation duration and $\rho_{NP}$ determines the targeted protein denaturation window. (C) Lower limit (red surface) and upper limit (blue surface) for targeted protein denaturation in terms of excitation duration and $\rho_{NP}$.

Next, we analyzed the effect of heating power ($g$) on protein denaturation. We found that as $g$ increases, $D_2/D_1$ drops from 100 % to ~0 % at certain heating power $g_1$, and dramatically increases back to 100 % at $g_2$. Here $g_1$ and $g_2$ represent the boundaries for heterogeneous protein denaturation zone (Fig. 3A), where targeted denaturation is possible. Importantly, we found the limits for this targeted denaturation window are determined by excitation duration and $\rho_{NP}$ (Fig. 3B), *i.e.,* targeted protein denaturation is possible only when NCH is established. Within this targeted denaturation window, we further define critical heating powers $g_3$ and $g_4$ to quantify the limits of targeted denaturation in terms of g, *i.e.,* sufficient denaturation around NP ($g_3$, $D_1 = 50\%$) without widespread cellular damage ($g_4$, $D_{total} = 5$ %, less than 5 % total protein denaturation; Fig. 3A). Considering all these factors we determined the quantified limits for targeted protein denaturation in terms of excitation duration, $\rho_{NP}$, and $g$ (Fig. 3C).

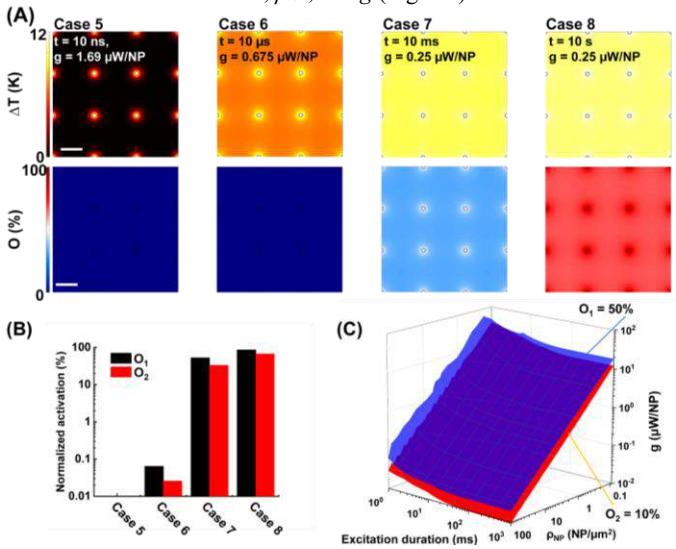

**Figure 4. Analysis of TRPV1 channel activation by NP array heating.** (A) $\Delta T$ profile and $O$ profile for case 5-8, $\rho_{NP}$ = 9 NP/μm$^2$, scalebar represents 200 nm. (B) $O_1$ and $O_2$ for case 5-8. (E) Threshold for on-target TRPV1 activation ($O_1$ = 50%, blue surface) and off-target TRPV1 activation ($O_2$ = 10%, red surface).

Lastly, we investigated whether NP array heating could selectively activate the TRPV1 channel. Following the similar framework in Fig. 1, NCH is observed with short excitation duration(Fig. 4 A&B, case 5&6). However, due to the mismatch between the nanosecond excitation durations required for NCH and the millisecond timescale needed for channel activation[8], there is no obvious TRPV1 activation for case 5&6. As excitation duration increases, MCH is established (Fig. 4 A&B, case 7&8), resulting in widespread TRPV1 activation. Here we set a threshold of on-target TRPV1 activation ($O_1$ = 50 %), and off-target TRPV1 activation ($O_2$ = 10 %). Fig. 4C shows the threshold for on-target TRPV1 activation (blue surface) is always higher than off-target activation (red suface), indicating that either no TRPV1 activation or widespread TRPV1 activation is possible by NP array heating.

## DISCUSSION

In this study, we found nanoscale selective activation of TRPV1 is not feasible based on our current understanding of its millisecond activation kinetics. It should be noted, however, that it is unclear if TRPV1 can be activated at faster rates at a higher temperature. According to molecular dynamics simulations, channel opening was not observed within 200 ns at temperatures of 60 and 72 ° C, suggesting that TRPV1 activation may be unlikely to occur at nanosecond timescale[9].

## INTRODUCTION

Over 120,000 Anterior Cruciate Ligament (ACL) injuries occur in the United States every year [1] and the rate of ACL reconstruction surgeries is steadily increasing [2]. The choice of graft used in ACL reconstruction influences the resulting knee loading following ACL reconstruction, and may contribute to increased rates of osteoarthritis [3]. The patellar tendon is the most common graft used as an ACL replacement, but has different microstructural [4] and mechanical properties [5] than those of the ACL. To better guide the selection of ACL grafts, *in vivo* imaging techniques that can provide microstructural information to better match the native tissue are required.

Diffusion Tensor Imaging (DTI) measures the diffusion properties of water through tissue [6] thereby inferring the underlying microstructure [7] governing the diffusion. In order to translate the quantitative data provided by DTI into relevant biomechanical information, it's important to establish relationships between the parameters measured by DTI and the mechanical structure-function relationships of soft collagenous tissues. However, doing so in biological tissues presents challenges due to the natural heterogeneity and complexity in the microstructure of ligaments and tendons.

Previously, we used spun fibers as a mimic of the microstructure of collagen-based tissues to develop material constructs of ligaments [8]. These constructs have tensile [8] and shear properties [9] similar to those of ligaments and tendons, with the benefit that their microstructure is controllable and more homogeneous. As a first step to understand the diffusion-structure-function relationships, the objective of this study was to evaluate the effects of mechanical loading on fiber microstructure and DTI parameters using ligament-mimicking fibers. We hypothesized that fiber diameter and ply-angle would change with loading and result in differences in diffusion properties.

## METHODS

*Yarn samples.* Ten fiber (Caron, 570 tex) samples (5 pre-loaded, 5 loaded, length = 10 cm) were used for mechanical loading and imaging.

*Mechanical loading and sample preparation.* All samples were pre-loaded to 0.3 N to standardize the initial length. Five samples were held at the pre-load value and fixed using water-resistant epoxy in a custom imaging container (Figure 1). Next, five samples were pre-conditioned to 30N (50 cycles, rate = 106 mm/min) loaded to 10 N (rate = 106 mm/min) and the tensioned samples were secured with water-resistant epoxy into the imaging containers.

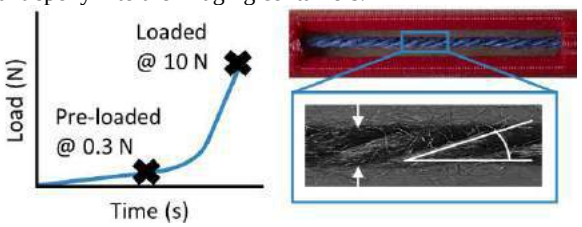

**Figure 1: Points on load curve at which the samples were imaged (left). Measurement of the yarn diameter and ply twist angle from the high-resolution images (right).**

*High-resolution structural imaging.* The fiber samples were imaged using a high-resolution camera (100MP, PhaseOne, Denmark). Apparent fiber diameter and twist angle was measured from the images using custom Matlab code. For diameter, the fiber was segmented from the background, binarized, and the mean distance between the fiber edges was calculated. Grey scale versions of the images were used to measure the ply twist angle based on textural differences between the plies. The central region of the fiber was isolated and the gradient structure tensor was calculated from which the eigenvectors were determined. The ply twist angle was defined as the principal eigenvector.

*Diffusion Tensor Imaging.* The fiber samples were next submerged in water and imaged using a 9.4T MRI system (Bruker, MA, USA). DTI

was performed using an echo-planar imaging sequence (TE/TR = 180/4200 ms, 12 directions, 12 averages, and $b$ = 600 s/mm$^2$). Twenty slices were acquired for each fiber (slice thickness = 375 µm, in-plane resolution = 150 x 150 µm, field of view = 19.2 x 19.2 x 7.5 mm). Fractional anisotropy (FA), apparent diffusion coefficient (ADC), and radial diffusivity (RD) were calculated from the DTI images using MRtrix3 (https://www.mrtrix.org/) and custom Python code. Fiber tractography was performed using DSI Studio (https://dsi-studio.labsolver.org/).

*Statistical Analysis.* Normality of the microstructural and DTI metrics was tested and confirmed using a Shapiro-Wilks test. An unpaired t-test was used to evaluate differences in the microstructural and DTI metrics between the pre-loaded and loaded samples.

## RESULTS

Loading decreased the diameter of the fibers by 32% ($p < 0.001$), while no significant change was observed in ply twist angle (Table 1). The FA in loaded samples increased by 5% ($p < 0.01$) while RA and ADC decreased by 30% ($p < 0.01$) and 25% ($p < 0.01$), respectively. Local differences in FA and RD and diametrical compression of the loaded samples were observed in the fiber tractography (Figure 2).

**Table 1: Mean ± standard deviation values of fiber structural parameters (*** = $p < 0.001$)**

| Structural Parameter | Pre-loaded | Loaded |
|---|---|---|
| Yarn Diameter (mm) | 1.85 ± 0.09 | 1.25 ± 0.08*** |
| Ply twist angle (°) | 16.26 ± 3.59 | 14.25 ± 1.77 |

## DISCUSSION

We have used a combination of high-resolution structural imaging and MRI to evaluate the structure-function relationships of ligament mimicking fibers under different load states. Our data indicate that loading has a greater effect on fiber compaction than angular rearrangement. During the early pre-load (toe) phase, diametrical fiber compression results in an increase in fiber density in agreement with theoretical models [10].

The lack of change in ply twist angle suggests that angular rearrangements of fibers may occur outside the bounds measured by our study - either at loads lower than 0.3 N or greater than 10N. Fiber compaction correlated with changes observed in the DTI metrics: loading resulted in increased FA and both the RD and ADC decreased. Highly aligned fiber networks present more barriers for water molecules to diffuse since fiber density is increased and result in more anisotropic diffusions [11]. The diffusion directions obtained from the fiber tractographies agree with the alignment direction of the fibers and support our interpretation.

One limitation of our study is that our optical image measurement of fiber rearrangement was limited to ply angles and it is possible that smaller scale rearrangements may occur such that the fibers within a given ply may change orientation in response to loading. This lower length scale variation is more readily seen in the visualization of FA and RD where local heterogeneities are observed. The presence of air bubbles was also noted in some images and care was taken to avoid using DTI measures in those regions when possible.

Our results show that DTI is sensitive to the microstructural changes in ligament-mimicking fibers. Importantly, MRI is a clinically viable technique and the use of DTI will open new opportunities for the assessment of musculoskeletal tissues. These diffusion-structure relationships can bridge *in vitro* findings of collagen fiber alignment on knee ligament mechanics [12] and *in vivo* clinical images of knee ligaments [13-15]. With an enhanced clinical characterization of ligament microstructure and mechanics, appropriate graft selection and improved outcomes for ACL reconstructions are possible.

## ACKNOWLEDGEMENTS

## INTRODUCTION

Coronary heart disease (CHD) is the cause of mortality for about 300,000 Americans each year [1]. Treatment of CHD includes medication, angioplasty, and, for severe vessel occlusion, coronary artery bypass grafting (CABG) that is a procedure requiring the use of an autologous vein or artery from the patient's body. Autologous grafts can frequently become unavailable, necessitating the need for fabricating non-autologous grafts. Tissue-engineered vascular grafts (TEVGs) aim at mimicking the microstructure and mechanical properties of the native coronary artery [2]; however, current TEVGs fail to replicate these properties due to a lack of understanding in the mechanical and structural requirements of the target vessel. In addition, surgeons frequently select anastomotic sites based on different factors, resulting in the variability in the portion (proximal, medial, or distal) of the artery connected to the graft [3]. Thus, it is of a paramount importance that the local tissue microstructural and mechanical properties are characterized for the development of TEVGs. In this study, we aim to characterize the porcine left anterior descending artery (LADA) via biaxial testing, polarized light imaging and multiphoton microscopy. Our findings demonstrate the unique regional properties of the vessel, creating the need for biomaterials for CABG that can potentially mimic the unique properties of native coronary artery tissue.

## METHODS

*Tissue Preparation & Dissection*: Healthy porcine hearts (n=14) were obtained from a local abattoir (Chickasha Meat Company, OK). Upon arrival at our lab, hearts were dissected through the following procedures: (i) excising surrounding tissue of the LADA and sectioning the artery immediately next to the branching of the left coronary artery, (ii) delicately exposing the complete artery by cutting open the epicardium and surrounding fatty tissue, (iii) delicately removing connective tissue, and (iv) cutting the excised artery in thirds. Each third was then stored as proximal, medial, and distal specimens.

*Biaxial Testing*: The CellScale BioTester system was used in the biaxial tissue mechanical characterization. The tissue circumferential (C) and longitudinal (L) directions were aligned with the device *x*- and *y*-axes. Once mounted via four BioRakes, glass beads were glued to the surface of the specimen as fiducial markers for the quantification of in-plane strains [4]. All testing was performed in phosphate-buffered saline at 32°C, and the specimens were subjected to 15 preconditioning cycles, followed by a series of biaxial tension ratios: $T_{CC}$:$T_{LL}$ = 1:1, 1:0.75, 1:0.5, 1:0.25, 0.25:1, 0.5:1, 0.75:1. Tissue strains were then calculated using digital image correlation together with a single bilinear finite element, and the first Piola-Kirchhoff stress tensor was calculated by $\mathbf{P} = \mathrm{diag}[T_{CC}, T_{LL}]/t$, where $t$ is the tissue thickness measured by a non-contact laser sensor. The stress-stretch curves were used to calculate several derived mechanical parameters. (**Fig. 1**).

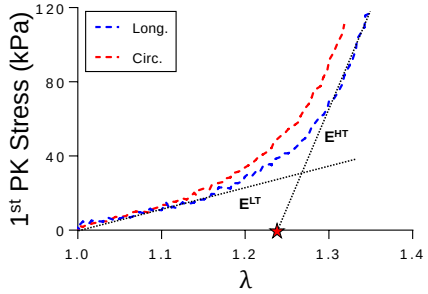

**Figure 1: Biaxial stress-stretch data of a representative porcine left anterior descending artery (LADA), for deriving the low- and high-tension moduli ($E^{LT}$ and $E^{HT}$) and tissue extensibility $\lambda^*$.**

*Polarized Spatial Frequency Domain Imaging (pSFDI):* The specimens were illuminated using an LED projector coupled with a light polarizer. The back-scattered light intensity response was imaged at a series of polarization states (0°-180°, every 5°) at several loading points of the biaxial tension ratios. The reflective intensity of each loading state

was fitted with a 3-term Fourier series in MATLAB (MathWorks) to determine the degree of optical anisotropy (DOA, that describes the collagen fiber alignment). Changes in the DOA were also quantified to explore an increase/decrease in the collagen fiber alignment [5].

*Multiphoton Microscopy*: The specimens were optically cleared in a graded 1:2 BABB solution (50/50% ethanol/BABB and 100% BABB, each solution for 30 min, twice). The specimens were then imaged using a confocal microscope (Leica SP8) with a multiphoton laser for autofluorescence imaging (excitation: 830 nm, emission: 500-550 nm). The vascular wall was imaged in a 2 µm thickness resolution and a field of view of 290x290 µm.

*Statistical Analysis*: Quantities are shown as mean±standard error of the mean. The data was tested for normality and compared using applicable statistical tests, such as ANOVA or aligned rank transform. $p < 0.05$ was considered as statistically significant. All analyses were performed in R software v4.1.1.

## RESULTS

*Arterial Geometry*: The thicknesses for the arterial wall were: 388±27 µm (proximal), 439±42 µm (medial), and 289±10 µm (distal), where the distal region was significantly thinner than the others. The LADA diameter was reduced along the proximal-to-distal direction ($p<0.001$): 3.05±0.06 mm, 2.58±0.07 mm, and 2.27±0.11mm for the proximal, medial, and distal regions, respectively.

*Biaxial Stress-Stretch Behavior*: The LADA tissues exhibited a non-linear anisotropic response, with minimal hysteresis [6]. The specimens were compliant at low levels of stress, before reaching a transition point, where the stress increased exponentially. The longitudinal peak stretch ($\lambda^P$) did not vary across the LADA regions (average: 1.31±0.01), while the circumferential $\lambda^P$ was 1.30±0.02, 1.25±0.02, and 1.27±0.03 for the proximal, medial, and distal regions. Further, $\lambda^*$ was homogeneous across regions and loading directions with an average of 1.19±0.01. The distal region was the least extensible.

For the $T_{CC}$:$T_{LL}$= 1:0.5 loading ratio, which accurately mimics the stresses of thin-walled vessel models, $\lambda^*$ was 1.24±0.02, 1.19±0.02 and 1.21±0.02 for the proximal, medial, and distal regions. On the other hand, $\lambda^*$ in the circumferential direction was significantly greater than the one in the longitudinal direction (1.21±0.01 vs. 1.14±0.01; $p < 0.001$). The general average of $E^{LT}$ was 217.53±20.26 kPa, which did not vary across the loading directions and regions, whereas $E^{HT}$ for the circumferential direction was 1986.37±110.43 kPa, greater than the longitudinal $E^{HT}$ of 881.05±64.28 kPa ($p < 0.001$). In addition, the distal region exhibited greater $E^{HT}$ than the other LADA regions, but significance was not reached ($p = 0.14$).

*Microstructure Results*: pSFDI allowed the quantification of the *load-dependent* changes in the collagen architecture of LADA tissues. We observed that the DOA increases in all regions from Loading Point 1 (unloaded) to Loading Point 5 (peak biaxial tensions), $p < 0.001$. Further, DOA increase was more pronounced in the distal-to-proximal-direction ($p < 0.001$), indicating a higher degree of fiber recruitment in response to the load (**Fig 2.**). Moreover, multiphoton microscopy allowed us to understand the microscopic collagen/elastin organizations for the tissue. The tunica adventitia of the proximal region exhibited the traditional random distribution of fibers (**Fig. 3**). However, the tunica media exhibited a transition where the fibers became better aligned towards the longitudinal direction. This re-orientation further progressed into the distal region, where the fibers were found to be almost parallel in this direction. This behavior was observed throughout the entire layer depth, as demonstrated in the heatmaps (**Fig. 3**).

## DISCUSSION

The LADA tissue wall mechanics have been previously reported using a myriad of methods. However, its regional variations have not been fully characterized, limiting a comprehensive understanding of the regional requirements for the design of TEVGs for CABG that accurately mimic the native LADA. Given the significant geometrical differences between the LADA regions, we have characterized a uniquely varying microstructure of the vessel. These changes may be attributed by a series of factors: (i) the LADA, as all other coronary arteries, is of proepicardial origin and they penetrate the aorta at the last stages of the heart development, indicating that the proximal region, being the connection to the main left coronary artery, may serve as a transition to a LADA-specific microstructure; (ii) the LADA inward motion during the cardiac cycle [7] might induce a reorientation of the fibers of the adventitia at the distal section.

Previously, the LADA microstructure was assumed to have a homogeneous fiber arrangement in the entire artery. In this study, we demonstrate the unique mechanical, microstructural and load-dependent properties of the LADA across the vessel length. Our novel findings in this work elucidate the importance of the subtle microstructure, mechanical properties, and geometry that need to be holistically considered for the design of effective and durable TEVGs.

## INTRODUCTION

Coronary artery aneurysms (CAA) describe local dilatations of the coronary artery that exceed 1.5 the neighboring artery diameter. The prevalence of CAA ranges from 0.3 to 5% [1]. The pathogenesis of CAA is not well understood however, several factors come into play such as certain vasculitic and connective tissue diseases such as the Kawasaki disease (KD) [1]. CAAs are mostly not accompanied by symptoms and their finding is usually incidental. However, clinical symptoms can appear due to the presence of concomitant atherosclerotic disease or local thrombosis in the large CAAs among others causes, leading to angina and myocardial infarction [1].

Literature has shown that the blood flow stagnation and sluggish flow are correlated with thrombosis and atherosclerosis [2]. Several patient-specific computational fluid dynamics (CFD) and experimental investigations to analyze the flow and risk level of CAA cases based on hemodynamic indices were performed [3,4,5]. However, the effect of different aneurysm shape indices and resulting flow parameters on local hemodynamics in CAAs is not systematically investigated yet.

The goal of this study was to investigate the effect of CAA shape indices on local hemodynamics using the response surface method (RSM) through considering KD applications at rest (normal conditions) and during exercise. CFD was performed on idealized controlled geometries where different aspect ratios were considered. Regression models of time averaged wall shear stress (TAWSS), oscillatory shear index (OSI), and relative residence time (RRT) were developed. These models can be used as valuable tools to obtain a real-time assessment of CAA local hemodynamics and resulting risk stratification based on fusiform aneurysm shape indices.

## METHODS

An idealized aneurysm 3D model defined by a sinus curve was designed based on three geometrical parameters, similar to the works of Martufi et al. [6]. After that, the maximum and minimum values of these parameters were set according to previous clinical measurements in KD patients [7] (Table1). Then a Central Composite Design (CCD) design of experiments consisting of 15 cases was created in MINITAB software, and the corresponding geometries were generated in SOLIDWORKS (Figure1). A, B, and C are the linearly scaled parameters of Dneck, Dmax/Dneck, and L/Dmax in the interval [-1,1], respectively.

**Table 1: Maximum and minimum values of shape indices. A, B, and C are the scaled parameters of Dneck, Dmax/Dneck, and L/Dmax in the interval [-1,1], respectively.**

| | Levels | | | | |
|---|---|---|---|---|---|
| **Parameters** | 1 | 2 | 3 | 4 | 5 |
| A,B,C | -1 | -0.594 | 0 | 0.594 | 1 |
| Dneck(mm) | 2 | 2.6 | 3.5 | 4.39 | 5 |
| Dmax/ Dneck | 1.2 | 1.97 | 3.1 | 4.22 | 5 |
| L/ Dmax | 1 | 1.3 | 1.75 | 2.195 | 2.5 |

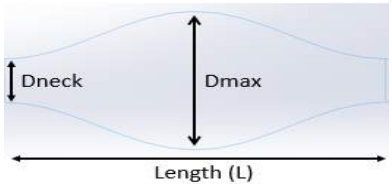

**Figure 1: schematic of idealized CAA.**

To develop the CFD simulations, CAA models were imported to ANSYS MESH and the computational domains were discretized. Then ANSYS CFX package was used to run the simulations. Velocity and pressure waveforms of the left coronary from Kim et al. [8] works were extracted and set as the inlet and outlet boundary conditions, respectively. In order to investigate the hemodynamic alteration in

exercise conditions, all the simulations at rest "normal" conditions (75 bpm) were repeated using new boundary conditions scaled to 120 bpm with an average velocity of 1.5 times the previous one. The arterial wall was assumed to be rigid, and the Carreau model was used to model the non-Newtonian behavior of blood [9]. TAWSS (Pa), OSI, and RRT ($Pa^{-1}$) are the most common hemodynamic indices studied in the literature, which are defined by the following equations with T being the cardiac cycle duration in seconds:

$$TAWSS = \frac{1}{T} \int_0^T |WSS| \, dt \quad (1)$$

$$OSI = \frac{1}{2}\left(1 - \frac{\left|\int_0^T WSS \, dt\right|}{\int_0^T |WSS| \, dt}\right) \quad (2)$$

$$RRT = \frac{1}{(1-2\times OSI)\times TAWSS} \quad (3)$$

In order to have a quantitative assessment of hemodynamics in CAAs, these indices were calculated in each case. For TAWSS and RRT, the thresholds adopted were 0.4 Pa and 4.15 $Pa^{-1}$, respectively[10]. These thresholds are correlated with the risk of thrombosis and atherosclerosis and were applied to the numerical values using RSM. Ideally, high TAWSS and low OSI and RRT are desired.

## RESULTS

Based on the obtained results for the CCD, full quadratic regression models were developed for each of the hemodynamic indices using RSM analysis in MINITAB. These models and the respective $R^2$ values are shown in Table 2. Based on analysis of variance for TAWSS and RRT models, B and A were found to be the most significant parameters with P-values of 0.0001 and 0.002 respectively ($p<0.05$). Hence, we plotted the contours that show the variations of TAWSS and RRT as A and B vary. We would like to emphasize that A and B should be in the linearly scaled format (ranging from -1 to 1 as explained in the methods section). The contour plots highlighting the effect of two input parameters (Dneck and Dmax/Dneck) on the mean TAWSS and mean RRT in exercise conditions is shown in Figure 2. For TAWSS and RRT, the thresholds adopted were 0.4 Pa and 4.15 $Pa^{-1}$, respectively[10]. It is clear from Figure 2 that exercise conditions lead to different effects as compared to normal or at rest conditions. For a Dmax/Dneck ratio less than 2 (considered defining of small aneurysms, and equivalent to B < -0.594 in the linearly scaled system), the TAWSS was shown to increase under exercise conditions irrespective of the absolute neck size (Figure 2, top row). Meanwhile, for the RRT, exercise conditions led to an increase of mean RRT for Dmax/Dneck ratios less than 2, depending on the absolute neck size as shown in Figure 2, bottom row. For Dmax/Dneck ratios > 2, higher mean RRT were generally obtained, however, also dependent on neck size. TAWSS generally increased under exercise conditions regardless of the geometry.

## DISCUSSION

In this study, a parametric CFD quantification of CAA was performed, and regression models of 2 hemodynamic metrics (Table 2) under normal at rest conditions and under exercise conditions were developed using the response surface method. The analysis of variance illustrates that the diameter of the artery before and within the aneurysm area is the most significant shape index affecting the local hemodynamics. This fact strongly highlights the importance of coronary Z-score as the gold standard in KD assessment of severity and treatment [11]. Our results show that the small aneurysms (low Dmax/Dneck) experience very high RRT values under exercise conditions (Figure 2), which is a neglected risk factor in Z-score criteria. The elevated RRT in small aneurysms lends credence to the recommendation to continue aspirin treatment in case of diagnosis, even in small aneurysms. These findings highlight the importance of computational tools to achieve a general understanding of the hemodynamics in CAA. Although some patient-specific studies in KD have been done in recent years, there is not any fast and affordable computational framework for real-time evaluation of hemodynamics in CAA. The proposed regression models can be used as a fast and straightforward estimator to assess the severity and risk level of CAAs, especially in KD patients. It's worth mentioning that these results are limited to idealized symmetric aneurysm models. This methodology can be implemented in more complicated asymmetric models in future works. Ongoing work includes model development using patient-specific data.

**Table 2: Regression models (N: Normal, at rest E: Exercise).**

| | | Regression models | $R^2$ |

# OPEN-SOURCE AUTOMATION OF PATIENT-SPECIFIC ATHEROSCLEROTIC ARTERIES REVEALS KEY BIOMECHANICALLY DRIVEN REMODELING

**Jeremy Warren (1), John Yoo (1), Federico Bernardoni (2), Brandon Boren (2), Clark Meyer (1), Stefano Leonardi (2), Heather Hayenga (1)**

(1) Department of Bioengineering, University of Texas at Dallas, Dallas, Texas, United States
(2) Department of Mechanical Engineering, University of Texas at Dallas, Dallas, Texas, United States

## INTRODUCTION

Despite advancements in early detection, imaging, and innovative treatments, atherosclerosis remains the leading cause of death across all cardiovascular disease (CVD). Clinical treatment decisions rarely consider biomechanics of the stenosed lesion due to the difficulties in obtaining this information; Even though biomechanical analysis of atherosclerotic lesions has been linked to increased likelihood of an adverse cardiovascular event [1]. Understanding the inherent biomechanics in atherosclerotic plaques is critical and a deeper interpretation will pave the way for more effective treatment plans, medication, and overall quality of life for coronary artery disease (CAD) patients. Previously, finite element analysis (FEA) has been used to determine stresses and strains within linear 2D artery models and non-linear materials or homogenous approximations of heterogenous tissues. Our novel, open-source tool automates the creation of anatomically accurate 3D models of arterial geometry with volumetric plaque composition using patient-specific virtual histology-intravascular ultrasound (VH-IVUS) data. The arterial geometry is integrated with in-house computational fluid dynamics (CFD) code to model hemodynamics and leukocyte transport, FEBio to model the internal stresses via FEA, and an agent-based model for growth and remodeling. Understanding patient-specific arterial mechanics can aid in personalized treatment care and the livelihood of patients.

## METHODS

A 6-month longitudinal dataset of 20 patients, with angiogram data and VH-IVUS images, were provided by Emory University. This dataset was used for creating our mesh creation code and validation. The following subsections outline mesh creation and FEA and CFD setup.

### Mesh Creation

Before FEA and CFD can be performed, a mesh of the patient's arterial geometry must be generated. To do so, VH-IVUS images are filtered to remove background noise and the plaque constituent data is extracted. The lumen and outer profiles are outlined, oriented along the 3D centerline, and lofted sequentially to create the surface mesh. This mesh is smoothed and resampled to create a uniformly distributed triangular surface mesh [**Figure 1**]. The surface mesh is then tetrahedralized to generate the volumetric finite elements necessary for FEA. These finite elements are assigned materials using data extracted from the VH-IVUS images.

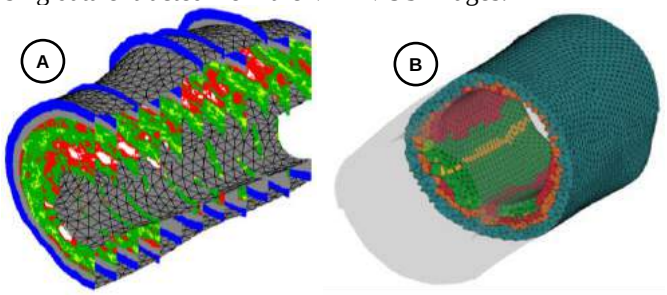

**Figure 1: Surface and Volumetric Mesh Generation**
**A**. The outer and luminal surface profiles extracted from VH-IVUS images are used to create the surface mesh. **B**. The surface mesh is tetrahedralized using open-source TetGen and the resulting elements are assigned a material using the VH-IVUS data.

## FEA Setup

Once associated with a tissue type, we use literature-derived values for Neo-Hookean materials [**Table 1**]. Although literature has shown that Mooney-Rivlin material models are best suited for describing the shear deformation in elastic materials [2], Neo-Hookean material models are acceptable for non-contact simulations. Boundary and loading conditions for the analysis consist of fixed nodes on inlet and outlets surfaces of the mesh, and a physiological pressure of 16 kPa on the lumen surface.

| Tissue Type | Young's Modulus [MPa] | Poisson's Ratio |
|---|---|---|
| Arterial | 0.3 | 0.48 |
| Fibrotic | 0.6 | 0.48 |
| Fibrofatty | 0.5 | 0.48 |
| Calcium | 10 | 0.48 |
| Necrotic | 0.02 | 0.48 |

**Table 1: Material Properties**

Neo-Hookean material properties used in the FE model.

## CFD Setup

The luminal surface mesh is passed to the in-house CFD code which solves the Navier-Stokes and continuity equations using a finite difference scheme coupled with a Runge Kutta algorithm for the time integration. Immersed Boundaries [3] are used to model the real geometry of the artery. The results from CFD are combined with a set of literature-derived rules to model leukocyte adhesion and transendothelial migration (TEM) [4].

## RESULTS

In a representative patient, mean von-mises effective stress was ~210 kPa with a peak stress of 597 kPa [**Figure 2**].

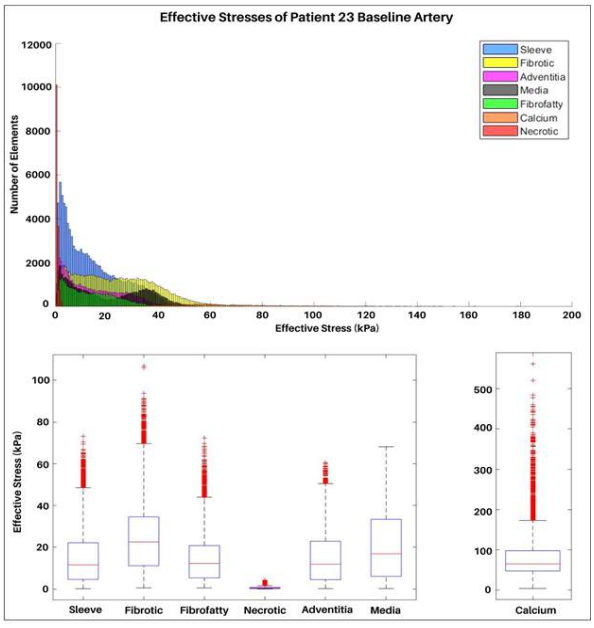

**Figure 2: Effective Stress Results**

Calcium elements present the highest average stress. When stiff calcium elements are adjacent to significantly softer tissues, large strains develop between them, resulting in higher stress in these areas.

## FEA

Areas of high stresses reside only around calcium while stresses around other tissues averaged below 100 kPa. In determining potential rupture, calcium content and location in the artery wall help identify potential sites of rupture. In addition to calcium, we use the widely accepted threshold of 300 kPa to determine regions where a rupture can occur. For this particular patient, the mean stress for micro and macro-calcifications were below the rupture threshold and were generally located >65μm from the lumen. Since this patient's plaque did not rupture, this suggests that plaque rupture is dependent on location, magnitude of stress, and calcium content.

## CFD

Post-analysis of CFD results revealed regions with low wall shear stress (WSS), below 4 kPa, correlated with increased rates of leukocyte adhesion and plaque growth over 6 months [5].

## DISCUSSION

Preliminary results from FEA reflect stresses seen in other studies and the leukocyte adhesion and hemodynamics agree well with clinical data inferred from baseline and six-month follow-up exam of the same artery [6]. Our current aim is to determine the impact of wall mechanics and biological factors on plaque remodeling. We plan to fully couple the CFD, ABM, and FEA to develop a comprehensive, well informed multi-physics growth and remodeling model. In addition, we plan to incorporate more patient-specific data as input to the model and validate our post-analysis techniques when determining potential rupture regions. A better understanding of the underlying factors and how they affect each other will validate previous models and drive future research on other frameworks.

## INTRODUCTION

Glioblastoma (GBM) is an incurable and highly aggressive cancer with a dismal prognosis of 15-months. [1] GBM progression is coupled with a proneural-to-mesenchymal transition (PMT), a molecular event consisting of a phenotypic shift that leads to heightened invasive potential and disease evolution. These events mirror the epithelial-to-mesenchymal transitions (EMT) seen in other types of cancers, which lead to increased metastasis and poorer prognosis. [2] Increased invasiveness in mesenchymal GBM notably occurs despite the presence of tight, physical barriers in the dense brain parenchyma, suggesting potential biophysical alterations that have yet to be elucidated. Recent studies have revealed that more invasive cells can navigate these confined microenvironments by significantly deforming their cell body; however, the details underlying these physical changes remain unclear. Here, we examine this phenomenon through a biophysical lens by investigating the relationship between mesenchymal transformation in GBM and mechanical alterations and its subsequent functional effect on confined migration.

We hypothesize that TGF-β1 promotes efficient confined migration by activating mesenchymal pathways to induce PMT, which may result in mechanical softening of the cells, especially in their nuclear regions, thus allowing them to rapidly bypass the tight, natural barriers in the brain microenvironment. In this study, we induced mesenchymal transitions via TGF-β1 and evaluated changes in cytoskeletal and nuclear protein expression, mechanical rigidity, and functional confined migration. Our data suggests an important role of the nucleus in enabling cell deformation and confined migration. These data reveal the biophysical alterations that arise from mesenchymal transformation, providing new insights into mechanical features of aggressive glioblastoma.

## METHODS

GBM cells were treated with 10 ng/mL TGF-β1 for 72 hours preceding all experiments. Western blots were used to confirm mesenchymal pathway activation (pSmad2, pSTAT3, ZEB1), and evaluate nuclear and cytoskeletal protein expression (Lamin A/C, F-Actin/G-Actin). To assess changes in biophysical properties, AFM was utilized to quantify the effect of mesenchymal transitions on the nucleus and cytoskeleton mechanics. The functional consequence of cellular stiffness changes was examined via PDMS microchannel platforms consisting of 1D channels at multiple widths (5 μm, 10 μm, 20 μm, and 50 μm). Confined migration experiments were conducted via time lapse microscopy on a Nikon Eclipse TE2000-U.

## RESULTS

TGF-β1 was sufficient to induce mesenchymal transitions within GBM cell lines. First, we verified TGF-β1 activation via Smad2 phosphorylation (Figure 1A). Then, we evaluated mesenchymal marker Stat3 and mesenchymal transcription factor ZEB1. As expected, TGF-β1 led to significant increases in both Stat3 phosphorylation and ZEB1 expression (Figure 1B, C), indicating a mesenchymal phenotype. To assess the biophysical changes that may be attributed to mesenchymal transitions, we wondered how structural proteins in the nucleus and cytoskeleton may be affected. TGF-β1 treatment led to decreases in Lamin A/C expression, although the difference was not significant (Figure 1D); however, we observed unexpected pore-like structures in the nuclei of the TGF-β1 treated cells that were not seen in the non-treated (NT) cells (Figure 1E). Further, we found that the ratio of F-actin to G-actin was dramatically reduced in treated cells, indicating that TGF-β1 treatment disrupted cytoskeletal organization and increased pools of depolymerized actin (Figure 1F).

SB³C2022-120

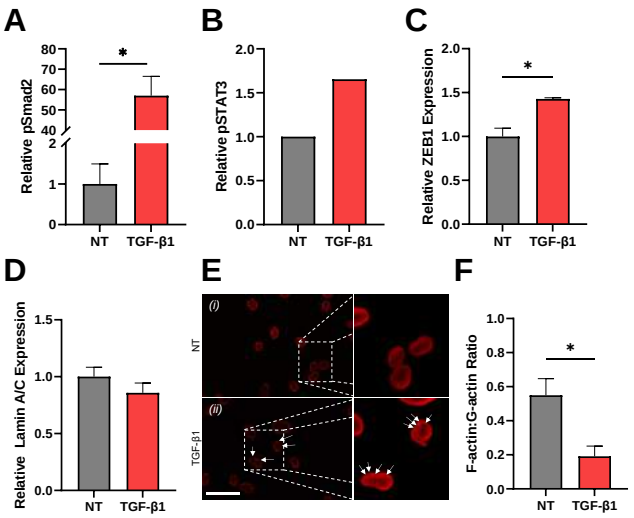

**Figure 1: TGF-β1 activates canonical signaling (A) and STAT3 signaling (B), leading to increases in ZEB1, a mesenchymal transcription factor (C). Additionally TGF-β1 cells displayed reduced Lamin A/C expression and aberrant organization (D, E) along with a significant decrease in F-actin/G-actin ratio (F).**

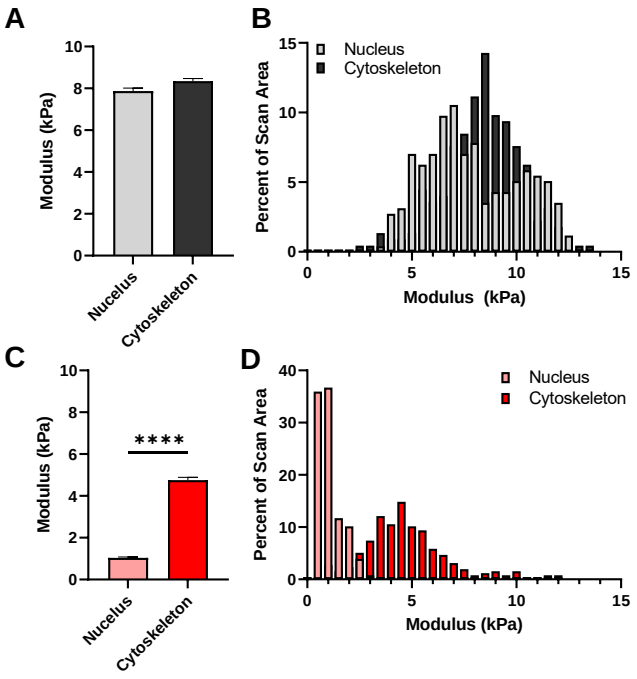

**Figure 2: AFM analysis reveals that TGF-β1 treatment significant reduces nuclear and cytoskeletal stiffness (A,C). Histograms illustrate that nuclear stiffness is more dramatically reduced in treated groups with > 60% of the scan area exhibiting a stiffness of < 1 kPa (B,D).**

We employed AFM to determine how protein level changes to the nucleus and cytoskeleton might affect cell rigidity. We found that cellular stiffness was reduced in the TGF-β1 treated group in both the nucleus and the cytoskeleton (Figure 2 A-D). Intriguingly, the relative nuclear stiffness was dramatically reduced while the decrease in cytoskeletal stiffness was less pronounced (Figure 2 B, D).

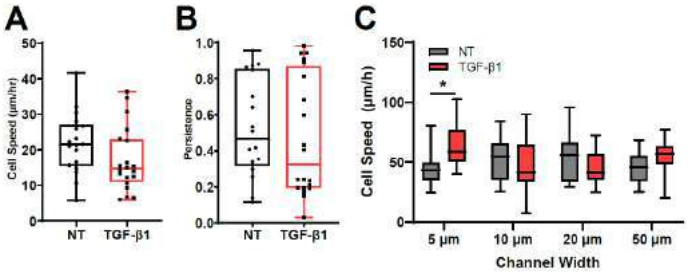

**Figure 3: 2D motility assays show minimal differences between NT and TGF-β1 treated GBM cells (A, B); however, microchannel platforms reveal that upon encountering tight physical constrictions in 5 μm channels, TGF-β1 treated cells exhibit a significant increase in cell speed whereas NT cells displayed a reduction in cell speed (C).**

We then evaluated the functional changes in NT and TGF-β1 treated cells using 2D motility assays and microchannel platforms. Interestingly, 2D cell speed and persistence did not change significantly in TGF-β1 treated groups (Figure 3 A, B). Using microchannel platforms, we found that while NT cells struggled to migrate under tight constriction (5 μm), TGF-β1 cells surprisingly displayed enhanced migration speed in 5 μm channels (Figure 3 C).

## DISCUSSION

In this study, we demonstrate that TGF-β1 induced mesenchymal transitions are coupled with changes to the nucleus and cytoskeleton, with reductions in Lamin A/C expression and F-actin G-actin ratios. Moreover, we provide evidence that the nuclear organization is altered with the presences of pores surrounding the nuclear membrane. Further, we demonstrate via AFM mapping that TGF-β1 treatment reduces cell rigidity in both nuclear and cytoskeletal compartments. Notably, the nuclear stiffness was reduced more substantially when compared to the cytoskeleton, which may provide the basis for efficient migration through confined spaces. We then show through microchannel platforms that TGF-β1 treated cells more easily navigate constrained environments by exhibiting more rapid cell migration speed under these conditions.

This study uncovers a novel relationship between mesenchymal transitions and mechanical rigidity and adds to the growing appreciation for the impact of cell mechanics on cancer aggressiveness. Deeper investigations of this relationship may aid in the development of novel diagnostic tools and help identify new targets for pharmacological intervention.

# THE FAILURE MECHANISM OF MOUSE SKIN: A MULTISCALE PERSPECTIVE

**Nathan J. Witt[1], Alan E. Woessner[2], Kyle P. Quinn[2], Edward A. Sander[1]**

[1]Department of Biomedical Engineering,
University of Iowa, Iowa City, IA, 52242, USA

[2]Department of Biomedical Engineering,

USA

## INTRODUCTION

The skin's biomechanical properties are dependent primarily on organization of collagen and other extracellular matrix (ECM) proteins in the dermis. With aging or disease, significant changes to the dermal layer can occur, altering the skin's mechanical function and the mechanobiological conditions necessary for normal ECM turnover. For example, as skin ages the dermal layer experiences fragmentation of the collagenous microstructure [1], a reduction in ECM remodeling [2], and an increased susceptibility to tissue injury and failure [3]. We have combined multiscale experiments of mouse skin with image-based multiscale mechanical models (MSM) that can predict the non-affine fiber kinematics observed under uniaxial tension prior to and during the progression of tissue failure. We are now using these models to understand and predict the age-dependent tissue failure observed experimentally in mouse skin and the corresponding mechanical basis for the loss of mechanical function.

## METHODS

**Experiments:** Dog-bone shape murine skin was gripped in a bioreactor mounted on a multiphoton microscope (MPM) [4]. The samples were notched in the gauge region to promote failure at the location where microstructural MSM imaging occurred. Samples were deformed uniaxially at a rate of 0.2 mm/min until failure. At each half mm of displacement, stretching was paused, and MPM image stacks of the collagen microstructure were acquired to create a mosaic of the region between the inner fiducial markers (Fig. 1). Quantification of tissue kinematics and changes in microscale directional variance (DV) were also made [ 5].

**Simulation:** To-scale image-based multiscale models (MSMs) were created from the geometry of the inner gauge region of the sample prior to testing as in previous work [6,7]. These models link the macroscopic domain of the model to microscopic fiber networks representative of the collagen microstructure via volume averaging theory [8]. A finite element (FE) mesh of 89 linear hexahedral FEs was then generated (one FE through the thickness). At the microscale, the volume fraction of the fibers and their DV approximated the average of the tissue's microstructure at 24% and 0.68, respectively. To represent the skin's non-collagenous matrix an additive stress from a compressible neo-Hookean material (G = 3.0 kPa, ν = 0.1) was included. Failure at the microscale was implemented by removing fibers when their stretch ratios exceeded 2.35. Parameters in the fiber-level constitutive equation were chosen to closely match the experimental loading curve.

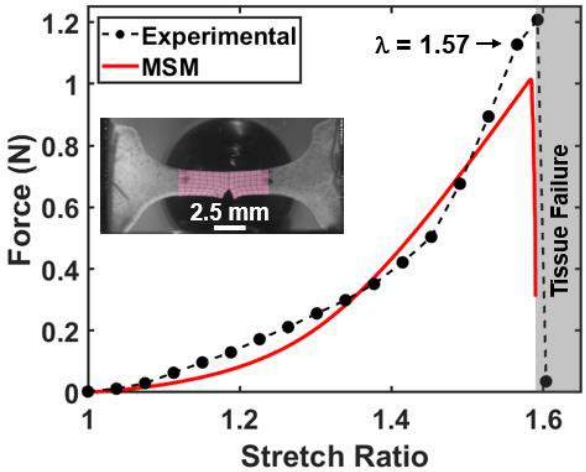

**Fig. 1. The multiscale model predicted a similar force curve and stretch ratio at which failure occurred as in the experiment. The last MPM image of the microstructure occurred at λ = 1.57.**

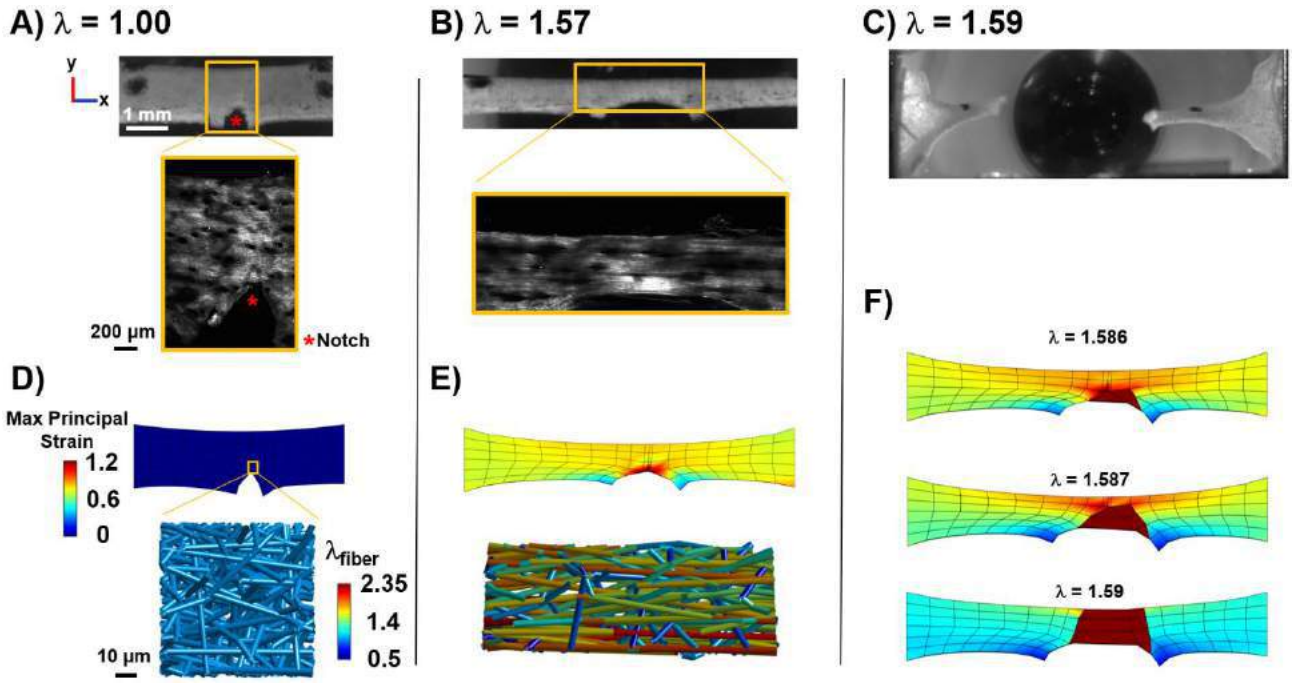

**Fig 2. (A) Macro- and microscale images of a sample show the notch and the organization of collagen. (B) As the tissue stretches collagen aligns in the direction of loading until (C) failure occurs. (D) Model predictions show the maximum principal strain and fiber stretch ratios for experimentally equivalent levels of stretch are concentrated (E) at and around the notch. (F) A zipper like tear from the notch is predicted to occur over a short period.**

## RESULTS

Macroscopically, the model deformed similarly to the sample (Fig. 2), including the manner in which the notch stretched before eventually tearing. Microscopically, and at a location adjacent to the apex of the notch, collagen reorientation into the directional of loading progressively increased while the tissue resisted tearing, consistent with experimental observations. Furthermore, the model predicted the largest maximum principal strains at the notch apex, where failure proceeded with a zipperlike tear at a similar stretch ratio to the experimental results. The mechanism of tear-resistance predicted by the model was a gradual recruitment of network-fibers into the direction of stretch, followed by increasing axial stretch and then rapid fiber failure (Fig. 3). Once the adjacent networks failed, the load propagated transversely to the next adjacent elements and quickly repeated the process until a complete tear formed. Interestingly, average fiber stretch levels were lower in the elements directly above the element adjacent to the notch (*c.f.*, Fig. 3), suggesting that stress shielding was occurring.

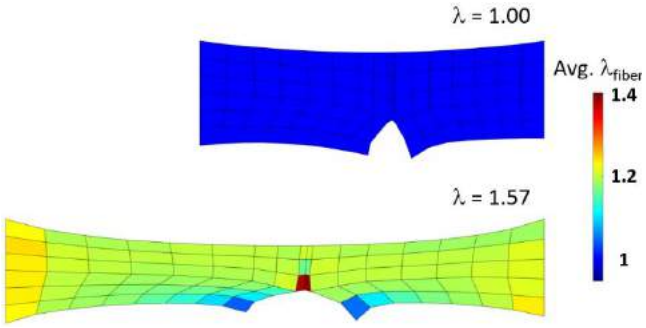

**Fig. 3. The multiscale model predicted large fiber level stretching concentrated at the apex of the notch at λ = 1.57. Comparatively, other regions experienced less fiber-level stretching while fibers at the base of the notch remained relatively unloaded.**

## DISCUSSION

Model predictions produced comparable deformations to the notched sample and reasonably predicted the experimental force at which failure occurred. Tear propagation at the notch was resisted by the ability of the collagen to reorient before recruitment into the direction of tissue stretch. We hypothesize that the increased risk of tissue tearing with aging could arise from a diminished capacity for fiber recruitment. Our combined experimental and computational approach is providing more insight into the mechanical effect of aging on skin and its susceptibility to injury and failure.

# REDUCING SKIN INJURIES INDUCED BY PROLONGED USAGE OF RESPIRATOR MASKS

**R.D. Jobanputra, K.K. Yap, M. Murali, M. Santos, M.A. Masen**

Department of Mechanical Engineering
Imperial College London

## INTRODUCTION

The prolonged use of respirator masks, such as worn by medical staff during the COVID-19 pandemic and by patients with respiratory conditions, can result in a range of skin issues. These include irritation and injuries such as urticaria, skin tears and pressure injuries, ranging from isolated indentation marks to deep tissue level bruising across a larger area (Fig. 1). The cause of such device-related pressure injuries are the prolonged shear stresses inside the tissue as a result of the interaction between skin and the respirator mask. High friction conditions are elevating these shear stresses further: mask-related skin injury is strongly correlated with heavy sweating and the use of high grade, tight-fitting masks [1]. Healthcare organizations have suggested the application of topical creams and hydrocolloid dressings to reduce skin injury [2]. The purpose of this current study is to evaluate these suggestions and offer more specific solutions to mitigate respirator mask-related skin injury.

**Figure 1: Skin damage following excessive PPE-skin interaction. Source: www.instagram.com/covid_nurses**

Our combined experimental and computational approach consists of three phases:

1) Conducting parametric studies to observe the effects of modifying the respirator mask's geometric, material, and interfacial properties on the skin's damage propensity.
2) Assessing short- and long-term skin friction levels against silicone following the application of commercially available moisturizers/lubricants.
3) Use these results to develop tailor-made, optimized lubricants to reduce interfacial shear forces at the skin-PPE boundary.

## A NUMERICAL INVESTIGATION OF FACE MASKS

### Method

A finite element model was developed [3] to assess the local maximum strain energy density (SED) in the dermis as the result of loading. The SED has been shown to be an indicative measure of skin injury occurring [4], whilst the focus of the investigation is the dermis, because skin bruising, and damage typically involve the rupturing of blood vessels in this skin layer. By performing a parametric study, the effect of changes to the design of the face mask in terms of material (elastic modulus, Poisson's ratio), geometry (thickness and area of skin-mask contact) and the interfacial friction coefficient are investigated.

### Results Summary

All investigated mask properties affect the dermal SED. Figure 2 shows the calculated effects of modulus and friction. The SED reduces when employing softer mask materials, whilst the interfacial friction has a very pronounced effect: reducing the friction in the skin-mask interface strongly reduces friction. Additional findings are that the contact area between the mask and skin should be maximized, whilst the use of a material that exhibits incompressible behaviour (e.g. many elastomers) should be avoided.

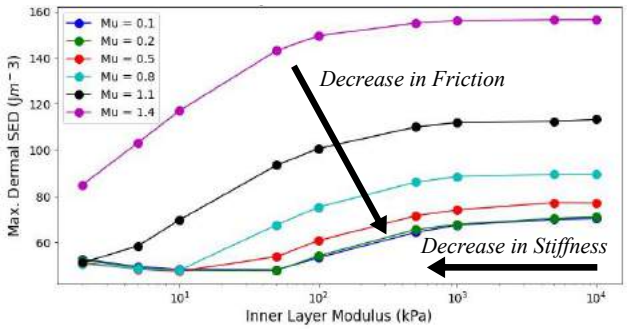

**Figure 2: Effect of changing the modulus and frictional coefficient of the mask's inner layer on the max. dermal SED.**

Friction in the interface between skin and mask was found to be having the largest effect on the SED. There are various methods to reduce the friction, including the application of micro-textures to the mask interface, controlling the humidity in the interface and by applying a lubricant, such as a cream. Whilst the first two options require significant design alterations and are therefore longer-term options, lubricants can be easily implemented.

## ANALYSING COMMERCIALLY AVAILABLE LUBRICANTS

### Method

An extensive literature review identified a range of potential commercially available products that may reduce friction. A custom-built, portable tribometer was used to evaluate the lubricating performance of the substances *in-vivo*. Commercial lubricants were applied to forearm skin before loading the test site with 1.1 N in order to replicate the contact pressures applied by respirator masks. A polydimethylsiloxane (PDMS) probe was rotated against the skin in order to observe friction levels immediately after application of the lubricant, as well as 5 to 10 mins and 4 hours after application.

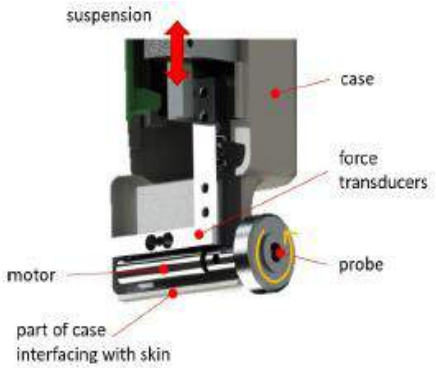

**Figure 3: The portable tribometer**

### Results Summary

Most products provided a strong initial reduction in friction, however only few products provided a long-lasting lubrication effect. Talcum powder, a lubricant comprising a mixture of petrolatum and lanolin, and waxy substance containing coconut oil, cocoa butter and beeswax showed excellent long-term performance. Whilst the short-term performance of the lubricants mainly depends on the shear strength of the applied substance, the longer-term performance also depends on the persistence of the applied product and the response of the skin to the product. Many moisturizing creams function by causing occlusion of the skin, resulting in water retention. This increases friction and should therefore be avoided. Wax-oil lubricants were identified as having the potential to offer significant long term reduced friction, thus reducing the risk of skin injury. The next step is therefore to investigate a range of wax-oil lubricants that provide long-term friction reduction in the skin-respirator interface.

## DEVELOPING AN OPTIMIZED LUBRICANT

### Method

Various wax and oil combinations were created by mixing paraffin wax, beeswax, mineral oil, and olive oil. *In-vivo* friction measurements were performed on 7 participants by sliding a PDMS probe against the volar forearm to simulate the skin-respirator interaction. The maximum static friction coefficient was measured immediately after application of the lubricant, as well as 4 hours after application.

### Results Summary

Figure 4 shows selected results, indicating that endured reduced friction is possible, but this depends strongly on the composition of the lubricant. The friction coefficient is predominantly governed by the ratio of wax and oil, as well as the thermal stability of the wax. Additionally, the absorption of oil into the respirator material must be considered. The best performing lubricant comprises 20 wt% beeswax, 40 wt% olive oil, and 40 wt% mineral oil. In contrast to unlubricated skin, this provides a 87% (P = 0.0006) reduction in friction immediately after application, and a 59% (P = 0.0015) reduction 4 hours after application.

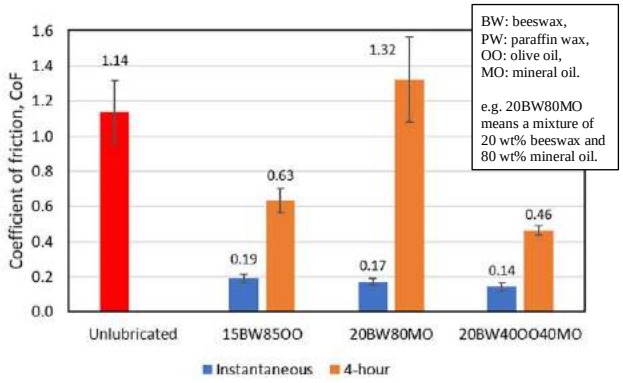

**Figure 4: Instantaneous and 4h friction performance of selected lubricants.**

## DISCUSSION & CONCLUSION

Based on an initial numerical study, friction was identified as the major parameter affecting the strain energy density in the tissue, and therefore directly affecting the risk of injury. Experimental investigations showed that excellent long-term friction performance can be achieved using a lubricant comprising 20% beeswax, 40% olive oil and 40% mineral oil. It needs noting that these results were obtained on the volar forearms of a limited number of subjects. The next step in this project will therefore be the implementation of the developed solutions in a clinical trial using respirator masks.

# COMPUTATIONAL FLUID DYNAMICS MODEL OF EMBRYONIC HEART AND SUPPORTING VASCULATURE ILLUSTRATES TEMPORAL AND SPATIAL VARIATION IN WALL SHEAR STRESS DURING CARDIAC CYCLE

**Kirsten B. Giesbrecht (1), Simone Rossi (1), Boyce E. Griffith (1)**

(1) Department of Mathematics, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

## INTRODUCTION

Intracardiac hemodynamics factors, such as blood velocity, blood pressure, and wall shear stress, are well recognized epigenetic factors contributing to congenital defects[1-11], but the relationship between blood flow and cardiac development remains poorly understood. Congenital heart defects (CHDs) are the most common congenital defect and are present in approximately 1% of newborns[12]. Only 20-30% of CHDs can be traced to genetic or environmental causes, while altered hemodynamic environments account for the pathogenesis of many CHDs[1-6].

Despite the recognition that hemodynamics plays a critical role in the pathogenesis of a variety of CHDs, there has been very little research on investigating regular hemodynamic patterns in both the early cardiac and circulatory systems. Specifically, establishing typical temporal and spatial patterns of wall shear stress, blood velocity, and blood pressure throughout both the embryonic heart, aortic arches, and dorsal aorta is critical to distinguishing between normal and pathogenic hemodynamic patterns, yet has proven to be difficult to obtain experimentally. Particularly, measuring wall shear stress in the developing heart *in vivo* is challenging due to the minuscule size of the developing heart and constant motion of the heart from beating. Often wall shear stress is roughly approximated by averaging blood velocity or pressure data[9,13]. In contrast, computational fluid dynamics models of the blood flow through the early heart and surrounding vasculature can reveal precise patterning of intracardiac wall shear stress. This study establishes a profile of wall shear stress, blood velocity, and blood pressure throughout the developing heart and surrounding vasculature using a computational fluid dynamics embryonic chick heart model.

## METHODS

Chick (*Gallus gallus*) embryos are an ideal system to study hemodynamics during cardiac development. The chick embryonic heart has a similar order of developmental events, such as cardiac looping and valvulogenesis[2,11], as well as a similar size to the fetal human heart, and it is easy to manipulate and visualize[14,15]. A stage HH16 embryonic chick heart and surrounding vasculature including the aortic arches and dorsal aorta were imaged using light-sheet fluorescence microscopy. Next, the images were segmented to obtain three-dimensional anatomic models and meshed. Then, blood was modeled to flow through the model using computational fluid dynamics described by the governing equations:

$$\rho\left(\frac{\partial u}{\partial t} + u \cdot \nabla u\right) = -\nabla p + \nabla \cdot \frac{\mu}{2}(\nabla u + \nabla u^T) \quad (1)$$

$$\nabla \cdot u = 0 \quad (2)$$

In which $\rho$ = 1.06 kg · mm$^{-3}$ is the fluid density, $\mu$ is the dynamic viscosity, and $p$ and $u$ are the fluid pressure and velocity fields, respectively. Where (2), the continuity equation, describes blood as an incompressible fluid. Blood is a non-Newtonian fluid. A rheological study on embryonic avian blood shows that embryonic avian blood can be closely described as a Carreau fluid[16] in which the dynamic viscosity depends on the shear rate, $\dot{\gamma}$ (3).

$$\mu(\dot{\gamma}) = \mu_{\text{inf}} + (\mu_0 - \mu_{\text{inf}})(1 + (\lambda\dot{\gamma})^2)^{\frac{n-1}{2}} \quad (3)$$

In this model, $\mu_{\text{inf}}$ = 3.7 Pa· s is the fluid viscosity at infinite shear rate, $\mu_0$ = 7.4 Pa· s is the fluid viscosity at zero shear, $\lambda$ = 0.033 s is the relaxation time, and $n=0$ is the power index[16]. No slip boundary conditions are imposed on intracardiac and vessel walls ($u$ = 0), and sinusoidal pressure profiles of distinct amplitudes and periods are assigned to the inflow and outflow boundaries.

## RESULTS

Laminar flow is observed with a roughly parabolic velocity profile (Fig. 1). As expected, the peak velocity is at the center of the luminal

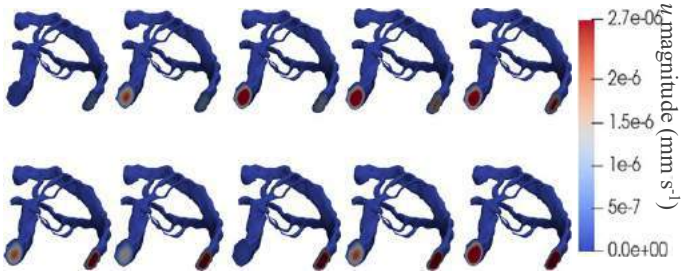

**Figure 1: Laminar flow is observed and velocity fluctuates as the pressure drop changes over time. Each time frame is taken an average of 2.7 ms apart.**

cross section and altered as the pressure drop varies from the imposed dynamic pressure boundary conditions at the inlet and outlet (Fig. 2) throughout the cardiac cycle.

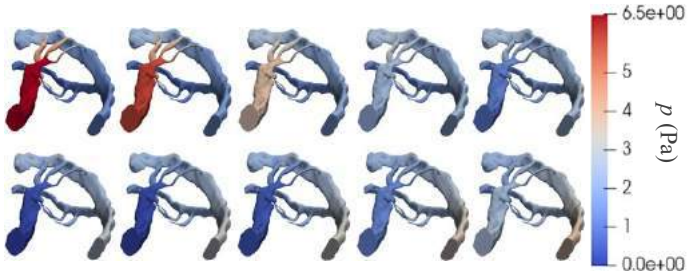

**Figure 2: Distinct sinusoidal pressure functions imposed at the inlet and outlet leads to variation in pressure drop and change in peak velocity over time. Each time frame is taken an average of 2.7 ms apart.**

Peak wall shear stress values are observed in the aortic arches, rather than in the heart (Fig. 3). Wall shear stress varies greatly throughout the embryonic heart and connected vessels, both spatially and temporally.

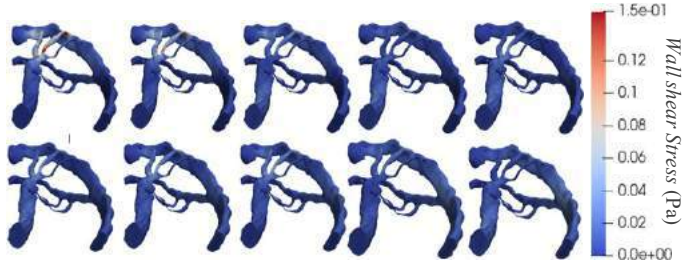

**Figure 3: Wall shear stress during the cardiac cycle had peak values in the aortic arches, rather than in the developing heart. Each time frame is taken an average of 2.7 ms apart.**

## DISCUSSION

This study illustrates the advantage of computational fluid dynamics models in estimating wall shear stress throughout the fluid domain over time. This model demonstrates the variation in wall shear stress both spatially and temporally during HH16 in embryonic chick hearts, which would be lost if averaging wall shear stress over space or time. Accurately describing the minimum and maximum wall shear stress values is critical to examining mechanosensitive developmental pathways since studies have shown that often high levels of shear stress or prologued exposure to shear stress are required to stimulate mechanosensitive pathways[17]. Describing the location, duration, and magnitude of peak wall shear stress values during development stages is critical to understanding the influence of wall shear stress on congenital heart defects.

Additionally, few computational models include both the developing heart and surrounding vasculature in the fluid domain. This model demonstrates that utility of including both the heart and vessels in the fluid domain, as peak wall shear stress was observed in the aortic arches, but could have eventual downstream impacts on heart development. Future directions include expanding this model to a fluid structure interaction (FSI) model to account for the motion from the beating heart.

# LATERAL DISTANCE AS A MEASURE OF BALANCE DURING 90 DEGREE PRE-PLANNED AND LATE-CUED TURNS

**Mitchell A. Tillman (1), Antonia M. Zaferiou (1)**

(1) Biomedical Engineering, Stevens Institute of Technology, Hoboken, NJ USA

## INTRODUCTION

Turning while walking comprises up to 50% of all steps [1]. The increased dynamic requirements of turns relative to straight-line gait likely challenges balance during the turn [2] especially in the frontal plane which requires more active balance control than in the sagittal plane [3]. Turns can be executed in either a pre-planned or late-cued manner, depending on the environment or the movement intent. Pre-planned turns are performed when the cue to turn is perceived early with respect to movement execution. Late-cued turns are required when the cue to turn is perceived later, therefore the movement planning duration is shorter. There is emerging evidence that turn kinematics may be affected by late cues, including increased maximum center of mass (COM) acceleration during the turn [4] and shifting turn execution methods from foot placement based in pre-planned turns to frontal-plane rotation during late-cued turns [5].

Balance control is often modulated by foot placement relative to the COM horizontal position [6], most typically quantified using the margin of stability metric proposed by [7]. However, the inverted pendulum assumption that this method relies on to compute the "extrapolated" COM may not be appropriate during different types of turns [2]. One prior study of pre-planned turning has removed the inverted pendulum assumption, using the "lateral distance" between the edge of the base of support (BOS) and horizontal COM position as a measure of balance [8]. When using either metric to assess balance, the smaller the value, the more precarious the balance state is thought to be, due to the COM being close to or outside of the bounds of the BOS.

The purpose of this study was to understand how frontal-plane balance is regulated during straight-line gait and 90-degree pre-planned and late-cued turns, quantified by the lateral distance between the COM and the frontal-plane lateral edge of the BOS. We hypothesized that minimum lateral distance decreases during late-cued and pre-planned turns vs. straight-line gait, and during late-cued vs. pre-planned turns.

## METHODS

Ten healthy adults (3 f, 7 m; 25.2±4.2 yrs; 73.9±14.8 kg; 1.79±0.1 m) provided informed consent according to the IRB standards. All participants indicated that they were free of pathologies and pain that would impair their ability to walk and turn during daily life.

We simulated the conditions of a grocery store using tape on the floor in a T-shape to emulate two aisles 0.91 m wide forming a perpendicular intersection. A 2.03 m screen at the end of the intersecting aisle served as the aisle's signage. Participants were asked to imagine that they were in a grocery store walking at a comfortable pace in three contexts: walking straight, pre-planned turns, and late-cued turns. First, they walked straight five times down the 10 m aisle. Next, they performed 10 pre-planned turns to the left, followed by 10 late-cued turns to the left. The foot that initiated gait was randomized evenly during turn trials. During pre-planned turns, the participants were instructed ahead of time that they should always turn 90 degrees left to walk down the intersecting aisle because it contained the item of interest, as though they were familiar with its location in the grocery store. In late-cued turns, participants knew there was a 50% chance they needed to turn left into the aisle, as though they were unfamiliar with this store and needed to check the signage to determine whether to turn. The monitor displayed green broccoli indicating to turn, or a red "NO" symbol (circle with line through it) to continue straight. Retroreflective markers were placed on participants to record motion data (200 fps, NaturalPoint, Corvallis, OR USA) and all analyses were conducted in MATLAB (Mathworks, Natick, MA USA)

Lateral distance is defined as the horizontal distance in the frontal-plane of COM position relative to the lateral edge of the BOS. It is negative when the COM is positioned lateral of the lateral edge of the BOS. COM position was computed using a whole-body model [9]. To quantify the BOS, markers on the foot were deemed in contact with the ground and part of the BOS (modeled by a convex hull) if they were

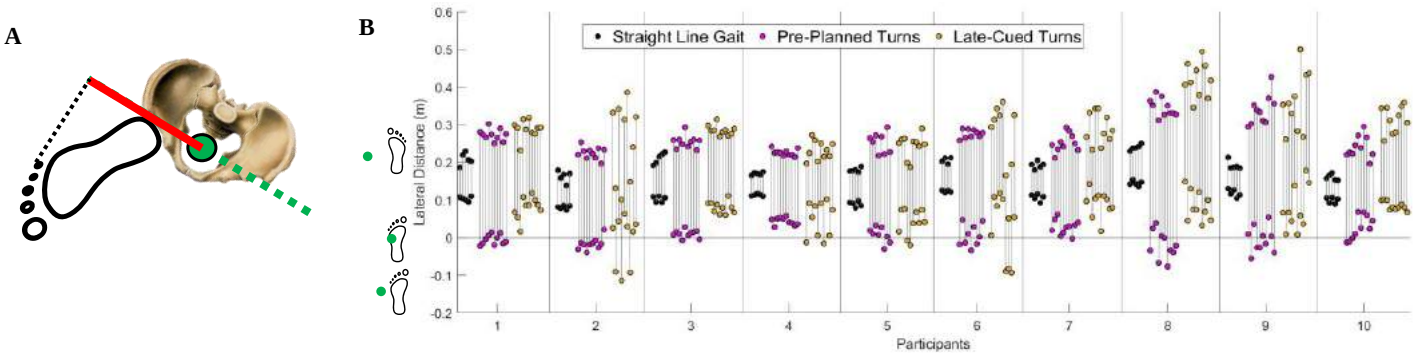

**Figure 1. (A) Horizontal-plane view illustrating the lateral distance. The red line indicates the lateral distance as the horizontal distance from the COM (green circle) to the lateral edge of the BOS in the frontal plane, defined by the pelvis mediolateral axis (green dotted line). (B) Lateral distance max & min for all trials in straight-line gait (black), pre-planned turns (purple), and late-cued turns (gold).**

below the height threshold established during quiet standing. During double support, only the front foot was considered as the COM velocity is always anteriorly directed. To define the frontal plane, we used a pelvis-fixed reference frame computed with respect to the global vertical and pelvis mediolateral axis [8]. Finally, the horizontal distance between the COM position and the lateral edge of the BOS in the frontal plane was the lateral distance (Figure 1A), computed throughout the phase of interest. For straight-line gait, the phase of interest was when the COM was within the center 3 m of the walkway. In turn trials, the turn phase was defined by when the pelvis began and finished rotating (when the pelvis heading angle passed three times the standard deviation of straight-line gait pelvis heading angles). We computed the median lateral distance for each trial and used the sign test to conduct all pairwise comparisons of the three tasks across participants ($\alpha$=0.05).

## RESULTS

Across all trials in all participants, lateral distance ranged from 0.07 to 0.25 m (straight-line), -0.08 to 0.43 m (pre-planned), and -0.11 to 0.5 m (late-cued) (Figure 1B). We found a significant decrease in minimum lateral distance in each turn type compared to straight-line gait (p=0.002 for each), and a larger minimum lateral distance in late-cued turns vs. pre-planned turns (p=0.002). We also found larger lateral distance maxima in each turn type vs. straight-line gait (p=0.002 for each) and in late-cued vs. pre-planned turns (p=0.022). We observed that negative lateral distances during a left turn indicate that the COM is positioned to the left of the left foot during single support, while the large positive lateral distances indicated that the COM was very far to the left of the right foot during single support. Qualitatively, we also observed a much larger variance in many participants' extrema values during late-cued vs. pre-planned turns and straight-line gait.

## DISCUSSION

This study focused on understanding how frontal-plane positioning of the center of mass relative to the base of support relates to balance maintenance during straight-line gait, pre-planned turns, and late-cued turns. We found a significant increase in lateral distance maxima and decrease in minima during each turn type vs. straight-line gait, as the COM translated in the direction of the turn (left) towards the inside (left) foot, which yielded lateral distance minima. COM translation in the direction of the turn (left), away from the outside (right) foot, yielded lateral distance maxima. During turns, lateral distance minima occurred during inside (left) foot single stance phase, and maxima during outside (right) foot single stance.

We theorize that the larger lateral distance minima and maxima in late-cued vs. pre-planned turns relate to distinct roles of each footfall. We found emerging evidence in both pre-planned and late-cued turns that more horizontal-plane body rotation occurs during the inside (left) foot single stance phase, and more COM trajectory redirection occurs during the outside (right) foot single stance phase. Thus, lateral distance minima are associated with more body rotation while the lateral distance maxima are associated with COM trajectory redirection towards the new direction of travel. We postulate that the role of each footfall becomes more distinct during late-cued turns due to the fewer number of footfalls used vs. pre-planned turns (median 3.25 vs. 4, p<0.01).

During late-cued turns, when the outside (right) footfall occurred first after the cue was presented, the outside foot typically redirected the COM trajectory within one single stance phase, leading to large lateral distance maxima. If the inside (left) footfall occurred first, the outside foot made contact with the ground earlier with a "half-step" that also resulted in large lateral distance maxima.

The benefit of increased lateral distance minima during inside (left) foot single stance phase of late-cued turns is still unclear. It may aid in horizontal-plane body rotation and/or facilitate balance.

This study expands on previous work on the role of relative COM and BOS positioning in straight-line gait [6] and pre-planned turns [5] and also provides evidence that late-cued turn execution induces changes in this relationship relevant to maintaining balance control. These findings encourage implementing late cues in turning while walking in clinical balance training paradigms. Future research should examine this phenomenon in balance impaired populations and explore its relationship to other factors of balance control.

## INTRODUCTION

A timely remodeling of the cervix is crucial for a healthy pregnancy because premature cervical softening can result in preterm birth (PTB), a serious medical condition [1-2]. A better characterization of cervical material properties is critical to uncovering the mechanisms behind premature cervical softening. Previous studies of the mechanical properties of the human cervix have characterized its fiber architecture and shown the impact of this architecture on its material behaviors, which manifested a large asymmetry between tensile and compressive loadings [3-5]. *In vivo* study of the human cervix is difficult, however, so only tissues at endpoints (nonpregnant [NP] and term-pregnant [PG]) were assessed. We explore mid-gestation properties using a nonhuman primate model (Rhesus macaque) for its similarities in anatomy and pregnancy physiology [6]. We combine spherical indentation and uniaxial tension tests with digital image correlation (DIC) and inverse finite element analysis (IFEA) to study the evolution of the equilibrium material properties of the macaque cervix throughout gestation.

## METHODS

Tissue preparation: We collected two disk-shaped cervical tissue samples (~4 mm in thickness and 25.25±5.06 mm in diameter) from the internal (proximal) and external (distal) cervical os of a group of Rhesus macaques at four different gestation points of the ~25 week gestation (nonpregnant [NP, n = 3], week 10 [n = 3, *early 2nd], week 16 [n = 3, *early 3rd], and weeks 20 and 23 [n = 7, *late 3rd]; * correspondence to human trimesters). We cut each sample into four quadrants and stored them in a -80°C freezer immediately after. Prior to testing, we equilibrated the samples in a 4°C phosphate-buffered saline (PBS) solution for 18 hours and flattened them using a microtome to create an even testing surface. To enable deformation tracking of the testing surface using DIC, we speckled the samples with water-insoluble ink.

Mechanical testing and data collection: We performed spherical indentation tests using a 2.5-mm diameter indenter and uniaxial tension tests to investigate tissue behaviors under compressive and tensile

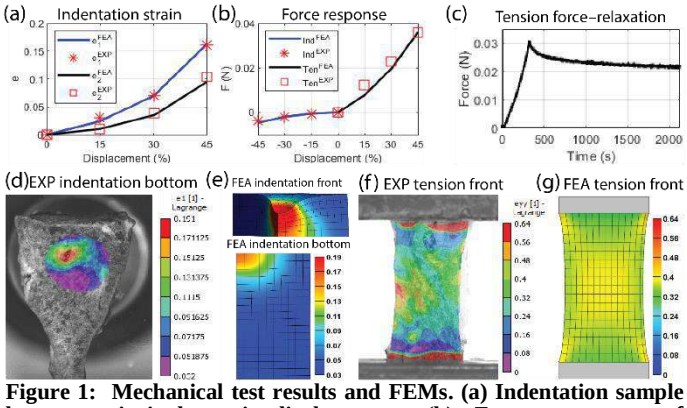

**Figure 1: Mechanical test results and FEMs. (a) Indentation sample bottom principal strain–displacement. (b) Force responses of indentation and tension. (c) Tension force–relaxation response to ramp–hold. (d)(e) The first Lagrange principal strain of one sample under indentation test and FEA. (f)(g) The vertical Lagrange principal strain of the same sample under tension test and FEA.**

loadings. We used a PBS-filled bath for tissue hydration and performed our tests on a universal testing machine (Instron). For both testings, we prescribed a three-level ramp–hold protocol similar to our human study [7]. For indentation, a front camera captured the sample bottom surface reflected by a prism located under the bath chamber; for tension, two orthogonal cameras captured the sample from the front and the side for geometry and surface deformation tracking. We collected force–extension–time data and calculated surface strain using DIC for both testings (Fig. 1(e)(g)).

FEM and IFEA: We created finite element models for both testings, where we modeled the sample and tension grips as rectangular cuboids, and the indenter as a rigid sphere (Fig. 1(f)(h)). For indentation, we adopted a quadrant model to reduce computational complexity (Fig. 1(f)). We meshed the geometries with hexahedron elements and applied

appropriate boundary conditions. We proposed a constitutive material model with an anisotropic continuous fibrous network embedded in an isotropic compressible ground substance. Briefly, the ground substance is described by a bulk modulus $\kappa$. The fiber network is the summation of entropic fibers, individually described by Langevin chain statistics, with the following material parameters: locking stretch $\zeta$, initial fiber stiffness $\xi_f$, preferential fiber direction $\theta$, and fiber dispersion $b$. For fiber direction $\theta$, we adopted a circumferential fiber alignment based on previous literature [8]. To fit our model to the experimental data, we performed IFEA. We used the first and second principal Lagrange strains of the indentation sample bottom surface and the force response of both indentation and tension tests as the fitting objectives, and optimized the four material parameters ($\kappa$, $\zeta$, $\xi_f$, and b) using a genetic algorithm for over 100 generations until the fitness criterion (5%) was reached. For indentation strains, we averaged the data within a 1-mm diameter circle under the indenter as our FEA showed an almost uniform stress distribution across that area.

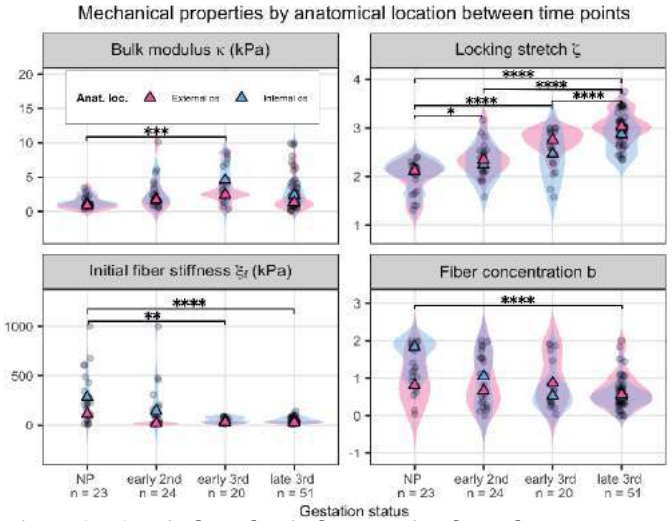

**Figure 2: Cervical mechanical properties throughout pregnancy. Triangles represent the medians of each data series. Statistical significance: * $p \leq 0.05$, ** $p \leq 0.01$, *** $\leq 0.001$, **** $p \leq 0.00001$**

Model validation: To examine the validity of the material model, we compared two forward predictions by the IFEA-fitted model with the experimental data that were not used for IFEA. For indentation, we compared the principal strains of the sample bottom surface within a 2-mm diameter circle under the indenter between the model prediction and experimental data; for tension, we compared the stretch ratios in both the width and thickness dimension between the model prediction and experimental data.

Statistical analysis: We performed a Shapiro-Wilk test to assess the data normality and a Kruskal-Wallis ANOVA to assess the statistical significance among different comparison groups such as gestational time points and anatomical locations (internal vs. external os).

**Table 1: Best-fit material parameters of all samples by IFEA**

| Gestational time point | Bulk modulus (kPa) | Locking stretch | Initial fiber stiffness (kPa) | Fiber concentration |
|---|---|---|---|---|
| NP | 1.37±0.84 | 2.01±0.33 | 272±257 | 1.29±0.61 |
| early 2nd | 3.19±3.68 | 2.33±0.35 | 152±223 | 0.94±0.69 |
| early 3rd | 3.87±2.53 | 2.55±0.43 | 46.2±27.4 | 0.83±0.62 |
| late 3rd | 2.81±2.60 | 2.98±0.33 | 44.3±28.7 | 0.62±0.43 |

## RESULTS

We observe the macaque cervical tissue exhibits (1) a nonlinear anisotropic strain response to the indentation displacement (Fig. 1(a)); (2) a nonlinear force–displacement relationship under both indentation and tension; (3) a large asymmetry between the indentation and tension stress responses (Fig. 1(b)); (4) a force–relaxation response to the ramp–hold displacement under both indentation and tension (Fig. 1(c)).

The best-fit material properties by IFEA are listed in Table 1 and plotted in Figure 2. We find that as gestation progresses: (1) in the early second and the early third trimester, the uterus presents a higher bulk modulus compared to in NP and the late third trimester; (2) the locking stretch increases significantly; (3) the initial fiber stiffness decreases significantly; (4) the fiber concentration (the reciprocal of dispersion) decreases from NP to the late third trimester; (5) values of the locking stretch, fiber stiffness, and the fiber concentration between the internal and external os converge.

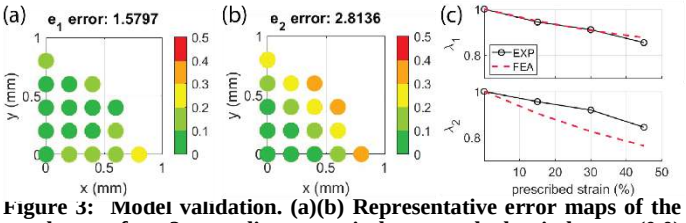

**Figure 3: Model validation. (a)(b) Representative error maps of the quadrant of a 2-mm diameter circle around the indenter (0,0) generated between the principal strain fields of experiment and FEA. (c) Representative stretch ratios of the width ($\lambda_1$) and thickness ($\lambda_2$) compared between the experiment and FEA.**

Our model captures the first and second principal strains of the indentation sample under the indenter well in terms of both magnitude and pattern, and captures the stretch ratios well under tension (Fig. 3).

## DISCUSSION

In this study, we characterized the evolution of the equilibrium mechanical properties throughout gestation using a nonhuman primate cervix. Our results suggest with the progression of pregnancy, cervical collagen fibers become more extensible and compliant. This is likely due to an increase in the proportion of immature crosslinks in the tissue. The ground substance stiffness increases from the beginning to mid-gestation and decreases into late gestation. Throughout pregnancy, the collagen fiber dispersion increases, indicating that its arrangement moves from aligned to randomly oriented; the bulk modulus, fiber stiffness, and locking stretch between the internal and external os all converge, indicating a material homogenization of the organ. These findings agree with previous studies on the human and murine cervix [4,9]. We recognize that the cervical tissue exhibits time-dependent behaviors which are also important for understanding tissue remodeling, such as poro-elasticity under indentation and visco-elasticity under tension. Therefore, a parallel study is currently underway to investigate these time-dependent and rate-dependent behaviors.

## INTRODUCTION

Patients with heart failure with preserved ejection fraction (HFpEF), where an ejection fraction of >50% is maintained, exhibit a wide range of phenotypes [1]. Thus, HFpEF is difficult to diagnose, and the mechanisms of the disease are not well defined. Left ventricular (LV) diastolic dysfunction is a key component HFpEF involving incomplete filling of the LV due to stiffening of the heart [2]. Therefore, good understanding of diastolic dysfunction is needed to uncover aspects of HFpEF. Mathematical modeling facilitates this by allowing the input of patient data to conduct in silico experiments and make predictions that are either difficult to conduct in vivo or otherwise not possible. In this study, we use routine patient data as inputs to conduct total blood volume loading experiments. We chose to use the LV, right ventricle (RV), septum three-segment "TriSeg" model [3] of biventricular function in conjunction with a cardiovascular system (CVS) and atrial elastance model because of the TriSeg model's ability to simulate interventricular dependence. However, when simulating diastolic function with this model, there are discrepancies between the simulated end-diastolic pressure-volume relationship (EDPVR) curve and the expected EDPVR curve. The EDPVR is an indicator of diastolic function, and an upward, leftward shift in the EDPVR of a subject indicates ventricular stiffening. So, being able to appropriately simulate the EDPVR in the model is important to the study of diastolic dysfunction. Thus, in this study we develop a modified TriSeg model that appropriately predicts the EDPVR curve in a healthy subject.

## METHODS

Klotz et al. [4] observed that the EDPVR curve may be represented by the same exponential formulation across species. Hence, they derived a method of normalizing the EDPVR curves by the end diastolic volumes (EDV). From their ex vivo studies on volume-loaded human hearts with different etiologies, they found that the normalized EDPVR curves were nearly identical independent of etiology. We employ their methodology to ensure the EDPVR curve produced by our model has the appropriate behavior.

Our modified TriSeg heart in conjunction with an atrial and CVS model comprises 8 arterial, venous, ventricular, and atrial compartments. The TriSeg model approximates the ventricles as semi-spherical and thick-walled: the LV free wall (LW), the RV free wall (RW), and the septal wall (SW). The CVS model is a 0D electrical circuit analog in which volume is conserved, flow is formulated using Ohm's law, heart valves are diodes, and vascular pressures are linear with respect to volume. This model incorporates routine patient data as inputs (systolic and diastolic blood pressures, heart rate, etc.) for patient-specific predictions; however, for this study we are using representative hemodynamic data as pseudodata.

Nominal parameters are calculated using end-diastolic and end-systolic pressures and volumes to determine passive and active stress scaling parameters, respectively. The passive stress, $\sigma_{pas,i}$, coincides with the formulation from [4], i.e.,

$$\sigma_{pas,i} = k_{pas}\left(L_{s,i} - L_{sc0}\right)^{\gamma} \quad (1)$$

where $i = LW, SW,$ and $RW$, $k_{pas}$ is the passive stress scaling parameter, $L_{s,i}$ is the sarcomere length, $L_{sc0}$ is the contractile element length when active stress is zero, and $\gamma$ is a dimensionless steepness parameter. $L_{s,i}$ depends on an estimated reference midwall surface area, $A_{m,ref}$, that is highly influential and analogous to the size of the heart.

To assess the EDPVR model prediction, we performed two experiments: (1) total blood volume loading, and (2) volume loading with morphological changes to the heart. Experiment (1) was performed on both the TriSeg and our modified model. Volume loading was induced by incrementally increasing the circulating volume. Experiment (2) is an in vivo simulation of the Klotz et al. experiments, where hearts of different sizes, adjusted by scaling $A_{m,ref}$, for both the LV and RV simultaneously, are volume loaded to obtain the EDPVR

curves. Ventricular volumes were normalized to determine normalized EDPVR curves as in [4].

## RESULTS

The TriSeg model exhibits unconstrained increases in chamber volume with minimal increases in pressure with volume loading as seen in **Figures 1A** and **1C**. In panel **C**, the solid curves are the approximation of the EDPVR curve using the Klotz formulation based on a "normal" total blood volume of 5 L. The EDPVR curve of the TriSeg model is linear rather than exponential in shape. In comparison, **Figures 1B** and **1D** show that our modified model exhibits exponential increases in pressure with incremental increases in volume. In fact, the model-predicted EDPVR closely follows the predicted Klotz EDPVR curve without optimization (**Figure 1D**).

Our modified model also exemplifies how Klotz normalization of the EDV across several heart sizes leads to similar normalized EDPVR curves as seen in **Figure 2**. In **Figures 2A** and **2B,** hearts of different sizes are volume loaded to produce their respective LV and RV EDPVR curves, which exhibit differing behavior across heart sizes. **Figures 2C** and **2D** show the same data from **2A** and **2B**, respectively, with normalized EDVs, resulting in normalized EDPVR curves that exhibit similar behavior across the different hearts for both the LV and RV.

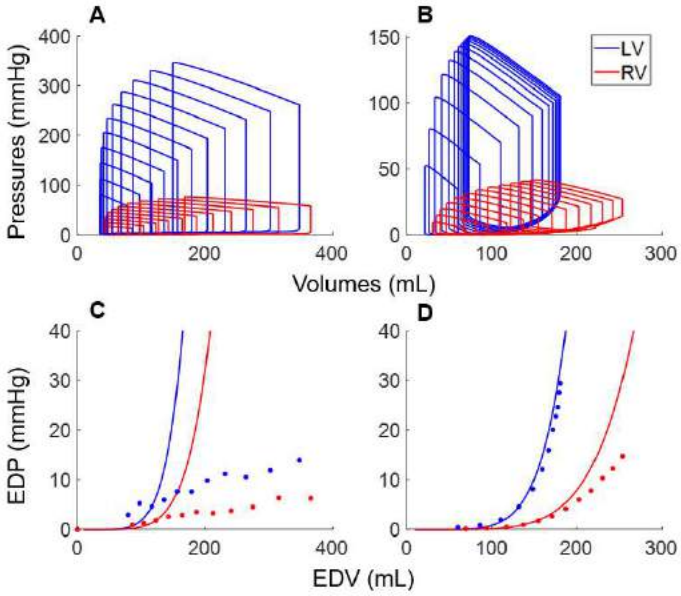

**Figure 1: A. and B. Pressure-volume (PV) loop progressions for the left (LV, blue) and right (RV, red) ventricles with increasing circulating volume for the TriSeg model [3] and the modified model developed in this study, respectively. C. and D. Model-predicted end-diastolic pressure-volume relationship (EDPVR) points from panels A and B superimposed with the Klotz EDPVR curve approximation [4] for the TriSeg and modified models, respectively. EDP – end-diastolic pressure. EDV – end-diastolic volume.**

## DISCUSSION

Our modified model slightly simplifies the passive stress formulation from the TriSeg model while maintaining similar function in the rest of the heart, producing appropriate EDPVR and Frank-Starling relationship curves with our few modifications. The normalized EDPVR curves for the LV and RV exhibit similar behavior (**Figures 2C** and **2D**), agreeing with the ex vivo studies by Klotz that show normalized EDPVR curves following the same curve across different hearts. There is some discrepancy between the approximated Klotz EDPVR curve and our model-predicted points for the RV as seen in **Figure 1D**. However, the Klotz EDPVR curve estimation was determined only for the LV; thus, it is possible that the RV exhibits slightly differing behavior. Regardless, there is a significant improvement of the RV EDPVR in our modified model compared to the TriSeg model.

