## INTRODUCTION

Developing organs often consist of multiple cell types which interact through biochemical signaling and mechanical interactions to pattern tissue structures. In the kidney, epithelial-mesenchymal interactions pattern key functional structures such as the collecting duct network and nephrons [1]. For example, collecting duct patterning involves Ret-GDNF signaling interactions between the epithelium and nephron progenitors as well as inhibitory interactions from the surrounding stroma. Ret-GDNF signaling activates downstream signals such as the extracellular signal-related kinase (ERK) pathway that guide collective epithelial cell movements and proliferation [2]. Tools to reconstruct these epithelial-mesenchymal tissue interfaces *in vitro* would improve our understanding of Ret-related congenital kidney defects [3] and efforts to guide proper organization of tubule networks in organoid models.

We have modified a previously published cellular micropatterning approach [4] to support cell adhesion to photoactive polyacrylamide (pPA) hydrogel substrates. This approach uses photolithography to deposit single-stranded DNA (ssDNA), which serves as an intermediate adhesion ligand. Cells are labeled with lipid-modified antisense ssDNA [5] enabling multiplexed cell patterning with high precision (~10s of μm) and specificity. We first demonstrate patterning and long-term pattern retention of multiple cell types on pPA hydrogels. We use this to investigate ERK signaling dynamics and cell migration in freely expanding Ret-expressing epithelial colonies of defined initial size and shape.

## METHODS

**Cell culture.** MDCK epithelial cell lines were cultured in MEM containing 10% FBS. 3T3 mouse fibroblasts were cultured in DMEM containing 10% calf serum. All cell lines were maintained at 37°C and 5% $CO_2$. Cell lines expressing fluorescent histone 2B (H2B) constructs were generated by lentiviral transduction.

**pPA gels**. 30 μm thick pPA gel sheets were cast on methacrylate coated glass slides using SU-8 photoresist shims anchored to a hydrophilic silicon wafer as guides. pPA gel precursor solutions contained between 3-10%/0.035-0.25% acrylamide/bis-acrylamide, 3 mM benzophenone-methacrylate (BPMAC) photosensitizer and other components as previously described [4].

**ssDNA photolithography**. pPA gels were impregnated with ssDNA, sandwiched against photomasks, and grafted to the pPA gel surface. using 254 nm light transmitted through transparent patches on a 5”x5” quartz-on-chrome photomask.

**Fibronectin coating**. pPA gel surfaces were functionalized with a surface layer of bis-acrylamide and N-hydroxysuccinimide (NHS) ester groups using the photo-crosslinker LAP and 365 nm light [6]. NHS-functionalized surfaces were then passively coated in 20 μg $ml^{-1}$ fibronectin and washed before plating cells.

**Lipid-ssDNA labeling and cell patterning**. Cell membranes were passively labeled with lipid-ssDNA anchor, co-anchor, and antisense handle sequences [5]. Labeled cells were introduced to pPA gels enclosed within clip-on 8-well chambered slides and allowed to adhere to gel-bound ssDNA patches. Cells outside of ssDNA patches were removed by gently washing the pPA gel surface with DPBS.

**Immunofluorescence.** Cells were fixed in 4% paraformaldehyde, permeabilized in 0.5% Triton X-100 and methanol, and stained for phospho-ERK and DAPI [7].

**Imaging**. Images of cells and ssDNA were captured at 4x-10x magnification using a Nikon epifluorescence microscope equipped with LED illumination. Time-lapse and immunofluorescence image stacks of cell monolayers were acquired at 10x-20x magnification using a Nikon microscope equipped with a Yokugawa W1 spinning disk and environmental chamber to maintain cells at 37°C and 5% $CO_2$.

**Data analysis**. Phospho-ERK intensities were quantified using Fiji/ImageJ and CellProfiler [7]. All other image quantification was performed in Fiji/ImageJ.

## RESULTS

Here we show a scheme to pattern ssDNA on pPA hydrogel substrates by applying UV light through a photomask (**Figure 1a**). ssDNA patches mark sites of lipid-ssDNA-labeled cell capture using DNA "Velcro" (**Figure 1b**). We patterned arrays of 250 μm diameter circular ssDNA features and benchmarked the technique by showing efficient capture of 3T3 mouse fibroblasts bearing matched (base paired) ssDNA, but not cells bearing mismatched pairs (**Figure 1c**). Next, we show that this technique can be multiplexed by patterning two unique ssDNA sequences into alternating arrays of square features and using these to capture MDCK epithelial cells expressing histone 2B labels with different fluorescent markers (**Figure 1d**). MDCK cells subsequently adhered to fibronectin ligands on the pPA hydrogel surface following ssDNA patterning (**Methods**) and retained their approximate original positions after 16 hours, suggesting that this technique can be used to establish and study complex tissue patterning *in vitro*.

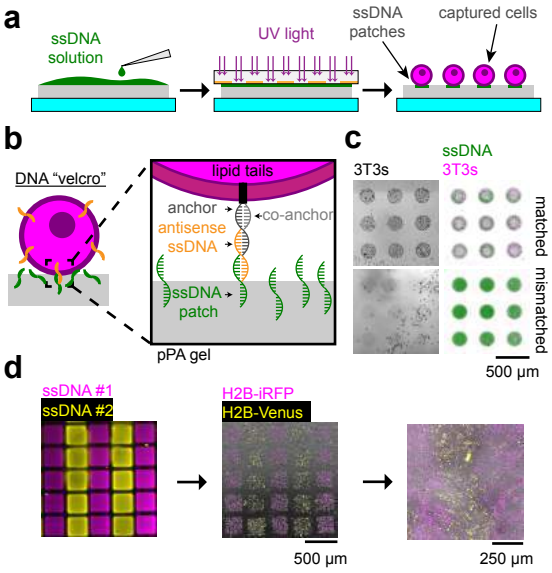

**Figure 1: ssDNA photolithography and cell capture on pPA gels.** **a.** Schematic of the ssDNA photolithography and cell capture process. **b**. Schematic of the DNA "Velcro" scheme used to specifically capture cells through base pairing. **c**. 3T3 fibroblasts captured on circular ssDNA patterns using DNA "Velcro". **d**. Multiplexed cell capture, adhesion, and long-term pattern formation of MDCK cells expressing fluorescent H2B reporters using multiple ssDNA sequences.

Since spatially regulated ERK signaling is involved in kidney tubule morphogenesis, we next used our micropatterning technology to study ERK signaling dynamics in patterned epithelial cell colonies (**Figure 2a**). We used MDCK epithelial cells expressing Ret [8] as a model of the ureteric epithelium, since application of exogenous GDNF activates the ERK signaling pathway in these cells (**Figure 2b**). Immunofluorescence staining of phosphorylated ERK reveals the spatial distribution of ERK within the tissue, with strongest activation near the colony edge. Furthermore, GDNF-treated MDCK colonies expanded at a faster rate than untreated controls (**Figure 2c**), suggesting that the spatially defined activation of ERK activates cytoskeletal machinery involved in collective cell migration.

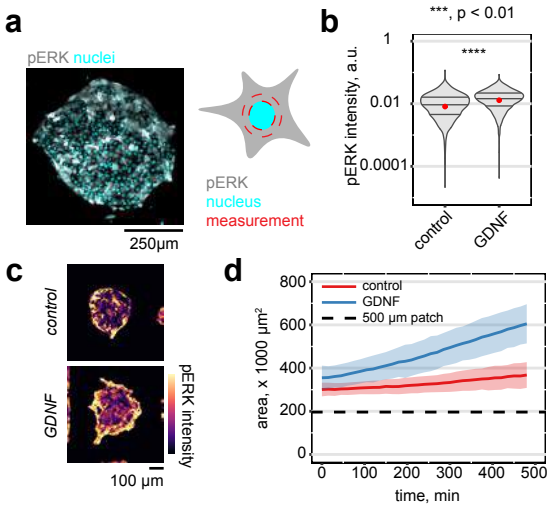

**Figure 2: ERK signaling within patterned epithelial tissues. a.** Immmunofluorescence image of phosphorylated ERK in a pattterned epithelial colony. **b-c.** Quantification of phosphorylated ERK intensity for cells stimulated with GDNF and controls. **d.** Area rate of expansion of patterned epithelial colonies treated with GDNF and controls.

## DISCUSSION

In this abstract, we introduce a technique for patterning cells across large (~cm$^2$) hydrogel surface areas with ~10-100 μm precision using ssDNA photolithography. Multiplexed cell patterning with unique ssDNA sequences allows the creation of long-term patterns within epithelial monolayers. We show that ssDNA photopatterning can be used to investigate signaling dynamics across epithelial colonies. GDNF activates leading edge ERK signaling and increases collective migration speed in patterned epithelial colonies. This technique is compatible with standard hydrogel chemistry, meaning that it can be applied to investigate combinatorial effects of colony size, geometry, cell-cell interactions, and substrate stiffness on cell behaviors. Future work will use this technique to test whether cell polarity proteins expressed in the kidney stroma are sufficient to restrict ERK signaling and erroneous branching of collecting duct cells [9]. Other future applications include modeling tumor-stroma interactions, and investigations into developmental patterning and boundary formation.

## ACKNOWLEDGEMENTS

We thank members of the Hughes, Bugaj, and Burdick laboratories for their helpful comments and assistance with experimental protocols. Thanks to G. Dressler for MDCK-RET cell lines. ## INTRODUCTION

An estimated 6.2 million Americans above 20 years old have heart failure (HF). It is known that the mechanical behavior of myocardium contributes to the diastolic function and the tissue mechanics change during HF development [1]. But there remains limited understanding of the alternation in anisotropic, viscoelastic behavior of myocardium in HF progression, particularly for the right ventricle (RV). To fill these gaps in knowledge, it is critical to investigate changes in RV tissue viscoelasticity during RV failure development.

To date, the only group that reported increased stiffness and viscous damping in pressure overloaded RVs investigated the papillary muscles [2,3]. But the one dimensional measurement of individual muscles cannot fully reveal the anisotropic properties of the entire myocardial wall. The **goal** of the study was to investigate the changes in the passive, anisotropic viscoelasticity of the RV in RV failure development. We **hypothesize** that the RV failure progression leads to increased viscoelasticity in the longitudinal direction and that the failing RVs exhibit more anisotropic behavior than the healthy RVs. Our results provide novel findings in the dynamic mechanical property changes of the RV with RV failure development, which brings a more complete understanding of the tissue's mechanical function in energy storage as well as energy dissipation in RV failure patients.

## METHODS

To test these hypotheses, ex vivo cyclic biaxial tests were performed on normal and PH rat RVs, using a monocrotaline (MCT) rat model of pulmonary hypertensive (PH). All procedures were approved by Colorado State University Institutional Animal Care and Use Committee. Monocrotaline (60 mg/kg) was injected (s.c.) into 6-week-old male rats for 3-4 weeks to induce PH. Similar healthy rats were used as the control group (CTL). Prior to tissue harvest, echocardiography was performed, and RV function was quantified. The establishment of RV failure in the MCT rats was confirmed by dilated RV and reduced fractional shortening (data not shown).

After harvest, the hearts were placed in cardioplegic solution (CPS) on ice. Prior to the mechanical tests, the RV tissue was excised, measured, and then placed in CPS combined with the 30 mM of 2,3-butanedione monoxime (BDM) solution at body temperature (26-37°C) for 30 minutes to ensure fully relaxation of cardiomyocytes. The outflow tract (OT) direction was the longitudinal direction. Each sample was marked with 4 equally spaced markers for strain analysis.

The samples were mounted on an in-house biaxial tester designed specifically for small animal viscoelasticity measurement. The samples were preloaded by approximately 0.05 N and underwent 15 cycles of equibiaxial stretch at 1Hz and 20% strain (physiological strain) for preconditioning. Then, cyclic equibiaxial tensile tests with 20% strain (at 0.1, 1, 2, 5, and 8Hz) were performed with sufficient resting periods between tests. 2$^{nd}$ Piola-Kirchhoff stress ($\sigma$) and Green's strain ($\varepsilon$) were calculated from the last cycle of stress-strain data. From the hysteresis loop, the stored energy ($W_S$) was calculated for RV elasticity, and the dissipated energy ($W_d$) was calculated for RV viscosity. These methods are described previously [4]. All data are shown as mean±SE. Statistical significance was determined as $p<0.05$ calculated with a student's t-test.

## RESULTS

**Different frequency-dependent viscoelastic behavior between MCT and CTL RVs.** First, we examined the elastic behavior of the RV at different frequencies. We found that there was a general trend of increasing stored energy ($W_S$) as frequency increased for both the CTL and MCT groups in the longitudinal direction, with the CTL group showing significant larger $W_S$ at 2 and 5Hz in the longitudinal direction (Fig. 1A). The similar frequency-dependent behavior was seen in the $W_S$ of CTL group in the circumferential direction with a larger $W_S$ at 1, 2, and 5Hz in the circumferential direction (Fig. 1B). However, the MCT group tended to have increased $W_S$ from 0.1 to 1Hz and then it

plateaued (Fig. 1B). Thus, PH led to a change in RV frequency-dependent elasticity in the circumferential direction.

From the viscosity measurement, we found that the dissipated energy ($W_d$) tended to increase with increasing frequency in the longitudinal direction for both MCT and CTL groups (Fig. 1C). But in the circumferential direction, the frequency-dependent increase in $W_d$ was seen in the CTL group (except for the 5Hz) whereas the MCT group barely showed frequency independency (Fig. 1D). Thus, the RV frequency-dependent viscosity in the circumferential direction was altered by PH development.

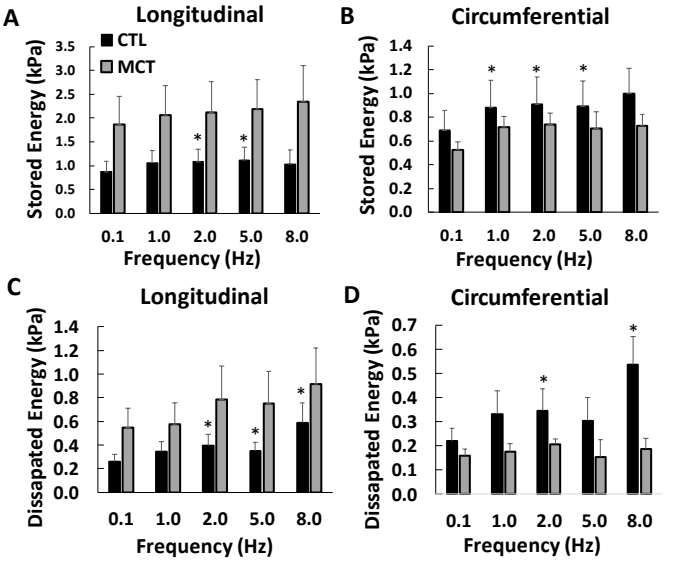

**Figure 1: Frequency-dependent viscous (A&B) and elastic (C&D) behavior of rat RVs in the longitudinal and circumferential directions. *P<0.05 vs. 0.1Hz in CTL group.**

**Reduced ratio of viscosity to elasticity in the circumferential direction and trends of increased viscoelasticity in the longitudinal direction in MCT RVs.** We then further compared the dynamic anisotropic viscoelastic changes of the RV during PH development. Because some data were incomplete at 5Hz (physiological heart rates), we presented the data obtained at 2Hz here. In the longitudinal direction, a trend of increased $W_S$ with PH development is seen, while the opposite trend in $W_S$ was shown in the circumferential direction with PH development (Fig. 2A). Therefore, our data suggest that in PH the RV is stiffer in the longitudinal direction but more compliant in the circumferential direction. As a result, the MCT RV became more anisotropic in elasticity than the CTL RV. Similar trends were observed for other frequencies (see Fig. 1A&B).

Examining viscosity through the dissipated energy ($W_d$) showed that with PH development, the RV tended to become more viscous in the longitudinal direction and less viscous in the circumferential direction (Fig. 2B). This led to a more anisotropic viscous behavior in the MCT group compared to the CTL group. Similar trends were observed for other frequencies (Fig. 1C&D). Moreover, when examining $W_d/W_S$ we found the ratio was reduced significantly in the MCT group in the circumferential direction (Fig. 2C).

## DISCUSSION

This study is the first to investigate the changes of RV passive, anisotropic viscoelastic properties with PH development by cyclic biaxial tests. The pilot data suggested that the MCT RV was stiffer and more viscous than the CTL RV in the longitudinal direction, while interestingly a decrease in circumferential viscoelasticity as well as decreased $W_d/W_S$ were found. Increased viscoelasticity is similarly reported in prior studies using RV papillary muscles [2,3]. These trends of increasing viscoelasticity in the longitudinal direction and decreasing viscoelasticity in the circumferential led to a more anisotropic viscoelasticity with the RV failure progression. During the early stage of HF, the myocardium adapts to its new environment to preserve cardiac output, which will often result in significant remodeling of the tissue [5]. But in late stage of HF, the remodeling can no longer maintain the cardiac output and it remains unclear what drives the transition from adaptation to maladaptation. Here, we suspect that an increase in anisotropy with a stronger viscoelasticity in the longitudinal direction will impair the RV function significantly as this is the main axis of shortening in normal conditions.