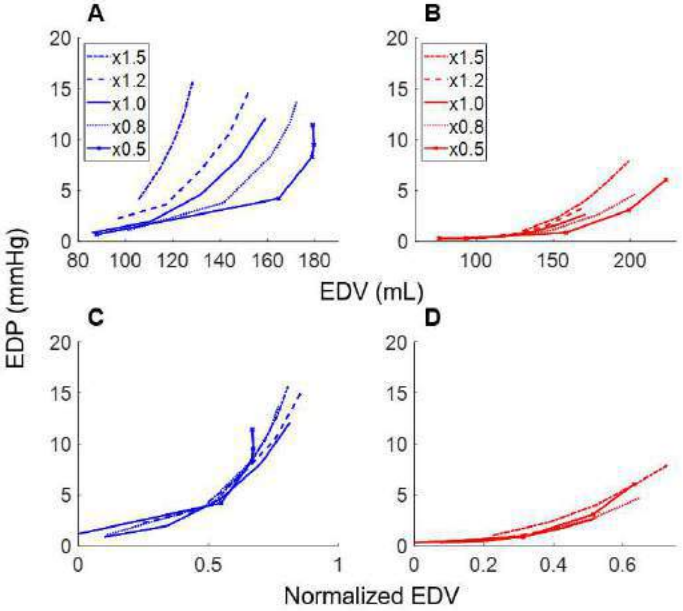

**Figure 2. A. and B. Model-predicted end-diastolic pressure-volume relationship (EDPVR) curves for the left ventricle (LV, blue) and right ventricle (RV, red), respectively, as the midwall reference area, $A_{m,ref}$, for both ventricles are scaled from 0.5-1.5 the normal blood volume. C. and D. EDPVR curves from A and B with normalized end-diastolic volume (EDV). EDP – end-diastolic pressure.**

Limitations of this modeling framework include assumptions and limitations propagated from the TriSeg model, such as the assumptions of spherical ventricular geometry and sarcomere lengths determined from isolated rat cardiac muscles [3]. In addition, in Experiment (2), we perform in vivo simulations whereases the Klotz study conducts ex vivo experiments. Also, we used representative hemodynamic data as input pseudodata for this study; however, our model is formulated for patient-specific modeling in the future.

This study establishes a modified TriSeg model that appropriately predicts a EDPVR in a healthy virtual patient across various heart sizes. Now, with understanding of the diastolic behavior in a healthy patient, we can investigate LV diastolic dysfunction that typically occurs in HFpEF patients.

## INTRODUCTION

Right ventricle (RV) failure is common in the advanced stage of pulmonary hypertension and is a useful predictor of mortality in these patients [1]. It has been noted that the RV becomes stiffer and more anisotropic with pressure overload [2,3]. Mesenchymal stromal cells (MSCs) are highly active paracrine cells with pro-angiogenic function, which has been found in various *in vivo* studies and is beneficial for reversing capillary rarefaction often observed in failing RV [4]. As a result, it is of great clinical interest to offer novel regenerative therapies for various diseases including RV failure.

Previous *in vitro* studies have further shown that MSC behavior and function are dependent on substrate stiffness. However, those investigations are limited to a narrow stiffness range (0.5-200 kPa) that does not encompass the complete range of RV tissue stiffness obtained *ex vivo* [5], especially with regards to RV end-diastolic stiffness at high strains. Only one study has examined the effect of anisotropy on MSC pro-angiogenic function, but the substrate stiffness was not quantified [6]. Thus, it remains unclear how RV-specific mechanics affect MSC pro-angiogenic properties. Motivated by the knowledge gaps and clinical needs, the aim of this study is to investigate the effects of the RV-like stiffness and anisotropy on MSC pro-angiogenic function. We hypothesize that the isotropic, diseased RV-like stiffness leads to the highest pro-angiogenic potential in individual MSCs.

## METHODS

To fabricate scaffolds, polyester urethane urea (PEUU) [7] was dissolved (6 or 12 w/v%) in hexafluoro-2-propanol and then electrospun into fibrous scaffolds using a custom electrospinning apparatus with a rotating mandrel (speed: 100-1250 rpm; diameter: 7.46 cm). In some scaffolds, 6% PEO was blended with the PEUU solution to alter nanofiber fusion and anisotropic behavior. The fixed parameters used for electrospinning all scaffold groups include: voltage: 16 kV, injection flow rate: 1.5 mL/h, and distance from collector: 9-10 cm. The Young's moduli ($E$) of the scaffolds along the fiber and cross-fiber directions were obtained by biaxial tensile tests at room temperature after 24 h of phosphate buffered saline soak. The degree of anisotropy was quantified as the ratio of the $E$ in the fiber direction to the $E$ in the cross-fiber direction (anisotropy index (AI)). Human bone marrow MSCs through passage 6 were cultured in 24-well plates at 10,000 cells/cm$^2$ on the sterilized scaffolds or tissue culture plastic (TCP). Human vascular endothelial growth factor (VEGF) expression in the MSC-derived conditioned medium (CM) was determined by ELISA (Invitrogen) after 48 h. Cell counts were determined via hemocytometer at 48 h. The overall pro-angiogenic potential was then evaluated by a tubulogenesis assay. Human umbilical vein endothelial cells (HUVECs) were plated on Geltrex (Thermo-Fisher) and cultured in collected MSC-derived CM at 20,000 cells/well (96-well plate). Images were taken of neovessel (tube) formation after 22 h and the total tube length was used as an indicator of angiogenesis. Data are presented as mean ± SEM. A one-way ANOVA (the data were normally distributed) and the appropriate post-hoc tests were performed: Tukey (equal standard deviations) or Dunnett's T3 (variable standard deviations). $p<0.05$ was statistically significant.

## RESULTS

To represent the end-diastolic stiffness of the RV, we fabricated the scaffolds with the Young's modulus in the fiber direction at ~550 kPa to mimic healthy RVs and at ~1.1 MPa to mimic diseased RVs [2,3]. Moreover, the scaffolds at the same stiffness range were fabricated with and without anisotropy to decouple the effects of stiffness and anisotropy on MSC behavior. Mechanical test data confirmed the mechanical differences in these scaffold groups (Table 1). The Norm scaffold groups had significantly lower Young's moduli

(p<0.05) than the Fail scaffold groups. The anisotropic index was ~1.0 in the isotropic groups and ~1.7 in the anisotropic groups, with the two anisotropic groups showing significantly (p<0.05) larger ratios versus isotropic groups with the same stiffness range.

**Table 1. Four electrospinning scaffold groups with altered stiffness that represent healthy and diseased RVs at end-diastole, with or without anisotropy. *p<0.05 vs. Norm group within the same anisotropy; §p<0.05 vs. Iso group within the same stiffness range.**

| | Isotropic (Iso) | Anisotropic (Ani) |
|---|---|---|
| **Normal RV Stiffness (Norm)** | *E*: 580±42 kPa<br>AI: 1.0±0.16 | *E*: 532±73 kPa<br>AI: 1.9±0.21§ |
| **Failing RV Stiffness (Fail)** | *E*: 1269±144 kPa*<br>AI: 1.0±0.09 | *E*: 983±83 kPa*<br>AI: 1.5±0.09§ |

After 48 h of culture on the scaffolds or TCP, we measured the total VEGF concentration in CM and the VEGF expression per cell (Fig. 1). There was a trend (p=0.09) of higher total VEGF production in the Norm&Ani group compared to the Norm&Iso group (Fig. 1A). But when we examined the VEGF production per cell, the Fail&Iso group had the largest value among all scaffold groups, and it had significantly higher VEGF production per MSC than the Norm&Iso group (p<0.05, Fig. 1B). Lower MSC counts in the Fail&Iso scaffold group were noted, although the difference was insignificant, and all other three groups had similar number of cells (data not shown). Finally, the stiffer scaffolds (Fail&Iso, Fail&Ani) tended to have higher VEGF production per cell compared to the soft scaffolds (Norm&Iso, Norm&Ani) in general (Fig. 1B).

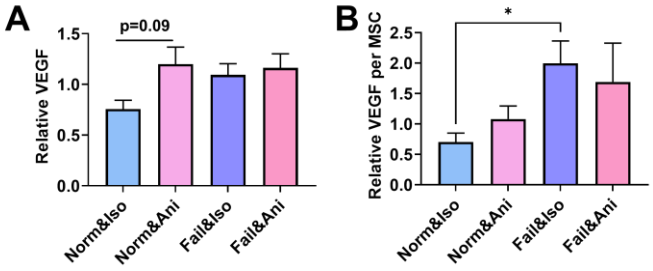

**Figure 1: Effects of stiffness and anisotropy on total VEGF production and VEGF per MSC normalized with TCP after 48 h. (A) Trend of higher total VEGF expression in Norm&Ani group versus Norm&Iso group. (B) VEGF expression per MSC is significantly higher in Fail&Iso group compared to Norm&Iso group. *p<0.05.**

Since there are other pro-angiogenic factors produced by MSCs besides VEGF, we further examined the overall pro-angiogenic potential of the MSC-derived CM by examining *in vitro* tube formation of HUVECs. There were no significant differences between the groups in terms of the total tube length (Fig. 2A). But when examining the total tube length formed per MSC, different pro-angiogenic potentials were found for MSCs cultured in different mechanical conditions. MSCs from the Fail&Iso group had the most pronounced pro-angiogenic function and led to significantly more pro-angiogenic potential compared to MSCs from the Norm&Iso group (p<0.05, Fig. 2B). There was also a strong trend (p=0.07) of greater pro-angiogenic potential made by MSCs from the Fail&Iso group compared to the Fail&Ani group (Fig. 2B). Therefore, similar to the VEGF production per MSC result (Fig. 1B), the Fail&Iso scaffold's mechanical environment led to the strongest pro-angiogenic potential for individual MSCs.

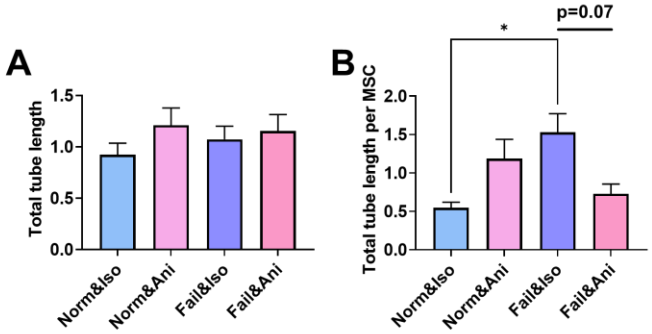

**Figure 2: (A) Total tube length and (B) total tube length/MSC normalized with TCP after 22 h. *p<0.05.**

## DISCUSSION

In this study, we assessed how these two mechanical factors - RV-like end-diastolic stiffness and anisotropy - affect MSC pro-angiogenic potential. By fabricating PEUU matrices that had varied matrix stiffness and anisotropy, we were able to use this *in vitro* platform to delineate the MSC behavior in response to the varied mechanical conditions.

From our data on the collective and individual MSC's pro-angiogenic properties, we found that this paracrine function and cell proliferation were not parallel. Despite the enhanced pro-angiogenic function per MSC in the Fail&Iso group (Figs. 1B&2B), the overall pro-angiogenic potential was limited by the low cell counts in this scaffold group. Actually, this group tended to have the lowest cell numbers after 48 h of culture, which indicated minimal cell proliferation. The 'opposite' effects of this mechanical environment (isotropic, stiff RV) on cell proliferation and pro-angiogenic function seemed to mirror that of the mechanical regulation on MSC phenotype and proliferation observed in TCP culture (versus hydrogel/polydimethylsiloxane) [8,9].

Moreover, there may be some synergistic effect of matrix stiffness and anisotropy on individual MSC behavior, but the effect is stiffness-dependent. In all experimental data (total VEGF production, VEGF/cell, tube length, and tube length/cell) from the Norm groups (when the stiffness was that of healthy RVs), the addition of anisotropy consistently led to a trend of higher value compared to the isotropic scaffold. But in the data from Fail groups (when the stiffness was that of diseased RVs), the 'beneficial' effect of anisotropy disappeared and the tube length result suggested a reduced pro-angiogenic function in anisotropic matrix.

Taken together, our results originally reveal the evidence of mechanical regulation of the MSC angiogenesis property in the context of RV mechanics and tissue anisotropy, which will help to inspire the development of tissue-specific, MSC-based therapies for heart failure patients.

## INTRODUCTION

Multipotent mesenchymal stromal cells (MSC) from different sources such as bone marrow and adipose tissue are highly promising candidates for tissue engineering and regenerative medicine. Despite having multi-differentiation ability, immunomodulatory and trophic properties, scalable application of MSC at the clinical endpoint is limited. To achieve a clinically relevant number of MSCs, a small amount of autologous MSCs must be expanded to millions of MSCs. However, in vitro expansion of MSCs results in gradual differentiation into a heterogeneous population of senescent osteoprogenitor cells through activation of the Runx2 pathway, causing the loss of MSC attributes [1]. Mechanics of the culture substrate is a potential candidate among several factors that might promote this loss of the MSC phenotype [2]. Cells exert contractile forces on their culture substrate and the substrate elasticity can alter the cell behavior, promoting the formation of cell-cell contacts [3]. We hypothesize that neighboring cells can communicate by force transduction through the soft growth substrate to maintain the MSC phenotype and stemness thus resulting in population level homogeneity. Our objective in this work is to understand how substrate mechanics in combination with seeding density plays a role in maintaining the MSC phenotype by examining nuclear morphology and chromatin architecture in human BM-MSCs.

## METHODS

*Cell culture*: Primary human MSC derived from bone marrow (BM-MSC) were cultured (PT-2501, Lonza). Passage 3 and 4 cells were cultured on either a soft PDMS substrate (Sylgard 527, Dow) or a stiff substrate: polymer with same mechanical property as tissue culture plastic, both coated with type I collagen for MSC adhesion.

*Imaging and analysis of nuclear morphology and chromatin architecture:* Cells were fixed with 4% PFA, washed in 1X PBS, and stained with DAPI (Thermo Fisher) then imaged using a confocal microscope (Zeiss LSM 980). Custom MATLAB code was used for the nuclear morphology analysis. Chromatin segregation index was calculated using a previously established technique [4].

*Statistics*: Student's t-test was used to compare different groups. *p value of $<0.05$ represents statistically significant difference. Heterogeneity of MSC population level phenotype was quantified using the interquartile range (IQR) of the data (Q3-Q1).

## RESULTS

At earlier passages, most adherent BMSCs are small, spindle shaped, exhibiting the well characterized MSC phenotype. Figure 1A demonstrates the significant cell spreading MSCs experience over passaging on the stiff TCP substrate, showing a more flattened, fibroblast-like phenotype with considerable actin stress fiber formation. Meanwhile cells on the soft substrate generally maintained the spindle-like shape and diffuse actin in the cytoskeleton. Upon quantification of nuclear shape parameters (Figure 1B), nuclei on the stiff substrate were significantly larger and more circular from P3 to P4 becoming more fibroblast-like. When cells were cultured on the soft substrate, nuclei did not show any significant change in area but became significantly more elongated, demonstrating the typical MSC phenotype. The MSC phenotype was preserved over a single passage on the soft substrate whereas cells became increasingly more fibroblast-like, and more heterogeneous on the stiff substrate.

Next, we examined how substrate stiffness in conjunction with seeding density can affect the nucleus phenotype and chromatin architecture. Cell density had a significant effect on nuclear morphology with 5-10,000 cells/cm2 having the most MSC-like phenotype whereas the low seeding density of 100 cells/cm2 had an extremely wide range of nucleus morphologies (Figure 2 A,B) spanning from fibroblast to MSC phenotypes. Examining the intranuclear chromatin architecture showed that chromatin segregation was significantly affected by seeding density, with cells grown on the soft substrate at high seeding densities showing overall more chromatin segregation (Figure 2 C,D).

SB³C2022-128

The stiff substrate and a low seeding density resulted in a diffuse chromatin architecture, deviating from MSC nuclear phenotype.

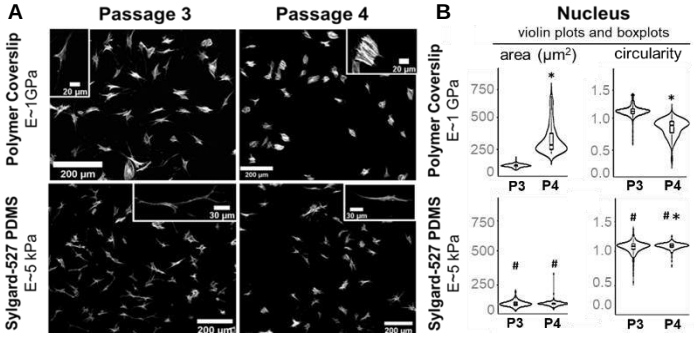

**Figure 1. (A) MSC phenotype was maintained on the soft gel over one passage. (B) Violin plots of nuclear geometrical parameters from one technical replicate. *represents significance between passages and # represents significance between substrates. n = 1000.**

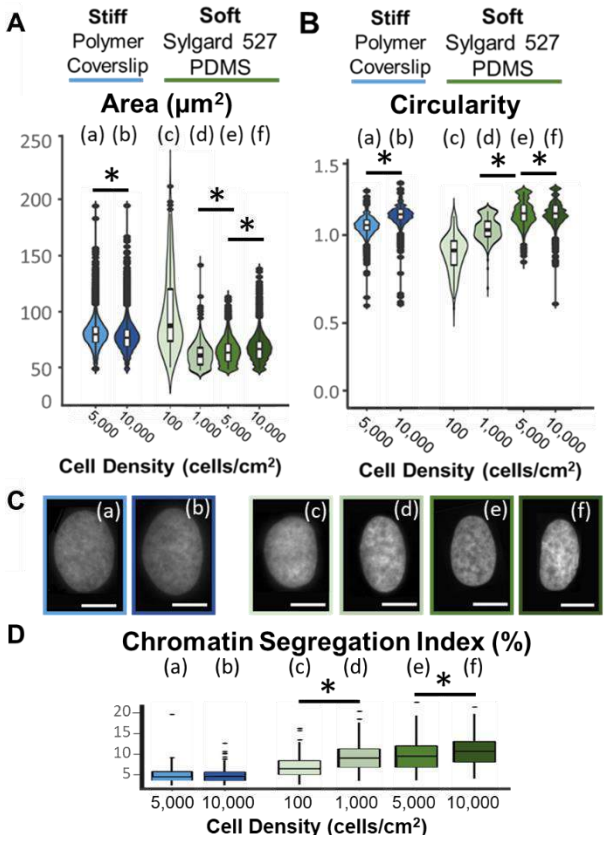

**Figure 2. (A,B) Violin plots of nuclear geometrical parameters from one technical replicate. n = 1000 (C) Representative nuclei from each experiment group to demonstrate the degree of chromatin condensation. (D) Quantification of the percent chromatin segregation within nuclei. n = 40.**

To understand if better substrate-mediated cell-cell mechanical communication leads to a more homogeneous population of MSCs we examined the IQR values for the nuclear shape quantification. It was found that a soft substrate leads to decreased heterogeneity in passage 4 (Figure 3A). One of two mechanics inhibitors that either stopped further actin formation or blocked actin-myosin contractions were applied to P4 cells grown on a stiff substrate (results not shown). This disruption of F-actin led to the same improved nucleus morphology changes as cells grown on a soft substrate, but surprisingly had no significant effect on the MSC population heterogeneity. This suggests that stiffness-dependent heterogeneity does not rely on actin formation and actin-myosin contractions as we previously thought. Seeding density did not have a largely significant effect on maintaining a consistent MSC-like population at densities between 1,000-10,000 cells/cm$^2$. However, when cells were grown at a very low seeding density of 100 cells/cm$^2$, the nuclear phenotype was extremely varied as indicated by the large IQR values, signifying higher heterogeneiy.

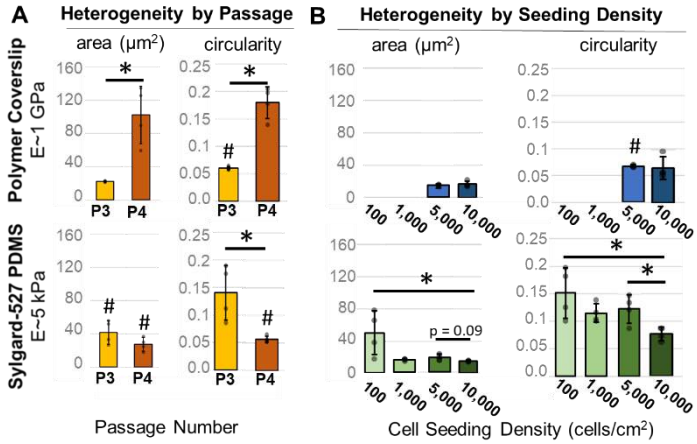

**Figure 1. Soft substrates in P4 and with a higher seeding density show a decreased heterogeneity. IQR values from 4 technical replicates for cells grown on stiff and soft substrates over a single passage (A) or with varying cell seeding densities (B).**

## DISCUSSION

In vitro expansion of MSCs results in gradual differentiation into a heterogeneous population of senescent osteoprogenitor cells through activation of the Runx2 pathway, that do not retain MSC attributes. Culturing MSCs on a soft substrate to avoid unintended differentiation may aid in maintaining a homogeneous population during in vitro passaging. We saw that when cells are cultured on soft substrates at a high enough cell density, they display the classic MSC phenotype and the soft culture substrate helps aid in maintaining this phenotype over a single passage, appearing to be a relatively homogeneous population of MSCs. Surprisingly, cell seeding density had a significant effect on the chromatin architecture. The open chromatin architecture seen on soft substrates at higher cell seeding densities is associated with transcriptional activation and is a hallmark of stem cells [5]. This is consistent with the literature in other cell types that also exhibit a uniform cell response in extremely soft environments that show a small cell diameter that are multipotent [1,5]. Consistent with our study results' small diameter and open chromatin architecture displayed by MSC when cultured on a soft substrate, we anticipate that MSCs will also demonstrate an increase in pluripotency markers. Further mechanistic and MSC based preclinical studies might reveal how the substrate mechanics functionally alters the MSC, opening novel possibilities to intervene such mechanism.

## INTRODUCTION

Bone osteoporotic fractures have been a great concern as its high prevalence in US population aged older than 50 or postmenopausal women [1]. Current clinical prognosis/diagnosis of bone fracture risks mainly relies on DXA image-based measurement of bone mineral density (BMD). However, BMD can only explain around 50% of variance in bone fractures as such fractures are also sensitive to the deterioration of trabecular bone microstructure. Recent successes of deep learning in biomedical image-based diagnosis/prognosis of diseases have motivated us to investigate the possibility of using Deep learning (DL) techniques to build high-fidelity predictive models to assess bone fracture risks. Our previous study showed that a high-fidelity DL model could be trained using 2D DXA images in multiple three-orthogonal projections to predict the histomorphometric parameters and elastic behavior of trabecular bone [2,3]. However, it is impractical to acquire three-orthogonal DXA images in clinical applications. As an alternative, quantitative computed tomography (QCT) images, which is a common 3D image modality for measuring BMD, could be used to train a DL model to evaluate 3D bone microarchitecture and anisotropic elastic behavior. Thus, this study was performed to determine whether a high fidelity QCT image-based DL model could be trained to predict the histomorphometric parameters and anisotropic elastic behavior of trabecular bone.

## METHODS

A total of 1,015 trabecular bone cubes (6mm × 6mm × 6mm) were acquired from six human cadaver proximal femurs of diverse ages (ranged from 22 to 79 years old, with an average age of 48.5 years) and different genders (three females and three males). These proximal femurs were scanned using a micro-CT system (SkyScan 1173) with a resolution of 35 μm, which is sufficient to capture the microstructural details of trabecular bone. The digitized trabecular cubes were then analyzed using ImageJ and BoneJ to determine the following six histomorphometric parameters: Degree of Anisotropy (DA), Connectivity Density (Conn.D), Bone surface (BS), Structure Model Index (SMI), Bone Volume Fraction (BV/TV) and Trabecular Thickness (Tb.Th). Furthermore, the anisotropic elastic behavior of trabecular bone was assessed using the apparent stiffness tensor. Firstly, trabecular cubes were aligned with the three orthogonal principal directions defined using their fabric tensor (**Fig. 1**). Secondly, three uniaxial compression tests in the three principal axes and three pure shear tests in the three principal planes were conducted using ABAQUS (2019/Standard software package) to assess the apparent elastic modulus ($E_{apparent}$), apparent shear modulus ($G_{apparent}$), and the Poisson's ratio of each trabecular cube in its three principal directions. Lastly, the apparent stiffness tensor of trabecular bone cubes can be described using the following equations:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl} \tag{1}$$

$$C = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{21} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{31} & C_{32} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} = \begin{bmatrix} \frac{1}{E_1} & \frac{-\nu_{21}}{E_2} & \frac{-\nu_{31}}{E_3} & 0 & 0 & 0 \\ \frac{-\nu_{12}}{E_1} & \frac{1}{E_2} & \frac{-\nu_{32}}{E_3} & 0 & 0 & 0 \\ \frac{-\nu_{13}}{E_1} & \frac{-\nu_{23}}{E_2} & \frac{1}{E_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{G_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{G_{31}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{G_{12}} \end{bmatrix}^{-1} \tag{2}$$

Where $\sigma_{ij}$ is the stress tensor, $\varepsilon_{kl}$ is the strain tensor, $C$ is the apparent stiffness tensor, $\nu_{12}$, $\nu_{13}$, $\nu_{21}$, $\nu_{23}$, $\nu_{31}$, $\nu_{32}$ are the Poisson's ratio in the orthotropic principal planes, and $E_1$, $E_2$, $E_3$ are the elastic modulus in three principal directions, while $G_{23}$, $G_{31}$, $G_{12}$ are the shear modulus in the three orthotropic principal planes, respectively. It should be noted that the trabecular cubes with significantly low BV/TV and trabecular number, as well as significantly high trabecular separation will be removed from assessing the apparent stiffness tensor, as some unknown errors will occur under these extreme conditions, thus influencing the calculation of apparent stiffness tensor of trabecular cubes.

Then, simulated QCT images of trabecular cubes with the resolution of 0.33 × 0.33 ×0.33 $mm^3$/voxel were digitally generated from the micro-CT images of the trabecular cubes that were aligned with the three orthogonal principal directions using ImageJ. A 3D convolutional neural network (CNN) model with subsequent 3D convolution filters and pooling layers was developed and trained to predict the histomorphometric parameters and apparent stiffness tensor of trabecular bone cubes using the simulated QCT images. During the training process, 85% of the entire dataset were randomly selected from as the *training data*, which include the QCT image and corresponding microarchitectural properties and apparent stiffness tensor for each trabecular cube. Of the training date, 80% were used for training the model and 20% for verifying the performance of the 3D CNN model. The remaining 15% of the entire dataset were used as the *testing dataset* to evaluate the efficacy of the 3D DL model in prediction of the histomorphometric parameters and apparent stiffness tensor, and compared with our previous DXA image-based DL models [2,3]. Among the DXA models, **Model 1** used nine projections of DXA images, whereas **Model 2** used only one projection of DXA image.

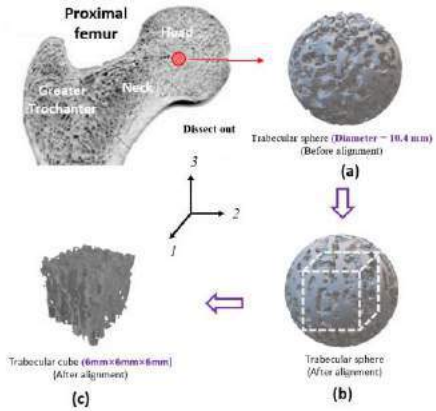

**Figure 1: Schematic representation of dissecting out trabecular bone cubes**

## RESULTS

In order to evaluate the efficacy of the QCT-based DL model in prediction of the histomorphometric parameters and apparent stiffness tensor of trabecular bone, linear regressions were performed to determine the Pearson correlation coefficients ($R^2$) between the DL model predicted and the measured histomorphometric parameters (**Table 1**) and elastic constants of the apparent stiffness tensor (**Table 2**). The results indicated that QCT-based DL model had high accuracy in predicting the histomorphometric parameters BV/TV, BS, Tb.Th and SMI, with the Pearson correlation coefficient ($R^2$) being 0.98, 0.95, 0.86 and 0.85, and had reasonable accuracy in prediction of Conn.D ($R^2$ =0.76) and DA ($R^2$=0.72). Furthermore, the QCT-based DL model demonstrated a high fidelity in predicting the apparent stiffness tensor, with Pearson correlation coefficients ($R^2$) being 0.94, 0.94, 0.94, 0.98, 0.97,0.97, 0.93, 0.94 and 0.93 for $C_{11}$, $C_{22}$, $C_{33}$, $C_{44}$, $C_{55}$, $C_{66}$, $C_{21}$, $C_{31}$ and $C_{32}$, respectively, thus verifying that QCT-based DL model could have high fidelity in predicting the histomorphometric parameters and anisotropic elastic behavior of trabecular bone.

**Table 1: Prediction accuracy in histomorphometric parameters using QCT-based DL model and DXA-based DL models**

| DL model | Pearson Correlation Coefficient (R2) | | | | | |
|---|---|---|---|---|---|---|
| | BV/TV | BS | Tb.Th | SMI | Conn.D | DA |
| QCT-based DL model | 0.98 | 0.95 | 0.86 | 0.85 | 0.76 | 0.72 |
| DXA-based DL model 1 | 0.99 | 0.94 | 0.95 | 0.76 | 0.69 | 0.64 |
| DXA-based DL model 2 | 0.90 | 0.87 | 0.90 | 0.62 | 0.61 | 0.61 |

Note: DXA-based DL model 1 uses nine projections of DXA images as input
DXA-based DL model 2 uses one projection of DXA images as input

**Table 2: Prediction accuracy in apparent stiffness tensor using QCT-based DL model and DXA-based DL models**

| DL model | Pearson Correlation Coefficient (R2) | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | C11 | C22 | C33 | C44 | C55 | C66 | C21 | C31 | C32 |
| QCT-based DL model | 0.94 | 0.94 | 0.94 | 0.98 | 0.97 | 0.97 | 0.93 | 0.94 | 0.93 |
| DXA-based DL model 1 | 0.94 | 0.96 | 0.94 | 0.95 | 0.95 | 0.97 | 0.93 | 0.90 | 0.91 |
| DXA-based DL model 2 | 0.80 | 0.83 | 0.83 | 0.86 | 0.84 | 0.87 | 0.77 | 0.75 | 0.73 |

Note: DXA-based DL model 1 uses nine projections of DXA images as input
DXA-based DL model 2 uses one projection of DXA images as input

## DISCUSSION

This study investigated the feasibility of using QCT-based DL model techniques to predict the histomorphometric parameters and anisotropic elastic behavior of trabecular bone cubes. The results provide convincing evidence that QCT images assisted by DL model have great potential for clinical prognosis of osteoporotic bone fracture risks.

The results (**Table 1**) showed that QCT-based DL model had significantly higher accuracy ($R^2$=0.72-0.98) than that ($R^2$=0.61-0.90) of DXA image-based DL model (using one projection of DXA image as input) in prediction of BV/TV, BS, SMI, Conn.D and DA (**Table 1**). It is not a surprise that the QCT-based DL model could have high fidelity in prediction of the microstructure of trabecular bone since QCT images contain 3D information whereas DXA is 2D. Our previous results showed that the accuracy of DXA-based DL model in predicting histomorphometric parameters will increase as the number of orthogonal projections of DXA increase. Nonetheless, QCT-based DL model still have higher accuracy in predicting SMI, Conn.D and DA and have similar accuracy in predicting BV/TV and BS compared with those of DXA image-based DL model with nine projections (**Model 2**). These results suggest that QCT-based DL model always has a higher fidelity in prediction of histomorphometric parameters of trabecular bone compared to the DXA image-based DL models.

The QCT-based DL model also show significantly higher accuracy ($R^2$=0.93-0.98) than that of DXA-image based DL models ($R^2$=0.73-0.87 for Model 2 and $R^2$=0.90-0.97 for Model 1) in prediction of the apparent stiffness tensor of trabecular cubes. These results indicate that QCT-based DL model has a higher fidelity in prediction of anisotropic elastic behavior of trabecular bone cubes than DXA image-based DL model.

In Summary, it is clinically impractical to acquire orthogonal projections of DXA images, thus limiting the application of DXA image-based DL model to clinical prognosis of bone fracture risks. However, the results of this study indicate that QCT-based DL model could be an alternative to DXA image-based DL model in predicting bone microarchitecture and anisotropic elastic behavior.

## ACKNOWLEDGEMENTS

The authors are grateful of Mr. James Schmitz at UT Health San Antonio for technical assistance in acquisition of micro-CT scans of human cadaveric proximal femur samples.

# FUNCTIONAL HYPEREMIA INCREASES INFLUX OF CEREBROSPINAL FLUID TO THE BRAIN

**Yiming Gan (1), Stephanie Holstein-Rønsbo (2), Douglas H. Kelley (1), Maiken Nedergaard(2,3)**

(1) Department of Mechanical Engineering, University of Rochester, Rochester, NY, USA

## INTRODUCTION

Neurons have little storage of energy metabolites, and are, therefore, highly dependent on tight regulation of blood flow. Upon neuronal activation, local consumption of metabolites increases. In response, cerebral blood flow increases to supply oxygen and metabolites to the depleted area, a process called neurovascular coupling or functional hyperemia. The neurovascular coupling involves arterial dilation, which displaces cerebrospinal fluid (CSF) and drives flow in perivascular spaces(PVS) around cerebral arteries. Flows of CSF in PVSs are believed to couple to a network of brain-wide fluid transport pathways known as the glymphatic system, which facilitates waste clearance [1]. It was speculated that reciprocal interchanges of blood and CSF volumes within the rigid cavity of the skull were responsible for initiating the movement of CSF[2]. Here, we hypothesize large vasomotions as a major driver of CSF flow in the perivascular space.

In this study, we employ a complementary range of optical imaging approaches to assess the effects of unilateral whisker stimulation on glymphatic system fluid transport of mice. In an intact skull preparation, we find via transcranial imaging that sensory stimulations result in a larger glymphatic influx to the stimulated hemisphere. Additionally, we find that functional hyperemia, induced by puffing air across the whiskers for 20 minutes, causes faster clearance of fluorescent tracer from the stimulated hemisphere. Using optogenetics, we induced artery constriction and found that manipulation of arterial diameter can accelerate glymphatic influx in the absence of neural activation. We used particle tracking to measure the velocity of CSF microspheres and found that arterial diameter change is negatively correlated to the CSF flow velocity. Lastly, we proposed an impedance pumping model that might explain our experimental observation of the vasomotion-driven flow. Altogether, our results demonstrate that changes in arterial diameter are important for CSF flow. We hypothesize that the glymphatic system is activated to clear away metabolites produced by the increased neuronal activity in response to sensory stimulation. Low glymphatic activity is associated with a buildup of metabolic waste [3], so maintaining high sensory stimulation to induce functional hyperemia could protect against age-related glymphatic impairment.

## METHODS

We used a mixture of male and female mice for the studies. For optogenetic experiments, we bred mice expressing channelrhodopsin in smooth muscle cells. Mice were anesthetized with a ketamine/ xylazine. The cisterna magna was exposed and a 30GA needle was inserted. The air puffs were delivered by a pneumatic pressure pump controlled by a digitizer. The air puffs were delivered for 30 seconds.

A cranial window was made above a branch of the middle cerebral artery. Just before imaging, an i.v. tracer was injected to visualize the artery. Red fluorescent microspheres were injected into the cisterna magna during 2-photon imaging. We recorded at a frame rate of 29.6 fps.

We used a custom-built, automated particle tracking software in MatLab to measure CSF flow velocity from the recordings. A Matlab algorithm was used to measure the artery and perivascular space width changes[4].

We used the IB2D, an open-source immersed boundary simulation tool to simulate CSF flow driven by the motion of the elastic artery in 2D[5][6][7].

For the awake mice studies, the anesthetized mouse was injected with the xylazine reverser atipamezole. This caused rapid elevation of heart and respiration rate, and when it had stabilized, we began whisker stimulation.

## RESULTS

### Whisker stimulation causes functional hyperemia through neuronal activation in the barrel field cortex

Whisker air puffing activates barrel cortex neurons and causes an increase in local blood flow. Using lightly anesthetized mice, we here found stable whisker-induced neuronal Ca2+ in the stimulated hemisphere(Figure 1).

### Functional hyperemia increases the glymphatic influx

We combined whisker stimulation with in vivo imaging of the glymphatic CSF tracer transport under anesthesia. The tracers appeared in both hemispheres, at which point air puff stimulations

were started. Glymphatic tracer signal continuously increased in both hemispheres as the tracer entered the perivascular space, yet the whisker stimulations consistently triggered a higher net tracer influx compared to the unstimulated hemisphere, demonstrating that sensory stimulation increases glymphatic influx.

**Whisker stimulation increases glymphatic clearance**

We let the tracer circulate for 30 minutes to saturate the perivascular spaces before air puffing the whiskers for 20 minutes. We found that whisker stimulation causes faster clearance of tracer from the stimulated hemisphere.

**Functional Hyperemia transiently decreases the CSF flow velocity**

To quantify CSF flow, we next injected fluorescent microspheres and imaged their transport using 2-photon excitation followed by particle tracking analysis. As the artery dilated, we found that the downstream velocity of the microspheres decreased indicating that glymphatic inflow is transiently impaired during whisker stimulation.

**Vasomotion changes the volume of the PVS**

From diameter measurement, we observed that the perivascular space width during hyperemia decreases as the artery dilates. We did not observe any movement of the outer perivascular space membrane, suggesting that the outer boundaries of the perivascular space are rigid.

**Vasomotion increases the glymphatic influx in the absence of neural activation**

We used Optogenetic mice to test the importance of vasomotion as a driver of CSF influx in the absence of neural activation[8]. We induced vasoconstriction by photostimulation of the arterial trunk. We found that the photostimulation increased the tracer signal in the perivascular space of the MCA compared with the unstimulated hemisphere.

The results show that both sensory stimulation and artificial manipulation of the arterial diameter result in an increased influx of CSF tracer confirming that vasomotion is a driver of glymphatic inflow.

**Impedance pumping simulation may reveal the mechanism of vasomotion-driven flow in the PVS**

We used the 2D numerical Immersed Boundary Method to simulate vasomotion-driven flow. We set the PVS outer boundaries to be rigid and the artery as a flexible tissue with both ends fixed to the Cartesian mesh. A net flow in the PVS is observed when we induce periodic vasomotion to the system, which matches our experimental observations in detail.

Upon the change of the PVS volume caused by vasomotion, we expect the local hydraulic resistance to change proportionally. A substantial increase in the PVS volume may attract fluid from both ends of the dilating area causing an inflow at one end and backflow at the other and vice versus. In the meanwhile, vasomotion wave reflections happen at both ends of the vasculature non-simultaneously, causing a unidirectional net flow component that is independent of the flow component driven by the local hydraulic-resistance change or the mass conservation law, which is described as impedance pumping in previous literature[9]. Our in-vivo experiments and simulation results suggest that impedance pumping may play an important role in the CSF flow.

**Functional hyperemia does not drive CSF flow in awake mice**

Earlier studies have shown that wakefulness strongly suppresses glymphatic influx[10]. Therefore, we woke up the anesthetized mice with atipamezole. Then, we began whisker stimulation and tracer measurement. The results showed that whisker stimulation caused no detectable changes in glymphatic influx.

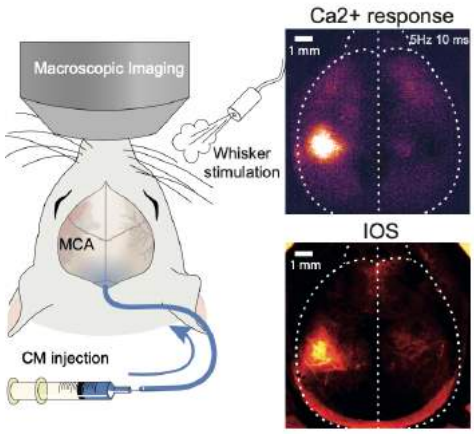

**Figure 1: Whisker stimulation setup and the response in the stimulated(Left) hemisphere**

**DISCUSSION**

Our study presents the first direct evidence that functional hyperemia accelerates CSF influx in anesthetized mice. The increased CSF transport is not only noticeable for the glymphatic influx, but causes also faster clearance of glymphatic tracer in response to whisker stimulation. In an optogenetic mouse model, we demonstrate that it is not neuronal activation per se that increases CSF influx, but rather changes in arterial diameter. To detail the CSF flow changes occurring in response to vasomotion, we used a unique custom-built velocity tracking software to yield kinetic data of injected microspheres in the perivascular spaces. We find a rapid velocity change in response to arterial diameter changes. Altogether, we observe vasomotion to greatly affect the CSF flow in the perivascular space, and that vasomotion is a major driver of CSF transport.

In this study, we present an impedance pumping model with the assumption of a non-distensible external layer. The inner tubing is elastic, and large waves, as those caused by functional hyperemia, can propagate along the arterial wall and causes the cerebrospinal fluid to move in a specific direction. Our data demonstrate an anti-correlation between arterial diameter and CSF flow velocity.

Our study on awake mice suggests that functional hyperemia drives no influx when the glymphatic system is suppressed by wakefulness.

**ACKNOWLEDGEMENTS**

This project has received funding from the Novo Nordisk Foundation, Lundbeckfonden, the NIH National Institute on Aging through grant RF1AG057575, and the Army Research Office through grant MURI W911NF1910280. We would like to thank Dan Xue for help with graphical design and Hajime Hirase for providing GLT1-GCaMP7 mice.

## INTRODUCTION

Increasing evidence links spatial organization of the genome to gene function and cell fate. For example, work from our lab has recently shown that different cell types have specific nuclear architectures [1]. A critical component of nuclear architecture is the lamina-associated domain (LAD) at the periphery of the nucleus. Genes localized in the LAD are generally repressed and not necessary to carryout cell-type specific functions. H3K27me3 and H3K9me3 are two histone modifications that are critical for repressing genes in the LAD. When the enrichment of H3K27me3 and H3K9me3 in the LAD is disrupted, variable reactivation of genes can occur leading to maladaptive states, such as cancer [2] or cardiac pathologies [1].

Our work explores how the disruption of the peripheral enrichment of H3K27me3 and H3K9me3 to the nuclear envelope leads to maladaptive cell states in cartilage regeneration procedures. Current cartilage regeneration procedures (e.g. MACI, ACI) require a cell expansion process of autologous chondrocytes to generate sufficient cells that can be transferred to damaged regions of cartilage to promote repair and regeneration of the tissue. However, during the expansion process, chondrocytes dedifferentiate leading to loss of the native chondrocyte phenotype and emergence of a fibroblast-like cell. How the dedifferentiation process is regulated, and methods to restore the native chondrocyte phenotype post expansion, are unknown. Thus, the objective of this study is to determine the extent to which H3K27me3 and H3K9me3 play a role in regulating chondrocyte dedifferentiation, and how these modifications could be disrupted to rescue the chondrogenic phenotype to improve cartilage regeneration procedures.

## METHODS

***2D and 3D Culture***: Bovine chondrocytes were isolated (N=3-6 animals) and plated on Tissue Culture Plastic (TCP) or encapsulated into 3D HA-PEGDA hydrogels directly (PD0-3D). Cells plated on TCP were cultured for 8 population doublings (PD8) and 16 population

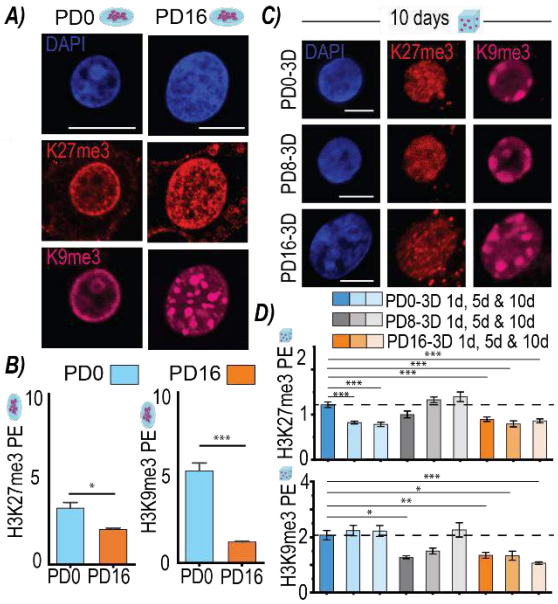

**Figure 1: Retention of chromatin architecture of expanded chondrocytes in 3D culture depends on time in 2D culture. A) Chromatin architecture of H3K27/K9me3 remodels and B) peripheral enrichment (PE) of H3K27/K9me3 is lost with increased population doublings of chondrocytes. scale= 10µm C) After 0, 8 and 16 population doublings (PD0, PD8, PD16), cells were transferred to 3D hydrogels and imaged. scale= 5µm D) PE levels of PD16-3D cells remained low in 3D culture, however, after 10 days in 3D culture the PE levels of PD8-3D cells returned to levels similar to PD0-3D cells. ±sem, *p<0.05, **p<0.01, ***p<0.001**

doublings (PD16) before collection for analysis or transfer to 3D hydrogels (PD8-3D and PD16-3D) for 1, 5, and 10 days. **Microscopy**: All samples were stained and imaged to visualize DNA (DAPI:405nm), H3K27me3 (561nm) and H3K9me3 (640nm). Additionally, 3D hydrogel samples were stained with calcein-AM and ethidium homodimer-1 to assess cell viability. **Peripheral Enrichment Analysis**: A custom MATLAB code was used to analyze nuclei (n>15 nuclei/treatment/animal) to calculate the ratio of relative intensity of outer H3K27/K9me3 signal to inner H3K27/K9me3 signal (Peripheral Enrichment: PE). **Gene Expression:** RT-qPCR was used to assess gene expression, normalizing to reference genes HPRT1 and GAPDH. **Epigenetic Treatments:** Cells were treated with inhibitors of epigenetic modifiers: Ezh2 inhibitor, GSK343 (2μM), to disrupt the methylation of H3K27; KDM4 inhibitor, ML324 (10μM), to influence methylation of H3K9; or DMSO (vehicle control). **Statistics:** A linear mixed effect model with a type III sum of squares ANOVA was used.

## RESULTS

While cultured on TCP, chondrocytes dedifferentiated, marked by a loss in the chondrocyte phenotype and cell morphology. At the same time, the chromatin architecture of H3K27me3 and H3K9me3 remodeled. H3K27 and H3K9 trimethylated chromatin enriched the periphery of PD0 cells (Fig. 1A,B). However, by PD8 and PD16 this peripheral enrichment (PE) of epigenetically marked chromatin decreased (Fig. 1A,B). When PD8 and PD16 chondrocytes were encapsulated in 3D hydrogels to mimic the change in environment after cell expansion in cartilage regeneration procedures, the alterations in chromatin architecture persisted (Fig. 1C). While PD8-3D cells regained the PE levels similar to PD0-3D cells after 10 days, the PD16-3D cells did not (Fig. 1C,D). After treating chondrocytes with GSK343, we found that the PE of H3K27me3 increased compared to PD16 DMSO treated controls (Fig. 2A). At the same time, GSK343 significantly decreased levels of H3K9me3 PE of PD16 cells compared to PD16 DMSO controls. Treating chondrocytes with ML324 did not change the PE of H3K27me3 for PD16 cells, but did restore PE of H3K9me3 of PD16 cells to similar levels of H3K9me3

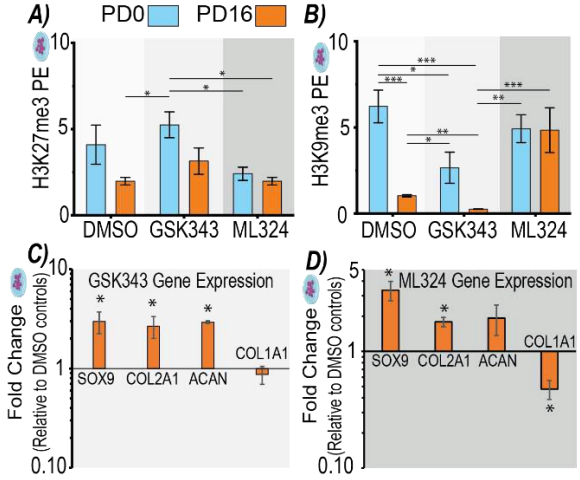

**Figure 2: Inhibiting epigenetic modifiers of H3K27me3 and H3K9me3 alters chromatin architecture and increases chondrogenic gene expression in 2D culture. A) While PE of H3K27me3 decreases with increased population doublings with DMSO treated cells, the PE of H3K27me3 increased with the GSK343 treatment. B) Treatment with ML324 maintains the high PE of H3K9me3. C) GSK343 and D) ML324 increased expression of chondrogenic genes. ±sem, *p<0.05, **p<0.01, ***p<0.001**

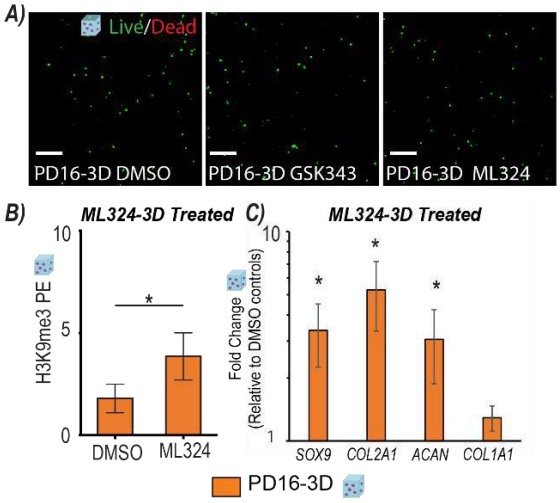

**Figure 3: Epigenetic treatments during 2D culture do not influence cell viability and enhance the chondrogenic phenotype when cells are encapsulated in 3D culture. A) PD16 cells treated with GSK343, ML324 or vehicle control (DMSO) were encapsulated into hydrogels and stained for live for cell viability. scale bar= 200μm B) H3K9me3 PE of PD16-3D cells previously treated with ML324 increased compared to DMSO PD16-3D cells. C) Chondrogenic gene expression of PD16-3D cells treated with ML324 increased compared to DMSO controls. ±sem, p<0.05**

PE of PD0 cells (Fig. 2B). Additionally, both inhibitor treatments increased expression of chondrogenic genes (Fig. 2C,D). Next, we encapsulated PD16 cells treated with GSK343 and ML324 and showed that the treated cells remained viable (Fig. 3A). The PE of H3K9me3 of ML324 treated cells in 3D hydrogels increased compared to encapsulated PD16-3D DMSO control cells (Fig. 3B). In addition, chondrogenic gene expression of ML324 treated PD16-3D cells increased compared to DMSO PD16-3D cells (Fig. 3C).

## DISCUSSION

We found that the chromatin architecture, specifically quantified as the PE of H3K27me3 and H3K9me3, remodels during chondrocyte dedifferentiation, supporting previous findings that disruption of the LAD leads to aberrant gene expression [3]. Additionally, chromatin architecture of H3K27me3 and H3K9me3 is retained even when chondrocytes are transferred to a different (3D) environment. The persistence of chromatin architecture overtime in 3D culture suggests that a memory from the previous environment is retained. Treating chondrocytes with epigenetic inhibitors, such as GSK343 and ML324, presents a promising method to prevent the memory from the expansion process and increase the therapeutic potential of chondrocytes [4]. More work is needed to assess how treatments of ML324 and GSK343 influences the chondrocyte phenotype when cultured in 3D hydrogels for longer time periods and if these treatments influence long-term matrix deposition to avoid fibrous matrices that often result from cartilage defect repairs [4]. Overall, understanding epigenetic regulation of chondrocytes could lead to chondrocyte reprogramming methods to improve strategies for cartilage defect repair.

# EXAMINING OVARIAN CANCER HSP27 REGULATION VIA MECHANOTRANSDUCTION SIGNALING IN A 3D MODEL

**Molly S. Buckley (1), Joel L. Berry (1,2), Mary-Kathryn Sewell-Loftin (1,2).**

(1) Biomedical Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

## INTRODUCTION

Ovarian cancer is the deadliest malignancy of all gynecological cancers with a 5-year survival rate of 49.1% [1], primarily due to the chemoresistant qualities of ovarian cancer cells which lead to high rates of recurrence. The current standard of care for epithelial ovarian cancer (EOC) patients is primary debulking surgery followed by a combination of taxane-based and platinum-based chemotherapies [2]. These therapeutic agents target the biochemical signaling that promotes cancer growth, but not the biomechanical signaling that is involved. Pathologic biomechanical forces within the tumor microenvironments (TMEs) of epithelial tumors of all types are emerging as potent regulators of cancer progression; these forces include compression at the tumor interior [3], tension at the tumor periphery [4] and altered or insufficient blood flow in the tumor vasculature due to high interstitial shear stresses [5]. When cells in a tumor sense these dynamic mechanical forces, a biochemical signaling response occurs called mechanotransduction [6].

Mechanotransduction studies of all epithelial cancer types have increased in number in the past 20 years, but few EOC mechanotransduction studies exist – and none have specifically focused on the effect of tensile stress on EOC chemoresistance. To address this gap in knowledge, this project studied the biomechanical regulation of EOC chemoresistance due to applied tensile strain using a 3D microfluidic device that is physiologically relevant to human EOC. The molecular relationship between the mechanotransduction response of EOC cells and their subsequent chemoresistance was examined through the expression and activation of the mechanosensitive heat shock protein 27 (HSP27). HSP27 is expressed and activated under stress conditions such as heat shock, hypoxia, and increased shear stress [7-9], is found to be upregulated in ovarian cancer [10], and has been shown to lead to increased chemoresistance in ovarian cancer cells [11, 12]. While these studies are a promising start to elucidating the role of HSP27 in ovarian cancer and determining its function as a possible biomarker or therapeutic target, determining how HSP27 is regulated in EOC through mechanotransduction signaling pathways that are modified by increasing tensile stress has not yet been explored. We hypothesized that tensile strain applied to the EOC cell line SKOV-3 and the chemoresistant EOC cell line SKOV-3.tr would increase HSP27 expression. A 3D microfluidic model of EOC with a fully formed vasculature was then developed with appropriate matrix components to further study the effect of tensile strain on EOC cells in a 3D environment.

## METHODS

Human epithelial ovarian cancer cell line SKOV-3 and the chemoresistant cell line SKOV-3.tr (taxane resistant) were seeded at 5 x $10^5$ cells/well (one cell type per plate) in 6-well collagen type I coated Flexcell plates with a flexible silicone membrane on the bottom of the well. Once seeded, the plates were placed in an incubator (37°C, 5% $CO_2$) for 24 hours such that an ~80% confluent monolayer was formed. The well plates were placed in the Flexcell FX-6000T tension system where an oscillatory tensile force of 10% strain and a frequency of 0.3 Hz was applied for 15 and 30 minutes. These cells were lysed and protein expression of HSP27 was determined through Western Blot analysis.

Next, a previously developed 3D microfluidic model was used [13] with EOC cells to create a physiologically relevant model of EOC. Briefly, a 3-chamber microfluidic model was used in which a 2:1 ratio of human microvascular epithelial cells (HMECs) to normal human lung fibroblasts (NHLFs) was seeded in conjunction in the middle chamber with a matrix of fibrin and collagen to create a fully formed vasculature network similar to that found in a tumor. SKOV-3 (n=3) cells were placed in the side chambers with the same matrix

components. Two concentrations of a fibrin: collagen mixture were used: 9:1 and 6:4, for a total of 10 mg/mL ECM protein. These devices were allowed to grow for eight days after which they were stained for CD31, collagen, and DAPI and imaged using immunofluorescence.

## RESULTS

A Western Blot analysis of SKOV-3 and SKOV-3.tr cells after application of oscillatory tension (Figure 1) showed differences in HSP27 expression between cell lines in each condition (experiment or control) at each time point. Trends towards a change in HSP27 expression over time within the same cell type under the different conditions were found.

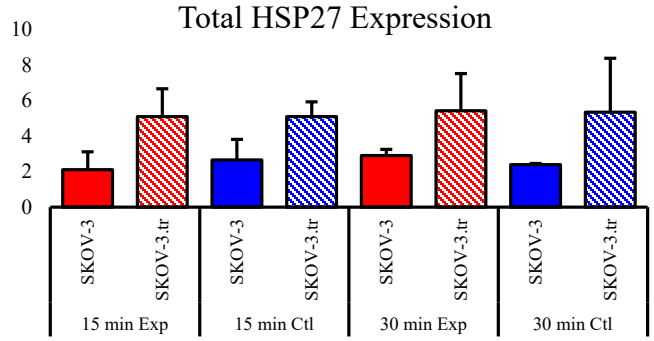

**Figure 1: Western Blot analysis of SKOV-3 and SKOV-3.tr cells placed under tensile strain for 15 and 30 minutes. N=2.**

Immunofluorescent staining and imaging were performed to analyze CD31 (TXRED), Collagen I (GFP), and DAPI expression (Figure 2A-B) in devices set up using the methods described above. Blood vessel formation was analyzed using the TXRED channel (Figure 2C-D) to determine if the collagen addition would hinder blood vessel development. This image was then analyzed in AngioTool using the skeletonization feature (Figure 2E-F) to highlight the fully formed vasculature network.

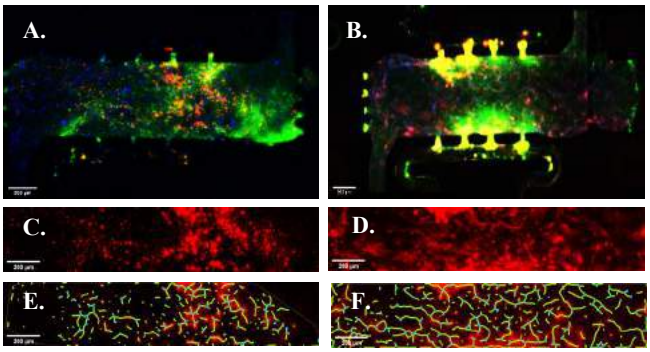

**Figure 2: 3D microfluidic devices with SKOV-3 cells with (A) 6:4 and (B) 9:1 ratio of fibrin: collagen matrix. Blood vessel formation in devices with (C) 6:4 and (D) 9:1 ratio of fibrin: collagen. AngioTool analysis of blood vessel formation with (E) 6:4 and (F) 9:1 ratio of fibrin: collagen. N=3 of each matrix composition**

## DISCUSSION

In previous studies with this particular 3D microfluidic device [13] the relationship between micro-strains in the ECM and angiogenesis was studied using endothelial cells and fibroblasts. The next step in developing this 3D model to study the biomechanics of cancer was to introduce cancer cells into these experiments as well as using the relevant ECM associated with cancer. Collagen type I is the most prevalent structural protein in EOC [14], therefore using it in conjunction with fibrin in this device would increase the physiological relevance of these experiments. However, collagen is an extremely stiff and contractile substance and replacing fibrin entirely with collagen in a microfluidic device needed to be tested to confirm a blood vessel network would still develop. Indeed, after testing the highest (6:4) and lowest (9:1) ratio of fibrin: collagen it was observed and quantified that blood vessel formation was hindered with a higher collagen concentration and flourished with a lower collagen concentration. Future experiments where different collagen concentrations in between the maximum and minimum to determine the optimum ratio will be needed.

As shown in Figure 1, there is a possible biomechanical signaling relationship between tensile strain, the chemoresistant quality of certain types of cancer cells, and the expression of HSP27. HSP27 expression increased after 30 minutes of tensile stretch in both SKOV-3 and SKOV-3.tr cells as opposed to 15 minutes of stretch, whereas the cells that were plated on the same plates but not stretched did not show much difference. Also, there is a stark difference between the total HSP27 expression in SKOV-3 cells vs. SKOV-3.tr cells. These results suggest that HSP27 expression is increased in chemoresistant cell types. As mentioned above, HSP27 is upregulated in many cancers including ovarian cancer and is implicated in EOC resistance of both paclitaxel and cisplatin [11, 12]. HSP27 is also highly sensitive to changing mechanical environments, such as heat shock, hypoxia, and increased shear stress [7, 9, 15]. Similar stresses, with the addition of compression and tension, are present in EOC. Studies are ongoing to determine the correlation between increased tensile stress and changes in HSP27 activation. Therefore, studying differences in HSP27 expression in cells that are first exposed to tensile strain then placed in the 3D microfluidic device provides the opportunity to explore changes in HSP27 expression and subsequent chemoresistant behaviors in a physiologically relevant 3D model which will have more insight than a standard 2D assay.

A unique aspect of this microfluidic model is that it allows for examination of cellular function without the added variable of soluble factors. The media in these devices is changed daily and flow is unidirectional each day, allowing for the influence of one single variable, in this case increased tensile strain, to be examined at a time. We will use this system to examine the differences in cells pre-treated with strain or without strain and compare HSP27 expression patterns and responses to chemotherapy to elucidate the relationship between increased tensile strain, HSP27 and EOC chemoresistance.

In conclusion, a connection between increased tensile strain and HSP27 expression was quantified. A previously designed 3D microfluidic device was further developed to be used for studies of EOC and their relationship with different mechanical stressors. Future experiments will further define the appropriate ratio of fibrin: collagen to be used in these devices, determine a link between HSP27 and tensile stress in a 3D environment, and elucidate a relationship between HSP27, tensile stress, and chemoresistance in EOC. This project helps generate sufficient understanding of the mechanisms of action of HSP27 expression or activation in EOC due to a mechanotransduction response that results in chemoresistance using a system where mechanical forces can be controlled, and the resultant cellular response is quantified.

# ANALYSIS OF AIR FLOWRATE STANDARDS FOR PORTABLE SUCTION DEVICES

**Saketh R. Peri (1&3), Robert A. De Lorenzo (1,2,3), R. Lyle Hood (1,2,3)**

## INTRODUCTION

Airway clearance is one of the primary functions performed during emergency or trauma situations. Airway obstruction is a major priority in prehospital emergency care and is also the second leading cause of preventable battlefield death [1]. Suction devices, also termed aspirators, are powered or unpowered devices employed to remove infectious materials from wounds or fluids from a patient's airway or respiratory support system [2]. Unfortunately, many of these commercial portable suction devices have not been scientifically validated for key performance measures relevant to prehospital care [3, 4]. The majority of suction devices advertised for use in prehospital tactical environments were well within the specifications dictated by the ISO 10079-1 standards, yet no device on the market meets even the most basic field requirements on size, weight, and suction performance [2, 5]. The current ISO 10079-1 standard for primary performance is maximum free air flow rate [5]. This is problematic, as maximum air flowrate overestimates the capability of the device. Peak flow rate at a single instant does not necessarily correlate to its performance for volume evacuation over time. Manufacturers maintain compliance with ISO – 10079-1 by reporting the peak/maximum air flowrate. The focus of this study was to measure and compare air flowrates of four (4) different commercially available suction devices, as well as assess their claims of instantaneous peak flowrate against their actual evacuation performance over a clinically relevant period of time.

## METHODS

The four (4) portable medical suction devices were Laerdal LCSU 4 & SSCOR Quickdraw, which were battery operated suction devices, and Laerdal V-VAC & AMBU RES-QUE, which were manually operated suction devices. The portable suction devices were selected based on their frequency of use among current first responders and their weight (<1.5 kg). A microelectromechanical system (MEMS) air flow sensor (Omron MEMS Air Flow Sensor - D6F-50A61-000) was used to measure the instantaneous air flowrate drawn by the suction device. The air flow sensor was powered with 12 V DC voltage and was connected to digital acquisition system (DAQ) (National Instruments 9221) to log the sensor output (Figure 1). The DAQ was connected to a laptop, where mathematical programming software, MATLAB, was used to record and analyze the data. The airflow sensor outputs the data in the form of volts which was converted to air flowrate unit, liters/minute (l/min), by a quadratic relation using MATLAB. All four (4) suction devices were tested using the experimental setup described in the diagram shown in Figure 1. The suction devices were operated for 30 seconds, where the air flow sensor captures the air drawn by the suction device for a period of 30 seconds at 100 Hz. All suction devices were operated at their respective peak settings. Each device was tested for 5 trials. Manual suction devices were operated by a single operator for 5 trials.

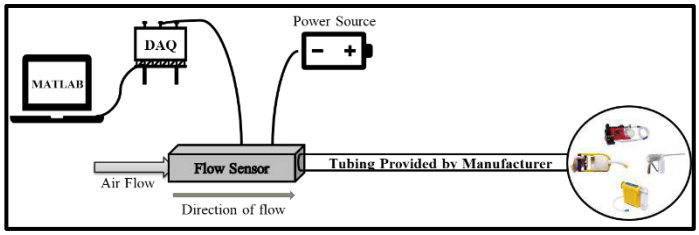

**Figure 1: Air Flowrate Experimental Setup**

## RESULTS

Tests were repeated 5 times for each suction device as described. Data was recorded via the DAQ and analyzed with MATLAB. Figure 2 shows the peak air flowrates of each suction device for 5 trials.

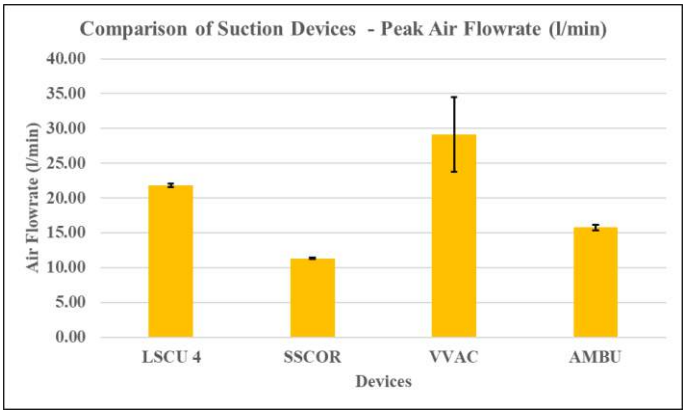

**Figure 2: Peak Air Flowrates of the Suction Devices**

The recorded flowrates were integrated with respect to time to determine the total volume of air drawn the by the suction device over the 60 second experimental timeframe. Figure 3 shows the total volume of air drawn in 60 seconds by each suction device for 5 different trials.

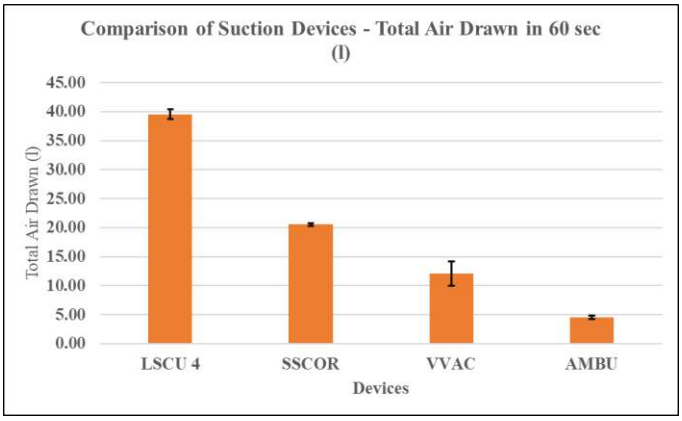

**Figure 3: Total Air Drawn (l) in 60 sec**

## DISCUSSION

Comparison of total air flowrate and instantaneous flowrate for manual suction devices show that, although the manual suction devices offer high instantaneous flowrate, the total airflow rates over time were far less. Peak instantaneous air flowrate is not a meaningful or relevant specification as it cannot provide information on total amount of air drawn by the suction device, which is of course an implied correlation to the liquid flowrate. Total airflow for 60 seconds, is more likely to imply liquid flowrates than peak air flowrate.

Performance of manually operating suction devices naturally changes with the user. In our test, a single user operated the manual devices. Observing the VVAC and AMBU peak flowrates and total volume of air drawn, one can infer that intra-operator variability is increased for VVAC relative to the AMBU as shown in Figure 4. Our results did not assess inter-operator variability, which is most likely significant.

Use of the peak/maximum air flowrate metric allows the manually operated suction devices to claim comparable, or even superior, performance to their battery-powered counterparts. As per the data herein, this is untrue and misleading to purchasers and users of these portable suction systems. Based on this data, we recommend total airflow rate over 60 seconds as an improved specification for analyzing the performance of the suction device. In addition, our data suggests that peak air flowrates reported by manufacturers may not be reproducible in the field.

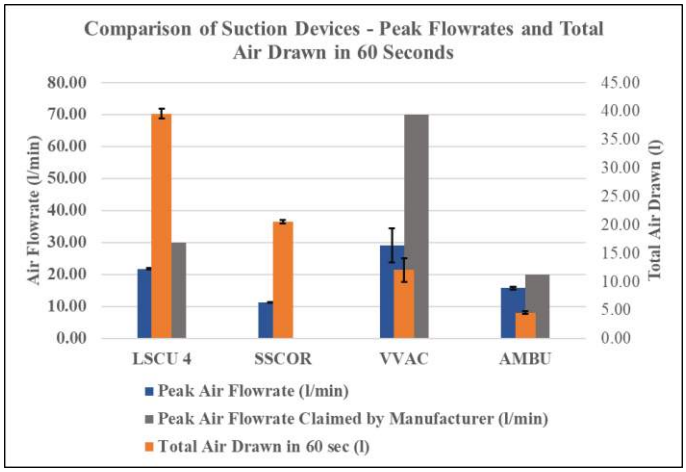

**Figure 4: Comparison of Peak Air Flowrates and Total Air Drawn for 60 seconds by Suction Devices for 5 Trials**

## INTRODUCTION

Collagen is the most abundant protein in mammals, and is the main structural constituent of musculoskeletal tissues such as tendon [1]. The base unit of collagen, the collagen molecule, can become denatured during injury and disease [1]. Our lab has recently demonstrated that sub-failure levels of tensile stretch in tendons can cause collagen damage in the form of denaturation, as indicated by collagen hybridizing peptide (CHP) binding [1,2]. Specifically, collagen denaturation is initiated at the yield point of the stress-strain curve regardless of tendon type [2]. However, questions remain about how load is transferred throughout the collagen hierarchy when tendons are stretched.

In this study, we characterized collagen denaturation in fibrils relative to features of the stress-strain curve using a microelectromechanical system (MEMS) device. We selected fibrils because they are the main structural unit in collagenous tissues and one level up from the collagen molecule in the physical hierarchy, allowing more direct assessment of how tensile load affects the collagen molecule. It's been previously shown that collagen fibrils exhibit denatured collagen as indicated by CHP binding when stretched to sub-failure levels of strain [3] and to failure [4]. We hypothesized that collagen fibrils would exhibit increased denatured collagen upon reaching the yield point of the stress-strain curve. This is based on coarse-grain models of collagen fibrils that predict collagen enzymatic crosslinks resist intermolecular sliding of collagen α-helices until the yield point, at which point the α-helices slide out, allowing CHPs to bind [5].

## METHODS

The MEMS devices were fabricated using published techniques [6]. Briefly, silicon on insulator (SOI) wafers with device and oxide thicknesses of 4 and 2 µm, respectively, were purchased. Photoresist was applied to the wafers, and the MEMS devices were patterned using photolithography. The polysilicon was etched using $SF_6$ plasma followed by wet etching with hydrofluoric acid. The MEMS devices were rinsed with isopropyl alcohol then critical point dried.

Collagen fibrils were isolated from rat tail tendon (RTT) fascicles from 12-16 week old male Sprague-Dawley rats using published methods [7]. Individual collagen fibrils were removed from solution using glass micropipettes, placed on the MEMS device, and adhered with epoxy droplets. The fibril and droplets were positioned such that a portion of the fibril was stretched, while a separate portion of the fibril was not stretched, providing a control region (Figure 1). The epoxy was allowed to cure overnight; the next day, endogenous biotin was blocked using a commercial kit (E21390, Invitrogen, Waltham, MA).

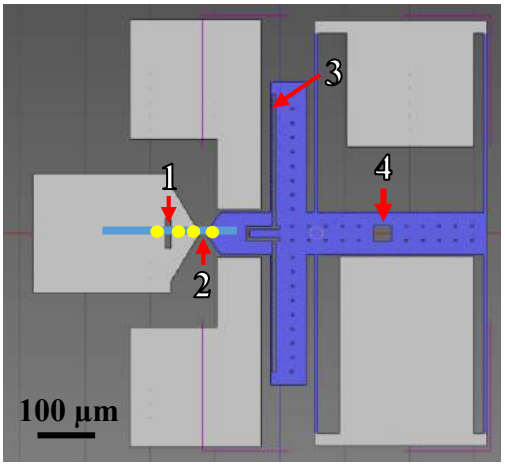

**Figure 1**: **Schematic of the MEMS device. The blue and gray portions represent the moveable and fixed pads, respectively. The blue line represents a collagen fibril adhered with yellow epoxy droplets. (1) Control region. (2) Test region. (3) Force gauge beam. (4) Porthole.**

The baseline amount of denatured collagen in the fibrils was quantified using CHPs. The MEMS device was stained in 3 mL of 15 µM biotinylated CHP (B-CHP, 3-Helix Inc., Salt Lake City, UT) in PBS overnight at 4°C. Excess B-CHP was removed by rinsing in 3 mL of 4°C PBS for ten min, three times. The MEMS device was subsequently stained with 3 mL of a 5 µg/mL solution of Streptavidin-Alexa Fluor 488 (S11223, Invitrogen, Waltham, MA) in 1% bovine serum albumin for two hrs. Excess Streptavidin-Alexa Fluor 488 that had not bound to B-CHP was removed by rinsing in 3 mL of 4°C PBS for ten min, ten times. Collagen fibrils were imaged with an upright microscope (BX51WI, Olympus, Center Valley, PA) in PBS with a 60× objective. Fluorescence intensity of the tested region of the fibril was quantified to measure the amount of denatured collagen.

The MEMS device was then adhered to a piezoelectric stage (Nano-H100, Mad City Labs, Madison, WI) and immersed in PBS. A tungsten probe was placed in a porthole on the moveable pad of the MEMS device to hold it in place, while the rest of the device was displaced at a rate of 0.05 µm/s. The test was recorded at a rate of 4 frames/second. The stretched region of the fibril was attached to a force-gauge beam, where its deflection was quantified and used to calculate the force applied to the collagen fibril. Therefore, the displacement of the piezoelectric stage was the sum of the displacement of the force gauge beam and that of the collagen fibril.

After stretching the collagen fibrils, the B-CHP and Streptavidin-Alexa Fluor 488 staining and imaging protocols were repeated. The post-stretch fluorescence intensity was divided by the pre-stretch intensity for each individual collagen fibril to calculate the increase in denatured collagen following tensile stretch, referred to as the relative fluorescence increase (RFI). The MEMS device was sputter coated with 5 nm of Au-Pd, and the control region was imaged using scanning electron microscopy (SEM) to measure the fibril cross-sectional area.

Image processing was performed on the video recordings of the tests. The images were thresholded and line tracking was used to calculate the displacements of the sample and the force gauge beam. We analyzed a finite element model of the MEMS device during stretch using FEBio to calculate the force that was applied to the collagen fibril. These results were used to construct a stress-strain curve for each fibril; the yield point was defined as the point where the linear region modulus reduced to 50% of its value.

The collagen fibrils were divided into two groups: those that reached the yield point, and those that did not. The mean RFI of the two groups were compared using a two-tailed t-test with $\alpha$=0.05.

## RESULTS

A total of n=8 collagen fibrils were tested. The initial length of the fibrils was 6.15±1.95 µm (mean±s.d.). The final strain levels of the eight fibrils ranged from 0% to 122.4% (Figure 2). Ultimately, n=3 fibrils reached their yield point, while n=5 fibrils did not. One collagen fibril failed at 70.3% strain.

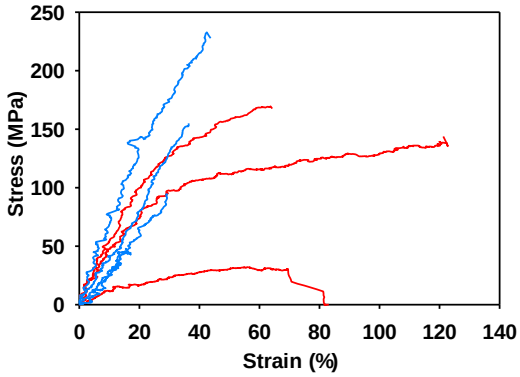

**Figure 2: Stress-strain plots for stretched collagen fibrils. Red lines represent samples that reached a yield point. Blue lines represent samples that did not reach a yield point.**

The three collagen fibrils that reached the yield point were stretched to the three highest strain levels in the dataset. The RFI of these three fibrils increased with increasing strain levels. The five fibrils that did not reach the yield point all had an RFI value that remained at a baseline level of ~2.0 (Figure 3). The mean±s.d. RFI for collagen fibrils that did and did not reach the yield point were 25.09±15.79 and 2.16±0.94, respectively. The difference between the mean RFI values of these two groups was statistically significant (p=0.0139).

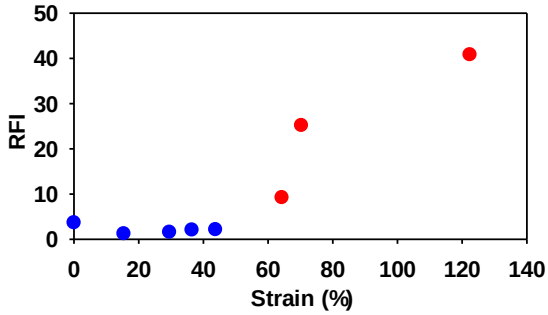

**Figure 3: Relative fluorescence intensity (RFI) of collagen fibrils, indicating denatured collagen increases with applied strain. Red circles represent fibrils that reached the yield point. Blue circles represent fibrils that did not reach the yield point.**

## DISCUSSION

The results of this study demonstrate that collagen fibrils exhibit increased levels of collagen denaturation only after reaching the yield point of the stress-strain curve. This is similar to results found at the tissue level [2] and coarse-grained models of collagen fibrils [5]. Depalle et al [5] predicts that crosslinks resist intermolecular sliding until the yield point, at which point the collagen molecules uncoil, leading to collagen chains sliding, exposing binding sites for CHPs. This is additional evidence that the shear-dominant loading mechanism is the mode of failure in collagen fibrils [1].

An interesting result of this study is that while our strain levels are consistent with strain levels when the same MEMS device was previously used [6], the observed strain levels were significantly higher than those reported by other studies that stretched fibrils [3,4]. Possible reasons for this could be due to the gauge length of the fibrils and the testing methods. The MEMS technique has relatively short gauge lengths (5-10 µm) compared to other methods that used the bowstring methods on much longer samples of ~50 µm [3,4]. Greater sample lengths increase the probability that local point weaknesses exist along the fibril length, leading to reduced failure strains [8]. Regardless, the overall shape of the stress-strain curves in this study is consistent with other studies that investigated collagen fibrils from positional tendons.

This study provides important insights into how load is transferred throughout the collagen hierarchy, the role of enzymatic collagen crosslinks, and how tendons ultimately fail during tension. Understanding these different mechanisms will lead to improved understanding of musculoskeletal injuries.

# THE RELATIONSHIP BETWEEN CARDIAC CYCLE INDUCED STRAIN IN THE BRAINSTEM AND CHIARI MALFORMATION TYPE I SYMPTOMATOLOGY

## INTRODUCTION

The goal of this study is to explore the relationship between Chiari malformation I (CMI) symptoms and cardiac cycle induced strain on the vestibulospinal tract (VST). Milhorat found 89 out of 126 CMI patients with Otoneurological disturbances [1]. The most common ones are tinnitus (81%), vertigo (69%), unsteadiness (49%), and dizziness (18%) [2,3,4]. It has been evident that CMI patients suffer from a significant impaired postural control in the anterior-posterior (AP) direction compared to healthy controls [4]. It is thought that impaired balance may be a result of traction and distortion of cerebellar pathways due to hindbrain (pons, medulla, and cerebellum) descent [5]. This article emphasizes the function of lateral VST (lVST) that ensures the coordination of different muscle groups during postural control [6]. In this work, the authors proposed a tool in which motion and strain in sub-sections of the vestibular circuitry can be investigated using DENSE MRI. We hypothesize that CMI subjects have higher VST strain than controls, and this higher strain impacts their postural control and balance.

## METHODS

Participants: 55 adult CMI subjects and 25 healthy adult controls were scanned at Emory University School of Medicine between 2017 and 2020 according to its institutional review board-approved protocol [7]. Symptomatology was collected via interviewing CMI subjects at the time of presurgical MRI scan. Those without clinical data were excluded from the correlation (n = 24). We examined symptoms relevant to vestibulocochlear nerve: vertigo (n = 14), imbalance (n = 12), tinnitus (n = 8), dizziness (n = 7), and nausea or vomiting (n = 14).

Imaging Protocol: Sagittal T1 and T2 weighted images of the brain were acquired using a PrismaFit 3T MRI scanner (Siemens Healthcare, Erlangen, Germany) employing a 20-channel head coil. DENSE scans were acquired in the midsagittal plane using a 2D spiral cine technique and peripheral pulse unit gating with spatial and temporal resolution [7]. Pixel size was 0.9 x 0.9 mm, and the slice thickness was 8 mm [7].

Processing: An in-lab developed MATLAB code (Mathworks, Natick, MA) was used to process DENSE images in midsagittal plane, neglecting the 3rd dimension (through plane) based on Pahlavian's reporting [7,8]. Further, the 2D displacement encoded in DENSE was used to calculate strain.

Region of Interest: There are 4 pairs of vestibular nuclei (superior, lateral, medial, and inferior) that are located along the lateral floor of the 4th ventricle in the lower pons [9]. Those nuclei are connected to the spinal cord through the medial VST (mVST) and lVST [6]. lVST originates from lateral and inferior vestibular nuclei and projects to the entire ipsilateral (same side) spinal cord through its anterior funiculus (white matter anterior to the anterior grey horn) [6]. Due to the very close proximity of lVST and mVST at vestibular nuclei and in the cervical spinal cord, they are considered one tract (VST) for the sake of the analysis. VST was analyzed using 2 investigational boxes placed along the structure in the midsagittal plane (Figure 1).

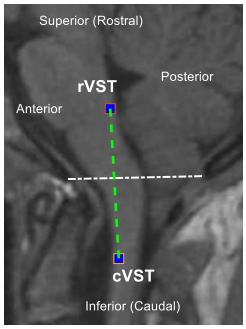

**Figure 1: Location of the region of interest (blue boxes) on an anatomical MRI of a CMI patient at the midsagittal plane.**

The rostral VST (rVST) box was placed at the start of the tract (most posterior aspect of the lower pons), and the caudal VST (cVST) was placed approximately 5-7 cm inferior to the rVST (most anterior aspect of the spinal cord at the level of C1/C2). Each box is a mask of 3 x 3 pixels in the midsagittal plane corresponding to a 3D displacement field measures 2.7 x 2.7 x 8 mm in the cephalo-caudal (CC or y-dir), anterior-posterior (AP or x-dir), and mediolateral (through-plane or z-dir) directions, respectively. Due to documented cardiac cycle-induced regional brain tissue motion [7], the displacement field changes with the cardiac cycle, so does the position vector which is the summation of location of the mask (box) and the displacement in each phase on each direction. Furthermore, the length ($d$) of the line, distance between the 2 boxes, changes throughout the cardiac cycle as well. The length is calculated using the equation (1). Lengthening ($L$) and strain ($\varepsilon$) are calculated using equations (2), and (3), respectively. Statistical Analysis: independent samples t-test was used to compare the maximum strain in CMI (n = 55) and control (n = 25). Correlation test was used to correlate the maximum strain on VST of CMI (n = 24) and imbalance. Correlation with the rest of symptoms is not appropriate because of the lack of strain data on the vestibular and cochlear nuclei.

## EQUATIONS

$$d(t) = i\sqrt{(X_{rVST} - X_{cVST})^2 + (Y_{rVST} - Y_{cVST})^2} \quad (1)$$

$$L = d_{max} - id_{min} \quad (2)$$

$$\varepsilon_{max} = \left(\frac{L}{d_{min}}\right) * 100 \quad (3)$$

## RESULTS

The brain tissue motion of rVST and cVST was traced over the cardiac cycle and the path was illustrated in Figure 2. This motion implies the motion and the lengthening that VST experiences over the cardiac cycle.

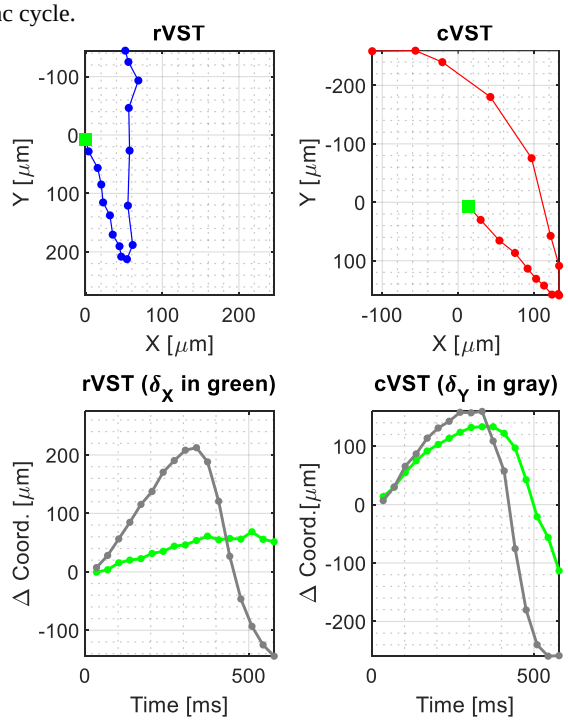

**Figure 2: Top: Brain tissue motion path of rVST and cVST for one CMI subject (the green box is the starting point). Bottom: The position time trace of rVST and cVST over the cardiac cycle.**

There is a statistically significant difference between the maximum strain on VST in Chiari and on that of the control ($p$-value = 0.009). The maximum strain on the VST in CMI, and control were 0.58 ± 0.38 %, and 0.36 ± 0.23 %, respectively.

A nonsignificant trend between the maximum strain on VST in CMI and the vestibulocochlear symptoms was seen. This nonsignificant trend varied from one symptom to another. While dizziness and tinnitus showed a positive trend with strain, vertigo and nausea or vomiting did not. A weaker nonsignificant trend was seen between imbalance and strain. This weak strain-imbalance trend is illustrated in the bar chart (Figure 3) where strain with imbalance is plotted in green, and strain without imbalance in grey. Finally, there was no significant correlation between maximum strain and imbalance (r = 0.282, $p$-value = 0.182).

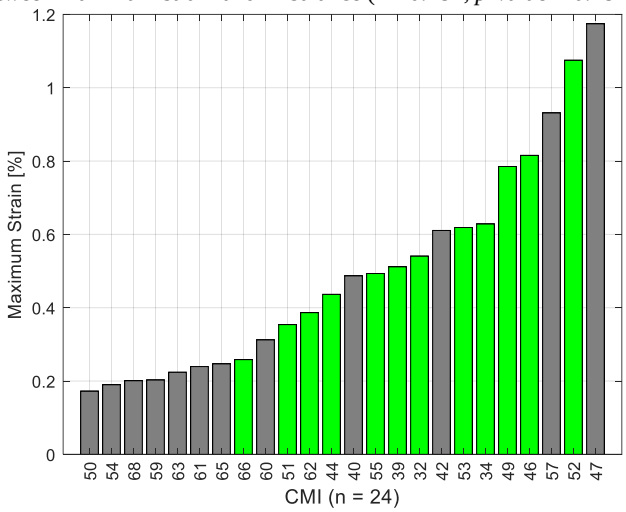

**Figure 3: Distribution of maximum strain for the VST in CMI subjects (green = with imbalance, grey = without imbalance).**

## DISCUSSION

We demonstrated that the cardiac cycle induced strain on the VST in CMI patients was significantly higher than that of the healthy control. We found no correlation between maximum VST strain in CMI subjects and imbalance. This may be due to the small strain values we observed (< 1 % for both CMI and controls). Based on our definition of lengthening and strain, strain was considered only in tension (Note: zero strain lengthening is unknown). Because the locations and dimensions of each subject's neuroanatomical structures are not known, anatomical landmarks were used to estimate their location. Due to a reduction in the signal-to-noise ratio at the end of the cardiac cycle caused by T1 decay, only the first two-thirds of each cardiac cycle are reliable [7]. Therefore, the rVST and cVST position at the end of the cycle does not match the start location.

# AN EXPERIMENTAL INVESTIGATION ON BENDING RESPONSE OF SCLERA TISSUE UNDER ELECTRICAL STIMULATION

**Hamed Hatami-Marbini (1), Jafar A. Mehr (1)**

(1) Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, USA,
Email. hatami@uic.edu

## INTRODUCTION

The sclera is the shell surrounding the eyeball attached to the cornea. It is a dense connective tissue constituting more than 80% of the eye's wall. The tough nature of the sclera protects the eye from serious damages as well as also providing a solid support for the extraocular muscles. From the microstructure point of view, the main compositions of the sclera include collagen, proteoglycans (PG) and elastin. PGs are polysaccharides units which are attached to glycosaminoglycans (GAGs) side chains. The GAGs play a key role in determining hydration, elasticity and resiliency of the sclera tissue. The main chemical compositions in the GAGs structure are carboxyl (i.e., $COO^-$) and sulfate (i.e., $SO_3^-$) groups. Within the physiological pH range (pH≅7.0) the GAGs are negatively charged, and the sclera tissue is considered as a natural polyelectrolyte hydrogel [1]. When an electroactive hydrogel is placed in a salt solution (e.g., NaCl) between two electrodes, upon the application of electrical voltage to the electrodes, the hydrogel bends towards one of the electrodes. The direction of the bending depends on the sign of the electrical charge inside the samples; a negatively charged gel bends to the cathode while a positively charged hydrogel bends to the anode. The sclera is a negatively charged tissue, so it is expected to behave like an electroactive polyanionic hydrogel, i.e. show a mechanical response when subjected to external electrical stimulations. The objective of the present work was to perform experiments and test the above hypothesis.

The electrical stimulation leads to water transportation due to migration of the counterions of the fixed charges inside the hydrogel (i.e., electroosmosis) [2]. The mechanism proposed for this electroactive bending response is the transient alteration in concentration of mobile ions (e.g., $Na^+$ and $Cl^-$) at the boundaries of the hydrogel and surrounding solution leading to local swelling/shrinking at the gel-solution interfaces. Aside from the content of the fixed charge, mechanical properties of the hydrogel, strength of the electrical field, the pH of the surrounding medium are other important contributing factors in electromechanical bending response of a polyelectrolyte hydrogel.

In the present study, we conducted experimental measurements to demonstrate the electro-responsiveness of sclera and investigate the effects of magnitude of the electrical filed on bending response of the tissue.

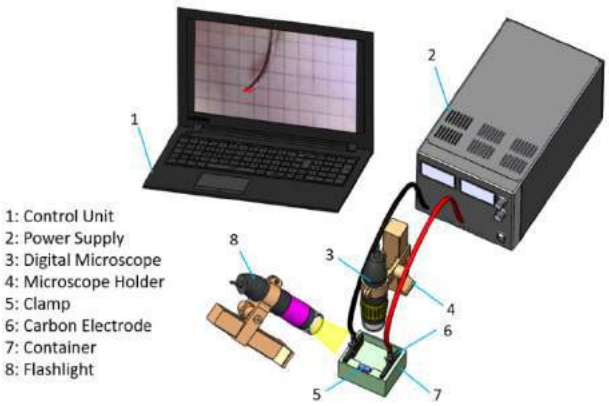
## METHODS

Fresh porcine eyes were collected from slaughterhouse (n = 18). After cleaning the globes by removing the fat and muscle, the globes were dissected, and sclera strips with dimensions of 2.5 mm × 20 mm were excised from the posterior of the eye globe in superior-inferior direction with 2 mm distance from the optic nerve head. The sclera strips were dried in desiccator for 24 hours. After measuring the weight of the dried samples, the strips were placed in 0.15M NaCl solution. The weight of the samples was monitored in time and their hydration H was calculated as

$$H = \frac{\mathrm{W_s} - \mathrm{W_d}}{\mathrm{W_d}}$$

where $\mathrm{W_s}$ is the wet weight of samples and $\mathrm{W_d}$ is their dry weight. After the samples reached to hydration of 2 mg water / mg dry weight, they were mounted in experimental setup. For conducting the experiments, we designed a container with two carbon electrodes 5 cm apart along with clamps for fixing the tissue from one side inside the container. We used a DC power supply for applying the electric voltage. In addition, we used a digital microscope to track the electromechanical bending response of the sample inside the container filled with NaCl solution (0.15M concentration). For this purpose, we developed a program in Python in order to capture the movement and calculate the

bending angle of the sample in real time. The main components of the experimental setup are shown in Figure 1. The bending angle of the samples was defined as deviation of their tip from the initial position as shown in Figure 2.



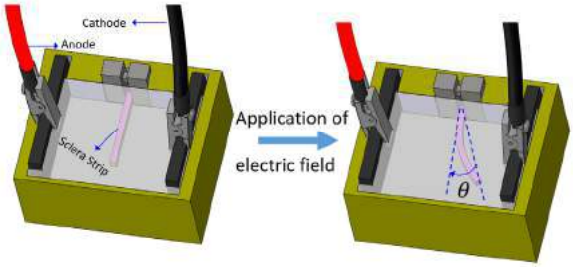


**Figure 2: Illustration of different components of the experimental setup. Sclera strips were mounted in the setup immersed in NaCl solution and their deformation was captured by a digital camera. The bending angle θ quantifies the amount of their bending under electrical stimulations.**

It is expected that the bending angle of the samples to depend on the pH of the solution since any change in the solution pH could change the amount of fixed charges inside the tissue. Upon applying the voltage, pH waves will be generated because of electrolysis of water. We used a universal pH indicator to monitor propagation of pH waves inside the container under different voltages.

## RESULTS

It was seen that with increasing the voltage, the pH waves propagate faster into the solution. For example, it took more than 2 minutes for pH waves propagating from the electrodes to reach the center of the container when an electrical voltage 15 V was used. It is also known that speed of pH wave propagation is proportional to the magnitude of the applied voltage. Since 15 V was the maximum voltage that we applied in the present work, we limited the duration of our experiments to 60 seconds in order to limit the pH variation inside the solution surrounding the samples.

The bending deformation of a typical sample under electric voltage is shown in Figure 1. Furthermore, the electromechanical bending response of scleral strips at 5 V, 10 V and 15 V of electrical stimulations was plotted as a function of time in Figure 2. It is seen that with increasing the voltage and time, the bending angle increases. The rate of scleral bending was fast in the beginning and it slowed down with increasing time.

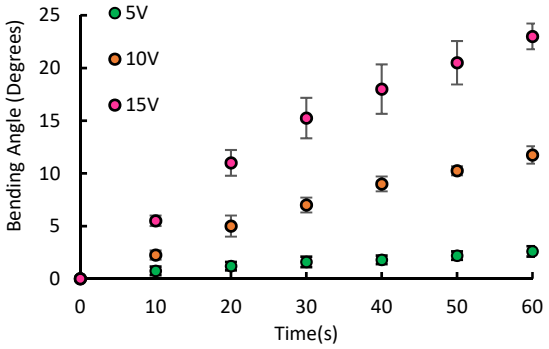

**Figure 2: The bending angle of scleral strips subjected to 5 V, 10 V and 15 V as a function of time.**

## DISCUSSION

The scleral samples showed mechanical bending response to the external electric voltage. We observed that samples subjected to 5V, 10V and 15V for 60 seconds reached to a maximum bending angle of nearly 3°, 10° and 23°, respectively. Thus, it is concluded that the deformation of sclera was significantly dependent on the magnitude of the applied external electrical field. This observation is in agreement with previous studies on the electroactive bending behavior of electroactive hydrogels [3]. This dependence on the strength of the electrical field is because increasing the voltage leads to increasing the speed of movement of the ions inside the solution. Subsequently, differential osmotic pressure at the boundaries of the samples and solution is created more quickly, which in turn increases the mechanical bending response of the tissue. The present experiments had some limitations. For example, the electrolysis of water and creation of pH gradient in the solution may have affected the electromechanical response of the tissue. This is because the pH waves alter the net electrical charges inside the tissue. In the present work, the strength of electrical field and time of electrical stimulation were limited to minimize the possible effects of pH gradient on electromechanical bending response of the samples. The present work characterized the electromechanical response of the sclera and its findings revealed some of the biochemical as well of biomechanical properties of this ocular tissue. We have also developed numerical models and tuned them against the experimental data [4]. We are currently working on applying the experimental framework of the present study to other biological tissue containing fixed electrical charges in order to increase our understanding of their electromechanical properties.

# FINITE ELEMENT SIMULATION OF ELECTROACTIVE MECHANICAL RESPONSE OF SCLERA USING A MULTI-PHYISICS CHEMO-ELECTRO-MECHANICAL MODEL

**Jafar A. Mehr (1), Hamed Hatami-Marbini (2)**

(1) Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, USA, Email. hatami@uic.edu

## INTRODUCTION

Electroactive hydrogels have gained great interest in the last years due to their wide range of applications from robotic and artificial muscles to drug delivery systems and biosensors. They can directly transform the electrical energy into mechanical work if placed in an electrical field. A polyelectrolyte hydrogel contains electrical charges which is bound to its polymeric network. According to the electroneutrality principle, when a charged electroactive hydrogels is placed inside a salt solution (e.g., NaCl), the unbalance between the electrical charges, causes the gel to swell. When an electrical voltage is applied to the electrodes, the local ionic strength is altered. The transient accumulation and transient depletion of mobile ions (e.g., $Na^+$ and $Cl^-$) at hydrogel and solution boundaries near the cathode side and anode side, in addition to causing swelling or shrinkage of the hydrogel-solution interfaces, create transient mechanical bending response of the electroactive hydrogel [1]. The purpose of this study is to propose and implement a numerical model for electro-actuation of the scleral tissue in support of recent experimental studies which showed that the sclera deforms when subjected to the electrical stimulations [2]. The sclera is composed of negatively charged proteoglycans and collagen fibers and we showed that it behaves like an electroactive polyanionic hydrogel. In these experiments, scleral strips were placed between two electrodes in a NaCl solution. We observed that the scleral strips bend in response to the electrical stimulations. Here, computational modelling will be used to understand and estimate the effects of various parameters on the electromechanical response of the sclera.

In the course of last decades, theoretical and computational models have been developed to study the electromechanical response of the electroactive hydrogels such as finite element models. These models are built based on principles of continuum mechanics and microscale level properties of hydrogels and their surrounding bathing fluid. In this work, we created a coupled chemo-electro-mechanical (CEM) model to investigate the electromechanical bending response of scleral tissue [3].

## METHODS

Figure 1 shows the numerical representation of the experimental studies of the sclera. The scleral strips of thickness of about 1.3 mm were clamped from one side inside the 0.15M NaCl solution at the center between two electrodes 5-cm away from each other; the same dimensions were used in the numerical simulations. The nonlinear coupled Poisson-Nernst Planck (PNP) system of equations are written as:

$$\frac{\partial c_i}{\partial t} + \nabla.\left(-D\nabla c_i - z\mu F c_i \nabla \emptyset\right) = 0 \qquad (1)$$

$$\nabla^2 \emptyset = -\frac{F}{\varepsilon_0 \varepsilon_r}\sum(z_i c_i) \qquad (2)$$

where $c_i$ is the concentration of mobile ionic species, D is diffusion constant of the ions, $\mu$ is mobility of the ionic species, R is universal gas constant, T is temperature, F is Faraday constant, $\emptyset$ is electric potential, z is the valence of the ions, $\varepsilon_0$ is vacuum permittivity, and $\varepsilon_r$ is the relative permittivity of the medium. We derived the weak form equations of the PNP system by multiplying the equations in appropriate test functions and integration by parts. The resulting PNP system of equations was solved using an open-source finite element platform (FEniCS) [4]. For this purpose, GMSH software was used to generate the domains and mesh [5]. As it is shown in Figure 1, the mesh was refined near the boundaries of the sample and solution to be able to capture the steep gradient of the ion concentrations at the sample-solution interfaces.

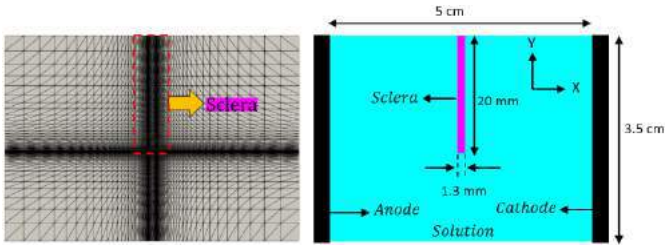

**Figure 1: Illustration of the mesh and computational domains.**

Furthermore, the equations of equilibrium are given by:

$$\sigma_{ij,j} + F_i = \frac{\partial^2 u_i}{\partial t^2} \qquad (3)$$

Where $\sigma_{ij}$ is the stress tensor, $u_i$ is the displacement vector, and $F_i$ corresponds to the body force. We defined the body force by introducing the osmotic pressure:

$$\Delta\pi = RT\sum[(c_i)_{Sclera} - (c_i)_{Solution}] \qquad (4)$$

In equation 4, $c_i$ represents the concentration of $i^{th}$mobile specie. Finally, the body force was defined as gradient of normalized differential osmotic pressures at the vicinity of anode side ($\Delta\pi_1$) and cathode side ($\Delta\pi_2$):

$$F_i = \frac{1}{RT}\nabla(\Delta\pi_2 - \Delta\pi_1) \qquad (5)$$

We used implicit backward Euler method to discretize the equations in time. We first validated our implementation of PNP equations in the FEniCS by reproducing the results of the reference paper [3]. The Young's modulus of the sclera, temperature, were taken equal to 0.2 MPa and 293K, respectively. The diffusion constants of the mobile ions, relative permittivity, and other constants were obtained from the literature. The simulation was performed for 60 seconds under 10 V of electrical voltage.

## RESULTS

The bending angle was defined as the angle that the tip of the sample makes with respect to the initial position that was calculated in each time step. The variation of the bending angle versus time along with deformation of the tissue in time are shown in Figure 2.

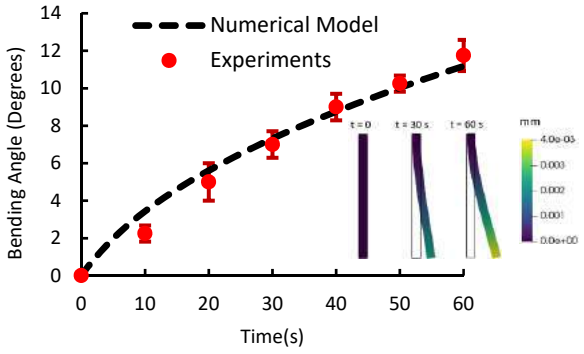

**Figure 2: The numerical results of the variation of the bending angle in time are compared with the experiments. The deformation of the sample along with contour of displacement are also shown.**

In this figure, the symbols show the experimental results. From fitting the model to the experimental data, the fixed charge density of 10 mM inside the tissue was found.

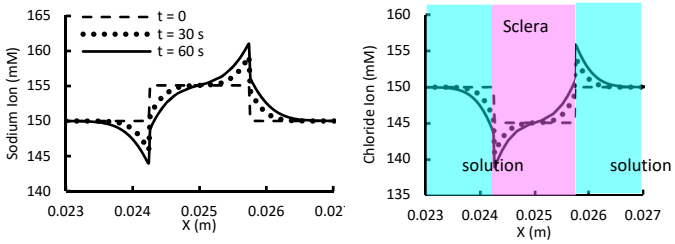

**Figure 3: Concentration of the sodium (Left) and chloride (Right) ions in different times under 10V of electrical stimulation along the horizontal line**

## DISCUSSION

We developed and implemented a CEM model for the simulation of electroactive bending behavior of polyelectrolyte hydrogels. The focus of our study was to use this computational model for investigating the electromechanical response of the sclera.

By looking into the variation of the mobile ion concentrations in time, we observe a step-shaped of distribution of the concentration of both ions along the width of the domains before applying the electrical voltage and in equilibrium state. Once the voltage is applied, these concentrations decrease in time at the anode side (i.e., left electrode) while they increase at the cathode side (Figure 3). This is in agreement with the theory of depletion polarization [6] demonstrating the bending of the sclera to the cathode based on generation of the differential osmotic pressure at the interfaces of the sclera and solution domains.

It should be noted that we simplified this simulation to a 2D geometry in order to reduce the computational cost. However, it could be extended to a more complex 3D geometry to achieve more realistic results in future. In addition, the linear elastic material model was employed in this study for simplicity. However, the sclera is fibrous tissue and orientation of the collagen fibers plays an important role in its mechanical response. This is another important fact that we are currently working on, i.e. using a nonlinear material model for the sclera. The numerical framework of the present study could be used to estimate to model the electroactive mechanical response of both electroactive biological tissue and hydrogels.

## INTRODUCTION

Endothelial cells (ECs) form the innermost layer of all blood vessels, and act as a barrier between blood and tissue to direct the transport of essential compounds within the body. These cells mediate transvascular transport in response to a variety of chemical and mechanical microenvironment including inflammation and shear stress [1,2]. Endothelial dysfunction, resulting in compromised vascular barrier function, is a hallmark of and contributes to the pathogenesis of various diseases including chronic kidney disease and cancer [3,4]. To quantitatively characterize vascular barrier function, two metrics are commonly employed: 1) the diffusive permeability ($P_d$), a measure of the barrier to molecular diffusion, and 2) the hydraulic conductivity (HC), a measure of the resistance to convection [5,6]. $P_d$ governs the rate of mass transport of a given solute across the vascular wall in response to a gradient in solute concentration, while HC governs fluid velocity in response to a transmural pressure gradient [5,6]. Previous work by our group and others have quantified $P_d$ in engineered vascular models as a measure of barrier integrity [7,8]. Here, leveraging a microfluidic model of the vasculature and live imaging techniques, we demonstrate a technique to determine the role of HC in governing transmural flux.

## METHODS

A microfluidic device featuring two parallel, cylindrical channels within a type I collagen hydrogel derived from rat tail was designed and fabricated as previously described (Fig. 1A) [7]. After seeding one channel with human umbilical vein endothelial cells (HUVECs), devices were placed either on a laboratory rocker (30 angle at 5 cycles/minute) or a static shelf within an incubator to precondition ECs with luminal flow applying a peak wall shear stress of 3 dynes/cm$^2$ or static culture, respectively (Fig. 1B). Devices were then flooded with 200 µg/ml 10 kDa Cascade Blue dextran. We then applied a defined concentration and pressure gradient across the vessel wall by emptying the non-seeded channel and adding a cocktail of 125 µg/ml 70kDa Fluorescein or Texas Red dextran and 200 µg/ml 10kDa Cascade Blue dextran to the seeded channel. Specific volumes of the dextran cocktail were added to generate pressure gradients of 0, 0.5, 5, and 50 Pa/mm across the two channels (Fig 2A). The endothelialized

channel was imaged every second for 1 minute as dextran entered the vessel and extravasated into the subluminal collagen matrix (Fig. 2B). Total transluminal flux of 70 kDa dextran was quantified as previously described [7]. Fluorescence recovery after photobleaching (FRAP) was then utilized to bleach a circular region of the 10kDa dextran, and the resulting bleached region was imaged every 0.25 seconds for 30 seconds. A Matlab code was written to track the displacement of the bleached region and to calculate the interstitial fluid velocity (Fig. 2C).

## RESULTS

ECs cultured on a rocker formed confluent monolayers, and the cytoskeletal structure of ECs aligned in the direction of flow; whereas, ECs cultured in static conditions demonstrated pericellular gaps, and ECs did not align in any direction (Fig. 1B). For applied pressure gradients up to 5 Pa/mm, the presence of ECs and flow preconditioning did not have an effect on total flux of 70 kDa dextran (Fig. 2D). At 50 Pa/mm, transluminal flux of 70 kDa dextran exceeded the magnitude of flux in unseeded channels, and transluminal flux was not a function of flow preconditioning (Fig. 2D). At pressure gradients less than and including 5 Pa/mm, interstitial velocity magnitude was significantly higher in unseeded channels, and velocity magnitude in seeded channels was not a function of flow preconditioning (Fig. 2E). When subjected to a 50 Pa/mm pressure gradient, interstitial flow velocity magnitude was highest in vessels with static preconditioning, followed by vessels with flow preconditioning, and vessels with no cells (Fig. 2E).

## DISCUSSION

The changes in EC actin alignment with the direction of flow, and a confluent endothelial monolayer, are consistent with previous studies on ECs cultured under applied shear stress [7,9]. While the pressures applied (0-200 Pa) and resulting pressure gradients (0-50 Pa/mm) are smaller in magnitude than physiological transluminal pressures (130-400 Pa) and pressure gradients (20,000 Pa/mm), we achieve transluminal velocity magnitudes similar to those found *in vivo* of 0.1-2 µm/s [10-12]. These results imply superphysiological HC values, which can be attributed to the reductionist nature of the assay –vessels are comprised of only ECs in a type I collagen hydrogel, whereas native vasculature is comprised of layers of surrounding mural cells and dense basement membrane [13]. We found the presence of ECs reduced fluid velocity magnitude, except at high (50 Pa/mm) transmural pressure gradients, where seeded vessels demonstrated increased fluid velocity magnitude compared to empty channels. The fluid velocity magnitude (> 4µm/s) at these pressures is greater than what is seen in healthy tissue [14], and the increased flow may be caused by flow-induced expression of matrix metalloproteinases [15] and resultant collagen degradation [16]. Future work entails isolating diffusive and convective contributions to transluminal flux of 70 kDa dextran. The resulting technique can be utilized to quantify and probe the underlying mechanisms that govern regulation of vascular barrier function in physiological and pathophysiological settings.

## INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disorder that leads to the breakdown of protective cartilage on bone, inflammation in the joint capsule, and pain [1]. OA is the most common form of arthritis and affects 32.5 million adults in the US [2]. Current treatments for OA include non-surgical intervention, surgery, and the administration of therapeutics. While there are some promising results using locally injected therapeutics to treat OA, they currently provide only short-term pain relief and fail to remain in the joint space for periods long enough to provide long-term benefits for patients [3].

The overall goal of this research is to develop a new strategy to extend the retention time of therapeutics, such as hyaluronic acid, within the joint space to slow disease progression and deliver long-term analgesic effects. To extend the retention time of therapeutics within the joint, we propose using collagen hybridizing peptides (CHPs), which are small, synthetic peptides that selectively bind to denatured collagen. CHPs can be conjugated to different functional groups, including therapeutics and imaging markers [4]. To better understand how CHPs behave following an intra-articular injection, CHPs were conjugated to near-infrared fluorophores (NIRF; excitation: 675 nm, emission: 720 nm) and the retention time of CHPs in healthy and osteoarthritic joints of a rat model was examined over two weeks using fluorescence imaging. Peptide with a scrambled sequence was used as a control. We hypothesize that the targeted CHPs (t-CHPs) will remain in the joint longer than the scrambled-sequence CHPs (ss-CHPs) since the targeted CHP can bind to denatured collagen within the joint.

## METHODS

Male Sprague Dawley rats (N=16) weighing 126-150 g were kept in accordance with the approved IACUC protocol through the University of Utah. Animals were assigned to one of four groups (n=4 per group): OA, t-CHP; OA, ss-CHP; healthy, t-CHP; or healthy, ss-CHP.

CHP (1 nmol in 25 µL of saline) and monosodium iodoacetate (MIA; 10 mg/mL in saline) solutions were prepared in a sterile environment.

Animals were anesthetized using isoflurane and the stifle joints were shaved. The skin was sterilized using isopropanol. Using a sterile 27-gauge/0.5-inch needle, a single intra-articular injection of 25 µL of MIA was administered to induce OA [5]. OA developed for one week before the respective CHP solutions, activated by heating for 10 min at 80°C and quenching for 30 sec on ice, were injected into the joint space under isoflurane. Healthy animals received only a single CHP injection.

Following the CHP injection, animals were kept under isoflurane and imaged (<2 hr following CHP injection) using an in vivo imaging system (IVIS; Perkin Elmer, Waltham, MA). During each subsequent imaging session (6, 12, 24, 48, 72, 120, 168, 240, and 336 hr), animals were anesthetized using isoflurane and imaged using the IVIS. During each imaging session, regions of interest (ROIs) were selected to encapsulate the stifle joint and a background measurement was taken over the shaved fur. Measurements of total radiant efficiency were collected and analyzed. Area under the curve (AUC), representative of "solution available," was calculated (Eq. 1) for both t-CHP groups.

$$AUC = \sum_1^n \frac{(C_{n-1} - C_n)}{2} * (t_n - t_{n-1}), \quad (1)$$

where $n$ is the time point number, $C$ is total radiant efficiency ($\frac{p/\sec/cm^2/isr}{\mu W/cm^2}$) measured, and $t$ is time (hours).

Sample size was calculated using an alpha of 0.05, power of 0.9, and comparing pilot signal intensities between t-CHP groups. Between the t-CHP groups, total radiant efficiency at each time point was compared using two-tailed t-tests to compare independent means in Stata (College Station, TX, USA).

To confirm the development of OA, stifle joints were harvested following euthanasia and fixed in 10% neutral buffered formalin for 120

hr. Joints were then decalcified, paraffin embedded, sectioned, and stained using Safranin-O and Fast Green.

## RESULTS

Primary outcomes of this study included differences in retention time between t-CHP and ss-CHP, as well as between healthy and OA animals. Analysis began at the 12-hr mark when IVIS signal became stable. The t-CHP signals were present throughout the imaging period and were still measurable at the 336-hr time point (Fig. 1, top two rows). However, signal from ss-CHP was already nearly cleared from the joint at the 12-hour mark (Fig. 1, bottom two rows).

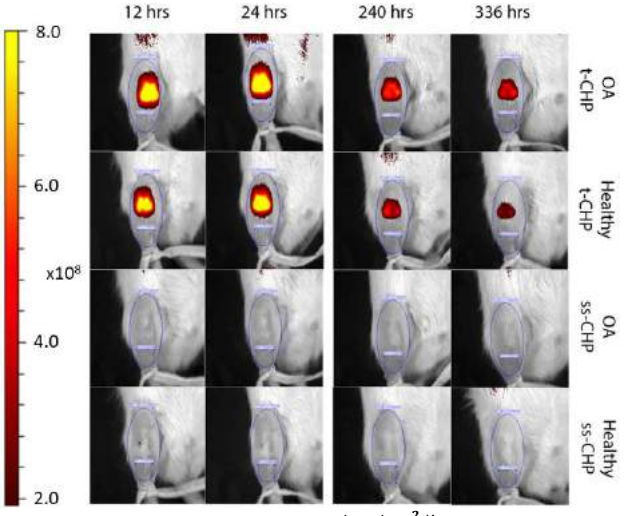

**Figure 1. Total radiant efficiency ($\frac{p/sec/cm^2/isr}{\mu W/cm^2}$) results from IVIS NIRF-imaging. Representative animal selected for each group. Time points 48-168 hr not pictured. Color bar ranges from 1.69E+10 to 8.0E+10.**

Independent t-tests comparing t-CHP between OA and healthy groups resulted in statistical significance ($p<.05$) for each time point (Fig. 2). Furthermore, AUC (mean±SD) between t-CHP groups was found to be statistically significantly different ($p=.0035$), where $AUC_{OA}$ = (2.41E+12) ± (3.31E+11) and $AUC_{healthy}$ = (1.62E+12) ± (7.68E+10).

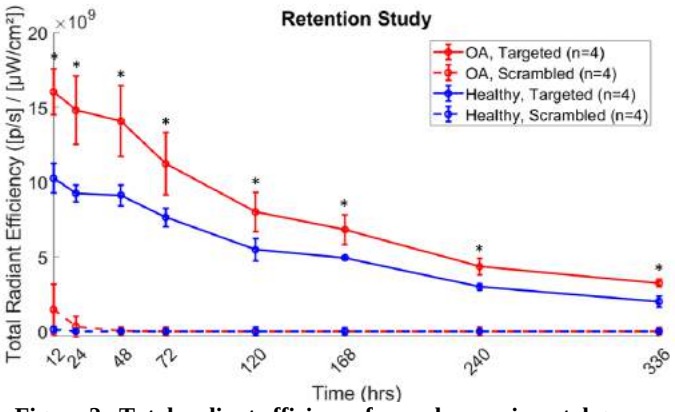

**Figure 2. Total radiant efficiency for each experimental group. Each time point represents mean±SD. * indicates $p<.05$ between OA targeted and healthy targeted at corresponding time point.**

Safranin-O and Fast Green staining showed a loss of proteoglycan content, hypocellularity, and an increase in calcified cartilage at the osteochondral interface in OA joints compared to healthy joints (Fig. 3).

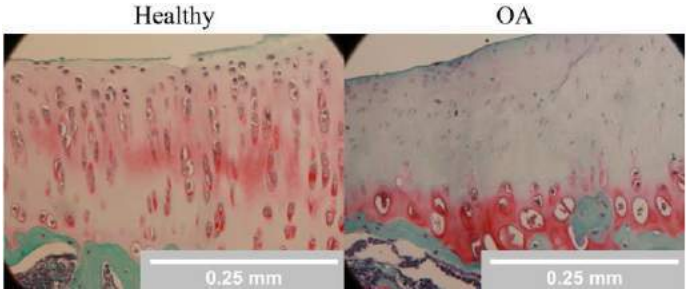

**Figure 3. Safranin-O and Fast Green staining of representative tibial plateaus. OA joints show a loss in proteoglycan staining (red) through the cartilage thickness, loss of chondrocytes (dark circles with surrounding white area), and an increase in calcified cartilage (dark red stain at osteochondral interface).**

## DISCUSSION

By longitudinally monitoring CHP presence through the use of NIRF markers (Fig, 1 and 2), we determined that t-CHPs remain in the joint space longer than ss-CHPs, confirming our initial hypothesis. This indicates that t-CHPs are, in fact, binding to collagen within the joint and remaining in the joint for the entire imaging period of 336 hr. On the other hand, ss-CHPs cleared quickly, within 12 hr of injection, as they do not bind to collagen and were cleared through the blood and lymphatics.

Further, between the t-CHP groups, OA joints retained the CHPs for a longer time than healthy joints. This is likely due to an increase in damaged and denatured collagens present in the OA joints, which are the primary targets that CHPs bind to. The CHPs stably bind to the collagen strands undergoing remodeling due to OA and remain in the joint for a longer period of time.

Through statistical analysis of the t-CHP groups, we determined that AUC, representative of "solution availability" in pharmacokinetic studies, was greater in OA joints than in healthy joints. This indicates that there is potential for an increased therapeutic availability in OA joints in future studies involving extended retention time of therapeutics.

Finally, through histological staining (Fig. 3), the development of OA was confirmed. Several features similar to OA seen in humans were present, including a loss of proteoglycans through the cartilage thickness, hypocellularity of chondrocytes, and an increase in calcified cartilage at the osteochondral interface.

IVIS imaging of NIRF-CHPs enables the longitudinal monitoring of CHP presence. This study represents a step towards establishing a method for extending the retention time of therapeutics within the joint space using CHPs functionalized with therapeutics to treat OA.

## INTRODUCTION

Abdominal aortic aneurysm (AAA) is the permanent expansion of the terminal aorta by more than 50% of its native healthy size and rupture is the 13th leading cause of death in the United States[1]. AAA rupture is a biomechanical event when the pressures induced wall stress exceeds the strength of the aorta to withstand the pressure. Researchers in the field of biomechanics have spent years trying to understand when rupture occurs and likely locations of where rupture could occur. Rupture potential index is defined as the ratio of the wall stress to wall strength to identify where rupture will occur in an AAA [2,3]. Experimentally measured material properties comprise constitutive models, which the stress model is based on. Assessing patient-specific wall strength is performed *ex vivo* through tissue extraction and subsequent mechanical testing. However, these destructive techniques cannot be performed *in vivo*. To address the need for a non-invasive assessment of wall strength, our lab previously developed a stochastic equation in 2006. This equation was derived using multiple regression to estimate wall strength from clinical factors, image-based indices, and experimental mechanical strength [4].

The purpose of the current study is to explore whether machine learning (ML) can more accurately predict the localized AAA wall strength. In addition, we will independently interrogate the sensitivity of individual factors (sex, smoking, and family history) in our model with the predicted wall strength values.

## METHODS

*Experimental Testing:* The previous mechanical testing and patient/imaging data from 23 patients and 83 tissue specimens were utilized [4]. The binary clinical factors gathered from each patient are sex, smoking status, and family history, as shown in **Table 1.** The tissue specimen was excised and CT image sets were used to measure the specimen diameters. The excised specimen was cut into 1.5 cm wide x 4 cm long sections and was uniaxially extended to failure.

**Table 1: Binary factors representation in the specimen cohort.**

| Factor | Number of Specimen | |
|---|---|---|
| **Sex** | 30% Male (n = 25), | 70% Female (n = 58) |
| **Non-Smokers** | 73% Smoker (n = 61), | 27% Non-smoker (n = 22) |
| **Family History** | 21% with Family History (n = 18), | 79% without Family History (n = 65) |

*Multiple Regression:* The multiple regression model (ranging up to 150 N/cm$^2$) as previously described by Vande Geest et al [4]. The factors considered in **Equation 1** are intraluminal thrombus thickness (in cm), the local normalized diameter (ratio 0–1), family history of AAA, represented by either no family history (-0.5) or family history of AAA (0.5), similarly, sex is striated by female (-0.5) or male (0.5).

$$Strength = 71.9 - 37.9 \times (\sqrt{ILT} - 0.81) - 15.6 \times (NORD - 2.46) - 21.3 \times HIST + 19.3 \times SEX \quad (1)$$

*Machine Learning:* A ML regression model, XGBoost, was used to fit the patient set (training set of 72 specimen, and 11 randomly selected validation specimen) which considers 13 variables: age, smoking history, local AAA diameter, maximum AAA diameter, proximal AAA diameter, three separate diameter ratios, predicted stress (from stochastic equation), and the four variables considered by the stochastic equation, from **Equation 1** [4]. To test the sensitivity of the algorithm, incorrect individual factors (from **Table 1**) were predicted.

*Statistical Comparisons:* The results of the wall strength predictions by the stochastic equation and ML model were compared by their correlation coefficients and $R^2$ values (using a zero y-intercept). Residuals were also compared between the previous stochastic model and trained ML model. The residuals of the wall strength predictions of individual factors were also compared to investigate if any binary factors have better predictions than their binary counterparts. Lastly, ANOVA was run with Dunnett's post-hoc to test the sensitivity of incorrect factors with the original ML predictions.

## RESULTS

The stochastically equation produced an R-value of 0.60 for the prediction of wall strengths below 150 N/cm$^2$ [4]. As shown in **Figure 1A**, ML predicted wall strength compared to experimentally measured wall strength below 150 N/cm$^2$ reports an R-value of 0.70 shown in **Figure 1B**, the residuals plots, the average error for the ML model estimating strengths below 150 N/cm$^2$ was 5.04 N/cm$^2$. When the curve is extended to 325 N/cm$^2$ the R-value increases to 0.83, but the average error increased to 9.89 N/cm$^2$.

Additionally, individual factors were inputted incorrectly to monitor how sensitive the algorithm is to binary factors. It can be seen in **Figure 2** that for both sex (0.36 ± 6.60 N/cm$^2$, correlation coefficient = 0.993, $R^2$ = 0.914) and smoking status (-0.17 ± 0.54 N/cm$^2$, correlation coefficient = 1.022, $R^2$ = 0.999), that the predicted wall strength is not statistically significant. Lastly, the predictions of family history (3.34 ± 14.17 N/cm$^2$, correlation coefficient = 0.938, $R^2$ = 0.694) are affected the most. It is important to note that statistically, none of these values are changed significantly different from the ML predictions.

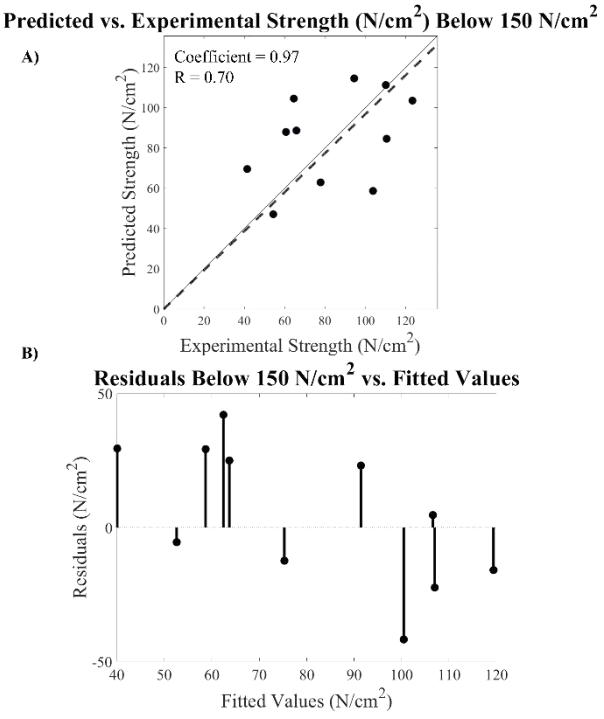

**Figure 1: A)** Plot of ML model's predicted versus measured wall strength below 150 N/cm$^2$ where R = 0.70. **B)** Residuals for ML predictions below where average error equals 5.04 N/cm$^2$.

## DISCUSSION

ML improved wall strength predictions compared to the previous stochastic model while also analyzing wall strengths up to 300 N/cm$^2$. The multiple regression equation was best suited for wall strengths up to 150 N/cm$^2$, whereas the ML model modeled wall strength predictions up to 300 N/cm$^2$. The ML predicted wall strengths below 150 N/cm$^2$ showed an improved R-value and decreased average error by 49% when compared to the ML predictions of wall strengths up to 300 N/cm$^2$.

In this study we find that the ML model is not sensitive to any factor. Particularly sex and smoking show nearly no effect on the estimated wall strength values. Family history is the factor that changed the ML prediction most. While it did not statistically change the predictions, it did lower the $R^2$ value (to 0.694). A study of the sensitivity of the stochastic model by Rengarajan et al., recently showed that family history was the most important factor to significant changes in the maximum RPI, and that the other three factors of wall strength stochastically (intraluminal thrombus thickness, NORD, and sex) did not significantly change the maximum wall strength predicted values, in the stochastic equation[5]. This suggests that the ML algorithm is less dependent on family history than the stochastic formulation was. While there is not a statistical difference in our results, trend-wise, incorrect family history led to the largest deviation of the predicted stress values.

This work is limited by a small data set. Therefore, future work will focus on data expansion techniques will be used to train our ML model on a larger variety of patient types. Future studies will incorporate this ML wall strength prediction into our rupture potential index pipeline, coupled with finite element models.

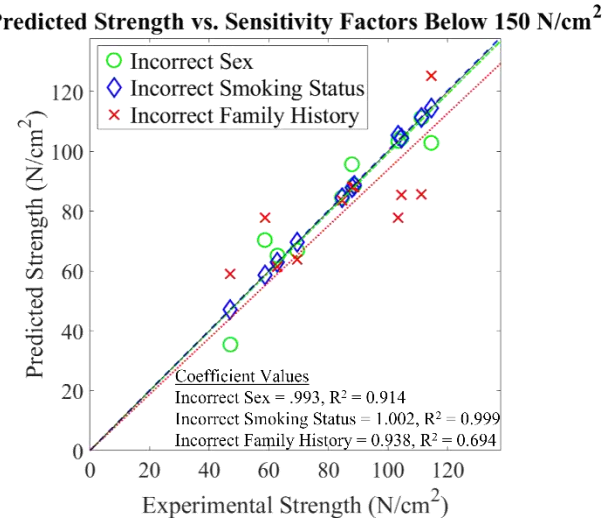

**Figure 2:** Plot of each incorrect factor mapped versus the original ML predictions of wall strength.

## INTRODUCTION

The cornea is the soft transparent tissue located at the anterior aspect of the eye, which helps bend light towards the retina [1]. It contains three distinct cellular layers (the endothelium, epithelium, and stroma), but the stromal compartment accounts for the majority of the tissue thickness. The corneal stroma contains a highly organized extracellular matrix (ECM) that consists of lamellae of aligned type I collagen fibrils [2], which imbue the tissue, in part, with its transparent optical properties [3].

In the healthy cornea, a population of cells called corneal keratocytes maintain this highly ordered ECM but remain otherwise mechanically quiescent [3]. Following injury or refractive surgery, however, damage to the cornea causes growth factors, such as transforming growth factor beta-1 (TGF-β1) and platelet derived growth factor-BB (PDGF-BB) to be released into the stromal space [4]. This process activates keratocytes into a repair phenotype and is associated with changes in tissue stiffness [5]. Previous work has shown that the TGF-β1-mediated myofibroblastic differentiation of corneal keratocytes depends on the mechanical properties of the ECM [6], but it is unclear if changes in ECM stiffness also regulate the response of keratocytes to other growth factors, such as PDGF-BB, or to combinations of growth factors like TGF-β1 and PDGF-BB.

Here, we used a polyacrylamide (PA) gel system to determine if changes in substratum stiffness regulate the proliferation and motility of primary corneal keratocytes treated with PDGF-BB, since PDGF-BB has been shown to promote both these phenotypes in cultured cells [7]. We also investigated how treatment with TGF- β1 and PDGF-BB influences the stiffness-dependent myofibroblastic differentiation of these cells.

## METHODS

PA substrata with an elastic modulus of either 1 kPa (soft) or 10 kPa (stiff) were fabricated to mimic the mechanical properties of either normal or fibrotic corneal tissue and then functionalized with unpolymerized type I collagen.

Primary rabbit corneal keratocytes (NRKs), harvested from rabbit eyes, as described previously [8], were plated on either the functionalized PA substrata or on collagen-coated glass coverslips and cultured in defined serum-free media. In some experiments, the media was supplemented with either PDGF-BB, TGF-β1, or a combination of both growth factors.

We used a freeze injury model to assay changes in keratocyte motility [9]. Briefly, a circular wound, approximately 1.5 mm in diameter, was created by holding a liquid nitrogen-cooled aluminum rod against the underside of the culture dish. The samples were then placed in a stage-top incubator, where time-lapse phase contrast images were captured at 1-hr intervals for 4 days. We used the Click-iT EdU Imaging Kit to quantify rates of cell proliferation. In other experiments, cells were fixed and stained with phalloidin and DAPI, to label F-actin and nuclei, respectively, as well as for alpha-smooth muscle actin (α-SMA), a marker for myofibroblastic differentiation, or phosphorylated myosin light chain (pMLC), a marker for active actomyosin contractility. To compute cell-generated traction stresses, we also performed traction force microscopy (TFM) experiments. Confocal images of fixed samples were captured on a Zeiss LSM 800, and quantitative image analysis was performed in ImageJ.

## RESULTS

In the presence of PDGF-BB alone, cultured NRKs exhibited stiffness-dependent differences in morphology and proliferation. In serum-free conditions, on substrata of all stiffnesses, the cells retained the branched, dendritic morphology indicative of a mechanically quiescent phenotype, as well as negligible amounts of EdU incorporation. In the presence of PDGF-BB, however, NRKs cultured on stiff PA substrata (or collagen-coated glass coverslips) exhibited a

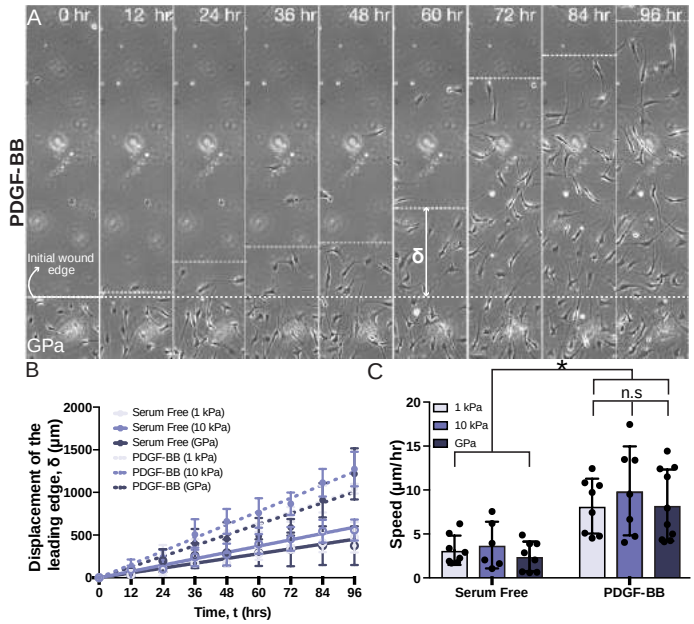

**Figure 1. PDGF-BB-treated keratocytes do not exhibit stiffness-dependent differences in motility. (A) Kymograph depicting the motion of the leading edge of a freeze-injury-induced wound. (B-C) Quantification of the (B) displacement, δ, and (C) speed of the leading edge of the wound.**

more highly spread and elongated morphology, as well as a higher rate of proliferation than cells cultured on soft PA gels (data not shown).

Changes in substratum stiffness, however, did not affect the migratory behavior of PDGF-BB-treated keratocytes. We created freeze injuries on both soft (1 kPa) and stiff (10 kPa) PA substrata, as well as collagen-coated glass coverslips (GPa), and quantified cell motion into the decellularized wounds. On substrata of all stiffnesses, PDGF-BB-treated cells migrated further into the wound and exhibited faster migration speeds than their counterparts in serum-free conditions, as assayed by both the tracked displacements of individual cells (data not shown), as well as the motion of the leading edge of the wound (Fig 1A-B). We did not, however, observe stiffness-dependent differences in the motility of keratocytes cultured in the presence of PDGF-BB (Fig. 1C).

We also cultured keratocytes in the presence of both TGF-β1 and PDGF-BB to determine how combinations of soluble cues impact stiffness-dependent differences in cell behavior. Surprisingly, we found that treatment with PDGF-BB disrupts the effect of substratum stiffness on the TGF-β1-mediated myofibroblastic differentiation of these cells (Fig. 2). In the presence of TGF-β1 alone, NRKs exhibited decreased α-SMA immunofluorescence on soft PA substrata as opposed to the elevated levels observed on stiff PA or collagen-coated glass coverslips, consistent with previous work (Fig. 2A) [6]. When treated simultaneously with PDGF-BB, however, we no longer observed stiffness-dependent differences in levels of myofibroblastic differentiation; elevated levels of α-SMA immunofluorescence were seen on substrata of all stiffnesses (Fig. 2B-C). No α-SMA-positive cells were observed in either serum-free media or when treated with PDGF-BB alone (Fig. 2C).

## DISCUSSION

Taken together, these data indicate that PDGF-BB modulates the stiffness-dependent behavior of corneal keratocytes. Changes in substratum stiffness alter the proliferation and morphology but not the motility of cells cultured in the presence of PDGF-BB alone. In addition, somewhat surprisingly, treatment with PDGF-BB disrupted the stiffness-dependent myofibroblastic differentiation of keratocytes also treated with TGF-β1. These data are suggestive of potential mechanotransductive crosstalk between the signaling pathways downstream of TGF-β1 and PDGF-BB. Indeed, previous work has shown that the TGF-β1-induced myofibroblast differentiation of corneal fibroblasts requires synergistic signaling between TGF-β1 and PDGF-BB [10], but the influence of biophysical cues on this process is completely unexplored. In vivo, corneal keratocytes are subjected to a multiplicity of soluble cues, and future work will be necessary to investigate how changes in ECM stiffness influence keratocyte behavior in response to combinations of different growth factors.

## INTRODUCTION

Low back pain (LBP) is a wide-spread, debilitating ailment that is currently listed as the leading cause of disability in the world[1]. It hinders the quality of life of roughly 80% Americans during their lifetime.[1] As a result, the disability has a high cost both from a health and a socioeconomic perspective. Root causes of LBP are challenging to diagnose and only a select few pathologies can be localized to a specific etiology. The facet joints have been identified as a potential origin of LBP, and studies confirm this idea with evidence of nociceptors in the facet capsular ligament (FCL)[2-4]. Mechanical nociceptor activation necessitates that a deformation and strain analysis be performed on the ligament to determine its potential contribution to LBP. An orthopaedic test known as the Kemp's test has shown the potential to specifically assess facet joint pain via a multiplanar motion that attempts to load the joint and recapitulate sympotomology.[5] **This study aims to quantify the three-dimensional strain fields across the FCL during dynamic activities.** The outcome of the study will relate dynamic activities to FCL strains, and lead to a better understanding of the mechanical environment surrounding the neurons.

## METHODS

One osteoligamentous lumbar spine (male, age 73) was obtained by the University of Minnesota Anatomy Bequest program and screened for spinal abnormalities. The L4 and L5 segment was scanned via a 3T MRI (Siemens MAGNETOM, Germany) utilizing T1 volumetric interpolated breath-hold examination sequences where the facets were scored with the Fujiwara scoring metric.[6] The left was scored a 3 for sclerosis and the right was scored a 2 for joint narrowing. Four 2mm tantalum beads were then embedded into each transverse process and into the vertebral bodies of L4 and L5. The spinal unit was then imaged with a CT scanner utilizing a B60 kernel scan sequence to maximize contrast between the bone and the surrounding tissue (Siemens Biograph PET/CT, Germany). Following imaging, the superior and inferior portion of segment was potted in polymethyl methacrylate in preparation for testing, and micro-dissected to expose the FCL. The specimen was then loaded into a calibrated Spine Kinetic Simulator (8821 Biopuls, Instron, USA), retroreflective markers were rigidly adhered to each vertebral body, and the ligament was speckled with an ultraviolet reflective paint to reduce glare and enhance contrast (Figure 1). The tissue remained hydrated using a saline soaked gauze.

Pure moments of up to 7Nm were applied to the segment in axial rotation, flexion/extension, and lateral bending at 0.015Hz for 3 cycles of preconditioning and 1 cycle for data analysis. Motion capture data was recorded at 100Hz, and three digital single-lens reflex (DSLR) cameras recorded videos of the ligament at 20fps. A multiaxial Kemp's test was simulated through 7Nm of extension and 6Nm of both axial and lateral bending. The Kemp's was performed to the ipsilateral and contralateral side and data were analyzed for both the right and left FCL.

**Figure 1: Experimental Set Up: The spine (circled) is shown loaded in the spine kinetic simulator while the optical motion capture cameras (yellow arrow) and DSLR system (gray arrow) recorded its motion.**

The CT scans were segmented within Mimics Software (Materialise NV, Leuven, Belgium). Anatomic landmarks were identified at adjacent surfaces of each endplate, and their relationships to the position of the tantalum beads within the CT coordinate system were established. Spine tester and optical motion capture data underwent a spatial frequency analysis to determine lowpass Butterworth cutoff frequencies and were filtered at 15Hz and 1.75Hz, respectively. The optical motion capture system, spine tester, and DSLR cameras were all time synchronized. The synced kinematic data collected via optical motion capture were transformed to the anatomic landmarks via a custom MATLAB code using the digitized beads to bridge the coordinate systems. The range of motion (ROM) was established to provide context for the recorded strain of the FCL.

The videos for digital image correlation (DIC) were converted into images and inverted to allow tracking. The images were decimated down to 0.5Hz and loaded into the MultiDIC MATLAB package.[7] To ensure an accurate measure of strain, an image of the ligament under zero load was used as the neutral frame. DIC analysis quantified the three-dimensional 1st principle Lagrangian strain fields across the FCL throughout each induced motion.

## RESULTS

Table 1 displays the segments ROM and translations for each activity. Figure 2 displays both the left and right FCLs at the maximum torque for each of the applied motions. A strain between 0.05 and 0.40 is shown between the interface of the joint consistently while the surrounding areas experienced little to no strain for all the motions. The ligament strained across the joint (i.e. in the bone-to-bone direction) with an oblique influence driven by the direction of primary motion. The Kemp's trial proved successful at deforming the ipsilateral FCL and created a lesser strain on the contralateral ligament.

## DISCUSSION

The results from this collected specimen showcase the feasibility of the introduced protocol. The areas of the highest strain for this specimen are near the articular surfaces and this is likely due to the orientation of the joint surfaces, direction of motion, and the FCL's predominant role in stabilization.[8] There is also an association between amount of motion of the segment and the corresponding strain of the ligament, as kinematic motions with a higher ROM had a larger strain.

A major limitation for this study is the use of a single specimen without active musculature and axial loading. Other limitations of the work are the inability to record the dynamic response of the FCL due to the quasi-static natures of the testing protocol, and the limits on speckle resolution due to spatial constraints.

The preliminary kinematic data aligns well with what has been recorded in the literature and we see ROM and strain that fall within expected ranges.[9-12] We plan to establish resultant strain field trends moving forward and isolate regions with consistent levels of high strain. Localizing these regions will be crucial in developing our understanding of the FCL's role in mechanical LBP.

**Table 1:ROM and Translations for each applied motion**

| | Rotations (°) | | | Translations (mm) | | |
|---|---|---|---|---|---|---|
| | Axial | Flexion | Lateral | Antero-posterior | Superior-inferior | Medio-lateral |
| Axial Rotation | 3.97 | 0.29 | 0.97 | 0.96 | 0.53 | 2.13 |
| Flex/ Ext | 1.61 | 6.63 | 1.00 | 6.42 | 0.97 | 1.96 |
| Lateral Bending | 1.31 | 0.61 | 5.73 | 2.08 | 0.85 | 2.94 |
| Kemps Left | 1.71 | 1.78 | 4.04 | 1.90 | 1.12 | 2.82 |
| Kemps Right | 2.32 | 3.49 | 4.34 | 2.37 | 0.49 | 3.42 |

# DYNAMIC MECHANICAL LOADING OF PHOTOPOLYMERIZED HYDROGELS AS A TOOL FOR STUDYING PULMONARY FIBROSIS

**Qi Wang (1, 2), Jacob Herrmann (1), Edward A. Sander (1) Kristan S. Worthington (1)**

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, IA, USA
(2) Medical Scientist Training Program, Roy J. and Lucille A. Carver College of Medicine, University of Iowa, Iowa City, IA, USA

## INTRODUCTION

Pulmonary fibrosis is a hallmark and final consequence of several lung diseases including idiopathic pulmonary fibrosis and post-COVID-19 pulmonary fibrosis. Although these diseases have distinct etiologies, the outcome is fibrogenesis that leads to impaired pulmonary function. Fibrotic lesions and scarring of the lung connective tissue are a result of alterations in extracellular matrix (ECM) composition and biochemistry. Current treatments, such as nintedanib and pirfenidone, have been shown to slow the progression of idiopathic pulmonary fibrosis. However, they cannot stop or reverse lung fibrosis.

Mechanosensing pathways can potentially mitigate lung fibrosis. However, animal models do not allow for isolated study of mechanical or chemical cues. Reductionist cell culture systems are essential for understanding the molecular mechanisms of fibroproliferative response and resolution of fibrosis. However, the lung is a dynamic environment in which cells experience cyclic mechanical loading in addition to biochemical and static mechanical cues from the extracellular matrix (ECM). Thus, a new *in vitro* culture system that allows for precise manipulation of mechanical and biochemical cues is needed to advance our understanding of how changes in the ECM influence fibrotic lung disease progression, so that better therapies can be developed.

Photopolymerized hydrogels are useful substrates for the study of cellular responses to ECM alterations. The composition and concentration of pre-polymer mixtures can be tuned to yield desired biochemistry and stiffness of hydrogels, respectively. In addition, the crosslinking of methacrylated polymers using UV light provides superior spatial and temporal control. These hydrogels are also biocompatible, and some can be used with no additional coating for cell attachment. They can also be attached to a bioreactor that applies dynamic mechanical loading. In this study, we describe how these elements can be combined to produce alveolar ECM mimics that serve as simple model systems of the native lung ECM.

## METHODS

Fabrication of hydrogels

Methacrylated gelatin (GelMA), methacrylated hyaluronan (HAMA) and non-methacrylated gelatin (Gel) were mixed in various concentrations as base materials. Hydrogels were formed via ultraviolet light (1W/cm2), with Irgacure-2959 used at 1% vol as a photoinitiator.

Material property measurements using Photo-rheology

Rheology was performed during the photo-crosslinking process using Kinexus Ultra+ (Malvern Panalytical) fitted with an Omnicure S2000 UV light source. Storage modulus during polymerization ($G'$) was fitted to **Equation 1** to determine final storage modulus ($G'_\infty$ ). Crossover point ($t_c$) was defined as the point in which storage modulus is greater than loss modulus ( $G''$)1

$$G' = G'_\infty\left(1 - \exp\left[-\alpha\left(\frac{t}{t_c - 1}\right)^\beta\right]\right) \quad (1)$$

Hydrogel biocompatibility

IMR-90 human fetal lung fibroblasts were seeded on polymerized hydrogels overnight. Standard viability assay was performed according to manufacturer's protocol. Cells were imaged and analyzed using ImageJ. Statistical analysis was performed using Graphpad PRISM.

Application of dynamic strain to hydrogels

Pre-polymer mixtures were applied to custom attachments designed for the bioreactor (ADMET Inc.) before photopolymerization at pre-determined photopolymerization times. The hydrogels were then deformed cyclically at physiological rates and over amplitudes spanning 5% and 80% strain.

## RESULTS

Photo-rheology results (**Fig 1A**) demonstrate that by changing the initial concentration of GelMA and Gel, the final storage modulus of photopolymerized hydrogels can be manipulated to fit desired substrate stiffnesses between 10 and 100 kPa. Photopolymerized hydrogels also allow precise spatial control of the biochemistry within the hydrogel,

such as shown in **Fig 1B**, where GelMA with rhodamine was photopolymerized with drops of HAMA approximately 2 mm in diameter. HAMA volume can be calibrated or 3D printed to achieve higher precision in the future.

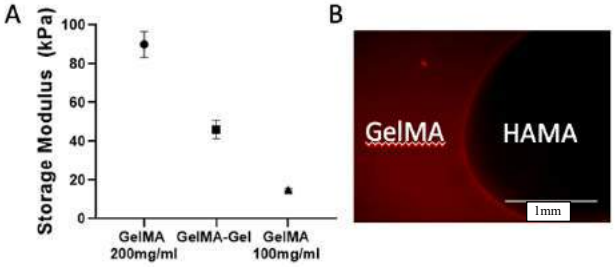

**Figure 1: Precise control of hydrogel stiffness and spatial composition**

Pre-polymer mixtures can also be applied to surfaces and polymerized to allow for attachment. **Fig 2C** demonstrates how these hydrogels can be attached on a bioreactor fitted with a servo-controlled linear actuator to apply prescribed waveforms. Five-second cycles (12 breaths per minute) were applied to photopolymerized hydrogels over amplitudes spanning 5% to 80% strain (**Fig 2A**). Force displacement curves were also obtained (**Fig 2B**). The gels exhibited nearly linear elasticity over this strain range.

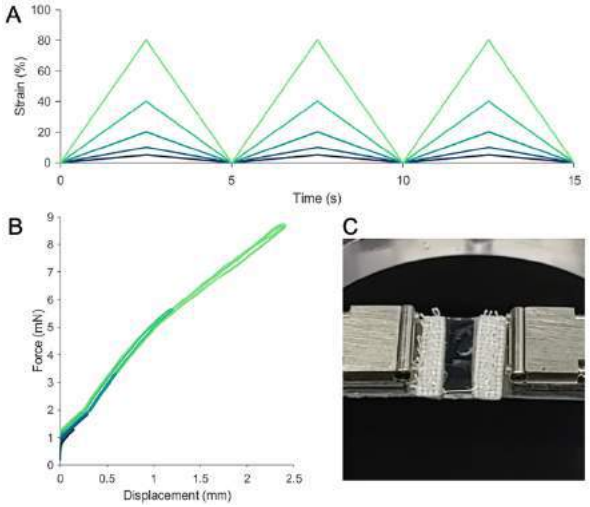

**Figure 2: Cyclic strain can be applied to hydrogels at controlled frequencies and strains**

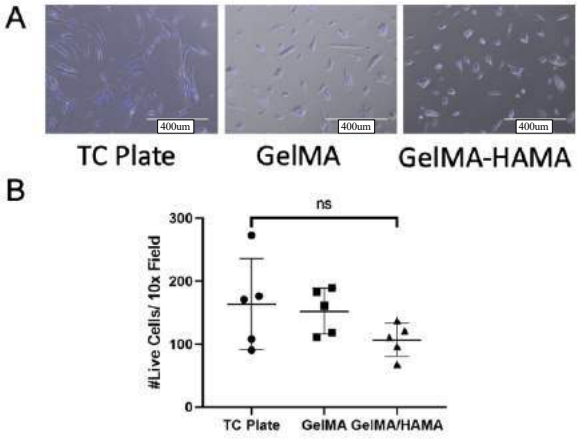

**Figure 3: Photopolymerized hydrogels allows for cell attachment without additional coating and are biocompatible**

IMR 90 fibroblasts were seeded overnight on GelMA and GelMA/HAMA (70/30) photopolymerized hydrogels. Qualitatively, seeding on tissue culture plastic (TC) caused more cell spreading compared to seeding on hydrogels, an observation consistent with the idea that cell area increases with substrate stiffness (**Fig 3A**). Live-dead viability assays were also performed and the number of live (blue) and dead (green) cells were analyzed using ImageJ. Despite the morphological differences observed, no statistical differences in cell viability were found between surfaces (**Fig 3B**).

## DISCUSSION

Overall, our results demonstrate that photopolymerized hydrogel stiffness, biochemistry and spatial composition can be precisely controlled to facilitate the study of ECM alterations in pulmonary fibrosis. The ability to manipulate stiffness with the addition of Gel not only allows for a wider range of hydrogel stiffness but also maintains similar number of Arg-Gly-Asp (RGD) binding sites at lower moduli. This capability is important for the study of pulmonary fibrosis because previous studies have demonstrated that inhibition of RGD binding sites ameliorates fibrosis.[2] The ability to include hyaluronan homogeneously or as concentrated foci is also important, as various studies of patients with fibrotic lung disease have shown an increase in hyaluronan deposition.[3] Hyaluronan is also a component of fibrotic foci, which is a hallmark of idiopathic pulmonary fibrosis.

Under physiological conditions, lung cells are continuously subjected to mechanical stimulation and in some instances, the mechanical stimuli can promote fibrogenesis.[4] This is the case for mechanical ventilation, which saves patient lives, but can also lead to ventilator induced lung injury, and thereby to pulmonary fibrosis. The ability to apply strain to photopolymerized hydrogels is therefore important for the study of cell behavior in the lung. As demonstrated by our results, photopolymerized hydrogels can be strained up to 80%. This is important for studying injurious ventilation associated with overdistension; our calculations suggest that dynamic conditions should include a 35% pre-strain and additional 20% cyclic strain.

Inherent cytocompatibility of these hydrogels is also an advantage for this application. Inconsistency in stiffness between coating and bulk material can impact strain experienced by cells. Conversely, the use of photopolymerized hydrogels composed of GelMA allows for direct cell attachment and showed no toxicity.

In our future work, we will use this system to identify individual contributions of stiffness and ECM composition in diseased lungs to the progression of lung fibrosis. Specifically, we will subject IMR90 fibroblasts to strain and strain frequencies modeling physiologic breathing and mechanical ventilation. Photopolymerized hydrogels ranging from 2kPa to 16kPa will be used to represent healthy to fibrotic lungs. We will then analyze these fibroblasts using an RT-qPCR panel of 32 genes. These experiments are expected to answer many questions regarding the relative contributions of ECM stiffness, composition, and cyclic mechanical loading to the progression of lung fibrosis.

# AN INVESTIGATION OF THE CHANGE IN pH FOLLOWING ADMINISTRATION OF PULSED ELECTRICAL FIELDS

**Zaid S Salameh, Kenneth N Aycock, Melvin F. Lorenzo, Rafael V. Davalos**

Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, USA

## INTRODUCTION

Irreversible electroporation (IRE) is an electric field-based treatment in which cell death is triggered by creating pore formations across the cell membrane.[1] It is well established that the non-thermal ablation treatment generates electrochemical effects.[2,3] In some instances, the electrolytic effects of pulsed electrical fields (PEFs) are intentional and combined with electroporation to maximize ablation volumes in a treatment termed E2.[4] However, these electrochemical effects can also disturb physiological pH, which may lead to unwanted side effects in surrounding tissue. These effects are thought to be more pronounced in monopolar pulses as compared to bipolar pulses. The second generation of IRE, known as high-frequency irreversible electroporation (H-FIRE)[5] utilizes shorter pulses of alternating polarity, which are known to mitigate these electrochemical effects. As different clinical treatments have their unique objective for these effects, there is a need to establish a relationship between treatment paradigms of PEFs and their subsequent electrochemical effects. Here, we utilize an agar solution and bromothymol blue, a pH indicator, to investigate and compare pH disturbances from treatments with different pulse parameters and in tissue phantoms with varying electrical conductivities.

## METHODS

*Experiment 1:* A 1% weight/volume agar solution was prepared with DI water and a 1/10 ratio of bromothymol blue. Bromothymol blue is a pH indicator that turns from green (pH 7.0) to dark blue (pH > 7.6). The solution was boiled, stirred, and split into three groups with varying concentrations of NaCl: 0%, .25%, and .5%. The solutions were pipetted into a 12 well culture plate (1 mL per well) and allowed to solidify for 24 hours. The same treatment was applied in each well using an ECM 830 Square Wave Electroporator (Harvard Apparatus, Holliston, MA): 100 V, 1 ms pulse width, and 99 pulses applied at 1 Hz. Current readings were collected using a wideband current monitor (Pearson Electronics, Palo Alto, CA) connected to an oscilloscope (Wavesurfer 3024z, Teledyne LeCroy, Chesnut Ridge, NY). Treatment was applied using a custom single needle-grounding ring electrode configuration. Photographs were captured and ImageJ (NIH, Bethesda, MD) was used to quantify pH disturbance area. pH disturbance areas were defined as areas with a pH greater than 7.6 after treatment, with the initial pH being neutral (pH 7). *Experiment 2:* The solution was prepared in the same manner as experiment 1. Applied voltage was adjusted between different groups to normalize the current using Ohm's law. A single diagnostic pulse (100 V, 50 µs) was applied to determine initial resistance. There are no significant electrochemical effects from this single pulse. The resistance of each group was used to find the necessary voltage unique to each group to normalize current to 250 mA. Treatment was administered identically to Experiment 1, but with different voltages applied to achieve this target current across each group. *Experiment 3:* The solution was prepared in the same fashion but with constant NaCl concentrations across all groups (.25%). The solution was added to a 12 well plate and 3 different treatments were applied. The treatments were uniform in applied electrical dose but varied in pulse width and voltage. The dose was kept constant using equation 1 with $E$=electrical field, $\eta =$ pulse number, and $\tau$ = pulse width.

$$Dose = E^2 * \eta * \tau \quad (1)$$

Voltage ($V$) can be substituted for the electrical field ($E$) because the electrical field is dependent on the geometry of the electrodes and our geometry is constant. Treatment consisted of 99 monopolar pulses applied at 1 Hz. The groups were treated with 500, 158, and 50 V with pulse widths of 100 µs, 1 ms, and 10 ms, respectively. *Experiment 4:* Experiment 3 was repeated, with the on-time, frequency, and conductivities of each treatment kept constant but the pulses were set to be bipolar. Treatment was applied via 50-10-50 µs pulses (positive pulse–delay–negative pulse) with 1, 10, and 100 being the number of cycles per burst for the 3 treatments. Each burst correlates with a pulse width group in experiment 3, hence constant on-time.

For each group, the conductivity was computed with equation 2. The shape factor k is from the analytical equation of two finite concentric cylinders (equation 3).

$$\sigma = \mathrm{k} * \frac{I}{\mathrm{V}} \quad (2)$$

$$k = {2\pi L}\Big/{\ln\left(\frac{r_2}{r_1}\right)} \quad (3)$$

*Statistical Analysis:* An ordinary one-way ANOVA and post-hoc Tukey's multi-comparison test was used to assess differences in pH disturbance sizes.

## RESULTS

The experiments were designed to investigate the effects of voltage, current, conductivity, pulse width, polarity, and ionic concentration on pH change. The goal of the first experiment was to isolate the effects of induced electric current by varying the tissue phantom's electrical conductivity. A significant increase in pH disturbance area was observed among all treated tissue phantoms as shown in Figure 1A. The change in pH area was 61.83 $mm^2$ between 0.050 A and 0.350 A ($p<0.001$) and 21.54 $mm^2$ between 0.350 A and 0.700 A ($p<0.001$). Experiment 2 was necessary to isolate the effects from the concurrent change in conductivity and ionic concentration. Voltage was adjusted to normalize the current through each tissue phantom, and we recorded a statistically insignificant difference among all tissue phantom groups as seen in Figure 1B.

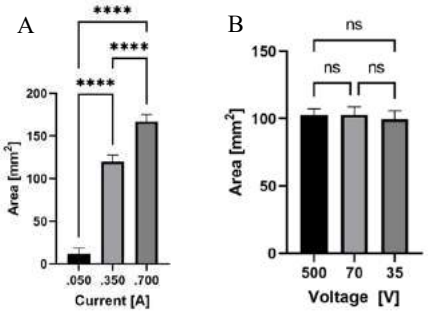

**Figure 1: A) Increased conductivity resulted in an increased current, which correlates with a greater pH disturbance. Conductivities were found to be 0.1, 0.7, and 1.4 S/m from left to right. (n=4) B) Area of pH disturbance generated by constant-current treatment (0.250 A) within tissue phantoms of different electrical conductivities. (n=4)**

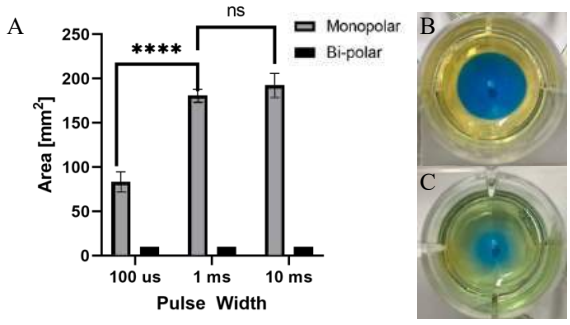

**Figure 2: A) Increased pulse width increases area of pH disturbance in dose matched treatments. Voltage decreases from left to right [500, 158, 50 V] to ensure constant dose. The bipolar pulsing method show minimal effects on pH. (n=4) B) Tissue phantom treated with 10 ms monopolar pulse width applied at 50 V. C) Tissue phantom treated with 100 µs monopolar pulse width applied at 500 V.**

To isolate and investigate the effects of pulse width and voltage, the total dose was kept constant in accordance with equation 1, with pulse width increasing inversely with voltage. The change in pH area was statistically significant from 100 µs to 1 ms ($p<0.001$) and statistically insignificant from 1 ms to 10 ms. Figure 2A shows minimal change in pH across the bipolar treatment groups when compared with each other and are negligible when compared with their correlating monopolar group. Figures 2B – 2C provide visuals of the tissue phantoms dyed with bromothymol blue following monopolar treatment. The yellow, green, and blue coloring represent pH of less than 6.0, between 6.0 and 7.6, and greater than 7.6, respectively. The tissue phantoms were green prior to treatment (pH 7.0).

The results from switching the needle's polarity from the anode to cathode show the anode generates an acidic pH and the cathode generates a basic pH. These effects are equal and opposite. These data show current and pulse width dominate the electrical field in generating electrochemical effects.

## DISCUSSION

These data offer new insight into the electrochemical effects of PEFs and demonstrates pH change is driven from the flow of electrons. Tissue phantoms in experiment 1 were all treated with the same pulse parameters while the conductivity was varied by increasing concentrations of the electrolyte NaCl. This experiment was able to show a statistically significant increase in pH disturbance area although the voltage was constant. In translation, as electrical properties vary drastically between different tissue types[6], organ-specific protocols will need to be developed if these pH changes are to be used for therapeutic purposes. Experiment 2 furthers this notion by demonstrating a statistically insignificant difference in pH disturbance area among groups with different voltages. Experiment 3 demonstrates a significant increase in pH disturbance area as pulse width increases inversely with voltage, followed by experiment 4 which confirms bipolar pulses have a significantly smaller effect on pH than monopolar pulses. However, due to the broad pH threshold of the dye (pH 6.0 – 7.6) we were limited in investigating the extent of bipolar pH changes which most likely occur within that margin. The results of this study show that in monopolar pulses, current and pulse width dominate the subsequent electrochemical effect, suggesting that electrochemical effects are less dependent on the electrical field. H-FIRE is a competitive treatment for applications in which pH change is unwelcome because of its bipolar pulsing mechanism. These data provide insight for applications of PEFs which seek to leverage these electrochemical effects, such as to increase ablation volumes with the combination of electroporation and electrochemical effects.[4] This study evaluates the driving mechanisms behind electrochemical effects of monopolar pulses and can provide guidance in modulating these effects for clinically relevant treatment paradigms.

## INTRODUCTION

The development of numerous organs in the body, including the lung, kidney, and salivary gland, involves a series of branching events referred to collectively as branching morphogenesis. In the embryonic lung, this process constructs the bronchial tree, a ramified architecture that facilitates the transport of air to the distally located alveoli, where gas exchange occurs [1]. Normal airway branching depends crucially on cell proliferation, and several signaling pathways, including those downstream of sonic hedgehog (Shh), Wnt, and various fibroblast growth factors (FGFs), have been shown to regulate this process. Recent work, however, has shown that mechanical forces can also influence airway branching. The embryonic airways are fluid-filled, and changes in luminal fluid pressure can modulate rates of branching morphogenesis in cultured embryonic lungs [2]. The embryonic airway epithelium is secretory, and fluid pressure is controlled by the amount of fluid secreted into the luminal space. Even so, it is completely unclear how changes in epithelial fluid secretion and luminal fluid pressure impact the patterns of proliferation that sculpt the bronchial tree.

Here, we focus on lateral branching morphogenesis and use as a model system the embryonic avian lung, which forms exclusively via lateral branching, wherein daughter branches form along the length of the parent branch. We thus used pharmacological modulators of epithelial fluid secretion to alter the transmural pressure in cultured embryonic chicken lungs. These experiments were then combined with quantitative fluorescence microscopy to determine how changes in fluid secretion affect patterns of proliferation during the formation of lateral branches. We also microinjected a small volume of biologically inert oil into the lumen of some lungs to locally dilate the embryonic airway. These explants were then cultured and quantified for changes in proliferation in the neighborhood of the locally distended lumen.

## METHODS

Fertilized White Leghorn chicken eggs were incubated at 37°C in a forced-draft incubator to Hamburger and Hamilton stage 26. Embryonic lungs were dissected in phosphate-buffered saline (PBS) using fine forceps and cultured for 24 hr on Nucleopore membranes at the air/liquid interface in DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS) and antibiotics. In some experiments, the culture medium was supplemented with either an agonist (10 μM forskolin, 100 μM CPT-cAMP) or antagonist (200 μM bumetanide, 100 μM CFTR inhibitor-172) of epithelial fluid secretion. In other experiments, to locally (and more directly) alter epithelial tension, a pulled glass micropipette was filled with biocompatible oil and inserted into the lumen of the embryonic airway. A small amount of oil was then injected into the lumen with the use of a pneumatic pump.

Bright-field images of cultured explants were captured at 0 and 24 hr. We used the Click-iT EdU Imaging Kit to quantify rates of epithelial proliferation. Samples were pulsed with EdU 20 min prior to fixation. Fixed explants were then co-stained with LCAM immunofluorescence and DAPI, to label the airway epithelium and nuclei, respectively, and then optically cleared. Confocal fluorescence images of whole-mount explants were then captured using a laser scanning confocal microscope. Quantitative image analysis was performed using ImageJ.

## RESULTS

To determine how changes in fluid secretion impact branching and proliferation during early lung development, we used pharmacological modulators of epithelial fluid secretion to alter the transmural pressure in cultured embryonic chicken lungs. Treatment with forskolin, an activator of cAMP and agonist of fluid secretion, caused the embryonic airways to dilate dramatically and produced a significant decrease in the formation of new branches (Fig. 1). Similar results were obtained using explants treated with 100 μM CPT-cAMP, another activator of cAMP

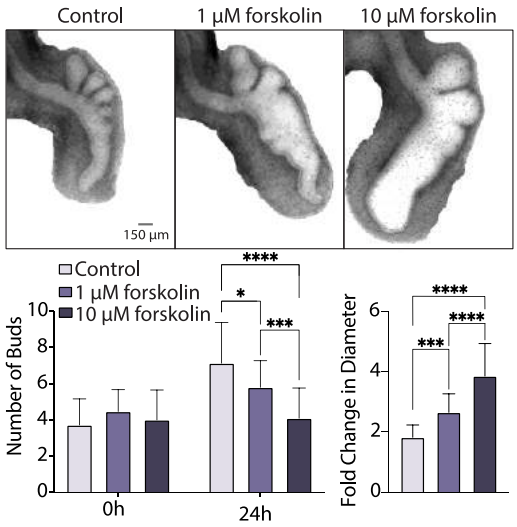

**Figure 1: Embryonic chicken lungs treated with forskolin, an agonist of fluid secretion, show decreased branching morphogenesis.**

and agonist of fluid secretion. Then, to determine if the observed decrease in branching was associated with a concomitant change in proliferation, we quantified rates of EdU incorporation in explants cultured in the presence of forskolin. Increased levels of fluid secretion modified patterns of proliferation along the airway epithelium (Fig. 2), increasing slightly the rate of proliferation in the nascent buds and, more surprisingly, elevating levels of proliferation in non-branch-forming regions along the ventral epithelium. Proximal regions of the airway, which remained undilated after treatment with forskolin, did not show dose-dependent changes in proliferation, suggesting that proliferative

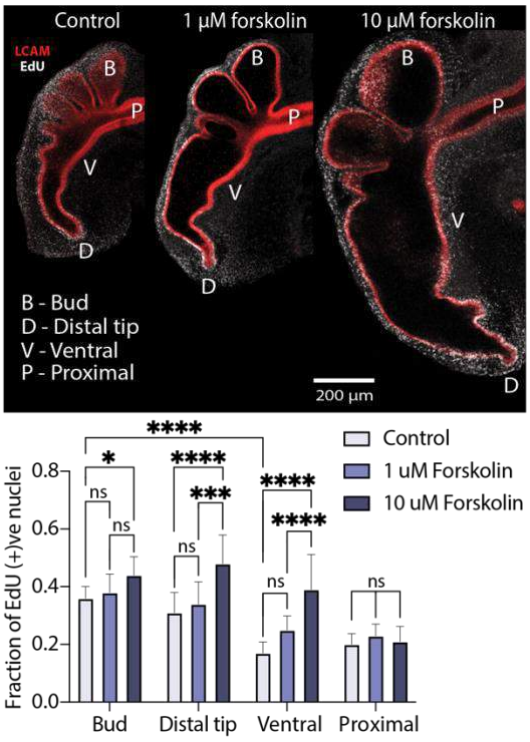

**Figure 2: Increased luminal pressure promotes proliferation in a non-branch-forming region of the embryonic chicken airway epithelium.**

differences along the dilated epithelium were caused by increased fluid pressure, as opposed to other off-target effects associated with increased cAMP activity.

To more locally perturb the transmural pressure, we also microinjected a small volume of flourinert FC-70, a biocompatible oil, into the lumen of the embryonic airway in other explants (Fig. 3). Each localized distension of the airway inhibited the formation of new epithelial buds (Fig. 3) and produced a localized increase in EdU incorporation around the dilated lumen, consistent with our fluid secretion experiments (data not shown).

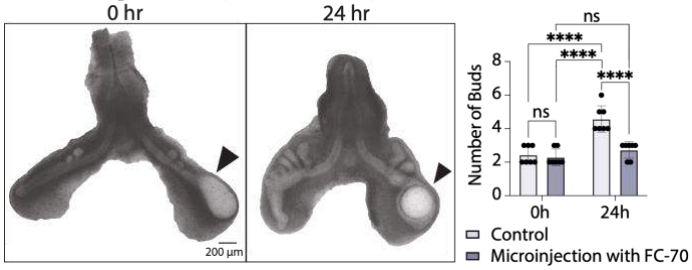

**Figure 3: Microinjection with bioinert oil produces local dilation of airway epithelium leading to disrupted branching morphogenesis.**

Lastly, to determine the effect of decreased fluid pressure on branching morphogenesis, we cultured other explants in the presence of either 200 μM bumetanide or 100 μM CFTR inhibitor-172 to inhibit epithelial fluid secretion. Treatment with each of these inhibitors caused the embryonic airways to collapse and increased the number of new epithelial buds. Taken together, these data suggest that changes in fluid secretion and luminal fluid pressure can modulate proliferation and branching morphogenesis within the developing bronchial tree.

## DISCUSSION

Many congenital lung malformations, including pulmonary hypoplasia and congenital diaphragmatic hernia (CDH), are associated with defects in the mechanical environment surrounding the fetal lung [3]. To treat patients with CDH, surgeons perform a risky surgery known as fetoscopic endotracheal occlusion (FETO), which involves inserting and inflating a balloon in the fetal trachea to increase the fluid pressure within the lung. This operation can rescue the hypoplastic lung phenotype by increasing lung growth, but it is unclear if changes in fluid pressure impact the patterns of proliferation that underlie airway branching morphogenesis. Our experiments suggest that increased epithelial fluid secretion, and thus luminal fluid pressure, alters the spatial pattern of proliferating cells in cultured embryonic lungs. Previous studies using embryonic mouse lungs have shown that elevated fluid pressure can increase rates of branching morphogenesis [2]. Our experiments, using cultured embryonic chicken lungs, however, suggest the opposite. Since avian lung development depends exclusively on lateral branching, whereas branching morphogenesis in the mammalian lung involves both lateral branches and bifurcations, these results suggest that particular branching modes may be affected differently by changes in luminal fluid pressure.

# AN PHYSIOLOGICAL ON-CHIP VESSEL PLATFORM TO STUDY VASCULAR TRANSPORT OF CIRCULATING TUMOR CELLS

**Yue Wu[1], Yuyuan Zhou[1], Ratul Paul[2], and Yaling Liu[1, 2, *]**

[1]Bioengineering Department, Lehigh University, Bethlehem, Pennsylvania, 18015, USA

## INTRODUCTION

Cancer is a major public health problem in the world and metastasis is the direct culprit of most cancer related deaths[1]. By releasing the circulating tumor cells (CTCs), primary solid tumor can initiate the metastasis process and disseminate to distant organs (Fig.1)[2]. Among them, blood vessels function as highways for CTCs transportation[3,4]. Due to the rarity of the event and limited *in vivo* characterization techniques, the cancer metastasis still remains enigmatic.

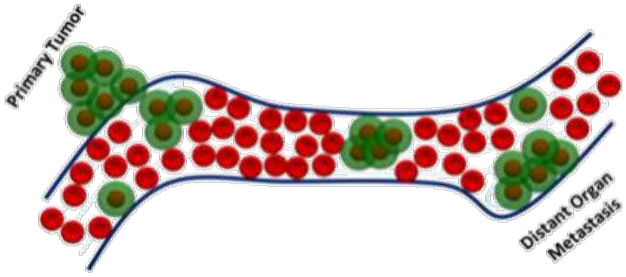

Figure 1. Vascular transport of CTCs from primary tumor to distant dissemination.

To date, microfluidics has become a powerful modeling and screening platform to investigate cancer biology and develop cancer therapy[5–7]. Here, we report an microphysiological vessel platform. With facile on-chip modelling of vessels, vascular transport of CTCs can be recapitulated and characterized *in vitro*. As a demonstration, the influence of vascular glycocalyx (VGCX) status on CTC adhesion was investigated. It is believed that our microphysiological vessel platform will not only help address critical steps in complicated metastatic cascades but also contribute to advanced cancer therapy development.

## METHODS

Human umbilical vein endothelial cells were cultured in EGM-2 medium (Lonza). Prostate cancer cell, PC3, were cultured in F-12K medium (ATCC). All cells and experiments were incubated at 37 °C with 5% CO2.

The microfluidic devices were fabricated using standard soft lithography techniques (Fig. 2A). A PDMS rod was used as mold and loaded in the chamber[8]. Then, fibrinogen solution was mixed with thrombin and injected into the device through side ports. After hydrogel polymerization, the rod was extracted and HUVEC suspension was seeded int the tubular channel. The channel endothelialization can be finished in 24 hours.

Suspended PC3 cells were perfused through the vessels of different VGCX thickness and the adhered cancer cells were counted. The VGCX was labeled with biotinylated wheat germ agglutinin (WGA; Vector Labs) lectin. Neuraminidase (Neur) enzyme in PBS was used for VGCX degradation[9].

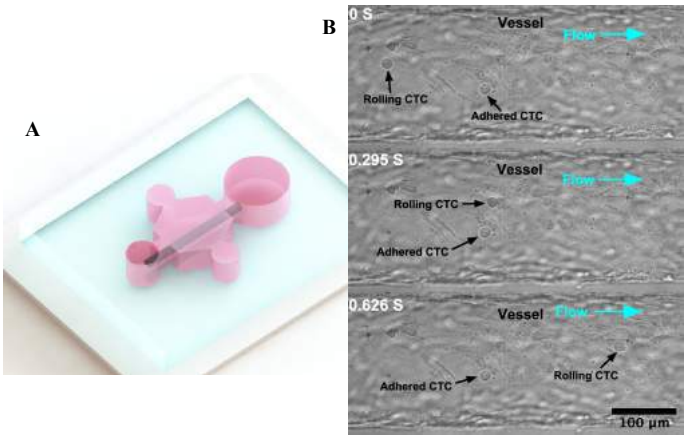

Figure 2. Microfluidic on-chip vessel platform. A) Schematic of microfluidic device. B) Representative images of CTCs transport on the vessel. CTCs move on the vessel inner surface in a rolling manner.

## RESULTS

With high-speed camera recording, CTCs were observed to move on the inner surface of the blood vessel in a rolling manner (Fig. 2B). Once adhered, the CTC would stop movement and not be detached easily by

flow within a certain flow rate. Our observation is consistent with some theories which claim that hematogenous metastatic behavior of CTCs maybe similar to leukocyte transport in the bloodstream, during the inflammatory response[10].

Furthermore, as the VGCX thickness decreased, the number of adhered CTCs increased significantly (Fig. 3). The potential explanation would be that degraded VGCX increase the probability of direct contact between various adhesion receptors, such as integrins, immunoglobulins, and selectins[11] with ligands on CTCs.

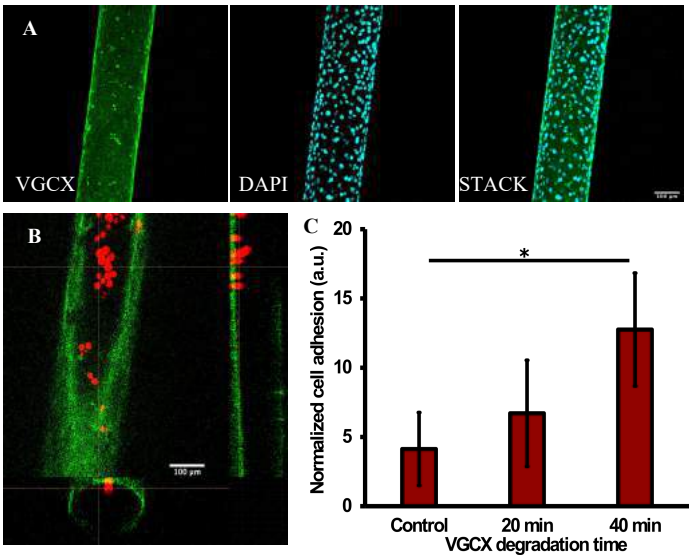

Figure 3. CTC adhesion result on vessels under various VGCX conditions. A) VGCX characterization of the on-chip vessels. Fluorescent staining of VGCX (green). The VGCX was labelled by WGA, which targets some main components of VGCX, including sialic acid and N-acetylglucosamine. DAPI signal (blue) stains cell nuclei. B) Confocal scanning of adhered CTCs on VGCX. VGCX were labeled with WGA (FITC). C) Normalized rate of adhered CTCs on the vessels with VGCX degradation treatment of different times.

## DISCUSSION

In addition to the above-mentioned biophysiological factors, we will also study the effect of biomechanical factors such as flow rate and vascular geometry on CTC transport on this platform. As a demonstration, a stenotic vessel model will be constructed on-chip and CTCs' movement in the resulted hemodynamic disturbed flow will be probed in real-time. Moreover, cancer intravasation and extravasation of vessel will be modelled *in vitro*. By recapitulating these key steps of cancer metastatic cascade, our adaptable vessel-on-a-chip platform is envisioned to facilitate cancer metastasis interpretation and has potential for personalized therapy screening.

## INTRODUCTION

Osteoarthritis (OA) is a multifactorial disease of synovial joints with degeneration and loss of articular cartilage as a hallmark feature. Nearly 20% of the US population suffers from OA, affecting quality of life through pain, functional limitations, lost earnings, anxiety, and depression. While mechanical stimuli is essential to maintain healthy cartilage, overloading (e.g. trauma) and reduced loading (e.g. immobilization) induce molecular and microstructural changes that lead to mechanical softening, fibrillation, and erosion [1].

In response to mechanical stimuli, chondrocytes (the cells within cartilage) express chemicals (e.g. cytokines, growth factors, collagenase, and aggrecanase) which promote degradation or production of structural constituents, e.g. collagen and proteoglycan. Existing investigations on effects of mechanical loading on cartilage – including both *in vitro* experiments with human cartilage and *in vivo* animal models – fall short of true human physiological relevance [2]. Current mathematical models of signaling pathways lack mechanical effects while biomechanical models lack the chemical effects [3].

To facilitate better understanding of the coupled chemo-mechano-biological evolution of OA in cartilage, we seek coupled functional forms among intra-tissue mechanics and cell-driven mass/volume changes mediated by cytokines and chemical species. Here we establish a framework incorporating the evolution of chemical, mechanical, and biological constituents generating anisotropic volumetric changes in cartilage. We leverage our established constitutive model of cartilage [4] and adapt a biochemical pathway model [5] to predict the evolution of relevant cellular and biomolecular species during OA. We demonstrate our framework by predicting the effects of immobilization and overloading on the progression of OA (and relative to homeostasis).

## METHODS

*Constitutive Model.* To capture the nonlinear mechanics of cartilage, we employ an additive decomposition of the superimposed solid Helmholtz free energy $\psi^{\mathrm{S}}$ into $\psi^{\mathrm{S}}_{\mathrm{IM}}$ and $\psi^{\mathrm{S}}_{\mathrm{FN}}$, representing an isotropic matrix and a distributed, fiber network respectively as [5]

$$\psi^{\mathrm{S}} = (1-\nu)\psi^{\mathrm{S}}_{\mathrm{IM}}(J_{\mathrm{S}}, I_1) + \nu\psi^{\mathrm{S}}_{\mathrm{FN}}(I_4, \mathbf{M}) \,, \tag{1}$$

where $\nu$ is the volume fraction of collagen to total solid, $J_{\mathrm{S}}$ is the Jacobian, $I_1 = \mathrm{tr}(\mathbf{C}_{\mathrm{S}})$ with $\mathbf{C}_{\mathrm{S}}$ the right Cauchy-Green tensor, and $\mathbf{M}$ is the reference fiber orientation with $I_4 = \mathbf{M}\cdot\mathbf{C}_{\mathrm{S}}\mathbf{M}$. We modeled the densely packed proteoglycan using a neo-Hookean strain energy function for $\psi^{\mathrm{S}}_{\mathrm{IM}}$. We modeled the network of collagen fibers as [5]

$$\psi^{\mathrm{S}}_{\mathrm{FN}} = \frac{1}{\rho^{\mathrm{S}}_{0\mathrm{S}}}\int_{\Omega}\rho(\mathbf{M})\frac{k_1}{2k_2}\left\{e^{[k_2(I_4-1)]^2-1}\right\}\mathcal{H}(I_4-1)\,\mathrm{d}\Omega \tag{2}$$

where $\rho(\mathbf{M}), k_1, k_2$ are an orientation distribution function and two model parameters, respectively, and $\mathcal{H}$ is a Heaviside function.

*Anisotropic Volumetric Growth and Remodeling.* We defined the target volume change $\hat{v} = \nu\hat{m}_{\mathrm{co}} + (1-\nu)\hat{m}_{\mathrm{pg}}$, where $\hat{m}_{\mathrm{co}}$ and $\hat{m}_{\mathrm{pg}}$ are the normalized mass of type II collagen and proteoglycan, respectively. We exploit the very different time scales between daily activities, e.g. walking ($t$ in sec), and progression of OA ($\tau$ in mos), which allows iterative rather than simultaneous solutions. We define the overall deformation gradient $\mathbf{F}$ by a multiplicative decomposition of $\mathbf{F}(\tau,t) = \mathbf{F}^{\mathrm{e}}(t)\mathbf{F}^{\mathrm{g}}(\tau)$ [6]. Here, we define anisotropic cartilage loss as $\mathbf{F}^{\mathrm{g}} = \mathbf{I} + (1-\hat{v})\mathbf{n}\otimes\mathbf{n}$, where $\mathbf{n}$ is a unit vector normal to the articular surface.

*Signaling Pathways Biochemical Model.* In health and with moderate daily activities, chondrocytes maintain cartilage homeostasis and do not proliferate. In OA, and both in immobilization and overloading, homeostasis is lost and chondrocytes express catabolic and anabolic cytokines, along with structural proteins. We propose the following system of ODEs to model the key components in cartilage

$$\frac{\mathrm{d}\hat{n}_{\mathrm{c}}}{\mathrm{d}\tau} = \left(r^{\mathrm{c}}_1 + r^{\mathrm{c}}_2\hat{c}_\beta\right)\hat{n}_{\mathrm{c}} - \left(r^{\mathrm{c}}_3 + r^{\mathrm{c}}_4 f(\sigma_{\mathrm{sh}})\hat{c}_\beta + r^{\mathrm{c}}_5\hat{c}_{\mathrm{p}}\right)\hat{n}_{\mathrm{c}} \tag{3}$$

$$\frac{\mathrm{d}\hat{n}_{\mathrm{hc}}}{\mathrm{d}\tau} = r^{\mathrm{hc}}_1 f(\sigma_{\mathrm{sh}})\hat{c}_\beta\hat{n}_{\mathrm{c}} - r^{\mathrm{hc}}_2\hat{n}_{\mathrm{hc}} \tag{4}$$

$$\frac{\mathrm{d}\hat{m}_{\mathrm{co}}}{\mathrm{d}\tau} = \left(r_1^{\mathrm{co}} + r_2^{\mathrm{co}}\hat{c}_\beta\right)\hat{n}_{\mathrm{c}} - \left(r_3^{\mathrm{co}} f(\sigma_1) + r_4^{\mathrm{co}}\hat{c}_{\mathrm{ca}}\right)\hat{m}_{\mathrm{co}} \quad (5)$$

$$\frac{\mathrm{d}\hat{m}_{\mathrm{pg}}}{\mathrm{d}\tau} = \left(r_1^{\mathrm{pg}} + r_2^{\mathrm{pg}}\hat{c}_\beta\right)\hat{n}_{\mathrm{c}} - \left(r_3^{\mathrm{pg}} f(\mathrm{E}_3) + r_4^{\mathrm{pg}}\hat{c}_{\mathrm{ag}}\right)\hat{m}_{\mathrm{pg}} \quad (6)$$

$$\frac{\mathrm{d}\hat{c}_{\mathrm{ca}}}{\mathrm{d}\tau} = \left[\frac{r_1^{\mathrm{ca}} + r_6^{\mathrm{ca}}\hat{c}_{\mathrm{p}}}{1 + r_2^{\mathrm{ca}}\hat{c}_\beta}\right]\hat{n}_{\mathrm{c}} + r_3^{\mathrm{ca}}\hat{n}_{\mathrm{hc}} - \left(r_4^{\mathrm{ca}} + r_5^{\mathrm{ca}}\hat{c}_{\mathrm{i}}\right)\hat{c}_{\mathrm{ca}} \quad (7)$$

$$\frac{\mathrm{d}\hat{c}_{\mathrm{ag}}}{\mathrm{d}\tau} = \left[\frac{r_1^{\mathrm{ag}} + r_6^{\mathrm{ag}}\hat{c}_{\mathrm{p}}}{1 + r_2^{\mathrm{ag}}\hat{c}_\beta}\right]\hat{n}_{\mathrm{c}} + r_3^{\mathrm{ag}}\hat{n}_{\mathrm{hc}} - \left(r_4^{\mathrm{ag}} + r_5^{\mathrm{ca}}\hat{c}_{\mathrm{i}}\right)\hat{c}_{\mathrm{ag}} \quad (8)$$

$$\frac{\mathrm{d}\hat{c}_{\mathrm{i}}}{\mathrm{d}\tau} = \left(r_1^{\mathrm{i}} + r_2^{\mathrm{i}}\hat{c}_\beta\right)\hat{n}_{\mathrm{c}} - \left(r_3^{\mathrm{i}} + r_4^{\mathrm{i}}\hat{c}_{\mathrm{ca}} + r_5^{\mathrm{i}}\hat{c}_{\mathrm{ag}}\right)\hat{c}_{\mathrm{i}} \quad (9)$$

$$\frac{\mathrm{d}\hat{c}_{\ell\beta}}{\mathrm{d}\tau} = \left(r_1^{\ell\beta} + r_2^{\ell\beta}\hat{c}_\beta\right)\hat{n}_{\mathrm{c}} - \left[r_4^{\ell\beta} + r_5^{\ell\beta} f(\sigma_{\mathrm{sh}})\right]\hat{c}_{\ell\beta} \quad (10)$$

$$\frac{\mathrm{d}\hat{c}_{\beta}}{\mathrm{d}\tau} = r_1^{\beta} f(\sigma_{\mathrm{sh}})\hat{c}_{\ell\beta} - r_2^{\beta}\hat{c}_\beta \quad (11)$$

$$\frac{\mathrm{d}\hat{c}_{\ell\mathrm{p}}}{\mathrm{d}\tau} = \left[\frac{r_1^{\ell_{\mathrm{p}}} + r_2^{\ell_{\mathrm{p}}}\hat{c}_{\mathrm{p}}}{1 + r_3^{\ell\mathrm{p}}\hat{c}_\beta}\right]\hat{n}_{\mathrm{c}} - \left[r_4^{\ell\mathrm{p}} + r_5^{\ell\mathrm{p}} f(\sigma_1)\right]\hat{c}_{\ell\mathrm{p}} \quad (12)$$

$$\frac{\mathrm{d}\hat{c}_{\mathrm{p}}}{\mathrm{d}\tau} = r_1^{\mathrm{p}} f(\sigma_1)\hat{c}_{\ell_{\mathrm{p}}} - r_2^{\mathrm{p}}\hat{c}_{\mathrm{p}} \quad (13)$$

where, $\hat{n}_{\mathrm{c}}$, $\hat{n}_{\mathrm{hc}}$, $\hat{c}_{\mathrm{ca}}$, $\hat{c}_{\mathrm{ag}}$, $\hat{c}_{\mathrm{i}}$ $\hat{c}_{\ell\beta}$, $\hat{c}_\beta$ $\hat{c}_{\ell\mathrm{p}}$, $\hat{c}_{\mathrm{p}}$, are the normalized living cells, hypertrophic cells, collagenases (MMP-3,13, etc.), aggrecanases (ADAMTS-4,5, etc.), tissue inhibitors of metalloproteinase (TIMP), latent growth factors (TGF-$\beta$, BMP, etc.), active growth factors, latent pro-inflammatory cytokines (IL-1, TNF-$\alpha$, etc.) and active pro-inflammatory cytokines, respectively. We define $f(\sigma_{\mathrm{sh}})$, $f(\sigma_1)$ and $f(E_1)$ as well-shaped, double-sigmoidal functions of shear stresses, first principal stresses, and third principal Green-Lagrange strains, respectively. The $r_i^X$ are rate parameters for the variables, where $i \in \{1,2,3,\dots,N\}$ and $X \in \{\mathrm{c}, \mathrm{hc}, \mathrm{co}, \mathrm{pg}, \mathrm{ca}, \mathrm{ag}, \mathrm{i}, \ell\beta, \beta, \ell\mathrm{p}, \mathrm{p}\}$.