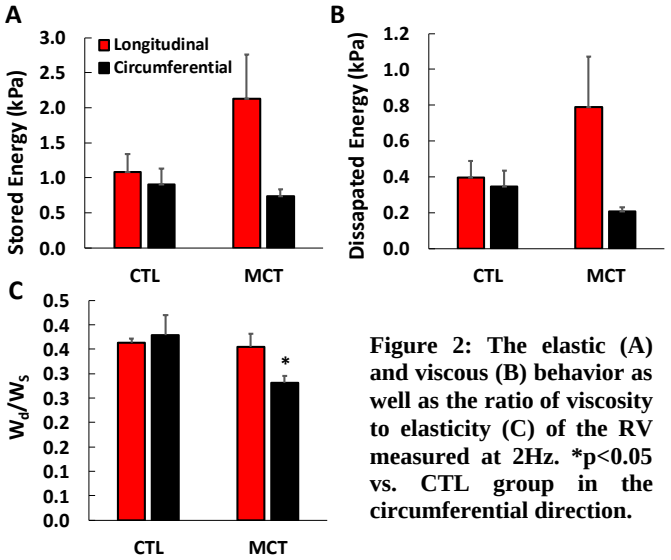

**Figure 2: The elastic (A) and viscous (B) behavior as well as the ratio of viscosity to elasticity (C) of the RV measured at 2Hz. *p<0.05 vs. CTL group in the circumferential direction.**

We also noticed altered frequency-dependent viscoelastic behavior in the circumferential direction in the MCT RV. PH seemed to result in a loss of frequency dependency at high frequencies (2-8Hz). This indicates that the pathological remodeling reduced the tissue's response to stretch-rate circumferentially, probably due to the fiber orientation change toward longitudinal direction as reported previously [6]. We speculate that the myofibers and collagen fibers are loaded differently in diseased tissues and it cannot be explained by 'collagen accumulation' alone. Further study should investigate the microstructures of RVs to study the underlying molecular mechanisms.

In summary, our study provides novel insight into the frequency-dependent and anisotropic viscoelasticity of RV during PH development. The results enhance our understanding of RV biomechanics by investigating both elasticity and viscosity and in different directions. Further study will involve more RV samples for mechanical tests and computational modeling analysis.

# PERSONALIZED ULTRASOUND-BASED FLUID-STRUCTURE INTERACTION MODELING OF ABDOMINAL AORTIC ANEURYSMS: FROM MODEL DEVELOPMENT TO EX-VIVO VERIFICATION

## INTRODUCTION

Currently, the prediction of rupture risk in abdominal aortic aneurysms (AAAs) solely relies on the maximum diameter. However, wall mechanics and hemodynamics have shown to provide better risk indicators. Research on abdominal aortic aneurysm development, growth and rupture risk requires a large, longitudinal, biomechanical study. Furthermore, a patient-specific assessment is required, based on fluid-structure interaction (FSI) models. Time-resolved 3-dimensional ultrasound (3D+t US) is the preferred image modality to extract the patient-specific geometry, since 3D+t US is safe, affordable and provides geometric information during the full cardiac cycle. A previous study has shown the feasibility of 3D+t US-based FSI simulations and the importance of incorporating the pre-stress [1].

Due to the limited field-of-view of 3D+t US, the aorto-iliac bifurcation is often not included in the 3D+t US acquisitions. It has been shown that the presence of the aorto-iliac bifurcation does not significantly influence the wall mechanics in the AAA region [2]. However, previous studies have shown that the bifurcation does influence the hemodynamics in the AAA. Part of our study aims at quantifying the influence of excluding the bifurcation in FSI simulations. Secondly, part of our study aims at experimentally verifying the obtained patient-specific FSI framework.

## METHODS

To quantify the influence of excluding the aorto-iliac bifurcation in the FSI simulations, patient-specific geometries including the bifurcation geometry from 20 patients were derived from CT-scans. The CT-based geometry was elongated by 3 cm in proximal and 2 cm in distal direction. The AAA wall geometry was obtained by extruding the inner-wall geometry by 2 mm. For each patient, an additional AAA geometry was obtained by replacing the bifurcation by a single outlet. For both FSI simulations, the same time-varying flow profile was prescribed at the inlet and a 3-element Windkessel (WK) model was used to prescribe the patient-specific outlet pressure. In the simulation with bifurcation, the flow division, needed for calculating the WK parameters, was approximated using Murray's law. The pre-stresses in the AAA wall geometry were estimated using the Backward Incremental Method. The FSI simulations were initialized with the patient-specific diastolic pressure and multiple cardiac cycles were modeled to ensure a stable, periodic solution. The last cycle was used for result evaluation. The results in the aneurysm region were compared to quantify the influence of excluding the bifurcation.

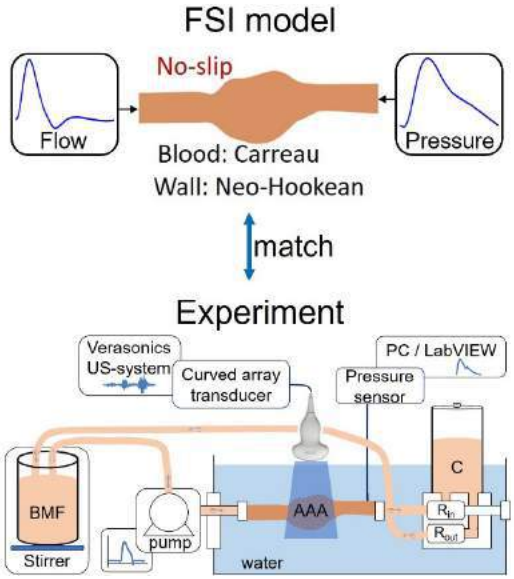

**Figure 1: Schematic representation of the experimental verification of the FSI model using a mock-loop circulation with blood mimicking fluid (BMF) and high-framerate US acquisitions.**

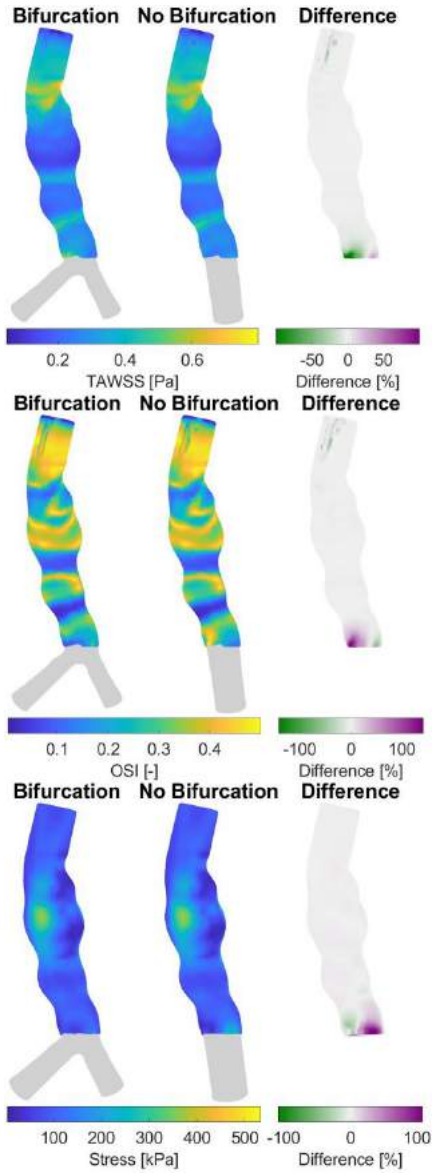

**Figure 2: Preliminary results of the influence of excluding the bifurcation on time-averaged wall shear stress (TAWSS, top) and oscillatory shear index (OSI, middle) and systolic wall stress (bottom) in the AAA region**

Experimental verification of the FSI framework will be performed using an experimental mock-loop circulation. In this study, an experimental set-up to mimic the in-vivo hemodynamics was developed (Fig. 1). An elastic, 3D-printed US-based AAA geometry was mounted in a mock-loop circulation [3]. A realistic inlet flow profile was supplied by a PC-controlled gear pump and physiological pressures were obtained using the 3-element Windkessel model at the distal side of the AAA geometry, consisting of a vertical column as compliance (C) and adjustable inlet ($R_{in}$) and outlet ($R_{out}$) resistances. During the experiment, high-framerate (~1300 Hz) US acquisitions were obtained and processed with a motion estimation algorithm to determine the wall strain and blood velocities. A blood-mimicking fluid (BMF) was used within the mock-loop circulation to ensure US speckle signals in the AAA lumen. The circulation was surrounded by water to suppress US signal around the AAA geometry.

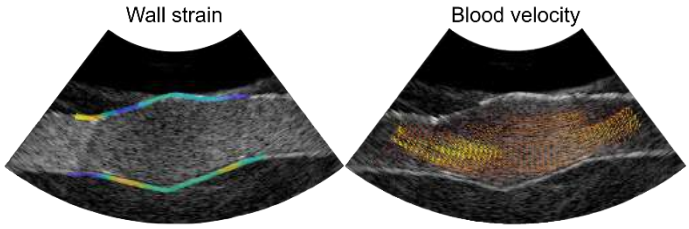

**Figure 3: Preliminary results of the experimental wall strain (left) and blood velocity (right) extracted from the ultrasound acquisitions in the mock-loop circulation.**

## RESULTS

Figure 2 shows the time-averaged wall shear stress (TAWSS), oscillatory shear index (OSI) and systolic wall stress for a single patient with and without the bifurcation geometry. Mean differences in the aneurysm region equaled 1.2% (std: 5.6%), 0.1% (std: 8.8%) and 1.3% (std: 6.3%) for the TAWSS, OSI, and systolic wall stress, respectively. The largest differences for all quantities were found in the most distal part of the aneurysm region.

Using the gear pump and the 3-element Windkessel system, physiological inlet flow and outlet pressure waveforms were obtained in the experimental set-up. With a mean flow of 0.97 L/min, the pressure ranged between 81 and 127 mmHg. US acquisitions with sufficient signal in the AAA lumen were obtained and (preliminary) wall strain and blood velocities in the AAA geometry were calculated (Fig. 3).

## DISCUSSION

In this study, the influence of excluding the aorto-iliac bifurcation was quantified. Preliminary results show only slight differences in hemodynamics and wall mechanics in the aneurysm region, except for the most distal part. FSI simulations for the remaining patients in the dataset should be executed and analyzed before any conclusions can be drawn regarding the influence of the bifurcation geometry.

Furthermore, an experimental mock-loop circulation to mimic the in-vivo hemodynamics was developed in this study. In ongoing research, improvements in US acquisition and processing are implemented. Moreover, the acquired flow and pressure waveforms will be used as boundary conditions for the FSI simulation (Fig. 1). Finally, the experimental results will be compared to the FSI results to verify the simulation.

In future studies, the FSI framework will be further personalized by including the patient-specific shear modulus [4] and inlet velocity profile. The envisioned framework for personalized 3D+t US-based FSI simulations paves the way for future longitudinal studies on AAA development, growth, and rupture risk.

## INTRODUCTION

The quantitative characterization of the large-scale features of the aortic hemodynamics is currently based on spatially and/or temporally-averaged quantities which do not fully capture the four-dimensional complexity of real cardiovascular flows. Aiming at extracting as much information as possible from *in vivo* hemodynamic data, this study proposes a network-based approach [1] to analyze the spatiotemporal correlation of large-scale flows in a 4D flow MRI dataset of 42 healthy thoracic aortas [2]. In detail, the correlation between the flow rate waveform at the inflow of the ascending aorta (AAo) and the axial velocity waveforms obtained from measured phase velocities at each voxel of the aortic domain was used to build a subject-specific *"one-to-all"* network [3]. An ad-hoc network metric was introduced to quantify the anatomical length of persistence of the correlation between the inflow rate and the large-scale fluid structures along the main flow direction. The analysis was then completed with a geometric characterization of the investigated subjects, exploring possible links between aortic geometric attributes and the dynamic similarity between inflow rate and axial flow.

## METHODS

The adopted methods are summarized in **Fig. 1**. The study population comprises 42 healthy volunteers with a tricuspid aortic valve. All details on 4D flow MRI acquisition protocol and data processing are reported elsewhere [2,4]. The study was approved by the ethics committee of the Vall d'Hebron Hospital and written informed consent was obtained from all participants. Subject-specific 3D geometry of the thoracic aorta was semi-automatically reconstructed from an angiography derived from 4D flow MRI data using ITK-Snap and its centerline was computed using VMTK (www.vmtk.org). Anatomical landmarks of the sinotubular junction (STJ), first and last supra-aortic vessels and location of the pulmonary artery (PA) bifurcation were identified from co-registered 2D cine images. For each subject the time-resolved waveforms along the cardiac cycle of the three velocity components in each voxel were obtained as reported elsewhere [2], and 3D velocity data were exported using in-house Matlab code (MathWorks Inc, USA).

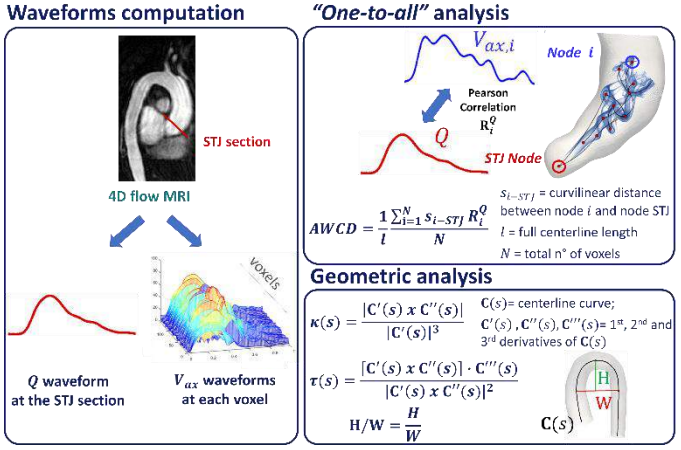

**Figure 1: Overview of study methods.**

The inflow rate $Q$ waveform was computed at the STJ cross-section and the (through-plane) axial velocity component $V_{ax}$ waveform in each voxel of the investigated aortic domain was obtained as proposed in [5]. Inspired by a previous *in silico* study on carotid bifurcation hemodynamics [3], here an *in vivo "one-to-all"* network approach was adopted to characterize the aortic large-scale intravascular hemodynamics by investigating the relationship between the shape of the subject-specific inflow rate waveform and that of the $V_{ax}$ component in each voxel. In this study, the nodes of the *"one-to-all"* network are represented by the center of the STJ section and by all the voxels of the

aortic domain. The link between the STJ node and each voxel was weighted by the Pearson correlation coefficient $R_i^Q$ between $Q$ and $V_{ax}$ waveform at the *i-th* voxel, which measures the dynamic similarity between the inflow rate and the axial velocity waveforms in the aorta. To quantitatively characterize the *"one-to-all"* network structure, the curvilinear distance $s_{i-STJ}$ between the STJ node and voxel $i$ was calculated along the centerline, weighted by the value of $R_i^Q$ and averaged over all the $N$ voxels, obtaining the ad-hoc network metric *Averaged Weighted Curvilinear Distance AWCD* [3] that quantifies the anatomical length of persistence of the $Q$ *vs.* $V_{ax}$ waveforms correlation *in vivo*:

$$AWCD = \frac{1}{l}\frac{\sum_{i=1}^{N} s_{i-STJ} R_i^Q}{N}. \qquad (1)$$

To account for the geometric variability of the investigated dataset, *AWCD* was normalized with respect to the full thoracic aorta centerline's length $l$. To complete the analysis, the aortic geometry was characterized in terms of average curvature $\bar{\kappa}$ and torsion $\bar{\tau}$ [6], width W of the aortic arch (3D distance between the points of the AAo and descending aorta (DAo) at the level of the right PA), height H of the aortic arch (maximal vertical distance between W and the highest point of the aortic arch) and height over width ratio (H/W).