*Cartilage in Homeostasis, Immobilization, and Overloading.* We simulated cartilage undergoing physiological loading (i.e. normal daily activities), immobilization, and overloading for 30 months duration. We defined ($f(\sigma_{\mathrm{sh}})$, $f(\sigma_1)$ and $f(E_1)$) following literature [7].

*Numerical implementation.* In the constitutive model we used $\mu^S = 1i\mathrm{MPa}$, $k_1 = 0.43i\mathrm{MPa}$, $k_2 = 8i[-], i\ \nu = 0.8i[-]$ [4]. The initial conditions for the coupled pathway model are $\hat{n}_{\mathrm{c}} = \hat{c}_{\mathrm{ca}} = \hat{c}_{\mathrm{ag}} = \hat{c}_i = \hat{c}_{\ell\beta} = i\hat{c}_{\ell\mathrm{p}} = 1$ and $\hat{c}_\beta = \hat{c}_{\mathrm{p}} = \hat{n}_{\mathrm{hc}} = 0$, and we estimated the rate parameters following literature. We implemented the chemo-mechano-biological framework in Matlab R2021b (The Mathworks, USA) and solved the system of ODEs using a backward-finite-difference Euler approach with a fixed step size of $\mathrm{d}\tau = 0.1$ months.

## RESULTS

During the moderate loading of normal daily activities cartilage remained in homeostasis, i.e. no changes in the constituents or cytokines (dashed lines in **Fig. 1**). During immobilization we predicted a reduction in living cells (-16%), proteoglycan (-25%), and collagen (-28%) (**Fig. 1(a)**). We also predicted gradual increases in collagenase, aggrecanase, latent growth factors, and latent pro-inflammatory cytokines, all which remained upregulated (**Fig. 1(b)**). However, TIMP followed the opposite pattern due to its inverse relationship with both collagenase and aggrecanase. Active growth factors and active pro-inflammatory cytokines increased and stabilized at ~10% and ~6% with respect to the latent forms, respectively (**Fig. 1(c)**). We also predicted volume loss (-28%) consistent with experimental measurements (**Fig. 1(d)**) [8]. In overloading we observed greater volume loss (results not shown).

## DISCUSSION

We introduced a modeling framework for cartilage considering the chemo-mechano-biologically induced turnover of key constituents in resulting from mechanical loading and/or biochemical activity. We included the complex chemical and mechanobiological mechanisms within cartilage, and addressed the key constituents in formulating our model. With representative rate parameters, our simulations for immobilization successfully predicted the loss of cartilage volume quantified experimentally as loss of thickness [8]. The upregulation of pro-inflammatory cytokines and the growth factors in immobilization is also consistent with to the experimental studies [9]. There is a lack of data quantifying the long-term effects of overloading human cartilage, but we simulated the evolution of constituents supported by *in vitro* and *in vivo* experiments leveraging animal models [10]. Both immobilization and overloading caused the progression of OA, demonstrating the potential of our framework to predict degradation.

*Limitations and outlook.* We considered only a subset of known signaling pathways, while many more exist [11]. We also, as a starting point to establish our framework, combined the chemical species into classes based on their roles, although not all members within each class have the same effect on cartilage homeostasis. We aim to implement our chemo-mechano-biological framework for finite element analyses, thus enabling advanced understanding of patient-specific pathological changes due to biomechanical factors, improved clinical diagnostics and therapies [12], and new methods for non-invasive diagnosis and pre-/post-operative decision making.

## INTRODUCTION

Rapid and accurate assessment of hemostasis is imperative in various clinical settings to diagnose, treat, and monitor patients with impaired hemostasis[1].Over 15 million people worldwide receive oral anticoagulant therapy to prevent and treat life-threatening thromboembolic events[2]. Despite their effectiveness in lowering the risk of acute thrombosis, effective anticoagulation management in these patients remains challenging because of the narrow therapeutic window between either increased risk of thromboembolic events or higher probability of dangerous hemorrhage and life-threatening organ failure, which is influenced by numerous factors[3]. Therefore, patients require frequent laboratory testing of blood clotting status to ensure appropriate selection of anticoagulant agent and dosing, which imposes a staggering service load on health care providers.

Traditional laboratory-based clotting assays and devices are limited to not only time-consuming and expensive, but also insufficient information due to partial analysis of various individual facetted clotting elements, such as coagulation function (aPTT, PT, TT), fibrinogen, platelet function (PFA, LTA) or blood cellularity (hematology analyzers), or lack sensitivity and specificity to key clotting parameters such as platelet dysfunction (viscoelastic assays- TEM, TEG). As a result, each current assay or testing technology has provided an incomplete assessment of bleeding and thrombosis status and risks[4]. This has also stymied the fields of clinical and experimental hematology given the interdependence among the clotting elements.

In this study, we present a novel capacitance-based approach for blood permittivity measurement using a carbon nanotube-paper composite (CPC) capacitance sensor. A major advancement of the proposed approach is that the capacitance signal obtained from a single measurement could provide three parameters with distinctive sensitivity towards coagulation function, platelet count or function, and hematocrit. The CPC sensor exhibited high fringing field to detect permittivity changes in a blood sample placed in a glass vial on top of the sensor, eliminating the need for physical electrical contact. The feasibility and sensitivity of this approach was demonstrated using clinically relevant human blood samples. The results were compared against a conventional TEG analyzer to validate the effectiveness of the sensor.

## METHODS

### CPC sensor and capacitance measuring system

The experimental setup used for capacitance measurement consists of two CPC capacitance sensors, FDC 2214 capacitance evaluation module (Texas Instruments, TX, U.S.A), glass vials (Agilent Technologies, CA, U.S.A), 3D printed plastic fixtures and orbital shaker. A blood sample in glass vials was precisely positioned using plastic fixtures on top of the crack region in the sensor.

### Clotting assay protocol & Data Analysis for signal parameters

A baseline capacitance was measured for 5 min with the glass vials placed on the sensors. Then, 325 µL of the blood sample was added to the reference sensor. Immediately, 300 µL of the same blood was added to the detector sensor and 80-rpm orbital shaking was applied. The glass vial on the detector sensor was prefilled with 25 µL of 162.5 mM $CaCl_2$ solution (final $Ca^{2+}$ concentration: 12.5 mM) for recalcification of the blood sample. Differential capacitance was measured for an additional 30 min after activation. From the capacitance signal, three parameters were chosen for analysis ($T_{Cpeak}$, $\Delta C1$ and $\Delta C2$; *Fig 1a*). $T_{Cpeak}$ was the timepoint for maximum capacitance value after activation. $\Delta C1$ was evaluated as the magnitude decrease in capacitance from peak to a steady state value. Steady state capacitance was the averaged value between 28-30 min after activation. $\Delta C2$ was the maximum capacitance value after activation.* denotes a $p < 0.05$, ** $p < 0.01$. Pearson's coefficient ($r$) was used to evaluate linearity between the pairs of data. $p$ values calculated from ANOVA.

## RESULTS

Whole blood based hemostasis assessments were conducted on clinically relevant human whole blood samples. We found that $T_{Cpeak}$ decreased with increasing $CaCl_2$ concentration (Fig. 1b), which indicated a trend in $T_{Cpeak}$ and coagulation time ($p < 0.00001$). For the remaining studies, 12.5 mM $CaCl_2$ was used to activate clotting in the samples. When we tested blood samples with a predefined platelet count, we found that *ΔC1* linearly increased with increasing platelet count (Fig. 1c). From measurements using blood samples incubated with aspirin, which inhibits platelet activation, we found that *ΔC1* dose-dependently decreased with increasing aspirin concentrations (Fig. 1d). Together, the above two results (Fig. 1c, d) showed that *ΔC1* was sensitive to both platelet count and function. When we tested blood samples with a predefined hematocrit, we found that *ΔC2* linearly increased with increasing hematocrit (Fig. 1e). Collectively, the above results showed that the sensor can offer a multiparameter assessment of hemostasis by providing concurrent information on coagulation function, platelet count or function, and hematocrit.

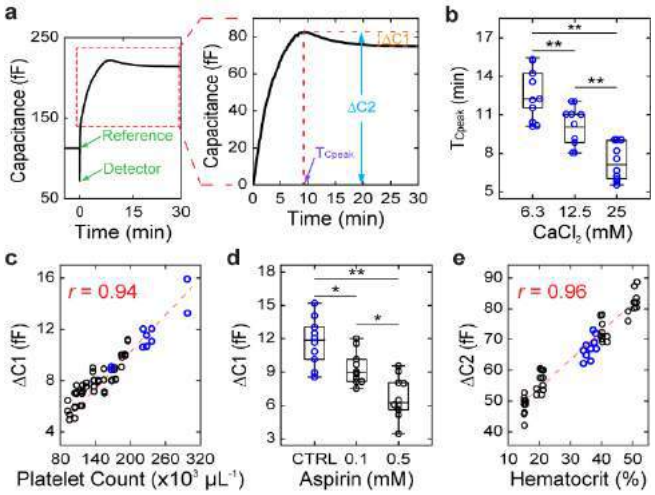

***Figure 1.*** *(a) Left: A representative overall capacitance signal for a blood sample, Right: Zoom-in view of the region of interest (b) $T_{Cpeak}$ decreases with increasing concentration of activating CaCl2 (mM). (c) ΔC1 linearly increases with platelet count (d) ΔC1 decreases dose-dependently with aspirin treatment. (e) ΔC2 linearly increases with hematocrit, n = 5 healthy donors with two replicate measurements.*

To evaluate the potential clinical utility of our sensor, we compared the coagulation time and platelet parameters with the clinically relevant diagnostic parameters of citrate native thromboelastography (CN-TEG) assay. Results illustrated a strong positive correlation between $T_{Cpeak}$ and Reaction time (*R-time)* (Fig. 2a). The obtained data validated the effectiveness of the presented sensor in evaluating coagulation function and is in good agreement with the viscoelastic TEG assay. However, there was a relatively less degree of correlation between *ΔC1* and Maximum Amplitude (*MA)* (Fig. 2b). The reason for such discrepancy is likely because the *MA* parameter, which measures clot strength, may be affected by both the number of cells in the clot and passive fibrin elasticity[5]. To examine the hypothesis, we rearranged the data as illustrated in Fig. 2c. Interestingly, a much stronger correlation between *ΔC1* and platelet count than to *MA* was observed, suggesting *ΔC1* may be solely dependent on the platelet count. This also implies that *ΔC1* might be a better alternative in evaluating platelet count-related diseases as it may have a higher sensitivity and specificity to platelet count. Our results suggests that the proposed sensor could potentially eliminate the need of using additional specialized inhibitors to assay platelets in whole blood, which could further minimize the chances of pre-analytical errors that complicate existing assays.

## DISCUSSION

Motivated by the importance of having a rapid, accurate and convenient hemostasis assessment device, we have developed the first reported capacitance-based approach with a unique ability to multiplex the assessment of coagulation function, platelets and hematocrit in a single measurement. The CPC capacitance sensor described here provides several attractive advantages over existing clinical assays and devices as summarized in Table 1. Its ease of use without the necessity of extensive sample preparation or highly trained laboratory personnel, and additional benefits, such as non-contact, high reusability and low cost, makes it an ideal tool to readily evaluate clotting status while significantly reducing the financial burden on primary care resources.

| Features | **Presented System** | Viscoelastic assays | Traditional laboratory Assay | Blood gas or handheld analyzers |
|---|---|---|---|---|
| Provide global assessment of hemostasis and evaluate bleeding risk in a single device | ✓ | | | |
| Provide global assessment of hemostatic status (coagulation time + platelet function) | ✓ | ✓ | | |
| Can measure platelet count | ✓ | | ✓ | |
| Can measure hematocrit | ✓ | | ✓ | ✓ |
| Rapid Turnround Time (TAT) | ✓ | ✓ | | ✓ |
| Ease of use and cost efficient (reusability): | ✓ | | | ✓ |

# AORTIC STRUCTURAL AND FUNCTIONAL REMODELING IN RESPONSE TO CHRONIC E-CIGARETTE OR CIGARETTE EXPOSURE IN THE APOE$^{-/-}$ FEMALE MOUSE

**Yasmeen M. Farra (1), Jacqueline Matz (1), Jessica M. Oakes (1), Chiara Bellini (1)**

## INTRODUCTION

Notwithstanding a decline in prevalence, cigarette smoking remains the principal cause of preventable death worldwide[1]. Electronic cigarettes have recently emerged as a popular alternative for both current and former smokers[1], and continue to attract novice users[2]. While a causative link between smoking and cardiovascular disease exists[1], the long-term effects of e-cigarette use are unknown and will take decades to observe in humans. Animal models of e-cigarette exposure are therefore necessary to identify the health hazard of this practice, with cigarette smoking as a requisite condition for comparison. To address this need, we present here the structural and functional characterization of the Apoe$^{-/-}$ mouse aorta following chronic inhalation of combustible and electronic cigarette aerosols.

## METHODS

We exposed adult, female Apoe$^{-/-}$ mice daily to either filtered air (AIR, N=15), cigarette smoke (CS, N=8), or e-cigarette aerosols (JUUL, N=10) for 24 weeks. To evaluate vascular ageing over the treatment window, we also analyzed mice at baseline (BASE, N=5). We tracked blood pressure and body mass weekly in awake mice. At the end of the exposure period, we dissected the suprarenal abdominal aortas (SAAs) for mechanical testing. We performed passive inflation/extension tests using a computer-controlled device that measures luminal pressure, outer diameter, axial force, and axial length. We fit a microstructurally-motivated constitutive relationship to the experimental data by nonlinear regression and used the estimated parameters to predict mechanical metrics at systolic pressure[3]. Finally, we analyzed tissue microstructure using histological assays. Data is presented as mean ± SEM. ANOVA was used to determine statistical significance ($p < 0.05$).

## RESULTS

While systolic blood pressure in AIR-exposed mice remained close to baseline, CS and JUUL-exposed mice experienced a progressive increase in systolic blood pressure over the first half of treatment, then stabilized around values that were modestly but significantly elevated from AIR control (by 22% in CS mice and by 15% in JUUL mice; Figure 1A). Although body mass increased from baseline in all groups over the 24 weeks, growth was significantly blunted in CS and JUUL-exposed mice when compared to AIR controls (Figure 1B), resulting in lower body mass at the time of sacrifice (AIR: 23.9 ± 0.4g, CS: 22.3 ± 0.4g, JUUL: 22.9 ± 0.2g). Change in body mass from baseline was not significantly different between CS and JUUL-exposed mice at any time over the duration of exposure ($p = 0.235$).

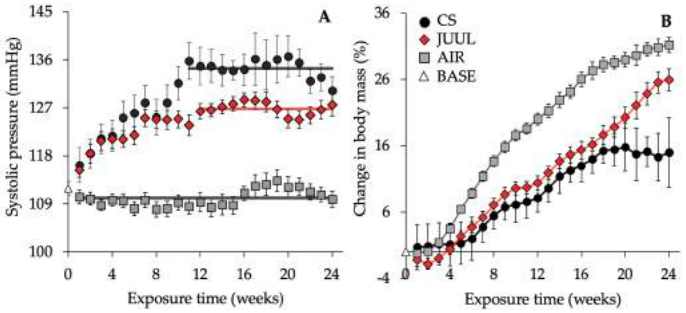

**Figure 1: (A) Systolic pressure and (B) body mass at baseline (white) or with exposure to AIR (grey), CS (black), or JUUL (red).**

The mechanical behavior of the AIR-exposed abdominal aorta did not significantly differ from baseline (Figure 2). At any given level of stress, aortic tissues from CS and JUUL-exposed mice experienced larger deformations than AIR-exposed and baseline tissues. However, the rightward expansion of the stress vs. stretch response was more pronounced in the CS compared to the JUUL group.

Consistently, the circumferential stretch at systolic pressure was significantly larger in both exposure groups when compared to control,

but there was also a significant difference between samples from CS and JUUL-exposed mice (AIR: 1.56 ± 0.02, CS: 1.89 ± 0.05, JUUL: 1.68 ± 0.03; Figure 3A). In part because of this differential effect, JUUL exposure alone compromised the ability of aortic tissues to store elastic energy (CS: 52 ± 2 kPa, JUUL: 44 ± 1 kPa, AIR: 50 ± 1 kPa, Figure 3B). Nevertheless, the overall softening of the material response contributed to maintaining the intrinsic stiffness of tissues near control values in both the CS and JUUL groups, despite larger hemodynamic loads (data not shown). However, the aorta from mice exposed to either CS or JUUL aerosols was significantly thicker than AIR control (AIR: 39 ± 1 μm, CS: 46 ± 1 μm, JUUL: 49 ± 1 μm at systole, Figure 3C). As a result, both exposure groups experienced a significant decline in aortic distensibility when compared to AIR control (AIR: 20 ± 1 $MPa^{-1}$, CS: 14 ± 1 $MPa^{-1}$, JUUL: 12 ± 1 $MPa^{-1}$, Figure 3D).

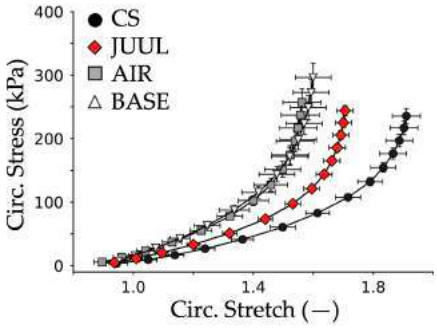

**Figure 2: Circumferential stress vs. stretch response of tissues.**

Microstructural analysis indicated that chronic exposure to either CS smoke or JUUL aerosols significantly increased adventitial collagen when compared to AIR control (Figure 4). Additionally, collagen was significantly more abundant in the media of JUUL-exposed aortas but remained similar to control levels in CS-exposed samples. The increased collagen content of the media contributed to a significant decline in the area fraction of elastin in JUUL-exposed samples, compared to the AIR and CS-exposed groups (AIR: 0.25 ± 0.01, CS: 0.24 ± 0.02, JUUL: 0.20 ± 0.01). Finally, both CS and JUUL-exposed mice developed larger atherosclerotic lesions than AIR controls. Lesion progressed to a vulnerable phenotype with thinner fibrous cap, less collagen, and more macrophages in the CS group.

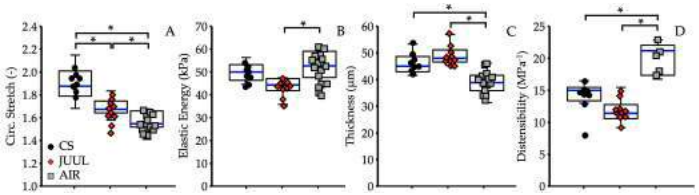

**Figure 3: Mechanical parameters of (A) thickness, (B) circumferential stretch, (C) elastic energy, and (D) distensibility.**

## DISCUSSION

Although the public continues to perceive e-cigarettes as less harmful than combustible cigarettes[4], levels of particulate emissions in the two aerosols are similar[5]. Furthermore, pod e-cigarette devices contain high concentrations of nicotine that is easier to inhale than cigarette smoke[6], increasing their addictive potential[7]. Answering the need for preclinical data that elucidate the long-term cardiovascular outcomes of vaping, we assessed changes in the passive structure and function of the abdominal aorta following 24 weeks of daily exposure to JUUL aerosols, with CS as a necessary comparison[8].

While exposure to both CS and JUUL aerosols caused systolic blood pressure to rise, the increase was smaller with JUUL (Figure 1A). Similarly, both CS and JUUL-exposed mice gained less weight than controls, though more so in the CS group (Figure 1B). These findings suggest that the adverse cardiovascular effects of vaping may be less severe than those of smoking, or that they may take longer to manifest.

Consistent with previous animal studies[9], chronic inhalation of CS and JUUL aerosols promoted aortic thickening via collagen deposition, in part as a mechanoadaptive response to increased blood pressure[10] (Figure 3A). While CS-exposed samples contained more collagen in the adventitia alone, exposure to JUUL aerosols promoted collagen deposition in both media and adventitia (Figure 4), causing the area fraction of elastin to decrease. In addition to lower blood pressure, more abundant collagen in the media may have contributed to limit the systolic circumferential stretch in JUUL aortas compared to CS samples, though it remained above control values in both exposure groups (Figures 2, 3A). Furthermore, larger systolic circumferential deformation in CS aortas may have compensated for the decline in axial stretch (data not shown), preventing the loss of elastic energy storage that occurred with JUUL exposure (Figure 3B).

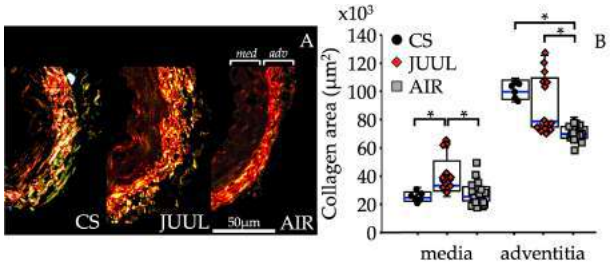

**Figure 4: (A) Picrosirius red stained aortic cross-sections for collagen and (B) plots of medial and adventitial collagen content.**

Finally, coupled with wall thickening (Figure 3C), elevated central blood pressure reduced the distensibility, or increased the structural stiffness, of CS and JUUL-exposed samples (Figure 3D). Structural stiffening of the aorta increases the workload on the heart and has been previously reported in animal models of chronic exposure[11] and recapitulates clinical findings in smokers[12].

In conclusion, our study offers new insights on how vaping and smoking may contribute to cardiovascular disease. Our findings suggest that chronic JUUL e-cigarette use may lead to cardiovascular complications comparable to those of smoking. This data may help inform regulators seeking to provide guidance and limit the potential hazards of chronic e-cigarette use over the coming decades.

## INTRODUCTION

Chiari malformation type 1 (CMI) is a neurological disease characterized by elongation of the cerebellar tonsils five millimeters or more below the foramen magnum [1] and when a part of the brain (the cerebellum) bulges through the spinal canal at the back of the skull, causing pressure on the brain and spinal cord. Often patients who have the radiological definition of CMI, do not experience any symptoms. However, in some cases, CMI patients experience signs and symptoms such as severe headaches, neck pain, unsteady gait, poor hand coordination, numbness and tingling of the hands and feet, dizziness, difficulty swallowing, sometimes accompanied by gagging, choking, and vomiting, and speech problems, such as hoarseness. People with symptomatic CMI usually experience severe headaches, neck pain, unsteady gait, poor hand coordination, numbness and tingling of the hands and feet, dizziness, difficulty swallowing, sometimes accompanied by gagging, choking, and vomiting, and speech problems, such as hoarseness.

In addition to altered brain morphology, CMI patients have more resistance to cerebrospinal fluid (CSF) motion [2] and have increased tissue motion in the cerebellum and brainstem [3]. To quantify the CMI patients' resistance to CSF, a hydrodynamic property called *longitudinal impedance* (LI) is defined as the ratio of pressure harmonic to the flow harmonic at the same frequency. To obtain the *integrated longitudinal impedance* (ILI), which represents the overall CSF resistance, the resulting LI is integrated from 1 to 8 Hz.

The present study considers the interaction of CSF motion and brainstem/cerebellum tissue displacement to understand the severity of the CMI disease in the patients. The relationship between ILI and tissue displacement at the brainstem and the cerebellum was examined.

## METHODS

The MRI exams were acquired at Emory University under an IRB-approved research protocol. Twenty-three CMI patients were analyzed by determining ILI and displacement in the brainstem and cerebellum. All patients had cerebellar tonsillar position (CTP) greater than *5mm.*

To calculate ILI, axial T2 weighted images were used with axial slice thickness 0.9 mm and pixel spacing 0.85 mm to segment the subarachnoid space into a 3D model of CSF space.

*ANSYS ICEM CFD* was used to generate the mesh for the CSF space. Depending on the shape and size of the flow geometry, the mesh ranged between 0.75 to 1.1 million tetrahedral elements. The following conditions were considered as the boundary limits: *velocity inle*t for the inlet, *pressure outlet* for the outlet, and *wall* for the wall. The commercial finite volume solver *Ansys Fluent* was used to run computational fluid dynamics (CFD) simulations of CSF motion. ILI was calculated using a MATLAB program.

To quantify brain tissue motion, a MATLAB program was employed (DENSEPro) which utilized DENSE phase images to compute the average displacement of the brain tissue over the cardiac cycle [4]. A *30 mm²* circular ROI was automatically identified in sections with the greatest amount of displacement or principal strains to obtain a more homogeneous representation of maximum displacement and principal strain in each brain region. The decision to use *30 mm²* was based on the previous findings, which showed that DENSE MRI requires approximately 80 averaged voxels to provide a reliable displacement measurement [4]. The average of the peak displacements within each circular area for all brain regions was used to determine the maximum displacement in each circular area. An example case taken from Nwotchouang et a. [4] is shown in Figure 1.

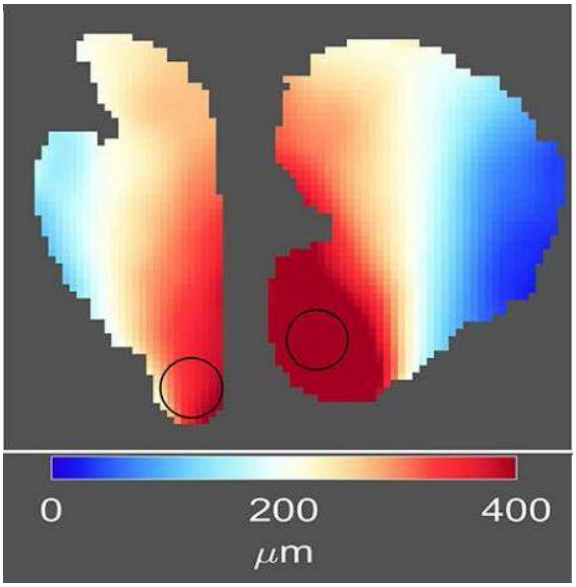

**Figure 1: Two-dimensional Eulerian displacement maps of the brainstem and the cerebellum of a CMI subject [4]**

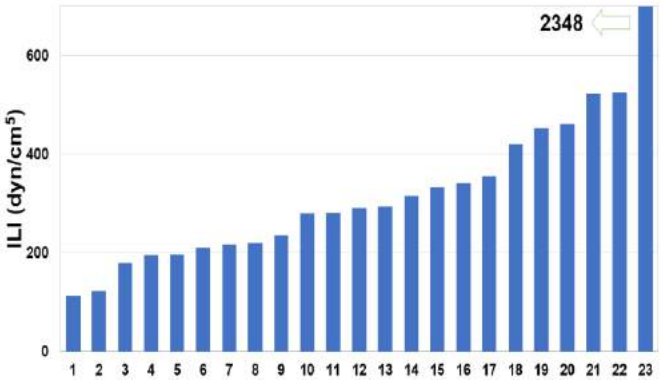

**Figure 2: ILI (resistance to CSF flow) distribution**

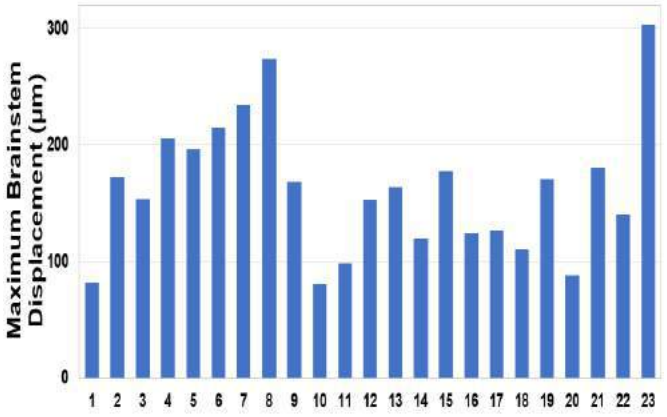

**Figure 3: Maximum displacement at the brainstem**

## RESULTS

Figure 2 shows the ILI for all 23 subjects (note that this figure is scaled and the ILI for the final patient is *2348 dyn/cm*$^5$). The corresponding maximum displacement for brainstem is shown in Figure 3, and for cerebellum in Figure 4. There was a weak correlation between ILI and the displacement at the brainstem (*r=0.14, p=0.03*) and the cerebellum (*r=0.47, p=0.02*).

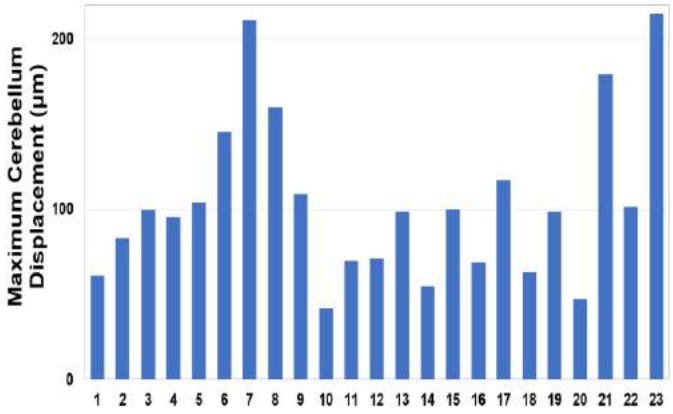

**Figure 4: Maximum displacement at the cerebellum**

## DISCUSSION

Subjects with CMI have tonsillar herniation which often results in an increase in resistance to CSF motion between the cranium and spinal canal. The magnitude of ILI provides a quantitiate measure of this resistance. ILI and brain tissue motion have both been shown to be elevated for CMI subjects [2, 3]. Thus, we postulated there was a connection between resistance and tissue motion. However, this study demonstrates only a weak correlation between ILI and brain tissue displacement. Thus, brain tissue motion is not necessarily related to the increased pressure caused by an increase in resistance in the spinal canal (spinal canal blockage). One case that a had a particularly large ILI (*2348 dyn/cm*$^5$) also had a large tissue displacement both for the brainstem and cerebellum. However, several subjects also had large displacements but with ILI values near that of healthy controls (*220 dyn/cm*$^5$) indicating that ILI alone does not dictate brain tissue motion magnitude [5]. Elevated brain tissue motion has been associated with elevated brain tissue strain and may imply nerve damage [3, 4]. Thus, understanding the underlying biomechanics present in cardiac induced brain tissue motion/strain could help further understand the how various clinical symptoms arise. While ILI clearly plays a role in the unsteady pressure environment within the spinal canal, the relationship between ILI and tissue motion requires further study.

## INTRODUCTION

Cancer is the second leading cause of death after cardiac disease globally [1], [2]. These two drivers of mortality intersect in the field of cardio-oncology. As the number and longevity of cancer survivors continues to increase, clinicians and scientists have become increasingly aware of the need to understand, diagnose, mitigate, and ultimately prevent cancer therapy induced cardiotoxicity [3], [4]. Meeting this need begins with serial assessment of patient-specific cardiac structure and function before, during, and after cancer therapy (e.g., chemotherapy and radiotherapy (RT)). In current clinical practice, cardiac function is primarily assessed by global metrics such as left ventricular ejection fraction (LVEF) [5] and global longitudinal strain (GLS) [6]; however, global metrics may not detect local and/or early myocardial changes, which are more likely to be reversible if detected soon after the initiation of therapy when the damage is limited.

The main aim of this pilot study is to assess the use of advanced quantitative MRI-based metrics to monitor cardiac structure and function, both globally and regionally, before and after radiotherapy, to detect early changes, and to evaluate correlations between radiation doses and MRI-derived metrics.

## METHODS

Four lung cancer patients who received ≥5 Gy of radiation to ≥10% of the heart were recruited for this study. Each patient underwent cardiac magnetic resonance (CMR) at baseline (before RT) and 3 months following RT. The CMR protocol contained standard cine MRI to measure LVEF and calculate strain (radial, circumferential, longitudinal) by feature-tracking algorithm, T1/T2 mapping for tissue characterization, late gadolinium enhancement (LGE) MR to evaluate scar tissue, and T1 volumetric breath hold examination (VIBE) forimage registration purposes. All CMR examinations were done using a 3T Magnetom Avanto Scanner (Siemens, Munich, Germany).

To map iso-dose lines onto MR sequences, radiation dosimetry maps from each patient's clinical CT planning dataset were registered onto the T1-VIBE MR images and subsequently registered from T1-VIBE onto the other MR sequences (e.g., T1/T2 mapping, LGE MRI) using MIM software (MIM Software Inc, Cleveland, OH) (Figure 1). Further post-processing and analysis were performed on cvi42 (Version 5.10.1, Circle Cardiovascular Imaging; Calgary, Canada). Statistical analyses (ANOVA, t-test, and Pearson correlation) were performed on JMP software (version Pro 14, SAS Institute Inc.) using a significance of $P < 0.05$.

## RESULTS

In this small pilot study, no significant differences in global metrics were detected (Table 1), though a decrease in GLS magnitude neared significance ($P = 0.06$). In regional evaluation of MRI-derived metrics, mean regional T1 signal showed an insignificant increase at 3 months FU (1287 ± 64.6 ms) compared to baseline (1283.7 ± 72.9 ms). Mean regional T2 values remained unchanged (43.5 ± 4.5 - 43.7 ± 3.9 ms). Interestingly, regional radial strain (RRS) showed a significant increase ($P = 0.04$) from 31.95 ± 13.8 to 35.12 ± 18.4. Regional circumferential strain (RCS) and regional longitudinal strain (RLS) demonstrated insignificant increase in magnitude between (-18.3 ± 4.7 to -18.9 ± 6) and between (-15 ± 7.1 to -15.7 ± 5.7), respectively. Notably, regional percent enhanced LGE areas were significantly higher at 3 months FU (10.2% ± 13.5) compared to baseline (7.4% ± 9.5), $P = 0.04$. Figure 2 shows enhanced LGE areas (pointed by an arrow) at highly radiated regions before and after RT treatment.

In addition to evaluation of individual global/regional metrics, significant percent changes of regional metrics (i.e., the difference of 3 mo. metrics from baseline values divided by baseline values) at highly irradiated regions (>30 Gy) and low irradiated areas (<30 Gy) were compared. No significant differences were noted for T1 signal changes

at either region. However, T2 signal showed significant differences (P = 0.013) between changes at high dose regions (mean T2 signal +5.5% at >30 y regions) and low dose regions (mean T2 signal +0.04% at <30 Gy regions). Interestingly, RRS and RCS values demonstrated significant increase (P = 0.012 and P = 0.009) at high radiated regions (mean RRS +38.9%, mean RCS +22.8%) compared to low radiated areas (mean RRS +7.6%, mean RCS +3.8%). No significant differences were found for changes in RLS (P = 0.25). Surprisingly, no significant changes were found in LGE between the high-dose and low-dose regions despite greater increase of mean percent LGE area in >30 Gy regions (+10.3%) compared to <30 Gy regions (+2%).

Finally, Pearson correlation test results between percent changes of regional MRI-derived metrics and the maximum RT dose at corresponding segmental regions demonstrated no correlation between changes of T1/RLS/LGE and the maximum dose. However, segmental correlations were noted for percent changes in T2, RRS, RCS and the maximum dose (T2: r = 0.3, P =0.025; RRS: r = 0.28, P = 0.024; RCS: r = 0.3, P = 0.016).

**Table 1. Mean ± SD global metric values at baseline and 3 months follow-up (FU) along with P-values**

| Metric | Baseline | 3 months FU | P value |
|---|---|---|---|
| **LVEF (%)** | 53.5±11.4 | 53±14 | 0.36 |
| **T1 (ms)** | 1285.4±50.4 | 1287.4±45.2 | 0.43 |
| **T2 (ms)** | 43.7±3.7 | 44.3±4 | 0.3 |
| **GRS** | 25.1±7.8 | 26.8±13 | 0.56 |
| **GCS** | -16.1±3.2 | -16.2±4.6 | 0.43 |
| **GLS** | -16.1±5.2 | -15.1±2.1 | 0.06 |
| **LGE (%)** | 8.03±2 | 9.5±1.6 | 0.37 |

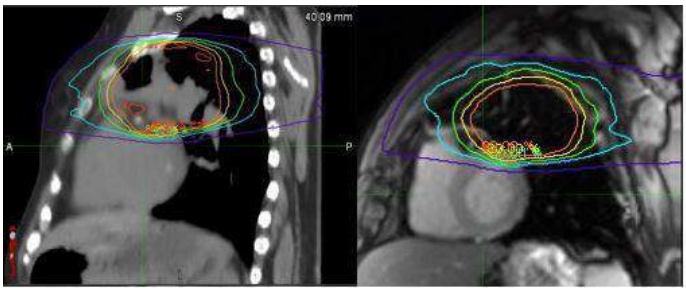

**Figure 1: Registration of the dosimetry map from CT planning (left) onto MR T1 map (right).**

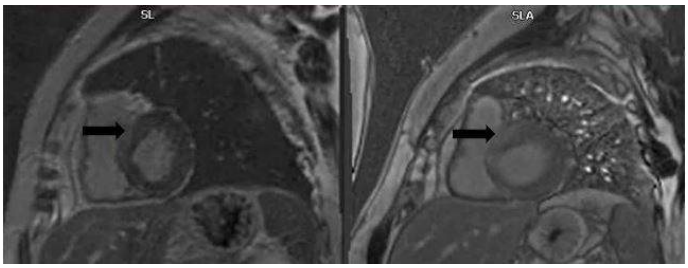

**Figure 2: LGE MR images of the same patient and LV basal cross-section in Figure 1 at baseline (left) and 3 months follow up (right). Arrows show focal areas of LGE in the basal anterior and basal anteroseptal wall where radiation dose was high.**

## DISCUSSION

Even though small changes were observed in global metrics 3-months following RT, none reached significance. Given that some of the changes were in opposite directions (e.g., GLS decreasing while GRS increases) while LVEF was maintained suggests that the heart may be able to functionally compensate for early minor deficiencies in myocardial contraction in the longitudinal direction.

As opposed to global metrics, significant changes were found in a few regional metrics. Notably, percent enhanced areas of LGE images were significantly increased (7.4 to 10.2%, P = 0.04), suggesting that regional fibrosis [8] may precede global functional changes of myocardium. The potential increase of mean regional T1 signal (1283.7 ms to 1287 ms), though not significant, supports this interpretation as T1 increase is also associated with fibrosis [7]. Significant increase of RRS might be in compensation to damages in other cardiac substructures to keep the same global function/output. A similar effect could be responsible for elevated RRS and RCS at highly irradiated regions. At this point, further investigations are required to fully examine this matter. Apart from strain, greater increases of T2 value at highly radiated areas compared to lower radiated regions may introduce a dose-dependency relation between T2 signal changes and radiation doses. Correlations were noted for changes of T2 signal and maximum dose (r = 0.3, P = 0.025). Quantitative T2 relaxation time may represent regions of myocardial edema [7], with higher signal values potentially reflecting greater tissue damage. Finally, we note that the lack of significance in the increase of regionally enhanced LGE areas at highly irradiated regions may be due to missing LGE MR images for one of the patients who received the highest radiation doses to the heart.

Though larger sample sizes are required for confirmation, this early pilot study suggests that regional metrics may be more suitable in detection of early cardiac dysfunction/abnormalities. Moreover, it shows that the abnormalities are mostly found in structural variations of tissue rather than functional changes at 3 months following RT. Despite valuable findings of this study in early quantitative assessment of cardiotoxicity, further investigations with larger cohort of patients are required to fully monitor changes over longer time periods and find the possible relationships between dose and MRI-derived metrics.

## INTRODUCTION

Varus-valgus stress testing is a commonly used clinical method to assess the integrity and laxity of the knee joint [1]. This method has also been useful in assessing osteoarthritis (OA) to probe for weakened tibiofemoral cartilage [2-4] and ligaments [5]. However, varus-valgus stress tests are mostly performed by physicians manually, and the assessment is more qualitative rather than quantitative. Here, with the help of a customized magnetic resonance imaging (MRI-) compatible varus-valgus loading apparatus, the same exam can be done automatically in combination with modern imaging techniques, where the mechanical behavior and material properties of the tibiofemoral cartilage can be revealed by functional analysis. Therefore, the status of the knee cartilage can be accessed by physicians with more quantitative and precise insights.

The primary objective of this study was to design, validate, and verify the varus-valgus loading apparatus for use in a common 3 Tesla (T) MRI scanner. One part of the validation and verification process of the apparatus was done using an independent laser-based displacement sensor, while another part was performed using specialized MRI methods, including spiral Displacement ENcoded Stimulated Echo MRI (spiral DENSE) sequences. Besides spiral DENSE, we also acquired T1, T2, T2*, and T1ρ weighted data before and after loading. We developed a functional MRI-compatible loading apparatus for varus-valgus stress test on human patients, which may assist in the quantitative diagnosis of OA.

## METHODS

*Varus-valgus Loading Apparatus:* A customized MRI-compatible varus-valgus loading apparatus was designed (**Fig. 1A**) based on defined design parameters. The device was geometrically compatible with both a SIEMENS Prisma$^{fit}$ 3T MRI scanner and a QED 15-channel knee coil. Major parts were designed in-house and machined by ProtoLabs®, while other parts were either commercially purchased from manufacturers or fabricated in-house. The apparatus provides loading either the left or right knee with a quick-release structure, while the flex angle of the knee was also adjustable on the device. All parts were made from MRI-compatible materials. The load magnitude of the cylinder was pre-calibrated for both varus and valgus loading conditions over a range of 0-400N force.

*In-Lab Validation and Verification:* The performance of the apparatus was validated and verified in the lab. Three individuals (2 male and 1 female) with healthy left knees were recruited to perform repeatability and precision testing. Independent displacement data was collected during loading using a laser-based displacement sensor system (Keyence). Here, the participant was placed in a neutral position first, with the mock MRI gantry and knee coil put in place, followed by varus loading. Three individual (20 min) tests were performed on each participant, with two 10-min intervals in between (**Fig. 1B**). We applied 25N cyclic loading to the ankle at a frequency of 0.5Hz (1s loading session, 1s unloading) to mimic a walking cadence, resulting in approximately 0.5 times body weight at the knee. The sensor captured displacement versus time. Statistical analysis of the data was conducted using customized software (MATLAB).

*MRI Validation and Verification:* The performance of the apparatus was additionally validated using MRI. Here, a 25-year-old female with a healthy left knee was recruited for MRI mechanical and relaxivity analysis using a 3T MRI system. To conduct the validation and verification process, we obtained DESS (proton density weighted; morphology) images, in additional to images with T1, T2 [6], T2* [7], T1ρ [8] weighting, before and after applying 25N loading. Additionally, spiral DENSE MR images were acquired under repetitive varus loading. The spiral DENSE sequence was capable of capturing *in vivo* full-field displacement and strain fields within the tibiofemoral cartilage while under repetitive varus-valgus loading conditions [9]. Before running the spiral DENSE session, the geometry of the tibia was measured and a moment balance was applied to calculate the desired output force from the apparatus.

The loading scheme was controlled using a customized digital control system. During the spiral DENSE sequence, we loaded the medial condyle using cyclic force for varus loading conditions, and the images were captured only during the loading portion of the cycle. The loading regime was identical to the in-lab session, but with calculated force from the tibial geometry and customized for the patient. Before the scanning session, 8 min of preconditioning was applied to the knee to eliminate the viscoelastic response of the tissue.

*Displacement and Strain Mapping:* Using the phase data from the spiral DENSE sequence, in-plane smoothed displacements ($d_x$, $d_y$) and 2D Green-Lagrange strains ($E_{xx}$, $E_{yy}$, $E_{xy}$) were calculated on a pixel-by-pixel basis [10] using customized software (MATLAB).

## RESULTS

The data from the laser system demonstrated that the pooled standard deviation of the displacement during cyclic loading among all 3

participants was 270 μm, which corresponded to 16 μm displacement in cartilage, noticeably lower than the pixel size (360 μm). We also observed an increase (from 16 to 19 μm) in displacement error if data acquired during a typical preconditioning period was used. Additionally, the loading device did not prevent acquisition of relaxometry (e.g., T1, T2, T2*, and T1ρ weighted) images, which depicted the motion of the tibia as well as the value changes in cartilage (**Fig. 1**). Meanwhile, the increase of displacement and strain values with respect to time was observed, as well as the increase of values from the lateral side to the medial side of the medial cartilage for both displacement (**Fig. 1**) and strain (**Fig. 2**) fields.

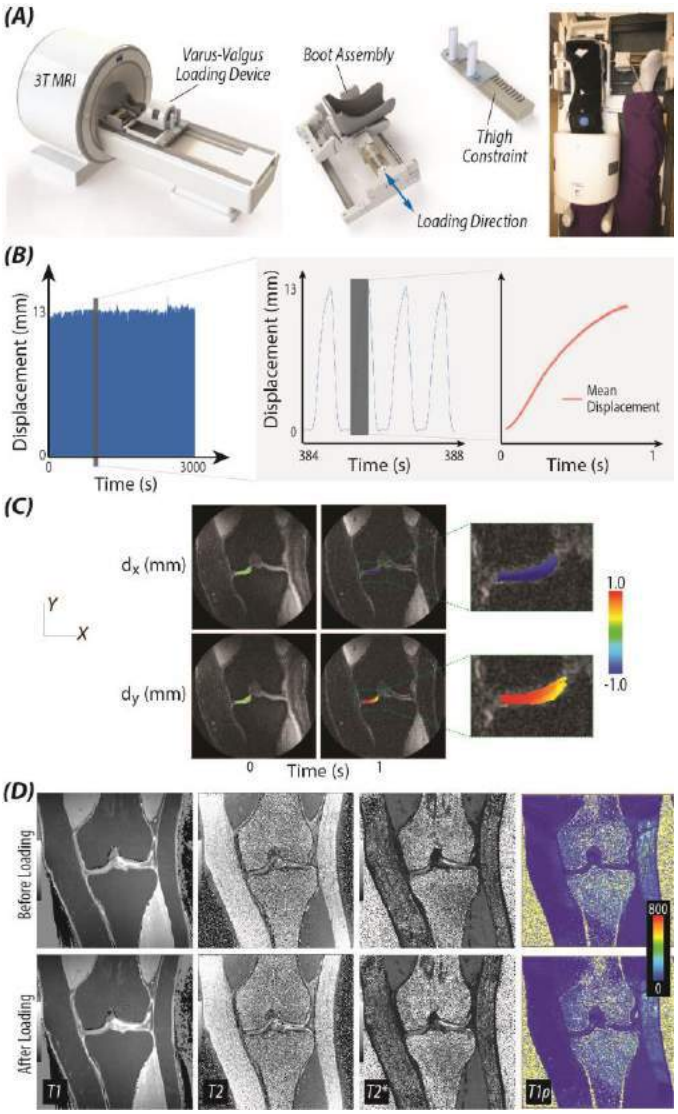

**Figure 1: Validation and verification of an MRI-compatible *in vivo* knee varus-valgus loading apparatus using in-lab and MRI sessions. (A) Assembly of the apparatus in a 3 Tesla MRI system. (B) In-lab validation and verification process. Multiple repeated loading cycles were applied for each participant. Data was gathered using a laser displacement sensor. (C) MRI-based displacements were obtained using a spiral DENSE sequence, with full-field maps captured at the beginning and the end of loading cycle. (D) Relaxometry (weighted) images were obtained before and after applying a loading.**

## DISCUSSION

Previous work from our lab has demonstrated that intratissue displacement and strain maps of cartilage can be acquired *in vivo* under pure compressive loading [9]. Here, we provide a clinically-relevant, varus-valgus loading scheme, which can be used to examine cartilage strain, ligament weakness, and joint instability, all early indicators of OA in the early stage [5,11]. Additionally, we found that patients more comfortably prefer varus-valgus loading over direct compression. The MRI data collected under varus-valgus loading scenario will also likely provide us a deeper insight into material property alternations of articular cartilage during OA pathogenesis, and may reveal potential biomarkers of early OA detection.

In this work, the standard deviation of the displacement during the scanning session proves this apparatus can provide a stable, robust, and precise platform for image-based mechanics. Increased displacement errors were found when adding the data from the precondition session, supporting the idea that it is essential to load the joint prior to the scanning session in order to obtain high-quality data. The pattern of the displacement and strain demonstrates the apparatus is capable of applying varus and valgus loading conditions to the knee. We believe this work is the first to implement varus and valgus stress test in a clinical 3T MRI setup to acquire *in vivo* full-field displacement and strain maps of the tibiofemoral cartilage at the pixel level, and obtain relaxometry values under load. Further steps will include recruitment of additional participants with healthy and OA knees, examining the behavior of ligaments and other load-bearing cartilages under the motion with a similar concept, and linking *in vivo* MRI results with *ex vivo* pathological analysis of the damaged articular cartilage to identify the potential biomarkers of OA. By doing so, we would hope that we can establish novel diagnostic methods to evaluate disease therapies.

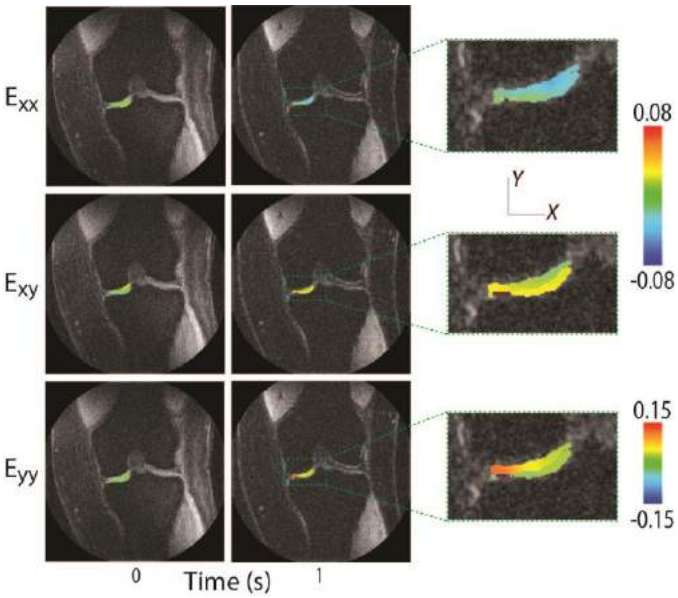

**Figure 2: *In vivo* cartilage strain in the medial femoral condyle and tibial plateau was obtained during varus loading of the knee. Here, strain values at time step 0 (0.0 seconds) and 27 (1.0 seconds) are shown, with heterogeneous strain magnitudes approaching +/-8% in $E_{xx}$ and $E_{xy}$, and +/-15% in $E_{yy}$.**

# COMPUTATIONAL NUCLEOTYPING IN ACUTE ISCHEMIC STROKE CLOT HISTOPATHOLOGY IS PREDICTIVE OF UNDERLYING ETIOLOGY

**Briana A. Santo (1,2), Tatsat R. Patel (1,3), Andre H. Monteiro (4), Muhammad Waqas (4), John Tomaszewski (2), John Kolega (2), Adnan H. Siddiqui (1,4), Vincent M. Tutino (1,2,3,4)**

## INTRODUCTION

Acute Ischemic Stroke (AIS) remains a leading cause of morbidity and mortality. Clinical trials have shown that mechanical thrombectomy (MT), a recent innovation for clot retrieval, is associated with improved functional outcomes in patients after AIS. Following treatment, secondary stroke prevention is the chief clinical concern. In cryptogenic cases, which comprise 20-40% of strokes, this is problematic as, etiology identification could have aided in management of future ischemic events. Recent studies indicate that the biologic composition of the occlusive clot, retrieved during MT, may be related to the underlying etiology, since the origin of the thrombotic material is different for different types of stroke. However, prior histological studies correlating clot composition and etiology have produced mixed results; reported proportions of red blood cell and fibrin-platelet components for clots of similar origins have often been disparate. Further, many of these studies overlooked white blood cells (WBCs), a key component that can affect pro-thrombotic mechanisms and structural components during clotting. In this study, we hypothesized that WBC diversity in clot histopathology would correlate with etiology and designed the following computational study.

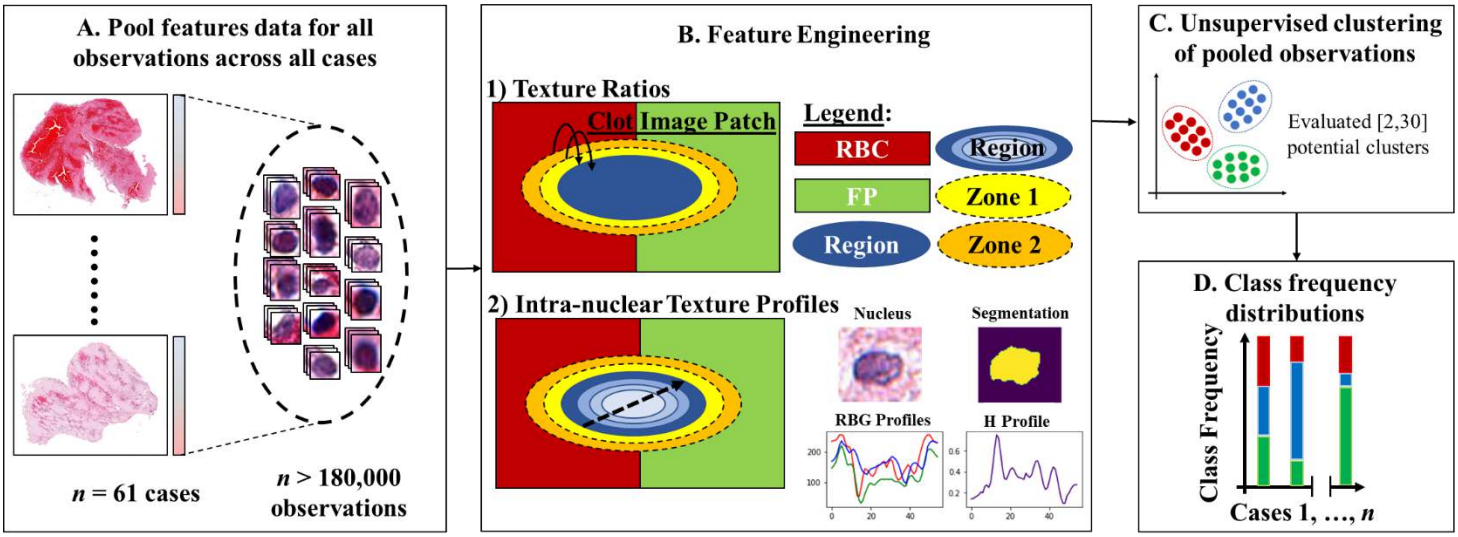

**Figure 1: Determining Distribution Frequencies of Unsupervised Classes of WBCs. A.** Pool features for all WBC instances across all WSI images. **B.** Extract texture ratios and intra-nuclear texture profile-based features for each WBC instance. **C.** Perform unsupervised clustering of pooled observations using texture ratios and texture-profile based features. **D.** Calculate frequency distribution of each class per WSI.

## METHODS

Histological sample preparation, H&E staining, and whole-slide scanning were completed to produce a digital histopathology dataset comprised of 61 whole-slide images (WSIs) of AIS clot samples collected via MT between 11/2018 and 7/2021 at the Gates Vascular Institute in Buffalo, NY (UB institutional review board study 00002092). The underlying etiology of each AIS clot was identified using the Trial of org 10172 in Acute Stroke Treatment (TOAST) score. This TOAST classification denoted the following subtypes of AIS: large artery atherosclerosis (LAA) ($n$ = 11), cardiac embolism (CE) ($n$ = 34), other determined etiology (e.g. hypercoagulable states) ($n$ = 4), and cryptogenic (undetermined etiology) ($n$ = 12). LAA and CE cases were the primary focus in this work.

WBC nuclei were segmented from each WSI using a H&E stain deconvolution approach [1], resulting in ~180,000 unique WBC instances. For each WBC, computational image analysis was used to engineer 645 quantitative histomorphometric features from intra- and extra- nuclear regions (***Fig 1***). To quantify intra-nuclear texture, red-green-blue (RGB) and hematoxylin (H) intensity profiles were extracted from WBC nuclei and analyzed (***Fig1B-2***). To quantify extra-nuclear texture, statistical and structural texture features were extracted from computationally-defined zones (***Fig1B-1***) using PyRadiomics [2]. WBC histomorphometrics were then pooled across all 61 cases and filter-based feature selection was applied to reduce the dimensionality of the feature set. Using the reduced feature space, unsupervised, k-means clustering was completed for k = [2,30] (***Fig1C***) and the optimal number of clusters was identified based on the Davies-Bouldin Index [3]. Within the context of this work, each cluster represented a unique, computationally defined WBC nucleotype or class. From the optimal clustering experiment, the WBC class distribution frequency (CDF) per case was computed as input for supervised classification tasks (***Fig1D***).

WBC nucleotypes differentially enriched in the LAA and CE clot subset were identified and ranked using uni- and multi- variate statistical analysis ($\alpha$ = 0.05), including Mann-Whitney U tests and SHapley Additive exPlanations (SHAP) [4]. The capacity of WBC class frequencies to predict LAA and CE was assessed using linear support vector machine (SVM) trained with five-fold cross validation.

## RESULTS

Filter-based selection reduced the dimensionality of the feature set from 645 to 94 features. The minimum Davies-Bouldin Index was achieved for a k-means model trained with 23 potential clusters. Therefore, CDFs were computed per case assuming 23 distinct WBC nucleotypes. Statistical comparison using univariate statistics identified seven WBC nucleotypes that were significantly different between LAA and CE etiologies (***Fig2***). Multivariate SHAP Analysis identified the five most significant WBC classes (***Fig2***). A linear SVM trained to classify LAA vs. CE using the CDFs of the five most significant WBC classes achieved mean AUCs of 0.87±0.02 and 0.85±0.1 in training and cross-validation testing, respectively (***Fig3***). These computational observations suggested that WBC instances in AIS are diverse and can be classified based on intra- and extra-nuclear texture. Further, the frequency of unique WBC instances in AIS clots was predictive of and may be tied to underlying etiology.

## DISCUSSION

Computational nucleotyping has demonstrated tremendous potential for improved prognostication of diseases with structurally complex histopathology [5]. Unfortunately, biological interpretation of prognostically relevant nucleotypes remains difficult due to the use of deep-learning for feature extraction. In this study, for the first time, we present a novel approach for computational nucleotyping in AIS clot histopathology that harnesses image processing, featuring engineering, and classical machine learning to produce interpretable, quantitative histomorphometrics for (i) WBC subtyping based on nuclear attributes, and (ii) prediction of underlying stroke etiology. While preliminary, these findings suggest that WBC structural diversity in clot histopathology has clinical potential and warrants further study. Future work for conference presentation includes qualitative and quantitative interpretation of WBC instances representative of each class.

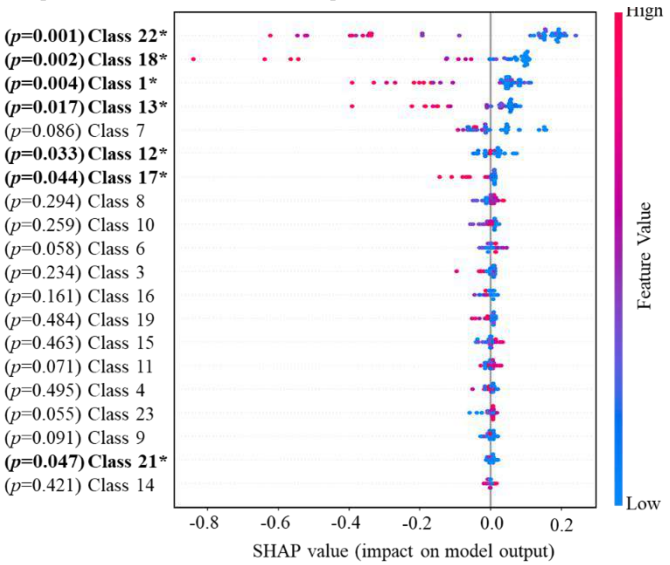

**Figure 2: Significant WBC Classes between LAA and CE.** Univariate statistics and SHAP Analysis were used to rank WBC classes based on their differential enrichment in LAA and CE clot WSIs. *Asterisks mark significantly different class frequencies

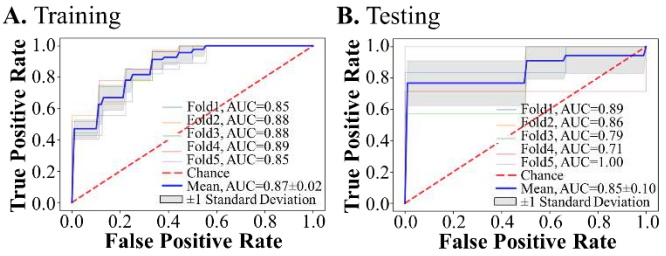

**Figure 3: The frequency of distinct WBC nucleotypes in AIS clot histopathology is predictive of underlying etiology.** Linear SVMs trained to classify LAA v CE based on the five most significant WBC class frequencies for five-fold cross validation achieved mean AUCs of (A) 0.87 in training, and (B) 0.85 in testing.

## INTRODUCTION

The kidney is a highly complex organ that maintains the volume and composition of fluids in the body. It does so, in part, using a tree-like network of collecting ducts, which forms during embryonic development via a process known as branching morphogenesis. The embryonic kidney originates as a simple ureteric bud, which then undergoes a series of branching events to build the ureteric tree, the tips of which interact with cells in the metanephric mesenchyme to direct the formation of developing nephrons [1]. Branching morphogenesis is thus intimately tied to nephron number, and defects in this process can lead to congenital abnormalities that compromise renal function.

Proper renal branching morphogenesis depends crucially on proliferation, and elevated levels of proliferation are thought to be localized to the morphogenetically-active tips of the branching ureteric tree [2]. It is unclear, however, how the spatial patterns of proliferation that sculpt the ureteric tree are developmentally patterned. Mechanical forces are known to regulate the morphogenesis of other branched organs, such as the lung and mammary gland [3], but the role of biophysical cues during renal branching morphogenesis is completely unexplored. Recent experiments have shown that the embryonic renal interstitium is highly patterned [4] with distinct spatial differences in the expression of several ECM-modifying genes which modulate ECM crosslinking and stiffness. It is unknown if there are regional differences in stiffness within the embryonic kidney and, if so, whether these differences impact spatiotemporal patterns of proliferation, along the ureteric tree.

Here, we used microindentation to quantify spatial patterns of tissue stiffness within embryonic mouse kidneys. These distributions were then compared to patterns of proliferation and sub-cellular localization of Yap along the developing ureteric tree, since disrupted Yap signaling is associated with renal branching defects [5]. Finally, we used a polyacrylamide (PA) gel system to determine if changes in substratum stiffness were sufficient to regulate the proliferation and sub-cellular localization of Yap in cultured collecting duct epithelial cells.

## METHODS

*Embryonic kidney dissection and culture:* Embryonic kidneys were dissected from timed-pregnant CD1 mice between embryonic day 13 and 16. In some experiments, E13 kidneys were cultured at 37°C at the air-fluid interface in DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS) and antibiotics. In other experiments, E16 kidneys were fixed in 4% PFA solution, dehydrated in 30% sucrose in PBS, embedded and frozen in OCT compound for cryosectioning. We used a cryostat to obtain 10 μm sections, which were processed for antigen retrieval and stained.

*Microindentation:* We used the CellScale MicroSquisher to measure tissue stiffness within E16 mouse kidneys. Briefly, we created thick (~400 μm) mid-sagittal sections of the kidneys (Fig. 1A) by embedding them in a 6% w/v solution of low temperature gelling agarose and sectioning with a Vibratome. A 70 μm-diameter cylindrical microindenter was used to probe tissue stiffness at different locations along the cortical-medullary axis.

*Polyacrylamide gel fabrication:* PA gels of varying stiffnesses were fabricated on glass coverslips, as described previously [6]. These substrata were then functionalized with 50 μg/ml of fibronectin and plated with inner medullary collecting duct epithelial cells (IMCD3).

*Confocal microscopy:* Confocal stacks of stained samples were obtained using a Zeiss LSM 800. Quantitative image analysis was performed using ImageJ and Imaris.

## RESULTS

We observed clear regional differences in the stiffness of the tissue along the cortical-medullary axis in mid-sagittal sections of E16 mouse kidneys (Fig. 1). The cortical region, where branching morphogenesis

occurs, was significantly stiffer than locations within the medullary zone of the kidney.

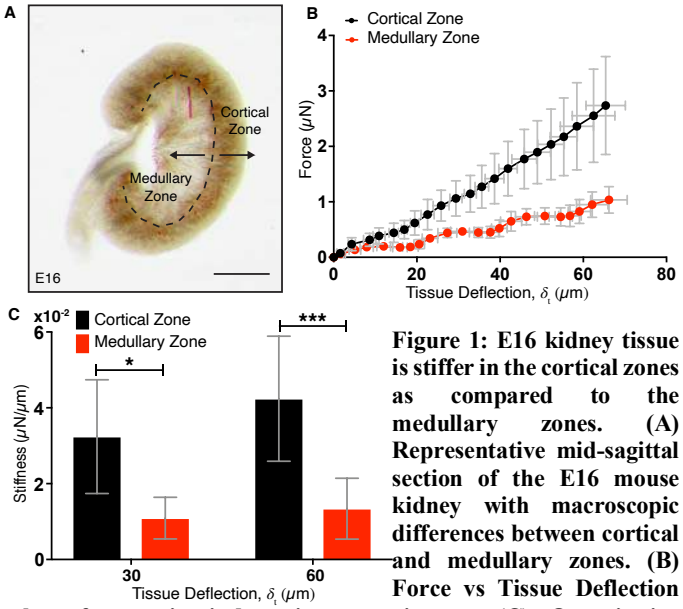

**Figure 1: E16 kidney tissue is stiffer in the cortical zones as compared to the medullary zones. (A) Representative mid-sagittal section of the E16 mouse kidney with macroscopic differences between cortical and medullary zones. (B) Force vs Tissue Deflection plots from microindentation experiments. (C) Quantitative differences in tissue stiffness between the cortical and medullary zones.**

To compare the measured regional differences in stiffness to patterns of proliferation along the ureteric tree, we cultured embryonic kidney explants ex vivo for up to 72 hr and measured distributions of EdU incorporation along the ureteric epithelium (Fig. 2A). Elevated levels of proliferation were observed in the distal-most generations of branches, which were situated within the cortical zone of the kidney, where our microindentation data indicated increased tissue stiffness.

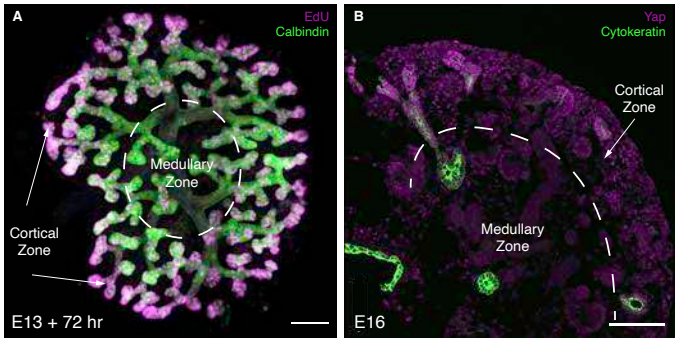

**Figure 2: Proliferation and sub-cellular localization of Yap is patterned in the developing kidney (A) 3D confocal imaging of an E13 kidney, cultured for 72 hr and stained for EdU and calbindin (B) Stained cryosections of E16 kidneys show that Yap is localized to the nucleus in cells at the branching regions of the ureteric epithelium and to the cytoplasm in cells along the non-branching, stalk region of the ureteric epithelium.**

Since Yap signaling is essential for proper renal branching morphogenesis, we also compared these patterns of proliferation to distributions of the sub-cellular localization of Yap along the ureteric tree, as assayed by Yap immunofluorescence in cryosections of E16 mouse kidneys stained for both Yap and calbindin, a marker for the ureteric epithelium (Fig. 2B). In the cortical region of the kidney, Yap was localized nuclearly within cells at the tips of the ureteric tree, but cytoplasmic within cells along the stalk regions. Taken together, these data indicate that proliferation, stiffness and Yap activity are correlated in different regions of the ureteric tree. In the cortical zone, where branching occurs, proliferation and tissue stiffness are elevated and Yap is localized to the nucleus of ureteric epithelial cells. In the medullary zone, these trends are reversed: stiffness and proliferation are reduced and Yap is sequestered in the cytoplasm.

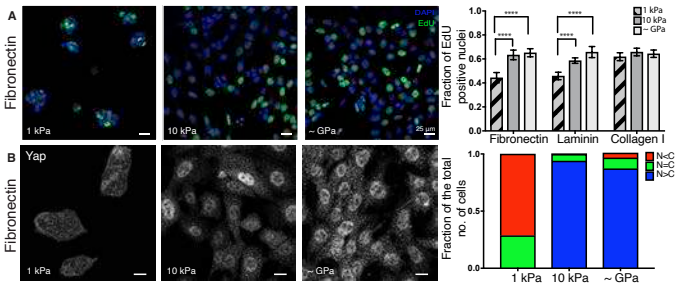

**Figure 3: Proliferation and sub-cellular Yap localization in IMCD3 cells depends on substrate stiffness (A) EdU and DAPI co-staining and quantification of proliferation of cells seeded on Fibronectin coated polyacrylamide gels of 1 kPa, 10 kPa and glass coverslips of ~GPa stiffness (B) Yap staining and quantification.**

To determine if differences in stiffness sufficiently regulate the proliferation and sub-cellular localization of Yap in collecting duct cells, we cultured IMCD3 cells on PA gels of different stiffnesses. Proliferation was elevated on stiff (10 kPa) substrata, as well as on ECM-coated glass coverslips, but lower on soft (1 kPa) gels (Fig 3A), trends consistent with our observations in embryonic kidneys. We also observed stiffness-dependent differences in the sub-cellular localization of Yap. Yap was preferentially localized to the nucleus in cells seeded on stiff substrata but absent from the nuclues in cells on soft PA gels (Fig. 3B). When Yap signaling was disrupted using either verteporfin or genetically ablating Lats 1/2, the kinases that phosphorylate Yap to modulate its activity, we no longer observed stiffness-dependent differences in proliferation (data not shown).

## DISCUSSION

Taken together, these data suggest that regional differences in stiffness are present within the embryonic kidney, which correlate with the patterns of proliferation and Yap activity along the developing ureteric tree. Previous studies have shown that changes in stiffness can modulate the differentiation of progenitor cells in vitro, but there have been little efforts to apply these ideas to organogenesis. Embryonic kidneys with disrupted Yap activity undergo abnormal renal branching morphogenesis [5] and it would be interesting to determine whether altering patterns of ECM stiffness in the embryonic kidney can recapitulate this phenotype. Future work will investigate how ectopic patterns of ECM stiffness modulate branching dynamics in embryonic kidneys cultured ex vivo.

# A MULTI-METHOD APPROACH FOR ASSESSING NON-LETHAL CUTANEOUS IMPACT INJURIES

**Omar Elsafty (1), Christopher Berkey (2), Reinhold H. Dauskardt (1,2)**

## INTRODUCTION

Cutaneous wounds have the highest incidence of all bodily injuries in survivors of blast debris [1]. Even after survival, there is an increased risk of mortality due to wound infection, and a possible decline in a person's well-being due scar formation which can have long lasting functional, aesthetic, and psychological effects on the wounded. These non-lethal cutaneous wounds are not only prevalent in military settings, but they are also often observed in civilian life due to natural disasters and construction accidents [2]. However, while their significance is clear, a thorough understanding of these types of injuries has yet to be achieved, as emphasis in the research field has been on lethal injuries [3]. To design for the treatment and prevention of these injuries, a high-fidelity model that can accurately predict the ensuing damage caused under distinct circumstances is necessary.

Recently, we quantitatively characterized the damage mechanisms that occur for non-lethal cutaneous injuries for single projectile impact using experimental techniques and a high-fidelity 3D finite element (FE) damage model. However, a transition to multi-projectile analysis is needed to accurately assess these injuries and to relate them to specific settings, since the injury severity is highly dependent on the impact angle, impact velocity, and projectile attributes. Furthermore, the analysis will often need to be performed in real-time, and so, developing a finite element model for multi-projectile impact on a full body would be too time-consuming and computationally costly. Here we develop a multi-method approach that utilizes FE analysis, machine learning, and 3D computer graphics to analyze injury severity variability under customizable circumstances.

## METHODS

Three multi-class classification machine learning algorithms were developed to assess injury severity, which can be characterized by evaluating wound area, wound depth, and wound shape. The features used for each neural network were the impact angle, cross-sectional kinetic energy at impact, cross-sectional area, and coefficient of friction between the projectile and the skin. As for our output parameters, wound area and wound depth were discretized into ranges of 5.0mm2 and 200um, respectively, and had upper limits of 35.0mm2 and 2000um, respectively. To characterize wound shape, we used our recently developed wound damage index for spherical projectiles, see Figure 1, providing a score of 0 to 11 based on the expected wound shape. In addition, the predictions of the wound area and wound depth algorithms were also used as features for the wound shape algorithm, constructing a machine learning pipeline in the process, see Figure 2a. To have adequate data to train the models, we ran several FE simulations, see Figure 2b, and performed experimental tests under various input conditions. Furthermore, owing to the high variability of these injuries, and the clinical need to differentiate between them, the models provide the two most probable results to ensure the appropriate treatment can be performed.

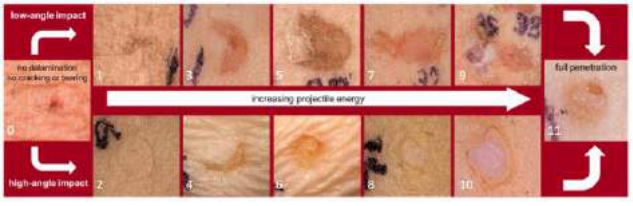

**Figure 1: Wound damage index for non-lethal cutaneous injuries.**

A multi-projectile full-body model was developed using Python API on Blender. The model positions a meshed human body, see Figure 2c, a user-defined distance away from the blast source and distributes fragments equidistantly across the surface of the blast source. Considering drag, the model uses Newtonian physics-based equations to derive the projectile path for each fragment that could be in the vicinity of the human body. The initial projectile angle is taken to be the

angle between the ray connecting the fragment position and blast center and the XZ-plane where the blast center is located. Once the projectile path intersects the body, the incident angle is measured between the projectile path ray and the triangular mesh element that the ray intersected. The velocity at the point of impact is also calculated and used to obtain the cross-sectional kinetic energy at impact. Using the calculated impact angle, cross-sectional kinetic energy, and the user-defined fragment parameters, the model utilizes the multi-class classification algorithms to assess the injury severity at each impact location.

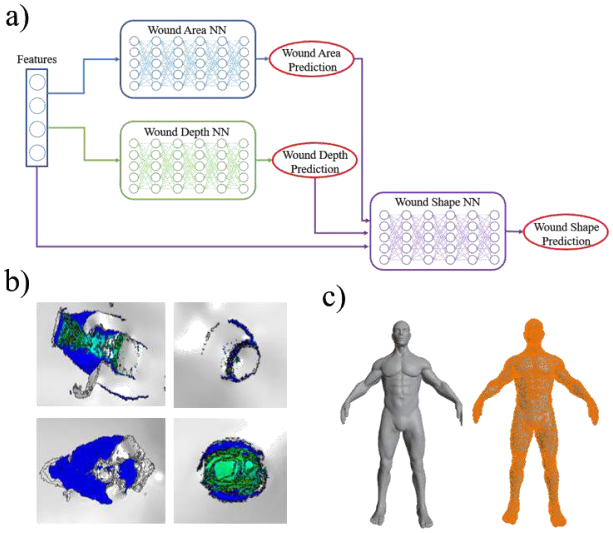

**Figure 2: a) Neural network pipeline b) Injury results from finite element simulations. c) The meshed full body human model.**

## RESULTS

After training and model optimization, accuracies of 71.99%, 71.76%, and 83.2% were obtained for the wound area, wound depth, and wound shape multi-class classification algorithms, respectively, indicating that these models can be used with good fidelity.

In Figure 3, we show features of the multi-method approach for the example of a 1.8m person standing 5m and 8m away from a spherical blast source of 64mm diameter. Owing to the variability of the debris impact, the diameter, mass, and initial velocity of each fragment was randomized within the ranges of 3-5mm, 0.1-0.4 g, and 100-150m/s, respectively, since fragment velocity can vary by up to 50% [4].

The model identified 8 impact points and 4 impact points for the 5m and 8m distance, respectively. After appropriate calculations of the impact angle and impact velocity, the model provided its top two predictions regarding the injury severity parameters at each point, and we provide the average values of these predictions, see Table 1. The maximum time taken to run one complete simulation was 4.86 minutes without the use of high-performance computing.

## DISCUSSION

In this study, we developed a customizable multi-method model to investigate injury severity of a full human body for high-speed debris impact. The model allows for real-time analysis of non-lethal injuries and can be tailored to a specific setting, as the fragments, blast source, and the target can all be adjusted by the user. In the example scenario, the model accurately predicted a significant reduction in wound distribution and injury severity with increasing distance away from the blast site. It should be noted that the average wound area increased with increasing distance due to a reduction in full-penetration wounds, which are commonly associated with small wound areas and large wound depths. These results illustrate the model's capability to simulate realistic injury distributions, a step beyond single projectile impact currently observed in the literature.

Further improvements to the model await more extensive data sets, including quantitative analysis of injuries caused by irregularly shaped projectiles, since current analysis has focused on regular shaped projectiles such as spheres and cylinders.

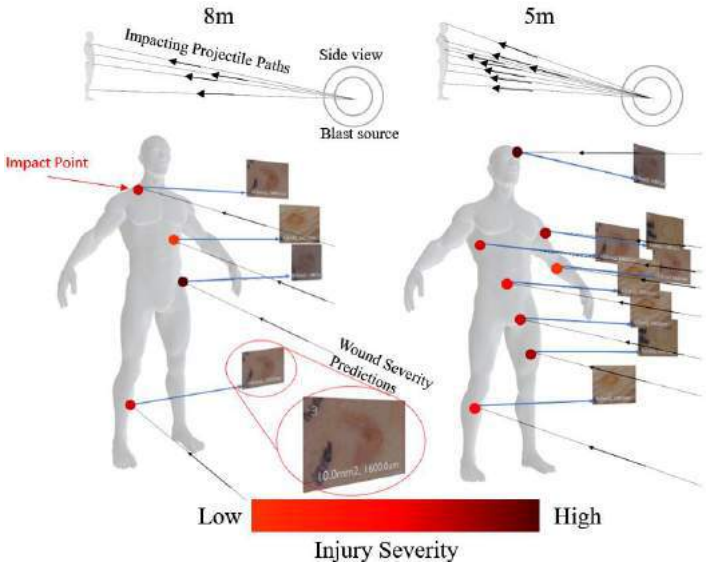

**Figure 3: Resulting injury severity and distribution at 8m and 5m from blast source.**

**Table 1: Average Injury severity predictions at each distance**

| Distance (m) | Number of Impact Points | Wound Area (1st) ($mm^2$) | Wound Area (2nd) ($mm^2$) | Wound Depth (1st) ($\mu m$) | Wound Depth (2nd) ($\mu m$) | Wound Shape (1st) | Wound Shape (2nd) |
|---|---|---|---|---|---|---|---|
| 5 | 8 | 8.125 | 6.25 | 1450 | 1175 | 6.375 | 7.25 |
| 8 | 4 | 12.625 | 11.25 | 1290 | 1075 | 5.875 | 8.05 |

The model provides visual and quantitative investigations of the injury severity and distribution for non-lethal cutaneous injuries. As such, we believe it will be highly advantageous for the advancement of wound treatment methods and for the development of protective equipment, as it can be readily customized to suit the design space.

## INTRODUCTION

The inefficiencies of modern computers in energy become apparent when dealing with large amounts of data or performing computationally hard problems, such as combinatorial optimization problems [1]. Vertex coloring problem, defined as assigning colors to each vertex such that every two adjacent vertices have different colors, is an archetypal combinatorial optimization problem. Recently, coupled oscillator systems have been reported to provide a new computational platform to address combinatorial optimization problems [2-3]. Inspired by the biological system's natural ability to minimize their energy to reach a ground state, we present new hardware for the coupled oscillator system, cardiac muscle-cell-based bio-oscillator network, for solving vertex coloring problems (Figure 1).

## METHODS

We used neonatal rat ventricular cardiac cells isolated from 2-day-old Sprague-Dawley rat hearts as the model cell source. The isolated cell mixture of rat cardiomyocytes (rCMs) and rat cardiac fibroblasts (rCFs) was preplated to enrich the rCMs, and the ratio of rCM to rCF was about 7:3. The cell mixture was suspended in the culture medium and used as the cell source throughout the study.

To create a well-defined network of the bio-oscillators, we started by patterning the rCMs and rCFs on the micro-electrode array (MEA) substrate. We used PDMS blockers to partially cover a cell adhesive protein micropattern. After seeding, the rCMs within the clusters started to beat after one day of culture. Then, the blocker was carefully removed. rCFs in the cell mixture would proliferate and migrate to fill in the gap, therefore bridging the beating cell clusters. After cells began to beat, the cell membrane potential was continuously measured by the MEA-2100 system. The optical videos were recorded using a microscope and the impedance was measured with a potentiostat.

## RESULTS

In the proposed cardiac cell-based bio-oscillator system, we mapped the graph of coloring problem into the bio-oscillator network, such that each vertex (or node) of the graph is represented by a bio-oscillator, a cardiac cell cluster composed of rCMs and rCFs. Any two nodes connected by an edge in the graph are coupled in the bio-oscillator system by an rCF bridge. We fabricated pairwise bio-oscillators (Figure 2a) and a more complex multi-node bio-oscillator network using a simple cell-patterning method. Immunofluorescence staining results of the multi-node network (Figure 2b) were used to observe cell distribution and rCF growth. No troponin T signals (rCM marker) but only vimentin signals (rCF marker) in the bridges verify blockers successfully obstructed the initial rCM attachment, and rCF proliferated in the empty bridge sections.

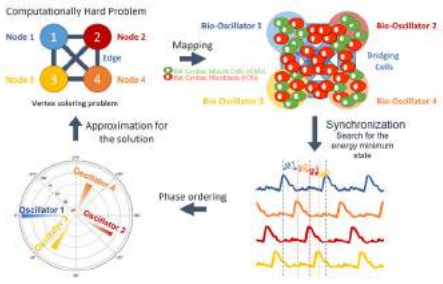

**Figure 1: The schematic of cardiac muscle cell-based bio-oscillator network for vertex coloring problem.**

Computing of oscillator systems is driven by the coupling (i.e., synchronization) of oscillators. We studied the coupling dynamics of the pairwise bio-oscillators with different rCF length. After coupling, the synchronization dynamics of cardiac cell-based bio-oscillators was recorded using the MEA system. The waveforms, fast Fourier transform

(FFT) and the long-term dynamics are shown in the Figure 2. Although there is a variation in the extracted phase–frequency points, we can conclude in a statistically significant fashion that the phase between the clusters is modulated by the rCF length and the frequency. In order to understand the electric nature of the synchronization dynamics, we measured the impedance between the two oscillators and the Nyquist plot reveals that the rCF bridge can be regarded as a resistor parallel with a capacitor and provides an RC-type coupling between two oscillators (Figure 3a-b). To further studied the relation between phase and frequency, we re-ploted long-term dynamics as the figure 3c. We can see that for a higher length, at any frequency, the resistance increases; therefore, the capacitance coupling dominates, and the phase difference becomes bigger. On the other hand, the smaller coupling length increases the conductance, thus reducing the phase difference between oscillators.

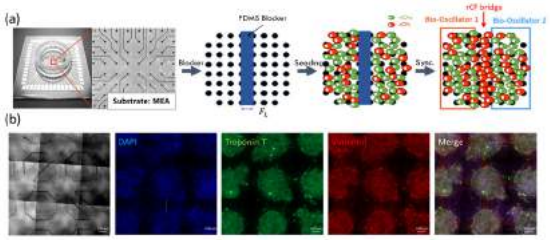

**Figure 2: Cell-patterning approach for constructing a well-defined network of bio-oscillators and rCF bridges.**

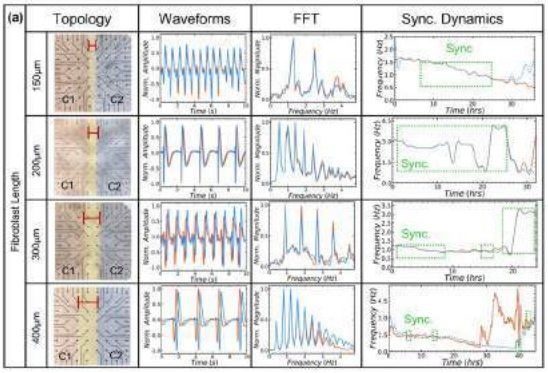

**Figure 3: (a) The synchronization dynamics of two cardiac cell clusters (C1 (red) and C2 (blue)) connected by an rCF bridge (yellow) of different lengths.**

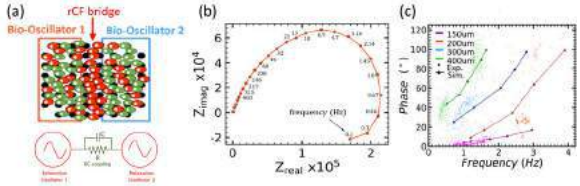

**Figure 4: (a) Electric nature of the rCF coupling. (b) Nyquist plot of rCF coupling. (c) The relation between phase and synchronization frequencies at different rCF length.**

Based on the pairwise bio-oscillator results, we selected 300 μm of rCF length to implement the three-clusters bio-oscillator network. The topology and the dynamics are shown in Figure 5. We used C1 as the reference cluster to measure the phase differences of C2 and C3. Figure 5b shows the phase evolutions of C2 and C3 over the entire experiment in a polar histogram, displaying that the three separated bio-oscillators present a stable phase lock.

Figure 6 simulates the application of the rCF-coupled cardiac cell-based bio-oscillators to solve the minimum vertex coloring problem in a 9-node graph. The equivalent circuit models of bio-oscillator and rCF connection are described in figure 6a-b. The resulting steady-state sequence of the bio-oscillators represents a unique ordering of phases (Figure 6c-f) which can subsequently be partitioned into three independent sets using a simple polynomial time operation [4]. Assigning each set a color implies that a minimum of three colors are required which is the optimal solution to "color" the 9-node graph. We further mapped the same 9-node graph onto the cardiac cell clusters to demonstrate the potential of the bio-oscillator network to be scaled up to a larger number of nodes. The experiment results are shown in Figure 6g-h which shows the exact same optimal solution of simulation.

(e-h) Resulting coloring solution obtained from the simulated and experimental phase ordering of the bio-oscillators**

## DISCUSSION

Combinatorial optimization problems are often regarded as energy minimization problems that can be implemented by the coupled oscillator system. Here, we used a simple cell-patterning method to encode the coloring problem into the cardiac cell-based bio-oscillator network, following the rules that each graph vertex is represented by a bio-oscillator, a cardiac cell cluster, while the edge is represented by an rCF bridge. The bio-oscillators interconnect with each other with the rCF bridge which provides an RC-type coupling between the separated bio-oscillators. As the bio-oscillators coupled, the network naturally searches for the minimum energy state through the mutual interaction. The final steady state of the bio-oscillator network exhibits ordered phase differences which can be used to approximate the solution of the minimum vertex coloring problem.

In this paper, we have demonstrated the potential of cardiac muscle cells as an oscillatory building block to implement the multi-node bio-oscillator systems for solving coloring problem.

# A GRAVITY-DRIVEN MULTI MICRO PHYSIOLOGICAL SYSTEM TO STUDY TISSUE RESPONSES TO CANCER THERAPEUTICS

**Pouria Rafsanjani Nejad (1), Hossein Tavana (1)**

(1) Department of Biomedical Engineering, The University of Akron, Akron, OH, USA

## INTRODUCTION

Multi Micro Physiological Systems (MMPS) provide relevant in vitro models to study systemic drug responses in preclinical studies [1]. However, many MMPS technologies are complex, and their assembly is time-consuming. Additionally, existing MMPS platforms often have a low throughput and do not meet the research need for testing and identifying of effective therapeutics while minimizing systemic toxicity for diseases such as cancer. We have developed a multi-well MMPS that is similar to standard 96-well plates. Our system has three main compartments that represent liver, tumor, and bone marrow. We selected liver and bone marrow because they are both common sites of off-target toxicity from cancer therapeutics and because liver is a major site of drug metabolism. Our system is facile, utilizes 3-dimesional extracellular matrix-embedded cells, captures tissue toxicities, and is compatible with automated liquid handling. This model will facilitate evaluating effects of cancer therapeutics on both tumor and normal tissues in preclinical studies.

## METHODS

The MMPS was designed in SolidWorks. The distance between the wells match that of a standard 96-well plate. The wells are fluidically connected via microchannels (d=800 µm) that reside higher than the well surface. Fluid flow among different tissue compartments is driven by the pressure difference between two end reservoirs caused by gravity and tilting of the device. The device is placed on top of a plate rocker to tilt ± 7 degrees at 1-minute intervals and is kept inside a cell culture incubator. Partial removal of media from the device stops the fluidic connection of wells and enables individual assessment of wells using metabolic assays such as Prestoblue (ThermoFisher). Fluidic flow and mass transport in the device were simulated using COMSOL Multiphysics. The device was fabricated using a polymethyl methacrylate (PMMA)-based biocompatible resin (BMCL) with a Form-3B (Formlabs) 3D printer. To enable high-resolution imaging, the device was printed without a bottom layer. A single sheet of sealer film was then used to seal the bottom of the wells.

Ten MMPSs were generated on each plate and each MMPS has five linearly-connected wells (Fig 1a, b). Out of the five wells, the outer two were used as media reservoir and the inner three were used as tissue compartments. Human cell lines HEPG2/C3A, MDA-MB-231, and HS-5 were used in these compartments to represent liver, tumor, and bone marrow stroma, respectively. Spheroids of cancer cells were formed prior to placing them in the device using our previously established aqueous two-phase system (ATPS) [2]. The spheroids were harvested from their original plate and suspended in a 4 mg/ml rat tail collagen I solution (VitroCol, advanced biomatrix) in the tumor compartment. Liver and bone marrow cells were suspended as single cells in 25 µl of collagen and at a density of $10^4$ cells/well in their respective compartments. MDA-MB-231 cells were previously transfected to produce GFP. Cells in all the wells were stained with Calcein AM (ThermoFisher) prior to confocal microscopy. A chemotherapy drug, Fluorouracil (5FU) (100 µM) and its prodrug, Tegafur (200 µM), were used to test the drug response of different cells over 4 days of culture. Tegafur was mixed with uracil at a 1:4 molar ratio, also known as a UFT cocktail, to prevent 5FU break down by hepatic cells [3]. Each experiment had 4 replicates. Statistical significance was calculated using two-way ANOVA in GraphPad Prism.

## RESULTS

Fluid flow in the MMPS was simulated using an estimated pressure function. The simulation shows that metabolites are transported well across different compartments by the cyclical advective flow. Fig. 1c shows how a hypothetical compound (200 µM, 12.5 µl, $D=10^{-9}$ $m^2/s$) introduced in one of the reservoirs is evenly distributed among the compartments in about 20 minutes. Following the computational validation, we fabricated the two-layer device. There was no leakage

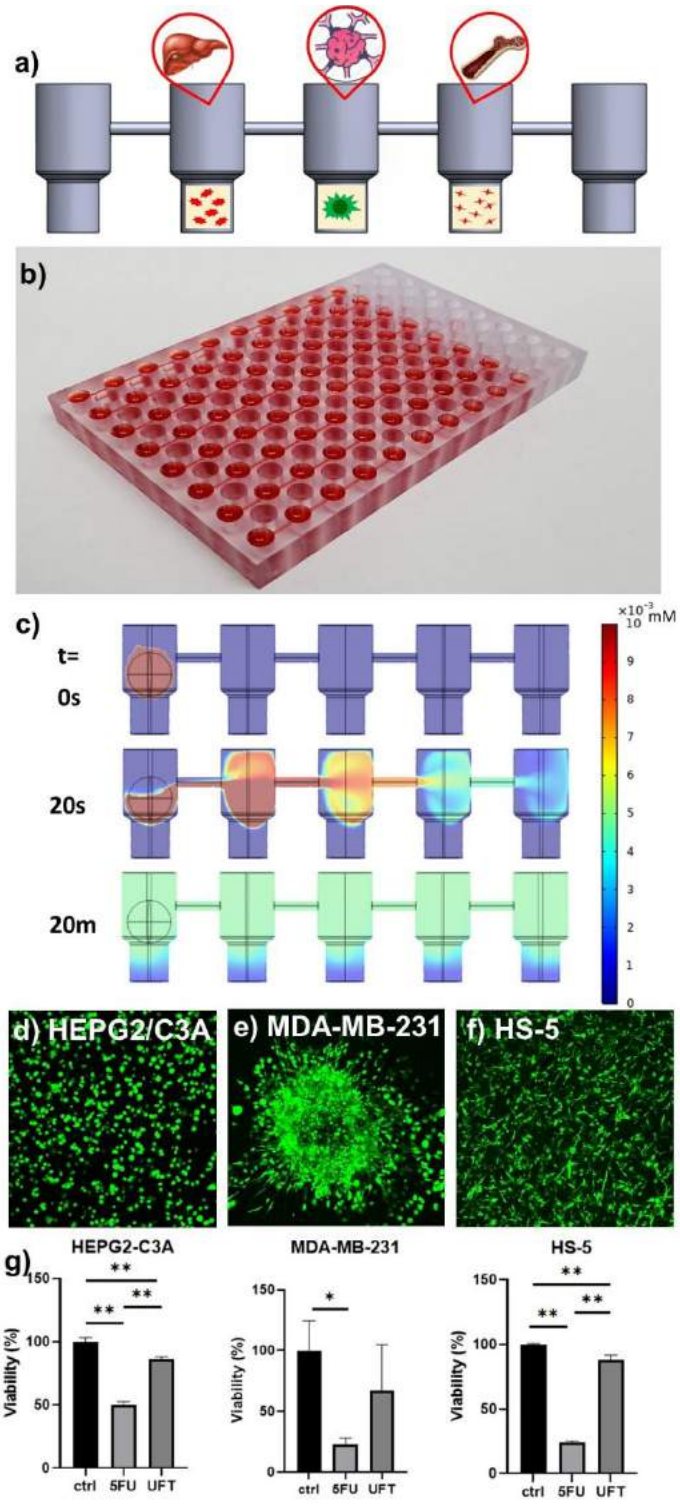

**Figure 1. (a) schematics of a single MMPS (b) image of a 3D printed array of MMPS on a plate filled with food coloring (c) transport simulation of a compound (200 µM, 12.5 µl, D=10-9 m2/s) administered in one of the reservoirs (d-f) Confocal images of cells from liver, tumor, and bone marrow compartments on day 4 in the device (g) responses of cells in each compartment to 50 µM 5-FU and 200:800 µM Uracil: Tegafur (UFT), *p<0.05, **p<0.01**

between the adhesive layer and the printed plate during two weeks of incubation with culture media. After 4 days of culture, all the compartments had highly viable populations of cells (Fig. 1d-f). Cancer cells invaded from the spheroid into the collagen matrix, and single-cell cultures had uniform distribution in collagen. Next, we measured the toxicity of 5FU and UFT to cells in all compartments (Fig. 1g). Viability of cells dropped to 50.4%, 22.6%, and 23.9%, respectively, for HEPG2/C3A, MDA-MB-231, and HS-5 cells when exposed to 5FU and 86.6%, 67.3%, and 87.8% when exposed to UFT.