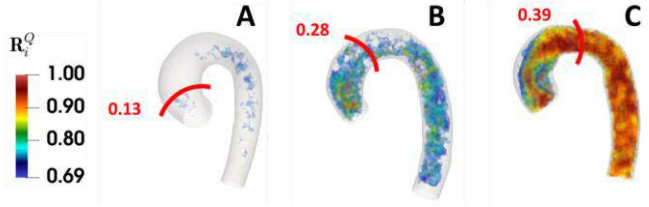

**Figure 2: $R_i^Q$ volumetric maps and *AWCD* (red line) for three representative subjects (presenting, respectively, the minimum, around the mean and the maximum $R_i^Q$ value). Only $R_i^Q$ values above the full dataset median value ($\widehat{R^Q} = 0.69$) are shown.**

## RESULTS

The influence of the subject-specific inflow rate on the aortic axial flow structures is presented in **Fig. 2**, where the volumetric maps of $R_i^Q$ values above the median ($\widehat{R^Q} = 0.69$) of the distribution pooled over the entire dataset is displayed. In detail, the three subjects presenting the minimum, around the mean and the maximum value of $Q$ *vs.* $V_{ax}$ correlation are presented here. Notably, it emerged that, in those subject with $R_i^Q$ mostly below the median, $Q$ and $V_{ax}$ waveforms are weakly correlated ($R_i^Q$ = 0.30 on average for case A), with a non-negligible amount of negative $R_i^Q$ values (i.e., indicative of retrograde axial flow [3]). In subject C, on the other hand, axial structures waveforms are strongly correlated with the inflow rate ($R_i^Q$ = 0.84 on average) and the negative correlations are mostly confined to the AAo inner wall. To quantify the anatomical persistence length of the $Q$ *vs.* $V_{ax}$ correlation, *AWCD* is reported in **Fig.2** and represented with a red line. Consistently with the $R_i^Q$ distribution, subject A presents the lowest *AWCD* with the correlation between $Q$ and $V_{ax}$ only persisting for 13% of the full thoracic aortic length, whereas in subject B the dynamical similarity between axial flow and inflow rate vanishes, on average, at the distal end of the AAo. In subject C, *AWCD* is among the highest in the dataset, with the $Q$ *vs.* $V_{ax}$ correlation propagating almost for the 40% of the full aortic length. Regarding the geometric analysis, as an example **Fig.3** displays *AWCD* box plots obtained after stratifying the 42 subjects in three groups based on H/W tertiles. In the range of H/W values ([0.31,0.64], median = 0.43) characterizing the healthy aortas, an increasing trend for *AWCD* emerged, even if not significant ($p$ = 0.62). Similarly, no significant links emerged between the *"one-to-all" AWCD* metric and all the other investigated geometric attributes.

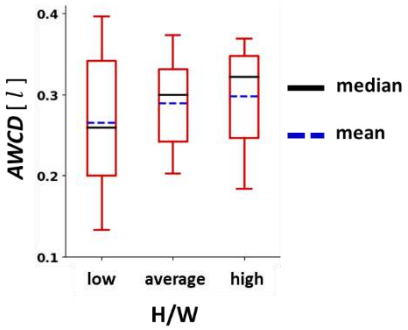

**Figure 3: Box plots of *AWCD* distributions obtained by dividing H/W in three groups based on tertile values.**

## DISCUSSION

In this study, a *"one-to-all"* network approach is adopted to quantitatively investigate the anatomical length of persistence of the similarity between the inflow rate at the STJ and the large-scale fluid structures along the main flow direction *in vivo* on a 4D flow MRI dataset of healthy human aortas. To do that, an ad-hoc network metric, the *AWCD*, was introduced to measure the anatomical persistence length of the correlation. The findings of the study suggest that in those healthy subjects where $R_i^Q$ values are low, the $Q$ *vs.* $V_{ax}$ correlation generally persists up to the mid AAo, whereas in cases where the correlations are higher their anatomical persistence length extend distally up to one third of the full thoracic aortic length (i.e., *AWCD* > 0.33) to include large portions of the aortic arch. No significant association emerged between the anatomical persistence length of the correlation and the geometric attributes, although a clear trend was observed between *AWCD* and H/W suggesting that the role of geometric features in transporting large-scale fluid structures dynamically similar to the inflow rate waveform downstream in the healthy aorta deserves further investigation. In conclusion, the here-proposed approach allows for the first time to evaluate the anatomical length of healthy aorta over which the subject-specific inflow rate waveform markedly shapes the large-scale fluid structures, thus providing a measure of the spatiotemporal aortic flow coherence *in vivo*. Besides investigating more in detail the role of geometric attributes on aortic flow heterogeneity, future studies should also adopt the here presented approach to analyze the impact that aortic stiffness and distensibility might have on large-scale hemodynamics.

# RELATIONSHIP BETWEEN LUMBAR INTERVERTEBRAL DISC DEGENERATION AND SPATIAL DISTRIBUTON OF T1ρ RELAXATION TIMES

**Anika Kumar (1), Noah B. Bonnheim, Ph.D. (1), Ravi Chachad (1), Jiamin Zhou (1), Thomas M. Link, M.D., Ph.D. (2), Roland Krug, Ph.D. (2), Aaron J. Fields, Ph.D. (1)**

## INTRODUCTION

Intervertebral disc degeneration in the lumbar spine is believed to be an important contributor to low back pain (LBP) in some patients [1]. Disc degeneration is associated with an overall loss of glycosaminoglycans (GAG), which help regulate disc swelling and biomechanical function [2]. However, the details regarding how GAG content changes throughout the disc at different stages of the degenerative process are not well understood. Such information could help elucidate the mechanisms and/or uncover unknown phenotypes of disc degeneration and possibly help identify new diagnostic and therapeutic targets for LBP.

The goal of this study was to quantify the spatial variation in GAG content in human discs at various stages of the degenerative process. To do this, we used T1ρ MRI because it provides an accurate, non-invasive estimate of GAG content [3]; additionally, T1ρ relaxation times decrease with increased degenerative grade [4].

The avascular discs receive their nutrients via diffusion from the vertebral capillaries terminating in the cartilage endplates [5]. Thus, we hypothesize that the early stages of disc degeneration begin in the center of the disc, farthest from the endplate nutrient sources.

## METHODS

Sagittal MRI data acquired using a T1ρ mapping sequence (slice thickness = 4 mm, FOV = 28x28 cm, acquisition matrix = 256x256, TE/TR = 12 ms/3,000 ms, 3 echoes per TR) [3] and standard clinical T1- and T2-weighted fast spin-echo sequences from $n$ = 80 patients with chronic LBP were utilized in this study. Discs were automatically segmented using a neural network [6] before voxel-by-voxel relaxometry was used to compute T1ρ relaxation times (ms) for all voxels in the L4/5 and L5/S1 discs. Separately, degenerative grade was scored by a trained radiologist using the Pfirrmann classification system [7] using the T2-weighted images. According to this system, Pfirrmann I represents a healthy (non-degenerate) disc, Pfirrmann V represents a fully degenerate disc, and the intermediate grades represent a progression of degeneration (Table 1). Patient-reported measures for disability and pain were collected using the Oswestry Disability Index (ODI) and Visual Analog Scale (VAS), respectively.

**Table 1: Patient demographic information. Values are mean ± SD.**

| Characteristic | $n$ = 80 patients | |
|---|---|---|
| Age (years) | 40.4 ± 12.2 | |
| Female, male | 38, 42 | |
| ODI | 26.77 ± 14.52 | |
| VAS | 6.55 ± 2.48 | |
| Pfirrmann Grade | L4/L5 | L5/S1 |
| I | 9 | 6 |
| II | 23 | 25 |
| III | 20 | 22 |
| IV | 19 | 17 |
| V | 9 | 10 |

Sagittal and axial line-scans bisecting the disc from a single mid-sagittal section were used to quantify T1ρ values as a function of anatomic location (Figure 1). For each disc, the sagittal/axial extents from the mid-sagittal section were divided into twelve equal regions (each region representing ~8% of the disc). The median T1ρ value of all voxels in each region was used to reflect the T1ρ value for that region (~5 voxels/region). Then, the median values in each region were averaged for each Pfirrmann grade. A mixed effects regression model accounting for multiple measurements per patient (from multiple spinal levels) followed by a Tukey post-hoc test was used to compare T1ρ values as a function of anatomic location between discs grouped according to Pfirrmann grade. In the sagittal direction, values were

compared between an anterior, central, and posterior location (sagittal 0%, 50%, and 100%). In the axial direction, values were compared between an inferior, central, and superior location (axial 25%, 50% and 75%).

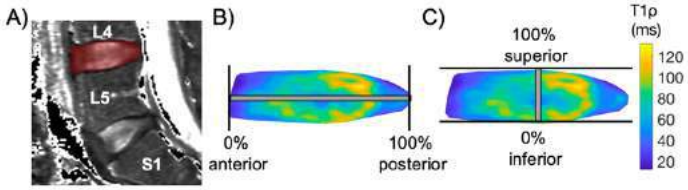

**Figure 1: A) Cropped T1ρ MR image showing segmentation of L4/L5 disc (red). T1ρ maps of disc with B) sagittal and C) axial line-scans. Grey bars annotate thickness and location of line-scans.**

## RESULTS

The spatial variation in T1ρ depended on Pfirrmann grade (Figure 2). T1ρ values tended to decrease with increased degenerative grade throughout the disc. Higher Pfirrmann grades (more severe degeneration) were also associated with a more homogenous T1ρ distribution both axially and sagittally. For example, in Pfirrmann I and II discs, the maximum difference in T1ρ as a function of sagittal locations was always above 48 ms, but for Pfirrmann III, IV, and V discs, this maximum difference was always below 16 ms.

Along the inferior-superior direction, in Pfirrmann grade II and III discs, T1ρ values in the disc center (50%) were lower than adjacent superior (75%; $p = 0.03$ and $< 0.0001$ for Pfirrmann II and III, respectively) and inferior regions (25%; $p = 0.002$ and 0.02). Differences in T1ρ between the disc center and these superior and inferior regions were not statistically significant in Pfirrmann grade IV and V discs ($p > 0.801$).

Along the anterior-posterior direction, Pfirrmann grade I, II, and III discs had significantly higher T1ρ values centrally compared to anteriorly (0%) and posteriorly (100%; $p \leq 0.0001$, 0.0001, and 0.0006 for Pfirrmann I, II, and III respectively). Statistically significant differences as a function of location were not detectable in for Pfirrmann IV and V discs. Sagittally, the differences in T1ρ values between the anterior/posterior regions of statistical comparison and the disc center were on average 43, 29, 10, 7, and 2 ms for Pfirrmann I, II, III, IV, and V respectively, demonstrating a more homogenous distribution of T1ρ values as degenerative grade increased.

## DISCUSSION

These data demonstrate that the distribution of T1ρ values both decreases and becomes more spatially homogenous with increased Pfirrmann grade, suggesting that GAG decreases and becomes more homogenous with increased disc degeneration.

The axial data for Pfirrmann II and III discs (mild and moderate degeneration) suggest that early-stage degeneration is characterized by diminished GAG content in the central region relative to adjacent superior or inferior regions. This finding supports the mechanistic hypothesis that disc degeneration may begin farthest from the vertebral capillary nutrient sources in the cartilage endplates (i.e., the region with the longest diffusion distance from the nutrient source).

The sagittal pattern in T1ρ values suggests that GAG content is greater in the nucleus pulposus than the annulus fibrosis, but that the differences in GAG content between those regions become much lower as the discs degenerate. Using published regression data relating dry weight of GAG content to T1ρ values [4], our estimated measurements of GAG in mildly and moderately degenerate discs range from 120-390 μg GAG/mg dry tissue: these data are consistent with the range of 50-400 μg GAG/mg dry tissue reported in a prior study of mildly and moderately degenerate discs in which GAG content was measured directly [8], supporting our computational methodology. Our data expand these prior works by estimating GAG distribution *in vivo* in a large number of LBP patients with varying disc degenerative grades.

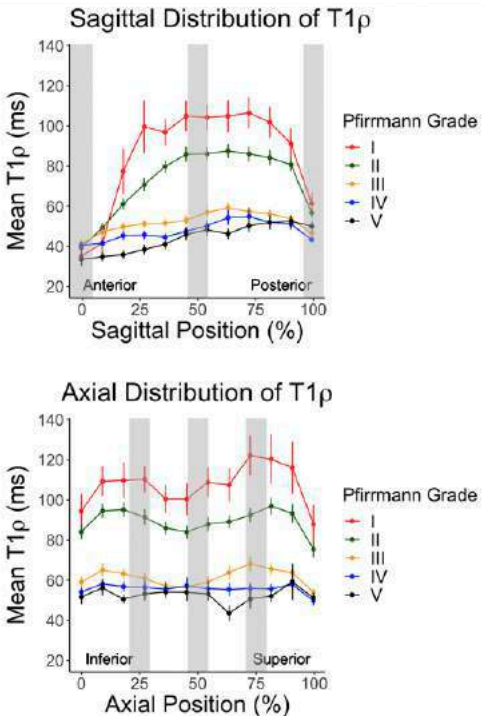

**Figure 2: Mean ± SE T1ρ relaxation times as a function of sagittal (top) and axial (bottom) location for each Pfirrmann grade. Grey vertical bars represent regions of statistical comparison.**

These data are limited in that the analysis was restricted to a single mid-sagittal cross-section and therefore neglects coronal variation in GAG content. However, the mid-sagittal region analyzed here is consistent with the Pfirrmann methodology relying primarily on mid-sagittal images [7]. Additionally, this study is inherently limited in its use of Pfirrmann grade to estimate degeneration, as it is a subjective, semi-quantitative measure of whole-disc degeneration.

Finally, these data reinforce the use of T1ρ-weighted MR imaging as a method for quantitatively, objectively, and non-invasively measuring and characterizing GAG content in lumbar intervertebral discs. Understanding the relationship between spatial distribution of GAG content in the disc and the progression of degeneration can be an important tool in the study of the etiology of disc degeneration.

# TISSUE-ENGINEERED COLLAGENOUS FIBROUS CAP MODELS TO EXPLORE ATHEROSCLEROTIC PLAQUE RUPTURE

**Tamar B. Wissing (1,2), Kim van der Heiden (1), Sheilla Serra (1), Anthal Smits (2), Carlijn Bouten (2), and Frank Gijsen (1,3)**

## INTRODUCTION

Thin cap fibroatheromas are the plaque types that are most prone to rupture and are therefore termed "vulnerable" plaques. They are characterized by a soft lipid core embedded in a collagenous matrix, separated from the bloodstream by a fibrous cap[1]. The stability of a plaque largely depends on the integrity of this fibrous cap, but little is known about its mechanical properties and rupture mechanism.

The mechanical properties of the of fibrous cap are mainly determined by the fibrillar collagenous matrix. The mechanical properties of the collagenous matrix are subject to change, as production, remodeling, and degradation are known to be locally controlled by the mutual interplay between the cellular population and environmental cues, like mechanical strain [18–20].

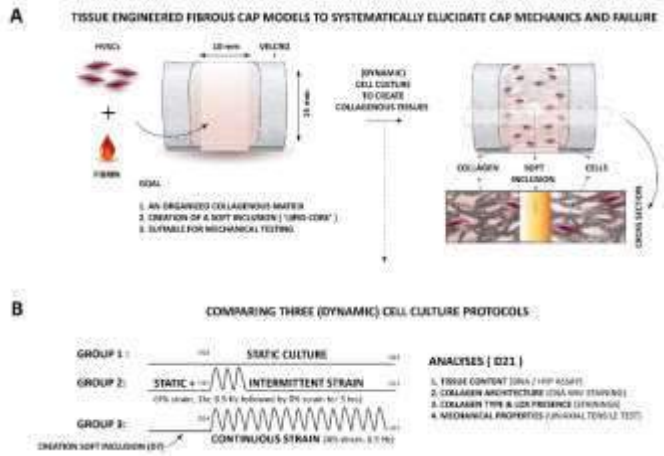

**Figure 1: Protocol for developing fibrous cap analogs.**

The cap strength values reported in literature very widely, at least partly reflecting the different cap failure mechanisms. Several failure mechanisms have been proposed[2]. However, due the paucity of experimental data, the conditions that underlie each failure mechanism remain still largely unknown.

Innovative models should be developed that aid in the systematic investigation of human cap rupture with high experimental control with relatively high throughput. Within this study, we take the first step in developing a human disease model for atherosclerotic plaques using concepts from the tissue engineering domain.

## METHODS

*Development of fibrous cap analogs*

Plaque analogs were created by seeding human vena saphena cells. The samples were statically cultured for 7 days, whereafter a 2 mm Ø soft inclusion (SI) was created by punching a core in the center of each analog and filling this core with fibrin (Fig 1A). This fibrin inclusion mimics the soft lipid core of atherosclerotic plaques. The analogs were statically cultured for 7 more days, after which they were exposed to 7 days of dynamic culturing using the Flexcell FX-4000T Three different loading protocols were applied (Fig 1B), static, intermittent strain (I-strain) and continuous strain (C-strain) with n=5 for each group. Velcro strips were added for mechanical testing[3].

*Collagen imaging*

At day 21, the samples were exposed to multiphoton microscopy (Leica TCS SP8X) with second harmonic generation to visualize the collagen architecture. The samples were incubated with CNA35 probe to visualize the collagen. Collagen fiber organization was quantified using second harmonic imaging. Fibrillar collagen or cell nuclei were visualized in cross-sections stained for Picrosirius Red (PSR) or Hematoxylin and Eosin (H&E), respectively[3].

*Uniaxial tensile tests and DIC*

After imaging, the samples were mechanically tested. A speckle pattern for digital image correlation (DIC) was applied to the top surface of each sample using an airbrush and a tissue dye. After pre-stretch (15 mN) and preconditioning (10 cycles of 10% strain), the samples were uniaxially strained until failure at a speed of 100%/min. The samples were strained in the direction, which biologically corresponds to circumferential strain. The nominal engineering stress-strain curves were derived from the force and displacement measurements utilizing the average initial thickness and width measurements. Data averaging was performed on the stress-strain data and the stiffness values were computed as the linear slopes at 2%, 5% and 10% strain based on the DIC analyses[3].