## DISCUSSION

**W**e presented a new MMPS to study the effects of chemotherapeutics on cells from multiple interconnected tissue compartments simultaneously. Our design builds upon our previously established tumor model [4] and connects it with other tissues in a way that is compatible with automated liquid handling. The gravity-assisted flow avoids complexities associated with tubing needed in pump-driven flows and bubble entrapments. Furthermore, our design is based on PMMA and avoids lipophilic compound absorptions associated with silicone. We demonstrated sustainability of cells in our MMPS in short-term experiments. Our future studies will test the feasibility for longer-term cultures. We also showed responses of tissue compartment to a classic chemotherapy agent. While the response to 5FU was as expected, reduction in the viability with the UFT treatment was less than that predicted based on available literature. We intend to further investigate this issue by optimizing culture conditions of the liver compartment, drug doses, and molecular analysis of the metabolized media. Finally, we aim to present an MMPS that can be utilized for screening cancer treatments earlier in the drug discovery process by further developing this system to include cancer associated fibroblasts and immune components.

# INCORPORATING VASCULAR STASIS BASED PERFUSION TO PREDICT THE THERMAL SIGNATURES OF CELL DEATH USING MODIFIED ARRHENIUS EQUATION WITH REGENERATION OF LIVING TISSUES

**Manpreet Singh**

Department of Mechanical Engineering,
University of Maryland Baltimore County,
Baltimore, MD, USA

## INTRODUCTION

The thermal damage predictions by first-order Arrhenius kinetic rate equation gives us monotonic degradation of living tissues alongwith cancerous lesions. For low temperature hyperthermia (T≤41℃) i.e. at diathermic temperatures, biological tissues shows an accelerated tissue recovery and repair with an evident rise in blood perfusion levels and associated metabolic demands. At the temperature range of 40-42℃, some transformations and molecular-level changes in tumour cells might have been already initiated. According to the hypothesis of Dombrovsky et al., 2015 [1]; continuous regeneration of living human tissues due to the continuous supply of oxygen through arterial blood must be taken into account to counter balance the thermal degradation at quasi-static thermal conditions. However, previous studies [2-3] implemented regeneration term into Arrhenius formulation; however, to incorporate the effect of hyperemic region through vascular stasis (fractional injury) based non-linear perfusion change [4-5] is not addressed for such regeneration based model. This study aims to investigate this issue in the context of magnetic nanoparticle assisted thermal therapy.

## METHODS

Pennes Bioheat Transfer Equation (PBHTE) [6] is used to compute the temperature field distribution in both the healthy tissue and cancerous tissue domain as per **equations (1a)** and **(1b)** respectively;

$$\rho_h c_h \frac{\partial \mathrm{T}_h}{\partial \mathrm{t}} = k_h \nabla^2 \mathrm{T}_h + \omega_{h,0} \rho_b c_b (\mathrm{T}_b - \mathrm{T}_h) + Q'''_{met,h} \quad (1a)$$

$$\rho_c c_c \frac{\partial \mathrm{T}_c}{\partial \mathrm{t}} = k_c \nabla^2 \mathrm{T}_c + \omega_{c,0} \rho_b c_b (\mathrm{T}_b - \mathrm{T}_c) + Q'''_{met,c} + Q'''_{source} \quad (1b)$$

Here, the subscripts, *h* and *c* represents healthy and cancerous tissue domains respectively. Also, *met* represents metabolic *b* represents blood and *source,* is the heat source contribution of heterogeneously distributed magnetic nanoparticles [6] known as Specific Absorption Rate (SAR) mapped at different tumour locations (refer **fig.1**).

It is well known that during heating, the blood perfusion rate first increases at hyperthermic temperature due to vasodilation of vessels and then starts decreasing due to total collapse of vasculature due to thermal damage. This phenomenon is known as "*degree of stasis*" [5]. In this problem formulation, the blood perfusion of cancerous lesion is defined as a piecewise function of vascular stasis as per **equation 2** and **fig. 2**;

$$\omega_{c,0}(t) = \begin{cases} \omega_{b,o}(1 + 30 \cdot \Theta); \text{ if or } 0 < \Theta \leq 0.02 \\ \omega_{b,o}(1.86 - 13 \cdot \Theta); \text{ if or } 0.02 < \Theta \leq 0.08 \\ \omega_{b,o}(0.884 - 0.79 \cdot \Theta); \text{ if or } 0.08 < \Theta \leq 0.97 \\ \omega_{b,o}(3.87 - 3.87 \cdot \Theta); \text{ if or } 0.97 < \Theta \leq 1.00 \\ 0; \text{ if or } \Theta > 1.00 \end{cases} \quad (2)$$

Here, the baseline value of blood perfusion, $\omega_{b,o}$ is extracted from the thermal infrared imaging by adjusting the metabolic heat generation rates and blood perfusion values using inverse heat transfer analysis to match the thermal maps of infrared images [6]. The degree of vascular stasis (collapse of vasculature) can be calculated as per **equation (3)**;

$$\Theta(\mathrm{x}, \mathrm{y}, \mathrm{z}, \mathrm{t}) = 1 - \exp(-\Omega(\mathrm{x}, \mathrm{y}, \mathrm{z}, \mathrm{t})) \quad (3)$$

As per the traditional Arrhenius equation, the spatio-temporal thermal cell-death parameter, Ω (dimensionless), can be computed as per **equation (4)**;

$$\Omega(x, y, z, \tau) = \ln\left\{\frac{C(0)}{C(\tau)}\right\} = \int_0^{\tau} A e^{-E_a/R_g T(x,y,z,t)}\, dt \quad (4)$$

where, $C$ represents concentration of cells, $R_g$ is the universal gas constant ($8.314 J/(mol \cdot K)$), $\tau$ is the duration of exposure(s), T is the temperature (K). The thermal damage parameter, $\Omega = 1$ represents 63.21% of denaturation of proteins sufficient to initiate coagulation. It should be noted that the induced thermal damage is zero before the onset of nanoparticle assisted heating. According to Rai and Srivastava, 2009 [7]; Ω=0 represents no burn, Ω=0.5 first degree burn, Ω=1 shows

approaching second degree burn and $\Omega=10^4$ represents third degree burn. The Arrhenius kinetic coefficients used to evaluate the degree of vascular stasis, $\Theta$ are summarized in **Table-I**. It is to note that these coefficients of vascular collapse or vascular shut-down are specific to perfusion changes and must not be compared with thermal damage coefficients reported in this context of work on thermal ablation [4-5].

**Table-I**: Arrhenius coefficients considered in this study [1-5].

| Parameters | Symbol [Units] | Vascular Stasis | Thermal damage |
|---|---|---|---|
| Frequency factor | $A$ [$s^{-1}$] | $1.98 \times 10^{106}$ | $3.1 \times 10^{98}$ |
| Activation Energy | $E_a$ [$Jmol^{-1}$] | $6.67 \times 10^5$ | $6.28 \times 10^5$ |

The Arrhenius kinetic equation is recently modified by Dombrovsky and Timchenko, 2015 [1] and later revisted and implemented by Kumar and Rai, 2016 [2] and Liu and Chen, 2021 [3]. One additional term is introduced in Arrhenius equation to account for regeneration of the healthy cells. Thermophysical properties can be referred from **Table-II.**

$$\frac{d\Omega(\mathrm{x,y,z,t})}{d\mathrm{t}} = A\big(1-\Omega(x,y,z,t)\big)\exp\left(\frac{-E_a}{R_g T(x,y,z,t)}\right) - B\omega_{c,o}\Omega(x,y,z,t) \qquad (5)$$

where, B is a dimensionless coefficient= $9 \times 10^{-3}$[2].

**Table-II**: Thermophysical properties [6].

| Property | Symbol [Units] | Healthy Tissue | Cancerous Tissue | Blood |
|---|---|---|---|---|
| Thermal conductivity | $k_i$[W/(m K)] | 0.5 | 0.5 | 0.55 |
| Density | $\rho$ [kg/m$^3$] | 1060 | 1060 | 1060 |
| Specific heat capacity | $c$ [J/(kg K)] | 3780 | 3780 | 3780 |
| Baseline blood perfusion | $\omega_b$ [m$^3$/(s m$^3$)] | 0.00285# | 0.00111# | - |
| Metabolic heat generation | $Q_{met}$ [W/m$^3$] | 9265# | 3602# | - |

*#extracted from thermal imaging using inverse heat transfer analysis*.

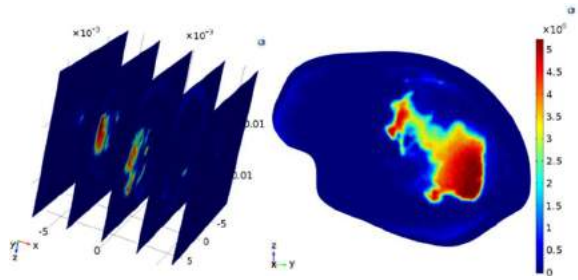

**Figure 1.** Heterogeneously distributed magnetic nanoparticles-SAR.

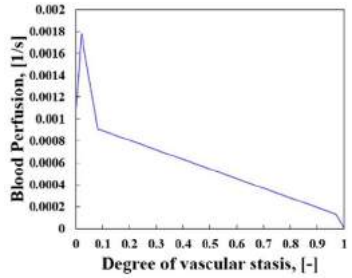

**Figure 2.** Perfusion dependence on stasis.

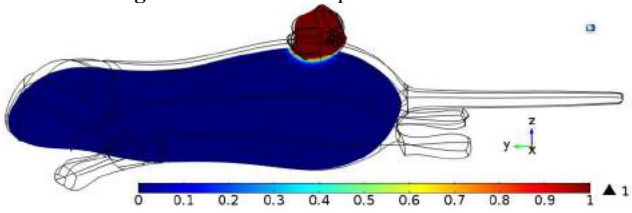

**Figure 3.** Modified thermal damage incorporating the effect of regeneration term thereby preserving healthy tissues at interface.

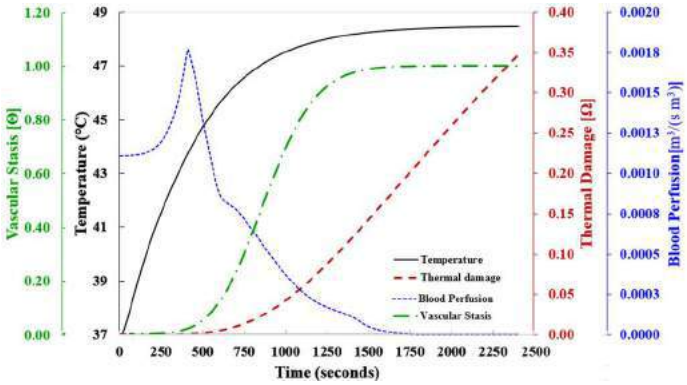

**Figure 4.** Perfusion, Vascular stasis, Thermal damage, Temperature variations at minimal temperature location of tumour.

## RESULTS AND DISCUSSION

Perfusion mediated heat-sink impairs the efficacy of cancer treatment. Vascular stasis based perfusion variation is a predictive indicator of cancer response to the thermal treatment. **Fig. 4** demonstrates spatio-temporal variation of parameters: $\omega_{c,0}$,$i\Theta$, $\Omega$ and T at the minimum temperature location. Modified thermal damage is computed via **equation (5)** (shown in **fig. 3**) is in agreement with the results of Dombrovsky et al., 2015 [1]. The inclusion of regeneration of living tissues to compute the thermal signatures of cell-death suggests that the modified Arrhenius equation seems to restrict within the damage limits of $\Omega = 1$ (63.21% denaturation of protein). The physical interpretation of this regeneration term implies that thermal damage would not propagate deep inside the healthy tissue fringes. Thus, it can inferred that regeneration phenomenon prevents and suppress the collateral thermal damage spread at the interface which is in agreement with the findings of literature [3-5]. We speculate that for a tumour needs to be treated within the hyperthermic temperature range, it will not only predict accurate ablation volumes but also restricts the damage propagation front to cross the fringe layers at the interface of tumour and healthy tissue. Such a model based on vascular shunt-off is a real assessment of the thermal damage spread within bound of $\Omega = 1$. The implication of this work would help design better heating protocol designs in future. However, more experimental exploration is needed in this context. Similar simulation approach can be utilized by the physicians in clinical treatment planning to address the likelihood of achieving complete thermal ablation at cancerous lesion while sparing the critical surrounding organs. For the deadliest cancers like Glioblastomas, or chest wall recurrence (CWR) where the clinical margins are not enough to be sacrificed, these estimates will aid in better treatment planning.

## INTRODUCTION

Sickle Cell Disease (SCD) is a chronic and clinically heterogeneous disease that is characterized by high levels of hemolysis, which gives rise to anemia and an unpredictable course of vaso-occlusion, pain crises, and stroke[1]. In the context of venous circulation, the dynamics of SCD have been well characterized. However, there remains a gap in the understanding of the root of the arterial pathologies that arise in SCD, such as stroke.

While arterial flow is primarily laminar, fluctuations in blood flow velocity and viscosity can cause turbulence[2]. Turbulent regimes are typically transient, but chronic exposure to them can negatively impact the blood and arterial condition[3,4]. Previous studies have suggested that anemic conditions, exhibit a higher propensity for turbulence, due to their lowered hematocrit values and thus reduced viscosities[5]. As mentioned, chronic exposure to turbulent flow is known to increase the red blood cell (RBC) susceptibility to damage, though no data exists for the extent to which this affects sickle RBCs (sRBCs). Considering the presumed propensity for turbulence in SCD, and the major role hemolysis plays in the pathophysiology of SCD, *it is critical* to investigate the connection between circulatory turbulence and its impacts on sRBCs and the downstream arterial and thromboembolic phenomena seen in SCD, which likely occur downstream of turbulence[6].

Determining the direct impact turbulence has on the sRBC, the local vessel endothelium, and the distal endothelium will improve our understanding of SCD vasculopathy and the anatomic regions that will be most likely be impacted. However, blood turbulence is challenging to study due to the lack of convenient technologies to investigate these processes. Here we demonstrate an easy paradigm for doing so.

## METHODS

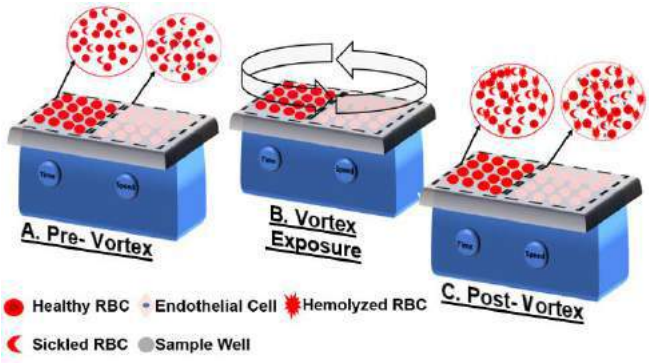

**Figure 1. Experimental set-up.**
**The schematic above demonstrates the experimental set-up for exposing small volumes of RBCs to turbulence. This method can be applied to test as many conditions as there are wells in parallel for various vortex speeds and times. (A) Baseline hemolysis levels are measured[7]. (B) Turbulent conditions are introduced by applying set speeds for desired durations of exposure. (C) Post- vortex exposure hemolysis levels are measured and subsequent cellular imaging and endothelial labeling for desired targets are conducted.**

RBCs from healthy and sickle cell donors were isolated from their plasma and resuspended in a physiological buffer to achieve target hematocrit levels. Turbulent flow regimes were applied to healthy and sickle RBCs using a multi-well plate vortex-mixer (Figure 1). Hemolysis percentages were quantified via obtaining absorbance measurements of free hemoglobin levels in the supernatant of the experimental well plate following the vortex condition and

centrifugation. Concurrently, of the above wells, some were endothelialized to observe the local impacts of turbulent sickle cells on the endothelium. Sickle and healthy RBC hemolysate from the turbulent vortex conditions were saved and perfused through endothelialized straight channel microfluidic devices to observe the impacts of turbulence on the distal vessel endothelium. Glycocalyx stains were used to assess endothelial damage. The damage was quantified via measurement of total pre- and post-perfusion fluorescence of Wheat Germ Agglutinin, a fluorescent glycocalyx stain.

## RESULTS

Figure 2 displays the change in percent hemolysis that in sRBCs and healthy RBCs at varied hematocrits and from unique donors, following exposure to laminar (1000RPM) and Turbulent (2000RPM and 2300RPM). All RBC groups exhibited an increase in hemolysis when exposed to turbulent regimes. The greatest increase in hemolysis was seen in sRBCs exposed to "high turbulence" magnitudes (2300RPM). In figure 3, our preliminary microfluidic experiments assessing the distal impacts of the hemolysate on the endothelium suggest that sRBC hemolysate (vortexed sRBCs) result in the highest amount of endothelial disruption glycocalyx, as indicated by the lowest amount of total WGA fluorescence. Experiments assessing the localized impacts of turbulent sickle cells suspensions are ongoing.

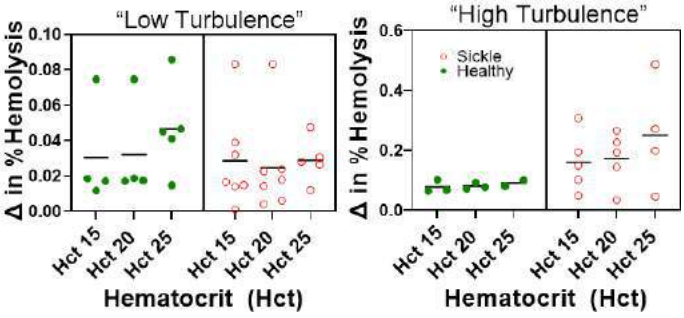

**Figure 2. Hemolysis Profile of sRBCs and Healthy RBC.**
**Magnitude of sRBC and healthy RBC percent hemolysis increase resulting from exposure to "high" (2000RPM) and "low" (2300RPM) magnitude turbulence conditions relative to baseline laminar regime (100RPM).**

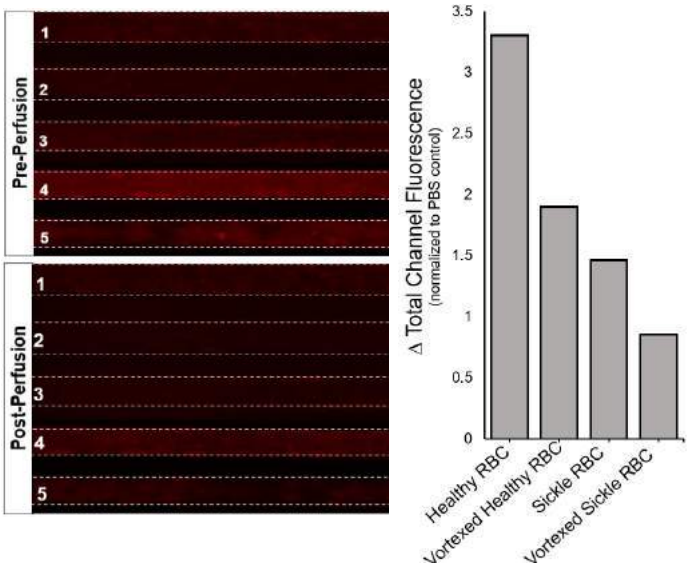

**Figure 3. Turbulence-exposed sRBCs Disrupt the Endothelial Glycocalyx.**
**Fluorescence microscopy image of a microvasculature-on-chip system stained with Wheat Germ Agglutinin (WGA) to label endothelial glycocalyx. Images were captured before and after perfusion with 1. Physiologic Buffer Saline (PBS), 2. healthy RBCs suspended in PBS (Hct 10%), 3. healthy RBCs exposed to vortex-induced turbulence (Hct 10%), 4. sickle RBCs resuspended in PBS (Hct 10%), and 5. vortexed sRBCs resuspended in PBS (Hct 10%). (right) Glycocalyx reduction was quantified by measuring the total fluorescence of the channels prior to perfusion and afterwards. The change in total fluorescence was normalized to the PBS control channel.**

## DISCUSSION

Traditional assays do not allow for the observation of the cellular processes that result from turbulent sRBCs traveling through the vasculature. Thus, we have adopted a multi-well-plate vortex mixer paradigm to subject small volumes of sickle cell blood to turbulence with the advantage of assaying multiple cellular and temporal conditions. The contributions of this investigation are two-fold. First, by better understanding the dynamic conditions that cause sickle cell hemolysis we can begin to predict when and where it will occur in the vascular network and how to mitigate it. As the lifespan of SCD patients increases, these patients are at heightened risk of vascular conditions that can alter their physiologic flow regimes. This data can inform treatment guidelines for this population. Second, characterizing how turbulent sickle cells affect the endothelium can provide more insight into the mechanisms of endothelial dysfunction observed in SCD.

Extensive computational modeling and experimental validation to truly characterize turbulence in this simple benchtop system are ongoing. Once the turbulent conditions that induce sRBC hemolysis and endothelial dysfunction are determined, our future work includes locating those pathologic areas in circulation based on existing published data to develop a predictive arterial map for sRBC hemolysis. This information can then encourage the development of a novel modality for identifying hotspots for potential arterial disease in SCD patients which can inform treatment regimes and improve the overall care for this aging patient population.

## INTRODUCTION

Disrupted endothelial cell metabolism is linked to vascular dysfunction and cardiovascular disease [1]. Recent efforts have focused on manipulating endothelial metabolism to alter cell signaling pathways and thereby cell function [2]. However, the cellular metabolic network consists of interlinked metabolite and reactions. Therefore, supposedly targeted inhibition in specific metabolic pathways could have unexpected effects on glycolysis, the tricarboxylic acid (TCA) cycle, and other metabolic pathways [3].

Although glucose primarily fuels glycolysis to generate pyruvate, it can enter side branch pathways such as the pentose phosphate pathway (PPP) and the polyol pathway. In glycolysis, glucose is metabolized into glucose-6-phosphate (G6P), which can continue down the glycolytic pathway or enter the PPP. The PPP is vital for generation of nucleotide precursors as well as the reducing agent NADPH. PPP activity increases during cell proliferation or oxidative stress [4]. The polyol pathway reduces excess glucose into sorbitol in a step that generates NADP+ from NADPH. This pathway has been implicated in diabetic neuropathy and endothelial dysfunction [5].

Although each of these pathways plays vital roles in cellular function, the impact of targeted inhibition of these pathways remains unclear. Reductionist approaches focused on specific pathways do not fully account for the interconnected nature of metabolic networks, which limit understanding of off-target or compensatory mechanisms that occur during inhibition. Thorough understanding of systemic metabolic changes requires advanced analytical and computational tools that can contextualize metabolomic data within a network-based context. Isotope-assisted metabolic flux analysis (iMFA) is a computational approach that utilizes isotope labeling experiments and mathematical representations of metabolic networks to quantify systems-level metabolic activity [6].

The goal of this study was to utilize iMFA to understand how inhibiting glycolytic side branch pathways impacted endothelial metabolism at a systems-level. We utilized pharmacological inhibitors of the polyol pathway (fidarestat) and PPP (dehydroepiandosterone, DHEA) to determine whether inhibition triggered off-target or compensatory metabolic changes. Human umbilical vein endothelial cells (HUVECs) were treated with metabolic inhibitors and analyzed using mass spectrometry and iMFA. Our results demonstrate that each of these inhibitors incurred systemic metabolic changes. This study highlights the need to study systemic metabolic therapeutic effects as well as the potential for data-driven, computational approaches in improving our understanding of cardiovascular health and disease.

## METHODS

HUVECs were cultured to confluence and then treated with either 0.1% DMSO as solvent control, 25 µM DHEA or 18 µM fidarestat in endothelial basal media for 24 hours. Following treatment, cells were labeled with DMEM containing 5 mM [$U^{13}$-$C_6$] glucose for 24 hours. Metabolites were extracted and analyzed via liquid chromatography-mass spectrometry. Mass spectrometer data was corrected for natural isotope abundance. Extracellular metabolite concentration changes were quantified with the YSI Bioanalyzer 2900. Metabolic fluxes in the network were determined using the INCA metabolic flux analysis software suite. A metabolic network map was manually constructed to include TCA cycle, glycolysis, PPP, and hexosamine biosynthetic (HBP) pathways. Isotopomer mass spectrometer and external flux data were incorporated into the model. Steady-state metabolic fluxes were estimated through an iterative process where flux estimates are used to simulate isotope distributions that are then compared to experimentally derived isotopes. At each iteration, goodness-of-fit is assessed and used to refine the flux estimate until it reaches a sufficient error threshold. The flux distribution that results in simulated isotopomers that optimally fit experimental isotopomers are returned as the best flux estimate.

## RESULTS

We first measured extracellular flux changes in all three groups. Interestingly, there were no significant changes in glucose consumption, lactate secretion, or glutamate secretion. However, fidarestat-treated HUVECS significantly increased glutamine intake (Figure 1). DHEA-treated cells also increased uptake of glutamine, although this effect was not statistically significant.

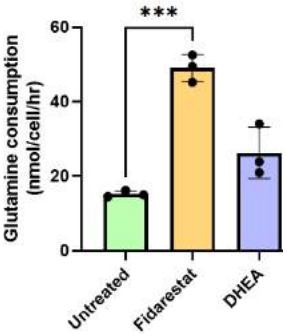

Figure 1. Glutamine intake significantly increased in fidarestat-treated HUVECs. Statistical significance was determined with one-way ANOVA followed by Dunnett's multiple comparison test. * $p < 0.05$; ** $p < 0.01$

We then created a baseline endothelial mode using extracellular flux and isotope labeling data from control groups to quantify metabolic fluxes in untreated HUVECs. Initial results showed that TCA cycle activity was approximately 20% the rate of incoming glucose flux.

We then analyzed each inhibitor individually by refitting the baseline model to data from the treated groups. iMFA of fidarestat-treated and DHEA-traated cells estimated a significant decrease in PPP fluxes and increases in overall carbon intake, primarily into the TCA cycle. As a result, all TCA cycle fluxes increased. In fidarestat-treatment, activity of the malate-pyruvate shuttle reversed direction from mitochondrial import towards mitochondrial export (Figure 2).

## DISCUSSION

These results demonstrate the importance of assessing the system-wide effects of targeted metabolic inhibition. In this work, we identified systemic metabolic changes that occurred with inhibition of glycolytic side branches.

Fidarestat treatment resulted in increased TCA cycle and PPP activity. Interestingly, fidarestat is known to increase SIRT1 which promotes glutamine uptake [7,8]. This may have been one of the driving forces in increased glutamine uptake and TCA cycle activity. Fidarestat inhibits aldose reductase, the enzyme that metabolizes glucose and NADPH into sorbitol and NADP+. Therefore, fidarestat treatment may result in NADPH accumulation, which can allosterically downregulate the PPP.

Similar changes were observed in DHEA-treated cells. However, in this case, decreased PPP fluxes are likely to be due to direct downregulation by DHEA. This may have driven DHEA-treated cells to drive NADPH production through malic enzyme activity, which is an important generator of NADPH. Increased glutamine intake may have been used to supply malic enzyme activity. This simultaneously could have increased overall TCA cycle activity.

These results demonstrate that HUVECs may attenuate metabolic disturbances by dramatically modifying TCA cycle activity. Furthermore, these inhibitors dramatically affect pathways beyond their intended targets, which suggests that the off-target effects of these drugs should be further investigated. Together, this work highlights the powerful application of metabolic flux analysis to quantify systemic metabolic changes and its potential to elucidate off-target effects of pharmacological compounds.

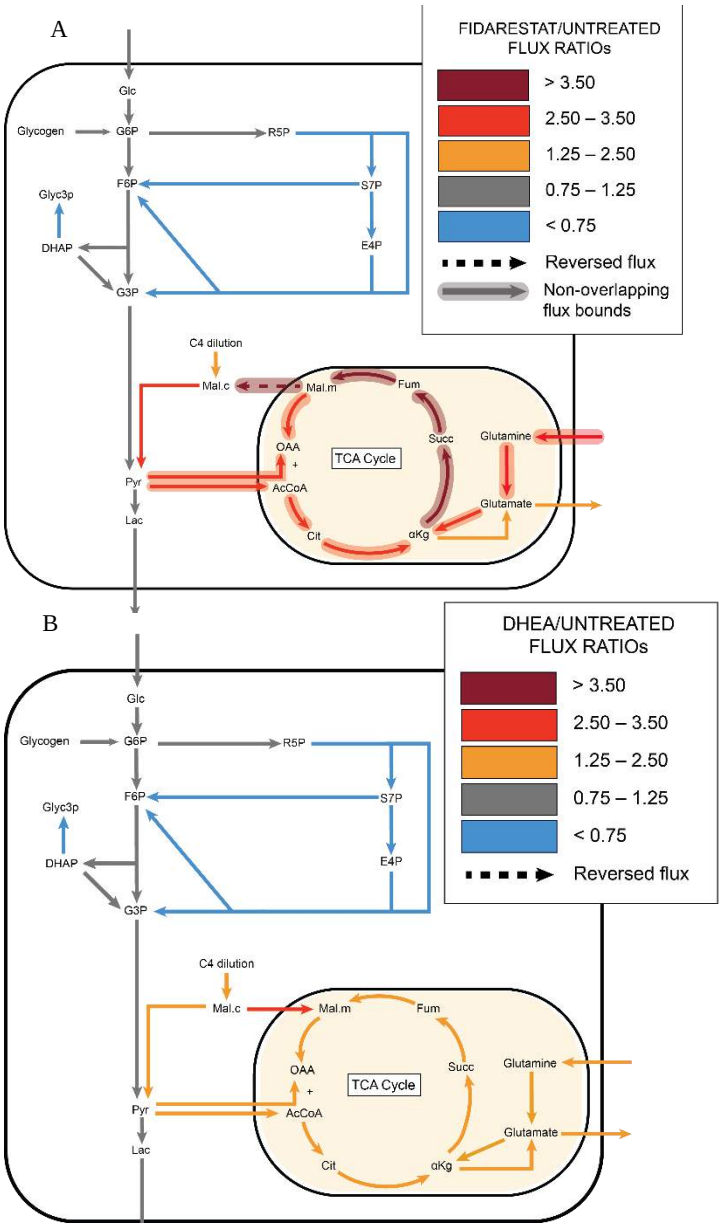

**Figure 2.** Metabolic flux analysis demonstrates that (A) fidarestat and (B) DHEA treatment elevate PPP and TCA cycle fluxes

# A BAYESIAN APPROACH FOR INVERSE PROBLEMS ON PATIENT-SPECIFIC CFD SIMULATION OF AORTA USING AN ML-BASED SURROGATE MODEL

**Pan Du (1), Jian-xun Wang (1)**

(1) Department of Aerospace and Mechanical Engineering,
University of Notre Dame,
Notre Dame, IN, U.S.

## INTRODUCTION

Cardiovascular disease (CVD) remains the first leading cause of death and morbidity in the U.S., posing a major healthcare concern. Physically principled computational modeling, often combined with medical imaging, plays an important role in the diagnosis of CVD by virtue of its capability of providing comprehensive hemodynamic flow information (e.g., blood flow velocity, pressure, wall shear stress) [1-2]. The ever-growing computational capability and understanding of cardiovascular fluid mechanics spur the development of more realistic and sophisticated CFD models, yet bring many challenges to inverse optimization and uncertainty quantification (UQ) of unknown/uncertain model parameters due to large number of uncertain inputs and excessive computational burden. Many attempts have been done to solve inverse UQ problems of cardiovascular flow under the Bayesian framework [3-4]. Direct coupling of Markov Chain Monte Carlo (MCMC)-based posterior sampling approach and non-trivial forward CFD modeling involves numerous expensive trials which can easily be computationally prohibitive especially for complex flows. As a result, surrogate models for cardiovascular simulation (e.g., lumped parameter models, multi-fidelity CFD simulation, neural networks) are introduced to reduce the online cost of the forward propagation step. Neural network (NN) is a highly preferred choice for surrogate models because it is capable of approximating complex high-order nonlinear mapping between inputs (geometry, boundary conditions, parameters, etc.) and field outputs, and features a fast online prediction speed. However, building interpolation-based surrogate models such as neural networks requires a significant amount of sample points. Therefore, more efficient sampling strategies are needed to achieve the same accuracy with fewer samples. Iterative ensemble Kalman method (IEnKM), for example, is more efficient in terms of sampling compared to fully Bayesian methods such as MCMC.

Moreover, besides common parameters (e.g., viscosity, Re, velocity, etc.), quantifying the uncertainty of 3-D geometries is quite challenging especially for complex cardiovascular systems. Graph neural network (GNN) or dimensionality-reduction methods such as primary component analysis (PCA) are typically used for the parameterization of complex 3-D geometries. GNN learns a point-to-point mapping between input and output but requires considerable computational resources when the mesh resolution is large. The latter one is more efficient since it directly encodes the 3-D mesh into a lower-order latent space, reducing the complexity of the neural network in the surrogate model if present.

In this study, we propose a novel deep learning solution to address these challenges and enable scalable geometric UQ and optimization. Specifically, a statistical generative model for 3-D patient-specific shapes will be constructed based on a handful of available baseline patient geometries. An unsupervised shape correspondence solution is used to enable geometric morphing and a compact geometric design space can then be constructed by the statistical generative shape model. In order to build a fast forward map between geometric input space to the solution space of functional information, we propose a supervised deep learning solution. With the fast surrogate model, we ran test cases to demonstrate its application in shape optimization and UQ analysis in a massively scalable manner.

## METHODS

### 1). Aorta geometry dataset parameterization

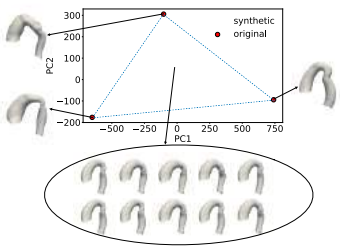

**Figure 1: geometry parameterization and synthesis**

Eight 3-D aorta geometries are reconstructed from MRI scans of patients with Coarctation of the aorta (COA) conditions at the German Heart Institute Berlin [5]. A statistical shape model (SSM) is built and performed to parameterize input geometric space and synthesize virtual shapes to form a large-size aorta geometry dataset.

**2). Automatic CFD routine**

A python program is built to automatically conduct CFD simulations on each aorta sample to produce the desired fluid quantities (e.g., pressure, velocity and wall shear stress).

**3). ML-based surrogate model**

The shape inputs and field outputs are encoded into a latent space using PCA transform and an MLP is used to learn the non-linear relationship in between. Once the training is done, the surrogate model will be able to predict the 3-D hemodynamic flow information within a split second for any new aorta shape.

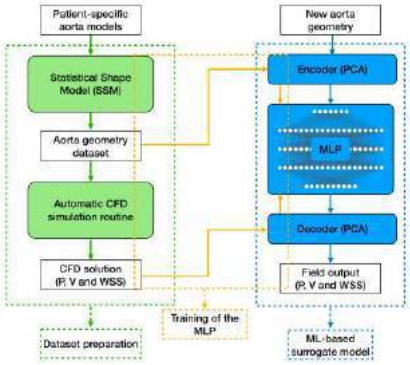

**Figure 2: Diagram of the surrogate model**

**4). Hybrid Bayesian approach**

The proposed surrogate model is embedded into a hybrid Bayesian method to quantify geometry uncertainty. The observation data is sparse measurements of the velocity field and a prior is assumed for the PCA encoded vector. The hybrid Bayesian method operates in two phases: the IEnKM coupled with full-resolution CFD modeling is used to find the posterior mean; A ML-based surrogate model is built by sampling around the found mean and importance sampling incorporating the surrogate model is performed to quantify the uncertainty.

**RESULTS**

Among the eight patient-specific aorta geometries, one aorta is randomly selected as the template and seven diffeomorphisms are calculated from the template to the rest of the geometries using the SSM, which yields seven deformed geometries replacing the original ones. Later, the synthesizing method expands the eight original geometry set to a dataset containing 1000 samples. The samples are then passed to a CFD solver to generate field outputs. All CFD simulation cases were run in parallel (4 CPUs per case) using the Simple solver in OpenFOAM. Each simulation takes about 20 minutes to reach convergence.

The learning of the MLP was conducted on an Nvidia RTX A6000 card and a minimum of 2000 epochs were executed for each MLP to ensure convergence. The average relative mean squared error (ARMSE) of the predicted flow fields with respect to the ground truth is reported in Table 1. A visualization of the field outputs is shown in Figure 3.

| | Pressure | Velocity | Wall shear stress |
|---|---|---|---|
| ARMSE | 1.336% | 0.640% | 1.203% |

**Table 1: Error of prediction of the surrogate model**

Figure 4 shows the first phase of the hybrid Bayesian approach. The ensemble size is 18 and samples for the first and second iterations are displayed.

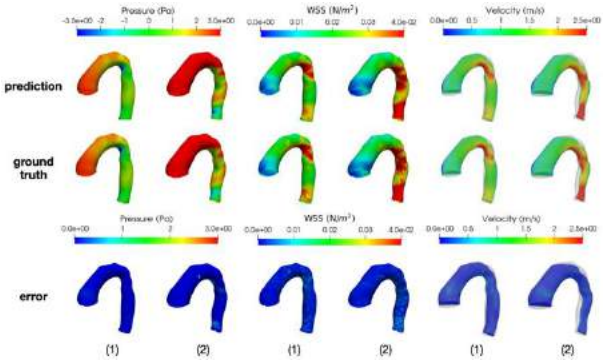

**Figure 3: Comparison of prediction and ground truth**

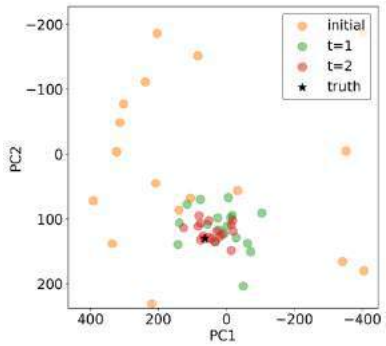

**Figure 4: Determination of posterior mean via IEnKF**

**DISCUSSION**

In this study, a set of patient aorta geometries is collected and an SSM is built to parameterize the 3-D topological space of the aorta shapes and synthesize virtual aorta geometries. An ML-based Surrogate model is proposed to predict desired field outputs.

The prediction errors in Table 1 are small, indicating a great prediction accuracy for the proposed ML-based surrogate model. The visualization (Figure 3) also proves that the proposed model is in good agreement with the ground truth generated from CFD simulation. However, certain discrepancies are inspected near the stenosis of the descending aorta, exposing the inherent limitations of neural networks in capturing local details. For uncertainty quantification, the first phase of the hybrid Bayesian method successfully found an ensemble close the truth after 2 iterations. In future work, phase two will be implemented, where a local surrogate model will be built around the found mean and importance sampling will be utilized to calculate the posterior of the input shape. A good agreement between the posterior and the truth is expected.

**ACKNOWLEDGEMENTS**

I would like to express my gratitude to my advisor Prof. Jian-xun Wang for providing insights and guidance in building up the workflow. Many thanks to my colleagues including Han Gao, Luning Sun, and Xinyang Liu who shared their thoughts and suggestions with me.

## INTRODUCTION

Patient-derived organoids contains more heterogeneity and tissue architecture of the parental tumor than tumor cell-lines and therefore provide the possibility for an in vitro personalized prediction on the anticancer drug responses. Lung cancer remains one of the most challenging diseases due to the heterogeneities in the medical treatment procedures. As the current 2D culturing methods have been provided poor physiological relevance to clinical therapeutics, therefore, 3D models are being developed to better reproduce physiological responses. 3D culturing methods often require large initial cell populations and a long growth period before the organoid models are ready for therapeutic testing. As a solution, a 3D culturing system has been developed capable of producing physiologically relevant organoid modal in an expedited fashion while only requiring a small number of initial tumor cells for the prediction of therapeutic response. The expedited growth of organoids has been facilitated by our inhouse developed bi-layer microfluidic system through active convective nutrition supply and toxin removal. Furthermore, we demonstrated the utility of lung adenocarcinoma organoid lines as a model for drug testing to advance personalized medicine.

## METHODS

The human samples were sectioned with sterile blades into 1-2mm size on ice. Transferred 6-8 pieces of sectioned tissues and washed three times with cold adDMEM/F12 medium (ThermoFisher) and were incubated with 0.001% DNase (Sigma-Aldrich, MO, USA), 1 mg ml$^{-1}$ collagenase/dispase (Roche, IN, USA), 200 U ml$^{-1}$ penicillin, 200 mg ml$^{-1}$ streptomycin, and 0.5 mg ml$^{-1}$ amphotericin B (2% antibiotics, Sigma) in DMEM/F12 medium (Lonza) at 37 °C for 2 h with on roter. After incubation, the suspensions were repeatedly triturated by pipetting and passed through 70 µm cell strainers (BD Falcon, CA, USA). The strained cells were centrifuged at 1300 RPM for 5 min, and the pellet was resuspended in 100 µl Matrigel (serum-free medium DMEM/F12 supplemented with 20 ng ml$^{-1}$ of bFGF (Invitrogen, CA, USA), 50 ng ml−1 human EGF (Invitrogen), N2 (Invitrogen), B27 (Invitrogen), 10 µM ROCK inhibitor (Enzo Life Sciences, NY, USA), and 1% penicillin/streptomycin (Gibco, OK, USA).

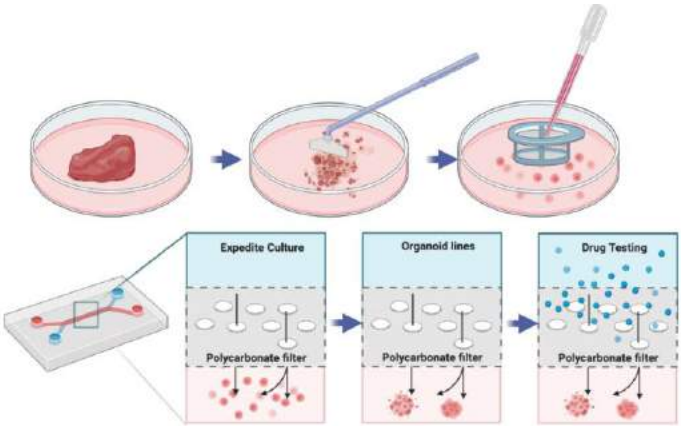

**Figure 1:** Schematic of bi-layer microfluidic model for lung adenocarcinoma patient-derived organoid expedited growth and drug evaluation

To ensure sufficient nutrition and oxygen supply and optimized metabolite clearance, the microfluidic devices were designed as shown in Fig. 1. Both apical and basal pieces were made with PDMS, and the embedded channels were formed from a pre-obtained silicon wafer by photolithography. The two pieces were separated by a semipermeable membrane, which usually has dense 200–800 nm pores, allowing for water, nutrient, oxygen, and metabolite diffusion, while preventing cell transportation. Four outlets (diameter = 2 mm) on the apical piece were matched to the four circle areas for the apical and basal channels. The two channels share the same size (500 µm width and 200 µm height), and they have more than 80% overlapping area, as shown in Fig. 1. Since the two PDMS pieces are separated by the semipermeable polyurethane membrane, which has a surface that cannot be activated by plasma treating, an additional thin layer of PDMS was applied onto the whole membrane, excluding the channel area to ensure strong bonding.

Paclitaxel was used as a model drug for the Lung Adenocarcinoma organoid. The drug displays a remarkable efficacy on the organoid after 1 day under 100 nM of drug concentration. The drug was applied using hydraulic force through a pipette tip that inserted at the inlet of the device.

## RESULTS

To establish the lung adenocarcinoma organoid lines, we received surgical discard from Cooperative Human Tissue Network (CHTN). The organoid establishment and drug efficacy tests can be assessed using dead and live staining and confocal microscopy. Small organoid has started forming after 3 days and reach 100um after day 7, as shown in Fig. 2. The growth of the organoid can be measured directly under confocal imaging using Cell Tracker green stain. The application of the flow has generated by hydraulic force with pipette tip fixed at the inlet. The various flow rates withing the microfluidic devices were controlled with the amount of medium loaded in the tip.

In our previous published work [1]-[2], Paclitaxel of a high concentration has negative effects on the HCT116 cells and the cocultured EC cells. In order to evaluate the efficacy of the patient-derived organoid to the anticancer drugs, we perfused the Paclitaxel as the model drug into the system for 24 hours. The organoids were treated one day and stained with live/dead stains. In Fig. 3, it shows that the organoid was sensitively responded in the device to as little as 10nM of drug concentration.

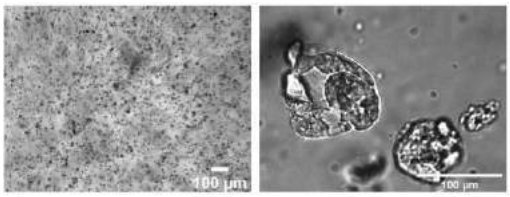

**Figure 2:** Bright field image of Lung adenocarcinoma patient-derived cell seeding and established organoid.

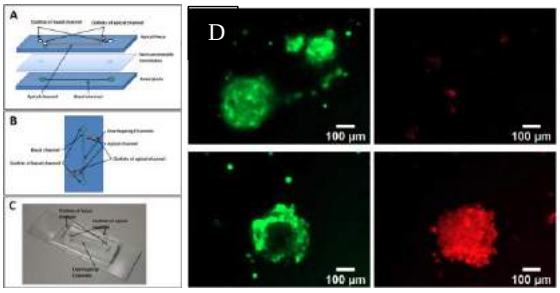

**Figure 3:** Diagram of the microfluidic device using PDMS molds with basal and apical channels. (a) Layer diagram, (b) top view, and (c) photo of the microfluidic device, (d) Fluorescent images of organoids subjected to 1-day 100 nM paclitaxel (Pac) treatment. The organoids were stained with Calcein AM and propidium iodide (PI) (live/dead)

## DISCUSSION

The expedite growth and drug testing of the lung adenocarcinoma organoid provide an opportunity to bridge the gap between traditional c ell lines and patient-derived xenograft animal models. The in vitro antitumor drug-screening platform presented that consisted of two layers with two channels and a semipermeable membrane. The membrane between channels has allowed the infiltration of medium and drugs, and showed both permeability and resistance to several molecules, including drugs. Additionally, direct seeding of tumor-derived cells more closely mimicked the in vivo nature of tumors, while the Matrigel served as a scaffold for the tumor organoid, which functioned as ECM. The drug efficacy has been expressed by the viability of tumor cells, which can be quantified by dead/live staining using confocal microscopy. More drugs will be selected for our bi-layer microfluidic system based on their clinical relevance. The half-maximal inhibitory concentration (IC50) will be presented. Since both the cell culture in the microfluidic device and the drug screening characterization techniques can be automated, we believe this work can dramatically increase the efficiency with shorter turnaround time and cost on antitumor drug screening.

# STIFFNESS MAPPING FOR EARLY DETECTION OF BREAST CANCER: SENSITIVITY TO ERRORS IN MODULUS

**Lorraine G. Olson (1), Robert D. Throne (2)**

## INTRODUCTION

Early detection of breast cancer is crucial for improving patient survival rates. Manual breast exams and mammograms are currently the most effective and widely used early detection techniques. Manual breast exams depend on tissue stiffness but are limited in their ability to detect tumors. Mammograms, while effective, expose the patient to radiation. In addition, mammograms are sensitive to tissue density rather than stiffness, so identifying cancerous sites in the half of women over 40 with dense breasts can be challenging.

Our ultimate goal is to develop a system that automates/refines the manual breast exam process to detect the roughly 10x stiffness difference between healthy and cancerous tissues. An electro-mechanical device will gently indent the tissue surface in various locations, recording the forces required and the tissue surface deflections on the remainder of the surface. This force and deflection data will be used with inverse techniques involving finite element methods and genetic algorithms to provide detailed 3D maps of the elastic modulus of the interior of the breast tissue.

We have developed 3D mapping algorithms and have conducted experiments on tissue phantoms to validate our approach [1]. Figure 1 shows a prototypical 3D stiffness map. We tested 14 tumor-free phantoms and 14 tumor-containing phantoms. Using a combination of 10% force data and 90% displacement data we could correctly classify all phantoms as tumor-containing or tumor-free, which was substantially more robust than either measurement modality alone.

These experiments were conducted with a background phantom stiffness (Young's modulus) $E_h$= 3.3 kPa and a tumor phantom stiffness $E_c$=22 kPa, which closely mimics experimental data for healthy and cancerous breast tissues reported in the literature [2]. The computations assumed $E_h$ =3.2 kPa and $E_c$ = 22.6 kPa – effectively the correct values. In actual applications we will not know the stiffnesses yet we would still like to correctly classify phantoms as tumor-containing or tumor-free.

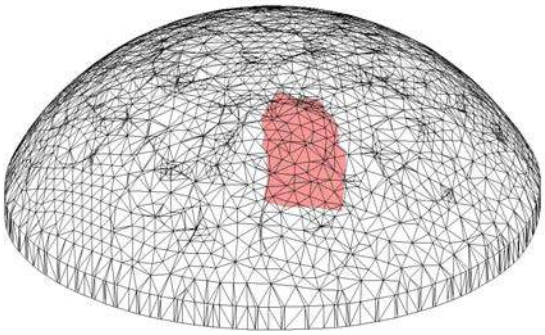

**Figure 1: Prototypical 3D Stiffness Map. (Stiff Cancerous Tissues are Red, Normal Healthy Tissues are Transparent.)**

In this abstract we study the sensitivity of the tumor presence/absence classification to errors in the assumed modulus in the computations.

## METHODS

Experimental Methods. Before we review the computational methodology – which is the focus of this abstract – it is useful to understand the data collection.

Figure 2 shows the experimental set-up. The phantom sits on a turntable underneath the indenter. The phantoms themselves are made of silicone and are for average-sized (180g) breasts. The tumors are 2g which would correspond to a 100% 5-year relative survival rate for the patient. A structured light scanner is used to capture the initial phantom geometry. The indenter has 4 possible locations on the arc and the turntable rotates to 9 positions for a total of 36 measurement sites.

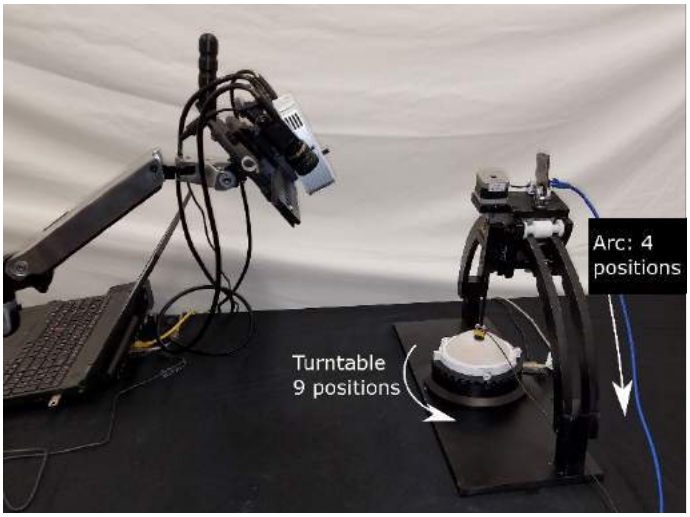

**Figure 2: Experimental Setup. (Structured light scanner is attached to arm at left. Arc positions indenter above phantom. White phantom sits on turntable below indenter.)**

At each measurement site we indent the tissue 5 mm and measure the force required to produce that indentation. At the same 36 indentation sites, we use the structured light scanner to capture "before indentation" and "after indentation" geometries. These geometries allow us to estimate the normal displacement of points on the phantom surface.

Computational Methods. The initial phantom geometry, the forces from the 36 indenter sites, and the normal displacements of points on the surface (36 sets of them) are the inputs to the computational algorithm. The cost function to be minimized balances the error in the match to the measured data and the size of the tumor:

$$\begin{aligned} \text{Cost} = \quad & (1-\alpha)*(\text{Error in Forces}) \\ & + \alpha*(\text{Error in Displacements}) \\ & + w*(\text{Tumor Radius}) \end{aligned} \qquad (1)$$

α adjusts the relative importance of errors in the force data and errors in the displacement data. $w$ is the weighting that adjusts the balance between the errors in the match to the measured data and the tumor size, which regularizes the problem, and choosing $w$ appropriately is important. The output is the 3D stiffness map.

Our experimental validation indicated that $\alpha = 0.9$ gave the best balance between force and displacement data. $w$ in the range from 0.4 to 0.7 correctly classified all samples as tumor-containing or tumor-free. These results were obtained with the correct values of the moduli in the computational algorithm.

We then varied the moduli in the computational model to examine how sensitive our stiffness mapping algorithm is to having the correct moduli. In doing this, we held α at 0.9 and $w$ at 0.6. We first varied the tumor modulus in the computational model while holding the healthy modulus at 3.2 kPa. Next we held the tumor modulus fixed at 22.6 kPa and varied the healthy modulus.

## RESULTS

Figure 3 shows the results. Notice that the horizontal axis is the ratio of the tumor modulus to the healthy tissue modulus in the computational model – the results for a given ratio were the same regardless of whether we varied the tumor modulus or the healthy tissue modulus. The vertical axis gives $w_{cross}$ for each test—this is the value for which a given test crosses from being correctly classified to being incorrectly classified. Red lines indicate results for tumor-containing phantoms and blue lines indicate results for tumor-free phantoms.

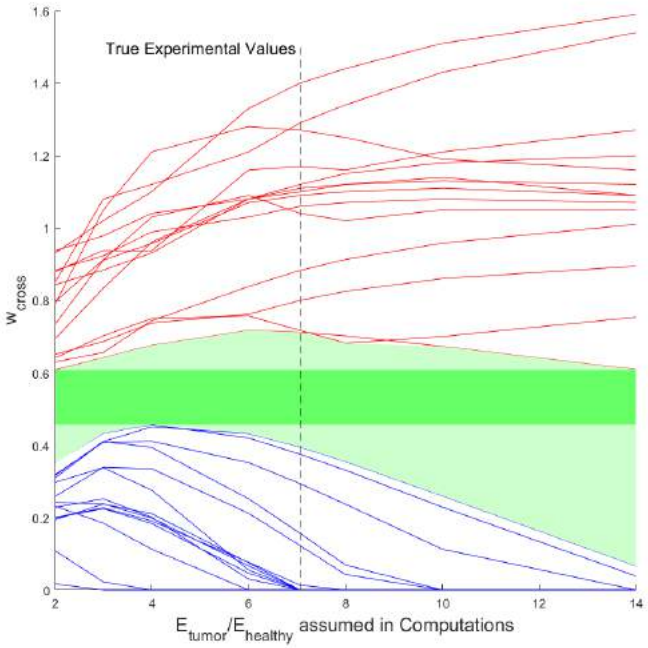

**Figure 3: Correct classification of tumor-free and tumor-containing (light green region) is robust to errors in the assumed computational stiffness ratio. (Dark green region: correct classification over all tested stiffness ratios.)**

## DISCUSSION

Figure 3 shows that method is quite robust over a range of modulus ratios– when the ratio is at the true value of approximately seven we see almost the same performance as when the ratio is 14 or even 2. The dark green region represents the range of w's for which we would correctly classify all samples over the entire range of modulus ratios. This range is w = 0.46 to w = 0.61. Thus, choosing $w = 0.55$ along with $\alpha = 0.9$ would give good results even with errors in the assumed stiffnesses.

It is important to note that this does not mean that we can experimentally detect tumors at stiffness ratios of 2 or 14 – it means that when the data is collected from one of our samples (stiffness ratio of 7) we do not need to have the correct ratio in our computational algorithm to make a correct prediction of the presence or absence of a tumor.

It is also important to realize that this insensitivity to the modulus ratio means that we will almost certainly be unable to predict the stiffness of the tumors – merely presence/absence.

# EARLY REMOVAL OF THE INFRAPATELLAR FAT PAD IN A SPONTANEOUS RODENT MODEL OF OSTEOARTHRITIS MAY BENEFICIALLY ALTER THE DEVELOPMENT OF OSTEOARTHRITIS

**Tammy L. Haut Donahue (1), Mary F. Afzali (2), Nicole Vigon (3), Ryan J. Ek (3), Gerardo E. Narez (3), Kelly S. Santangelo (2,3)**

## INTRODUCTION

Adipose depots described in the knee joint include the infrapatellar fat pad (IFP), the posterior knee fat pad, the quadriceps fat pad, and the pre- femoral fat pad [1]. The IFP is the largest of these and is found in the anterior aspect of the joint in the space shaped by the patella, femoral condyles, and tibial plateau. While the exact functions of the IFP are not completely understood, it is thought to facilitate the distribution of synovial fluid and absorbs loads through the knee [2.3].

Osteoarthritis (OA) is a painful, debilitating disease often found in the elderly population. While the exact mechanisms of OA development are not well understood, recent studies suggest a strong inflammatory role of the IFP in OA. Additionally, resection of the IFP in human cadavers was shown to decrease tibial external rotation, increase medial translation of the patella, reduce retro patellar contact pressure and decrease patellofemoral contact area and force [4].

Only a few studies have documented the change in biomechanical properties of the knee as a whole, as well as tissues such as cartilage, meniscus and bone, following removal of the IFP from this joint. We have previously shown that, after resection of the IFP in the Hartley Guinea pig model of spontaneous OA, a fibrous connective (FCT) was formed in its place [5] (Figure 1). Thus, the goal was to investigate the biomechanical behavior of cartilage, meniscus, and bone following removal of the IFP and compare it to the native joint.

## METHODS

All procedures were approved by the University's Institutional Animal Care and Use Committee and were performed in accordance with the NIH Guide for the Care and Use of Laboratory Animals. Male Hartley guinea pigs (n=8) were purchased at 2 months of age to allow acclimation for 4 weeks. Surgical removal of the IFP was performed at 3 months of age (prior to the development of OA) on one limb while the contralateral limb had a sham surgery.

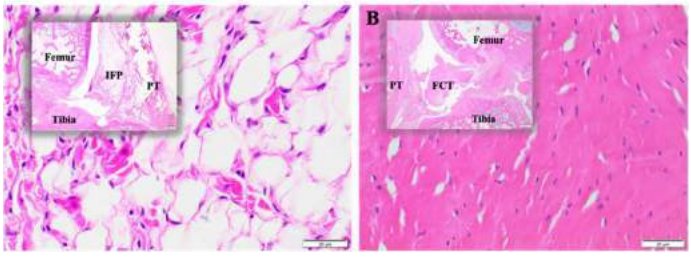

**Figure 1. Representative mid-sagittal H&E photomicrographs of a stifle joint from a sham control (A) and IFP removal (B) guinea pig. 40X objective for main photo; 2X objective for inset. (A) Control joint from 7-month-old guinea pig depicting the normal histoanatomic features of IFP in its native state. (B) Knee joint from a 7-month-old guinea pig, which demonstrates the dense, collagenous nature of the replacement FCT.**

Whole knee joints were scanned using a Bruker Skyscan 1276 for micro-computed tomography (uCT). Osteophytic bone was identified by its reduced bone mineral density compared to the native bone, as well as being outside the original joint margins. Osteophytes then manually outlined every 10 slides such that representative volumes could be determined.

Cartilage and menisci from both native IFP and FCT knee joints were subjected to indentation relaxation tests in a phosphate buffered saline bath to determine instantaneous and equilibrium moduli. The bath was mounted to a two degree of freedom camera mount and an X-Y stage to allow for the indentation surface to be oriented normal to the indenter tip. Both the femoral and tibial cartilage was indented on the medial and lateral plateaus, which is a location where there would be cartilage on cartilage contact. To test the cartilage, the tibia was potted distally and adjusted to indent perpendicular to the surface. The cartilage was assumed to be 0.5 mm thick on the femur and 0.75 mm

thick on the tibia and following a pre-load of 50 mN, indentation was conducted to 10% strain in 1 second and held for 420 second to reach equilibrium. The menisci were extracted off the tibial plateau at the anterior and posterior root attachments. They were then glued onto a plexiglass mounting plate to allow the proximal surface to be mounted perpendicular to the indenter tip. The medial and lateral menisci were indented at both the anterior and posterior locations. Menisci were assumed to be 1.2 mm thick and, following a preload of 50mN, menisci were indented to 10% strain (0.12 mm) in 1 second and held for 900 seconds to reach equilibrium. Hertzian contact between an elastic half space (meniscus) and a rigid sphere (indenter) was assumed [6,7]. A custom MATLAB algorithm (Mathworks, Natick, MA) was used to calculate the instantaneous and equilibrium moduli from the collected data.

## RESULTS

Osteophyte volume was significantly decreased in the limbs containing the replacement FCT compared to the contralateral limb (Figure 2). The equilibrium modulus of the medial hemijoint articular cartilage and the instantaneous modulus of the lateral hemijoint articular cartilage were significantly decreased in the FCT limbs compared to the contralateral limbs with the native IFP (Figures 3,4). The only significant change in meniscal properties between the FCT and IFP limbs was the medial posterior meniscus equilibrium modulus (Figure 5).

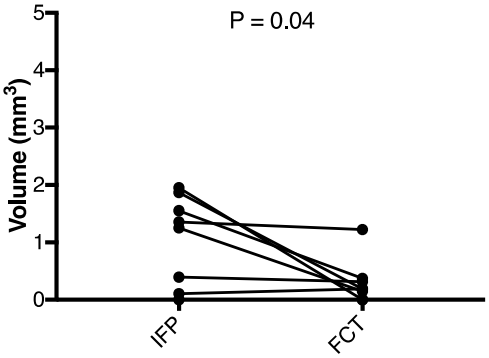

**Figure 2. Osteophyte volume for IFP and FCT limbs.**

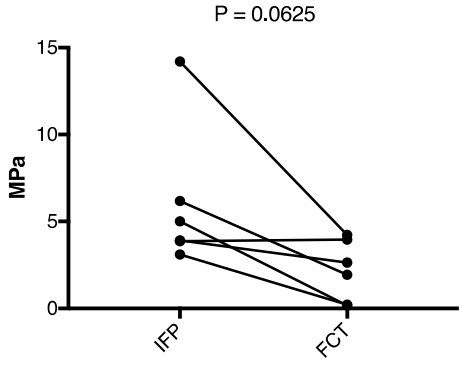

**Figure 3. Equilibrium modulus for the medial tibial plateau articular cartilage.**

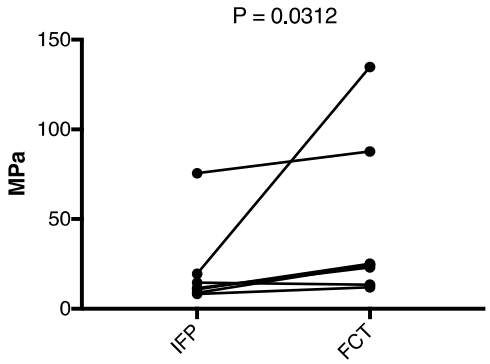

**Figure 4. Instantaneous modulus for the lateral tibial plateau articular cartilage.**

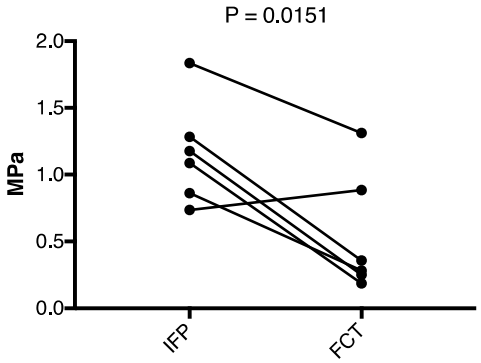

**Figure 5. Equilibrium modulus for the medial posterior region of the meniscus.**

## DISCUSSION

Removal of the native IFP and replacement by the FCT results in significant changes in the bone, cartilage, and menisci of the knee. The fact that the instantaneous and equilibrium modulus were decreased in the FCT-containing joint could imply an altered loading environment in these tissues, perhaps as a result of unloading of the of soft tissue of the joint in favor of more load through the FCT. This is the first data to report biomechanical changes in joint tissues following early removal of the IFP. The results of this study elude to the role of the IFP in OA and thus warrants further investigation as to the mechanism by which the IFP may influence joint health.

# A DOPPLER-EXCLUSIVE NON-INVASIVE COMPUTATIONAL FRAMEWORK FOR PERSONALIZED VALVE DYNAMICS IN PATIENTS WITH AORTIC STENOSIS AND TRANSCATHETER AORTIC VALVE REPLACEMENT

**Nikrouz Bahadormanesh (1), Zahra Keshavarz-Motamed (1,2,3)**

## INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is an emerging treatment alternative to surgical aortic valve replacement that covers a range of patients suffering from moderate to severe aortic stenosis (AS). AS is one of the most common and serious cardiovascular problems and if left untreated, often leads to death. Surgical valve replacement remains the standard treatment method for AS, however, many patients suffering from this pathology are at a high risk for surgery and may suffer death or other complications [1].

TAVR is a growing alternative for intervention of AS patients across a broad risk spectrum and has lower death rates in severe cases compared to a surgical approach. Although TAVR has critical benefits for surgical high-risk patients, there are several drawbacks that patients may experience [2]. *Given the associated risks with TAVR, it is crucial to determine: how the implant will affect the cardiac function? when is the proper timing for intervention? Will TAVR improve or worsen the outcome of the patient [3].*

The condition of the heart valves heavily relies on the geometry and material properties of the leaflets as well as the interaction between the flow and the valve [3,4,5,6]. Valvular disease, including AS, often results in, or is a result of abnormal stress and strain distributions on aortic valve leaflets for both pre- and post-interventional cases.

In this study, we developed a highly innovative non-invasive Doppler-exclusive computational-mechanics framework that can function as a diagnostic tool to assess aortic valve dynamics in pre and post-TAVR states at no risk to the patients. The developed diagnostic tool is able to dynamically couple the local valve dynamics with the global circulatory system [4] which provides a platform for testing intervention scenarios (e.g. TAVR) and evaluating their effects.

## METHODS

We developed a Doppler-based computational mechanics diagnostic framework to non-invasively investigate the dynamic behavior of the aortic valve (e.g., transient 3-D distribution of stress and displacement field, 3-D deformed shape of leaflets, geometric orifice area, angular positions of leaflets, stiffness, etc.). This framework is based on a Doppler-based patient-specific lumped parameter algorithm (LPM) [4] along with a 3-D Doppler-based nonlinear (using anisotropic hyper elastic) finite element solver CalculiX with some supplements. The developed LPM algorithm [4] consists of a parameter estimation algorithm and a lumped-parameter model that includes several sub-models allowing analysis of any combination of complex valvular, vascular and ventricular diseases. A Doppler-based parametric method was developed to construct the 3-D geometry of the asymmetric aortic valve leaflets. Calculations of this Doppler-based computational mechanics diagnostic framework were validated against clinical Doppler echocardiography data in patients with AS.

## RESULTS

In patients with aortic stenosis, the healthy instantaneous LV pressure and/or volume are altered which ultimately overloads the heart. We investigated metrics of cardiac function (global hemodynamics) computed by our Doppler-based lumped parameter algorithm to determine the effects of TAVR on patient condition. The impacts of the TAVR on the aortic valve pressure gradient were not always be associated with reduction in LV function parameters, e.g., LV workload, normalized LV workload to stroke volume and maximum LV pressure. LV hemodynamics metrics worsened in some patients, and they were not significantly improved in the others (Figure 1, panel c)

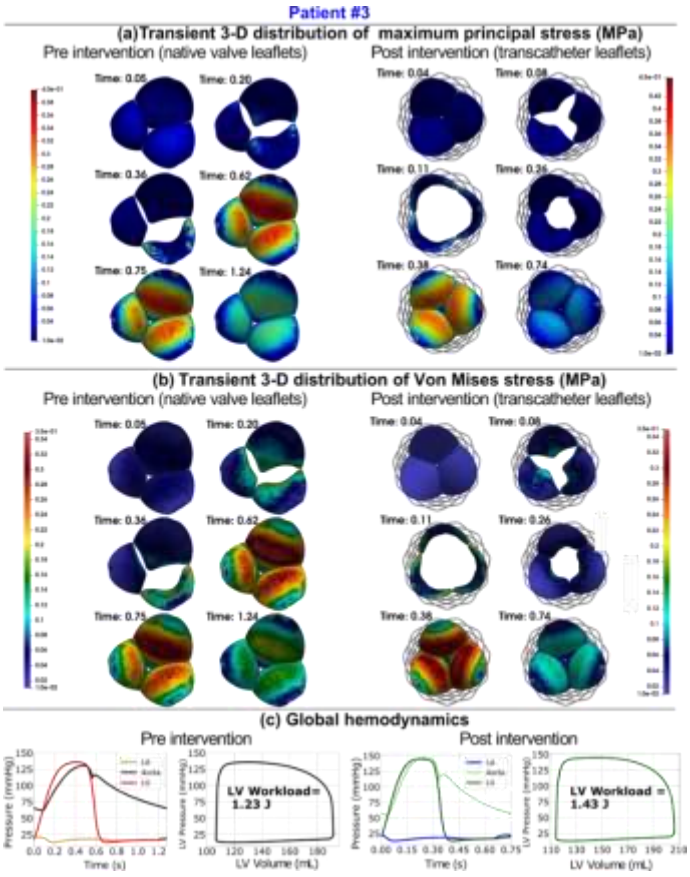

**Figure 1. Changes in valve dynamics and global hemodynamics in patient #3 between baseline and 90-day post-TAVR.**

Biomechanical factors resulting from hemodynamic loads are a common dominator of a variety of vascular diseases. Various mechanical metrics including 3-D Mises stress (the derivative format of principle stress), 3-D major principal stress (the maximum value of the three principal stresses), as well as displacement magnitude resulted from our Doppler-based computational framework reveled that TAVR worsened valve dynamics in some patients. Indeed, mechanical forces are the driving force behind the degeneration and failure of prosthetic heart valves and must be measured regularly to prevent the deterioration of the replacement valve.

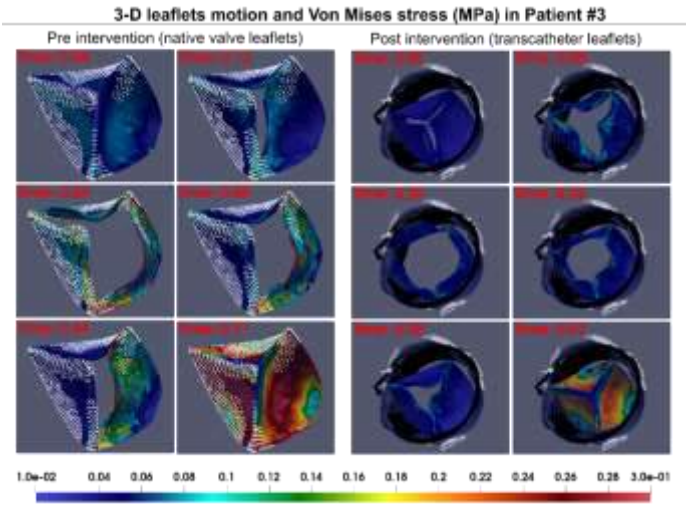

**Figure 2. 3D motion and 3D distribution contours of Mises stress in patient #3 at six time points throughout the cardiac cycle in both pre- and post-intervention states**

## DISCUSSION

TAVR does not always improve cardiac function metrics. LV hemodynamics metrics worsened in some patients, and they were not significantly improved in the others. TAVR does not always improve valve dynamics metrics. Valve dynamics post-intervention should be quantified and monitored to ensure the improvement of patient conditions and prevent any further complications. Improper evaluation of biomechanical valve features pre-intervention as well as post-intervention may result in harmful effects post-TAVR in patients including paravalvular leaks, valve degeneration, failure of TAVR and heart failure.

## INTRODUCTION

Benign prostatic hyperplasia (BPH) is the nonmalignant growth of the prostate, commonly observed in aging men. Lower urinary tract symptoms (LUTS) is the most common manifestation of BPH. Over 50% of men aged over 60 years suffer from BPH, and 15%-30% of these men have LUTS [1]. Multi-channel urodynamic studies are performed to measure bladder pressure and flow during voiding, and when coupled with 2D fluoroscopy, allows visualization of urine flow. However, these techniques are invasive and do not provide sufficient information on biomechanical properties, bladder anatomy, and detrusor muscle function in BPH/LUTS [2]. Image-based computational fluid dynamics (CFD) has been used to study biomechanics in cardiovascular diseases [3]. Our group has investigated MRI-based CFD, with a focus on cardiac flows as well [4]. In this study, we expand the tools we developed and apply them to urinary flows. Here, we present an MRI-based computational method that enables in-silico CFD simulation of bladder voiding.

## METHODS

In-vivo MRI studies were performed on two male volunteers with no history of LUTS following an IRB-approved HIPAA-compliant protocol. Subject 1 was 29 years old and Subject 2 was 55 years old. Both subjects were scanned on a clinical 3T scanner (Premier, GE Healthcare, Waukesha, WI, USA) using 3D Differential Subsampling with Cartesian Ordering (DISCO) Flex sequence. Before the scan, the subject was equipped with a condom catheter to allow the void event while scanning, and volumetric dynamic images of the bladder were collected throughout the void. The MR images were manually segmented using semiautomatic segmentation software Mimics and 3-matic (Materialise NV, Leuven, Belgium), providing an anatomical geometry of the bladder at each time instant, i.e., each MR temporal phase during the voiding event. Each anatomical geometry was represented as a surface, composed of discrete triangular elements. We developed a novel algorithm that maps one surface to another by calculating displacements and building a transformation matrix. Figure 1 shows a schematic of the mapping algorithm.

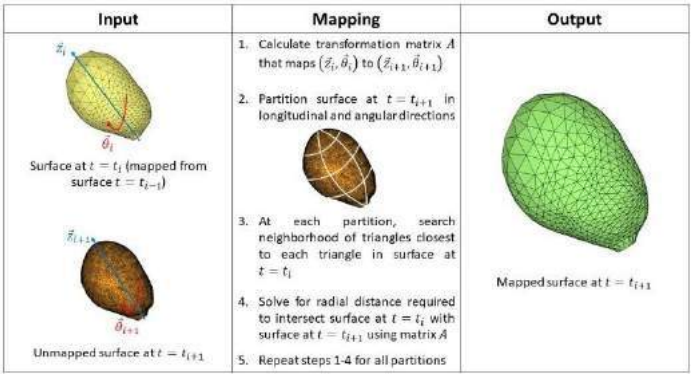

**Figure 1: Steps of the novel mapping algorithm.**

This algorithm is executed between each MR time phase and provides surfaces of the bladder wall that have the same topology. The surfaces in this sequence are applied as a moving wall boundary condition into the CFD software package CONVERGE 3.1 (Convergent Science, Inc., Madison, WI, USA), which automatically constructs the finite volume mesh according to the instantaneous surface position. The mesh consisted of 1 mm × 1 mm × 1 mm cubic elements. The Pressure-Implicit with Splitting of Operators (PISO) algorithm was used as the Navier-Stokes solver. Pressures at the outlet, i.e., bladder neck, were determined from separate CFD simulations of the urethra anatomies. Wall motion was set as the transition from one mapped surface to the next, and the motion rate was determined by the time resolution of the MRI scan. Figure 2 illustrates the stages of our methods, starting from

in-vivo MRI to CFD. Tecplot 360 EX (Tecplot, Inc., Bellevue, WA, USA) was used to visualize and quantify the in-silico results.

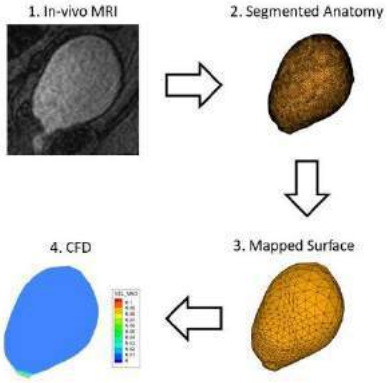

**Figure 2: Schematic of methods.**

## RESULTS

Both healthy subjects were successfully imaged and time-resolved contrast-enhanced images of the bladder during voiding were obtained in a single MRI session for each subject. The time resolution was 3.7 seconds. The total void times were 74 seconds for Subject 1 and 81 seconds for Subject 2. After implementing the mapping algorithm, we executed two CFD simulation for the two subjects using MRI-based wall motion. Velocity, pressure, and wall shear stress were calculated from CFD results and are visualized in Figures 3 and 4.

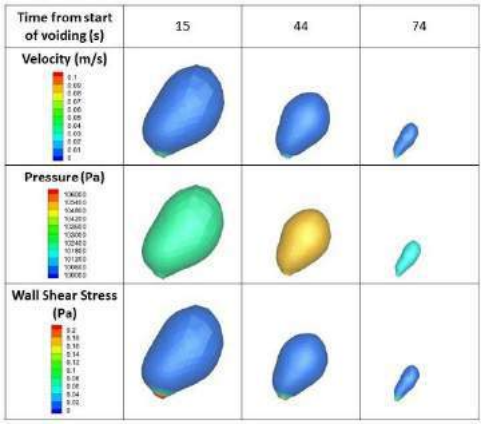

**Figure 3: CFD results for Subject 1.**

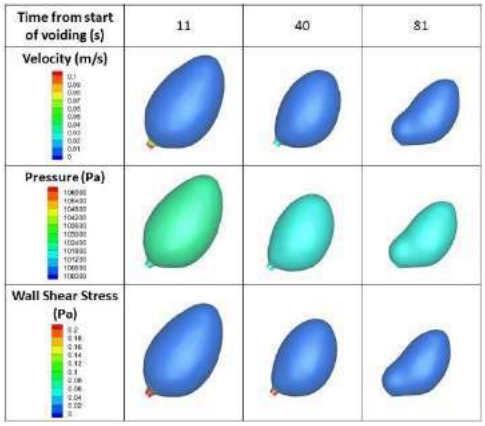

**Figure 4: CFD results for Subject 2.**

CFD predicted the maximum urine flow rate, $Q_{max}$, and detrusor pressure at maximum flow, $P_{det}Q_{max}$. For Subject 1, $Q_{max}$ = 19.23 $cm^3/s$ and $P_{det}Q_{max}$ = 38.45 $cmH_2O$, and for Subject 2, $Q_{max}$ = 15.12 $cm^3/s$ and $P_{det}Q_{max}$ = 9.13 $cmH_2O$. Values for Bladder Outlet Obstruction Index (BOOI) and Bladder Contractility Index (BCI) were calculated. These indices are defined as flows, BOOI = $P_{det}Q_{max}$ - 2*$Q_{max}$ and BCI = $P_{det}Q_{max}$ + 5*$Q_{max}$, where $P_{det}Q_{max}$ is in $cmH_2O$ and $Q_{max}$ is in $cm^3/s$. For Subject 1, BOOI = -0.01 and BCI = 134.6, and for Subject 2, BOOI = -21.11 and BCI = 84.73. The CFD simulations were executed on a high performance computing cluster with 40 CPU cores. The runtime was about 4 hours per simulation.

## DISCUSSION

The goal of this study was to implement a non-invasive methodology to comprehensively assess bladder biomechanics using MRI-based CFD. Previously, bladder biomechanics, including BOOI and BCI, were measured using invasive multi-channel urodynamics. The in-vivo MRI results only showed real-time images of the bladder at different instants but provided no information on urine flow dynamics or bladder contraction dynamics. Coupling CFD with MRI has enabled a non-invasive method to characterize bladder biomechanics by quantifying and visualizing urodynamics. To impose bladder motion in our CFD simulation, we developed an algorithm that maps the bladder wall surfaces (from MR images) at successive time phases. Execution of CFD simulations is a result of the successful surface mapping algorithm. The subjects in this study did not present BPH/LUTS and our results show no obstruction in their bladder outlet or urethra since BOOI < 20. Subject 1 showed normal bladder contractility because BCI was between 100 and 150. Subject 2 showed impaired bladder contractility because BCI < 100. This is due to the subject's inability to void completely while in the scanner. Image-based CFD has primary focused on cardiovascular flows. We expanded the computational tools to simulate urinary flows and introduced a new application for MRI-based CFD.

## INTRODUCTION

Benign prostatic hyperplasia (BPH) is the nonmalignant growth of the prostate, commonly observed in aging men. Lower urinary tract symptoms (LUTS) is the most common manifestation of BPH. Over 50% of men aged over 60 years suffer from BPH, and 15%-30% of these men have LUTS [1]. Standard imaging techniques to assess urethral abnormalities are retrograde urethrography (RUG) and voiding cystourethrography (VCUG) [2]. However, both RUG and VCUG have become uncommon and the limited exposure of radiologists to these examinations can make it challenging to interpret results [3]. Image-based computational fluid dynamics (CFD) has been used to study biomechanics of cardiovascular diseases [4]. Our group has investigated MRI-based CFD with a focus on cardiac flows as well [5]. In this study, we expand the tools we developed and apply them to urinary flows. The purpose of this study was to develop and implement a non-invasive MRI-based computational methodology for the simulation of urinary flow inside urethra.

## METHODS

In-vivo MRI studies were performed on five male subjects (51 ± 19 years old) with no history of BPH/LUTS following an IRB-approved HIPAA-compliant protocol. Subjects were scanned on a clinical 3T scanner (Premier, GE Healthcare, Waukesha, WI, USA) using 3D Differential Subsampling with Cartesian Ordering (DISCO) Flex sequence. 15 minutes prior to the start of the imaging session, 1/3 of a single weight-based dose (0.1 mmol/kg) of gadolinium-based contrast was slowly hand injected intravenously outside and the subjects were asked to walk around to ensure enhancement of the urine. Right before the scan, each subject was equipped with a condom catheter to allow the void event while scanning, and volumetric dynamic images of the bladder and urethra were collected throughout the void. The MR images were manually segmented using the semiautomatic segmentation software packages Mimics and 3-matic (Materialise NV, Leuven, Belgium). For the computational simulations, anatomical models of the urethra at the moment of maximum flow were generated from the segmented images for all subjects. To determine, the inlet boundary conditions, bladder volumes were segmented and the urinary flow rate in the urethra was calculated as the rate of change in volume of the bladder over time. The outlet boundary condition was atmospheric pressure. The CFD simulations were executed on software package CONVERGE 3.1 (Convergent Science, Inc., Madison, WI, USA) [6]. Tecplot 360 EX (Tecplot, Inc., Bellevue, WA, USA) was used to visualize the in-silico results. Figure 1 shows age, MR images, urethral anatomy, and calculated flow rates of all subjects.

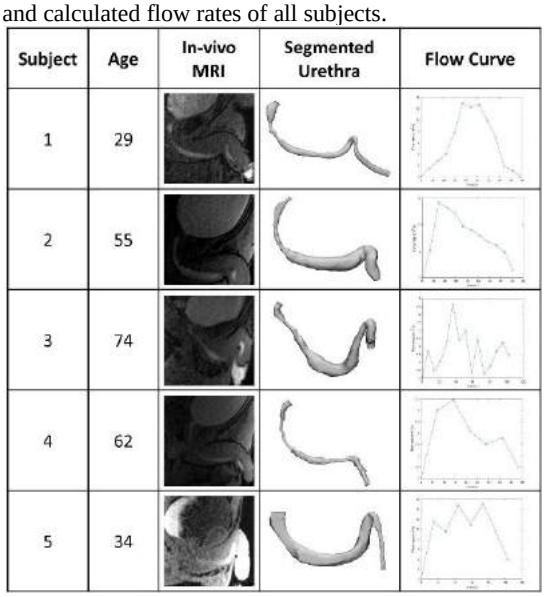

**Figure 1: Age, MRI scans, urethra anatomies, and flow rates.**

## RESULTS

Contrast-enhanced MRI studies provided real-time anatomies of urethra and bladder during voiding. The flow rates and geometries extracted from the in-vivo studies were used to successfully simulate the urine flow inside each subject's urethra during voiding. The CFD simulation results are visualized in Figure 2.

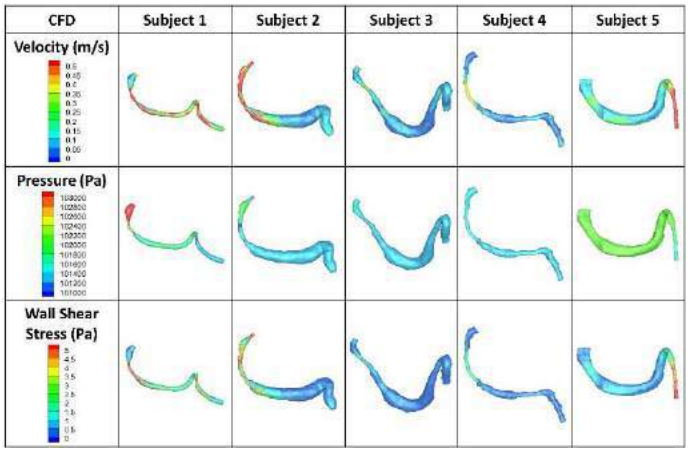

**Figure 2: Velocity, pressure, and wall shear stress from CFD.**

The flow curves in Figure 1 show that Subjects 1 and 2 voided the largest volumes. This is reflected in our CFD results, with these two subjects having the highest velocities. For Subjects 1 to 4, the membranous urethra was the narrowest section of the urethra, and that corresponded to the peak wall shear stress. For Subject 5, the peak wall shear stress was at the penile urethra, which was the narrowest section for this subject. Furthermore, CFD predicted the pressure drops in the prostatic, membranous, and penile urethra for all subjects. The pressure drops are plotted in Figure 3.

In Subjects 1 and 4, the pressure drop across the membranous urethra is larger than pressure drop across prostatic urethra. In Subjects 2 and 3, the pressure drop across the prostatic urethra is larger. For Subjects 1 to 4, the pressure drop in the penile urethra is the smallest, corresponding to the thickest section of the urethra for these subjects. Since the penile urethra is the narrowest section for Subject 5, the pressure drop across the penile urethra is the largest.

## DISCUSSION

Real-time MRI data alone does not provide any insight into the flow dynamics of urine. Our method combines MRI of the urinary system with CFD to present a computational methodology that quantitatively and qualitatively characterizes urine flow in the urethra. Furthermore, the MRI-based CFD simulation calculates the pressure required at the bladder neck (start of the urethra) to flow urine at a prescribed rate. Information on the pressure at the bladder neck is useful because it can be imposed as the outlet boundary condition when simulating the bladder voiding process. Unlike the current procedures used to measure urine flow in the urethra, namely RUG and VCUG, our MRI-based approach is non-invasive and provides not only anatomical but functional information not available with any other diagnostic method.

This study shows that MRI-based CFD can be expanded to study pathological flows in the urinary system. Comparing urine flow dynamics in healthy subjects versus subjects with BPH/LUTS is of interest in future studies. Our simulations assumed the urethra to be rigid, which is anatomically unrealistic. Future studies should include the motion of the urethra wall in their model extracted from the real time MR images and fluid-structure interaction. Further studies should compare results from our method with results from benchmark clinically used techniques.

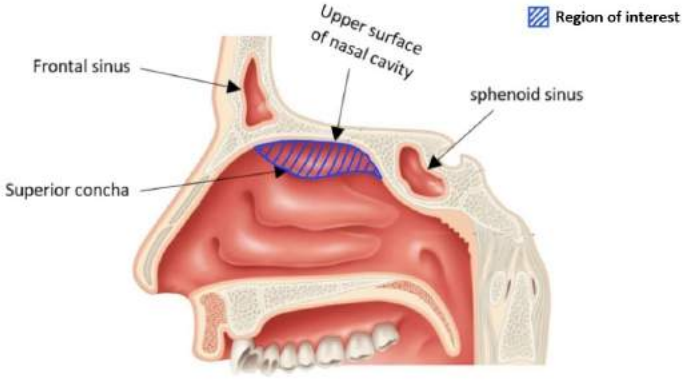
# CORRELATION BETWEEN ANOSMIA AND AIRFLOW IN THE NASAL CAVITY

**Shashwat Shah (1), Zach Soler (2), Ethan Kung (1,3)**

(1) Mechanical Engineering Department, Clemson University, Clemson, South Carolina, USA
(2) Otolaryngology Department, Medical University of South Carolina, Charleston, South Carolina, USA
(3) Bioengineering Engineering Department, Clemson University, Clemson, South Carolina, USA

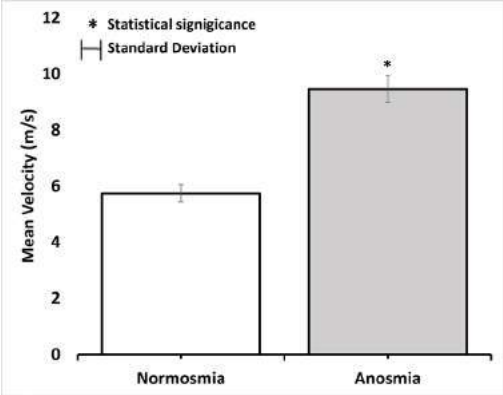
## INTRODUCTION

Anosmia is a medical condition where the patient loses their sense of smell. It can be temporary or permanent; a permanent and severe condition can lead to a loss of sense of taste. Identifying the causes of anosmia can help doctors diagnose it more accurately and decide operational procedures accordingly. Researchers have studied the effect of odorant particles in the nasal cavity by different experimental and numerical methods. With evolving technology in 3D imaging and segmentation, creating an anatomically accurate representation of the Nasal Cavity is now more accessible than ever. With the help of the latest meshing techniques, a very fine and precise mesh can be generated for simulation. This study aims to correlate anosmia with airflow in the olfactory cleft region simulated using computational fluid (CFD) dynamics.



## METHODS

6 Test subjects of different ages and genders were chosen, three each with and without anosmia. In this study, we performed CFD simulations to simulate realistic air flow conditions using ANSYS Fluent. Boundary conditions were prescribed based on the flow rate of normal breathing for an adult human, with the inlet being 5 m/s velocity and outlet being zero-gauge pressure. In all cases, convergence criteria of $10^{-4}$ residual for continuity equation and velocities were reached with the k-omega SST turbulence model. Since olfactory sensors are located in the olfactory bulb, we analyzed the flow data within the corresponding region bounded by the upper surface of nasal cavity (superior), the superior concha (inferior), the frontal sinus (anterior) and the sphenoid sinus (posterior) as shown in Fig-1. The study's primary objective was to find patterns in the flow parameter that can differentiate between people with and without anosmia.



## RESULTS

Flow velocity provides a good surrogate on how long odorant particles may stay in the olfactory cleft region without the need for calculating more resource-intensive residence time. Nasal cavities associated with anosmia demonstrated a statistically significant increased average velocity (9.4667 m/s) near the olfactory bulb region, compared to those not associated with anosmia (5.74 m/s, $p = 0.0029$) (Fig-2). This represents a ~60% increase in flow velocity for the subjects with anosmia than in those without.

## DISCUSSION

Higher velocity implies less contact between odorant particles and olfactory sensors, leading to partial or total loss of smell. Going forward, further examination of other flow parameters can give more insights on flow patterns inside the nasal cavity with deformities and assist anosmia diagnosis and treatment planning.

# EXTRACTING AND BUILDING WITH THE ENGINEERING PRINCIPLES OF KIDNEY DEVELOPMENT

**John M. Viola (1), Catherine M. Porter (1), Jiageng Liu (1), Ananya Gupta (1), Mariia Alibekova (1), Louis S. Prahl (1), Alex J. Hughes (1,2,3)**

(1) Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, USA

## INTRODUCTION

The intricate branching of the kidney's urinary collecting duct tree occurs in response to tightly choreographed cues passed between ureteric epithelial tubules and surrounding tissue layers during development. The tips of this epithelial network are then the engines that drive formation of the 200,000-2 million nephron filters present in adult kidneys. However, the engineering principles governing the remarkable development of this tubule network are not well understood. Thus, there is massive potential to study and apply new engineering rules that would shed light on the wide variability in nephron number between individuals, which correlates with adult disease, and to build large enough kidney tissues for functional replacement.

## METHODS

All mouse experiments followed NIH guidelines and were approved by the Institutional Animal Care and Use Committee of the University of Pennsylvania. Embryos were collected from timed pregnant CD-1 mice (Charles River) at developmental stages between embryonic day (E)14 and E18, dissected and processed for live analysis or studied by confocal immunofluorescence. Physical modeling was performed in the Kangaroo Physics environment in Rhino 3D software.

Kinomorphs were created through photolithographic DNA-programmed assembly of cells (pDPAC). Briefly cells were incubated with lipid-ssDNAs and attached to polyacrylamide substrates bearing complementary ssDNAs photopatterned onto them. These cell patterns were then transferred to Collagen-1/Matrigel hydrogel sheets in microfluidic flow cells, before floating them into culture for cell-directed folding and tubule formation. Model-guided design of morphogenesis trajectory was performed in MATLAB and Kangaroo Physics.

## RESULTS

Epithelial organs perform diverse functions - lung alveoli exchange gases, kidney tubules exchange water and ions, and mammary acini secrete milk. However, little is known about how developmental constraints and compromises affect adult organ function per unit volume.

However, while some organs like the lung fill 3D space during branching, ureteric branching occurs at the kidney surface. This should create a conflict between the available organ surface area and exponentially increasing tip number. How then does the kidney navigate this conflict?

We first cast tubule network formation in the developing mouse kidney as a packing problem using organ explants and physical models [1]. Our data indicate that developing kidneys visit only a narrow range of possible tubule packing solutions and highlight two classes of packing defects – tip burial within deeper tissue layers or "short circuits" through adjacent tip fusion – examples of which can be found in published literature. Furthermore, they suggest that internal, radially oriented forces on tubules are required to avoid these defects and for tubule trees to resolve into vertically packed arrays. We validate this by perturbing live kidney explants and matching outcomes to our physical models.

We next outline a route to synthetically create ureteric tubule networks by drawing parallels between programmed strain in micropatterned tissues and the ureteric branching program [2]. We reconstitute these mechanics in tissue scaffolds that progressively encode 3D extracellular microenvironments by programmed shape change.

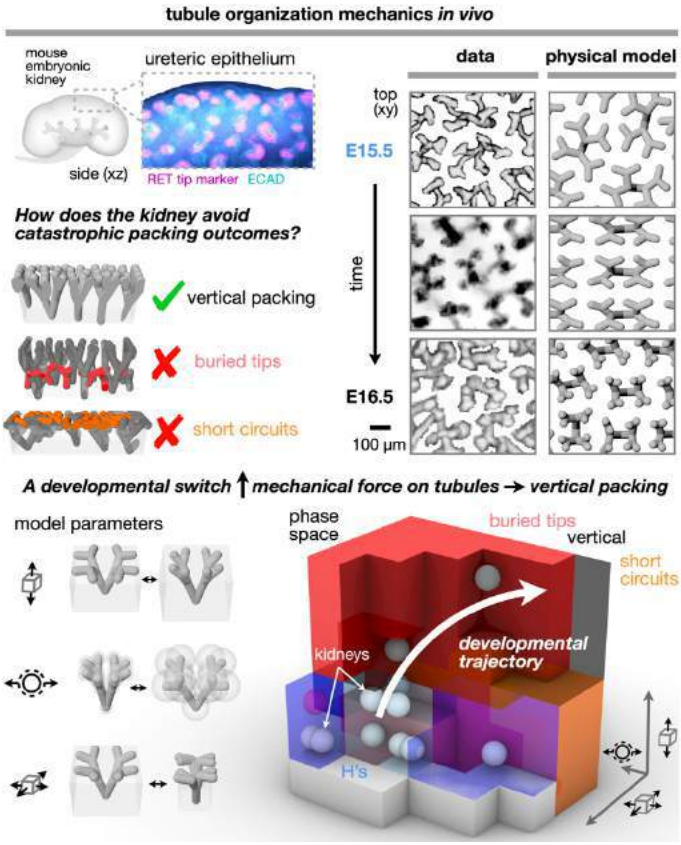

**Figure 1: The ureteric epithelium forms a tree-like network, where tips induce and fuse with nephrons. We studied this as a packing problem, discovering several phases of packing geometry, including two forbidden ones found in mutants. We show that active mechanical tension on tubules is required for developing kidneys to traverse the packing phase space without entering forbidden phases.**

We first noted that mechanical compaction of floating sheets of Collagen-1/Matrigel ECM by randomly seeded MDCK kidney epithelial cells tended to lead to fusion of nearby spheroids and tubule formation. We therefore sought to control the spatial patterning of tubules formed by self-organization through the initial cell pattern by pDPAC. Creating this photolithographic cell assembly technology allowed us to pattern millions of adhesive ssDNA spots over large areas (~size of a postage stamp). Transfer of adhered cells to ECM sheets then creates folds due to cell traction mechanics in prescribed regions, generating mountain or valley folds according to custom mechanical modeling. In analogy with origami paper folding, we generated complex fold networks called flashers that emanate from a single point, similar to the ureteric collecting duct network. Indeed, patterned MDCKs condensed and created polarized and lumenized tubules along hundreds of folds, verified by immunofluorescence staining. We are currently extending this technology for iPSC-derived ureteric epithelial and early nephron lineages, towards production of long-range ureteric networks spanning cm length-scales. These arrays have strong potential applications in iPSC-derived models of human kidney disease, and for kidney replacement therapies.

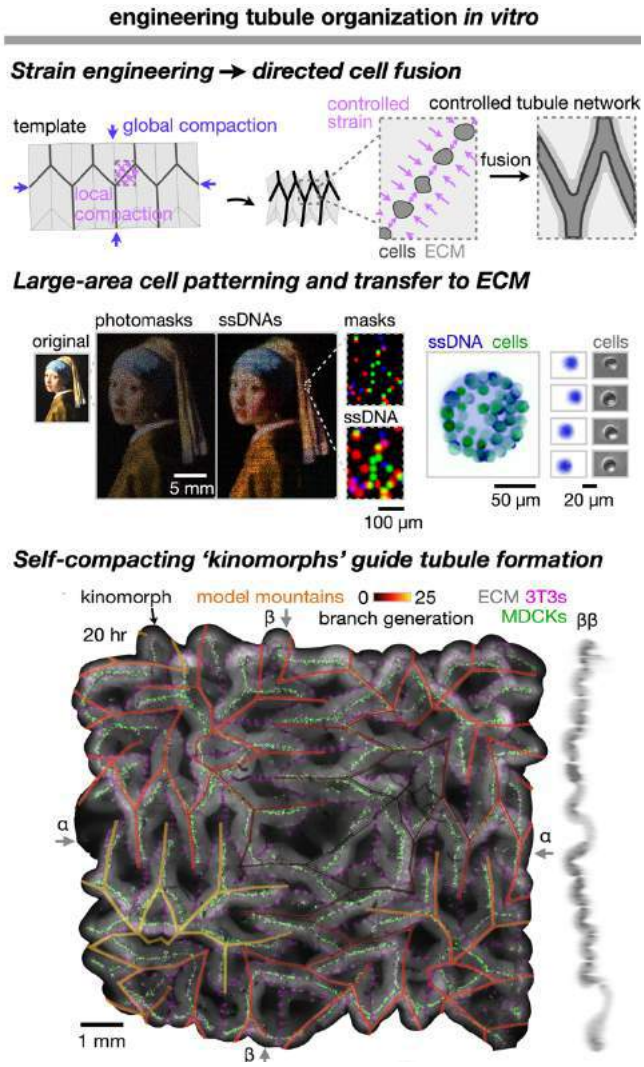

**Figure 2: Synthetic creation of cm-scale kidney tubule networks in "kinomorphs" – autonomous shape-change hydrogels driven by active cell mechanics. Cells are patterned precisely and at massive scale by pDPAC into ECM sheets. Cells actuate folding and formation of tubule niches at creases in the sheet, and self-organize as polarized and lumenized tubule networks.**

## DISCUSSION

By integrating microfluidic cell and matrix patterning, kinematic models, and tubule engineering, we describe a vision for encoding long-range patterning in next-generation kidney organoids.

# TWO WAY COUPLED FSI ANALYSIS OF PATIENT'S SPECIFIC STENOSED LEFT CORONARY ARTERY (LCA) WITH MULTIPHASE PULSATILE BLOOD FLOW

**Abdulgaphur Athani (1), Nik Nazri Nik Ghazali (2), Irfan Anjum Badruddin (3)**

## INTRODUCTION

In developed and developing countries, atherosclerotic coronary artery disease is a significant cause of illness and death due to cardiac arrest [1]. Atherosclerosis shows the primary distribution, implying that various parameters caused by blood flow can contribute towards its development. Coronary arteries are a clinically important anatomical region because of their high risk of developing atherosclerotic plaque, the constriction of coronary arteries, which affects cardiac perfusion, and the related risk of heart failure. The synchronised presence of double plaques and disturbed flow in anatomical regions with more complex geometries, such as arterial bifurcations, has indicated that hemodynamic (HD) stresses play a significant role in atherosclerosis pathogenesis. In this context, computer-aided engineering (CAE) in connection with diagnostic imaging (CT-scan), which enables patient-specific computational fluid dynamics (CFD) and fluid structure interaction (FSI) simulations and other computational modelling [2] were implemented, that provides a broad application for identifying potential links between local flow patterns, RBC behaviours, artery wall elasticity [3]. The objective of this research was to perform a preliminary CFD on the impact of using two way coupled FSI simulations on HD near wall as well as intravascular flow descriptors on the reconstructed patient's specific left coronary artery. No study has previously conducted by considering stenosis with multiphase (RBC and Plasma) pulsatile blood flow in LCA with side branches. The syndrome associated with this disease occurs at rest and with a temporary alteration of the electrocardiogram (ECG). However, with the patients involved; may or may not have coronary atherosclerosis, may have stable and unclear data, but they encountered ischemia, atria and ventricles block, and coronary heart death in extreme cases were also found [4].

## METHODS

The 2D images of CT scan (DICOM formatted) report converted into 3D model using image processing software (**MIMICS Materialise NV, a Belgian)**. The patient's pulsatile blood flow given as inlet boundary condition and outlet is maintained as outflow. The carreau non-Newtonian viscosity model is preferred for the simulation of LCA [3]. The FSI is created between blood domain and wall of elastic artery. The frictionless support was assigned at outer area of artery wall structure. The two ways coupled FSI analyses transfers the forces initially which occurred initially from blood domain to target defined structure and vice versa. The governing equations are solved for LCA model using software **(ANSYS Inc. Canonsburg, PA, USA).**

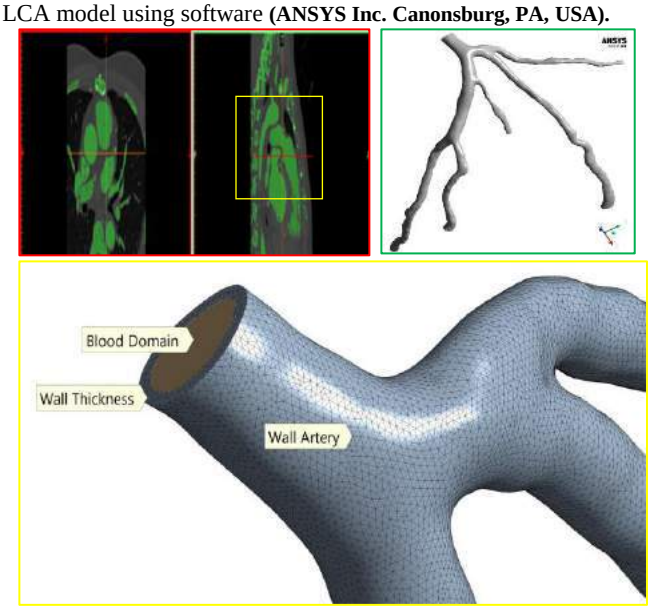

**Figure 1: a)2D CT-Scanned data in MIMICS window (Red outline); b).stl format reconstructed LCA 3D-model(Green**

**outline); c) Fluid and Solid mesh model's close-up view (Yellow outline labeled) with tetrahedral elements of LCA model.**

***Material properties:*** The structural properties of the arterial wall required for establishing FSI simulations and the fluid properties mimicking blood composed of blood Plasma and RBCs are adopted from an earlier study [3].

**RESULTS AND DISCUSSION**

In the current study, hemodynamic parameters such as Velocity, WSS, and pressure are calculated for the patient's left coronary stenosed artery. The structural results like deformation and von-misses stresses were also estimated for the flexible artery wall.

As mentioned before, the current analysis objectives are to simulate left coronary artery model with the FSI model. The pressure drop was extreme across the stenosis area compared to other regions of artery model. The velocity streamlines represent the flow direction of mimic of blood with respect to irregular diameter of LCA. The results show that, high areas of stenosis regions have high blood velocity (~3.59m.s) due to reduction of diameter in artery. It was also observed that, velocity streamlines are visible more after the exact stenosed area which is shown in square box in fig 2a. The maximum pressure drop was found at high stenosed region by 16217.54 to 6357.43 Pa. whereas a slight difference in wall pressure was noted across the second bifurcation regions as shown in fig 2b.

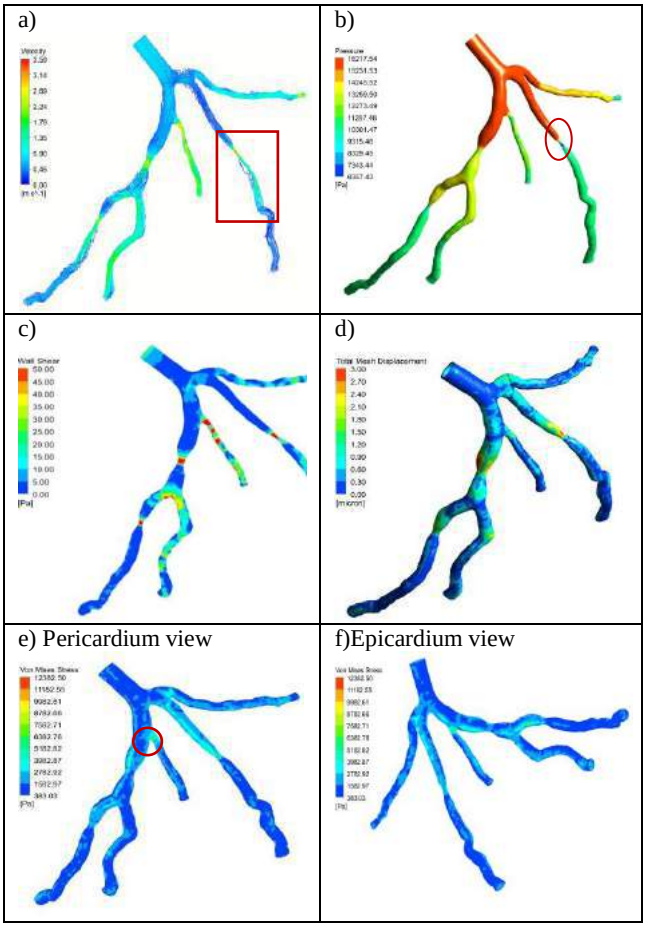

**Figure 2: a) Velocity streamlines; b) Wall Pressure; c) Wall Shear Stress (WSS); d) Displacement e) and f) Von-misses stresses for Epicardium and Pericardium views respectively.**

The wall shear stress is an important factor in determining the artery's strength, and it's thought that a larger wall shear stress may aid in arterial wall rupture. The cumulative WSS in the segmented left coronary artery (LCA) varies slightly depending on the artery model's area decrease (percentage of stenosis). It is observed that, the highest WSS at the high area stenosis was found in the range of 40 to 50 Pa as shown in fig 2c. At the bifurcation or compared to LAD and LCx branches the WSS at $LC_X$ regions are more because of its more complex artery. The side branches LAD and $LC_X$ also plays important role hence it is necessary to simulate always the complete model to achieve the accurate results.

The wall structure results help to determine the initiation of cracks in the artery models. The various results can predict the failure of artery wall such as Deformation and von-misses stresses. In the present study we have also calculated the deformation and von-misses stress for LCA model. It is clearly visible that, the maximum deformation of 3µm is observed before the highest stenosed region. Whereas at smaller reduction area or less stenosed artery areas the deformation is negligible that indicates the less chances of rupture of artery compared to the highest stenosed surrounded area as shown in fig 2d.

The blood flows inconsistently if there is stenosis in the artery. The wall is flexible elasticity properties hence the future study for crack initiation will be more important sector to determine the artery wall failures.

The von-misses stresses are also evaluated in the present case. The von-misses stresses are highest at before the stenosed areas. The highest von-misses observed are at the bifurcation area which is around 5182.82 Pa and lowest of 383.03 Pa at the ends of artery where the pressure is lesser as shown in figure 2e and 2f. There is additional advantage of multiphase blood flow simulations compared to single phase blood flow. This method gives the clear results for two separate fluids which are present in the whole blood (such as RBC and Plasma volume fractions) [3].

As a result, it is concluded that a large increase in velocity and a recirculation region around the stenosis may lead to stenosis growth and development. As a result, artery wall results play a crucial part in accurate WSS estimations. Furthermore, stenosis of greater degree may necessitate an emergency interventional therapy to cure the condition.

# DEGENERATION OF THE LUMBAR FACET JOINT OCCURS IN BOTH THE FACET CAPSULAR LIGAMENT AND THE FACET JOINT ARTICULAR CARTILAGE

**Jill M. Middendorf (1), Victor H. Barocas (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN

## INTRODUCTION

Despite the importance of the facet joint to the stability and pain-free function of the lumbar spine, degeneration of the facet joint, including the facet capsular ligament and the articular cartilage, is poorly understood. Clinically, degeneration of the lumbar spine is often characterized using magnetic resonance imaging (MRI) to quantify intervertebral disc (IVD) health (Pfirrmann grade) and facet joint health (Fujiwara score) using standard scoring systems [1,2]. Increased IVD degeneration and increase facet joint arthritis as characterized using MRI have been associated with decreased stiffness of the IVD and decreased stiffness of various spinal ligaments [3].

However, mechanical changes in the facet joint cartilage and facet capsular ligament are not well understood with respect to MRI scores of the lumbar spine. This correlation is made more difficult to explore by the fact that reliability of Fujiwara scores can be characterized as fair at best [4,5]. Nevertheless, this study explored which mechanical changes in the facet capsular ligament and the facet joint articular cartilage can be associated with MRI scores of the lumbar spine. Additionally, decreases in the stiffness of one spinal soft tissue may cause altered loading and degeneration of another spinal tissue [6]; therefore, degeneration of the facet joint as a whole was characterized by examining the relationship between facet capsular ligament stiffness and the modulus of facet joint cartilage.

## METHODS

A total of 7 human cadaveric lumbar spines were obtained through the University of Minnesota Anatomy Bequest Program. These cadavers ranged in age from 62 to 98, with 2 males and 5 females. 3T MRI were taken of each lumbar spine using T1- and T2-weighted scans with a knee coil. Then, three spine researchers independently scored the L2-L3, L3-L4 and L4-L5 IVDs and facet joints using standard Pfirrmann grades [2] and Fujiwara scores [1].

A linear inverse mechanics approach [7] was used to characterize the anisotropic tensile mechanics of the capsular ligament. First, the ligament was removed from the facet joint and loaded into a biaxial testing system with independently actuated arms. During testing, videos of the ligament motion were recorded so DIC analysis could be performed and a strain field across the surface of the ligament could be determined. Using this strain field and the forces on the boundary, the average 2D generalized linear stiffness tensor $C_{ijkl}$ was determined. The coordinate system was defined such that the 1 direction was roughly parallel to the joint surface and the 2 direction was roughly bone-to-bone. These defnition allows the $C_{2222}$ component to be a measure of stiffness in the bone-to-bone (primary fiber) direction and $C_{1111}$ to be a measure of the transverse stiffness. The $C_{1111}$ and $C_{2222}$ stiffnesses were plotted against the Pfirrmann and Fujiwara scores.

The mechanical behavior of the facet joint cartilage was assessed using unconfined compression. Osteochondral plugs with 5mm diameters were taken from the lateral side of the facet joint. The thickness of the articular cartilage was measured. Then, each osteochondral plug was compressed to a total of 25% strain in 5% increments. The articular cartilage was allowed to relax for 5 min between each pair of loading steps. The Young's Modulus of the articular cartilage was calculated from the slope of the stress-strain curve and compared to Pfirrmann grades and Fujiwara scores.

Finally, a joint-based correlation between the Young's modulus of articular cartilage and the FCL stiffness parameters was created. A linear ($C_{1111}$) or a log based ($C_{2222}$) correlation was used to compare the Young's modulus of cartilage to the FCL stiffness.

Some facet joints contained large amounts of bone growth, which caused fusion of the joint and made cartilage testing impossible.

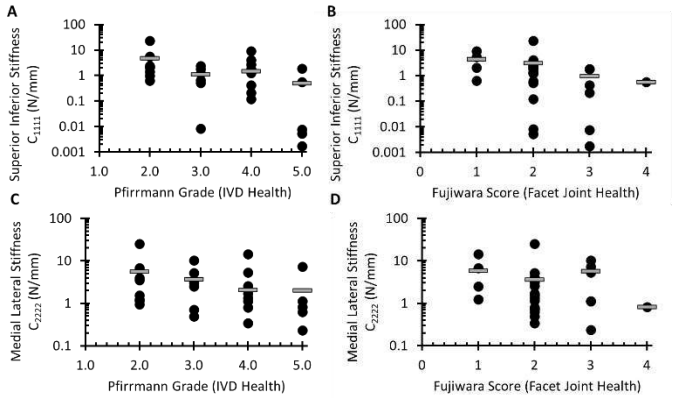

**Figure 1: Stiffness of the facet capsular ligament decreases with increased signs of lumbar spine degeneration. A) medial lateral stiffness versus Pfirrmann grade; B) medial lateral stiffness versus Fujiwara score; C) superior inferior stiffness versus Pfirrmann grade; D) superior inferior stiffness versus Fujiwara score. (gray bars = average; black dots = individual sample values)**

## RESULTS

Stiffness of the facet capsular ligaments decreased slightly with increases in both the Pfirrmann and Fujiwara scores (Fig 1A). Stiffness in the superior-inferior direction ($C_{1111}$, transverse direction) decreased by an order of magnitude between Pfirrmann grades of 2 and 5, and it decreased by a factor of 4 between Fujiwara scores of 1 and 4. Similarly, stiffness in the medial-lateral direction ($C_{2222}$, primary direction) decreased by a factor of 2.5 between Pfirrmann grades of 2 and 5 and decreased by a factor of 6 between Fujiwara scores of 1 and 4. However, all groups contained large error bars which reduced the statistical significance of these changes.

The Young's modulus of the facet joint cartilage did not change with increases or decreases in the Fujiwara or Pfirrmann grade. (Fig 2A & 2B). This lack of change may be the result of small sample sizes in the highest and lowest Pfirrmann grades (1,2 and 5) and Fujiwara scores (1 and 4).

In contrast, facet capsular ligament stiffness and the articular cartilage Young's modulus were correlated with each other. First, the superior-inferior stiffness (transverse direction, $C_{1111}$) showed a linear correlation with the Young's modulus of the facet joint cartilage ($R^2$ = 0.55, $p < 0.01$, Fig 3A). The slope of the linear fit is 0.11 MPa of cartilage for every 1N/mm increase in ligament stiffness. Similarly, the facet capsular ligament stiffness in the bone-to-bone (primary, medial-lateral, $C_{2222}$) direction, correlated with the Young's modulus of facet joint cartilage ($R^2$ = 0.16, p = 0.18, Fig 2B). The relationship between this stiffness parameter of the FCL and the facet joint cartilage is logarithmic, indicating the Young's modulus of facet cartilage approaches a plateau value at large FCL stiffnesses .

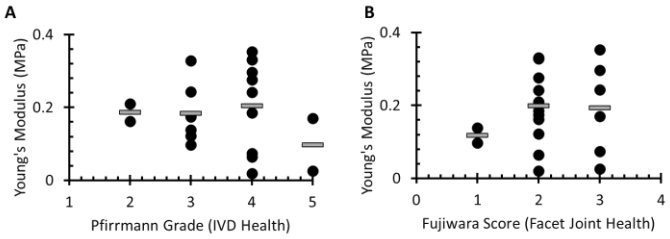

**Figure 2: Young's Modulus of facet joint articular cartilage does not correlate with MRI scores of lumbar spine degeneration: A) Pfirrmann grade and B) Fujiwara score. (gray bars = average; black dots = individual sample values)**

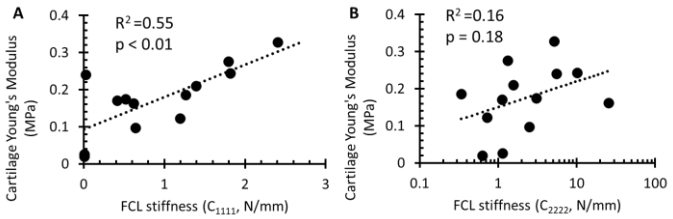

**Figure 3: Correlations between the Stiffness of the facet capsular ligament and the Young's Modulus of the facet joint articular cartilage were strongest for A) $C_{1111}$ versus Young's Modulus and weaker for B) $C_{2222}$ versus Young's Modulus**

## DISCUSSION

In this study, we showed how multiple stiffness parameter of the facet capsular ligament correlate with the Young's modulus of the articular cartilage. This result indicates that degeneration of the lumbar facet capsule may be a joint-scale process, associated with both degeneration of the articular cartilage and decreased stiffness in the facet capsular ligament. However, this study did not explore the mechanisms that cause these changes. Patient-specific loading patterns or biochemical factors, including facet joint inflammation, may contribute to the observed correlations [8].

Pfirrmann grades and Fujiwara scores are imperfect measures of facet joint articular cartilage health. The lack of correlation between articular cartilage and the FUiwara or Pfirrmann grade was unexpected and may be caused by the low sample size of the healthy (low Pfirrmann and Fujiwara scores) and very degenerated spines (high Pfirrmann and high Fujiwara scores). Healthy cadaveric spines are difficult to obtain, while severe degeneration of the facet joint usually implies boney growth and fusion of the vertebral bodies at the facet joint. Additionally, current T1- and T2-weighted MRI may not be sensitive enough to characterize the heterogeneity of facet joint articular cartilage. Depth-dependent mechanical properties of articular cartilage may be causing differences in cartilage stiffness that cannot be measured by the current MRI techniques. Further non-destructive evaluation of the facet joint may be necessary to understand lumbar spine degeneration more accurately.

## INTRODUCTION

Separation of target cells from a diverse population is crucial to many biomedical applications [1]. For example, isolation of circulating tumor cells (CTCs) from a blood sample may allow reliable early detection of cancer. Cell separation using Dielectrophoresis (DEP) technology has been attracted attention as a non-invasive method with less mechanical damage to cells. However, significant technical challenges arise in applying DEP for clinical application when it comes to process extremely large numbers of cells with high throughput. In the present study, a novel DEP device is proposed to effectively separate nonviable cells from viable cells by exploiting their different behaviors in response to AC electric fields. We conducted experiment of cell-separation to evaluate the performance of the proposed device.

## METHODS

In this study, live and dead human mammary epithelial (MCF10A) cells were used. Cells were cultured in a 5 % $CO_2$ incubator and cells of 10-15 passages of the cell culture were used for the experiment. To distinguish live cells from dead cells in the separation process, live cells were labeled with fluorescent calcein and then suspended in a 300 mM mannitol solution together with dead cells. After the cell separation, the sample solution was collected and the cell-separation ratio was obtained by flow cytometry analysis.

Figure 1 shows the experimental setup. The flow channel of dimensions 0.5 (H) ×40 (L)*i*× 10 (W) mm was constructed with parallel top and bottom glass plates separated by 0.5 mm with a silicon rubber spacer. Thin-film aluminum counter-interdigitated electrodes of thickness 300 nm were vacuum-deposited on a glass substrate by standard photolithography. The width of the electrode finger was 50 µm. A sinusoidal AC voltage of 20 $V_{pp}$ was applied to the electrodes by a wave generator. A digital syringe pump was used to provide a continuous flow of the cell suspension. Cells behaviors were monitored using a CCD camera equipped on the microscope and movies were recorded. Cells collected at the exit of the flow channel before and after the voltage application were analyzed by a flow cytometer. Cell-separation ratio was calculated using the following equation.

$$\text{Separation Ratio}(\%) = \frac{\text{Live cell \% } (before-after) \text{ separation}}{\text{Live cell \% before separation}} \times 100 \quad (1)$$

In order to evaluate in detail how the various parameters affect the cell-separation performance, experiments were conducted by varying the frequency *f*; 20, 200, 2000 kHz, the volumetric flow rate *Q*; 5, 10, 20 mL/h and the distance between electrodes; 50 µm (Type A), 75 µm (Type B) (Fig 2). Live and dead cells with the ratio of 1:1 suspended in the mannitol solution having an electric conductivity of 1mS/m were introduced into the device. The cell density of the sample solution was ~$6 \times 10^6$ cells/mL.

## RESULTS AND DISCUSSION

Figure 3 shows the cell's behavior in the flow channel before and after the voltage application for $f$=20 kHz. In the range of AC frequency 20-2000 kHz, dead cells experience n-DEP and move away from electrodes while live cells experience p-DEP and attach to electrodes. We confirmed that live cells attached to electrodes while dead cells went through the flow channel without being trapped on electrodes.

Figure 4 shows the ratio of live and dead cells in the collected sample solution, before and after the separation. In the graph, graph bars on the left are the cell ratio before separation and bars on the right are after separation. Results demonstrated that the cell-separation ratio was frequency dependent and it dropped down significantly for extremely high frequency (not shown). It is because the magnitude of DEP force maybe reduced for high frequencies [2]. The highest cell-separation ratio attained was ~ 90 % for $f$ = 20 kHz and $Q$ = 10 mL/h.

Results of the separation experiment using the type A and the type B electrodes with the fixed frequency $f$ = 200 kHz and the flow rate $Q$ = 10 mL/h are shown in Fig.5. Cell-separation using the type A electrode showed higher separation efficiency than type B. This implies that the non-uniform electric field generated by the type A electrode induced stronger DEP force on cells than the type B electrode. Figure 6 shows distributions of square of the electric field strength for 2 types of electrode, type A and B, obtained by numerical simulations. Areas of large electric-field strength generated by the type A electrode is wider than those of the type B electrode, resulting in higher separation efficiency for the type A electrode.

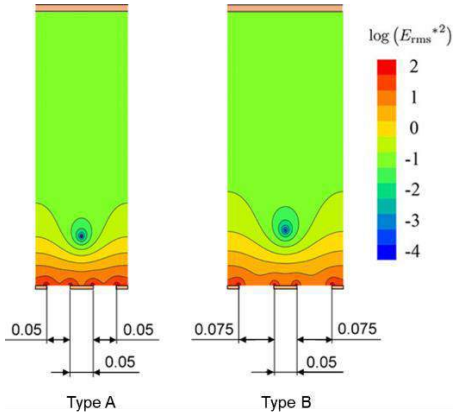

**Figure 6: Electric field distributions in the cross-section of the flow channel for type A and B electrodes**

## SUMMARY

The performance of the DEP device proposed in the present study was evaluated and the optimum operation condition of the present device was explored by varying dominant physical parameters. It was found that the cell-separation ratio of 90 % was attained by the proposed device. In the future, we will improve the structure of the device and adjust values of dominant parameters to achieve higher cell-separation efficiency necessary for separation of rare cells from large population.

# THE BIOTRIBOLOGY OF TOUCH: NUMERICALLY MODELLING TACTILE PERCEPTION

**R. D. Jobanputra (1), G. Luengo (2), D. Dini (1), M. A. Masen (1)**

## INTRODUCTION

Touch is fundamentally a biomechanics problem that is not fully understood. A better understanding of tactile perception has implications in a variety of fields including product design, the treatment of skin injuries, artificial skins and robotics, and cosmetic products.

The propagation of stimuli such as pressures and vibrations, from the skin-surface boundary to the sites of our mechanoreceptors is obscure due to the complexity of the skin. Mechanically, the skin can be characterized by its inhomogeneity, non-linearity and viscoelasticity. Each layer of the skin possesses different mechanical and structural properties; in addition to having different functional roles. The outermost layer, the stratum corneum, is the major load bearing component of the skin. The fingerprints filter and amplify vibrations, which, in addition to applied stresses and strains, propagate through the viable epidermis to the dermal mechanoreceptors.

The space-time variation of stress, strain and energy fields throughout the skin causes the mechanoreceptors to deform and respond with corresponding variations in their discharge rates (Fagiani et al., 2012). This triggers our neurological response by causing an influx of ions into the receptors via voltage and stretch-gated channels within the axon. The influx is a prerequisite for the release of synaptic transmitters which prompt the receptors to fire action potentials to the central nervous system (Halata, Grim & Baumann, 2010; Hamann, 1995).

Researchers have previously described how surfaces that are smoother than the fingerprint geometry are perceived as more desirable than their rougher counterparts. The duplex theory of tactile perception (Bergmann Tiest, 2010) describes how surface roughness features of different magnitudes are distinguished and discriminated during sliding contact against textures. Fine textures with transverse spatial periods below 100 microns are perceived dynamically by vibrations induced through sliding contact against the fingerprint ridges. Coarse textures can be perceived statically as uneven pressure distributions and textures with spatial periods above 200 microns are perceived by spatial code generated by the firing variation of mechanoreceptors. Within the characteristic region of 100 to 200 microns, both spatial and temporal mechanisms play an important role in tactile perception

Previously, a microscale finite-element finger skin model was used to test the effects of biomechanical skin ageing on tactile perception (Jobanputra et al., 2020). This two-dimensional, hyperelastic model was employed to examine the stress, strain and energy fields at the locations of the Type-1 (high spatial resolution) mechanoreceptor in response to age-related mechanical and geometric skin alterations. In the current study, we incorporate viscoelasticity into the model, before conducting a parametric study to investigate the effect of altering the surface roughness on the mechanical state of the dermal mechanoreceptors.

This newly developed model enables the observation of the mechanoreceptors' stress, strain and energy fields in response to changing the amplitude and wavelength of rigid sinusoidal rough surfaces during a parametric study. Surface design engineers can use the outputs of this investigation to generate product surfaces to manifest desirable sensations amongst consumers.

## MATERIALS & METHODS

ABAQUS CAE 2021 was used to develop a skin model comprising the stratum corneum, viable epidermis, dermis and hypodermis. Quadric, quadrilateral, hybrid, plane strain elements were used to mesh the model. To simulate tactile perception, the model was compressed with a uniformly distributed load of 1 N and before sliding against a geometrically rough counter surface at 20 mm/s, whilst a coefficient of friction of 0.5 was applied at the skin-surface interface. Non-linear behavior of skin was represented using an Ogden model (Eq. 1.) whose moduli $\mu$, and exponents $\alpha$, were established experimentally, by compressing and shear-loading glabrous skin (Boyle et al., 2019).

$$U = \sum_{i=1}^{N} \frac{2\mu}{{\alpha_i}^2}\left({\lambda_1}^{\alpha_i} + {\lambda_2}^{\alpha_i} + {\lambda_3}^{\alpha_i} - 3\right) + \sum_{i=1}^{N} \frac{1}{D_i}(J-1)^{2i} \quad Eq.\ 1.$$

Viscoelastic characteristics were implemented into the material model using a Prony series (Eq. 2.) using data presented by Wu et al., 2006.

$$g_R(t) = g_0 - \sum_{i=1}^{N} g_i \cdot \left[1 - e^{-\frac{t}{T_i}}\right] \quad Eq.\ 2.$$

In this investigation, the wavelength and amplitude of the sinusoidal countersurface are independently altered during sliding contact to observe the effect on the Type-1 mechanoreceptor sites (Merkel and Meissner receptors) along the dermal-epidermal junction (DEJ – Fig. 1). The wavelength of the countersurface was varied between 0 and 500 μm, whilst the amplitude wave varied between 10 and 80 μm.

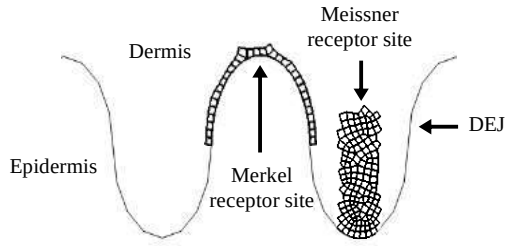

**Figure 1: Finite element mesh at the locations of the Merkel and Meissner receptors.**

From literature, it is reported that the Type-1 receptors are particularly sensitive to localized stretch and deformation (i.e. strain), deviatoric (Von Mises) stresses, and strain energy density (SED) (Wang & Hayward, 2008; Pham et al., 2017; Johnson, 2001). Consequently, these responses were monitored as the finger model was brought into sliding contact against a range of rigid rough surfaces.

## RESULTS

The mechanical stimuli recorded at the receptor sites following sliding against each counter surface exhibited oscillatory behavior due to the periodicity of the surface topology. These stimuli were decomposed into the average and range (max-min) for each surface. Figure 2 illustrates the effects of altering surface wavelength on the deviatoric stresses at the Meissner site, for different surface amplitudes.

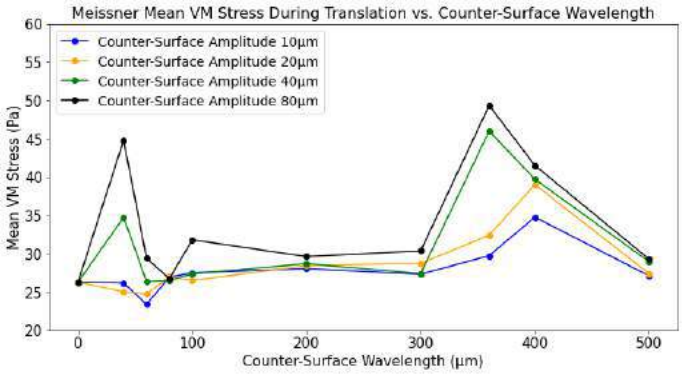

**Figure 2: Average deviatoric stress at the Meissner site following translation against surfaces with different wavelengths.**

Overall:

- For surface wavelengths above 100 μm, increases in roughness amplitude resulted in increases in average stimuli magnitude and oscillation range at the receptor sites.
- For surface wavelengths above 100 μm, further increases in wavelength resulted in increases in stimuli range (oscillatory response) at the receptor sites.
- Mechanoreceptor responses to surfaces with spatial periods below 100 μm cannot be explained by surface roughness alone.
- Surface wavelengths approaching that of the fingerprint (360 μm), result in peaks in average stress and oscillatory behaviour.

## DISCUSSION & CONCLUSION

The results show the effect of altering microscale topological features on stimuli propagation to the sites of our Type-1 mechanoreceptors. For textures with wavelengths above 100 μm, increasing amplitude increases stimulus magnitude and oscillatory behavior at the receptor sites. Furthermore, as the surface periodicity approaches that of the fingerprint, resonant and interlocking effects occur, increasing friction and mechanoreceptor response. For finer textures, below 100 microns, countersurface geometry alone cannot explain stress field at the location of the receptor. This finding confirms neuropsychological experiments reported in literature concerning the duplex theory of tactile perception and current research focuses on the spectral analysis of the elicited mechanical vibrations.

## INTRODUCTION

Injuries of tendons are characterized with painful, slow healing time and usually insufficient, in terms of restoring its strength and various functions. Tendon tissue engineering has presented a promising approach to promote tendon healing or its replacement [1]. This approach is usually based on the use of three-dimensional porous scaffolds, combined with biological factors such as cells and growth factors, to support the tendon temporarily. The scaffold ideally mimics the structure and the physical properties of the native tissue until its regeneration [2].

A promising biodegradable, biocompatible material that has suitable physical properties for use in tendon tissue engineering is poly(glycerol sebacate urethane) (PGSU). Furthermore, PGSU was found to be angiogenic and to promote tissue ingrowth depending on the ratio of the reactants [3]. In this study, three different PGSU scaffolds, with different ratios of HDI and polymer concentration, were fabricated and investigated for specific physical properties such as: microstructure, pore size, swelling ratio and drug release kinetics.

## METHODS

PGSU scaffolds were fabricated as described by Samourides et al. [2] with HDI ratios of 0.8 and 1.0 and polymer concentrations (w/v%) equal to 10% and 15% which were found to exhibit the highest mechanical properties between the other PGSU scaffolds that were synthesized. Briefly, the PGS pre-polymer was dissolved in 1,4-dioxane at the required w/v concentration and HDI was added at 0.8 or 1.0 ratio to glycerol. The solution was left to react for 5 hours at 55 ºC. The solution was then frozen in an in-house customized mold (see [2]) and freeze dried for 16 hours. PGSU scaffolds were characterized for their microstructure using scanning electron microscopy (SEM) (SEM Quanta 200, FEI, United States). The hydrophilicity was studied using contact angle and swelling ratio calculations. Finally, the scaffolds were studied for their ability to be loaded with bovine serum albumin (BSA) and the drug release rate was subsequently derived.

**Pore size:** The pore size of the samples was measured from the SEM images using ImageJ and the free hand selection tool. Images were taken from all views and 50 fully defined pores were used to determine the average pore size of the top view, cross section and bottom view of the PGSU scaffolds.

**Swelling ratio:** The swelling ratio of the scaffolds was measured to determine their swelling ability in phosphate buffered solution (PBS). The samples were dried, weighted and soaked in PBS for a total of 24 hours. Mass measurements of the scaffolds were taken at multiple time points to calculate their swelling ratio according to Eq. (1):

$$SR_i(\%) = \frac{W_w - W_d}{W_d} i x i 100 \qquad \text{Eq. (1)}$$

with $W_w$ and $W_d$ to be the sample's wet weight at different time points and the sample's dry weight, respectively. The experiment was repeated three times in technical triplicates.

**Drug loading:** The PGSU scaffolds were loaded with BSA using an in-house dynamic vacuum loading method. A BSA solution was prepared at 500 μg/ml in PBS and 200 μl of the solution was placed on top of the scaffolds. The samples were moved into a vacuum chamber where the vacuum pressure was increased until air bubbles began to form and rapidly ventilated to atmospheric pressure. This cycle was repeated 12 times. The drug loaded scaffolds were then submerged in PBS and placed on a rocker at 100 rpm for 28 days. Samples were collected at various time points throughout the study and a bicinchoninic acid (BCA) assay was used to quantify the amount of protein that was released over time.

**Statistical Analysis:** All experiments were repeated three times and the statistical analysis was performed using two-way ANOVA in

GraphPad Prism 8. Results are shown as mean ± standard deviation and the statistical significance was considered at $p < 0.05$.

## RESULTS

Figure 1 shows representative macroscopic and microscopic images of the scaffold fabricated using ice-templating and freeze-drying.

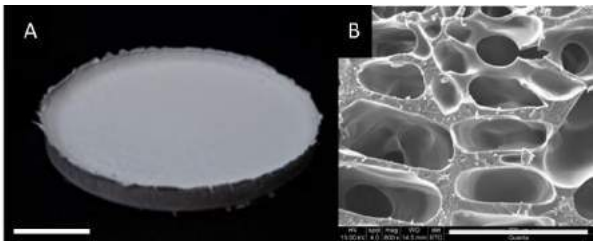

**Figure 1: Representative macroscopic and microscopic images of the PGSU scaffolds. Scale bars for A = 10 mm, B = 200 µm.**

The assessment of the pore size showed that the scaffolds exhibited a range of pore sizes, from 54.6 ± 18.3 to 66.1 ± 23.7 µm depending on the polymer concentration and HDI ratio (see Figure 2). The PGSU scaffolds fabricated with 1.0 HDI ratio had the most uniform pore sizes between the different viewing angles.

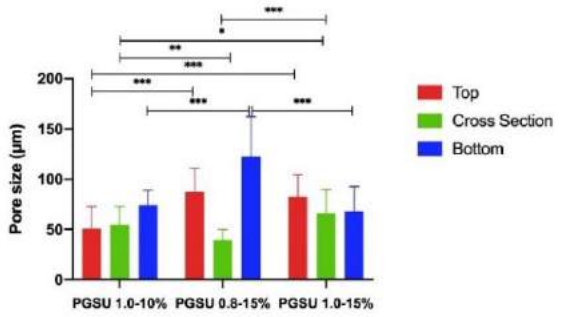

**Figure 2: The pore sizes of the PGSU scaffolds viewed from different angles using SEM. * when $p < 0.05$, ** when $p < 0.01$ and *** when $p < 0.001$.**

The measurements for the swelling ratio are shown in Figure 3 and at 24 hours it ranged between 71.3 ± 7.3%, 115.9 ± 7.1% and 140.8 ± 15.5%. for PGSU 1.0-10%, 0.8-15% and 1.0-15% respectively. The samples showed statistical difference and the swelling ratio increased with the increase of polymer concentration and HDI ratio.

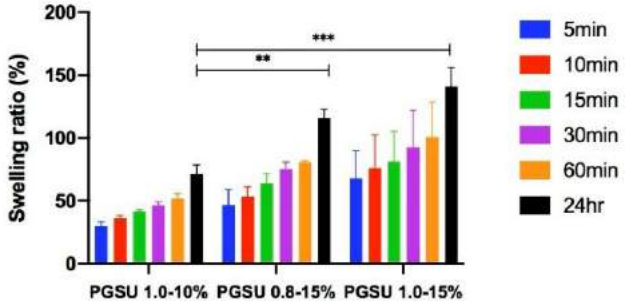

**Figure 3: The swelling ratio measurements for the samples. ** when $p < 0.01$ and *** when $p < 0.001$.**

Finally, the drug release rate of BSA loaded into the PGSU scaffolds was examined using a BCA assay. A linear release rate was found and almost all samples withheld and released the protein over a period of at least 19 days.

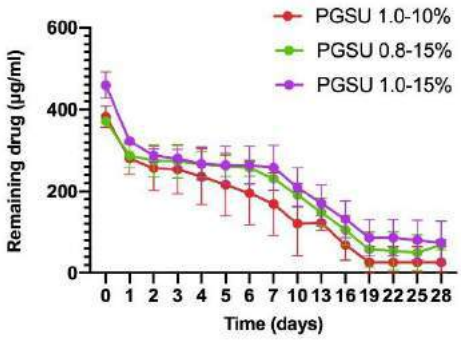

**Figure 4: Drug release rate of the PGSU scaffolds over a period of 28 days using BCA assay.**

## DISCUSSION

Large PGSU scaffolds were fabricated, and a controlled pore orientation was achieved using ice-templating and freeze drying. The scaffolds exhibited significantly different pore sizes between sample groups. However, a uniform microstructure in terms of pore size was achieved from the scaffolds that were synthesized using 1.0 HDI (PGSU 1.0-10% and PGSU 1.0-15%). Furthermore, a linear swelling rate was also observed from the swelling testing of the scaffolds which is considered an advantage in drug loading because a uniform distribution of the drug within the scaffold construct is promoted. The PGSU scaffolds have also shown a fairly linear release of the BSA over time which correlates with our previous swelling and degradation studies in [3] and further adds to the advantages of the anisotropic PGSU scaffolds that were fabricated in this study. The loading and steady release of proteins that can stimulate the biological response for tendon regeneration indicated no significant difference between the examined PGSU scaffolds. Finally, the drug loading technique that was developed by our group for this purpose allowed us to load BSA at approximately the 3-folds the mass of the scaffold with an average of 75% loading efficiency. This method can be modified to be used with almost any scaffold.

# THE INFLUENCE OF PLAQUE STRUCTURAL STRESS AND WALL SHEAR STRESS ON HUMAN CORONARY PLAQUE PROGRESSION

**Aikaterini Tziotziou (1), Eline Hartman (1), Suze-Anne Korteland (1), Antonius F.W. van der Steen (1), Joost Daemen (2), Jolanda Wentzel (1), Ali C. Akyildiz (1,3)**

## INTRODUCTION

Atherosclerosis, defined as plaque formation within the arterial wall, is one of the most widespread diseases in our cardiovascular system. It is a primary cause of death as its progression and rupture can lead to myocardial attack or stroke [1]. Atherosclerotic plaque progression over time in coronary arteries is affected by local hemodynamic and biomechanical factors, such as the Wall Shear Stress (WSS) and the Plaque Structural Stress (PSS) [2]. WSS is due to the friction caused by blood flow on the endothelial surface of the arterial lumen and low WSS is known to be associated with plaque progression [3]. PSS is stress developed within atherosclerotic plaque tissue due to the blood pressure and there are no well-established scientific findings revealing the association between PSS and plaque progression yet. Furthermore, the combination of different values of WSS and PSS, and their association with plaque progression is yet to be examined [3]. In this work, we aimed to study the influence of PSS and WSS on human coronary plaque progression over time.

## METHODS

Data Acquisition

Forty-nine non-stented, non-culprit coronary arteries from 48 patients with acute coronary syndrome were imaged at two time points (baseline and one-year follow-up) using near-infrared spectroscopy intravascular ultrasound (NIRS-IVUS) and optical coherence tomography (OCT) imaging techniques, within the protocol of the earlier reported IMPACT study [4]. The baseline and follow-up images of the coronary arteries with at least 30 mm length were segmented (lumen, plaque and necrotic core) (Figure 1), and 2D plaque geometries and 3D lumen surfaces were generated based on the combined IVUS and OCT frames.

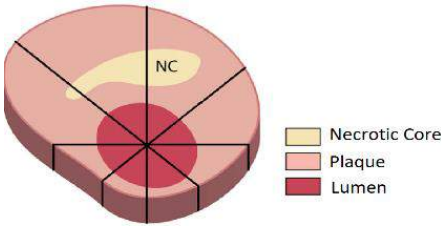

**Figure 1: Every cross-section is divided into 8 sectors with 1,5mm thickness based on the center of the lumen [4].**

Plaque Structural Stress

The 2D patient-specific plaque cross-sections, generated from the combined IVUS-OCT frames via MATLAB scripts, were transferred to the finite element software ABAQUS. An adventitia layer (not visible in IVUS or OCT) of uniform thickness (0.15 mm) [5] was added to plaque geometry. The material properties of the individual plaque components (i.e., NC, plaque and adventitia) were obtained from literature [3, 6]. Since, the IVUS-OCT images were obtained from coronary arteries under blood pressure, the backward incremental method was applied to calculate the initial stresses within the plaque structure [6]. The 2D finite element analyses in ABAQUS was performed under plane strain assumption and eight PSS parameters under the intraluminal pressure loading of 120 mmHg were computed. These parameters included the maximum and average of Max Principal and von Mises stresses on the lumen surface and in the plaque tissue.

Wall Shear Stress

WSS of the coronary data set was calculated previously [4]. Briefly, computational fluid dynamics simulations (Fluent, ANSYS) were performed for every patient-specific 3D lumen geometry, implementing blood flow as an incompressible, homogeneous, Carreau

fluid. Time averaged wall shear stress (TAWSS) was calculated along all coronary arteries.

Statistical Analysis

The impact of PSS and WSS on the human coronary plaque progression was estimated using Linear Mixed Model (Regression) in SPSS Software. The 3D artery geometries were divided into 1,5mm/45º sectors (Fig.1) and the statistical analyses were based on the PSS and WSS values per sector. A p-value < 0.05 was considered significant. The plaque thickness change from the baseline to the follow-up was used as the parameter to quantify plaque progression in the analyses.

## RESULTS

A representative patient-specific case is illustrated in Figure 2. Figure 2A demonstrates the max principal stress distribution of a cross-section. The results show greater stresses in the thin wall region and in the plaque cap region, which separates the NC from the lumen. Figure 2B demonstrates the average max principal within the plaque tissue per sector for the entire 3D artery geometry. The large range of values indicate the non-uniform stress distribution over the geometry. Figure 2C is the cut-open demonstration of the 3D stress distribution. Similar representation is provided for TAWSS in Figure 2D.

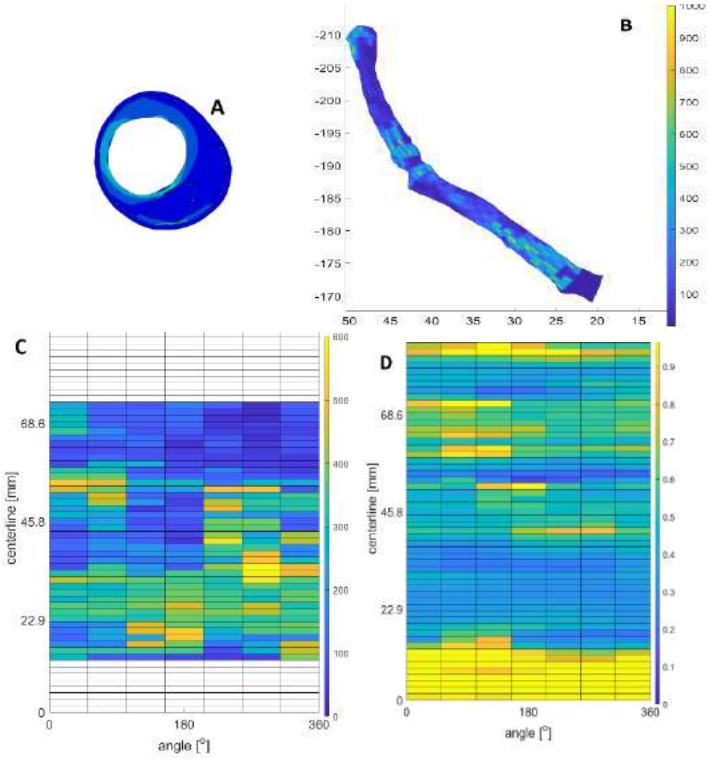

**Figure 2: (A) Max principal stress distribution on a 2D cross-section. (B) Average max principal stress distribution in 3D vessel model. (C) Max principal stress distribution and (D) TAWSS distribution in the cut-open demonstration of 3D artery geometry.**

So far, the analyses of 17 patients have been finalized. Based on the obtained results, of the 8 PSS metrics, many correlated with each other statistically significantly, except the maximum max-principal stress on the lumen and maximum max-principal stress in the plaque tissue. Hence, these two PSS metrics were further used in the statistical analyses.

All stress categories were divided into three groups (tertiles: low, mid, high) for the linear mixed models. According to the statistical analysis, the effect of TAWSS, PSS on the lumen and PSS in the plaque individually, and the effect of their combination on the plaque thickness change over time were statistically significant. Specifically, as demonstrated in Figure 3A, low lumen PSS associated with plaque regression (negative plaque thickness change) while high lumen PSS associated with plaque growth (positive plaque thickness change). Figure 3B shows the combined impact of lumen PSS and WSS on plaque thickness change: high lumen PSS combined with low TAWSS correlated with maximum plaque progression whereas low lumen PSS with high TAWSS correlated with maximum plaque regression.

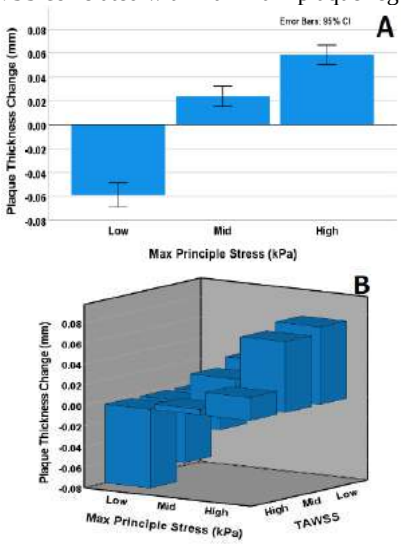

**Figure 3: (A) Impact of Max Principal stress on the lumen only and (B) Impact of Max Principal stress on the lumen and TAWSS combined on plaque thickness change over 1-year follow up time.**

## DISCUSSION

In this work, we have generated 2D and 3D patient-specific coronary computational models to investigate the influence of PSS and WSS on atherosclerotic plaque change over time, from a unique data set of IVUS and OCT combined. We calculated the PSS on the lumen and within the plaque tissue as they are regions with high interest regarding plaque progression. The analyzed cross-sections included healthy and diseased sectors and based on the results the higher PSS were mainly observed in the healthy sectors. Our analysis of the first 17 coronaries already showed the statistically significant impact of PSS and WSS on plaque change over time individually and combined. Next immediate step of our study is to finalize the analyses of the entire data set of 49 coronaries. We also plan to further analyze the relatively healthy-sectors and the diseased-sectors separately. These will unravel the important correlation of PSS and WSS with plaque progression (or regression) and provide great insights for better understanding the plaque growth mechanisms and for developing plaque progression prediction models.

# SPINAL CORD INJURY INCREASES ARTERIAL STIFFNESS AND PERIVASCULAR ADIPOSE TISSUE INFLAMMATION IN MICE

## INTRODUCTION

Progressive stiffening of large arteries underlies the development of cardiovascular disease (CVD), the primary global cause of mortality [1]. Spinal cord injury (SCI) causes accelerated arterial stiffening, contributing to the disproportionate ~2-fold greater risk for CVD in SCI patients [2]. The mechanisms underlying arterial stiffening in SCI are incompletely understood, but the chronic inflammation characteristic of SCI [3] may contribute by promoting vascular smooth muscle cells (VSMC) to switch from a healthy, contractile to a synthetic phenotype. It is not only important to determine the mechanisms underlying arterial stiffening in SCI patients to develop preventative interventions specific to this population, but SCI may serve as a unique model to investigate inflammation and arterial stiffness.

Perivascular adipose tissue (PVAT) directly surrounds almost all arteries in the body and regulates vascular health via the release of paracrine factors to adjacent VSMCs [4]. In response to CVD risk factors, PVAT can become dysfunctional and alter its paracrine secretions, which may contribute to arterial stiffening and CVD development [4]. Specifically, dysfunctional PVAT is inflamed and releases more pro-inflammatory cytokines and less anti-inflammatory adipokines [5]. Thus, our overarching hypothesis is that SCI induces PVAT inflammation, which causes dysfunctional paracrine signaling and initiates a pro-inflammatory feedback loop promoting a synthetic VSMC phenotype and arterial stiffening.

In this study we used a mouse model of SCI and *ex vivo* cultured PVAT to determine 1) how SCI affects PVAT inflammation, 2) how inflammation impacts PVAT secretions, and 3) how paracrine factors released from inflamed PVAT affect VSMC phenotype.

## METHODS

SCI was induced in female C57Bl/6 mice by moderate contusive injury to the thoracic spinal cord (T9) at 14-15 weeks of age. Females were used as they are less susceptible to complications after SCI (e.g. bladder infection) and we showed similar arterial stiffening to males. Mice were euthanized 1, 3, 7, or 14 days after SCI. The aorta was collected and portions of it stored separately for atomic force microscopy (AFM), staining, or RNA isolation. Blood was collected and centrifuged to collect serum, which was stored at -80°C until analysis. Age-matched uninjured mice were used as controls because sham-operated mice do not have increased aortic stiffness.

AFM was used to assess aortic stiffness. Macrophage infiltration into PVAT surrounding the aorta was determined by immunofluorescent staining for CD68. PVAT area was determined by Oil Red O staining. Serum was analyzed in triplicate for the levels of 16 cytokines and chemokines via multiplex ELISA (Quansys Biosciences).

For *ex vivo* experiments, thoracic aortic PVAT was obtained from euthanized uninjured mice and cultured for generation of conditioned media (CM). PVAT was cultured in DMEM at 5 mg / 250 µl with 100 ng/ml TNFα (TNFα-treated) or without (untreated) for 24 hours. The resulting media was then collected as CM and stored at -80°C. Aortas were also collected and used to isolate VSMC by enzymatic digestion. VSMC were cultured and expanded for later experiments.

CM generated from PVAT of four mice was pooled to determine the expression of 38 adipokines using the Proteome Profiler Mouse Adipokine Array kit (R&D Systems). Separate dotblot membranes were incubated with CM from either the untreated or TNFα-treated PVAT, imaged, and analyzed using ImageJ (NIH). ELISAs (Raybiotech) were used to verify levels of adiponectin, IL-6, and lipocalin-2. CM samples for both conditions were generated from four mice and analyzed in duplicate. To determine the effects of CM on VSMC gene expression, mouse VSMC were treated with 25% CM for 24 hours. CM of both conditions generated from three mice was tested on triplicate wells of VSMC. Gene expression of both aortas and VSMC was determined using RT-qPCR.

Statistical analyses were performed using Prism Graphpad 8. Groups were compared using nonparametric tests with $p<0.05$ considered statistically significant. Kruskal-Wallis tests were used for comparisons of three or more groups with adjusted Mann-Whitney tests used for post-hoc comparisons or comparisons of two groups.

## RESULTS

SCI significantly increased mouse aortic stiffness ($p<0.0001$), as demonstrated by AFM (Figure 1). Four weeks after SCI, elastic modulus of the thoracic and abdominal aortae were 5.5 and 7.5-fold greater, respectively, compared to uninjured controls.

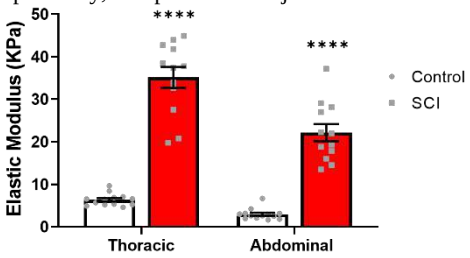

**Figure 1. Aortic stiffness increased in response to SCI, as measured by AFM. n=12-13. ****p<0.0001**

Up to two weeks after SCI, PVAT quantity did not increase with SCI ($p=0.59$; Oil Red O). However, PVAT macrophage infiltration into PVAT increased two weeks after SCI ($p=0.02$), as signified by increased number of CD68+ cells (Figure 2).

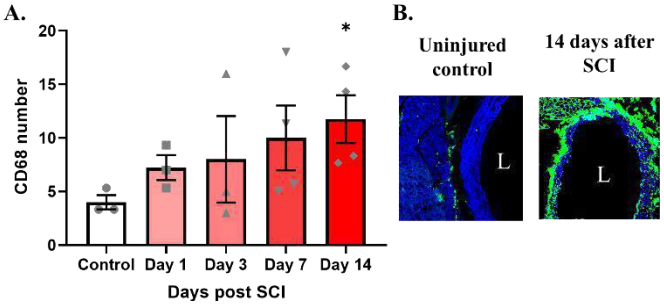

**Figure 2. CD68+ macrophages increased in PVAT two weeks after SCI. A) Macrophage quantification and B) Immunofluorescent images (green: CD68; blue: nuclei). L = lumen. n=3-4. *p<0.05.**

Aortic MMP12 gene expression was significantly decreased ($p=0.03$) by 44% on day one and 49% by day three after SCI, before returning to baseline. Conversely, aortic collagen ($p=0.07$) and adiponectin ($p=0.48$) gene expression were not significantly affected by SCI. Compared to control mice, SCI mice exhibited significant elevations in serum circulating concentrations of pro-inflammatory cytokine IL-6 ($p=0.03$, 1 and 7 days post SCI) and chemokines CXCL1 ($p=0.02$, 1 day post SCI) and CCL1 ($p=0.05$, 1 and 7 days post SCI). Other circulating proteins, including IL-1b, IL-2, IL-3, IL-4, IL-12, IL-13, CCL2, and GM-CSF, were not significantly affected ($p>0.05$) up to two weeks after SCI.

Using dot blots, 15 proteins were detected in CM from either untreated or TNFα-treated PVAT. The three proteins with the highest concentrations in both conditions were adiponectin, MCP-1, and serpin E1. TNFα was present only in the TNFα-treated PVAT CM while VEGF, IGFBP-3, IGFBP-6, and M-CSF were present only in the untreated PVAT CM. Other proteins exhibiting the greatest differences between the untreated and TNFα-treated PVAT CM were TIMP-1 (2.6-fold), IL-6 (1.9-fold), RBP4 (1.8-fold), and lipocalin-2 (1.6-fold). Protein-specific ELISAs confirmed that adiponectin decreased by 38% ($p=0.002$) and IL-6 increased by 50% ($p=0.05$) in CM from PVAT treated with TNFα (Figure 3), while the difference in lipocalin-2 was not confirmed ($p=0.55$).

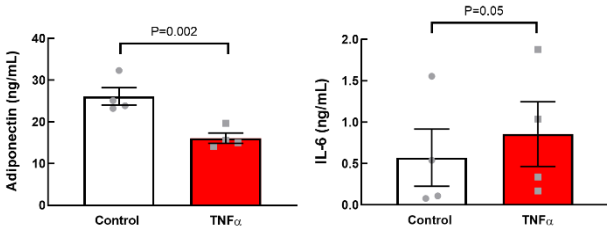

**Figure 3. ELISAs confirmed a decrease in adiponectin and increase in IL-6 in conditioned media of PVAT treated with TNFα. n=4**

There were no significant differences in gene expression of alpha smooth muscle actin (ACTA2), smooth muscle myosin heavy chain (MYH11), calponin (CNN1) (Figure 4), collagen (COL1A1), or MMP-12 (MMP12) (all $P>0.05$) in mouse VSMC following 24 hours of culture with CM from untreated versus TNFα-treated PVAT.

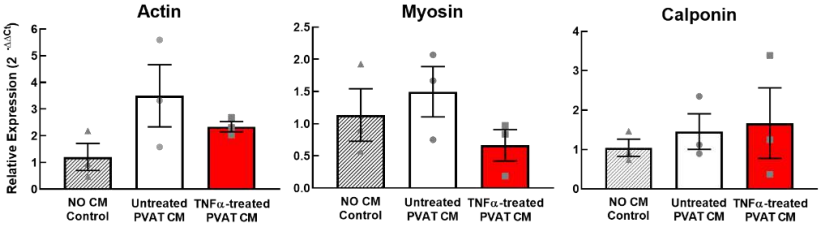

**Figure 4. Conditioned media (CM) from PVAT ± TNFα had no significant effect on VSMC phenotype-related gene expression. n=3**

## DISCUSSION

The primary findings of our study were that SCI increased aortic stiffness and markers of inflammation in the blood and thoracic aortic PVAT. Inducing inflammation in PVAT *ex vivo* using TNFα caused changes in the release of paracrine factors including an increase in the inflammatory cytokine IL-6 and a decrease in the anti-inflammatory adipokine adiponectin. These pro-inflammatory changes in paracrine factors would be expected to promote a shift in VSMC phenotype from contractile to synthetic. However, CM from inflamed PVAT had no significant effects on VSMC gene expression related to either synthetic or contractile phenotype. Still, further experiments, using more functional measures, are needed to better determine VSMC phenotype after treatment with PVAT CM before conclusions can be made.

The increased aortic stiffness and systemic inflammation following SCI that we observed in mice are in line with previous studies in humans [2, 6]. Increased macrophage infiltration in PVAT following SCI is also a novel finding of our study that adds to the current understanding of chronic inflammation associated with SCI. A limitation is that we did not perform experiments with CM from SCI mice PVAT, and this is a future direction of study. Further studies using CM from SCI mouse PVAT will provide insights on how PVAT modulates arterial stiffness.

# OPTIMIZING AND VALIDATING SOFT CALLUS MECHANICAL PROPERTIES IN OVINE BONE FRACTURE HEALING MODELS WITH BIOMECHANICAL DATA

**Brendan J. Inglis (1), Peter Schwarzenberg (1), Karina Klein (2), Brigitte von Rechenberg (2,3), Salim Darwiche (2,3) Hannah Dailey (1)**

## INTRODUCTION

There is an unmet clinical need to diagnose poorly healing fractures using imaging-based methods. In a recent ovine study, we demonstrated that a virtual torsion test outperforms subjective methods like radiographic scoring for predicting the progress of healing and that it is a reliable surrogate for postmortem physical torsion testing in intact tibiae [1]. The key to success in reliable virtual torsion testing of bone mechanics is the use of appropriate scaling laws for converting the radiodensity (gray value) in each voxel of the scan to a Young's modulus, $E$. Our previous ovine study found that extending a density-modulus scaling law developed for cortical bone to include regions of callus produced strong correlations between virtual and physical biomechanical tests, but that the virtual tests over-predicted the measured torsional rigidity in osteotomized specimens by an average of 58% [1]. This over-prediction of rigidity when callus is present suggests that a material model derived for cortical bone does not completely capture the mechanical behavior of callus and that more work is needed to virtually replicate the in-vivo biomechanics of healing fractures. Therefore, the purpose of this investigation was to develop a new constitutive mechanics model for fracture callus that captures its dual nature—hard and soft—and to test this method for assigning material properties in finite element models of healing ovine long bones.

## METHODS

Thirty-three adult female Swiss alpine sheep (2-3 years old, weighing 59-87 kg) were part of previously completed research studies [1]. All animal experiments were conducted according to the Swiss laws of animal protection and welfare. All animals had postmortem biomechanical testing and CT scans available for analysis. CT scans were processed to create the virtual models using Materialize Mimics (21.0, Plymouth, MI). and virtual mechanical testing was performed in ANSYS (2020 R2, Canonsburg, PA). Virtual torsional rigidity ($VTR = ML/\phi$) was calculated using moment reaction ($M$), segment length ($L$), and angle of twist ($\phi$) and compared the biomechanical rigidity (GJ) from postmortem bench testing of each sample.

Density-dependent material properties were assigned on an elementwise basis, with the baseline material model being a linear function optimized for ovine cortical bone [1]. The dual soft-hard material model was implemented using a piecewise function:

$$E = \begin{cases} E_{sc} & \rho_{QCT} < \rho_{cut} \\ 10{,}225\rho_{QCT} & \rho_{QCT} \geq \rho_{cut} \end{cases} \quad (1)$$

where the elemental modulus, $E$ [MPa], depends on the local bone mineral density ($\rho_{QCT}$). Above a to-be-determined density cutoff ($\rho_{cut}$), tissue within the callus was modeled as bone using a scaling function derived for ovine tibial cortical bone [1]. Below the cutoff, elements were considered soft tissue with a modulus ($E_{sc}$) ranging from 0.5 to 500 MPa based on literature reports.

The 33 animals were divided into a Training group (N = 17) and a Testing group (N = 16) and an optimization procedure encompassing 2,363 simulations was used to determine $E_{sc}$ and $\rho_{cut}$ that produce best agreement between VTR and GJ from physical testing (Fig. 1).

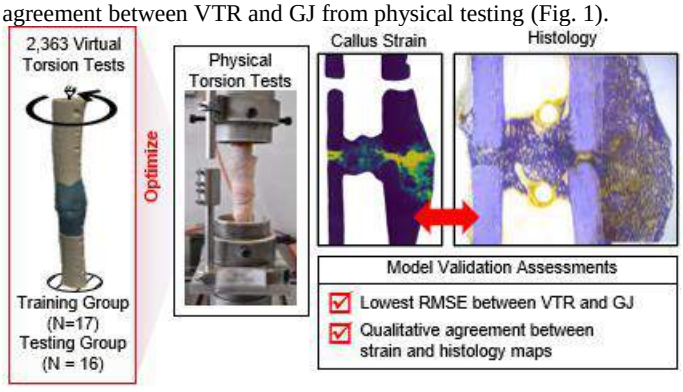

**Fig. 1: Dual-zone material model optimization study.**

Predictive validity was evaluated by calculating the root-mean-square error (RMSE) between VTR and GJ. Success was defined as virtual tests producing RMSE less than the standard deviation of the datum set (GJ) across training and validation stages. Qualitative comparisons of predicted callus strains and stained histology sections (Toluidine Blue) were also used to evaluate model performance. Statistical analysis was performed in IBM SPSS 27 (Armonk, NY).

## RESULTS

The optimization was successful in identifying a value for $\rho_{cut}$ at each level of $E_{sc}$ that minimized the difference in torsional rigidity between the virtual and physical biomechanical tests. Compared to the single-zone material model from our previous study [1] (Fig. 2a), the dual-zone model produced had better absolute agreement between physical and virtual torsion tests (Fig. 2b).

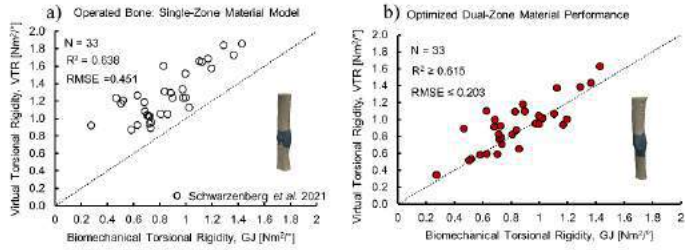

**Fig. 2: (a) Modeling callus using a single-zone material model derived for cortical bone overpredicts the rigidity of healing ovine tibiae. (b) Predictive accuracy was greatly improved by the dual-zone model (Equation 1) for callus in both the training set (shown) and testing set (not shown).**

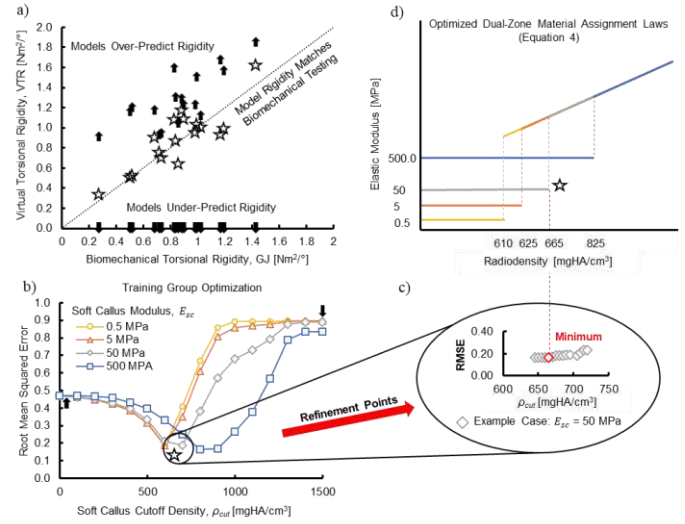

**Fig. 3: (a) The single-zone material model (Eq. 3, up arrows) overpredicted the rigidity of osteotomized ovine tibiae. When the soft callus density cutoff was set too high (example shown: $E_{sc}$ = 50 MPa, $\rho_{cut}$ = 1500 mgHA/cm$^3$) rigidity was clearly underpredicted (down arrows). At the optimized soft callus cutoff value (example shown: $E_{sc}$ = 50 MPa, $\rho_{cut}$ = 665 mgHA/cm$^3$ (stars), the dual-zone material model out-performed the single-zone material model. (b) The minimum RMSE between the VTR and GJ was identified for each $E_{sc}$ level by sweeping the $\rho_{cut}$ space. (c) Refinement point simulations about the initial minimum were performed to identify the optimized $\rho_{cut}$ value (red diamond) (d) The resulting four optimized combinations of soft callus modulus and density cutoff can all be represented using Equation (1).**

At all tested levels of soft callus modulus, the optimized dual-zone material models produced moderate-to-strong correlations between VTR and GJ with absolute agreement that met our defined success criteria for material model validation (all $R^2 \geq 0.558$ and RMSE $\leq 0.248$ versus datum SD = 0.268).

Evaluation of strain contour plots showed that increasing $\rho_{cut}$ was associated with increasing concentrations of strain in and around the fracture gap. Below the optimized $\rho_{cut}$, strain was low throughout the callus volume. Above the optimized $\rho_{cut}$ value, non-physical strain artifacts began to appear in the solution, originating at the defect line (data not shown). At the optimized combinations of $E_{sc}$ and $\rho_{cut}$, the regions filled with soft material in the finite element models and the resulting strain contours were qualitatively well-matched with the localization of less-mature callus in the histological sections.

## DISCUSSION

The development of a clinically relevant, reliable, scalable, non-invasive test to detect problems in bone healing earlier could have profound impacts on the care of nonunion fractures. Image-based virtual mechanical testing shows promise for addressing this need, but one key problem is the material modeling in fracture callus. Unlike native bone, the mechanical properties of callus cannot be studied in human cadavers, so our understanding of the material mechanics and structural organization of this tissue must be strongly informed by observations from large animals.

The results of this study clearly demonstrate that the material properties of the tissues in the callus region for ovine long bones are not monolithic and should therefore not be treated as such. From a structural mechanics perspective, soft tissues within the callus are not functioning simply as low-density bone. This can be inferred because using a bone-derived radiodensity scaling law to assign their mechanical properties leads to a systematic over-prediction of limb rigidity.

The data from this study showed that virtual mechanical testing with a dual-zone material assignment law that captures both the hard and soft nature of callus out-performs single-zone material modeling when validated to physical biomechanical data. To rule out any potential for dependency on randomization in assignment to the training and testing groups, a cross-validation of the optimization was performed. The conclusions were unchanged and the results met our validity criteria based on RMSE.

Future work will be needed to translate the dual-zone material model for callus to other species. A current study in progress seeks to determine a similar density cutoff in human tibiae. It should be noted that the dual-zone material model is not limited to a linear association between mineralized tissue density and modulus and a constant value to model soft callus tissue. The two zones of the material model are not required to be coupled and theoretically could be defined using any equations that are appropriate for the species and anatomic site of interest. Further exploration of combinations of curve segments is warranted.

## INTRODUCTION

Cancer is among the leading obstacles to improving life expectancy worldwide. Specifically, colorectal cancer accounts for 1 in 10 cancer cases and deaths, making it the third most common cancer with the second highest mortality rate [1]. More specifically, there is a 90% survival rate among patients over a 5 year period in Stage 1. This drops to a 10% survival rate in Stage 4 [2] There is increasing evidence to suggest that mechanical changes to microenvironment elicit an oncogenic response. However, this pathway has yet to be investigated in detail [3] and there has been no robust mechanical analysis of the colon at a microscale. It has been established that diseases of the colon are associated with a failure of the colonic biomechanics [4]. Therefore, in order to truly understand the disease process it is necessary to characterise the biomechanics of healthy colonic tissue.

While macroscale mechanical characterisation obtains the bulk properties of tissue, it does not capture the heterogeneity of soft biological tissues at the microscale. However, microscale mechanical characterisation requires tissue to be sectioned into compatible sizes. The gold standard for tissue sectioning is cryosectioning, but this procedure requires the tissue to be fixed and snap frozen beforehand, leading to the loss of some of the native mechanical properties. Therefore, the aim in this study is develop a protocol for sectioning fresh biological tissue, using a Compresstome® VF-210-0Z for downstream mechanical analysis of fresh tissue, avoiding deleterious freezing of the tissue. Ultimately, this protocol can lead to the creation of a microscale map of fresh tissue to better understand the mechanics of tissue on this scale.

The aim of this study is to carry out a robust biomechanical characterisation of porcine colon tissue. This will involve at both the macroscale and microscale mechanical characterisation for both fresh and frozen tissue. The information gained from this analysis should lend itself to a realistic profile of the physiological mechanical properties of the healthy tissue.

## METHODS

**Tissue Sectioning Protocol** Porcine colonic tissue is sourced from a local abattoir (n=6), cut into 1 $cm^2$ sections, and kept at 4 $^oC$ until required. Three technical samples of tissue per pig are prepared (n=3). Certain conditions remain constant across the majority of studies. The embedding reagents used are cooled to 37 $^oC$ before embedding to prevent heat shock [5]. Once this step is complete, the buffer temperature is maintained at between 0-4 $^oC$ to promote tissue viability.

The variable chosen to optimize for the study is reagent concentration. Three different agarose concentrations (2%, 2.5% and 3%) and 3 gelatin concentrations (1%, 1.5% and 2%) will be tested (n=3 per concentration combination). Section thickness achieved is between 250 – 400 µm.

**Nanoindenter Protocol** Fresh and frozen porcine colon tissue layers were nanoindented using the Optics 11 Chiaro Nanoindenter, which is designed for fresh soft biological tissue mechanical analysis. This will be compared to macroscale compression testing of fresh and frozen porcine colon tissue using the Mecmesin 2.5-dV. The optimised protocol of 2.5% Agarose and 1.5% is used to section the fresh and frozen porcine colons. The approach and retraction speed was set to 2 µm/s as it has been demonstrated that for speeds $\leq$ 2 µm/s tissue

demonstrates elastic behaviour [6]. For this study, the probe used to perform this analysis was probe 0.32 N/m cantilever stiffness and 52.0 µm radius spherical tip. The analysis is performed at room temperature in PBS x1. The tissue was kept hydrated with X1 PBS at room temperature for approximately 30 mins prior to sectioning. Approximately 20 indents are carried out on each tissue sample, beginning at the serosa layer, and then indenting the muscle and mucosal layer. This provides a surface area map of an Effective Young's Modulus (E.$eff$) of the tissue section using the Hertzian Model. The Hertzian contact model follows the fit of the loading curve using the following equation:

$$F = \frac{4}{3} E_{eff} \sqrt{R_i} \cdot h^{3/2} \quad (1)$$

Where $F$ is the force applied, $E_{eff}$ is the Effective Young's Modulus, $R_i$ is the spherical tip radius and $h$ is the indentation depth [7]. $E_{eff}$ values were calculated using the Optics 11 Piuma DataViewer v2.4.13 software. The Hertz contact model was fitted to 50% of the indentation loading curve. The software outputs both $E_{eff}$ and $E$ values, but as the Poisson's ratio for the tissue was unknown the $E_{eff}$ values are used [7].

## RESULTS and DISCUSSION

The preliminary data of the ongoing study is presented in Figure 1 is of a frozen colon tissue sample, and it shows a unique profile for each layer with a statistical difference seen between the mucosa and muscle layers; the serosa (61.68 kPa ±9.302 kPa); the muscularis propria (88.85 kPa ±16.48 kPa); and the mucosa layer (32.65 kPa ±3.62 kPa). The muscularis propria appears to be the stiffest layer with the greatest variability and the mucosa layer is the softest layer with the least variability.

The study highlights that fresh porcine colonic tissue in can be sliced to between 250 – 400 µm which allows for accurate mechanical testing of the native tissue environment on a microscale. It is not recommended to cut tissue sections less than 100 µm as this damages the cells and therefore would not be a true representation of the native microenvironment [5].

The concentration at which agarose is used varies across studies, and is important to ensure precise tissue section cuts. For example, concentrations range from 0.5% to 4% for the preparation of precision cut lung slices [5, 8]. Agarose combined with gelatin preserves the native microenvironment of cells and tissue viability, and allows the tissue to remain flat once sectioned [9] this is useful for downstream microscale mechanical analysis. This optimised protocol for soft biological tissue is the first step in robust microscale mechanical characterisation. A fresh tissue analysis should lend itself to a more realistic profile of the native mechanical microscale properties of the tissue to help develop our understanding of the effects of disease on tissue structure.

## INTRODUCTION

Despite extraordinary recent advances in unraveling the genetic and molecular mechanisms of bone fracture healing, clinical fracture care remains fraught with guesswork. The goal of surgery is to assemble an implant construct that will be strong enough to avoid fatigue failure, yet compliant enough to generate mechanical strain at the fracture site and stimulate bone healing. However, strain is impossible to measure *in vivo*, so surgeons rely on rules of thumb developed over decades of practice to help guide intra-operative construct selection.

Modern ideas about mechanoregulation of bone healing have their roots in Stephan Perren's seminal 1979 paper [1,2]. From this work, the widely reported strain limits for secondary bone healing are 2-10%, with strain greater than 10% predisposing a fracture to nonunion. Since the introduction of this strain rule, several preclinical studies, including a study coauthored by Stephan Perren himself, have demonstrated that fracture healing can occur at strains far greater than 10% [3,4], which is contrary to what surgeons are taught to believe in their clinical training.

Therefore, the purpose of this study was to use patient-specific finite element modeling to virtually measure the interfragmentary strain environment in clinically realistic fractures. The hypothesis of this study was that in the early post-operative period, the tissues in and around the fracture gap can tolerate a state of strain greatly in excess of 10%.

## METHODS

Patients with distal femur fractures (OTA/AO 33-A/B/C) treated in a single Level I trauma center over a ten-year period were retrospectively reviewed. Eight representative cases (6 males, 2 females; ages 22-95 years), all treated with lateral bridge plating, were selected for virtual mechanical testing. Routine preoperative computed tomography (CT) scans were imported into Mimics (v23.0, Materialise, Leuven, Belgium) for segmentation (Fig. 1A). As described in an earlier study, a lower threshold of 160 Hounsfield Units (HU) was used to isolate the distal femur fragments from the neighboring bones and soft tissue [5]. These fragments were individually identified (Fig. 1B). The proximal portion of the fractured femur, which is missing in routine pre-operative imaging of distal femur fractures, was virtually reconstructed using an intact femur (Fig. 1B-D).

Bone fragments were then virtually realigned to represent the surgical reconstruction. A minimum fracture gap of 2.5mm was created between all fragments, across all models. Where applicable, the articular surface was completely reduced and fused, representing standard clinical practice for articular reconstruction. A 3D interfragmentary strain visualization region was added to calculate strains within and around the fracture gaps. Each anatomically reduced model was then virtually fixated using a 4.5mm variable angle (VA) curved condylar locking compression plate (LCP) (DePuy Synthes, Pennsylvania, USA) (Fig. 1E). A physical plate was used as a reference to recreate the 3D virtual plate model in SolidWorks 2020 (Dassault Systemes SolidWorks Corps., Massachusetts, USA). Post-operative X-rays and the VA LCP surgical technique guide were both referenced to match each model to the clinical scenario for each case.

All finite element meshes were generated using 3-Matic (v15.0, Materialise, Leuven, Belgium). A quadratic tetrahedral (tet-10) element type with a maximum edge length of 1.5 mm was applied to both the surfaces and volumes of every model (Fig. 1F). Radiodensity [HU] in the scans was converted to bone mineral density using a phantom calibration, which in turn was used to calculate apparent density, $\rho_{app}$, and then Young's modulus, $E$, using a power-law scaling equation [7]:

$$E = 8.92 * i\rho_{app}^{1.83} \quad (1)$$

This material assignment relationship, along with a Poisson's ratio, $\nu$ = 0.3 was applied for all the elements (Fig. 1G).

Finite element simulations were carried out in ANSYS Workbench (vR2020, ANSYS Inc., Canonsburg, PA, USA). For each model, three different axial loads (20%, 60%, and 100% body weight (BW)) were

applied through the centroid of the femoral head, directed distally along the mechanical axis, replicating a common bench-test condition for single-leg stance (Fig. 1H). The axial displacement [mm] of the femoral head along the z-axis was recorded and used to calculate construct axial stiffness [N/mm]. The pre- and post- deformed locations of the medial-most nodes on the distal and proximal fracture surfaces were recorded for gap closing strain calculations.

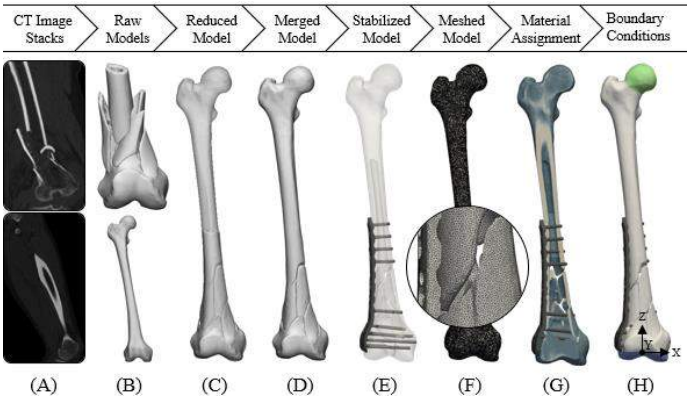

**Figure 1: Work flow for building a patient-specific finite element model of a plated distal femur fracture.**

## RESULTS

Models for the eight clinical cases are shown in Fig. 2A. Bridge spans (distance between screws across the fracture line) ranged from 21 to 126 mm. Elements with von Mises strains >10% are shown in Fig. 2 for the 100% body weight loading condition. For the three loading scenarios (20%, 60%, and 100% BW), as the bridge span increased, so did the maximum von Mises strain within the strain visualization region and the total volume of elements with strains greater than 10%. This behavior can be better visualized in the results shown in Figure 3. The average gap closing strain (mean ± SD) for all patient-specific models at each body weight (20%, 60%, and 100%) was 8.6% ± 3.9%, 25.8% ± 33.9%, and 39.3% ± 33.9%, respectively, while the corresponding max von Mises strain was 42.0% ± 29%, 110.7% ± 32.7%, and 168.4% ± 31.9%.

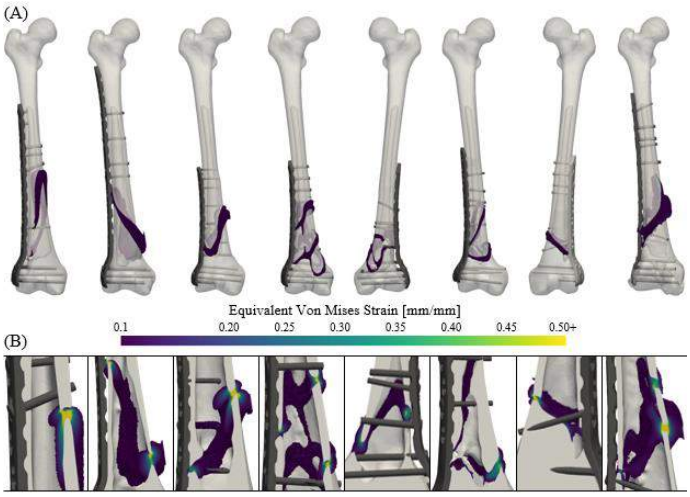

**Figure 2: (A) Anterior-posterior view of elements with strains >10%. (B) Magnified section views of each model illuminating the large strain values within the fracture gap. Note: Models were scaled to the same height for illustration purposes.**

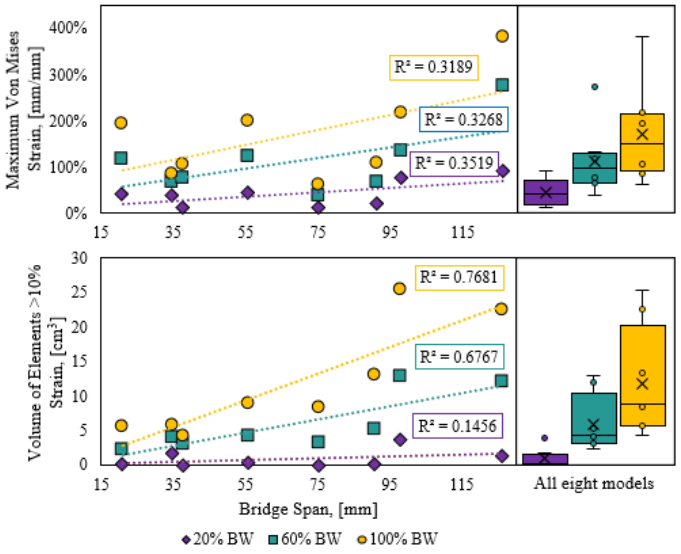

**Figure 3: The max von Mises strain and volume of elements with strains greater than 10% for three loading scenarios (20%, 60%, and 100% BW) across the eight models.**

## DISCUSSION

This study showed that strains in and around the fracture gap stayed in the 2-10% range only for the lowest load application level (20% BW). Moderate loading of 60% BW and above caused gap strains that far exceeded the upper limit of the classical strain rule (i.e., <10% strain for bone healing). Since all of the patients included in this investigation resulted in successful unions, these findings indicate that *in vivo* healing of distal femur fractures may be more robust to localized strains greater than 10%. Additionally, to better characterize the complex interfragmentary strain environment, the von Mises strain was evaluated in our study. Unlike the traditional, one-dimensional gap strain measurement, the method developed herein gives greater insight into the true strain environment which regulates fracture healing. Gap strain measures the motion between axially opposing points across an idealized fracture line, whereas the von Mises strain allows characterization of the full strain field throughout fracture pattern (see Fig. 2A). Gap strain is frequently reported because it is easily measured in both virtual and physical osteotomy models, but this parameter only assesses axial motion and disregards the associated shear strains entirely. This study showed that shear-dominated conditions can exist for the tissues in and around the fracture line, even without large gross shearing motions of the bone fragments. Excessive shear motion has been shown to be detrimental to the fracture repair process compared to axial motion [8], but this study revealed that shear-dominated strains may be much higher than has been previously appreciated and that this does not necessarily predispose a fracture to nonunion. These findings may have significant implications for the development of orthopedic implants because allowable fracture-site motion has long been a key design input, but the target specifications may be over constrained.

## INTRODUCTION

Glioblastoma (GBM) is a common and one of the most lethal types of brain tumor in adults [1]. Current treatment procedures for GBM are surgical resection followed by a combination of fractionated radiation and chemotherapy [1,2]. The main issue with current GBM treatment methods is that it recurs due to the infiltrated cancer cells which reside away from the tumor bulk, close to the tumor margins [1]. These cancer cells are found to be resistant to both chemotherapy and radiation therapy [1]. To overcome this problem, we propose the combined use of magnetic hyperthermia therapy (MHT) with chemotherapy and radiation therapy. MHT inhibits DNA-damage repair and enhances drug distribution through increased perfusion. MHT is a process of increasing the tumor temperature within the range of 41-46°C, from heat deposited by magnetic nanoparticles (MNPs) through magnetic hysteresis, when exposed to radiofrequency (RF) magnetic fields. The goal for MHT is to achieve a uniform isoeffect thermal dose of CEM 43 °C ~ 60-90 mins for ≥ 90% of tumor volume [1,3]. However, heterogeneous MNP distribution within the tumor results in non-uniform temperature and thermal dose distribution. Additionally, non-specific eddy current-based heating can result in damage of healthy tissue. In this study, we present the use of a feedback control system that achieves the target temperature and thermal dose through proportional-integral-derivative (PID) control of field amplitude and pulse width modulation (PWM) control of power to minimize heating of healthy tissue.

## METHODS

### a. 1.2 kW System-Small Animals

A 1.2 kW induction system was used for the small animal testbed. The system consists of the following main components: an induction system and custom coil, the temperature sensors, and the controls system hardware. The experimental setup is as shown in Figure 1.