## RESULTS

*Collagen imaging*

Fig. 2 demonstrates the created organized collagenous tissues for the I-strain sample. All top regions analyzed exhibited isotropic collagen organizations irrespective of the culture protocol applied. The predominant fiber angles ranged between 74°degrees for the statically cultured samples up till 61° and 45° degrees when exposed to intermittent and continuous loading, respectively. Moving towards the shoulder and mid cap regions, the fibers appear more anisotropic in the direction of the Velcro constraints for the dynamically loaded samples. Those samples showed predominant fiber angles of 4° and 3° degrees in the shoulder region and 4° and 5° degrees in the mid cap region for the I-strain and C-strain respectively. The static control demonstrated a more isotropic collagen fiber distribution with a predominant fiber angle of 77° degrees in the shoulder and 35° degrees in the mid cap region. Increased collagen alignment was observed in the direction of the Velcro constraints when moving from the top to the shoulder and ultimately the mid-cap region, especially when loading was applied during culture.

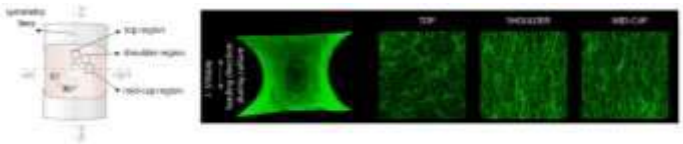

**Figure 2: Collagen fibre orientation**

Histological assessment of the tissue engineered fibrous cap models tissue content, demonstrated a similar collagenous architecture as observed in the fibrous cap of human atherosclerotic plaques, especially when loading was applied during culture (Fig.3). H&E and PSR staining shows a similar morphology, although the intensity of the H&E stain was less intense for the tissue engineered fibrous cap models in comparison to the human cap control.

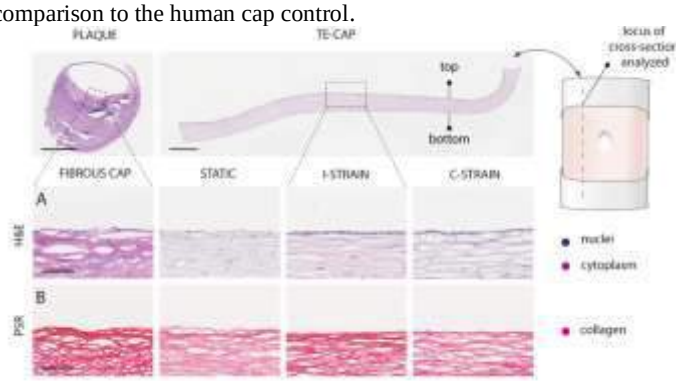

**Figure 3: Collagen fibre orientation**

*Uniaxial tensile tests and DIC*

Uniaxial tensile tests revealed that all engineered matrices demonstrated physiological strain stiffening responses (Fig.4A) with values that mimic plaque mechanical properties *ex vivo*. More specifically, stiffness values were 0.3 ± 0.2 (static), 0.3 ± 0.1 (I-strain) and 0.4 ± 0.2 (C-strain) MPa at 2% strain, 1.1 ± 0.5 (static) 1.1 ± 0.5 (I-strain) and 1.2 ± 0.4 (C-strain) MPa at 5% strain, and 2.3 ± 0.9 (static), 1.6 ± 0.3 (I-strain) and 2.2 ± 0.9 (C-strain) MPa at 10% strain (Fig.4B).

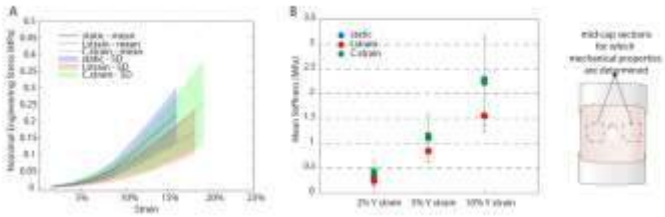

**Figure 4: Mechanical assessment of fibrous caps**

## DISCUSSION

In the newly developed platform, anisotropic collagen configurations, in the direction of loading, were observed. These matrix (re-)orientation responses are known to be a direct consequence of cellular (re-)orientations due to tissue constraints, contact guidance of the endogenous matrix and the magnitude and type of applied loads[4]. A predominantly isotropic collagen organization was detected in the top and base regions of the dynamically stimulated tissues illustrating that cellular (re-)orientation processes and consequent collagen fiber (re)distributions depend on the cumulative presence of constraints, matrix stiffness and local strain patterns. The histological analyses indicate that also the structural organization of the collagen mimics human cap composition adequately.

Although it is difficult to make a direct comparison to human caps, because of their complex composition and the variety of mechanical analyses performed in literature[5], all engineered tissues analyzed demonstrated physiological strain stiffening behavior and calculated stiffness values fell within the range reported for human carotid fibrous caps (i.e. 0.5-5 MPa) 5. Based on these initial data, we can conclude that not only the structural aspects of fibrous caps can be captured with this model, but we also generated a mechanical cap equivalent.

In conclusion, we present three tissue-engineered fibrous cap models that aid in the controlled and systematic investigation of the reciprocal relationships between cap composition and mechanical properties. By applying different (dynamic) cell culture protocols we were able to create reproducible naturally crosslinked tissues, with a tunable collagen content and organization, suitable for mechanical testing.

## INTRODUCTION

Atherosclerotic plaque rupture, a major cause of cardiovascular events, is a local mechanical failure of the plaque tissue [1]. However, the current knowledge on rupture characteristics of the highly heterogeneous plaque tissue and the association of these to the underlying tissue structure is very scarce and limited to global, aggregate tissue properties [2]. In this work, we aim to characterize local heterogenous rupture properties of atherosclerotic human plaques by using tensile testing and digital image correlation (DIC), and investigated their association to the structural collagen architecture derived from second harmonic generation (SHG) microscopy imaging.

## METHODS

Tissue Collection and Structural Imaging

Nineteen atherosclerotic human carotid endarterectomy (CAE) samples were collected at Erasmus Medical Center, in Rotterdam. Initially, the samples were scanned with a micro-CT scanner (Quantum GX 2, Perkin Elmer) to identify non-calcified regions (Fig.1). Based on the scanning results, rectangular tissue strips (n=31) of fibrous plaque tissue were prepared. The tissue strips had their long-axis in the circumferential direction of the artery. Subsequently, the fibrillar collagen structure of tissue strips were imaged with a multiphoton microscope (Leica SP5) using SHG imaging (Fig.1). Before the imaging, a tile scan was performed per each sample. Each tile element consisted of 512 x 512 pixels and had the size of 738 x 738 µm. In selected tile elements, in-plane Z stack images were obtained with step size of 3 µm starting from the luminal surface up to approximately 150 µm tissue depth. The fibrillar collagen orientation (the predominant angle (pDA) ± standard deviation (SD)) and the anisotropic fraction (AF) within each scanned tile element was extracted by Gaussian Distribution fit histograms, obtained from the maximum intensity projection (MIP) images, using the Fiblab Software [3] (Fig.2). The AF indicated the anisotropy (0=isotropic, 1=anisotropic) of analyzed areas.

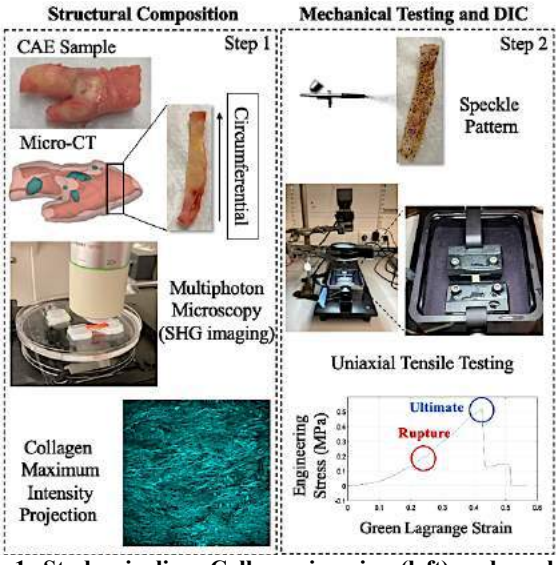

**Figure 1: Study pipeline: Collagen imaging (left) and mechanical testing combined with DIC (right) of plaque strips.**

Uniaxial Tensile Testing and Digital Image Correlation

After the structural imaging, a speckle pattern was applied to the luminal surface of the tissue strips. Then, the speckled tissue strips were placed into 37°C PBS filled in-house-built uniaxial tensile testing setup (Fig.1). A pre-load of 0.05N was applied. Then, the samples were preconditioned up to %10 strain for 10 cycles with a speed of 0.05mm/s. With constant speed, samples were continuously stretched along their long axis (circumferential direction of the artery) until complete rupture. The initial rupture was defined as the first failure detected in the gauge-length (GL) based stress-strain curve (Fig.1). Tissue deformation and

the local rupture(s) during the tests were recorded with a 5.3 MP CMOS camera (PL D 725, Pixelink). The local tensile strain (Green-Lagrange) within the tissue strips (excluding ~1 mm near-clamp regions) during the tensile testing were assessed from the camera recordings using a DIC software (Ncorr, version 1.2) [4] (Fig.3 (A)).

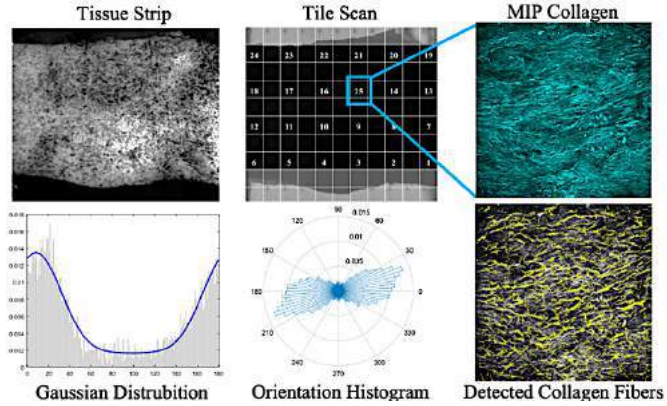

**Figure 2: SHG tile scan, MIP image and fiber detection to predict the local pDA and the SD of the peak.**

## RESULTS

Micro-CT scans, SHG based structural collagen imaging, uniaxial tensile testing and DIC of all samples were performed successfully. The pipeline was applied on 31 tissue strips from 19 CAEs, and the post-processing of 5 strips from 5 CAEs have been completed.

GL-based assessment revealed the average, global tensile strain properties of the tissue strips at the rupture initiation (range: 13-38% with a median of 22%) and the ultimate strains, at complete tissue separation (range:17-61% with a median of 28%). DIC analysis, on the other hand, enabled the local strain assessment: the plaque strips had a highly non-uniform, heterogenous strain distribution (a representative DIC map of CAE #3 demonstrated in Fig.3(A)). The averaged DIC based tensile strains at the rupture initiation time point for the whole strip (range:11-18%, median:16%) was lower than the global GL based measurements (Fig.3(B)). However, the DIC based local max strains at ROI (range:20-83%, median: 40%) was observed to be higher than both ultimate, and GL based global strain at the first rupture. Interestingly, 4 of 5 CAEs had a high or the maximum local DIC strain at the rupture.

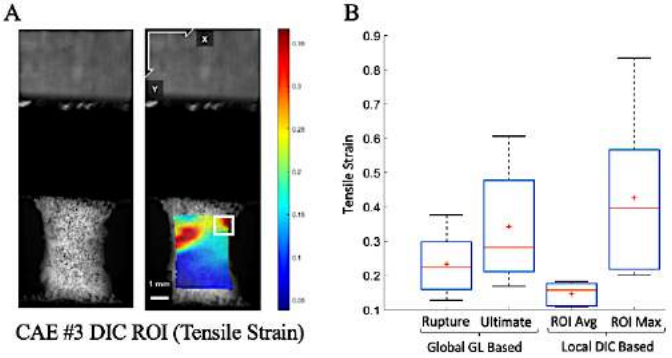

**Figure 3: (A) DIC based strain patterns of CAE (#3). The white square indicates the rupture. (B) Global GL based and DIC strains.**

Collagen Architecture of CAE Strips

All 5 CAEs were analyzed locally to obtain pDAs and SDs (Fig.4(A)), and AFs of each tile element. Mainly, all samples had circumferentially aligned pDAs (between -45° and 45°) with average ± SD of -34°±33°, 11°±34°, 0°±14°, 3°±14°, 11°±31° respectively for CAEs # 1, 2, 3, 4 and 5 (Fig.4(B)). The SDs (range:14° to 48°, mean:26) and AFs (range:0.10 to 0.82, mean: 0.53) of all CAEs demonstrated a variable anisotropy degree within and between samples.

The measured pDA ± SD and AF at rupture locations were 16° ± 29° and 0.72, 44° ± 21° and 0.43, -29° ± 26° and 0.44, -12° ± 26° and 0.59, and 30° ± 23° and 0.26 respectively for CAEs # 1, 2, 3, 4 and 5. All samples (n=5) were observed to have circumferential direction aligned pDAs at the rupture locations (Fig.4(B)).

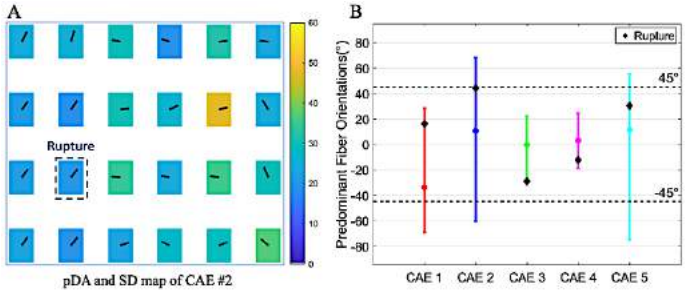

**Figure 4: (A) A representative pDA and SD map of CAE (#2). Black arrows and the colormap indicate the pDA and the SD within each tile element, respectively. (B) The pDA range of each CAE sample. Black diamonds indicate the pDA at the rupture locations.**

## DISCUSSION

In this work, we conducted a preliminary analysis of our pipeline developed to characterize the local mechanical rupture properties of atherosclerotic human carotid plaques, and their correlation with the underlying fibrillar collagen structure. The pipeline comprises pre-testing structural imaging, uniaxial tensile testing and DIC based local strain analysis. Thirty-one strips from 19 CAEs were tested, and the data of 5 strips from 5 CAEs have been analyzed. First, the commonly reported ultimate tensile strain, and the GL-based tensile strain at the first rupture were predicted. Yet, any GL-based strain assessment provides global, average tissue properties. Hence, we obtained DIC based strain measurements for observing the heterogenous nonuniform strain distribution of the plaque tissue. Our DIC-based average measurements were lower than the GL-based strains. This is likely due the exclusion of the near-clamp regions in the analysis, which show greater strains than the center region because of the clamping effects. However, DIC-based max strain measurements had a clear wide range of values within strips, up to ~80%, and was greater than both the ultimate and GL-based rupture initiation strains. Hence, the DIC based analysis was advantageous in avoiding overestimated averages due to the clamping, and the underestimated local high strains by the inherent homogeneity-based traditional ultimate analysis. Interestingly, the structural collagen analysis demonstrated predominant circumferential alignment at rupture regions, as well as for the rest of the tissue. However, the anisotropy varied inter- and intra- samples likely due to the heterogenous structure of plaque strips. For future work, all tested strips (n=31) will be analyzed to have a complete picture of structural and mechanical fingerprints of plaque rupture. This will provide us with unraveled insights of plaque rupture and as such, enable developing better treatment strategies for preventive medicine.

## INTRODUCTION

Brain metabolism produces waste, which must either be degraded or cleared from the brain tissue. Compounds that are not degraded and do not pass the blood-brain-barrier (BBB) are cleared by bulk efflux of interstitial fluid (ISF) [1]. The glymphatic model proposes that the driving mechanism behind bulk ISF efflux is influx of cerebrospinal fluid (CSF) from the subarachnoid space via arterial perivascular spaces (PVSs) [2]. This proposition has been challenged in subsequent studies and reviews [3,4], with differing anesthetic regimens as a possible confounding factor [5]. To assess the contribution of CSF influx to ISF clearance, we used magnetic resonance imaging (MRI) and single photon emission tomography (SPECT) to quantitatively measure both CSF influx and ISF efflux using different methods in rats under the same anesthetic regimen.

## METHODS

Experiments were carried out in male or female Sprague-Dawley rats (200-400g) under ketamine-dexmedetomidine anesthesia (K: 100 mg/kg, Dex: 0.5 mg/kg). MRI experiments were carried out on a Bruker BioSpec 94/30 USR magnet interfaced to a Bruker Advance III console using an 86 mm volume RF-transmit coil and a 4-channel phased array RF receiver coil (Bruker, Ettlingen, Germany). SPECT experiments were carried out on a Vector4CT (MILabs, Utrecht, Netherlands).