**Figure 1: Experimental setup of the 1.2 kW system**

The signals from the fiber optic probe (FISO Technologies) consisting of four gallium arsenide (GaAs) temperature sensors–spaced 2 cm apart–are sent to the signal generator (FISO EVO-RM-8 Rack-Mount with FISO FPI-HR modules) which converts the raw data to voltage signals. A National Instruments (NI) CompactRIO (NI cRIO 9042) with the Multifunction I/O module (NI 9381) converts the voltage signals to temperature data in °C. The cRIO 9042 also controls the power output of the 1.2 kW induction power supply (Ambrell EASYHEAT 0112) with a 0-5V analog signal.

The closed-loop temperature feedback control model (*Figure 2*) and graphical user interface (GUI) (*Figure 3*) were developed in NI LabVIEW. A PID controller is used to maintain the probe temperature ($T_{probe}$) at the setpoint value ($T_{ref}$). The temperature error:

$$e(t) = T_{ref} - T_{probe} \quad (1)$$

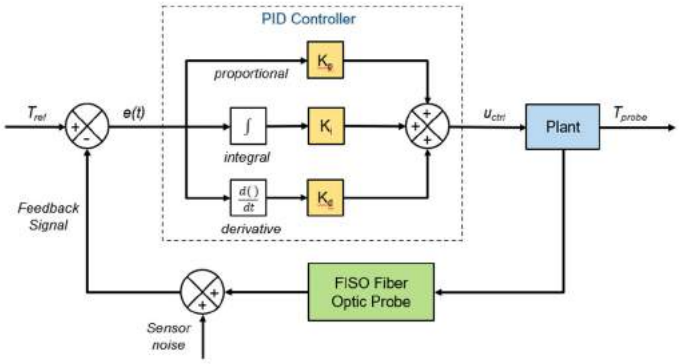

**Figure 2: Feedback controller block diagram**

was used to control the power output of the induction heating system by the following governing equation:

$$u_{ctrl} = K_p e(t) + K_i \int_0^t e(t)\,dt + K_d \frac{d}{dt} e(t) \qquad (2)$$

where $u_{ctrl}$ is the controller output. The initial gains ($K_p$, $K_i$, $K_d$) were determined with manual tuning.

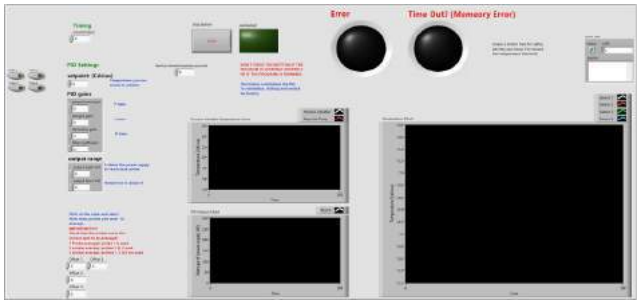

**Figure 3: GUI of the control system with user defined setpoint temperature, PID gain values, sensor selection and offset values.**

**b. 120 kW System-Large Animals**

The PID controller verified on the small animal testbed was implemented on a large animal system consisting of a 20 cm diameter water cooled modified Maxwell-type induction coil powered by a 120 kW induction power supply. Figure 4 shows the setup of the control system for large animals.

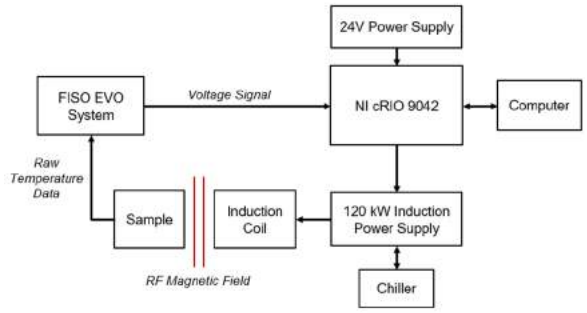

**Figure 4: Schematic of the 120 kW large animal system**

Initial evaluation of the developed closed-loop temperature feedback controlled 120 kW medical induction heating system was performed by heating a uniform distribution of MNPs in agarose gel in an Eppendorf tube. The FISO fiber optic probe was placed at the center of the gel with MNPs sample. A set point of 25°C was used. Commercial finite element (FE) software, COMSOL Multiphysics, was used to develop a coupled electromagnetic-thermal model. An initial set of PID gains ($K_p$ = 10, $K_i$ = 0.5, and $K_d$= 1) were obtained based on the FE simulation.

## RESULTS

Figure 5 shows the setpoint temperature, measured temperature of MNPs in agarose gel and the voltage response from the PID controller. The PID controller achieved setpoint temperature (25 °C) in 53 sec with a 0.08% error, overshoot < 0.034°C (0.13 %), and a shorter settling oscillation time (< 10 ms). The inset in Figure 5 shows the overshoot and stabilizing response of the temperature measurement.

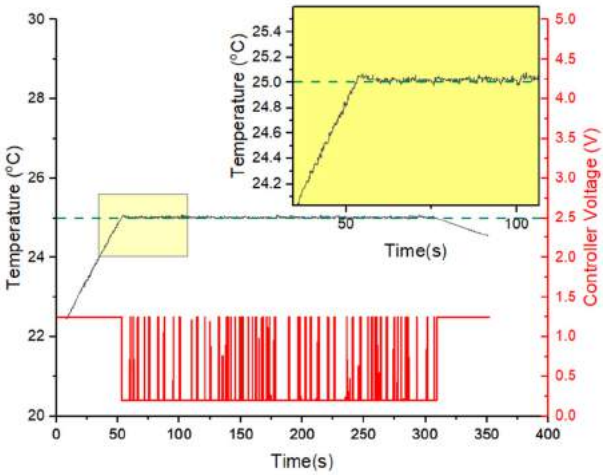

**Figure 5: Temperature of MNPs in agarose gel at 2.5 mg Fe/ml with time. Modulation of heating power using a PID controller to achieve and maintain $T_{ref}$ of 25 °C at the probe location.**

## DISCUSSION

The experimental results show that the experimental induction setup can successfully heat and maintain the heat source at the setpoint temperature. The developed PID controller achieved the target specifications of ±0.525°C within 200 sec. The controller also acted to minimize overshoot and stabilize the temperature response of the system. However, the controller fluctuation between the maximum and minimum voltage values still presents an issue. Fine tuning the PID gain parameters will help achieve optimization between target temperature control and eddy current heating. Future work will include an analytical approach to calculating the gain values, and additional safety features in compliance with FDA device design guidelines. A copper strip in agarose gel will be used for the validation and verification of the system.

## INTRODUCTION

In the United States, 12% of women undergo gynecological surgery to treat Pelvic Organ Prolapse (POP) [1]. POP is characterized by the descent of the pelvic organs, including the bladder, uterus, and rectum, causing lower intestinal and urinary tract disorders, as well as general discomfort [2]. Multiple factors known to be associated with POP include aging, increasing BMI, and parity (i.e., the number of times a woman has given birth), all of which decrease the mechanical integrity of the reproductive system support tissues [2,3]. These support tissues include the uterosacral ligament (USL), which is the primary structure for apical vaginal support. Damage to and failure of the USL due to biomechanical injury results in the protrusion of the uterus and/or vagina, or POP [2].

Traditional prolapse surgical techniques using native tissue repair have poor short-term outcomes, with up to 30% recurrent prolapse at 2 years postoperatively, due in part to insufficient knowledge on how to properly repair these damaged support tissues [1]. Histological studies have demonstrated decreased total collagen and elastin fiber content in the reproductive connective tissues following delivery and POP, suggesting diminished strength and impaired extensibility, but there lacks data and methodology to describe the tissue's change in mechanical behavior [3]. In combination with histological and proteomic data, this mechanical information will elucidate the relationship between structure and function in the USL which can help to better identify who is most at risk for POP, how we might mitigate their risk, and inform new POP treatment strategies. In this study, we developed a method to evaluate the mechanical properties of the murine USL. Mouse models are advantageous for studying the USL and POP due to their short gestation times and many genetically modified lines, which will help us study how pregnancy and extracellular matrix composition, respectively, affect USL behavior and injury.

## METHODS

Female mice (one nulliparous and two multiparous) were obtained and euthanized according to the University of Colorado Boulder's Animal Care and Use Committee. In each mouse, the bony pelvis, and the attached USLs and cervix were isolated. The cervical end of one USL was tied with a 5-0 polyglactin suture and the uterus was removed, leaving only the cervix attached to prevent the suture from sliding off the tissue. The other USL was removed, such that only one USL remained attached to the sacrum, which is within the extracted pelvic tissue. The freshly harvested cervix-USL-pelvis sample was placed in Ghost Dye Red 780 (Tonbo Biosciences) and NucBlue Reagent (ThermoFischer Scientific) stain for 2 hours at 4°C.

A custom loading chamber with a PBS bath was mounted under a confocal microscope (Leica STELLARIS), attached to a Femtotools actuator and an in-line 10 N load cell (Futek). Two custom 3D printed grips were fabricated to secure the cervix and pelvis in the loading apparatus (Fig. 1). Once secured, the actuator was positioned to remove all slack from the USL, with approximately a 0.01 N preload, which we referred to as the reference configuration.

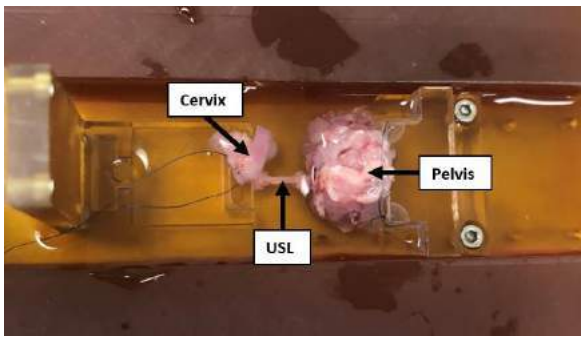

**Figure 1. Cervix-USL-pelvis in custom loading chamber**

The surface of the USL was imaged at 10× magnification in its reference configuration. Each USL was then subjected to three stress relaxation tests, coming back to its reference position following each test. Applied displacements were 1000 µm, 2000 µm, and 3000 µm, applied at 50 µm /s. Each stretched configuration was held for 10 minutes while the specimen's surface was imaged again at 10×. The confocal images of the stained USL were used to map deformation with the Matlab function 'imregdemons'.

Preliminary assessment of the viscoelastic behavior of the USLs was performed using macroscopic displacement and force data. Percent force relaxation was calculated as:

$$\frac{F_{max}-F_{eq}}{F_{eq}} \times 100\% \quad (1)$$

where $F_{max}$ is the maximum force and $F_{eq}$ is the equilibrium force.

## RESULTS

Our preliminary results demonstrate that deformation in the USL is inhomogeneous and the tensile response is nonlinear. Figure 2 shows the Lagrange strain fields of one USL from a multiparous mouse at an applied displacement of 1000 µm. The maximum strain experienced was 0.18 in the axial direction, and there was heterogeneous compression and extension experienced in the transverse (perpendicular) direction to loading. The strain is not uniform across the ligament, and there appears to be a periodicity to the strain in the main $E_{11}$ loading direction.

Moreover, global normalized force vs. time curves indicate that the USL is a nonlinear viscoelastic material (Fig. 3). The multiparous mouse USL held larger forces than the nulliparous USL at each global displacement state, with maximum forces of 0.156 N and 0.075 N respectively, both at the 3000 µm stretch. For both specimens, the equilibrium forces increased nonlinearly with increasing displacement. Over the three stretch states, the nulliparous USL exhibited 43.7% relaxation on average, and the multiparous USL experienced 31.7% relaxation on average. The amount of relaxation varied with each stretch state.

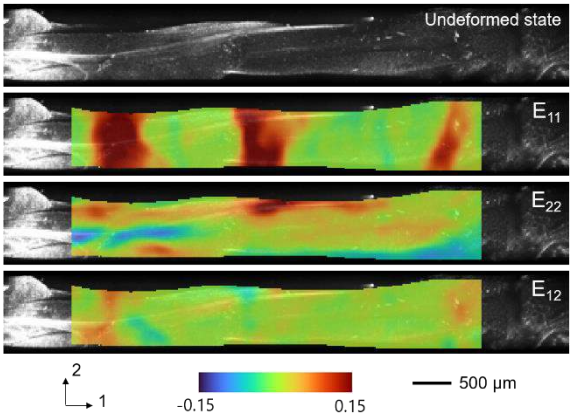

**Figure 2. Reference configuration and associated strain fields for a multiparous murine USL at an applied displacement of 1000 µm**

## DISCUSSION

The USL from the nulliparous mouse used in this study exhibited more viscoelastic relaxation than the USL from the multiparous mouse, despite lower overall loads. This finding is congruent with work from Yao et al. that demonstrates nonpregnant mice cervixes experience larger relaxation than pregnant mice [4]. The nulliparous USL also displayed a more nonlinear response than the multiparous USL, as determined by the larger disparity in loads and relaxations in each stretch state. Understanding how the viscoelastic and nonlinear properties of the USL change during pregnancy and postpartum may help in clinical settings to determine who is most at risk for POP. However, due to the heterogeneity of the strain field, strain homogeneity cannot be assumed for material modeling.

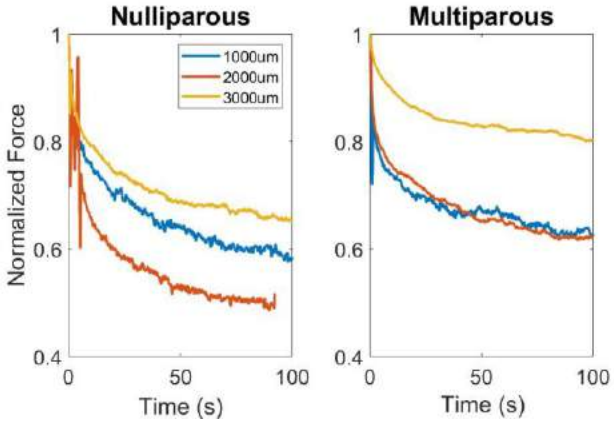

**Figure 3. Normalized force relaxation curves at applied displacements of 1000 µm, 2000 µm, and 3000 µm for a nulliparous (left) and a multiparous (right) murine USL**

The experimental methods developed and presented here will allow for the identification of USL viscoelastic properties from tensile tests with heterogeneous and multimodal strain. Nonlinear viscoelastic behavior will be confirmed and fully characterized. Full-field deformation maps like those shown in Fig. 2 will be used in conjunction with full-field inverse methods to build constitutive models and damage criteria for the USL in future work.

The work provided above reflects preliminary work, where the mice that have been tested were not age- or strain-matched. Future studies will control for these additional factors. Limitations of this preliminary study are in the small number of samples, the difference in USL length and preload in its reference state, and inconsistent staining. The planned future study will have n=8 mice in each group, will be more consistent in preload measures, and will use a newly constructed staining chamber to ensure the entire length of the USL is stained to improve deformation tracking.

We will use this new technique to examine how the mechanical properties of the murine USL change during pregnancy, post-partum, and after multiple births. In combination with proteomics and histology, this work will lend insight into new treatment and prevention strategies for POP.

## INTRODUCTION

Stroke and cardiovascular disease, conditions caused by thromboembolization, are leading causes of death in the United States [1]. Recent studies suggest that, in addition to embolus morphology, their mechanical properties contribute to complications in removal procedures [2,3]. Mechanical characterization of emboli is critical to the design of new procedures and techniques to improve clinical outcomes. However, the study of emboli removed from patients is complicated due to the time lapse between embolus removal and characterization in a lab. For this reason, embolus analogs (EAs) are commonly used in a laboratory setting and are often paired with computational modeling to bridge the gap to clinical applicability. EAs and clinical emboli are most commonly modeled as nonlinear viscoelastic tissues [refs. Irish group]. However, our recent experiments indicate that EAs discharge fluid when mechanically loaded, suggesting that their behavior might be poroelastic, as seen in brain tissue [4]. The goal of this project is to characterize the behavior of EAs with varied hematocrit when loaded in compressive relaxation and cyclic loading.

## METHODS

**EA formation conditions:**

To study the effect of EA composition and storage conditions on their load bearing properties, EAs were created using bovine blood, following approved institutional IACUC protocols. Briefly, extracted whole blood was anticoagulated with 6.45% wt. citrate-phosphate-dextrose with adenine (CPDA). Blood was separated into red blood cells, platelet rich plasma (PRP), and platelet poor plasma (PPP) via centrifugation. Blood was reconstituted to 214 x $10^6$ platelets per mL. Hematocrit was varied in EAs by addition of 0%, 20%, 40%, and 60% vol. red blood cells. To counter the effects of the anticoagulant, blood was recalcified with 11 mM calcium chloride ($CaCl_2$). Recalcified blood was mixed and injected into 24-well plates to form cylindrical clots for mechanical testing. To study the effect of static versus dynamic formation of EAs, blood was left in a warm room and formed statically on a benchtop or dynamically on a rocking plate. Blood was left for 24 hours at 37°C for EAs to form.

**EA mechanical testing:**

All EAs were tested in compression using an Instron (Norwood MA, USA) uniaxial load frame. To investigate the time dependent properties of EAs under the various conditions, EAs were removed from well plates and loaded at a rate of 5% strain per second to 10% strain and held for 30 seconds. Percent relaxation and peak stresses were calculated from the resultant curves. To investigate the time dependent effects of cyclic loading, EAs were compressed cyclically to 10% strain for 50 cycles, at 5% strain per second. Area between the loading-unloading curves were computed as an indicator of energy loss over time in the material.

**Statistics:**

Due to variability in coagulation, clot contraction, and other factors, multiple sources (n = 6) were collected with replicates (n = 6) tested for each source. For this reason, mean values were computed with standard error of the mean, and t-tests were performed between samples to determine significant changes in parameters.

## RESULTS

For the compressive relaxation tests, peak stresses for statically formed EAs were 0.55 ± 0.02, 0.49 ± 0.02, 0.48 ± 0.01, and 0.55 ± 0.01 kPa for 0, 20, 40, and 60% hematocrit, respectively. For the dynamically formed EAs, the peak stresses were 0.65 ± 0.04, 0.61 ± 0.02, 0.63 ± 0.02, and 0.73± 0.04 kPa for 0, 20, 40, and 60% HCT, respectively. The percent relaxation for static EAs was 100 ± 0, 100 ± 0, 100 ± 0, and 99.09 ± 0.67 kPa for HCTs from 0% to 60%, respectively. For dynamic EAs, the percent relaxation after 30 seconds was 100 ± 0, 100 ± 0, 100 ± 0, and 97.75 ± 0.67 for 0, 20, 40, and 60% HCT, respectively. These data were calculated as the final stress over the peak stress from the relaxation curves shown in **Figure 1.**

Preliminary data for area under the curve from **Figure 2.** were calculated from the area between the loading and unloading curves. The change in area from the previous cycle falls below 3% after roughly 25 cycles for all hematocrits.

## DISCUSSION

Peak stresses for each hematocrit decreased significantly, from 0% to 60% HCT, suggesting a softening of the material due to increased red blood cell content. However, no significant differences in peak stresses were observed between static and dynamic EAs, suggesting negligible differences between groups. This implies that the fiber distribution is similar for both formation protocols. From the percent relaxation data, complete relaxation was observed for nearly all hematocrits, except for the 60% HCT static and dynamic EAs. This suggests a high degree of relaxation, possibly related to the addition of highly viscous red blood cell content with increased hematocrit. This is similar to Boodt et al. who demonstrated no significant changes in lower elastic moduli in clinical EAs until hematocrit was above 60% [3].

The cyclic loading tests demonstrate an overall decrease in area between curves, with changes in area from cycle to cycle falling below 3% around cycle 25 for each hematocrit. This suggests an overall loss of energy stored in the EAs after repeated loading. Additionally, we observed fluid excretion at the end of each test, suggesting that the EAs hold fluid in a sponge-like manner until a stress is applied. Further investigation is needed to determine if fluid is reabsorbed after stress is released.

Overall, these data suggest a softening of these materials due to an increase in hematocrit content, and a corresponding decrease in hysteretic energy loss over time, as indicated by **Figure 2.** The static versus dynamic EAs showed no significant differences in peak stresses or percent relaxation, an indication that there is little difference in their load bearing properties. Finally, the cyclic loading demonstrates a behavior somewhat different from current understanding. Along with the observed EA leakage, the decrease in hysteretic energy loss suggests EAs behave more like a poroelastic material rather than a purely viscoelastic material. Future work will focus on the comparison of these two models and their relevance to modeling emboli.

## INTRODUCTION

Displacement encoding with stimulated echoes (DENSE) MRI provides deformation maps on a pixel level non-invasively, and is critical for analyzing the biomechanics of soft tissues [1]. Adapting *k*-space spiral scanning enhances the temporal resolution which ultimately extracts high resolution time-course displacement maps [2]. This approach allows for measurement of mechanical properties of soft tissue under rapid loading and motion such as walking, leading to potentially useful biomarkers for early joint degeneration. However, to gather high quality MR images using DENSE MRI, long scanning times are needed resulting in high cost, patient discomfort, and misregistration errors. To accelerate the imaging speed, we examine the use of compressed sensing (CS) on DENSE MR images collected on *in vivo* human knees. Subjects underwent varus loading at the ankle leading to compressive loading on tibiofemoral cartilage while the knee joint was imaged. Quantitative measures including signal-to-noise ratio (SNR) and displacement are compared between non-CS (NCS) and CS images, and we find that CS can reduce the MRI scanning time at least twofold while maintaining comparable image quality.

## METHODS

*Cyclic Varus Loading:* Six adults (3 males, 3 females, 25-35 years old) with no history of knee joint damage were recruited. A custom-built varus loading device was mounted on the clinical MRI (3T; Siemens Prisma$^{fit}$), and varus loading was applied on the ankle. We used a moment balance to make the varus load on ankle be equivalent to half body weight of force applied on the knee joint. Varus loading was applied on a cyclic fashion (100 ms delay, load 1 s, unload 1 s) leading to a loading frequency comparable with a walking cadence.

*Spiral DENSE MRI:* Multiple frames (27) of DENSE MR images were collected in magnitude and phase during varus loading. We used ten spiral interleaves to generate images, and two interleaves were collected for each loading cycle. An electric pulse triggered the MRI system to initiate and synchronize data acquisition. Imaging parameters were as follows: TE/TR=2.5/20ms, spatial resolution=360×360μm$^2$, slice thickness=1.7mm, displacement encoding gradient =0.32cycles/mm, and the number of image averages=8 (for high SNR images). Prior to spiral DENSE MRI acquisition, the loading cycle was applied for 8 minutes to achieve a quasi-steady state response [3], and high SNR doubled echo steady state (DESS) images were collected. The *k*-space data was archived to perform CS analysis.

*Displacement and Strain Calculation:* Articular cartilage regions of interest (ROIs) were manually segmented using custom software (MATLAB) and binary masks were created on the medial and lateral cartilage. Displacements for each pixel within the ROIs were determined from phase data [1]. Displacements were manually phase unwrapped followed by smoothing with a locally weighted scatterplot smoothing (LOWESS) filter for 10 cycles. Finally, in-plane Green-Lagrange strains were calculated from the smoothed displacements.

*Compressed Sensing:* We extracted the spiral trajectory and *k*-space data along the trajectory for each channel and image average. Subsequently the trajectory, *k*-space data, and the channel sensitivity map were analyzed using the Berkeley Advanced Reconstruction Toolbox [4] (BART) to run Parallel Imaging and Compressed Sensing (PICS) command for reconstructing the images. The regulation parameter was 0.01 and all processes underwent five iterations. The process was repeated for each image average and later were averaged after the reconstruction.

*Data and Statistical Analysis:* SNR of the DENSE MR images was calculated by analyzing regions depicting the medial condyle and background. We measured the average intensity for both regions and calculate the ratio. To measure the discrepancy of displacements with respect to the average 8 images, we calculated the root mean square error (RMSE) on selected ROIs for both NCS and CS images. To determine which image average was comparable with NCS average 8, we applied one-tailed paired t-test on the RMSEs for all averages of CS (n=6) with the RMSE of NCS average 7.

## RESULTS

Displacement and strain maps were collected on 27 time-lapse images during 1 s of loading. The DESS images reflected the displacement of the joint caused by varus load applied on ankle (Figure 1). Higher number of averages resulted in increased SNR, and additionally was linearly correlated with the scanning time (1 average=1.7 minutes, 8 averages=13.6 minutes). The displacement and strain in the medial condyle displayed heterogeneous patterns (Figure 2A). Low average displacement maps had an irregular pattern with more

noise compared to high average images laying out a smooth displacement pattern. CS reduced the roughness in displacement map. This displacement affected the strain measurement where clear compressive strain ($E_{yy}$) was observed on the medial condyle in the high average and CS images, but did not appear in the low average images.

We found that CS enhanced the image SNR and reduced the RMSE with respect to average 8 images (Figure 2B). SNR was consistently higher in CS images with any average than NCS images, while raw and smoothed RMSE were substantially lower in CS images. RMSE of both NCS and CS images gradually improved with averages. We found that the RMSE of average 4 CS image was 0.13mm, which was similar with the average 7 NCS image. The *p*-values comparing CS with NCS average 7 RMSE had a peak at average 3 and started to decline at average 4 indicating the non-significant difference with NCS average 7 and diverging starting from average 4.

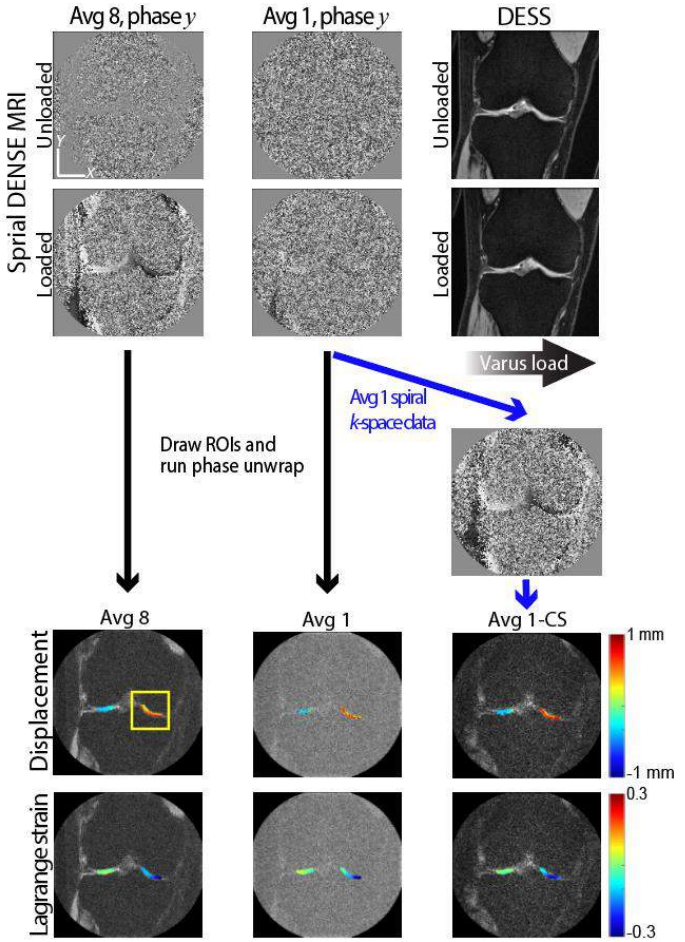

**Figure 1: Displacement and strain maps captured by spiral DENSE MRI with CS. DESS images show the translation of the knee due to varus load. To obtain the displacement maps, ROIs were drawn and we ran phase unwrapping on both low and high average images. CS was applied on the spiral *k*-space data, and followed the same process for obtaining displacement maps. Further analysis was conducted on the medial condyle (labeled in yellow box).**

## DISCUSSION

In this study, we explored the effects of CS on displacement and strain calcuation using sprial DENSE MRI. We confirmed CS can improve the image SNR and provides comparable results with high average images while needing half the scanning time (6.8 minutes). Further in-depth quantitative analysis is needed to assess the performance of CS on DENSE MRI. Nevertheless, this study demonstrates that CS applied on spiral DENSE MRI can significantly reduce the imaging time. As future work, this method can be applied to patients of different level of joint disease (e.g. in articular cartilage following ACL reconstruction), benefiting from the shortened imaging time, and can potentially discover biomarkers of tissue degeneration processes [5].

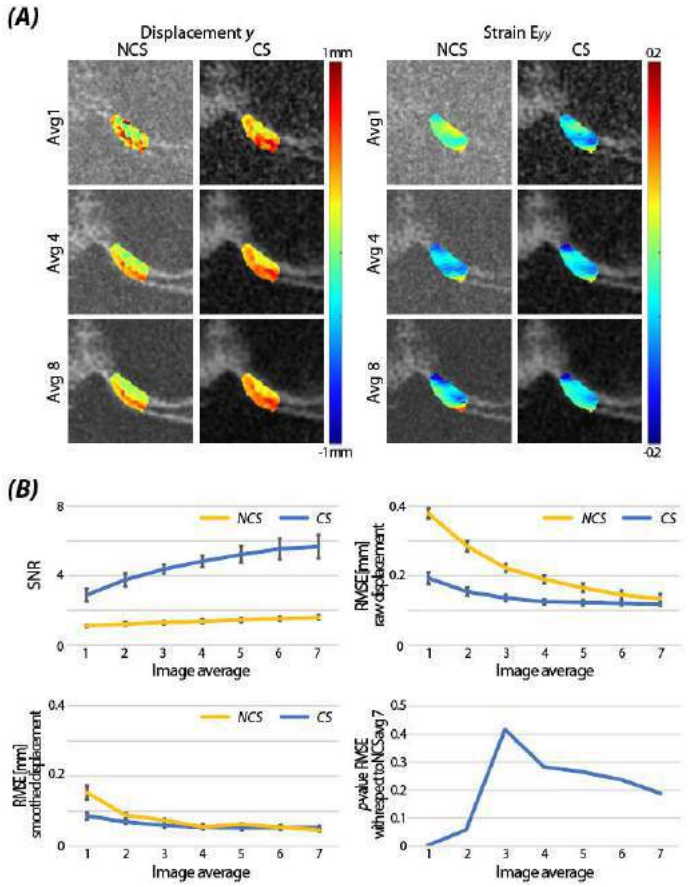

**Figure 2: NCS and CS comparison on displacement and strain. (A) Displacement *y* maps compared on frame 27 show SNR increases with more averages and applying CS smooths the displacement field. Compressive $E_{yy}$ strain is not observed in low average NCS images. (B) Quantitative analysis shows SNR increased and RMSE decreased after applying CS. Error bars represent the standard error.**

# BIOENGINEERED THREE-DIMENSIONAL LUNG AIRWAY MODEL TO STUDY NEONATAL INTRATRACHEAL SURFACTANT DELIVERY

**Hannah M. Combs (1), Hossein Tavana (1)**

(1) Department of Biomedical Engineering
The University of Akron
Akron, Ohio, USA

## INTRODUCTION

The lung contains a series of branching airways that lead to the respiratory zone. The respiratory zone houses the respiratory bronchioles and alveolar sacs. A low surface tension at the air-liquid interface of the alveolar sacs is critical to allow for the alveoli to remain open and facilitate gas exchange.[1] A low surface tension is maintained by the pulmonary surfactant secreted by mature alveolar cells. Pre-term infants have under-developed lungs and insufficient pulmonary surfactant production, causing breathing irregularities and potential lung collapse. This condition is known as Neonatal Respiratory Distress Syndrome (NRDS).[2] NRDS treatment consists of the intratracheal delivery of exogenous surfactant into the lungs in surfactant replacement therapy (SRT). Despite its benefits,[2] there is a high non-response rate of up to 35% to SRT, potentially due to inhomogeneous distribution of instilled surfactant. The optimization of delivery condidions is crucial to ensure a uniform distribution and increased efficieny that improves the outcomes of SRT. The goal of this study was to develop a 3D, biomimetic neonate lung model and study the distribution of surfactant in airways and the delivery efficiency.

## METHODS

A 3D computational lung model was designed in Solidworks using morphometric data from human lungs. The design began by constructing the trachea (z=0) with a diameter of 3.5 mm and a length of 17.5 mm.[3] The diameter of the trachea was designed to taper 13.5% to ensure for a smooth transition into the next generation. A bifurcation zone between each parent airway and daughter airways emerging from it was designed with an angle of $\theta$=80° and was rotated 90° in the gravitational space starting at z=3. The subsequent genrations were constructed following this strategy to create an eight generation model, i.e., z=0-7, of continuously branching airways (Figure 1a).[3,4] Physical models were fabricated using 3D printing. Prior to experiments, the model was subjected to oxygen plasma (Harrick Plasma) for 10 minutes to render the interior of airways hydrophilic. The model was pre-wetted with DI water. Then, a 140 µL plug of Infasurf (ONY, Inc) surfactant was instilled into the tracheal tube. The plug was propagated through the airways at a Capillary number of 0.016. The lung model was positioned at four different roll angles of $\alpha$=0º, 30º, 60º and 90º to simulate rolling of a neonate during SRT. A distribution index was quantified for the four lobes, upper right (UR), lower right (LR),

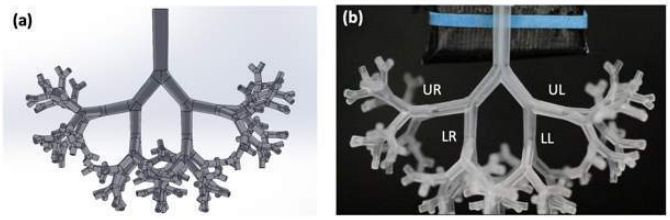

**Figure 1.** a) Computational multi-generation (z=0-7) neonate lung model developed in SolidWorks. b) Semi-transparent printed model. Four different lobes are labeled.

SB³C2022-186

lower left (LL), and upper left (UL) (Figure 1b) and an efficiency index was quantified using surfactant volume in z=5 airways.

## RESULTS

We found that rolling the model away from its center line at $\alpha$=0º to $\alpha$=30º, 60º, and 90º resulted in a significant increase in surfactant distribution to the UR lobe a decrease to the LL and UL lobes ($p < 0.05$). Our results indicate that as the roll angle increased, the gravitational force increased the fluid flow to the UR and LR lobes (Figure 2). We also found that the sum of the distribution indices for the four lobes increased as the model was rolled gradually to 90º. This result indicates that as the model was rolled, the surfactant passed through fewer airways, thus depositing less volume onto the walls and delivering more further down the airway tree.

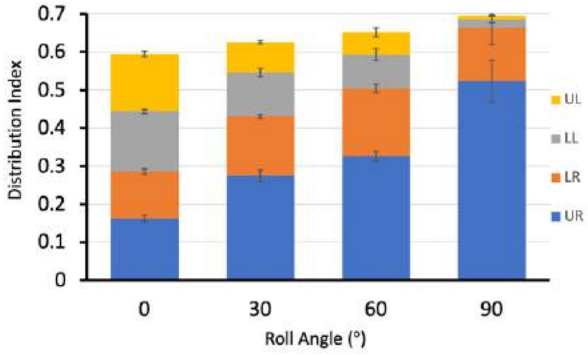

**Figure 2.** The distribution index for each lobe at various roll angles, representing the volume of surfactant to reach z=2 in each lobe.

We quantified volume of plugs in the distal airways (z=5) to determine the efficnecy of delivery when the model was rolled away from the horizontal plane. The efficiency was defined as the percentage of the total volume delivered to z=5 to the instilled dose in the z=0 airway. Our results showed that the efficieny increased significantly when the model was rolled from $\alpha$=0º to 60º, and 90º ($p < 0.05$). At $\alpha$=0º and $\alpha$=30º the efficiency was 43.0% ± 0.67 and 42.1% ± 0.67. As we increased the roll angle to 60º, the effiency increased significantly to 46.1% ± 0.67 ($p < 0.05$). A maximum efficieny of 60.1% ± 0.67 was found at $\alpha$=90º. The efficiency index indicates that a neonate positioned 90º on their side would receive a greater amount of surfantant to the distal airways than in any other position. We then evaluated how much of the instilled dose at a $\alpha$=0º was in certain regions of the lung model at z=5 for $\alpha$=0º and $\alpha$=90º. At $\alpha$=0º the right lung received 50.3% ± 2.46 of surfactant while the left lung received 49.7% ± 1.58 (Figure 3). At $\alpha$=90º the right lung receives 100% of the surfactant and the left lung received 0% (Figure 3). Although the maximum efficiency occurs at a $\alpha$=90º, fewer distal airways received surfactant in this orientation than at $\alpha$=0º. At a roll of 90º, the only lobe to receive surfactant was the UR lobe. The increase in effeicncy was due to the surfactant passing though fewer airways than at $\alpha$=0º but clearly indicates that the majority of the lung does not receive any surfactant, potentially decreasing the effectiveness of SRT at a roll angle of 90º.

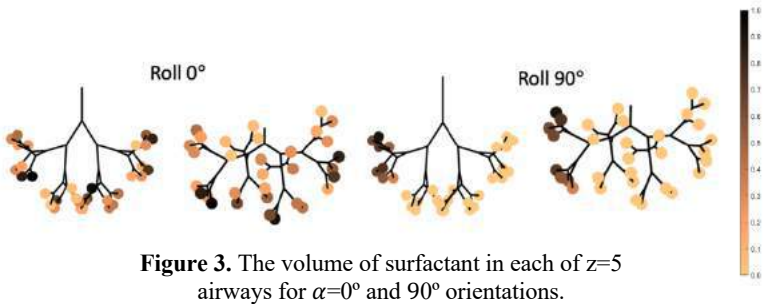

**Figure 3.** The volume of surfactant in each of z=5 airways for $\alpha$=0º and 90º orientations.

## DISCUSSION

Our 3D, eight-generation neonate lung airway model enabled simulating surfactant delivery. This case study suggests that when delivering surfactant during SRT, orientation should be considered prior to the delivery. Our findings showed that surfactant loss dependence on orientation could affect the clinical success of SRT. This study successfully demonstrated the utility of the model to study intratracheal therapeutics delivery taking into account orientation, hydrophilicity of airways, and flow rate of surfactant plugs. Our study presents a more elaborate understanding of SRT and validates previous computational studies in regard to the effects of orientation during SRT.[5] This model has the potential to advance drug delivery studies with respect to simulated environments and offers a device to study therapeutics effects at a cellular level. With the continuous use of these models, varies respiratory disorders may be studied for delivery methods, fluid dynamics, and the overall effects on the respiratory system.

# DETERMINING EFFECTS ON PIG GAIT AFTER INDUCED TRAUMATIC BRAIN INJURY: INTITAL ASSESSMENTS

**Sloan Kanat (1), Paige Cordts (1), Alesa Hughson (2), Galit Pelled, PhD (1), Tamara Reid Bush, PhD(1)**

(1) Department of Mechanical Engineering, Michigan State University, East Lansing, MI, United States
(2) Department of Biomedical Engineering, Michigan State University, East Lansing, MI, United States

## INTRODUCTION

It has been estimated that 1.7 million traumatic brain injuries (TBIs) occur annually in the US [1]. Additionally, there were over 50,000 deaths and almost 300,000 hospitalizations related to TBIs annually from 2002-2006. [1]. TBIs have been shown to have lasting negative effects on a person's health, learning, sociability, work, and relationships [2]. There are a vast range of causes of TBIs, with motor vehicle accidents making up the largest number of reported TBIs in adults, followed by falls [3]. In children, sports are a major contributor to TBIs, with falls being the second leading cause [4].

Due to many causes and severities of TBIs, it is difficult to classify them. A mild TBI could have symptoms such as balance or concentration problems. Mild TBIs are challenging to diagnose in people because the symptoms can be mistaken for other health problems, such as anxiety or headaches [5]. More severe TBIs are easier to diagnose since they have more significant symptoms. Evidence also shows that repeated small TBIs can lead to chronic traumatic encephalopathy [6], which has symptoms such as depression, dementia, and overall cognitive impairment [6]. Smaller TBIs can go undetected and can lead to long-term cognitive issues, so it is important to have a way of diagnosing smaller TBIs.

Since it is difficult to obtain quantitative human TBI data, the pig brain provides a reasonable comparison to the human brain. The size, organization, and makeup of a pig brain is closer to that of a human brain compared to the usual animal surrogates, which are rodents [7].

Previous research has shown that there are notable parameters for TBIs in pig gait. Pressure mats have been the most popular method of data collection and have yielded evidence to support gait changes after TBIs [8]. Pressure mats alone do not provide hoof height or 3-D data that can be used in gait analysis. This study builds on previous research by adding unique 3-D data including relative rotations between shoulders and hips with the head.

The goals of this study were to determine new methods and identify possible measures that can be used to study pig gait pre- and post-TBI.

## METHODS

This study investigated two Yucatan minipigs. The pigs were studied pre-TBI and then underwent a clinical induction of a TBI, after which they were studied again. The TBI was induced by a controlled drop indenter.

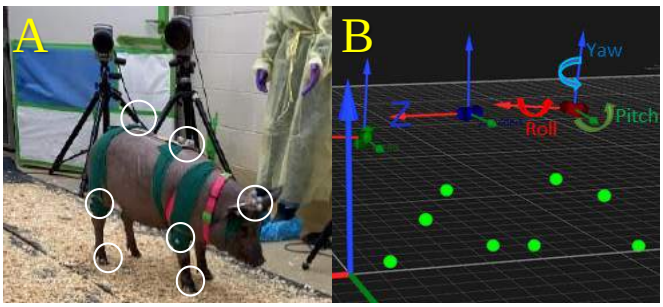

**Figure 1: A) Pig with markers on in motion capture testing space. Coban tape was used to secure rigid bodies and single markers, circled in white, to the pig. The hoof markers were secured using double-sided tape. B) Qualisys Motion Capture view of markers in 3-D space. Green markers show the knee and hoof markers. Three rigid bodies seen in dark green (head), dark blue (shoulders) and red (hips).**

Reflective markers were placed on anatomical locations of the pigs. Marker pods with four markers on each (referred to as rigid bodies) were used. The rigid bodies were placed at three locations: on top of the pigs' head; on the back between the shoulders; and on the hips. Individual markers were placed laterally on each knee joint and on the

outside of each hoof. The 3D locations of the marker were collected using a motion capture system at 100Hz. The vertical height of each hoof was determined and reported for each trial. The rigid bodies on the head, shoulder and hips were used to calculate the rotations of the shoulders and hips relative to the rotation of the head during each trial. Rotation of the x-axis (roll), y-axis (pitch) and z-axis (yaw) are labeled. The x-axis goes from the back of the pig to head, the y-axis is left to right side of pig, and the x-axis is vertical from the pig (Figure 1 B)

For each trial, the pigs were led by a trainer through the calibrated motion capture space. The trainers used treats to maintain the pigs' attention as they walked through the space. The trainer walked the pig through the calibrated space at a consistent pace. The number of times the pigs walked through the space varied depending on the cooperation and mood of the pig, which each time walking through the space counted as a trial.

## RESULTS

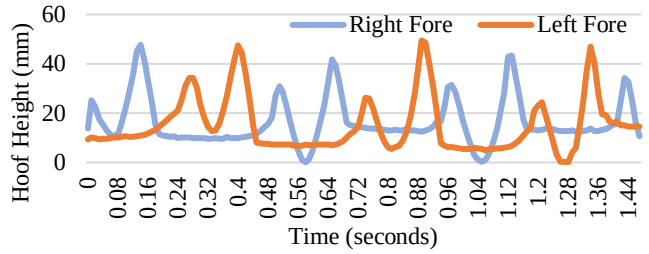

**Figure 2: Fore-leg hoof height variation with time for pig C post-TBI.**

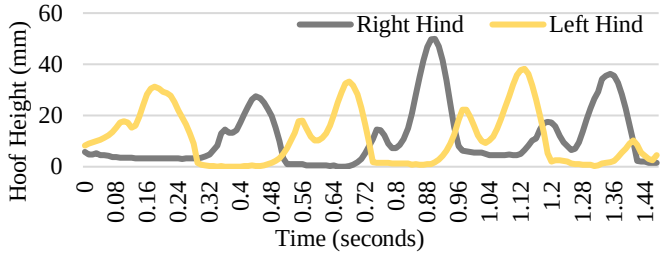

**Figure 3: Hind-leg hoof height variation with time for pig C post-TBI.**

Figures 2 and 3 present the heights of each hoof, timing of steps, and comparison between the right and left side of the pig gait for one trial of pig C. The fore legs had an average swing time of 0.290±0.014 seconds, and the hind legs had an average swing time of 0.283±0.039 seconds.

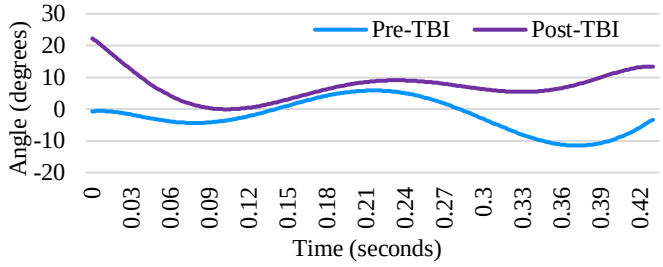

**Figure 4: Shoulder rigid body pitch rotation angles for pre- and post-TBI of pig B. The timing of the pre- and post-TBI data were scaled to show a full gait cycle starting with a right fore-leg step from 0-0.22 seconds and a left fore-leg step from 0.22-0.42 seconds.**

The pitch angles showed a parabolic pattern through the swing of each leg. The maximum rotation angles of shoulders and hips relative to the head during each trial are presented in Table 1. There was a decrease in the yaw deviation angles from both the shoulders to head and hips to head between the pre- and post-TBI pig

**Table 1: Maximum deviation angles (in degrees) from neutral position pre- and post-TBI of the shoulder relative to the head, and the hips relative to the head for one pass of pig B.**

| | | Pre-TBI (degrees) | Post-TBI (degrees) |
|---|---|---|---|
| Shoulders to Head | Roll | 18.020 | 13.052 |
| | Pitch | 11.847 | 13.891 |
| | Yaw | 18.148 | 12.142 |
| Hips to Head | Roll | 14.710 | 18.172 |
| | Pitch | 21.087 | 14.334 |
| | Yaw | 22.428 | 19.850 |

## DISCUSSION

This study investigated methods to assess pig gait and explored measurements of that gait to be used to evaluate quantitative signs of TBI.

Because of the complexity of evaluating the gait of pigs, the majority of the published research has focused on hoof contact patterns. There is limited TBI related gait research, particularly with the inclusion on relative movements between body segments. This work demonstrates the ability to gather hoof height, timing of each leg during gait and relative motions between body segments. All of these measures have the potential to provide insights to changes in movements pre- and post-TBI. Determining not only magnitude of movements, but timing of these movements will add to our understanding of functional changes in gait patterns. This is the initial step for a full evaluation of multiple pigs pre- and post-TBI injury.

This is an important first step. Measurement of pig gait was challenging as it was unclear how the pigs would tolerate the marker systems and if they would accept an environment with cameras. Interestingly, the pigs have very sensitive hooves, so initial attempts at full spherical markers on were unsuccessful. The small, flat hoof markers were well tolerated and able to be viewed for the entire trial with our system.

Additionally, the rigid body marker pods stayed securely on the animal during all trials. These rigid body pods successfully captured relative movement between the three segments.

Future work on this research will begin with three new cohorts of pigs introduced throughout 2022. The full pre- and post-TBI gait analysis will be conducted at least twice. First, once the pigs are trained to walk through the motion capture space and second, after the induction of the TBI. In addition, this study aims to combine the full gait analysis with pig play and behavioral changes pre- and post-TBI to create a more extensive list of TBI markers that could be adapted to human TBI assessments to improve diagnostic criteria for smaller TBI's that otherwise may go unnoticed.

# MEASURING THE EFFICACY OF RIGHT ATRIAL APPENDAGE TISSUE TO WITHSTAND PULMONARY HYPERTENSIVE CONDITIONS AS A FUNCTIONAL PULMONARY VALVE

## INTRODUCTION

Tetralogy of Fallot (TOF) is a congenital heart defect that affects blood flow to the lungs. There are four deformities associated with TOF: right ventricular outflow tract obstruction (RVOTO), ventricular septal defect, overriding aorta, and right ventricular hypertrophy. The focus of this study is on RVOTO. This deformity is associated with both pulmonary stenosis and pulmonary atresia. Pulmonary stenosis occurs when the pulmonary valve does not open properly, while pulmonary atresia is when the pulmonary valve fails to form at all [1].

During TOF repair, it is vital to prevent pulmonary insufficiency (PI). PI is a condition in which the function of the pulmonary valve is compromised and causes backflow. A new repair technique has been introduced that uses right atrial appendage (RAA) tissue from the patient to create a neo-pulmonary valve [2]. The aim of this study is to further the understanding of the efficacy of the neo-RAA valve to withstand increased pressurization conditions.

## METHODS

Adult porcine hearts were used in this experiment. Storage and thawing methods were adopted from a previous study [3]. To prepare the hearts, the right atrial appendage was resected, and then the right ventricle outflow tract (RVOT) was completely removed from the heart. The native pulmonary leaflets were then extracted from the RVOT. A portion of the RAA tissue was then dissected to form a bicuspid pulmonary valve [4]. The valve was then sutured into the pulmonary trunk (PT). Figure 1 shows the neo-RAA valve sutured into the PT from different angles.

The RVOT with its neo-RAA valve was then placed into a Plexiglass container that contained a hydrostatic pressure system. The hydrostatic pressure system was fabricated to induce pressurization of the pulmonary artery (PA). The reservoir for the system was set at various elevations to produce pressurization levels that ranged from 20 mmHg to 140 mmHg. A zip tie was used to secure the PA to the system's cannula to prevent backflow.

The PA was then pressurized to 20 mmHg to test the function of the bicuspid RAA valve. Pressurization was then increased by factors of 20 mmHg until reaching 100 mmHg, and then by increments of 10 mmHg thereafter. The PA was pressurized for ten seconds at each stage of pressurization to measure the efficacy of the bicuspid RAA valve. This was done until the bicuspid valve failed to withstand the pressurization.

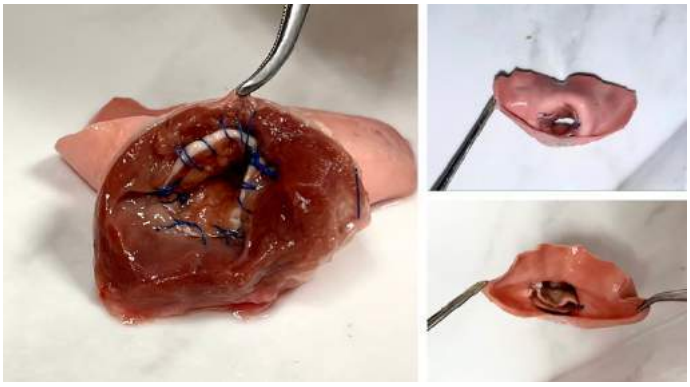

**Figure 1: Pulmonary valve replaced with bicuspid right atrial appendage valve in the right ventricle outflow tract.**

## RESULTS

Peak systolic and severe pulmonary hypertension (PH) conditions were simulated in the pulmonary artery and the RVOT [5]. The neo-RAA bicuspid valve was pressurized to close at various pressurizations, until it was no longer able to withstand the pressure exerted on it. The study revealed that the bicuspid valve functioned at 20 mmHg, 40

mmHg, 60 mmHg, 80 mmHg, and 100 mmHg. The valve failed at 110 mmHg. Therefore, the efficacy of the bicuspid RAA valve fell between the range of 100 and 110 mmHg. This clearly demonstrates that RAA tissue is able to function properly and withstand considerable PH conditions. Figure 2 demonstrates the PA and neo-RAA being pressurized to failure.

**Figure 2: Pulmonary artery and the right atrial appendage valve being pressurized to failure.**

## DISCUSSION

In this study, we evaluated the efficacy of RAA tissue for usage as a pulmonary valve. We found that the bicuspid RAA valve was able to withstand pressurization that exceeded 100 mmHg. A normal PA pressure has been found to be between 14 to 20 mmHg. Therefore, our results show that RAA tissue is able to function at pressures five times greater than the pressure the PA usually experiences [5]. This discovery is important because it shows us that as someone ages, the neo-RAA valve will be able to withstand PH that may develop overtime as the patient grows and develops.

Several limitations were present in this study. The first is that porcine heart tissue was used over human heart tissue. Porcine tissue may differ from the tissue of human hearts; however, porcine and human hearts do have similar characteristics [6]. The second limitation deals with the system used to induce pressurization on the pulmonary valve. The system used in the experiment was static, not a dynamic pressurization system. The third limitation is that a bovine patch was not used to repair the PT after the neo-RAA valve was placed. However, the PT was sutured closed with carefully placed sutures.

In conclusion, the results of the project are significant for furthering the understanding of the efficacy of RAA tissue being used as a pulmonary valve. Additionally, the current results reinforce the idea that RAA tissue is a good alternative material for reconstruction of the RVOT. Therefore, the experiment allowed us to quantify the pressure that the neo-RAA valve is able to withstand normal and severe PH conditions. With more experiments, the results could potentially lead us to the betterment of the surgical procedures used to correct the RVOT and PI.

# FACTORS CAUSING INTERVENTRICULAR INTERACTIONS IN THE HEART IMPLANTED WITH LEFT VENTRICULAR ASSIST DEVICE

**Lei Fan (1), Jenny S. Choy (2), Ghassan S. Kassab (2), Daniel Burkhoff (3) Lik Chuan Lee (1)**

(1) Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

## INTRODUCTION

Mechanical circulatory support devices such as the left ventricular assist device (LVAD) has been increasingly used to treat patients with end-stage heart failure. The incidence of right ventricular (RV) failure is common and is associated with substantial morbidity and mortality after LVAD implantation. The occurrence of RV failure has been hypothesized to be due to the alterations of mechanical interdependence between the left ventricle (LV) and RV, which refers to the effects of LV function on RV function and vice versa. The effects of LVAD on interventricular interactions have been observed in the clinic to vary between patients. The underlying mechanisms that cause such a variation is, however, unclear [1]. This is especially so when there are many possible factors contributing to an alteration in the interventricular interactions in LVAD patients. To address this issue, we develop computational models to investigate the effects of different factors on interventricular interactions.

## METHODS

An idealized biventricular finite element (FE) model is coupled with a closed loop lumped parameter circulatory model that describes both the systemic and pulmonary circulations (**Fig. 1a**). There are eight compartments with four cardiovascular components each in the systemic and pulmonary circulations. Conservation of total mass of blood in the circulatory model requires the change of inflow and outflow rates of each compartment be related to the rate of change of the volume. The functional relationship between the LV and RV pressures and volumes (i.e., $P_{LV,RV} = f(V_{LV,RV}, t)$) is obtained by minimizing a Lagrangian function consisting of myocardial tissue strain energy function and terms associated with the enforcement of constraints on **1)** myocardial tissue incompressibility, **2)** zero-mean rigid body translation and rotation, and **3)** cavity volume [2]. Mechanical behavior of the biventricular is modeled using an active stress formulation, in which the passive and active mechanical behaviors are described, respectively, by a Fung-type strain energy function and a modified time-varying elastance model [3]. The left atrium and right atrium are described by time-varying elastance models [4].

To model the LVAD, a pressure gradient-flow characteristics of a commercially available LVAD (Thoratec Corporation HeartMate III) is prescribed with an operating pump speed between 4k to 6k rpm (**Fig. 1b**). The LVAD pumps blood from the LV to the aorta at a flow rate that is determined by the aorta-LV pressure gradient and the operating pump speed based on the pump characteristics curve.

The modeling framework is first calibrated to obtain LV and RV pressure-volume (PV) loops that agree with clinical measurements from a patient with heart failure (HF). After model calibration, the model is

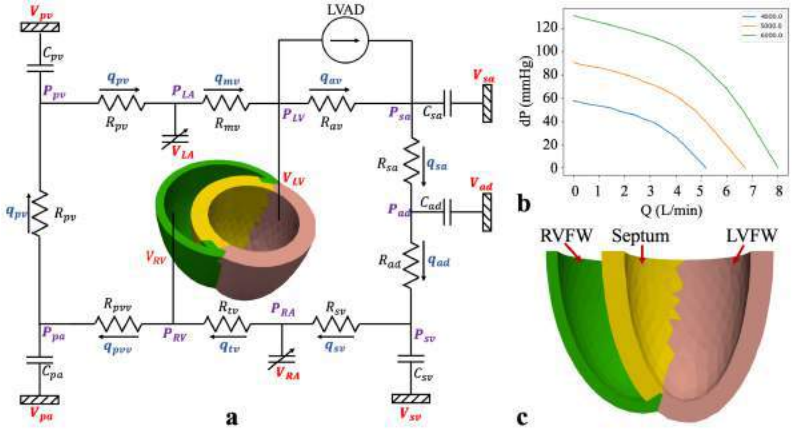

**Fig. 1**: **a.** Schematic of the coupled biventricular FE in a closed loop modeling framework; **b.** Pump characteristics curve used to model the LVAD; **c.** Schematic of the contours associated with the RVFW, septum and LVFW.

applied to investigate the effects of **1)** LVAD pump speed, **2)** myocardial contractility at 3 regions defined in **Fig. 1c**, and **3)** septal wall thickness (swt) on the LV and RV PV loops and interventricular interactions. Systolic and diastolic interventricular interactions are characterized, respectively, by changes in end-systolic pressure-volume relationship (ESPVR) and end-diastolic pressure-volume relationship (EDPVR) under different loading conditions. Specifically, ESPVR and EDPVR are obtained by connecting end-systolic and end-diastolic points in the RV PV loops with different RV preload. Changes in the gradient of ESPVR ($E_{es}$) and the RV volume at zero RV pressure ($V_0$) with different pump speeds are used to evaluate systolic interaction, while changes in RV volume at RV pressure of 20 mmHg ($V_{20}$) at different pump speeds is used to evaluate diastolic interaction.

## RESULTS

**Fig. 2** shows the effects of pump speed on the LV and RV PV loops, and the effects of pump speed regional contractility and swt on EDPVR and ESPVR. Without LVAD, the LV and RV PV loops predicted by the model show good agreement with clinical measurements from a HF patient (**Fig. 2a-b**). Implantation of LVAD resulted in a loss of isovolumic phases in the LV PV loop. When the pump speed was increased from 4k to 6k rpm, peak LV pressure was reduced from 104 to 71 mmHg. The LV PV loop shifted leftward (**Fig. 2a**) and became more triangular, indicating that the LV was increasingly unloaded. On the other hand, the RV PV loops shifted rightward toward higher volumes with elevated end-diastolic pressure (**Fig. 2b**). An increase in pump speed increased $E_{es}$ and $V_0$ of the RV ESPVR, indicating that the RV contractile function is affected by the LVAD (**Fig. 2c**). The quantity $V_{20}$ in the RV EDPVR was increased with increasing pump speed, implying that the RV passive chamber stiffness was reduced with LVAD (**Fig. 2c**). A reduction in contractility by 60% in either the LVFW, septum or RVFW (**Fig. 2d-f**) affects $V_0$ and $E_{es}$ in the RV ESPVR with respect to that at the same pump speed in baseline (**Fig. 2c**), suggesting alteration in systolic interaction. Conversely, EDPVR and $V_{20}$ are not affected, suggesting diastolic interaction is not affected. On the other hand, an increase in swt from 0.6cm in swt0 (**Fig. 2g**) to 3.0cm in swt3 (**Fig. 2h**) increases systolic interaction on ESPVR but reduces diastolic interaction on EDPVR.

## DISCUSSION

In this work, a biventricular computational modeling framework was developed to investigate the factors affecting interventricular interactions in the heart implanted with LVAD. The model predicted the LV and RV PV loops agree with the clinically measured data from a HF patient. The key findings of this work are listed as follows. **First**, with increasing pump speed, the LV PV loop became more triangular shaped with reduced LV peak pressure and volumes while RV volumes were increased with elevated RV filling pressure. **Second**, the model predicts that swt affects both systolic and diastolic interactions while regional contractility only affects the systolic interaction. These key findings, which clarifies the factors altering interventricular interactions in HF patients with LVAD, may have clinical implications in terms of patient selection for this treatment.

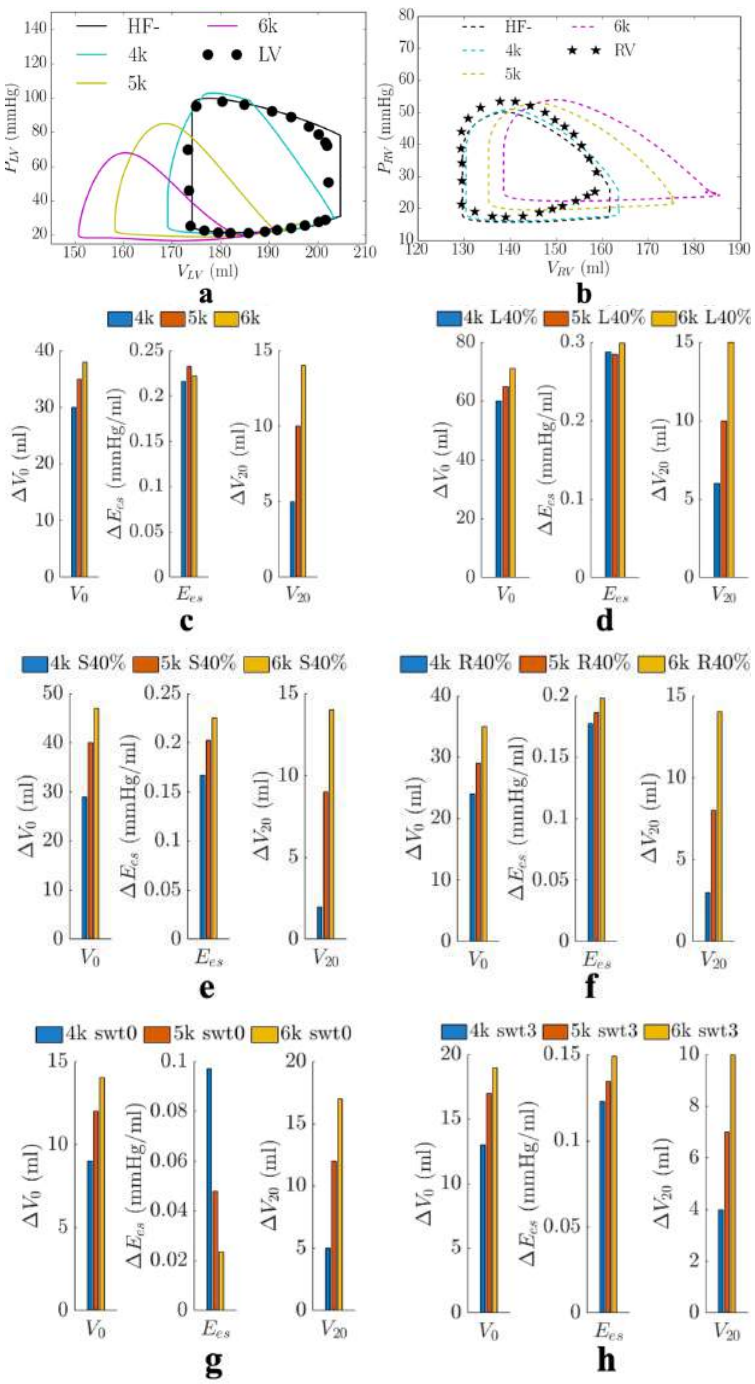

**Fig. 2**: Model predicted effects of the LVAD pump speed on the **a.** LV and **b.** RV PV loops are plotted together with clinical measurements from a patient with HF [1]; Effects of **c.** pump speed; reduction of regional contractility in **d.** LVFW; **e.** septum; **f.** RVFW; and **g.** reduced swt; and **h.** increased swt on systolic interaction indexed by $V_0$ and $E_{es}$, and diastolic interaction indexed by $V_{20}$. 'ED' and 'ES' denote EDPVR and ESPVR.

# PRE-EXPOSURE TO A PAINFUL STRETCH INCREASES BOTH LOCAL STRAINS & NEURONAL CALCIUM ACTIVITIY IN NEURON-COLLAGEN CONSTRUCTS ACROSS PHYSIOLOGIC & SUPRAPHSYIOLOGICAL STRETCH

## INTRODUCTION

The capsular ligament that encloses the facet joints of spinal vertebrae is comprised of collagen fibers and is innervated by afferent neurons [1]. Loading to the capsular ligament both directly and indirectly loads the embedded afferents via collagen fiber reorganization [2,3]. Supraphysiological loading of the capsular ligament activates nociceptive nerve fibers and increases calcium ion ($Ca^{2+}$) influx into the neuronal cytoplasm [4,5]. Further, repeated non-injurious distractions of the capsular ligament separated has been shown to be sufficient to induce pain [6,7], suggesting the initial stretch may lower the threshold for injury and neuronal activation. Despite these suggestions, it is unclear how afferent calcium activity is affected by a mechanical pre-exposure.

Primary afferents in the capsular ligament have mechanoreceptors that respond to matrix deformation [8]. Local strains that are at or below physiologic loading (~7%) are sufficient to upregulate and induce transport of NMDA receptor ion channels from the soma to extrasynaptic regions that would transport calcium ions intracellularly [9]. Although supraphysiological loading of afferents increases substance P and ATF3 expression after distraction [10,11], the extent to which a pre-stretch sufficient to induce pain may sensitize a neuron to subsequent stretch is unknown. Further, since local mechanical environment affects load transmission to afferents [11,12], defining relationships between neuronal activity and local strains after a pre-exposure provide important context.

The goal of this study is to examine the effects of a mechanical pre-exposure on modulating the local strains and neuronal calcium activity for different stretch scenarios within and exceeding the physiologic range. Neuron-collagen constructs (NCC) that mimic the microstructural environment of the capsular ligament were fabricated and a painful stretch was used a pre-exposure followed by another stretch after 2 days to allow for any transcriptional changes that may occur in the neuron [13-15]. NCCs were then exposed to macroscopic loading matching physiological, painful, and supraphysiological stretches experienced by the native ligament, and local strains and neuronal calcium activity were measured.

## METHODS

NCCs (n=9) were fabricated from 2mg/mL collagen and DRG neurons ($3x10^5$cells/mL) from embryonic day 18 rats [2,11]. The collagen solution was mixed with fluorescent microspheres (40nm dia; 558nm emission; 1:500; ThermoFisher) and self-assembled before plating neurons on the gel [16,17]. A DRG explant was also plated on each gel to serve as a reference for image tracking and analyses. After plating, neurons were cultured with neurobasal medium supplemented by 1% GlutaMAX, 2% B-27, 1% fetal bovine serum, and 10ng/mL 2.5S nerve growth factor (ThermoFisher). On day in vitro (DIV) 2, neurons were transduced with an AAV expressing GCaMP6f in the feeding media (1:5000 dilution) which causes them to transiently fluoresce at 488nm with calcium influx [18,19]. At DIV6, additional collagen (150µL) with fluorescent beads was added to encapsulate neurons in the NCC. For testing, NCCs were cut into a single strip (21mm x 7mm).

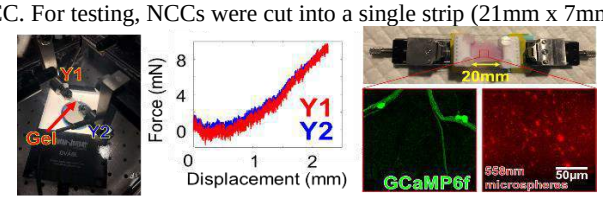

**Figure 1: NCCs were pre-exposed to painful PS before manual stretch measuring microsphere displacements & $Ca^{2+}$ activity.**

On DIV7, a subset of gels (n=5) was exposed to a uniaxial prestretch (PS) with each end clamped in a planar biaxial testing machine (TestResources) and displaced 2.3mm (Fig. 1) to induce strain (~22%) corresponding to capsular ligament distraction known to induce pain in vivo [20]. Distraction was applied at 0.06mm/s to match the rate of stretch applied manually during calcium imaging. Force and displacement data were acquired at 500Hz; a high speed camera

(500Hz; Phantom v9.1) tracked strains for each NCC. After prestretch, NCCs were transferred to fresh culture media supplemented by 1% penicillin-streptomycin for 48 hours.

On DIV9, PS (n=5) and unstretched (US; n=4) gels were clamped in a custom-built loading device for controlled manual stretch (Fig. 1). The device was placed on the stage of a Leica inverted spinning disc confocal microscope. A 20x water immersion objective imaged 2 fields of view (FOVs) for each gel. Image series (60s; 1024x1024 pixels$^2$) were taken at 20fps to visualize the initial position of the microspheres and baseline neuronal calcium activity as reference without any applied stretch [21]. The FOV x-y position of the microscope stage was stored; NCC were distracted to 3 relevant macroscopic stretch magnitudes as a proportion of its length: 10% (physiological), 25% (painful), and 40% (supraphysiological) [22]. At each stretch level, FOVs were imaged to capture microsphere positions and calcium activity. Microsphere displacements were tracked with ProAnalyst (Xcitex) and 4-node elements (n=139 PS; n=147 US) were generated; local maximum principal strain (MPS) was calculated for each element at reference and each stretch. Average elemental MPS was calculated and compared across stretch levels and group by a 2-way repeated measures ANOVA.

The custom MATLAB script, FluoroSNNAP, was used to segment neurons, and quantify the number of calcium events for each neuron (n=95 PS; n=71 US) in each FOV at each stretch level. Neurons were identified by a grader blinded to group and stretch level and segmented using each neuron's soma. The same neurons were analyzed throughout and the frequency of calcium events for each neuron was captured by a template-matching algorithm [23]. Average neuronal activity was calculated at each stretch level and compared using a 2-way repeated measures ANOVA. Histograms of neuronal activity were generated and distributions were compared using a non-parametric Mann-Whitney U test. The proportions of neurons with no or any calcium activity were also calculated and compared using Pearson's chi-squared tests.

## RESULTS

The prestretch generates macroscopic strains of 23.1±1.2% and a maximum force of 4.7±1.8N. NCCs exposed to prestretch experience greater ($p<0.04$) local strains at physiological (14.6±5.8%), painful (31.8±10.8%), and supraphysiologic (48.3±14.1%) stretch than gels that do not undergo the prestretch (13.3±3.8%; 26.0±12.5%; 39.4±16.4%) (Fig. 2). For both exposure groups, painful stretch generates greater ($p<0.01$) strains than the physiological stretch, and supraphysiological strains are greater ($p<0.01$) than those at painful stretch.

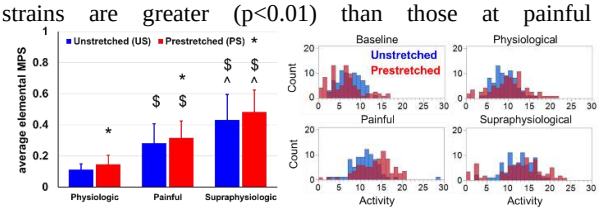

**Figure 2: Prestretched NCCs exhibit greater (*p<0.04) strains & calcium activity than unstretched NCCSs. Strain increases with stretch level for both groups ($^p<0.01).**

Although baseline calcium activity does not differ ($p=0.8$) between US (6.8±2.6), and PS (5.7±2.9), neuronal activity does differ ($p<0.01$) between exposure groups at all stretch levels. Also, the distributions of calcium activity differ between unstretched and prestretched NCCs, with more prestretched neurons exhibiting a greater frequency of calcium events (Fig. 2). This rightward shift compared to unstretched neurons is evident at each of physiological ($p=0.03$), painful ($p=0.04$), and supraphysiological ($p<0.01$) stretch (Fig. 2).

The proportion of neurons with increased activity between baseline and physiological stretch is greater ($p=0.04$) in unstretched NCCs (80%) than prestretched NCCs (76%) (Fig. 3). This trend differs at painful stretch where a greater proportion of neurons in prestretched gels than unstretched gels increase their activity over levels at physiologic stretch (US 62%, PS 72%; $p<0.001$) (Fig. 3). Yet, at supraphysiological stretch, the reverse occurs, with a smaller proportion of neurons experiencing increased activity from painful ($p<0.01$) to supraphysiological stretch in the prestretched (47.4%) group than the unstretched NCCs (Fig. 3).

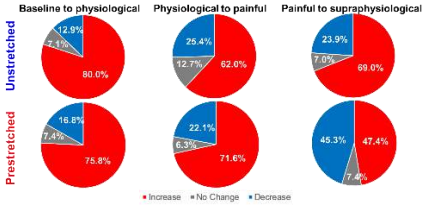

**Figure 3: Proportions of neurons that experience change in activity differs between pre-exposure groups ($p<0.04$).**

## DISCUSSION

The findings that a prestretch sufficient to induce pain (23%) imposed before mechanical stretch increases both the local strains and neuronal activity (Figs 2 & 3) is consistent with other in vivo and ex vivo studies reporting laxity in ligaments [6,24,25]. Since painful ligament loading can upregulate enzymes that remodel the extracellular matrix [26], the larger local strains in the pre-stretched specimens may be expected. Although the NCCs are primarily neuronal preparations, other cell types, like glia and fibroblasts, may be present due to isolation procedures and they can also upregulate matrix metalloproteinases and other digestive enzymes that may affect fiber-level kinematics, and bind selectively to neuronal receptors [17,21]. The increase in local strains and calcium activity observed in the PS gels (Figs. 2 & 3) could be attributed to increased receptor expression and/or enzymatic activity.

Painful prestretch also increases neuronal calcium activity (Fig. 2), which is not surprising since painful injuries increase neuronal hyperexcitability of afferents in loaded ligaments [8]. In fact, the prestretch magnitude in this study exceeds the threshold for neuronal activation via pERK upregulation (~11%) [2]. So, pre-exposed neurons would be expected to be sensitized and have a more robust response to loading [27]. Although immunohistochemistry was not performed here, studies probing associated mechanistic cellular responses are needed. Because local strains are greater in prestretched gels (Fig. 2), determining whether increased neuronal activity is due to more calcium channels, and/or changes in local mechanics is also needed.

# CRITICAL PRESSURE OF INTRAMURAL DELAMINATION IN AORTIC DISSECTION

**Ehsan Ban (1), Cristina Cavinato (1), Jay D. Humphrey (1)**

(1) Department of Biomedical Engineering, Yale University, New Haven, CT, USA

## INTRODUCTION

Aortic dissection is a deadly disease of the ascending aorta, where blood delaminates the arterial media as observed upon medical imaging after the acute onset of disease. Margot Roach et al. [1] performed seminal controlled experiments on porcine aortas and reported delamination of the aortic wall by ink injection using submillimeter-sized needles at ~547 mmHg (Fig 1a). The reported pressure is notably higher than normal blood pressure but could be within the range of the swelling pressure of glycosaminoglycans and proteoglycans by the Gibbs-Donnan effect [2]. The mechanics of tearing in the mentioned experiments have not been quantitatively analyzed. Here, we extended our previous model [3] of injection into a cut-open tissue to a cylindrical artery to model the mentioned experiments and assess the theoretical aspects of aortic delamination by fluid injection. We repeated the cited experiments to complement and verify our computational observations.

## METHODS

We computationally modeled the delamination process using a hydraulic fracturing phase-field finite element model [4]. The model consisted of ~500,000 elements and accounts for the deformation of medial elastin and smooth muscle, and four families of collagen fiber in the adventitia. The strain energy density of the wall is

$$W = \frac{\bar{c}}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) + \sum_{i=1}^{4} \frac{c_1^i}{4c_2^i}\left(\exp\left(c_2^i\left((\lambda^i)^2 - 1\right)^2\right) - 1\right). \quad (1)$$

$\lambda_i$'s and $\lambda^i$ are principal stretch ratios and stretch ratios along one of the four families of fibers, axial, circumferential, and two diagonal directions within the axial-circumferential plane. $c$'s are material constants determined from previous experiments on diseased aortic tissue [5].

Our contribution to the computational model was in the application of loading. We controlled the volume of injection or damage by adding the following term to the energy of the system, which was minimized to determine damage and deformation,

$$E_{\text{pressurized-fluid}} = mi\left(i\int_V \phi\lambda_1\lambda_2\lambda_3 idV - V_{\text{injection}}\right), \quad (2)$$

where $m$ is a global Lagrange multiplier. $\phi \in [0,1]$ is the tissue damage, and $V_{\text{injection}}$ is the prescribed volume of intramural fluid.

We performed complementary experiments by repeating the approach of Roach et al. [1]. Briefly, needles of two different sizes, 30- and 25-gauge, were used to assess the effect of the insult size on critical pressure. Eighteen descending aortic sections were harvested from Yorkshire pigs, used in separate studies, which did not affect the biomechanics of the aorta. Those studies were performed in accordance with protocols approved by the Institutional Animal Care and Use Committee of Yale University. The experiments included the injection of India ink within the medial layer of the aorta. As in the finite element model, the aortas were initially extended axially (to stretch ratios of 1.1 and 1.3) and pressurized to physiologic levels (130 mmHg), then injected locally with ink [4].

## RESULTS

The computational model reproduced the pressure-volume curves and shapes of the false lumens reported by Roach et al. (Fig. 1b and c). Moreover, the computational model indicated an increase of the critical pressure of tearing with increasing luminal pressure and decreasing size of the false lumen size (Fig. 2). The computational results were explained by a Griffith-type simplified analytical model (Fig. 2a, *inset*), indicating

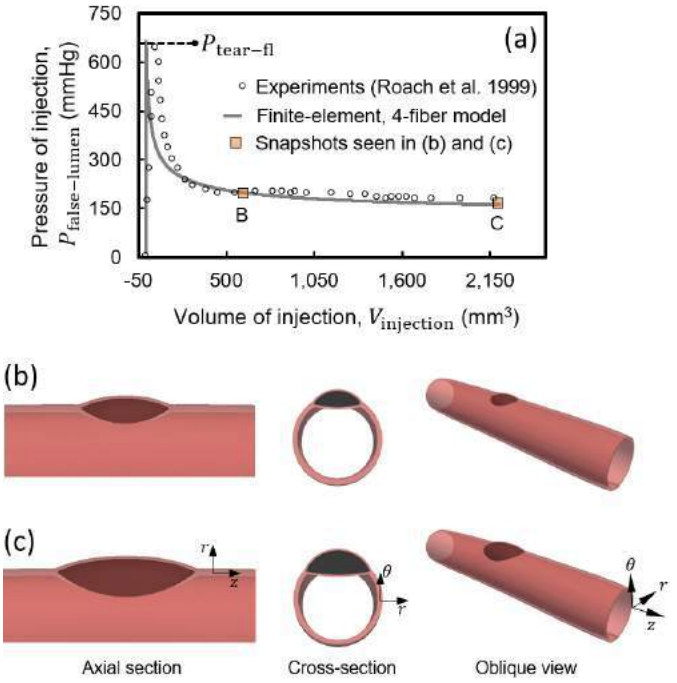

**Figure 1: Finite element hydraulic fracturing model of aortic delamination by fluid injection. (a) The pressure versus volume of injection, and (b and c) deformed and torn shapes of the aorta.**

$$P_{\text{tear-fl}}^{\eta} + (P_{\text{tear-fl}} - P_{\text{true-lumen}})^{\eta} = c^2 \propto K_t^{\alpha} G_c^{\beta} / A_{\text{torn}}^{\gamma}, \quad (3)$$

where, $P_{\text{tear-fl}}$ is the critical pressure of delamination, $K_t$, $G_c$, and $A_{\text{torn}}$ are related to tissue stiffness and strength and the size of the false lumen. $\alpha$, $\beta$, and $\gamma$ are positive exponents. The decrease of delamination pressure with increasing false lumen size was further verified by our complementary experiments (1.9-fold change between the 25- and 30-gauge needles, images in Fig 2b, *inset*).

## DISCUSSION

Unexpectedly, the results indicate a drastic drop in the pressure of delamination with increasing size of the false lumen. The critical pressure decreases from ~600 mmHg to ~200 mmHg as the tear size increases from less than a millimeter to 1 cm. While a large pressure is needed to initiate a weakening within the wall, this result confirms that an elevated pressure of blood may propagate centimeter-sized dissections. The tear propagation is unstable. As the tear propagates, the torn area becomes larger, and the pressure of delamination becomes smaller. This effect is consistent with the common observation of acute onsets of dissection.

The computational model did not restrict the path of tear propagation to any specific direction. But the tears propagated circumferentially in this model. This result agrees with the previous experiments [1] and our complementary ones (Fig. 2b, *inset*). Our additional computations using inhomogeneous wall properties confirmed the possibility of radial deviation of tears from the axial-circumferential plane by weakening or strengthenings in wall properties [4].

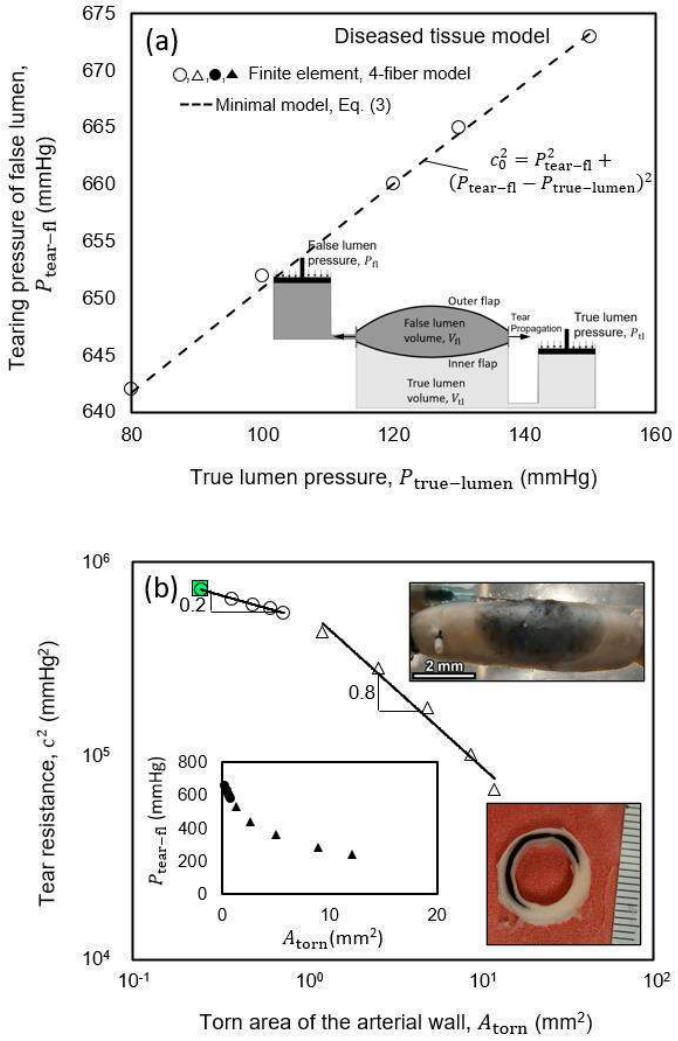

**Figure 2: Critical pressure of delamination versus (a) vessel pressure and (b) size of the torn tissue or the false lumen. Insets show (a) an schematic of the simplified analytical model, (b) and experimental images of tear propagation.**

## ACKNOWLEDGEMENTS

We thank the Sinusas Lab at Yale University for providing us with aortic tissue samples. This work was supported, in part, by a grant from the US National Institutes of Health (U01 HL142518).

# MECHANICAL CUES SUCH AS SHEAR STRESS AND PIEZO1 ACTIVATION GENERATE RED BLOOD CELL EXTRACELLULAR VESICLES

**Gurneet S. Sangha (1), Callie M. Weber (1), Ryan M. Sapp (1), Morgan E. Pettebone (1), Alisa M. Clyne (1)**

(1) Fischell Department of Bioengineering, University of Maryland, College Park, MD, USA

## INTRODUCTION

Red blood cells (RBCs) can affect vascular health by releasing extracellular vesicles (EVs), lipid-bound particles that facilitate intercellular signaling by transporting cargo (e.g., proteins, RNA) to other cells. RBC-EVs generated in pathological conditions, such as obstructive sleep apnea [1], sickle cell disease [2], or blood storage [3] exacerbate endothelial dysfunction, the initial hallmark of vascular disease. These atherogenic RBC-EV effects are partly attributed to hemoglobin, which can decrease endothelial nitric oxide synthase phosphorylation, scavenge nitric oxide, and increase oxidative stress [4]. However, healthy RBCs also lose 20% of their volume in the form of RBC-EVs throughout their 120-day lifecycle [5]. It is unclear how RBC-EVs generated in nonpathological conditions affect endothelial function and subsequent vascular health.

Shear stress may trigger RBC-EV production in nonpathological conditions by stimulating piezo1, a mechanosensitive ion channel that increases RBC $Ca^{2+}$ influx [6]. Indeed, RBC $Ca^{2+}$ influx caused by $Ca^{2+}$ ionophore treatment is a well-established method for RBC-EV production [7]. Furthermore, piezo1 activation also decreases RBC volume, possibly due to RBC-EV formation, and increases ATP [8], increasing atheroprotective nitric oxide in endothelial cells. Based on this evidence, we hypothesize that healthy RBCs undergoing capillary shear stress generate atheroprotective RBC-EVs through piezo1 induced $Ca^{2+}$ influx.

Here, we investigate whether shear stress generates RBC-EVs through piezo1 stimulation. To do this, we provide evidence that healthy RBCs generate RBC-EVs under shear stress conditions. We then show that chemical RBC piezo1 stimulation triggers RBC-EV production. Finally, we begin establishing methods to maximize piezo1 RBC-EV production and minimize protein contamination for future mechanistic studies. This research lays the groundwork needed to study the effects of healthy shear stress-induced RBC-EVs on endothelial function *in vitro*.

## METHODS

RBCs were pooled from two male and two female subjects and washed four times to remove the buffy coat consisting of white blood cells and platelets. RBCs were then resuspended in 50 mL PBS supplemented with 99 mg/dL glucose and 1 mM $CaCl_2$ at pH 7.4. All blood draws were approved by the University of Maryland Institutional Review Board.

To generate RBC-EVs via shear stress, RBCs (6% hematocrit) were sheared through a 2 inch, 25G needle 15 times. RBC-EVs were then concentrated from 50 mL to 400 µL using Amicon Ultra-15 centrifugal filter units (100 kDa molecular weight cut off). EV markers were detected in concentrated RBC-EVs samples by Western blot. Briefly, RBC-EVs were lysed by sonicating three times for 15 seconds and then loaded into NuPAGE 4-12% Bis-Tris protein gels. Proteins were then transferred to polyvinylidene difluoride membranes and detected using primary antibodies for ALIX (Santa Cruz; sc-53538), TSG101 (Santa Cruz; sc-7964), CD63 (Santa Cruz; sc-5275), and GAPDH (Cell Signaling, 2118S), along with the appropriate secondary antibodies. Lipid-bound EV particle size and concentration was quantified using tunable resistive pulse sensing (TRPS; qNano, IZON Science). CPC100 beads (mode diameter: 100nm) were used to calibrate NP100 nanopores to detect RBC-EVs between 50-330 nm. At least 500 particles were counted, using particle rate between 200-1500 particles/minute, at 5 and 10 mBar pressure.

To generate RBC-EVs via piezo1 stimulation, RBC (6% hematocrit) were treated with 100 µM piezo1 agonist yoda1 for 2 hours. 100 µM $Ca^{2+}$ ionophore was the positive control, and 0.28% DMSO was the vehicle control. RBC supernatant was centrifuged at 600xg for 20 min, 1600xg for 15 min, 3260xg for 15 min, and 10,000xg for 30 min to remove cell debris. The RBC supernatant was then ultracentrifuged two times at 100,000xg to concentrate and wash the RBC-EVs. RBC-EV size, concentration and EV markers were quantified as previously described. RBC-EVs were visualized using transmission electron microscopy (TEM).

To optimize the hematocrit % and yoda1 incubation time and concentration needed to generate piezo1 RBC-EVs, we treated 1) 1, 3, 6, 18% hematocrit with 100 µM yoda1 for 2 hours; 2) 6% hematocrit with 100 µM yoda1 for 0.5, 1, 2, 24 hours; and 3) 6% hematocrit with 1, 10, 100 µM yoda1 for 30 min. RBC-EV size and concentration, and EV markers were quantified as previously described. RBC-EV purity was calculated as the ratio between RBC-EV concentration measured using TRPS and total protein concentration measured using bicinchoninic acid assay.

Shapiro-Wilk normality test was performed on all datasets. We then performed a one-way analysis of variance (ANOVA) with a Tukey post-hoc test to determine statistical significance amongst groups. Data are shown as mean ± standard deviation.

## RESULTS

Needle shearing RBCs generated lipid-bound particles that contain EV markers. RBC needle shearing generated $6.3e^9$ particles/mL with a diameter of 101 ± 45.7 nm (**Figure 1a**). When RBC-EV were incubated with Triton X-100, which should lyse EVs, particle concentration decreased more than 10X to $3.7e^8$ particles/mL (**Figure 1a**). Western

blot confirmed that cytoplasmic EV markers ALIX and TSG101, and surface marker CD63 were present in shear stress RBC-EV (**Figure 1b**).

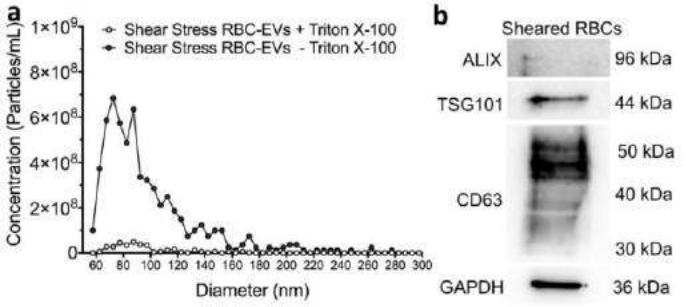

**Figure 1: RBC shear stress triggers RBC-EV production. TRPS measurement shows a decrease in lipid-bound particles after Triton X-100 treatment (a). Western blot confirms presence of cytosolic EV markers ALIX and TSG101 and surface EV marker CD63 (b).**

Chemical stimulation of mechanosensitive RBC piezo1 triggered RBC-EV production. RBC treated with piezo1 agonist yoda1 produced $2.8e^{12}$ RBC-EVs/mL at diameter 115 ± 49 nm. In contrast, $Ca^{2+}$ ionophore treatment produced EVs of similar size ($3e^{12}$ RBC-EVs/mL; 122 ± 52 nm diameter), while DMSO vehicle control produced 1000X less EVs of smaller size ($7e^{9}$ particle/mL; 78 ± 24 nm diameter; **Figure 2a**). Piezo1 RBC-EVs showed a biconcave morphology (**Figure 2b**) and were more enriched in ALIX and CD63 (**Figure 2c**; $p<0.05$) compared to $Ca^{2+}$ ionophore RBC-EVs.

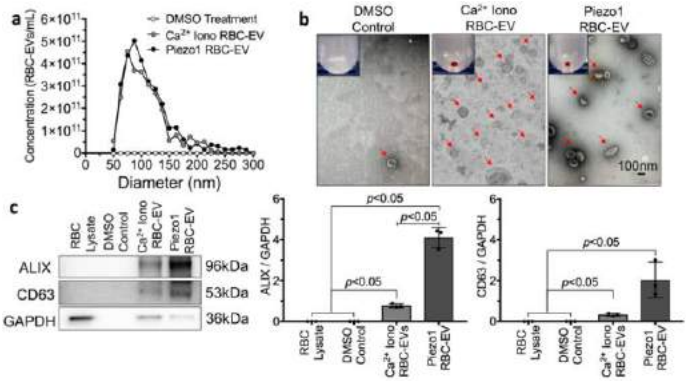

**Figure 2: Piezo1 activation produces unique RBC-EVs. RBC-EV size and concentration measured by TRPS (a). RBC-EVs visualized by TEM (b). Panel B inset shows RBC-EV pellet after ultracentrifugation. Red arrows highlight RBC-EVs. Western blot confirmed presence of EV markers ALIX and CD63 (c).**

Finally, we optimized our methods to generate piezo1 RBC-EVs using ultracentrifugation. While 1, 3, and 6% hematocrit showed increasing RBC-EV concentration ($2e^{11}\pm8e^{10}$, $6.7e^{11}\pm3e^{11}$, and $4.7e^{12}\pm2e^{12}$ particles/mL, respectively), 18% hematocrit did not generate significantly more RBC-EV than 6% hematocrit ($1e^{13}\pm6e^{12}$ particles/mL) when RBCs were treated with 100 µM yoda1 (**Figure 3a**). RBC-EV purity was greater in samples produced from 6% or 18% hematocrit than 1% or 3% hematocrit (**Figure 3b**). Yoda1 treatment for 30 min produced similar RBC-EV concentrations as 1, 2, and 24 hours treatments (**Figure 3c**). RBC-EV concentration did not increase when using yoda1 concentration above 10 µM (**Figure 3d**). Incubation time and yoda1 concentration did not affect RBC-EV purity. There were no significant differences in RBC-EV size when comparing the different hematocrit %, yoda1 incubation time, and yoda1 concentration conditions.

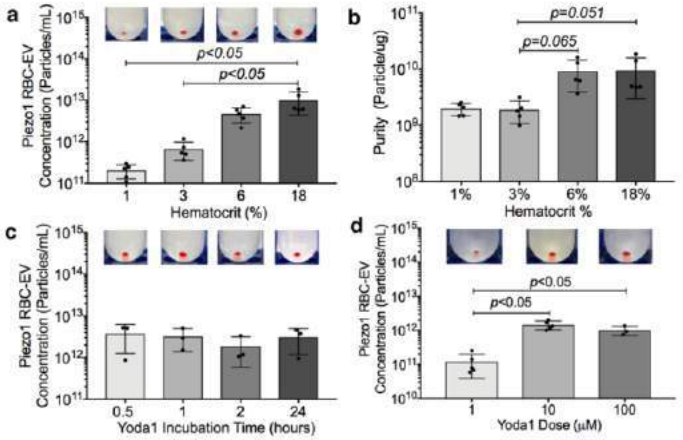

**Figure 3: Optimization of experimental parameters to generate piezo1 RBC-EVs. Both 6% and 18% hematocrit produced greater RBC-EV concentration (a) and purity (b) than 1 and 3% hematocrit. RBC yoda1 incubation time did not significantly affect RBC-EV concentration between 30 min and 24 hours (c). 10 µM Yoda1 maximized RBC-EV production (d).**

## DISCUSSION

This study provides evidence that shear stress may trigger RBC-EV production by stimulating mechanosensitive RBC piezo1. Furthermore, comparison of size, morphology, and EV biomarkers suggests that piezo1 RBC-EVs may be different from RBC-EVs generated by $Ca^{2+}$ ionophore or pathological conditions. Finally, 6% hematocrit treated with 10 µM yoda1 for 30 min yields the purest RBC-EVs isolated using standard ultracentrifugation.