**CSF influx quantification.** We estimated CSF influx through the PVS surrounding the middle cerebral artery (MCA), which supplies a large portion of the cortex. We measured flow as the product of the cross-sectional PVS area ($A$, mm$^2$) and the flow velocity in the PVS ($v$, mm·min$^{-1}$). We then converted the flow measurement to perfusion ($Q$, µl·g$^{-1}$·min$^{-1}$) by dividing by the weight of the perfused brain tissue ($m$, g), i.e.:

$$Q = v \cdot A/m. \quad (1)$$

**Flow velocity.** Flow velocity was measured using dynamic contrast-enhanced MRI (DCE-MRI; FLASH3D; TE/TR/FA/matrix/FOV: 3ms/16ms/20°/ 280x173x380/28x20x38mm) with infusion of Gd-DTPA (50mM, 40µl, 2µl/min) in cisterna magna to trace the flow of CSF. Along the MCA, we measured arrival time and distance from the circle of Willis, and the flow velocity was estimated at the slope of the fit between the arrival time and distance (Fig. 1).

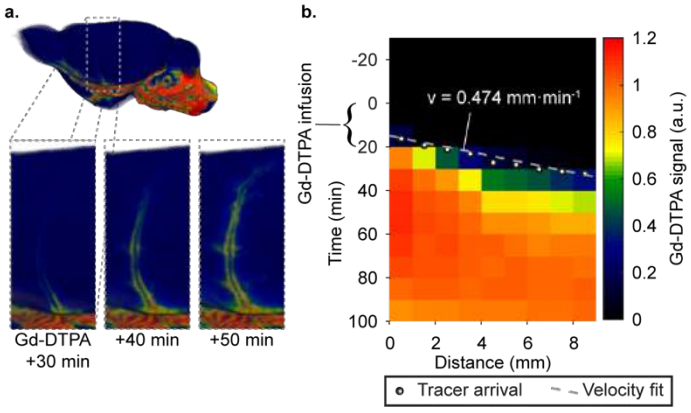

**Figure 1: Measurement of PVS flow velocity. a.** Visualization of Gd-DTPA distribution in PVS. **b.** Linear fit of arrival time over distance estimates the average flow velocity.

**PVS cross-sectional area.** Cross-sectional area was measured using high-resolution, long echo time T2-weighted MRI (TurboRARE, TE/TR/matrix/FOV/slices 24ms/16s/375x250/30x20mm/128, 8 repetitions) without contrast-enhancement. The images were converted to CSF partial-volume maps, and the cross-sectional area was estimated

as the summed CSF volume along the main trunk of the MCA divided by the length.

**Perfusion region mass.** We estimated the perfused area using quantitative DCE-MRI (FLASH3D; TE/TR/FA/matrix/FOV: 4ms/15ms/15°/128x128x128/ 30x32x30mm), to measure Gd-DTPA concentration quantitatively [6]. From these data, we calculated a voxel-wise tracer arrival-time map (Fig 2a), which allowed us to use a gradient-step algorithm to step against the direction of tracer distribution until reaching the subarachnoid or perivascular space (Fig 2b). Voxels from which the gradient-step algorithm reached the PVS of MCA were assigned to the MCA PVS perfusion region (Fig 2c), and finally the area of the region was multiplied by the density of rat brain (0.001045 g/mm$^3$) [7] to calculate $m$.

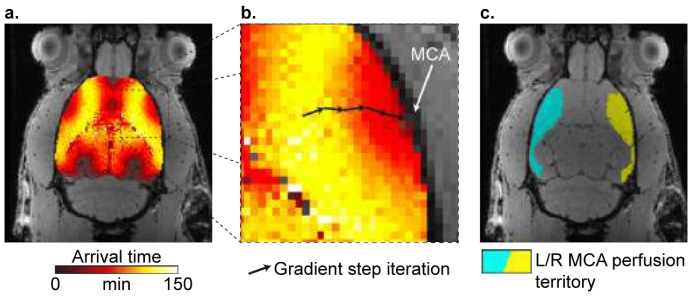

**Figure 2: Estimation of the perfusion territory. a.** Gd-DTPA arrival time map. **b.** Illustration of the gradient step algorithm. **c.** Example segmentation of left and right MCA perfusion territories.

Using these data, we further estimated whether a significant amount of the PVS flow bypassed the brain. To that end, we compared the accumulation of Gd-DTPA in the MCA perfusion territory to the cumulative amount of Gd-DTPA flowing through the MCA perivascular space in individual rats:

$$n_{\mathrm{CTX}}(T) = \int_{t=0}^{T} c_{\mathrm{PVS}}(t) \cdot v \cdot A \, \mathrm{dt}, \qquad (3)$$

where $n_{\mathrm{CTX}}(t)$ amount of Gd-DTPA in the MCA perfusion territory at time $t$, $c_{\mathrm{PVS}}(t)$ is the PVS Gd-DTPA concentration and $\dot{V}_{\mathrm{PVS}} = v \cdot A$ is the PVS flow.

**ISF clearance rate quantification.** To estimate the ISF clearance rate, we infused $^{99m}$Tc-DTPA through a chronically implanted cannula in striatum and measured the residual $^{99m}$Tc activity in the brain every ten minutes for 200 minutes using SPECT. After decay-correction we measured the tracer half-life ($T_{1/2}$) and converted it to a ISF clearance rate ($CL$) using the equation

$$CL = 0.693/T_{1/2} \cdot V_D \text{ [8]}, \qquad (2)$$

where $V_D$ is the distribution volume of the extracellular tracer, approximately 200 µl/g [9]

## RESULTS

Average flow velocity ($v$) was 0.61±0.17 mm·min$^{-1}$ (n=7), average PVS cross-sectional area ($A$) was 0.076±0.014 mm$^2$ (n=12), and average MCA PVS perfusion region mass ($m$) was 0.150±0.016 g (n=5). Applying eq. 1, we estimated CSF perfusion in the territory of the MCA ($Q$) to be 0.32±0.11 µl·g$^{-1}$·min$^{-1}$. Qualitative evaluation (Fig. 3) showed good agreement between Gd-DTPA accumulation and cumulative Gd-DTPA flow through PVS during the influx phase (0-100 min), indicating that the amount of flow bypassing the brain is negligible. The average ISF clearance was 0.471±0.053 µl·g$^{-1}$·min$^{-1}$ (n=12).

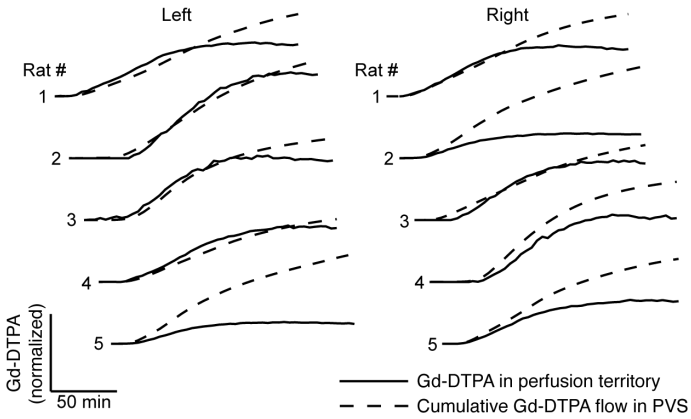

**Figure 3.** Qualitative assessment of CSF flow bypassing brain.

## DISCUSSION

We found a high degree of congruency between CSF influx and ISF clearance under the same anesthetic conditions despite applying very different measurement methods. These results indicate that CSF inflow is a major source of ISF and thereby of its clearance, contributing to the removal of metabolic waste from the brain tissue. We additionally found that PVS flow predominantly enters the brain parenchyma, that Gd-DTPA can freely enter the interstitium with CSF through PVSs, and that advection via PVS inflow is the dominant tracer influx mechanism.

# AUTOMATIC ESTIMATION OF MECHANICAL AND GEOMETRICAL PARAMETERS OF ABDOMINAL AORTIC ANEURYSMS USING 3D+T ULTRASOUND FOR UNDERSTANDING ANEURYSM PROGRESSION

**Esther J. Maas (1,2), Arjet H.M. Nievergeld (1,2), Judith H.C. Fonken (1,2), Mirunalini Thirugnanasambandam (1), Marc R.H.M. van Sambeek (1,2), Richard G.P. Lopata (1)**

## INTRODUCTION

In current clinical practice, the rupture risk of abdominal aortic aneurysms (AAAs) is estimated from their maximal diameter. When a critical maximum diameter of 5.5cm is reached, surgery is performed to prevent rupture. However, some aneurysms rupture before this threshold is met, while others remain stable at larger diameters [1].

Previous research has shown the added value of additional rupture risk parameters, such as the AAA volume, curvature, elasticity and maximum wall stress [2-5]. These studies typically used computed tomography (CT) data, whose acquisition requires the use of radiation and nephrotoxic contract agents, preventing longitudinal studies. The current study focusses on the use of time-resolved 3D ultrasound (3D+t US), which non-invasive character and low cost make it the preferred imaging modality. Furthermore, 3D+t US gives information on the whole AAA geometry during different phases in the cardiac cycle, enabling the study of many parameters from a single image acquisition.

The aim of this study is to 1) develop a method to automatically determine rupture-risk related parameters from 3D+t US acquisitions and 2) apply this method in a follow-up study of AAA patients, to relate these parameters to the progression of the aneurysm.

## METHODS

3D+t US images of AAA patients were acquired during follow-up visits in the Catharina Hospital in Eindhoven. Each visit, the AAA outer-to-inner wall diameter is determined using 2D US ($D_{meas}$, current clinical workflow). A 3D+t US acquisition is performed during breath hold in a supine position, using a Philips IU22/Epiq US scanner with an X6 matrix array probe. The blood pressure is measured with an arm cuff.

The acquired 3D+t US images have a volume rate of 4-8 Hz and contain 15-35 frames. These images were processed offline using MATLAB R2021a. The segmentation of the inner aortic wall from the images was performed automatically on transverse slices using an in-house created adaptation of a Star-Kalman algorithm [6], followed by 3D deformable contours [7]. This segmentation was repeated on all time frames of the 3D+t data, allowing studying the motion of the aorta.

From the time-average segmentation, a centerline (CL) was created using a Dijkstra shortest path algorithm. Next, the segmentations of all time frames were resampled to obtain slices perpendicular to the CL with 1mm spacing between them. From this, the maximal inner-to-inner wall diameter ($D_{max,perp}$) and volume in a region of 60 mm around the maximal diameter ($V_{part}$) were determined. The point-wise curvature of the whole aortic inner wall was determined (mean of the principal components) using a finite differences approach [8], from which the median value over the AAA was taken. Furthermore, the elasticity (Ep) of the aortic wall was determined from systolic and diastolic diameter ($D_{sys}$ and $D_{dia}$) and the pulse pressure ($\Delta p$):

$$Ep = \frac{133.3 \cdot \Delta p}{(D_{sys} - D_{dia}) / D_{dia}} i \qquad (1)$$

In addition, the pressure-independent relative diastolic-to-systolic volume change was determined.

These parameters were determined in a preliminary analysis of 22 patients from our follow-up study, who had at least 3 follow-up measurements. The average growth rate was determined. Furthermore, the development of these parameters with the AAA progression was studied by investigating the linear regression of these parameters with the diameter. For the elasticity and relative volume change, box-and-whiskers plots for different diameter groups were created and groups were compared with a Wilcoxon rank sum test.

## RESULTS

An example of a AAA inner wall segmentation result on the US data is shown in Fig 1a, showing good correspondence to the image features. This also shows the location of the maximal diameter, whose variation over time is shown in Fig 1b. The curvature map is presented in Fig 1c, showing regions of high curvature at the ends of the aneurysm.

Segmentations were successful for 99 out of 113 datasets (visual check). Furthermore, the pulsatility was clearly visible in 83 of these acquisitions. Patients with unclear vessel pulsation (caused by poor image quality) were not further analyzed.

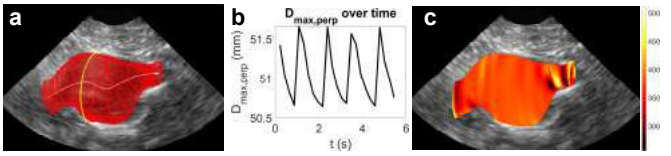

**Figure 1a: the segmentation plotted on the ultrasound data with the centerline (white), perpendicular slices with 5mm spacing (red) and the maximal diameter slice (yellow). b: The diameter variation over time. c: Curvature map of the geometry.**

Fig 2a shows the progression of the aneurysms over time. The growth rate of patients with at least 3 successful segmentations (N =15) was 2.2 [1.4-3.1] mm/year (median [IQR]), with a range of 1.0-6.0mm/year, indicating large variations between patients.

A clear relationship between $D_{meas}$ (outer-to-inner wall, from 2D US) and $D_{max,perp}$ (inner-to-inner wall, from 3D US) is shown in Fig 2b ($R^2$ =0.82). The average point-wise difference is 3.0mm, with IQR [1.4-4.7] mm, which is partially caused by wall thickness that is incorporated in $D_{meas}$. The differences seem slightly larger at larger diameters.

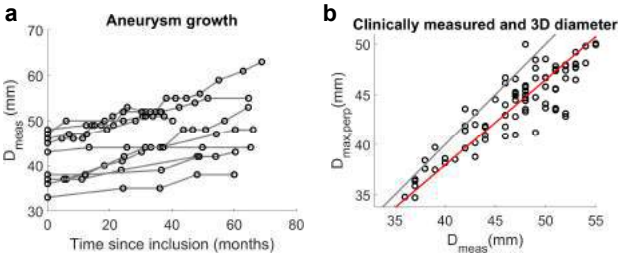

**Figure 2a: the growth of the aneurysm over time. For visualization purposes, only patients with at least 40 months of follow-up are shown (N = 9). b: relationship between $D_{meas}$ and $D_{max,perp}$; the identity line is indicated in grey and linear regression curve in red.**

The relation between $V_{part}$ and $D_{max,perp}$ is shown in Fig 3a, which demonstrates good correspondence ($R^2$ = 0.83) but also some spreading in the data. Fig 3b shows a negative correlation between the $D_{max,perp}$ and the median curvature of the AAA ($R^2$ =0.59, p <0.01).

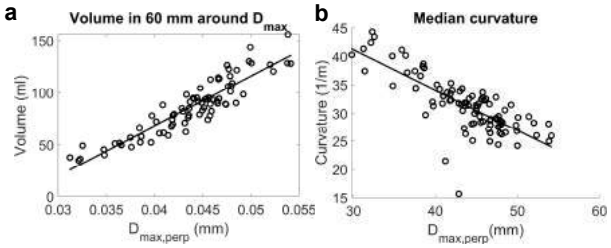

**Figure 3a: Relation between the maximal perpendicular diameter ($D_{max,perp}$) and volume in 30mm around $D_{max,perp}$. b:relation between $D_{max,perp}$ and curvature.**

The elasticity and relative volume change for different diameter groups are shown in Fig 4a and Fig 4b, respectively. The Wilcoxon rank sum test shows significant differences between the small and medium AAA group for both elasticity and volume change (P<0.01). There are no significant differences between the other groups. Both plots indicate that larger aneurysms pulsate less than smaller aneurysms, independent of whether the patient-specific blood pressure is taken into account.

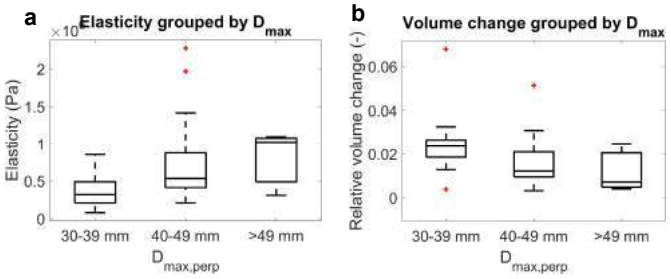

**Figure 4: Box-and-whiskers plots of the elasticity (a) and relative volume change (b) grouped by maximal diameter.**

## DISCUSSION

A tool to automatically determine many rupture-risk related parameters of AAA from a single 3D+t US acquisition has been developed. The good overlap between the clinically measured maximal diameter and diameter obtained from the automatic segmentation (Fig 2b) shows the accuracy of the segmentations. The good correlation between the volume and diameter is as expected, but the spreading in the data shows that investigation of the volume can add additional information about the state of the AAA.

The negative correlation between $D_{max,perp}$ and curvature could be explained by the increased proximal-distal size of the aneurysm with increasing diameter. The positive correlation between the diameter and elasticity corresponds to findings in research on 2D US [8], suggesting mechanical changes in the aneurysm wall occur as the dilatation progresses. Presence of an intraluminal thrombus could also play a role.

The next step in our research is to couple the workflow presented in this study to a method to determine the aortic stiffness and wall stresses using finite element modeling, which has already been developed in our group [10]. With this, more mechanical parameters can be investigated, including wall stress.

In conclusion, an important tool to study geometrical and mechanical parameters of AAAs has been developed, showing accurate geometrical results (Fig 2b), and expected correlation between geometry and elasticity (Fig 4). When applied to the whole dataset of 500 patients in our follow-up study, the predictive value of these parameters (volume, curvature, elasticity, and wall stresses) for AAA growth and rupture can be further investigated, to obtain more patient-specific rupture risk and growth predictors.

# CAROTID ARTERY STIFFNESS MECHANISMS ASSOCIATED WITH CARDIOVASCULAR DISEASE EVENTS AND INCIDENT HYPERTENSION: THE MULTI-ETHNIC STUDY OF ATHEROSCLEROSIS (MESA)

## INTRODUCTION

Higher levels of arterial stiffness are associated with higher risk for hypertension, cardiovascular disease (CVD) events, and overall mortality [1]. The central, elastic arteries stiffen via two main mechanisms: 1) Load dependent stiffening due to elevated blood pressure increasing collagen fiber loading without an intrinsic change to the artery wall, and 2) Structural stiffening due to arterial remodeling which manifests as intima-media thickening, elastin fragmentation, and collagen accumulation. We previously quantified the age-associated longitudinal changes in structural and load-dependent carotid artery stiffness in the Multi-Ethnic Study of Atherosclerosis cohort [2]. Over a decade of aging, the vast majority of the age-associated increases in carotid artery stiffness were due to structural stiffening intrinsic to the arterial wall rather than being a concomitant effect of increased systolic BP with aging. However, there was high individual variability, with approximately 1/3$^{rd}$ of participants having more load-dependent than structural stiffening. The roles of load-dependent and structural stiffening in the development of hypertension and CVD events are still unknown. We hypothesized that structural stiffness would have the strongest association with CVD events because it is representative of intrinsic changes to the makeup of the artery wall material, leading to subclinical atherosclerosis and thus contributing to future CVD events. The Multi-Ethnic Study of Atherosclerosis (MESA) cohort provides a unique opportunity to better understand the mechanisms for large artery stiffening and test their hypothesized relationship with hypertension and CVD development.

## METHODS

The Multi-Ethnic Study of Atherosclerosis (MESA) is a longitudinal study of 6,814 men and women without CVD at enrollment, from 6 diverse communities in the United States [3]. MESA participants with B-mode carotid ultrasound and brachial BP at baseline Exam in (2000-2002) and CVD surveillance (mean follow up 14.3 years through 2018) were included (n=5873). Peterson's elastic modulus (PEM) was calculated to represent total arterial stiffness. Structural stiffness was calculated by adjusting PEM to a standard BP of 120/80 mmHg with participant-specific models [2,4]. Load dependent stiffness was the difference between total and structural stiffness.

Cox proportional hazard models were used to evaluate associations with incident CVD events and hypertension. Models were adjusted for traditional CVD risk factors including non-linear interactions.

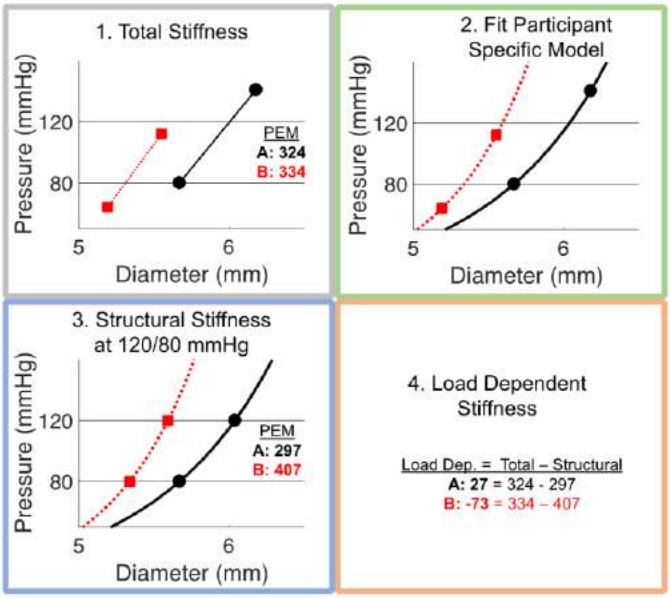

**Figure 1: Graphical representation for two participants of the methods to differentiate structural and load-dependent stiffness.**

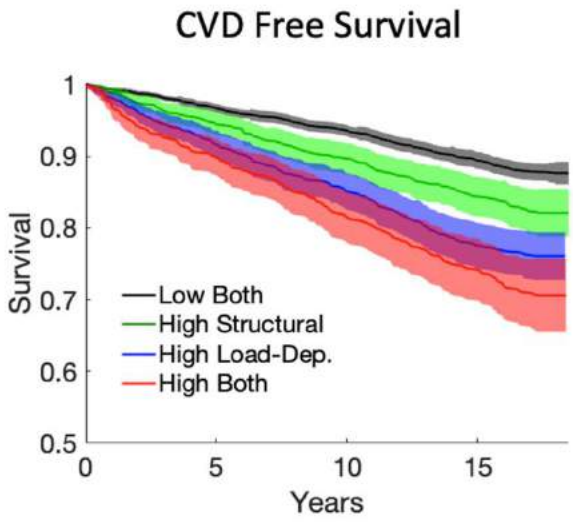

**Figure 2: Unadjusted Kaplan-Meier curves show that CVD free survival is greater for participants with high structural versus high load-dependent stiffness.**

## RESULTS

Based on 75th percentile cut-offs of PEM among these participants, groups of high structural, high load-dependent, high percentiles of both stiffness mechanisms, and low percentiles of both stiffness mechanisms were created for Kaplan-Meier curves (Figure 2). In this unadjusted analysis, CVD free survival was greater for participants with high structural stiffness versus high load-dependent stiffness.

In Cox models adjusted for traditional risk factors (Table 1), load-dependent stiffness was significantly associated with higher incidence of CVD events (hazard ratio per 100mmHg [HR] 1.21, 95% CI [1.09-1.34], p<0.001) events while higher structural stiffness was not (HR 1.03, 95% CI [0.99-1.07], p=0.10). Similar results were found for types of CVD events. Analysis of participants who were normotensive (BP < 130/80, no antihypertensives) at baseline exam (n=2122) found higher load-dependent stiffness was also associated with significantly higher incidence of hypertension (HR 1.53, 95% CI [1.35-1.75], p<0.001) while higher structural stiffness was not (HR 1.03, 95% CI [0.99-1.07], p=0.16).

**Table 1: Cox Models for Incident CVD and Hypertension**

| Events | Total PEM | | Structural PEM | | Load-Dep PEM | |
|---|---|---|---|---|---|---|
| | HR | p | HR | p | HR | p |
| CVD | 1.05 | 0.008 | 1.03 | 0.11 | 1.20 | <0.001 |
| Hard CVD | 1.04 | 0.08 | 1.01 | 0.59 | 1.26 | <0.001 |
| CHD | 1.04 | 0.08 | 1.03 | 0.26 | 1.17 | 0.017 |
| Stroke+TIA | 1.01 | 0.77 | 0.98 | 0.44 | 1.26 | 0.003 |
| Hypertension | 1.07 | 0.001 | 1.03 | 0.16 | 1.53 | <0.001 |

HR – Hazard ratio calculated per 100mmHg increment PEM, CHD – Coronary heart disease, TIA – transient ischemic attack

## DISCUSSION

Arterial stiffness is known to be an independent predictor of incident CVD [1]. The present study demonstrated that the underlying mechanisms of arterial stiffness were associated with both incident CVD events and incident hypertension. High load dependent carotid artery stiffness was significantly associated with future CVD events and hypertension, but that high structural carotid artery stiffness was not.

There are two primary advantages of using a participant specific model of arterial mechanics, as was done in this study, instead of a classical statistical adjustment based on blood pressure. The first advantage is that statistical adjustment is potentially correcting for two effects of BP on arterial stiffness at the same time, the chronic effect of increased BP due to remodeling and the acute effect of distending elevated blood pressure [5]. Using an exponential modeling approach these two mechanisms can be differentiated [2]. The second advantage is that the statistical adjustment for BP only gives the average effect of BP on arterial stiffness. Using participant specific models allows individual level correction for the effect of BP on arterial stiffness.

The results of this study support the idea that understanding the mechanism behind an individual's arteries are stiff is paramount. In heart failure, individuals receive different treatments based on etiology. This study presents a corollary regarding the mechanisms of arterial stiffness. We hypothesized that high structural stiffness would have the strongest association with CVD events because it is representative of intrinsic changes to the makeup of the artery wall material, leading to subclinical atherosclerosis and thus contributing to future CVD events. Instead, we found that higher load-dependent stiffness was significantly associated with future CVD events, but higher structural stiffness was not. Prior clinical studies have demonstrating that increased carotid artery stiffness in hypertension is primarily due to load dependent stiffening (from increased blood pressure) and not due to structural stiffening intrinsic to the vessel wall [6]. Taken together, these results suggest that the association of arterial stiffness and CVD risk in hypertension is due to load-dependent stiffening on a population level.

Measuring and treating arterial stiffness has not been used to improve CVD outcomes because there are no therapeutic strategies proven to reduce arterial stiffness independent of reducing blood pressure. This study provides valuable insight into the challenge of how arterial stiffness could best be used in in clinical practice. Recognizing and differentiating the mechanical components of arterial stiffness could provide a novel way to reduce CVD risk and personalize hypertensive care. Future trials focusing on improving load dependent arterial stiffness, either through personalized blood pressure goals or through specific antihypertensive regimens needs to be explored as a potential way to improve CVD outcomes. Our previous analysis in MESA suggests that, unlike structural stiffness, changes in load-dependent stiffness are modifiable through traditional CVD risk factors and individual hypertension management6. There is potential for elevated load-dependent carotid artery stiffness could be used as a threshold to initiate early hypertensive care.

These results provide valuable new insights into mechanisms underlying the association between arterial stiffness and CVD. Load-dependent stiffness was significantly associated with CVD events but structural stiffness was not.

# EFFECTS OF NITROGLYCERIN INDUCED VASODILATION ON ELASTIC VERSUS MUSCULAR ARTERY STIFFNESS IN OLDER VETERANS

**Ryan J. Pewowaruk (1,2), Amy J. Hein (2), Cynthia M. Carlsson (1,2), Claudia E. Korcarz (1), Adam D. Gepner (1,2)**

## INTRODUCTION

Studies of the biomechanics of the central elastic arteries like the aorta and carotid artery have predominately focused on passive contributions to arterial stiffness such as the extracellular matrix (ECM) and neglected active contributions to arterial stiffness from vascular smooth muscle (VSM). It has traditionally been believed that VSM and changes in VSM tone are unimportant to elastic artery stiffness [1] although recent studies have challenged this view [2,3]. In a recent retrospective analysis of several clinical studies, nitroglycerin (NTG) induced vasodilation was found to both increase and decrease arterial stiffness [2] depending on the ratio of passive-to-active stiffness along the continuum of young-to-old, healthy-to-diseased, and elastic-to-muscular arteries. Decreased VSM tone in the carotid artery of hypertensive individuals also bore striking resemblance to the effects of 10 years of aging [4], the carotid artery dilated and stiffened. These results suggest that VSM tone may be a key component of arterial aging and have different impacts on elastic versus muscular arteries. We performed the present study to test the responses of NTG induced vasodilation on arterial stiffness in the brachial and carotid arteries in older Veterans.

## METHODS

40 older Veterans (>60 years old), without known cardiovascular disease, were recruited for this study from the Madison VA Hospital (MVAH) and surrounding clinics. 20 were hypertensive and 20 were normotensive controls. Participants were administered 400mcg sublingual nitroglycerin NTG. NTG induced changes in arterial stiffness were measured locally with vascular ultrasound in the carotid and brachial arteries, and regionally by carotid-femoral pulse wave velocity (cfPWV) by tonometry.

Peterson's Elastic Modulus (PEM) of the carotid and brachial arteries were calculated:

$$PEM = \ddot{u}\frac{\Delta p D d^2}{(Ds^2 - Dd^2)} \quad (1)$$

where *Ds* is systolic diameter, *Dd* is diastolic diameter, and $\Delta p$ is pulse pressure. We used a recently developed arterial mechanics model based on pressure-diameter relationships to model the passive ECM and active VSM contributions to arterial stiffness for each participant [2].

Results are presented as mean and standard deviation. The arterial stiffness response to NTG was analyzed with a repeated-measures linear model with NTG administration as a within subjects factor and hypertension status as a between subjects factor. Results from modeling the active and passive contributions to arterial mechanics were compared using the Mann-Whitney U test due to non-normal distributions of some variables.

## RESULTS

Participant characteristics are shown in Table 1. Controls and hypertensive Veterans participating in this study were similarly matched for age (72.0±9.3 vs 70.8±6.6 year, p=0.64), sex (40% female vs 50% female, p=0.53), and smoking status. 85% of hypertensive participants were using antihypertensive medications and self-reported an average of 14.7±14.3 years since hypertension diagnosis (range: 2-60 years).

NTG decreased mean arterial pressure in control and hypertensive Veterans (NTG p<0.001, Figure 1). The carotid artery dilated more in control participants than hypertensive Veterans (Δ 0.54±0.19mm vs 0.42±0.12mm, p=0.022). Brachial artery dilation was similar, (Δ 0.55±0.26mm vs 0.51±0.20mm, p=0.46). With NTG, both control and hypertensive Veterans showed increased carotid PEM (Δ 66±90 vs 114±129 mmHg, NTG p<0.001) and cfPWV (Δ 1.1±2.2 vs 0.6±2.4 m/s, NTG p=0.020) NTG did not change brachial PEM in control and hypertensive Veterans (Δ 8±495 vs -82±476 mmHg, NTG p=0.69).

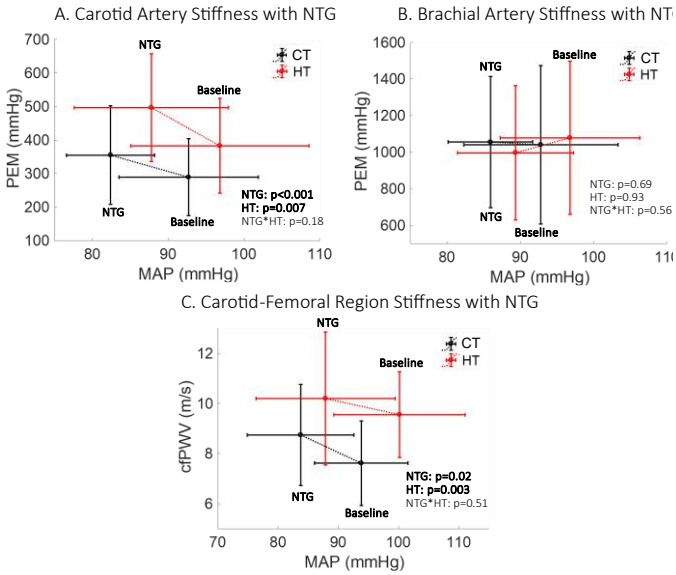

**Figure 1:** NTG A. increased carotid artery PEM, B. did not change brachial artery PEM, and C. increased carotid-femoral pulse wave velocity (cfPWV). CT – Control, HT – hypertensive

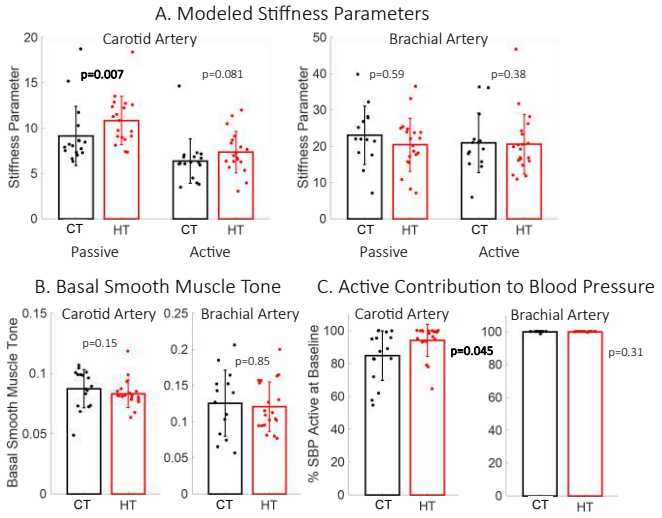

**Figure 2:** A. Carotid artery and brachial artery passive and active stiffness parameters. B. Basal smooth muscle tone for the carotid and brachial arteries. C. For the carotid artery, a greater percentage of baseline SBP was supported by active elements of the artery wall in hypertensive participants compared to control participants. For the brachial artery nearly all of baseline SBP was supported by active components of the artery wall for both groups.

Modeling results are shown in Figure 2. For the carotid artery, hypertensive participants had greater passive stiffness compared to control participants (10.8±2.7 vs 9.1±3.8, p=0.007) while active stiffness was not significantly different (7.3±2.3 vs 6.4±2.8, p=0.081). For the brachial artery, hypertensive and control participants had similar passive and active stiffness (Figure 4). Basal smooth muscle tone was similar between control and hypertensive participants (Carotid: 0.087± 0.026 vs 0.083 ± 0.011, p=0.15; Brachial: 0.115± 0.044 vs 0.121 ± 0.034, p=0.85). For the carotid artery, a greater percentage of baseline SBP was supported by active muscular elements of the artery wall in hypertensive participants compared to control participants (94.1±9.7% vs 84.8±24.7%, p=0.045).