In our future work, we will needle shear RBCs treated with piezo1 inhibitors to verify that piezo1 simulation during shear stress produces RBC-EVs. We will then perform functional assays to quantify how piezo1 RBC-EVs affect endothelial reactive oxygen species, inflammation, barrier function, and nitric oxide production. Understanding how shear stress-induced RBC-EVs affect endothelial function can lead to clinical biomarkers that improve cardiovascular disease diagnosis, treatment, and prognosis.

## INTRODUCTION

Prostate cancer (PCa) is the most frequently diagnosed cancer and the second leading cause of cancer death for men in the United States [1]. Radical treatments such as prostatectomy and radiation therapy are primary treatment options, but complications including erectile dysfunction (ED) and urinary incontinence are very common. Focal therapies are an emerging treatment modality that offer similar curative outcome but fewer side effects. Among them, cryosurgery represents an effective focal therapy treatment method for all stages of PCa [2]. One major complication associated with PCa cryosurgery is ED, caused by cryoinjury to the cavernous nerve in the neurovascular bundle (NVB), which is in close proximity to the prostate and is therefore directly exposed to freezing temperatures during cryosurgery. The use of cryoprotective agents (CPAs) to protect nerves against freezing temperatures is a method that has been used in nerve cryopreservation [3]. While existing literature establishes the idea of using CPAs to prevent nerve damage, there is still a lack of experimental data and quantitative models to study the effect of CPAs in preventing nerve cryoinjury during prostate cryosurgery. Moreover, no comprehensive study has assessed both the toxicity of CPA exposure to the nerve and the cryoprotective effectiveness within a repeatable and relevant biological model.

In this work, we developed an ex-vivo nerve model as representative of the NVB to investigate the toxicity and efficacy of a number of cryoprotective agent (CPA) in protecting the NVB from cryoinjury. The CPA cocktails includes different concentrations of DMSO-based, alcohol-based, and sugar-based cryoprotective agents.

## METHODS

**Prostate Cryosurgery Modeling:** To determine the thermal conditions experienced by the NVB during the PCa cryosurgery, we developed a model in COMSOL Multiphysics (Version 5.3) that mimics the conditions applied in a cryosurgery treatment of PCa. The 3D prostate model was reconstructed based on MRI images of a PCa patient. Four cryoprobes (P1-4) along with a urethral warmer (UW) are placed in the prostate as shown in Figure 1 A. The relative positions of the probes to the tumor and the NVB is shown on Figure 1 B. In order to find the temperature distribution within the prostate and on the NVB, Equation (1) was solved.

$$\rho c_p(T)\frac{\partial T}{\partial t} - \nabla(k(T)\vec{\nabla}T) + w_b c_b(T - T_a) = Q_{met} \qquad (1)$$

Where where T and t are temperature and time; $\rho$, $c_p$ and k are density, specific heat, and thermal conductivity of the biological tissues; $\rho_b$, $c_b$, $w_b$, $T_a$ and $Q_{met}$ represent blood density, specific heat, and perfusion rate, and arterial temperature and metabolic heat generation, respectively. Material properties used for the biological tissues in this model were taken from the literature [4,5]. The boundary conditions of the cryoprobe are determined by matching the isotherm (0, -20 and -40°C) diameters of the numerical model to those disclosed by the manufacturer, in a separate model.

***Ex vivo* Assessment of Neural Response to CPAs:** Freshly procured porcine phrenic nerves, supplemented with rat sciatic nerves, were rested in oxygenated modified Krebs-Henseleit buffer (KHB) before the experimental conditions were applied. There were 4 experimental groups: (1) control (No CPA exposure and no freezing) , (2) direct freezing (No CPA exposure, only freezing), (3) toxicity testing (No freezing, only CPA exposure) and (4) treatment (Both CPA exposure and freezing). The timeline of the experiment and the experiment setup are further elaborated in Figure 2. For CPA exposure, the nerves were exposed to oxygenated KHB mixed with CPA for 30 minutes before they were rinsed with the original KHB. The freezing condition was applied on the nerve using a cryostage (BCS 196, Linkam Scientific). The applied temperature profile, which is derived from the PCa cryosurgery model, was simplified and set as following: cooling to -10 °C with a cooling rate of -10 °C/min and thawing to room temperature with a warming rate of 10 °C/min. All nerves were further

incubated in oxygenated KHB at 37°C for 3 hours for recovery. To quantify acute cryoinjury, the AP was measured before and after the CPA exposure, right after the freezing and during 3 hours of recovery from freezing. The impact of the freezing was quantified by comparing the AP collected on the recording leads distal to the freezing point over time. The AP amplitude was normalized using the baseline of the AP amplitude of the first AP measurement, measured before CPA exposure or freezing. Normalized AP is the key indicator of the continuity of AP conduction, with 0 indicating complete blockage of the evoked AP at the freezing site.

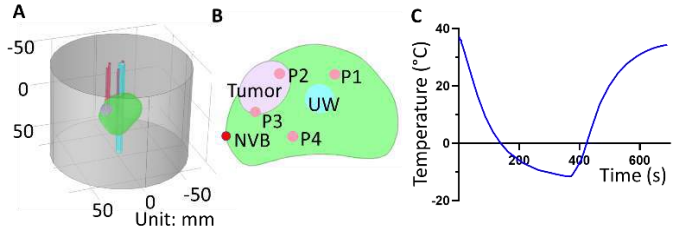

**Figure 1: A) Modeling geometry B) relative position of the probes, UW, tumor and NVB C) Temperature profile on the NVB**

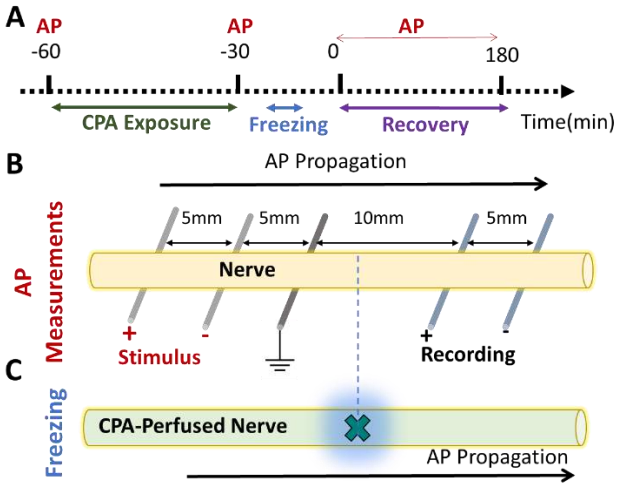

**Figure 2: A) Experiment timeline B) AP measurement setup C) Freezing location**

## RESULTS

The freezing condition that the NVB is experiencing during the cryosurgery is found by the modeling and is shown on Figure 1 C.

In both porcine phrenic and rat sciatic nerve models, the action potentials did not change substantially over time when the nerves were not exposed to freezing conditions or CPA, as confirmed by the positive control groups in Figure 3A (porcine phrenic nerve) and 3B (rat sciatic nerve). Exposing "Direct Freezing" group nerves (i.e. no CPA with freezing) result in an AP conduction halt and no recovery after freezing (AP amplitude =0 between 0 and 180 min) as shown in Figures 3A and 3B.

The CPAs which were tested on porcine phrenic nerves are listed on Figure 4A and 4B, along with their toxicity and cryoprotective efficacy. The CPA cocktail containing 5% DMSO and 7.5% Trehalose was non-toxic and showed the highest AP recovery ratio (0.48) at 180 min after freezing. The CPAs which were tested on the rat sciatic nerves are listed in Figure 4C and 4D, along with their toxicity and cryoprotective efficacy. Among all the CPAs evaluated, 5% M22 was not toxic to the nerves and showed the highest averaged AP amplitude after the freezing condition.

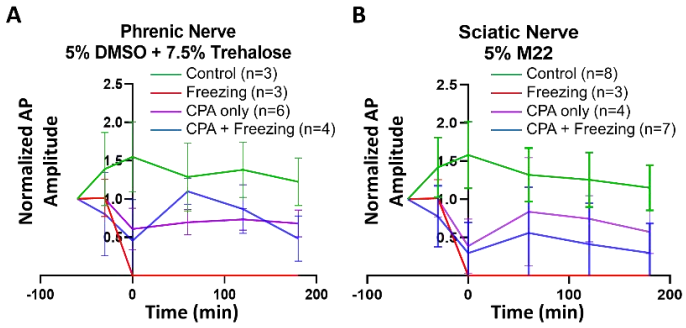

**Figure 3: Normalized AP amplitudes change over time for 4 experimental groups in A) porcine phrenic and B) rat sciatic nerve**

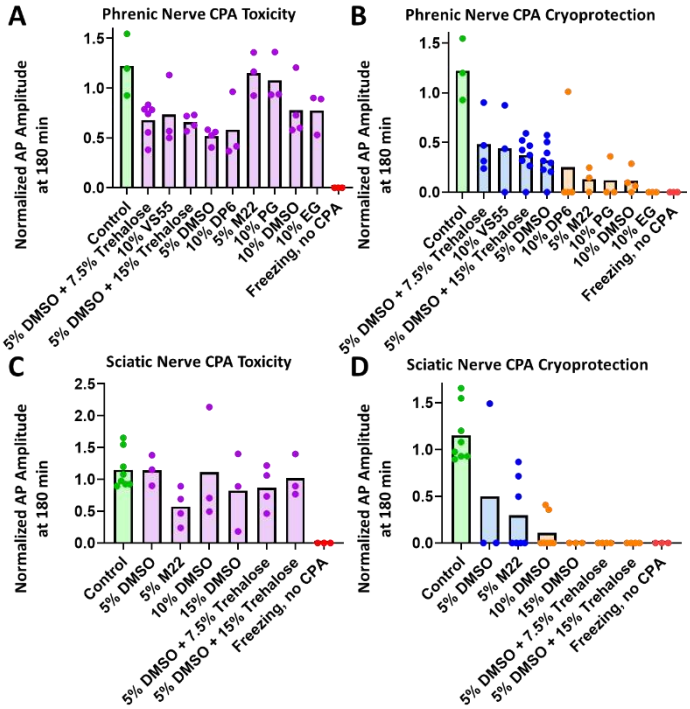

**Figure 4: Comparison of CPAs by their neural toxicity and cryoprotective efficacy.**

## DISCUSSION

In this work, we demonstrated preliminary feasibility of an approach to use cryoprotective agents to prevent cryoinjury to the nerves. This nerve-sparing approach have potential application in preventing cryoinjury to the NVB during prostate cryoablation. We developed an ex-vivo nerve model and tested different concentrations of several CPAs in terms of their toxicity and cryoprotective effects after freezing. The results show 5% DMSO and 7.5% Trehalose and 5% M22 are the most effective CPAs for protecting porcine phrenic and rat sciatic nerves after freezing, respectively. In-vivo and clinical studies will also be needed to confirm the efficacy and safety of this method.

## INTRODUCTION

COVID-19 disease, generated by a coronavirus called SARS-CoV-2, has caused a deadly worldwide pandemic. The viral infection can result in extensive tissue and organ damage, particularly in the lungs. Computed tomography (CT) images are valuable for analyzing heterogenous COVID-19 lung injuries such as ground-glass opacities (GGO) and areas of consolidation[1].

Physics-based computer models of the lung offer a virtual hypothesis-testing platform to gain a deeper understanding of pulmonary ventilation dynamics in healthy and disease states [2]. *In silico* modeling of COVID-19-afflicted lung mechanics may provide valuable insights into the multi-scale interactions of heterogenous acinar damage with lobar and whole-lung function.

This research aims to develop a physics-based multi-scale computational modeling pipeline for COVID-19-afflicted lungs by coupling airflow and lung tissue mechanics [3]. To this end, this study develops an *in silico* multi-scale workflow for simulating heterogenous patient-specific lung damage using a meso-scale acinar model coupled to a reduced-order conducting airway model.

## METHODS

This study utilized a 4D CT scan obtained during tidal breathing of a male patient hospitalized in Vidant Medical Center (Greenville, North Carolina, USA) with an advanced case of COVID-19. The methodology used in this paper was approved by the East Carolina University and Medical Center Institutional Review Board (UMCIRB) with study ID 20-001447. Informed consent was obtained from the patient.

The geometry of the first several airway generations visible in CT images and the lung lobes were segmented from the end-inspiratory and end-expiratory phase using Mimics 23.0 (Materialise NV, Belgium) and the Chest Imaging Platform in 3D Slicer [4]. A space-filling airway generation algorithm with random heterogeneity was then used to create 16 generations of conducting airways [5]. The model included 30,142 acini, each coupled to a terminal bronchiole. 3D Slicer was also used to segment the aerated, GGO, and consolidated COVID-19 regions using the Hounsfield values in the CT images [6].

The C++ simulation package CHASTE (Cardiac, Heart, and Soft Tissue Environment) was used to establish the multi-scale coupling between the macroscale airflow and the meso-scale acinar mechanics model[7]. The airflow equation was presented as a modified Poiseuille flow with corrections to dynamic resistance [3].

Airflow was driven by changes in acinar volume of each of the approximately 30,000 acini as a function of the fluctuating pleural pressure of the lung. Pleural pressure varied based on Equation 1:

$$P_{pl} = P_{plimax} + \frac{\Delta P_{pl}}{2}\left(1 - \cos\left(\frac{2\pi t}{T} + \Phi\right) + \pi\right) + P_g \qquad (1)$$

where $P_{pl}$ is pleural pressure, t is simulation time, T is the inspiration-to-inspiration breathing period (four seconds for this simulation), Φ is a phase shift, and $P_g$ is pressure due to gravity

Acinar mechanics were represented by a sigmoidal transpulmonary pressure-volume relationship, incorporating different levels of tissue damage through increased surface

tension and decreased compliance [8,9]. The coefficients for the sigmoidal acinar model were selected based on patient-specific characteristics, including patient sex, height, and age. A hypothetical healthy lung simulation without any tissue damage and a COVID-19-afflicted lung simulation with heterogeneously-distributed damage were run for 12 seconds (three breathing cycles) on a workstation with 128 GB of RAM and a 14-core Intel Xeon CPU.

## RESULTS

Our image analysis based on segmentation of CT images showed that the right middle lobe exhibited the least amount of COVID-19-induced damage (29.6% of the lobe volume was made of GGO and consolidated regions), while the right lower lobe had the highest COVID-19-induced damage presence (78.2% of the lobe volume was made of GGO and consolidation areas). In our simulations, the least damaged lobe (right middle) demonstrated a far more minor change in tidal volume and flow between healthy and diseased simulation scenarios (Figure 1).

Furthermore, the COVID-19 simulation scenario demonstrated a re-distribution of ventilation from the most injured lobes (right upper, right lower, and left lower) to the least injured lobes (right middle and left upper lobes). The pressure distributions in the lung for each simulation are shown in Figure 2. These images show that the diseased case simulation demonstrated more heterogeneity in air pressure distribution throughout the lung with lower pressure magnitude on average.

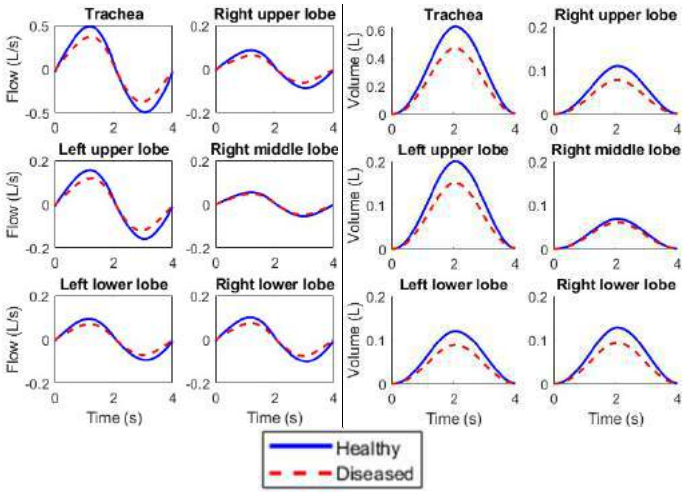

**Figure 1: Whole lung and lobar tidal airflows (left) and tidal volumes (right) for the healthy and diseased simulation scenarios.**

## DISCUSSION

This study presents a multi-scale modeling pipeline to simulate patient-specific heterogeneous COVID-19-induced damage and compares the results to a hypothetical healthy lung simulation scenario.

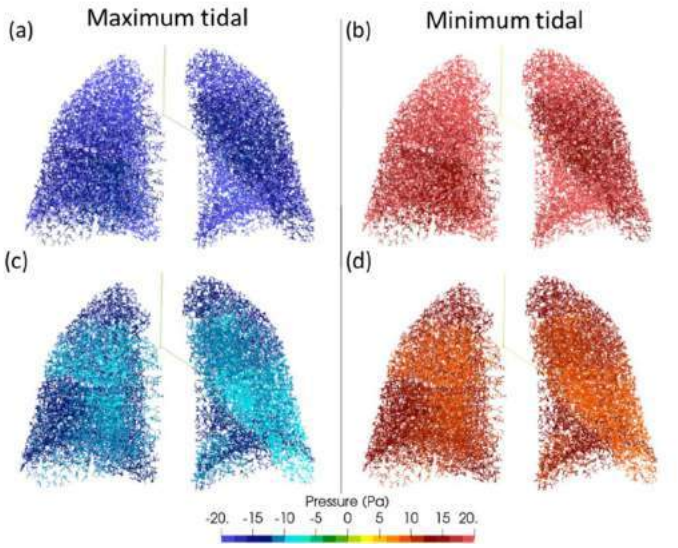

**Figure 2: Pressure distribution in coronal view of the healthy (a,b) and diseased (c,d) lung simulation scenarios at maximum inspiration and expiration.**

Our simulation results show that as damage manifested in the patient's right upper, right lower, and left lower lobes, ventilation was redistributed to the patient's less damaged lobes (right middle and left upper lobe), which is in agreement with recent clinical observations [10]. Moreover, our multi-scale model reasonably simulated a decrease in overall tidal volume as a consequence of tissue injury and surfactant loss in the meso-scale acinar mechanics model.

The presented *in silico* study is a step towards building digital twins of the human lung incorporating subject-specific heterogenous tissue damage to gain a deeper understanding of pulmonary ventilation and eventually individualized treatment strategies.

## INTRODUCTION

Articular cartilage (AC) covers and protects the ends of long bones in synovial joints, enduring roughly a million loading cycles every year for multiple decades. AC is surrounded by synovial fluid, a thick, viscous liquid that lubricates and provides nutrients for the tissue. While the lubricating properties of synovial fluid are mostly due to the presence of hyaluronic acid, since synovial fluid is formed from filtered blood plasma, it is also replete with plasma proteins such as albumin (the most abundant molecule in synovial fluid [1]). These macromolecules can freely diffuse into cartilage interstitial fluid (CIF), the liquid component of cartilage that comprises >70% of the tissue and provides most of the tissue's resistance to mechanical load [2]. Interestingly, concentrations of albumin and other plasma proteins are markedly increased in joints affected by osteoarthritis (OA) [3], a devastating disease whose most prominent feature is progressive cartilage degeneration. However, it is not known how soluble macromolecules (such as albumin) in CIF affect cartilage function and whether they may contribute to OA pathogenesis.

To begin to address this knowledge gap, the objective of this research was to determine how soluble macromolecules that accumulate in cartilage influence its mechanical properties and, consequently, the vulnerability of cartilage cells (chondrocytes) to loading. Since the size of albumin is close to the average size of cartilage pores, we hypothesized that albumin-sized macromolecules in cartilage would interfere with interstitial fluid flow and reduce permeability $k$, a measure of the ease with which fluid is squeezed from compressed cartilage. Given that fluid outflow diminishes fluid load support, we further hypothesized that soluble macromolecules would ultimately make chondrocytes in loaded cartilage less vulnerable to injury for short loading durations by slowing fluid exudation.

## METHODS

Mechanical testing was performed on a total of 168 C57BL/6 mouse humeral cartilage-on-bone specimens from 84 <10-month-old mice using our established method [4-5]. This method enables visualization of cell death in mouse cartilage-on-bone explants subjected to prescribed mechanical forces under controlled *in vitro* conditions. The explant is placed cartilage-side-down on a glass slide, and a prescribed load is applied on the opposite side by a weight directed by a guide block. The cartilage – which is stained with fluorescent live dead cell indicators – is imaged through the objective of an inverted fluorescence microscope under the glass slide. We previously showed that 1N loading generates a circular area of cell death in humeral explants whose area correlates strongly with peak cartilage strain.

In the current study, we used this method to assess chondrocyte death induced by 1N loading sustained for 20s or 5min in explants that had been cultured under varying conditions to facilitate uptake or release of soluble macromolecules into or out of the cartilage prior to mechanical testing. We investigated several soluble macromolecules, including albumin and both 40 kDa and 270 kDa dextran (a polysaccharide with a similar structure to hyaluronic acid) at concentrations ranging from 3 to 30 mg/mL. Explants were incubated in solutions containing high or low concentrations these macromolecules to drive them into or out of the tissue via concentration gradients. For specimens incubated in high concentrations of dextran, fluorescence micrographs of explants after incubation confirmed infiltration of this macromolecule into the tissue (not shown).

After mechanical testing, we used inverse finite element modeling (iFEM) to determine the biphasic/poroelastic material properties (permeability $k$ and solid matrix Young's modulus $E$) of tested specimens from select treatment groups based on the extent of cell death 20s and 5min (respectively) after 1N loading. First, we calculated the "experimentally measured" peak strain in each specimen (for a given loading duration) by converting cell death area to peak tissue strain using our previously established relationship between these parameters. Next, we simulated the loading experiment using a finite element model generated in FEBio and varied $k$ and $E$ until the peak strain output by

the model at 20s and 5min (respectively) matched the experimentally measured peak strains for these loading durations.

We also performed experiments to determine how diffusivity of small molecules – a measure related to tissue permeability – is influenced by macromolecular infiltration. First, humeral cartilage-on-bone explants were incubated in a solution of low MW (3kDa) fluorescent dextran, after which the tissue appeared bright under fluorescent illumination due to infiltration of the solute. Next, explants were incubated in solutions with larger macromolecules including 40kDa dextran, albumin, and polyethylene glycol (PEG). Finally, a 1N force was applied onto each specimen and removed after a prescribed duration. Immediately after *unloading*, a circular, dark (non-fluorescent) area appeared due to tissue intake of non-fluorescent buffer from the surrounding bath. This dark region briefly grew, reaching its maximum size in about 3s before shrinking as fluorescent 3kDa molecules diffused in from the edges, a process that lasted tens of seconds. Based on the speed of fluorescence recovery, the diffusion constant of 3 kDa FITC-dextran in the tissue was determined.

**RESULTS**

In experiments to test the relationship between area of cell death and loading time, as expected, we found that for both fresh explants and explants cultured for 2 days in standard media (2-day culture w/o dextran, used to desorb interstitial solutes present at baseline), significantly more cell death was induced for 5min loading (assumed to reflect the equilibrium state without load supported only by the solid matrix) than for 20s loading (**Fig. 1a**). However, cell death area in explants cultured for 2 days in media with 30mg/mL 40 kDa dextran (2-day culture w/ dextran) prior to 1N loading was not different for 20s and 5min loading durations. Moreover, cell death area for 20s loading in explants cultured with dextran was significantly higher than fresh explants and explants cultured without dextran. In contrast, cell death area for 5min loading was not affected by incubation in media with or without dextran. Using iFEM, we found that the solid matrix Young's modulus $E$ was not significantly altered by 2-day culture w/ or w/o dextran (**Fig. 1b**). However, 2-day culture w/o dextran led to decreased $k$, while explants subjected to 2-day culture w/ dextran had higher $k$ than both fresh explants and explants subjected to 2-day culture w/o dextran (**Fig. 1c**). The effects of 2-day culture with other macromolecular solutes including albumin (not shown) were similar to 40 kDa dextran (increased cell death area for 20s loading, but no change in cell death area for 5min loading). Moreover, the effects were reversible (not shown) and were not reproduced when a small solute (the ionic compound NaCl) replaced the tested macromolecules in the incubation media, even at high osmotic concentrations (485 mOsm for NaCl compared to 335 mOsm for 40kDa dextran).

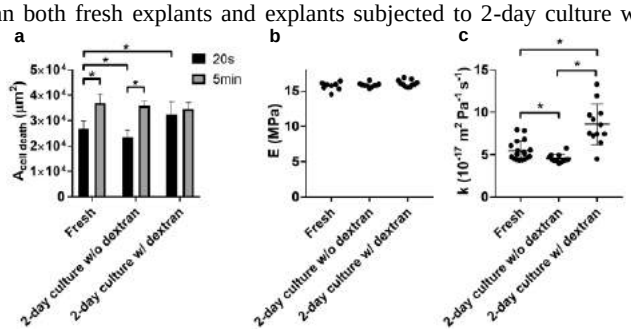

**Fig. 1: (a) Comparison of cell death area for 20s and 5min loading across treatment groups. Data are mean ± SD. (b-c) Comparison of (b) Young's modulus $E$ and (c) permeability $k$ across treatment groups as determined through iFEM.**

In experiments assessing the diffusion constant $D$ of cartilage for a small solute (3kDa dextran), we found that like $k$, $D$ was significantly increased by infiltration with macromolecular solutes including 40kDa dextran and albumin (data not shown).

**DISCUSSION**

Our data suggest that, contrary to our hypothesis, uptake of large (~40kDa) macromolecules into articular cartilage *increased* tissue permeability, while desorption of solutes from fresh explants *decreased* permeability. Increased permeability likely explains the measured increase in cell death area induced by 1N/20s loading after absorption of different macromolecular solutes. Under a constant load, fluid is gradually squeezed out of cartilage, leading to a progressive increase in tissue strain (creep) as fluid load support is lost. When permeability increases, this process is faster and tissue strain is higher for a given (short) loading duration. Thus, chondrocytes become more susceptible to injury after 20s loading. In contrast, our data suggest that macromolecular uptake does not affect equilibrium tissue properties (e.g., $E$). Specifically, cell death area for long loading durations (5min) that extend into the steady state – i.e., when fluid flow ceases and fluid support is absent – was not influenced by these molecules.

A limitation of this study is that permeability was not directly measured, but was rather inferred based on load-induced cell death area in combination with inverse finite element modeling. However, our finding of increased permeability is corroborated by our separate diffusion constant measurements, which demonstrate that macromolecular infiltration increased small molecule diffusivity – a metric that generally scales with permeability.

It does not appear that our unexpected findings can be explained by current models, which suggest macromolecules at the concentrations studied (orders of magnitude lower than the concentration of ions such as $Na^+$ in cartilage) should have a negligible effect on tissue mechanics. For example, biphasic solute/triphasic models (constructed in FEBio) did not reproduce the phenomenon we observed (data not shown). Moreover, the finding that permeability was not similarly altered by small molecules (ionic compounds) suggests the origin of the observed phenomenon was not tissue-wide alterations in osmolarity. Thus, we developed an analytic model that accounts for pore-size-dependent penetration of large macromolecules into the cartilage ECM, leading to osmotic pressure gradients that alter pore dimensions and modify tissue permeability. Our model assumes the tissue has a heterogeneous pore structure, consistent with findings of prior work [6]. We further assumed that because the size of the tested macromolecules is close to the average pore size in cartilage, these solutes can only infiltrate the widest pores, generating an osmotic pressure that in turn grows these pores at the expense of narrow pores and alters tissue permeability. Values of most model parameters were taken from the literature. A model parameter dependent on unknown variables (such as the pore tortuosity) was set to a value that ensured consistency with the measured tissue permeability after 2 days of culture in standard media without large solutes ($k^{measured}_{w/o i dextran} = 4.0 \times 10^{-17}\,\frac{m^2}{Pa \cdot s}$), when the tissue was assumed to be macromolecular solute-free. According to a calculation based on our model, we found that $k^{predicted}_{w/i dextran} = 7.9 \times 10^{-17}\,\frac{m^2}{Pa \cdot s}$, consistent with out experiments that yielded $k^{measured}_{w/i dextran} = 8.5 \times 10^{-17}\,\frac{m^2}{Pa \cdot s}$ with a range of $4.5 \times 10^{-17}\,\frac{m^2}{Pa \cdot s}$ to $13.2 \times 10^{-17}\,\frac{m^2}{Pa \cdot s}$.

**ACKNOWLEDGEMENTS**

We thank Dr. Whasil Lee for help with osmolarity measurements.

## INTRODUCTION

After aging, vaginal childbirth is the greatest risk factor for the development of pelvic floor disorders[1,2], which may result from acute injury or accumulated microdamage sustained by the pelvic floor tissues during vaginal delivery in conjunction with alterations to tissue architecture and function associated with aging and menopause. During vaginal childbirth, pelvic floor tissues must stretch to accommodate the fetus, peaking during fetal crowning which is when injury likely occurs.

It is apparent that the shape of the female pelvic anatomy plays a role in vaginal childbirth mechanics. Studies have shown that cephalopelvic disproportion (referring to the fetal head and maternal pelvis) can cause obstructed labor—when the fetus cannot physically fit through the obstetric outlet of the maternal pelvis[3]. While existing literature has predominantly focused on the shape of the bony pelvis, it is probable that the shape of the pelvic floor muscle complex would also impact childbirth biomechanics.

This study aimed to evaluate the influence of variation in maternal pelvic morphology on the biomechanics of vaginal childbirth—specifically, pubovisceral muscle and perineal body strains, which are common sites of maternal birth injury. We hypothesized that variation in specific shape attributes—quantified by principal component analysis (PCA)—would significantly impact predicted strains.

## METHODS

The 6 geometries in this study were outputs of a statistical shape model of the combined bony pelvis–pelvic floor muscle complex of pregnant women. This model was built based on imaging data from 34 pregnant women (17 in the 1st/2nd trimester and 17 in the 3rd trimester, ranging in age from 20-49 years and in race/ethnicity)[4]. PC scores (parameters that define the 3D shape) were chosen using Latin Hypercube Sampling[5]. The resulting geometries were imported into Houdini FX (SideFX, Toronto, CA) for computation and simulation.

Regions of interest were defined by the corresponding surface mesh vertices from the statistical shape model. Then volume meshes were created. Each coccyx was made of ~10,000 tetrahedral elements, the sacrum and innominate bones as a unit of ~50,000 tetrahedral elements, and the pelvic floor muscle complexes of ~28,000 tetrahedral elements. The fetal head—identical for each simulation—was a sphere with a diameter of 90 mm[6,7] and composed of 8,048 tetrahedrons.

The sacrum and innominate bones were fixed in all degrees of freedom. The superior coccyx was fixed to the last sacral vertebrae which allowed rotation about the sacrum, while the lower tip of the coccyx was fixed to nearby vertices of the pelvic floor muscle complex. The pelvic floor muscle complex was fixated to the bony pelvis at the ischial spines, inferior ischiopubic rami, pubovisceral muscle entheses, and at the location of the clitoral ligament. Contact was defined between all parts of the fetal head, pelvic floor muscle complex, and bony pelvis and optimized to minimize penetration between meshes.

The fetal head and bony pelvis were treated as rigid bodies, with Lamé parameters 3 orders of magnitude larger than the soft tissues. Pelvic floor muscle material properties were determined by approximating the slope of stress-strain curves from literature (obtained from *ex vivo* uniaxial tensile testing of younger human female cadaveric pelvic floor muscles)[8]. The estimated Young's modulus of 200 kPA and a selected Poisson's Ratio of 0.49 were converted to Lamé parameters. The anococcygeal ligament material properties were set as the secant modulus of human uterosacral ligament uniaxial testing along the main loading direction[9]. This resulted in a modulus of 8 MPa and a selected Poisson's Ratio of 0.49, which were also converted to Lamé parameters.

Each geometry underwent 2 simulations: 1) A force-driven simulation to determine a geometry-dependent fetal head path and, 2) A displacement driven simulation with a fully prescribed fetal head path from which strains were calculated (Figure 1). This workflow allowed for geometry-specific fetal head paths while increasing simulation stability and reducing penetration issues.

Strain was not measured at the element level in this study as issues with negative Jacobians are still being resolved. Pubovisceral muscle length was averaged across the left and right muscles and defined as the distance from the midpoint of the enthesis to the centroid of the perineal body. Perineal length was defined as the sum of the distance from the left edge to the centroid and the right edge to the centroid. Both lines were calculated as the perineal body bends significantly around the fetal head during childbirth (see Figure 1). Strain was defined as the change in length over the original length and peak strains were determined. Bivariate correlations analyzed relationships between shape (defined by a set of 7 PC scores) and pubovisceral muscle and perineal body strain.

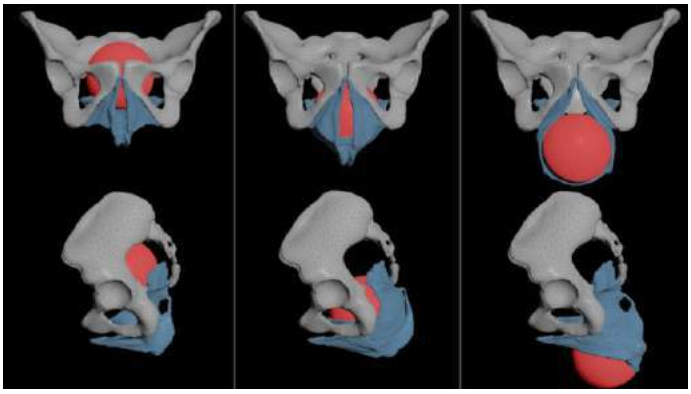

**Figure 1: A vaginal childbirth simulation from inferior (top row) and left, sagittal (bottom row) views. The fetal head (red), bony pelvis (gray), and pelvic floor muscle complex (blue) are shown at time 0 (left column), the halfway point (middle column), and at peak strain (right column).**

## RESULTS

Pubovisceral muscle and perineal body strains varied across the 6 simulations (Figure 2). PC 2 and 3 scores were significantly correlated with perineal body strains ($\rho$ = -0.747 and 0.811 and p = 0.044, and 0.025, respectively). PC 3 was significantly correlated with pubovisceral muscle strains ($\rho$ = 0.759 and p = 0.040). These PCs describe variation in the curvature of the bulbocavernosus muscle, relative location of the perineal body, iliococcygeus muscle convexity/concavity, and relative size of the coccyx. These correlations between strains and PC scores suggest that perineal body and pubovisceral muscle strains were higher when there was less anterior bulging of the bulbocavernosus muscle, a more superior perineal body, greater iliococcygeus convexity, and a proportionally larger coccyx.

## DISCUSSION

This study demonstrates that anatomical variation in the maternal bony pelvis and pelvic floor muscle complex morphology significantly impacts predicted strains in simulations of vaginal childbirth. This indicates that the shape of pelvic anatomy with respect to pregnancy and childbirth should be studied further and that studies need to consider morphological variation (or lack thereof in their work) when drawing conclusions from finite element simulations of vaginal childbirth.

The posterior and inferior displacement of the fetal head, and, therefore, the corresponding displacement of the pelvic floor tissues, is going to meaningfully impact the strains those tissues experience. As such, it is logical to assume the initial shape of the pelvic floor muscle complex would also impact resulting strains. For example, if the iliococcygeus muscle is in a more convex configuration at the onset of labor, that muscle will need to be pushed further posteriorly and inferiorly (resulting in increased strains) compared to a more concave iliococcygeus to accommodate a fetal head of comparable size. This explains how soft tissue morphology (alone, but also in conjunction with bony pelvis shape) influences pelvic floor muscle complex strains.

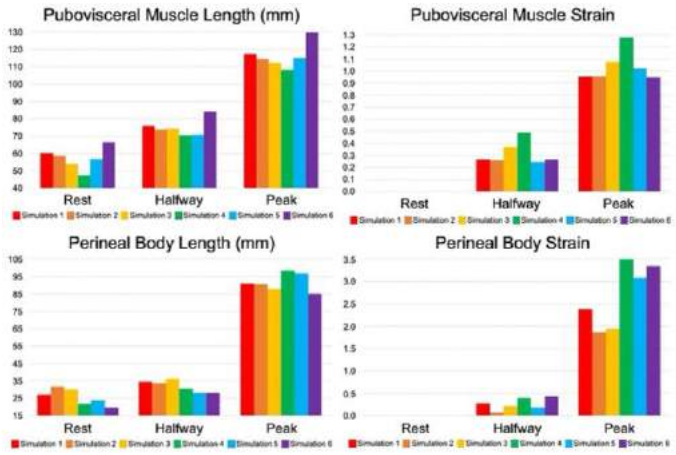

**Figure 2: Histograms demonstrating the variation in the length and strain (distension) measures calculated for each simulation.**

Strain was not measured directly in this preliminary study due to the presence of negative Jacobians (which ongoing efforts aim to resolve). However, Houdini is able to reasonably simulate gross motion and mechanics even in the presence of such issues, allowing for the use of the described approximate strain measures. With the resolution of these issues and the addition of more unique geometries, these results can be more robustly validated. Additionally, the statistical shape model these geometries were generated from only considered pregnant anatomy. Many existing simulations of vaginal delivery use nonpregnant, older, or even cadaveric data when building the geometry for such simulations, which likely results in even more disparity in predicted strain values than demonstrated here.

In its current form, this study demonstrates the utility of a combined statistical shape—finite element modeling workflow, which allows for more consistency across multiple geometries while still allowing for geometry-specific effects. This was a novel endeavor demonstrating that both bony pelvis and pelvic floor muscle complex shape play an important role in the biomechanics of vaginal childbirth.

## INTRODUCTION

Among all the morphological parameters, muscle volume has a good correlation with muscle strength[1]. Patients with Achilles tendon injuries experience structural changes of their tendons and significant atrophy of calf muscles[2]. Understanding the morphology of the gastrocnemius muscle and measuring muscle volume is important to determine the effectiveness of treatments and rehabilitation strategies for Achilles' tendon rupture. Currently, Magnetic Resonance Imaging (MRI) is the most precise imaging method for measuring muscle volume in vivo. While MRI provides detailed data, the employment of MRI technology is not free of cons. Obtaining MRI images is time-consuming, and it is more expensive comparing other imaging methods. In addition, MRI is not a convenient method for individuals with metal implants and other contraindications to MRI. 3D ultrasound (3DUS) is another technique that can be used to quantify muscle volume by combining multiple 2D cross-sections of the muscles [2, 3]. Requiring multiple cross-sectional images and time for combining these images make 3DUS hard to use for routine checkups. The second way of estimating the muscle volume is based on morphological parameters like a cross-section area, length, and thickness of the muscle. These morphological parameters can be obtained by ultrasound and/or panoramic ultrasound (PU) imaging. Since the muscles do not have simple geometries, the geometrical parameters must be 'calibrated' by shape factors to have an acceptable estimation of the volume of the muscles. Bandholm et al utilized ultrasound techniques for measuring the thickness and length of the muscle to estimate the gastrocnemius and soleus volume [5]. Vanmechelena et al combined the anatomical cross-sectional area of the muscle and muscle length to suggest the simple equations estimating the muscle volume [6]. Due to the complex shape of the gastrocnemius muscles, additional morphological information may be required to obtain a better estimation of muscle volume. The objectives of this study are to use two panoramic ultrasound images to capture the cross-section areas in two orthogonal planes and to evaluate an equation to estimate the gastrocnemius muscle volumes (GMV).

## METHODS

This study was approved by the Penn State University IRB (STUDY00019121). Five healthy young adults (three females, two males, age=30.8±1.9, weight=67.6±15 kg, height=167±7 cm) participated in this study. Participants had no recent injuries, disease, surgeries, or metals in their lower limbs. Participants were asked to lay on a bed still but relax during the MRI imaging procedure. Wedges are used under the participants' ankles to eliminate the contact of the gastrocnemius muscle and the MRI table. 3T whole-body MRI system (Siemens Prima Fit) was used to gather the imaging data with the following parameters: T1-weighted, time to echo= 3.69 ms, time to repetition= 7.8 ms, 6 mm slice thickness. 3D Slicer 4.13.0 was used to create segmentations and construct the volumes (Figure 1). The panoramic ultrasound images of the gastrocnemius muscles of the participants were taken within 15 days of the MRI test using a SIEMENS (ACUSON P300™) Ultrasound System. Panoramic images in the axial and sagittal planes were taken three times, and the average of the results was used for analysis. Figure 2 shows the axial cross-section and sagittal section in one of the participants.

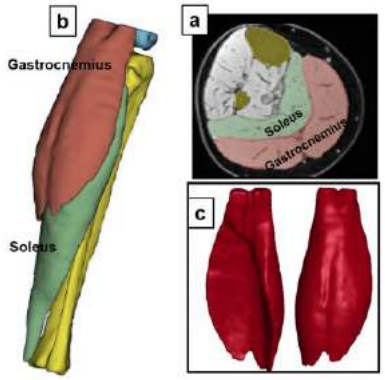

**Figure 1: a) Axial MRI image, b) Segmented volume in 3D slicer, c) Gastrocnemius muscle front and back view**

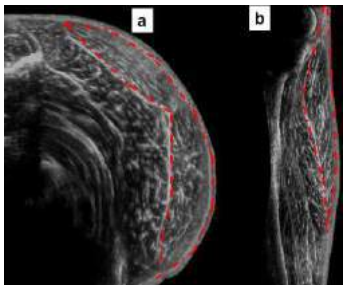

**Figure 2: a) Axial panoramic view of the gastrocnemius muscle, b) Sagittal view of the medial gastrocnemius muscle**

The equations that were suggested in the literature to estimate the muscle volume (MV) are based on the muscle length (ML), thickness (t), and anatomical cross-section area (ACSA) of the muscle, and generally can be illustrated as below [5, 6]:

$$MV = a + bi(ti \times ML) \quad (1)$$
$$MV = c + di(ACSAi \times ML) \quad (2)$$

Here we anticipate that the inclusion of a sagittal area (AS) of the muscle can result in a better estimation of the GMV (equation 3).

$$MV = e + fi\left(ACSA * \frac{AS}{t}\right) \quad (3)$$

Where a, b, c, d, e, f are constant parameters obtained from regression analysis. To understand the morphological changes of the GM among individuals, 'segment Geometry' modules of slicer are employed to get the graph of changes of the area in axial and sagittal planes from MRI 3D data.

## RESULTS

Figure 3 illustrates the normalized area over the length percentile in the axial direction, and figure 4 shows the normalized area over the width percentile in the sagittal direction from the MRI 3D data.

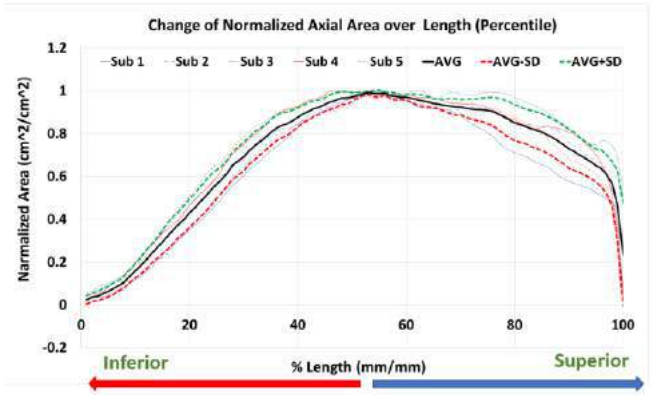

**Figure 3: Change of normalized axial area over Length percentile**

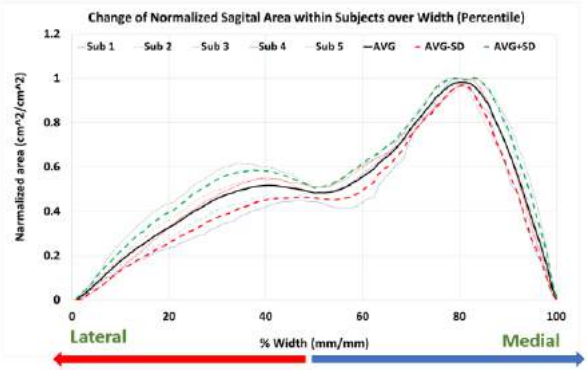

**Figure 4: Changes of the normalized sagittal area over width percentile**

Despite inter-individual differences, the normalized areas in two different directions for everyone had almost the same trends. Also, in both axial and sagittal planes, the graph of areas has minimum slopes around %50-60. This means that the areas do not change a lot around %50 of the length and %50 of the width of GM. Thus, obtaining panoramic ultrasound images in these locations can reduce the errors due to differences in probe location between trials.

Table 1 shows the parameters measured using ultrasound and MRI. Compared to MRI data, ultrasound data generally showed lower values.

**Table 1: Measured parameters by use of Ultrasound and MRI**

| | MRI data | | | | | Ultrasound data | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| Sub. No. | Volume of the GM $cm^3$ | Length of the Medial (Lm) $cm$ | ACSA $cm^2$ | As $cm^2$ | t $cm$ | Length of the Medial (Lm) $cm$ | ACSA $cm^2$ | As $cm^2$ | t $cm$ |
| 1 | 334.264 | 19.4 | 25.9 | 33.92 | 2.1 | 17 | 22 | 26 | 2.1 |
| 2 | 213.755 | 17.5 | 17.08 | 21.58 | 1.9 | 17.5 | 12.7 | 20.5 | 1.6 |
| 3 | 380.655 | 21.7 | 22.26 | 38.75 | 1.9 | 21 | 19 | 27 | 1.6 |
| 4 | 271.5 | 18.4 | 19.52 | 32 | 1.9 | 17.4 | 16.4 | 24.5 | 1.7 |
| 5 | 543.841 | 20 | 34.88 | 45.01 | 2.54 | 21.3 | 22 | 37 | 1.9 |

Table 2 demonstrates the regression analysis for differential equations in estimating the muscle volumes that were obtained from MRI data and segmentation in Slicer.

**Table 2: Regression analysis to estimate GMV**

| EQUATION | REGRESSION ANALYSIS MRI DATA | REGRESSION ANALYSIS ULTRASOUND DATA |
|---|---|---|
| $a + bi(ti \times ML)$ | a= -380.14, b=18.135 $R^2$ = 0.9816 | a= -454.27 b= 23.99 $R^2$ = 0.90 |
| $c + di(ACSAi \times ML)$ | c= -27.534 d=0.8037 $R^2$ = 0.9624 | c= -85.387 d= 1.24 $R^2$ = 0.91 |
| $e + fi\left(ACSA * \frac{AS}{t}\right)$ | e= 32.096 f= 0.7866 $R^2$ = 0.958 | e= -9.38 f= 1.26 $R^2$ = 0.98 |

## DISCUSSION

Normalized cross-sectional data of the muscle in sagittal and axial directions show that the healthy muscle has almost the same geometrical trends among individuals. And %50-%60 of the length and width are good places to capture the panoramic image since the sagittal and axial areas have the minimum changes in these positions. Our analysis showed that to reduce the possible errors, ultrasound measured values must be captured from these locations. Regression analysis showed that by use of MRI data all the suggested equations can potentially predict GMV accurately; since the use of freehand ultrasound data is not free of errors, our suggested method of combining sagittal and axial areas (and thickness) shows a slightly better estimation of muscle volume. This may be due to the additional morphological information captured in the two panoramic images. A limitation of this study is the difficulty in capturing the proximal insertion of the medial gastrocnemius muscle and obeying the curvature of the muscle without tilting the probe. In conclusion, this study showed the possibility of using simple equations, by choosing correct locations for obtaining the PU imaging.

# THE INTERPLAY BETWEEN TRANSCATHETER AORTIC VALVE REPLACEMENT COMPLICATIONS AND CORONARY ARTERY DISEASE

**Seyedvahid Khodaei (1), Zahra K. Motamed (1,4,5)**

(1) Department of Mechanical Engineering, McMaster University, Hamilton, Ontario, Canada

(2) School of Biomedical Engineering, McMaster University, Hamilton, Ontario, Canada

(3) School of Computational Science and Engineering, McMaster University, Hamilton, Ontario, Canada

## INTRODUCTION

Over the past several years, transcatheter aortic valve replacement (TAVR) has surpassed the traditional treatment method, surgical aortic valve replacement (SAVR), for patients who suffer from aortic stenosis, specifically those who are of a high-risk of an unsuccessful surgery. TAVR is becoming popular for patients who are of an intermediate or low risk, indicating that it may become the superior treatment modality for aortic stenosis for all patient types. Unfortunately, there are drawbacks to TAVR – one of them being the presence of paravalvular regurgitation (PVR) (1). In addition, since the coronary ostia are located superior to the aortic valve, the presence of PVR jets may impede blood flow into the coronary arteries. Coronary Artery Disease (CAD) is present in approximately 50% of the TAVR population (2), and the question, however, of if CAD should be treated or reduced in severity prior to TAVR is still being debated (2).

Fluid mechanics plays an essential role in the development, progression, diagnosis, and treatment of cardiovascular disease (3, 4) – Indeed, the essential sources of cardiovascular mortality and morbidity can be explained on the basis of adverse hemodynamics (4, 5). There has been an emerging conclusion by many researchers that valvular disease is a complex disease that also depends on the dictates of the ventricle and the vascular system (6–9).

In this study, we developed a computational-mechanics diagnostic framework to assess the effect of TAVR complications, such as PVL on the coronary arteries and aortic root in both pre and post TAVR states to quantify local and global hemodynamics. Currently only lumped-parameter models have the capabilities to quantify global hemodynamics due to the complexity of the cardiovascular system and the unmanageable computational cost of 3-D models of hemodynamics in the entire cardiovascular system. Our diagnostic framework, therefore, uses an image-based patient-specific lumped-parameter algorithm and a 3-D strongly-coupled FSI model to quantify both local and global hemodynamics in patients who underwent TAVR.

## METHODS

*Global hemodynamics (LV workload)*. We developed a patient-specific lumped-parameter model that considers interactions of the aortic valve, LV and arterial system to estimate the LV workload non-invasively in both pre and post intervention states. The model uses a limited number of input parameters all of which can be reliably obtained using Doppler echocardiography and a sphygmomanometer.

*Local hemodynamics (blood flow dynamics)*. We developed a fluid-solid interaction and lumped parameter modeling framework to calculate 3-D blood flow dynamics in the aortic root, neo-sinus and coronary arteries. As described above, the lumped parameter model in this framework used few input parameters all of which can be measured using Doppler echocardiography and a sphygmomanometer.

## RESULTS

***LV workload (global hemodynamics).*** The LV workload is an effective metric of the LV load and clinical state and represents the energy that the ventricle delivers to the blood during ejection plus the energy necessary to overcome the viscoelastic properties of the myocardium itself. Pre-TAVR, untreated AS increased the load on the LV due to the augmented flow resistance which caused a LV pressure overload. Although the flow resistance and consequently the LV pressure decreased greatly post TAVR, the LV workload did not improve because PVL contributed to a switch from a ventricular pressure overload to a ventricular volume overload (Figure 1).

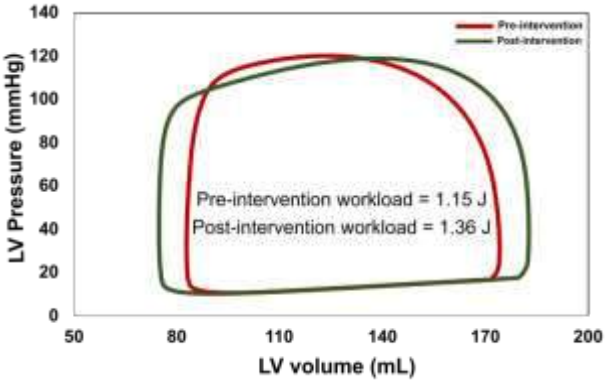

**Figure 1. LV workloads in a sample patient between baseline and 90 days post-TAVR. *Pre-TAVR*: severe aortic stenosis (EOA=0.6 cm2), coronary artery disease and dyslipidemia, diastolic dysfunction, ejection fraction: 38%, brachial pressures: 54 and 107 mmHg, forward LV stroke volume: 74 mL; *Post-TAVR*: aortic valve (EOA=1.8 cm2), diastolic dysfunction, ejection fraction: 51%, brachial pressures: 59 and 120 mmHg, forward LV stroke volume: 92 mL. *LV workload did not improve by TAVR.***

***Aortic root and coronary arteries fluid dynamics (local hemodynamics)***. It has been shown that for a TAVR without PVL, the coronary flow influences the flow patterns of aortic root and neo-sinus and favors the transfer of blood flow towards ostium during diastole (10). However, our results showed that in the presence of PVL, the aortic root vortices will not favor the transfer of blood flow towards ostium in the aortic root and neo-sinus region. We observed (figures 2) that in presence of PVL, considerable portion of the forward flow towards coronary ostium diverges towards the left ventricle, leading to a decreased coronary flow. TAVR can also disturb the vortical structures inside the Valsalva sinuses, which are essential for the washout of sinus flow and providing flow to the coronary arteries. Our findings demonstrate that PVL exacerbates the washout mechanism for the sinus and neo-sinus regions. Moreover, PVL leads to a significantly lower shear stress at the coronary walls due to the decreased blood supply during diastole after TAVR. This makes the coronary arteries susceptible to atherosclerosis, due to the low wall shear stress-induced inflammatory activation of endothelium mainly at the inner bend of curved arteries, ostia of branches and lateral walls of bifurcations

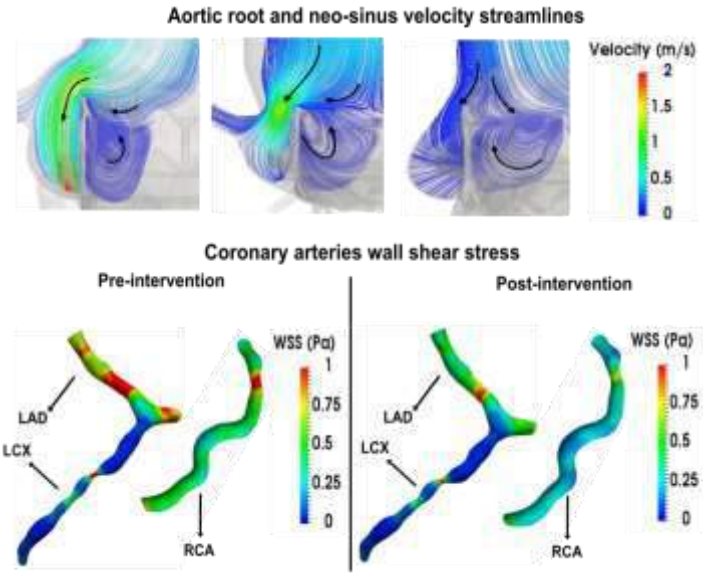

**Figure 2. Flow modeling in an Aortic root and coronary arteries with moderate to severe PVL in a sample patient. (a) Velocity vector during diastole. (b) Wall shear stress during diastole.**

## DISCUSSION

Concomitant CAD and PVL limit the benefit of TAVR: may increase the LV load, may potentially worsen coronary perfusion, and worsens heart failure. Atherosclerosis promotion through loss of physiological flow-oriented alignment of endothelial cells and its exacerbation by PVL will likely play an important hindering role in success of TAVR. The findings of this study suggest that beyond routine clinical indices for hemodynamic evaluation of the valvular disease (e.g, Doppler pressure gradients), valvular, vascular, and ventricular hemodynamics and their interactions should be clinically quantified and considered to better conduct the aortic valve management and treatment planning.

## INTRODUCTION

Transcatheter aortic valve replacement (TAVR) procedure is a minimally invasive procedure to treat patients with severe aortic stenosis. TAVR technology underwent a rapid evolution due to generational device design improvements, and the increase in the experience in TAVR procedures. However, few post-TAVR complications still remain persistent, with cardiac conduction abnormality (CCA) being one of the major ones. Post-TAVR cardiac conduction abnormality can occur due to any mechanical damage sustained by the atrioventricular conduction system located near the inter-leaflet triangle region between the non-coronary and the right-coronary leaflet. Conduction disturbances may eventually lead to permanent pacemaker implantation, abnormal cardiac function, and therefore to increased mortality[1]. This is particularly important in bicuspid aortic valve (BAV) patient population, as those tend to have higher risk of developing post-TAVR left bundle branch blockage (LBBB), which is a common form of conduction disturbance. BAV is the most common congenital cardiac defect, marked by an abnormal fusion of two aortic leaflets and often associated with early development of aortic stenosis. With the recent regulatory approval for TAVR in BAV, the number of younger patient cases receiving TAVR is likely to rise and requires to study the biomechanical aspects involved in TAVR deployment that may increase the risk of post-TAVR CCA development.

Several anatomical and biomechanical factors have been analyzed to assess the risk of CCA associated with TAVR. However, the effect of valvular calcium distribution on post-TAVR CCA development has not been conclusive and could be further analyzed using computational modeling approaches. The goal of this study was to first analyze the influence of tricuspid valvular calcification distribution on the TAVR device in dynamic physiological cardiac motion and the resulting risk of CCA throughout the cardiac cycle, then expanding our computational approach to BAV patients using patient-specific models to identify a strain threshold near LBB region which would help us identify BAV patients who are at the risk of developing post-TAVR CCA.

## METHODS

Five tricuspid models were created based on the most common shape and volume of annular calcium deposit[2] that were computationally incorporated into a dynamic beating, electromechanically coupled, 4-chamber adult male human heart model[3] (The SIMULIA Living Heart Model). Finite element (FE) simulation of the deployment of a 26 mm CoreValve (Medtronic plc, Minneapolis, MN) was performed using Abaqus Explicit 2019. Calcium deposits were tied to the aortic surface of the leaflets. In order to

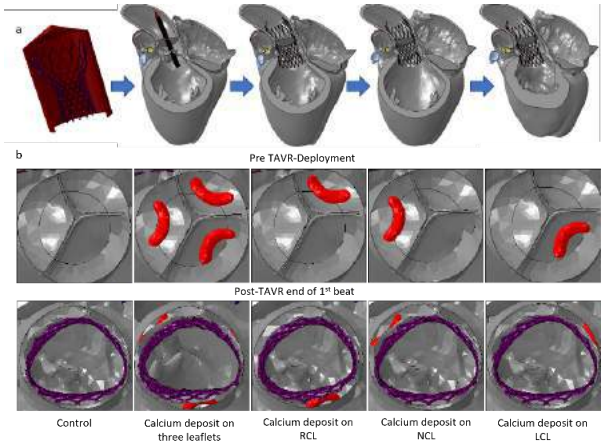

**Figure 1: (Tricuspid cases) TAVR deployment inside a 4-chamber beating heart model (tricuspid), (b) Control and 4 virtual patient model based on different valvular calcium deposit distribution; RCL - right coronary leaflet; NCL – non-coronary leaflet; LCL - left coronary leaflet**

quantify the strains that may trigger CCAs, area-weighted average maximum principle logarithmic strain (AMPLS) in the MS region of all the cases were measured during the TAVR deployment and two cardiac cycles.

For the patient-specific BAV study, we used de-identified cardiac CT scans (from Rabin Medical Center, Israel, with IRB approval) of 5 type I BAV patients who underwent TAVR procedure with self-expandable devices from Medtronic. Three patients had developed post-TAVR LBBB (LBBB patients) and the remaining did not develop any conduction disturbance (Control patients). Patient-specific stationary aortic root model preparation and FE simulation of TAVR procedure was performed based on our previous studies[4]. Clinical data and anatomical description found in the literature, were used to identify the approximate location of the LBB region in these patients.

**RESULTS:**

In the tricuspid valve cases, initial results demonstrated that the maximum AMPLS in the MS region of the patient cases with calcium deposits on non-coronary and right coronary leaflets (NCL and RCLs) were relatively lower during the deployment stage. Figure 2 (bottom row) demonstrates that the maximum AMPLS was higher for the calcium deposit on all three leaflets and RCL cases.

In majority of the BAV cases, highly eccentric stent deployments were observed (Figure 3 top row). Maximum principal logarithmic strain contour near the LBB region did not demonstrate any clear trend. However, the weighted AMPLS demonstrated a higher strain values (> 12.5%) near the LBB region in the LBBB patients (Figure 3 middle and bottom rows).

**DISCUSSIONS:**

Maximum AMPLS in the MS did not follow a similar trend during TAVR deployment and systole following TAVR deployment. The calcium deposits on RCL and NCL seemed to damp the impact of the TAVR prosthesis on the MS region during the deployment stage. Calcium deposit on the left coronary leaflet (LCL) seemed to push the

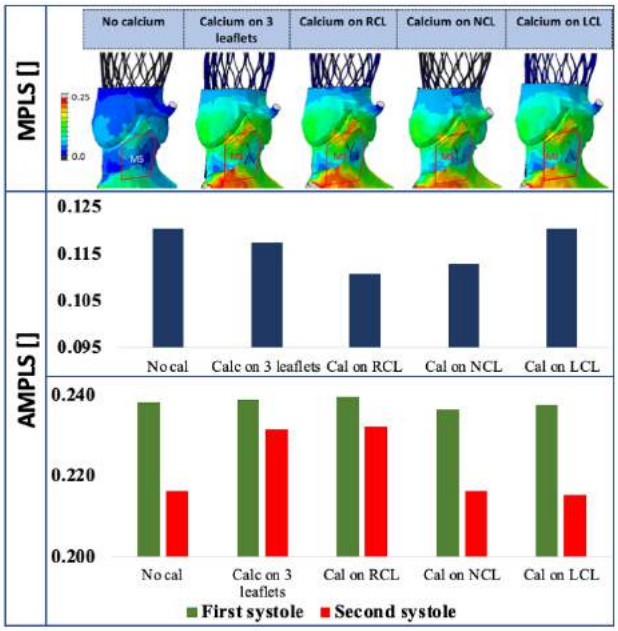

**Figure 2: (Tricuspid cases) Top row- Maximum principal logarithmic strain at the end of pre-load step in the MS region of 5 virtual patient cases; Middle and bottom rows – Maximum AMPLS in the MS during TAVR deployment and systoles following TAVR deployment, respectively**

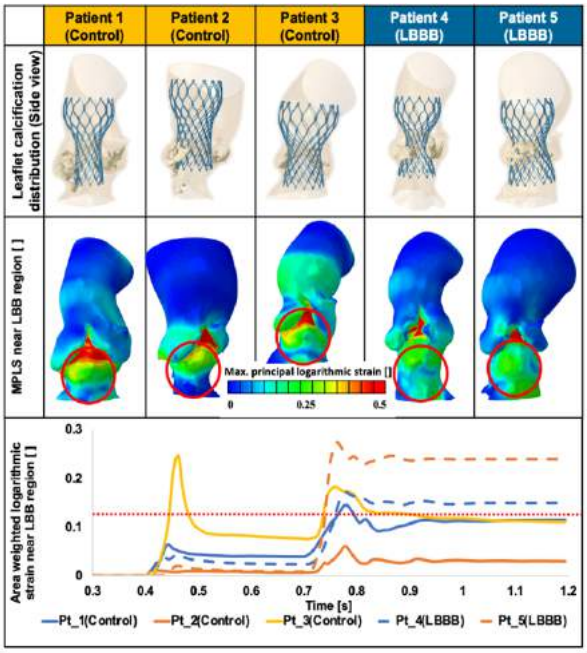

**Figure 3: (Bicuspid cases) Top row - Deployed TAVR device in each patient case; Middle row - Contour plot of maximum principal logarithmic strain on the aortic wall and the left ventricular outflow tract region. The MS and LBB regions are circled in red; Bottom row - Area-weighted AMPLS at the LBB region in each patient during different steps of TAVR simulation**

TAVR prosthesis towards the MS and resulted in relatively higher maximum AMPLS for cases with calcium deposits on all three leaflets and LCL (Figure 2-middle row). On the other hand, maximum AMPLS was higher for cases with calcium on three leaflets and RCL which was dictated by the location and the interaction between the calcium on the RCL and the TAVR prosthesis. Analysis was performed to understand the effect of the volume of calcium deposits on each leaflet. Further study on patient-specific beating heart is necessary to validate the novel technique of post-TAVR risk assessment.

For the BAV patient cases, *in-silico* data obtained from current patient models are consistent with clinical patient outcomes. All the control patients who did not have post-TAVR LBBB had lower strain values near LBB (~ <12.5%) compared to the LBB patients, making 12.5% a possible strain threshold for triggering CCA (Figure 3 bottom row– red dashed line) that may be used to identify the risk of post-TAVR LBBB - based on our area-weighted AMPLS approach. However, this threshold may vary with simulation parameters, and requires further investigation Future study will include analyzing the precision of this threshold using larger patient population and analyzing balloon-expandable cases in order to enhance the applicability of this method. Since BAV patients tend to have heavy and asymmetric leaflet calcification, the impact of leaflet calcification on the CCA would also be analyzed in future.

## INTRODUCTION

Platelet adhesion to bioreactive surfaces, while critical for hemostatic regulation, is also responsible for the onset of device-induced thrombosis [1]. Device-induced thrombosis is a potentially lethal complication that can be caused by either the supraphysiological high shear forces applied to blood by mechanical circulatory support (MCS) devices, or the absorption of proteins to device surfaces. These conditions permit platelet adhesion and the subsequent formation of occlusive thromboemboli. Device design is informed by a desire to prevent thrombus formation within the device domain. Careful consideration of device fluid mechanics and the use of non-thrombogenic biomaterials typically prevent intra-device thrombus deposition. However, thrombi often still form due to either protein surface absorption or downstream adhesion due to ultra shear forces within the device.

Platelet adhesion is mediated by fibrin binding to subendothelial proteins, as well as transient tethering by the von Willebrand Factor (vWF). While both mechanisms have been studied individually, it is unknown how these platelet receptors interact in the high shear flows characteristic of MCS devices [2,3]. Platelet-fibrin bonds, while strong, require longer formation times, and direct exposure by proximity to subendothelial proteins, making attachment difficult in high-shear flows. As a result, these bonds are typically formed in lower-shear environments, or as a stabilizing bond after platelet capture by vWF. Alternatively, vWF is important in arresting platelet transport in high shear flows, prior to the establishment of stronger fibrin-based bonds. The vWF unfurling mechanics, while tethered to the subendothelium, have been subject to much discussion [3-4]. Adhesion efficacy of vWF may be significantly altered by ADAMTS13, a cleaving enzyme within the blood that reacts with the exposed A2 domain to reduce vWF multimer length. Identification of the interaction between these mechanisms in conditions relevant to patients with MCS devices is critical to understanding downstream device-induced thrombosis. We hypothesize that a transitional shear range exists in which both vWF capture and platelet-surface interactions contribute to adhesion and that vWF begins to dominate deposition as shear rate increases past this range. By investigating the role of vWF and platelet-surface interactions in adhesion, novel targets can be identified for regulation of thrombosis due to pathological shear conditions.

## METHODS

The primary goal of this study was to observe vWF and platelet deposition as a function of shear rate and biochemistry. Polydimethylsiloxane (PDMS) microchannels were fabricated to act as a testing platform for shear-altered deposition. Channels were fabricated following standard soft lithography protocols for PDMS. A sudden expansion geometry was chosen to evaluate the effects on shear-mediated adhesion [5]. PDMS chips were cleaned in 70% ethanol and sealed to glass microslides using a plasma cleaner (Harrick Plasma, Ithaca NY). Shear rates were calculated in ANSYS FLUENT (ANSYS, Canonsburg PA) and verified by acquiring velocity data with a micro-PIV system (TSI Inc., Shoreview MN). Human blood was acquired in an IRB approved protocol for venipuncture and perfused through the microchannels with a Harvard syringe pump (Kd Scientific, MA). Channels were coated with human type I collagen (100 µg/mL) to create a reactive surface. Human vWF (Haematologic Technologies, Essex VT) was obtained and diluted to physiological concentrations of 12 µg/mL. Samples (n=6) were treated with ADAMTS-13 (0.5 µg/mL) and sheep anti-human vWF antibodies conjugated with AlexaFluor647 (Haematologic Technologies, Essex VT) in the case of vWF, and lipophilic dye $DiOC_6$ to stain platelets. During perfusion at 1,000, 5000, and 10,000 $s^{-1}$, real-time immunofluorescence images were acquired with an Olympus IX71 inverted microscope and DP74 camera (Olympus, Tokyo Japan). Images were converted to binary and processed in ImageJ (NIH, Bethesda MD) and MATLAB (Mathworks, Natick MA).

## RESULTS

Shear-mediated adhesion of platelets and von Willebrand Factor deposition onto a collagen surface within the sudden expansion. In total, deposition onto collagen at three shear rates was investigated for two biofluids, vWF and whole blood, under two conditions: ADAMTS-13 treated and untreated (n = 6 each). Shear rate was observed to be statistically significant ($p<0.001$) and was directly related to deposition of vWF and platelets. ADAMTS-13 also significantly diminished vWF deposition ($p<0.05$) at all shear rates **(Fig 1)**. However, the deposition of platelets was significantly affected by ADAMTS-13 only at 10,000 $s^{-1}$. This effect is summarized in **Figure 2**, where the relationship between adhesion of untreated vWF and platelets can be observed to follow a tight linear trend. While the deposition of vWF+ADAMTS-13 remained consistently low, platelet adhesion was unaffected by ADAMTS-13 until 10,000 $s^{-1}$.

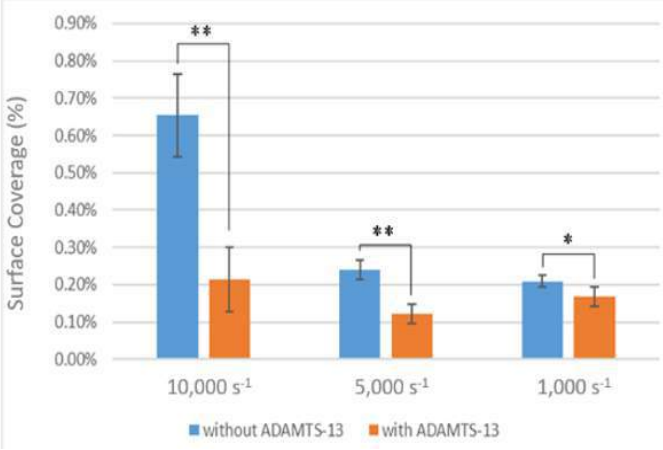

**Figure 1: Reduction of vWF adhesion and surface coverage due to ADAMTS-13 cleavage. Deposition was measured as % surface area covered. Data are presented as mean + SEM (n=6). Significance is denoted as * (p<0.05) or ** (p<0.01).**

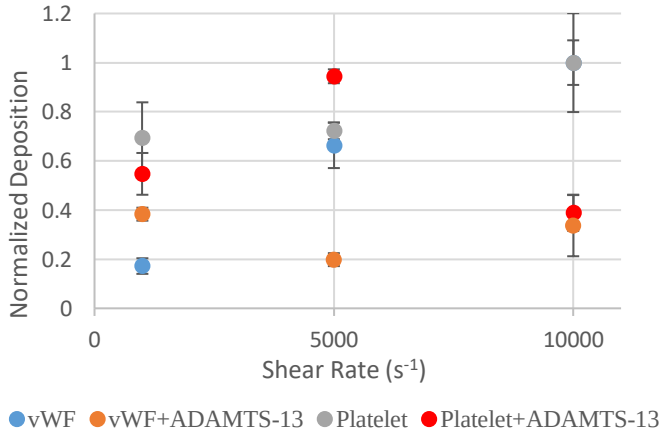

**Figure 2: Shear-mediated adhesion of platelets and vWF deposition. Deposition was measured as % surface area covered and normalized to the peak adhesion achieved for either metric, platelets or vWF. Data are presented as mean + SEM (n=6).**

## DISCUSSION

We observed that platelet and vWF deposition at high shear (10,000 $s^{-1}$) was hindered by ADAMTS-13, yet platelet deposition was not affected at lower shear rates (1,000-5,000 $s^{-1}$). vWF deposition was significantly diminished by ADAMTS-13 at all investigated shear rates. Shear rate was observed to have a significant effect on both untreated vWF and platelet deposition ($p<0.001$), while having no effect on the deposition of vWF treated with ADAMTS-13. A strong correlation between deposition of vWF and platelets was demonstrated *in vitro*.

The ADAMTS-13 protease inhibited vWF deposition at all shear rates, while only affecting platelet deposition at high shear. This indicates that at high shear, platelet adhesion is mediated by high molecular weight (MW) vWF multimers, while adhesion is possible through surface contact at lower shear rates. Low MW multimers have been shown to be ineffective in adhering and covering a functionalized surface *in vitro*, and this likely is true for platelet capture as well [6]. This study suggests the existence of a shear threshold between 5,000 and 10,000 $s^{-1}$ that requires uncleaved, high MW vWF multimers to facilitate platelet capture even on highly thrombogenic surfaces. These findings align with the range suggested by literature [7]. The behavior observed supports the hypothesis that the vWF-mediated mechanism of platelet capture is dominant only once a critical shear threshold has been reached. These findings match favorably with the current estimate of ~6,000 $s^{-1}$ [7]. The adhesion of enzymatically-treated platelets below this threshold is likely due to one of two mechanisms: the shear required for exposure of ADAMTS-13 reactive A2 domains within the vWF multimer has not been achieved, or that cleaved vWF multimers still mediate platelet adhesion at lower shear rates. Platelet adhesion at the investigated shear rates below this threshold (1,000 and 5,000 $s^{-1}$) is likely a result of contributions from both vWF and surface contact, rather than one mechanism dominating the other.

This study investigated mechanisms of platelet adhesion onto a thrombogenic protein surface and shed some light onto the contribution of vWF at various shear rates. To gain clearer insight, additional clinically relevant surfaces and shear rate conditions should be evaluated to determine if this behavior is conserved. Additionally, identification of the specific platelet integrins, such as GPVI and $\alpha_{2b}\beta_3$, that mediate surface contact adhesion would be useful in determining clinically relevant antiplatelet strategies. Further investigation of additional thrombogenic surfaces and platelet glycoprotein sites is necessary for deeper understanding of this phenomenon.

## INTRODUCTION

Cartilage tissue engineering (TE) is a promising osteoarthritis treatment strategy, whereby tissue constructs derived from cell-seeded scaffolds are fabricated for the repair of clinical cartilage defects. While the technology has exhibited growing clinical success, it continues to be encumbered—in both the clinical and research developmental stages—by the utilization of costly and laborious protocols needed to generate high quality tissues. Notably, for TE platforms, constructs are initially subjected to prolonged periods of *in vitro* cultivation (2-6 weeks) in chondrogenic media (CM) formulations to accelerate ECM biosynthesis [1]. While *in vitro* cultivation protocols beneficially give rise to functional constructs that can exhibit native composition and mechanical properties, they necessitate the use of frequent media replenishment procedures, constituting a significant time/cost burden for researchers and clinical technicians.

Periodic replenishment of culture medium is fundamental to cell/tissue culture applications, serving to restore cell-depleted nutrients (e.g., glucose, vitamins, amino acids), restore degraded signaling molecules (e.g., growth factors, hormones), and clear cell-secreted waste products (e.g., lactic acid). For *in vitro* cartilage TE protocols, the conventional paradigm to meet this need is to subject tissue constructs to relatively low media volumes but replenish the media frequently—daily or every other day. Interestingly, this convention is based on traditional cell culture protocols [2], rather than a fundamental understanding of the stability and cell consumption rates of constituents in media. As such, it is worth considering that state-of-the-art TE replenishment protocols may be far from optimized—i.e., it may be possible to generate functional engineered cartilage with larger media volumes and less frequent media replenishment or even to avoid replenishment entirely. Here, we hypothesize that the administration of larger media volumes can be used to: 1) mitigate the depletion of nutrients and accumulation of waste products in CM and, accordingly, 2) reduce the media replenishment frequency required to maintain construct viability and generate functional engineered cartilage. We examine this hypothesis through several experimental characterizations that consist of determining: 1) the minimum levels of media constituents and maximum levels of waste product accumulation that can achieve functional TE cartilage, 2) the depletion rates of critical CM constituents (insulin, ascorbic acid, and glucose) and accumulation rates of waste products (lactic acid assessed via pH) for different media volumes, and 3) the effect of varying culture medium volumes and replenishment frequencies on TE cartilage viability, composition, and material properties.

## METHODS

**Tissue constructs:** Immature bovine chondrocytes were seeded in 2% type VII agarose at $30\times10^6$ cells/mL. ∅4×2mm constructs were generated and cultured in serum-free CM, consisting of glucose, insulin, ascorbic acid, L-proline, sodium pyruvate, dexamethasone, and antibiotic–antimycotic [3]. To promote similar accelerated growth rates for all replenishment groups, all constructs were subjected to an initial 1-week exposure of 10ng/mL TGF-β3 with the media replenished (1mL/construct/media change) every other day. Varied media replenishment protocols and medium analysis of this study were subsequently performed in TGF-β-free medium over the next 6 weeks. **Requisite medium constituent levels:** Medium was administered to constructs with varied pH (7.6, 7.0, 6.8, 6.6, 6.4, 6.2) or varied constituent levels, relative to 1× CM standard concentrations (4.5mg/mL for glucose [GLU], 6.25μg/mL for insulin [INS], 50μg/mL for ascorbic acid 2-phosphate [AAP]) [4]: GLU (0.2×, 0.3×, 0.5×, 0.7×, 1×), INS (0×, 0.02×, 0.1×, 0.3×, 1×), and AAP (0×, 0.02×, 0.1×, 0.3×, 1×). **Media replenishment variation:** Media was administered over 6 weeks with parametric variation in replenishment frequency—thrice weekly [TW] (conventional frequency), weekly [W], biweekly [BW], or replenishment-free [RF], representing 17, 5, 2, and 0 replenishment points, respectively, over 6 weeks of culture—and cumulative media

volume (CMV) applied to each construct over the culture duration (3, 6, 9, 18 [conventional level], or 54mL). For each group, the administered media volume at each replenishment point can be computed as the CMV divided by the number of replenishments over the 6-week culture plus one for the initial day 0 supply. **Tissue analysis:** Constructs were analyzed for Young's modulus ($E_Y$), composition (GAG, DNA), viability (Live/Dead imaging/CellProfiler), and histology (Safranin O [Saf O]/Fast Green). **Medium constituent stability:** For RF groups and in the absence of tissue, medium was assayed at regular time points to monitor the decay of nutrient/constituent levels. Constituents for monitoring were selected based on those shown previously to be required to promote TE cartilage growth [4]: GLU (oxidase assay, Invitrogen), AAP [5], and INS (ELISA, R&D Systems)— Medium pH levels were also monitored.

## RESULTS

**Requisite medium constituent levels:** At day 49, constructs exhibited a decrease in $E_Y$ for levels of GLU below 0.5× ($p<0.05$), INS, AAP below 0.02× ($p<0.005$), and pH below 6.6 ($p<0.05$) (Fig 1). **Medium constituent stability:** In the absence of tissue, medium levels of GLU, AAP, and pH remained stable over 6 weeks (Fig 2A, 2C, 2D). In contrast, INS levels decreased by 38% over 35 days, indicating an intrinsic instability of the hormone (Fig 2B). In the presence of tissue, at low media volumes, all constituent levels (INS, AAP, GLU) and pH exhibited a more pronounced decrease. For GLU, INS, and pH, using higher media volumes mitigated this decrease.

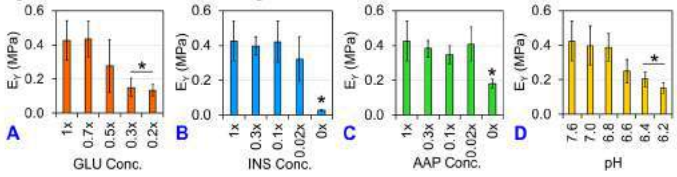

**Fig 1: Construct $E_Y$ after 7-week culture in response to varied levels of (A) GLU, (B) INS, (C) AAP, and (D) pH. * p<0.05: significant decrease below 1× level or pH 7.6.**

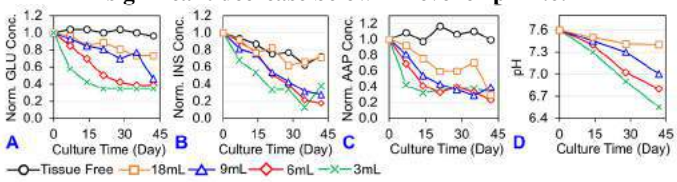

**Fig 2: Stability of (A) GLU, (B) INS, (C) AAP, and (D) pH over 6 weeks in un-replenished medium in the absence or presence of a TE construct for varying administered medium volumes.**

**Media replenishment variation:** At week 6, the conventional replenishment protocol of TW-18mL yielded constructs that reached native $E_Y$ (Fig 3A) and GAG (Fig 3B) levels. In general, $E_Y$ and GAG decreased to sub-native levels at lower CMVs and replenishment frequencies. However, at higher CMVs, lower media replenishment frequencies gave rise to increased $E_Y$ and GAG, with native levels reached for TW/BW/RF-18mL, and W/BW/RF-54mL. A similar trend was observed for cell density (Fig 3C) and viability measures (Fig 3D). Interestingly, for low CMV groups (TW-3mL & RF-3mL), viability loss was observed predominantly in the construct periphery, rather than the tissue interior (Fig 3F), suggesting that waste product accumulation, rather than nutrient depletion, serves as the limiting factor in requisite medium supply. Saf O staining showed consistent results, where reduction in GAG staining was observed for the low 3mL CMV groups but more intense staining was observed for high 18mL CMV groups (Fig 3E).

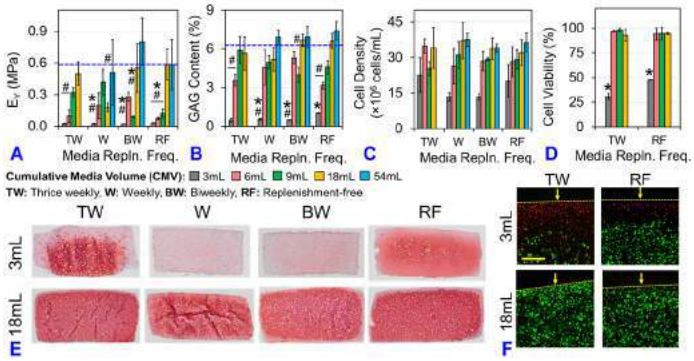

**Fig 3: (A) $E_Y$, (B) GAG, (C) cell density, (D) cell viability, (E) Saf O staining of TE constructs after 6-week culture for TW, W, BW, and RF replenishment frequencies and varied CMVs. ## DISCUSSION

In contrast to serum-based media, the use of chemically-defined, serum-free CM formulations in TE culture protocols provides a unique opportunity to optimize replenishment protocols based on the inherent stability of defined medium constituents. Here, we demonstrate that several critical growth-inducing medium constituents (GLU, AAP) exhibit high levels of intrinsic stability while constituted in CM—constituent levels decreased by less than 5% over 45 days in the absence of TE constructs. When TE constructs are present, the temporal depletion of GLU, INS, AAP is far more pronounced—likely as a result of cell-mediation internalization/consumption processes. However, their depletion can be effectively mitigated by increasing the initial volume of media supplied to tissues (Fig 2). Similarly, the accumulation of lactic acid (assessed via decreasing pH) in culture medium can be mitigated by increasing medium volume. As such, one can increase the likelihood of maintaining constituent levels over the culture duration above the requisite threshold needed to maintain construct viability and achieve functional cartilage growth (Fig 1). Accordingly, by administering larger media volumes at the beginning of culture, functional cartilage with native-matched properties can be generated with fewer media replenishments, and remarkably, can even be generated with replenishment-free culture. It is important to note that while reducing replenishment frequency requires increasing the supplied media volume initially and at each replenishment point, it does not require increasing the cumulative media volume supplied over the entire culture duration. Essentially, functional cartilage can be generated by "front-loading" the entire 18mL CMV at the initiation of culture, rather than administering it serially with 18 × 1-mL replenishments over 6 weeks. Replenishment-free media culture platforms can advance a paradigm shift in cartilage TE technology by significantly reducing the time and cost burdens required to generate functional cartilage tissue specimens in clinical and research-based platforms.

## INTRODUCTION

Chronic low-back pain (LBP) is one of the most common disorders causing long-term disabilities and approximately 15% to 45% of chronic back pain cases involve facet joints [1]. Monopolar radiofrequency ablation (RFA) of the medial branch of the dorsal rami is one of the treatments used to reduce facet joint pain. In this procedure, an electrode is placed near the medial branch and radiofrequency (RF) current is applied. Medial branch ablation induced thermocoagulation blocks pain signals to be sent from facet joint. However, there are a few mild to medium adverse effects associated with this procedure. Because the medial branch carries both the motor and the sensory nerves, RFA of medial branch not only destroys the sensory nerves but also damages the motor nerves innervating the multifidus muscle [2]. Denervation of the multifidus muscle is followed by the atrophy and fat infiltration observed after an RFA procedure [2,3]. Since the multifidus muscle plays an important role in spine stability, RFA of the medial branch nerve can alter the loading and biomechanics of the spine leading to other adverse effects such as disc degeneration [4]. Hence, while monopolar RFA may be beneficial in the short term, it may lead to the changes leading to other painful conditions in the spine in long term. To avoid multifidus muscle dysfunction, RFA can potentially be applied exclusively to the articular branch which provides sensation to the joint. By doing this, the motor nerves are going to be spared while the sensory nerves are going to be ablated to reduce facet joint pain. However, articular branches are smaller and a new RFA procedure would require a more precise control of the ablated volume. For this reason, temperature controlled bipolar RFA may be preferred. It is important to simulate RFA procedure to design a new RFA method targeting the articular branch and sparing the branch that innervates the multifidus muscle. During RFA procedure, spinal muscle is also being ablated since articular branch innervates the multifidus muscle. Commercial finite element analysis (FEA) software has been used to accurately simulate ablation process in several tissues [5],[6]; however, conventional FEA simulations have long run times in the order of hours to days. As an alternative method, neural networks can be used for the prediction of tissue temperature during RF procedure [7]. Apart from the work in [7] which predicts the midpoint temperature at three different antenna distances using the probe temperatures, to the best of our knowledge there exists no work predicting the temperature around the probes. In this study, we predict the final temperature field for several distances between probes positions using deep neural networks (DNNs). Our results show that our approach can accurately predict the tissue temperature.

## METHOD

### a. Finite Element (FE) simulation

COMSOL Multiphysics® modules, Bioheat Transfer and Electric Current, were used to couple the thermal and electrical effects of the RFA process. The model consisted of a cylinder of homogeneous muscle tissue (24 mm in diameter, 25 mm in height) with two parallel (bipolar) electrodes with an active length of 10 mm and diameter of 0.7 mm. Given the symmetry of the problem, 1/8$^{th}$ of the cylinder was modeled as shown in Figure 1. The initial temperature of the model was set to 21 °C and the initial voltage of the entire model was set to zero. While voltage of one of the electrodes was controlled by using a PI controller to keep the electrode temperature ($T_{electrode}$) at a target value ($T_{target}$), the symmetry plane was modeled as ground (V=0). Lastly, the temperature error (Eq. 1) was used to control the voltage of the active electrode by the following governing equation (Eq. 2):

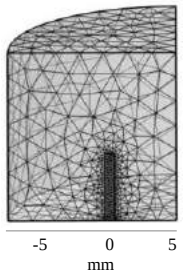

Figure 1: Model mesh distribution.

$$\text{iiie}(t) = T_{target} - T_{electrode} \quad (1)$$

$$V(t)\,i=iK_P\,ie(t)\,i+iK_i\,i\int_0^t e(\tau)d\,\tau i+iK_d\,i\frac{d}{dt}ie(t), \quad (2)$$

where $V(t)$ is the applied voltage (V). For this simulation, the optimal PID parameters were found as $K_p = 40$, $K_i = 0.01$ and $K_d = 0$ by parametric analysis. The target temperature is a function of time collected from ex-vivo experiments. Only the active tip of the electrode was modeled to make the model simpler and faster. Blood perfusion rate ($w_b$) was not considered. The mesh for the domain was generated using tetrahedral elements with a finer mesh size around the electrode to get a more sensitive temperature change [8].

## Deep Neural Network (DNN) Structure

Figure 2 shows the steps followed to train and verify the results from the DNN. FE simulations were used to generate the training dataset. Three different distances between probes were used, because the ablated region and the temperature distribution within the tissue is being affected by the probe locations. First, the FE model was run for three different distances between probe locations, 4 mm, 8 mm and 10 mm, to obtain the temperature distribution within the tissue. Second, a DNN that takes in features generated using the probe positions and outputs the temperature for a given probe position has been used. For a given sample $(i)$ with probe 1 position $p1(i)$, probe 2 position $p2(i)$, and the position of the target point $pt(i)$, the features $f_i$ are generated as follows:

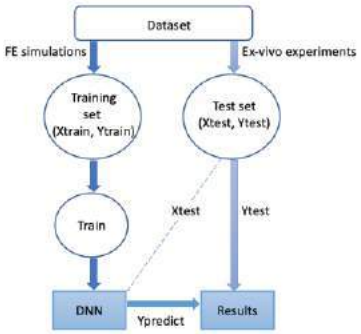

Figure 2: DNN prediction of tissue temperature after an RFA process.

$$f_i = [\ddot{u}correlate([p1(i) - \dot{p}t(i)]^T i[\dot{p}2(i) - \dot{p}t(i)]^T i \\ ||p1(i) - \dot{p}t(i)||i||p2(i) - \dot{p}t(i)i||)i \\ \ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}[p1(i) - \dot{p}t(i)]^T i[\dot{p}2(i) - \dot{p}t(i)]^T \ddot{u} \\ \ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}\ddot{u}||p1(i) - \dot{p}t(i)||i||\dot{p}2(i) - \dot{p}t(i)||i]i^T.\ddot{u}\ddot{u} \quad (3)$$

$X_{train}i$ contains features for all the N samples, i.e., $X_{train} = [f_1, f_2, \dots, f_N]$ and the target point temperature $T_i$ at 100 seconds has been used as labels which are collected in $Y_{train}$ as $Y_{train} = [T_1, T_2, \dots, T_N].i$ The DNN consists of three hidden layers with 100 hyperbolic tangent activations, 20 rectified linear unit (ReLU) activations, and 20 ReLU activations; and the output layer has one linear activation. The DNN has been trained with $X_{train}$ and $Y_{train}$ with mean squared error as a loss function using Adam optimizer. After training, a separate data set was constructed using ex-vivo experiments to test the performance of the DNN, which is explained next.

## b. Ex-vivo experiments

RF ablations were performed with an RF generator (Stryker Multigen) on a porcine spinal muscle sample. A target temperature of 90 ℃ for 100 seconds for the two active probes was set. Two passive probes were inserted into the tissue to measure tissue temperatures at given locations near the active probes. Ultrasound imaging was performed to visualize the probe locations. A distance between active probes of 9.5 mm was measured. The temperature measurements collected at 100 seconds of tissue ablation were used as a test data set for the DNN. The temperature field was predicted using the trained DNN for a 9.5 mm distance. The predicted temperature values using DNN were compared with the ex-vivo measurements and FE simulations to validate the approach.

## RESULTS

Table 1 shows the temperature of the two probes at 100 seconds for three different methods. The comparison was done when the distance between the probes was 9.5 mm. While the run time of the simulation is 3 hours 45 min, the training time for the DNN is only 20 min (Table 1). The DNN prediction yields 0.43% error for Probe 1 and 1.14% error for Probe 2 when compared to ex-vivo experiments. Comparing to FE simulations, the algorithm yields 0.2% error for Probe 1 and 1.23% error for Probe 2. The temperature field predicted in Kelvin with the DNN, and the FE simulation is given in Figure 3 when the probe distance is 9.5 mm. The results shown in Table 1 and Figure 3 show that the proposed approach is in a good agreement with both ex-vivo experiment and the FE simulation.

Table 1: Temperature comparison for three different methods.

| | *Ex-vivo* | *DNN* | *FE simulation* |
|---|---|---|---|
| *Probe 1 [K]* | 335.65 | 334.22 | 335.13 |
| *Probe 2 [K]* | 327.65 | 331.38 | 331.67 |
| *Run time [min]* | N/A | 20 | 225 |

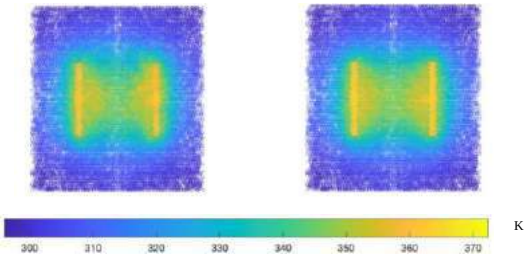

Figure 3: Temperature distribution around the electrode (a) DNN prediction, and (b) FE simulation.

## DISCUSSION

In this paper, a novel approach has been proposed using a DNN to predict tissue temperature at 100 seconds. Our work differs from [7] as our model takes in probe locations as inputs. The DNN takes in features generated from probe positions and the target probe positions and outputs the temperature. The DNN was trained using the data obtained from FE simulations and the efficacy of our algorithm was tested on a real life ex-vivo porcine tissue. The approach was matching well with the experimental and simulation results with as low as 0.2% error and reduced in run time by ~91% compared to FE simulation. For more complex geometry, FEA run time may increase to days or even weeks, but DNN run time might not change dramatically for the same DNN and the similar data size. The DNN approach presented has shown to be beneficial predicting the tissue temperature in a short time at a given point of choice. However, one of the limitations of this study is that it predicts the tissue temperature at 100 seconds only. As our ongoing work, the tissue temperature will be predicted for any given time. Predicting future tissue temperatures given the current probe temperatures and positions was kept as future work.