## DISCUSSION

This study assessed the effects of nitroglycerin induced vasodilation on the stiffness of elastic and muscular arteries in older Veterans. The major finding was that the stiffness of central, elastic arteries significantly increased following sublingual nitroglycerin administration. Based on prior studies examining overall CVD risk associated with arterial stiffness parameters, this is a clinically significant observation that equates to an approximate increase of 15% in CVD risk [5]. In contrast to the carotid artery and carotid-femoral region, nitroglycerin did not change the stiffness of the muscular brachial artery.

In this study vasodilator administration decreased brachial BP by approximately 10 mmHg, but also had the negative effect of paradoxically increasing elastic artery stiffness. Awareness of the increase in arterial stiffness despite a decrease in BP is paramount, because it could offset some of the benefits of lowering BP in older patients who are prescribed vasodilators as an antihypertensive therapy. These results emphasize that vasodilators should only be 4th-5th line antihypertensive therapy options, particularly in older patients, and prompt the need to test the impact of other hypertensive therapies on active and passive stiffness parameters.

Nitroglycerin induced vasodilation also had different effects on the stiffness of elastic versus muscular arteries. Vasodilation increased elastic artery stiffness and did not change muscular artery stiffness. We hypothesize that these different findings are due to the ratio of passive and active contributions to arterial stiffness based on a Hill-type partition of passive-elastic and active-contractile forces [2]. When an artery has high passive stiffness, decreasing VSM tone will increase arterial stiffness. The elastic arteries of older individuals likely have higher passive stiffness due to mechanisms such as collagen accumulation and elastin fragmentation.

The arterial stiffness response to vasodilation is likely important in the development of CVD. Carotid artery VSM in hypertensive participants supported the majority of the load imposed on the arterial wall by blood pressure, limiting excess stress on passive, elastic elements of the carotid artery wall. Increased VSM tone has been shown to promote adaptive remodeling by the same mechanism in hypertensive rodents [3]. Our data in Veterans who have had hypertension for years suggests that basal VSM tone may be a long-term adaptation in humans with hypertension.

Limitations of this study include the relatively small number of subjects and is limited to an older, albeit less studied, patient population.

In older Veterans, without known cardiovascular disease, NTG induced vasodilation increased elastic artery stiffness and did not change muscular artery stiffness. Elastic artery stiffening with vasodilation may be important for antihypertensive medication selection and influence CVD development.

## INTRODUCTION

Hypertension, which contributes to neurologic, renal, and cardiac disorders, is a leading cause of death [1]. Aortic stiffening is both a cause and consequence of hypertension and occurs as a homeostatic response to increases in tensile stress from elevated blood pressure [2]. Because of this increase in structural stiffness, the compliance of the aorta decreases and pulse wave velocity (PWV) increases, resulting in a further increase in blood pressure, creating an insidious positive feedback loop. It is important to broaden our understanding of this interplay to potentially develop therapies that target this positive feedback loop.

Angiotensin II (AngII) is an important hormone in the renin-aldosterone-angiotensin-system (RAAS), which regulates blood pressure and fluid balance in vivo [4]. Improper control of the RAAS system has been clinically linked to hypertension, cardiac hypertrophy, and heart failure [4]. Infusion of AngII in murine models can be used to investigate the effects of hypertension and aortic stiffening on the cardiovascular system, as it increases blood pressure and inflammation [5]. In this study, we combined experimental and computational studies to characterize the relationship between arterial mechanics and hemodynamics in mice with chronic infusion of angiotensin II (AngII) and wild-type control mice.

## METHODS

**Experimental:** Animal protocols were approved by Yale University's Institutional Animal Care and Use Committee (IACUC). *In vivo* and *ex vivo* data were collected for 3 control mice and 3 mice following two weeks of AngII infusion (1000ng/kg/min). First, Doppler ultrasound was performed on the ascending thoracic aorta (ATA), infrarenal abdominal aorta (IAA), and the left carotid artery (LCA) to measure dynamic velocity and luminal area waveforms. Second, micro-computed tomography (μCT) scans were performed to collect anatomical data on the aorta and main branches. Third, Millar catheterization was performed to obtained ATA pressure waveforms. Finally, biaxial tissue testing was performed on excised vessels at 7 anatomical locations: ATA, proximal (pDTA) and distal (dDTA) descending thoracic aorta, suprarenal abdominal aorta (SAA), IAA, LCA, and right carotid artery (RCA).

**Computational:** FSI models were created using the open-source software CRIMSON [3]. 3D models of the AngII-infused (**Fig. 1, A1-A3**) and control (**Fig. 1, C1-C3**) mice were reconstructed from μCT images. Spatially-varying wall stiffness and thickness were derived from biaxial tissue testing data by linearizing around the *in vivo* diameter determined from μCT. ATA flow waveforms, measured with Dopper ultrasound, were imposed at the aortic inlet. Lumped parameter three-element Windkessel models were prescribed at each outlet branch to represent the distal vasculature and tuned to match ATA pressure waveform and LCA and IAA mean flow within 10%.

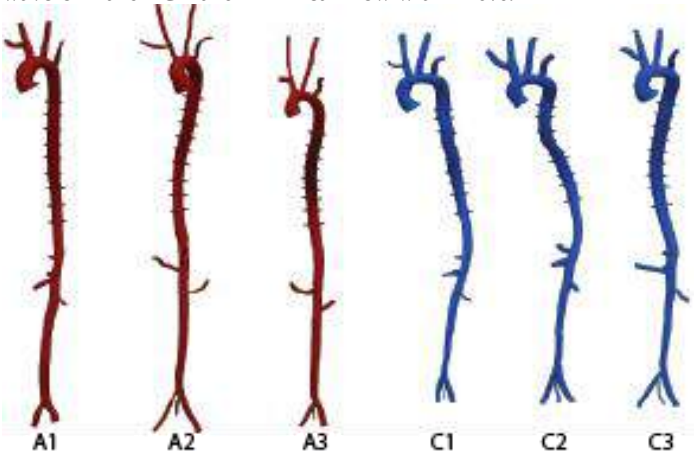

**Figure 1. Computational models for each mouse included in this study; AngII-infused: A; controls: C.**

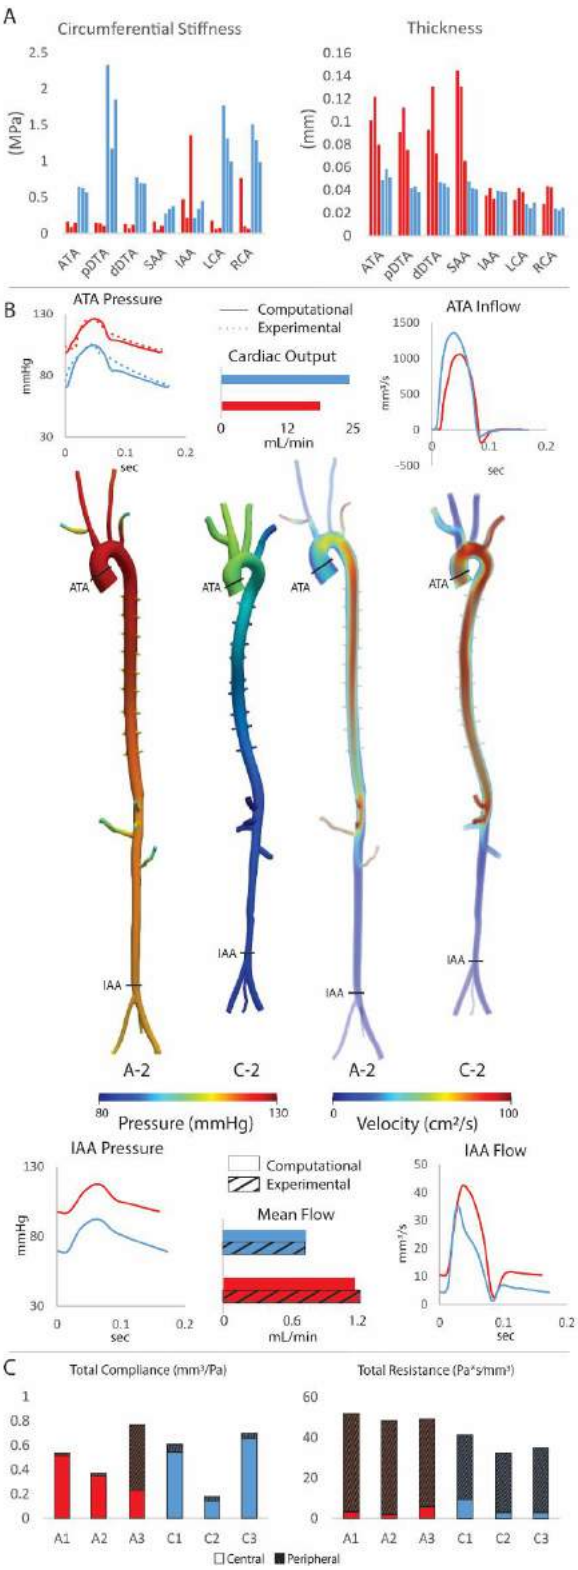

**Figure 2. (A) Measured arterial wall stiffness and thickness from biaxial testing. (B) Hemodynamic results of computational study. ATA and IAA pressure and flow waveforms were matched to the experimentally-acquired data. (C) Total resistance and compliance split into central (3D) and peripheral components.**

## RESULTS

**Experimental:** Mice infused with AngII exhibited a widely variable hypertensive phenotype compared to the controls (ATA mean arterial blood pressure (MAP): A1: 126 mmHg, A2: 109 mmHg, A3: 105 mmHg, C1: 88 mmHg, C2: 89 mmHg, C3: 105 mmHg; pulse pressure (PP): A1: 26 mmHg, A2: 28 mmHg, A3: 25 mmHg, C1: 37 mmHg, C2: 32 mmHg, C3: 32 mmHg). There were no differences in cardiac output (CO) between the AngII and control mice (A1: 24 mL/min, A2: 18 mL/min, A3: 15 mL/min, C1: 15 mL/min, C2: 22 mL/min, C3: 21 mL/min). In addition to having the most severe hypertensive phenotype, A1 also had an aortic dissection in the SAA. Biomechanical testing revealed that AngII mice (**Fig. 2A, blue**) had a higher wall thickness in the central aorta, but lower material and structural stiffness most aortic locations when compared to control mice (**Fig. 2A, red**).

**Computational:** The computational models successfully matched the mean, pulse, systolic and diastolic ATA pressures within 10%; mean flows at the LCA and IAA were also matched within 10%. Computational results for two representative mice (A-2, C-2) show that AngII mice had slightly lower cardiac output (CO) than control mice, but higher IAA flow (**Fig. 2B**). The AngII mice also had higher MAP but lower PP at all locations of the aorta. Furthermore, AngII mice had similar total arterial compliance and larger resistances than controls (**Fig. 2C)**. The observed increases in arterial resistance occurred largely in the peripheral arteries.

## DISCUSSION

Data-informed computational modeling allowed high-resolution examination of AngII-induced changes in hemodynamics, leading to new insights into effects of hypertension on aortic structure and function. Many of our results are consistent with known effects of AngII on the cardiovascular system [4]. An increase in mean arterial pressure is observed in the AngII-infused mice. Consistent with previous studies, AngII mice showed an increase in luminal thickness in all regions of the aorta, except for the IAA [5]. There is an increase in peripheral resistance in the AngII mice, which is attributed to known contraction of distal vasculature in response to AngII [4].

Previous studies of AngII-induced changes in aortic biomechanics have demonstrated no significant difference in circumferential material stiffness and an increase in structural stiffness [6], which is not consistent with our results. We show a decrease in material and structural stiffness consequent of AngII infusion, which contributes to the predicted decrease in PP along the aorta in these mice. However, it is important to note that we did not account for the possible changes in smooth muscle tone [7]. A possible explanation for the lower structural stiffness observed in the AngII-infused mice is that the anesthetic used for the *in vivo* measurements – isoflurane – had differential effects on the control and AngII-infused mice, which demands further study [8].

## INTRODUCTION

Regenerative engineering has tremendous potential as an alternative to over 2 million bone grafting procedures performed annually [1]. Toward that end, we have merged regenerative engineering techniques with existing clinical therapies to develop a treatment strategy for large-scale bone defects. This approach combines hydrogel-based cell delivery with low-intensity pulsed ultrasound (LIPUS), an FDA approved treatment for fracture repair. Our strategy involves the delivery of cell-laden hydrogels to bone defects followed by the application of transdermal, LIPUS-derived acoustic radiation force (ARF). Physical forces applied to cell-hydrogel constructs would stimulate the cells within the defect site to promote bone formation without disrupting the unstable bone defect. We have demonstrated the efficacy of this technique by observing the upregulation of load-sensitive markers in cell-loaded collagen hydrogels [2, 3]. Here, we sought to better understand the impact of acoustic radiation force on encapsulated cells using traction force microscopy (TFM) to predict forces experienced by encapsulated cells, and both *in vitro* and *in vivo* techniques to evaluate cellular responses to them. Briefly, a 3-D TFM algorithm was developed in which the physical forces on and around fluorescent beads embedded in hydrogels were computed as a predictor of mechanical forces experienced by hydrogel-encapsulated cells subjected to ARF. Additionally, to determine the optimal combination of hydrogel stiffness and ultrasound intensity for rapid bone repair early and late stage phenotypic markers of osteoblastic behavior were evaluated. Finally, the *in vivo* healing of critical size mouse calvarial defects filled with cell-hydrogel constructs and stimulated transdermally with ARF was evaluated. Results suggest enhanced healing as a result of ARF stimulation.

## METHODS

***TFM Algorithm:*** The MATLAB algorithm developed reconstructs the force-density field by 1) 3D interpolation of displacement data to obtain a displacement field, and 2) Fourier-domain inversion of the Green's function solution to the general problem in 3D linear elasticity.[4] This approach approximates the hydrogels as linearly elastic, isotropic mediums under small deformations compared to the bulk dimensions. To test the algorithm's accuracy in force-density reconstruction, simulated displacement data were first computed from user-defined, randomized distributions of point-forces with varied magnitude ranges. The force-density fields were then reconstructed from the simulated data and compared to the known input fields. In hydrogels subject to varied ARF, fluorescent beads were embedded in 0.1% w/v Type I collagen hydrogels (detailed below) and displacements were measured using imaging and tracking procedures in Volocity software and the force-density fields reconstructed as mentioned.

***Cell-Hydrogel Construct Synthesis:*** Bone Marrow Stromal Cells (BMSCs) were harvested from the long bones of wild-type mice and cultured for 7 days on TCP. Adherent cells were then lifted, resuspended, and encapsulated in type I collagen hydrogels ($5x10^5$ cells/gel) using two different collagen concentrations, 0.3 and 0.5%. Cell-hydrogel constructs were then maintained in 37°C and α-MEM media (10% FBS 1% pen/strep) for analysis.

***In Vitro Analysis:*** LIPUS-derived ARF was applied to cell-hydrogel constructs (0.3, 0.5% collagen) using a 1 MHz unfocused immersion transducer, by submerging the transducer in media and placing it directly above the cell-hydrogel construct. A one-time ARF treatment (300 $mW/cm^2$) was applied to the cultures for 20 minutes. After one hour, media and cells were extracted to measure $PGE_2$ expression and of COX-2 gene expression with ELISA and qRT-PCR, respectively. For long-term studies cell-hydrogel constructs were

treated with ARF for 5 out of 7 days per week for 2 weeks and either extracted to measure COL1 and RUNX2 gene expression or left *in situ* for an additional two weeks of ARF treatment and stained with alizarin red stain to evaluate hydrogel mineral formation. One-way analysis of variance (Tukey post-hoc) was used to determine statistical significance between groups ($p<0.05$, $n=3$).

***In Vivo Analysis:*** For the *in vivo* studies, a unilateral critical size calvarial defect (size: 4mm) was created in NSG mice and a 4.8mm diameter collagen hydrogel (0.3%) encapsulating $1x10^6$ reporter BMSCs per hydrogel was placed inside the defect. ARF was applied transdermally to the defect site once per day for 20 minutes, 5 days per week, for 4 weeks, at which time animals were sacrificed and evaluated using x-ray radiographs. Qualitative assessment of bone healing was done by observing the opacity of tissue within the defect as an indication of mineralized bone formation.

## RESULTS

Figure 1 displays the associated 3D vector fields of reconstructed force-density for hydrogel regions from the 50% and 100% duty cycle conditions. Corresponding data (not shown) suggests that as the duty cycle of LIPUS stimulation (and therefore force magnitude) increases, larger average displacements are measured, and larger reconstructed force-densities are predicted. In general, for a fixed spatial intensity ($mW/cm^2$) of LIPUS, higher duty cycles correspond to an increased

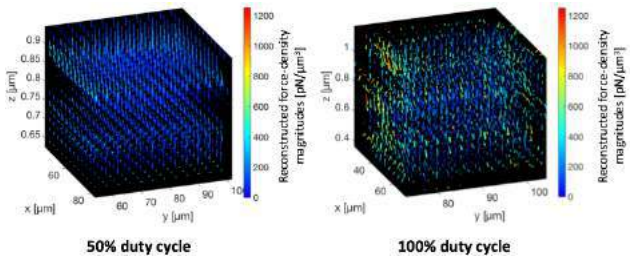

**Figure 1. 3D plots of the TFM-reconstructed force-density vector fields in the analyzed regions of 0.1% collagen hydrogels exposed to LIPUS at 50% (left) and 100% (right) duty cycles.**

time-averaged, apparent spatial intensity of ARF impinging upon cell-laden hydrogels. Therefore, these 3D-TFM experiments suggest that larger forces are transferred into hydrogels when exposed to greater apparent ARF (via higher duty cycle). Higher applied forces to the hydrogel resulted in higher measured forces within the hydrogel. This, it is theorized, would translate to greater forces being applied to encapsulated cells and would stimulate upregulations of key osteogenic markers commonly associated with bone repair. Indeed, when ARF was applied to cell-hydrogel constructs the forces to encapsulated cells increased, and expression levels of (figure 2A) COX-2 and (B) $PGE_2$ were upregulated when compared to control (no ARF) encapsulated cells. Interestingly just encapsulating cells in the 0.3% hydrogel (no ARF) upregulated COX-2 and $PGE_2$ when compared to cells on TCP (data not shown), but the combination of both encapsulation and ARF increased these expressions further. Similar trends were noted in gene expression for both type I collagen (2C) and RUNX2 (2D). Alizarin red staining showed that cells encapsulated within 0.3% gels had greater mineral formation over the other groups in response to ARF treatment after 3 weeks (figure 3) while *in vivo* analysis revealed that mechanically loading encapsulated cells resulted in better bone healing after 4 weeks (figure 4). X-ray radiographs show more bone formation with ultrasound (D-F)) than without (A-C).

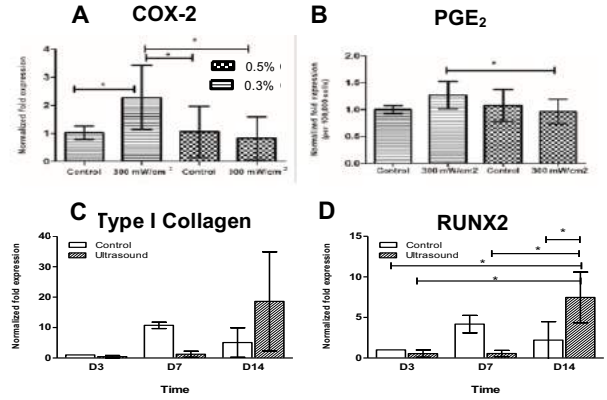

**Figure 2. Upregulation of early (A,B) and late (C,D) stage osteogenic markers indicate ARF influences the differentiation of encapsulated cells toward the osteoblastic phenotype.**

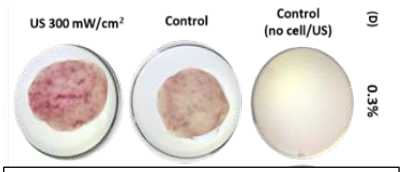

**Figure 3. Mineralization is enhanced from cells in 0.3% hydrogels exposed to ARF (left) vs. cells not exposed to ARF.**

## DISCUSSION

Here we propose a novel treatment for bone defects that delivers stem cells and mechanically stimulates them *in situ* through transdermal acoustic radiation force for the purpose of accelerating the healing of large scale bone defects. To that end, we have shown 3-D TFM simulations that suggest increasing force input to a cell-hydrogel construct results in increased physical forces experienced by encapsulated cells. This model will output forces

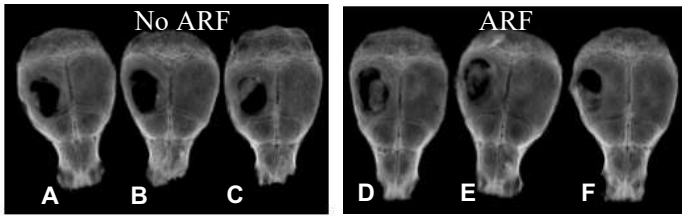

**Figure 4. Cell-hydrogel constructs implanted and subsequently exposed to ARF (right) showed more mineralized tissue than those not exposed (left), suggesting that ARF-derived forces stimulate rapid bone formation.**

applied to cells based on model input parameters such as ARF and hydrogel stiffness. *In vitro* and *in vivo* experiments demonstrate that increased forces result in elevated osteogenic expression by BMSCs, and that this translates to more rapid bone formation, which can be used to heal large scale bone defects. This may have far reaching clinical potential as a new tool in the clinical armamentarium.

# A CONSTRAINED MIXTURE MODEL OF THORACIC AORTIC ANEURYSM GROWTH

**David S. Li (1), Marcos Latorre (2), Jay D. Humphrey (1)**

(1) Department of Biomedical Engineering, Yale University, New Haven, CT, USA
(2) Center for Research and Innovation in Bioengineering, Universitat Politècnica de València, Valencia, Spain

## INTRODUCTION

Thoracic aortic aneurysms (TAAs), localized dilatations of the aortic vessel, increase the risk of aortic dissection or rupture and can be initiated from a variety of biomechanical and genetic factors. There is a pressing need to understand the complex roles of these factors in TAA development. While much has been learned through studies involving murine models and clinical data, risk factors are often present in combination and are challenging to isolate. Thus, computational models of aneurysm growth can offer insight by isolating the influence of individual effects on the progression of aneurysms.

Here, we apply a well-established computationally efficient mechanobiologically equilibrated constrained mixture model for arterial growth and remodeling (G&R) to describe the long-term evolution of TAAs arising from several predisposing factors investigated previously [1]. We contrast their effects on final aneurysm geometry and key biomechanical metrics and illustrate how preexisting hypertension and aging have dramatic impacts on disease progression.

## METHODS

*Constrained mixture model for arterial growth and remodeling*

The arterial wall is modeled as a mixture of three load-bearing constituents (elastin $e$, collagen $c$, and smooth muscle cells $m$) that undergo changes in mass (grow) and microstructure (remodel) in response to biomechanical stimuli. Each constituent $\alpha = e, c, m$ is governed by a mass density production rate $m^\alpha(\tau)$, survival (decay) function $q^\alpha(s,\tau)$, and stored energy density function $\widehat{W}^\alpha(s,\tau)$ that depends on its multiaxial deformation relative to its evolving natural configuration $\kappa_n(\tau)$, where $s$ is the current G&R time and $\tau \leq s$ is the time of deposition. We express production at time $\tau$ using a (potentially evolving) nominal rate $m_N^\alpha(\tau) > 0$ modulated by deviations from homeostatic set points in intramural stress $\sigma$ and wall shear stress $\tau_w$ by

$$m^\alpha(\tau) = m_N^\alpha(\tau)\left(1 + K_\sigma^\alpha \Delta\sigma(\tau) - K_{\tau_w}^\alpha \Delta\tau_w(\tau)\right) = m_N^\alpha(\tau)\Upsilon^\alpha(\tau) \quad (1)$$

where $K_i^\alpha$ are gain parameters controlling sensitivity to changes in stress $\Delta\sigma$ and $\Delta\tau_w$. These are summarized by the stimulus function $\Upsilon^\alpha$. Constituent removal is modeled by

$$q^\alpha(s,\tau) = \exp\left(-\int_\tau^s k_o^\alpha \left(1 + \omega\left(\Delta\sigma(t)\right)^2\right) dt\right) \quad (2)$$

where $k_o^\alpha$ is the basal removal rate and $\omega > 0$ is a gain parameter for stress changes. Lastly, the Cauchy stress at the tissue (mixture) level $\boldsymbol{\sigma}$ is described with passive contributions from each constituent along with an active stress $\boldsymbol{\sigma}^{act}$ from the smooth muscle cells

$$\boldsymbol{\sigma}(s) = -p(s)\mathbf{I} + \frac{2}{J(s)}\mathbf{F}(s)\frac{\partial W_R(s)}{\partial \mathbf{C}(s)}\mathbf{F}^{\mathrm{T}}(s) + \boldsymbol{\sigma}^{act}(s) \quad (3)$$

where $p$ enforces isochoric (transient) motion, $\mathbf{F}$ is the deformation gradient tensor for the tissue, $\mathbf{C} = \mathbf{F}^{\mathrm{T}}\mathbf{F}$, $J = \det \mathbf{F}$, and $W_R = \sum W_R^\alpha$ is the total (referential, with subscript $R$) stored energy of the mixture.

*Mechanobiologically equilibrated constrained mixture model*

In cases of TAA, where the characteristic timescale of G&R is frequently shorter than that of the biomechanical stimulus (e.g., elastin degradation or compromised collagen remodeling along with gradual hypertension or aging), G&R can be assumed to reach a quasi-static mechanobiological equilibrium at time $s$, thus allowing for a time-independent approach in which production balances removal $\forall s$. In particular, the stimulus function in Eq. 1 reduces to

$$\Upsilon_h^\alpha(\Delta\sigma_h, \Delta\tau_{wh}) = 1 \quad (4)$$

with $h$ denoting the evolved homeostatic state. This assumption allows for rule-of-mixtures expressions to be used for stored energy ($W_{Rh} = \sum \phi_{Rh}^\alpha \widehat{W}^\alpha$, where $\phi_{Rh}^\alpha$ are the referential constituent mass fractions) and

similarly Cauchy stress. Linearization of this formulation has been implemented in a finite element framework [1].

*Modeling TAA growth from prescribed mechanobiological insults*

Five types of contributors to TAAs are considered in this model: loss of elastic fiber integrity, compromised collagen cross-linking, dysfunctional smooth muscle contractility, loss of mechanosensing, and loss of mechanoregulation. Aneurysms were initiated by prescribing a localized insult in an individual predisposing factor onto an initially straight cylindrical vessel, with *in-vivo* geometric and mechanical properties derived from our previous studies [2]. Specifically, we modeled an insult defined in the $z_o$-$\theta_o$ (i.e., axial-azimuthal) plane by

$$\vartheta(z_o,\theta_o) = \vartheta_{end} + (\vartheta_{apex} - \vartheta_{end}) \exp\left(-\left|\frac{z_o - l_o/2}{z_{od}}\right|^{\nu_z}\right) \exp\left(-\left|\frac{\theta_o - \pi}{\theta_{od}}\right|^{\nu_\theta}\right) \quad (5)$$

where $z_o \in [0, l_o]$, $l_o$ is the initial axial length (15 mm), $\theta_o \in [0,2\pi]$, $z_{od}$ and $\theta_{od}$ are the axial and circumferential characteristic widths of the insult profile, respectively, $\nu_z$ and $\nu_\theta$ are decay parameters in the axial and circumferential directions, respectively, and $\vartheta_{end}$ and $\vartheta_{apex}$ are the values of the insult at the ends of the cylinder ($z_o = 0, l_o$) and the apex ($z_o = l_o/2$, $\theta_o = \pi$) of the profile, respectively.

We employed a 3D finite element model with 1x20x20 quadratic hexahedral elements in the radial, circumferential, and axial directions. Displacement of the vessel ends was fixed in the axial direction, and the vessel was pressurized and axially (pre-)stretched uniformly. The open-source software FEBio (febio.org) was used to perform the simulation and evaluate key biomechanical metrics related to aortic health such as stored energy and material stiffness. We also compared final remodeled states between insults applied uniformly throughout the geometry, axisymmetrically (variation along $z_o$ only), and asymmetrically (Eq. 5).

## RESULTS

For each of the factors considered, insult values ranging from mild to severe were simulated, all of which led to significant dilations of the vessel when applied nonuniformly. In Figure 1 we show the aneurysmal geometries and final stored energy resulting from mild and severe insults in elastic fiber integrity (analogous to a loss of functional elastin) and mechanosensing (representing an impaired ability of cells to sense changes in intramural stress).

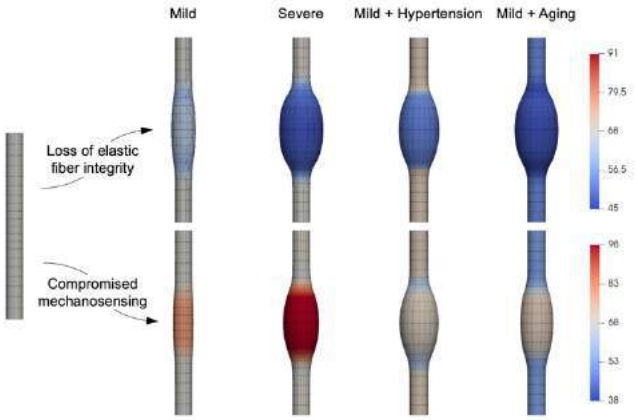

**Figure 1: Stored energy (kPa) for axisymmetric insults: (top) loss of elastic fiber integrity, (bottom) compromised mechanosensing; (left to right) mild, severe, mild + hypertension (1.5-fold pressure increase), mild + aging (30% uniform loss of functional elastin).**

In both cases, the location of the maximal change in stored energy coincides with the region of maximal dilatation; however, the two insults result in opposite trends in stored energy within the insult region, consistent with the stretching of compromised or functional elastic fibers. Additionally, each factor was modeled in combination with superimposed hypertension (increased blood pressure) or aging (diffuse loss of functional elastin), emphasizing how even a mild insult with modest dilatation can be exacerbated by the presence of risk factors.

Comparison of uniform, axisymmetric, and asymmetric insult profiles in Figure 2 highlights the importance of localized wall damage in aneurysm formation, where insults of the same value applied uniformly maintain their non-aneurysmal geometry. In the asymmetric cases, without total circumferential involvement of insult, the unaffected regions attenuate dilatation in the insult area, necessitating greater insult values to produce effects similar to the axisymmetric case.

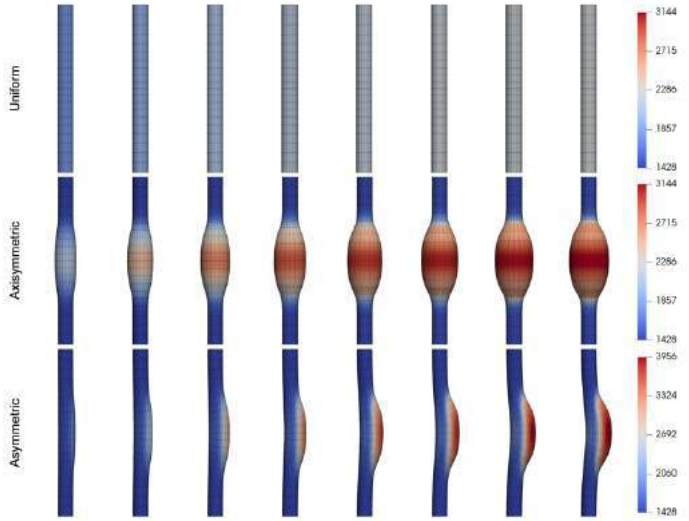

**Figure 2: Circumferential stiffness (kPa) for uniform, axisymmetric, and asymmetric losses of elastic fiber integrity from mild (left, 32%) to severe (right, 62–78%).**

## DISCUSSION

Herein we have presented an *in-silico* study on the effects of multiple combined predisposing and risk factors on the initiation and development of TAAs, demonstrating the feasibility of the model to capture a wide range of insult types and severities (Fig. 1) that can offer mechanistic insight into experimental findings. The progressive dilatation from mild to severe insults shown in Figure 2 provides an illustrative evolution of disease, in which an initially moderate loss of elastic fiber integrity progressively worsens, allowing this model to be easily parametrized for future longitudinal animal and clinical studies.

Ultimately, with increased *in-vivo* and *ex-vivo* data becoming available for human lesions, as well as the ability to couple tissue-level finite element models to cellular-level genetic models, we aim to further improve the applicability of such *in-silico* platforms to better inform the treatment of TAAs.

## INTRODUCTION

Single ventricle heart disease is a rare type of congenital heart defect affecting about five out of 10,000 newborns [1]. Traditionally, this is surgically palliated in three stages. Despite these procedures, the morbidity and mortality are high, and most will require heart transplantation [2]. Some fetuses with developing single ventricle heart disease are candidates for percutaneous transcatheter balloon valvuloplasty of the pulmonary valve or aortic valve in an attempt to prevent the development of hypoplastic right or left heart syndrome, respectively [3]. If the fetal intervention prevents single ventricle disease, the prognosis is thought to be improved, but the pulmonary or aortic valve ultimately needs to be replaced as restenosis or regurgitation develops. If this is done in childhood, the prosthetic valve often requires replacement due to somatic growth of the child, as well as degeneration of the valve, which can be hastened in a growing child. For instance, the average time to a second right ventricular to pulmonary artery valved conduit replacement in a child is 7.5 years [4].

A bioresorbable tissue-engineered heart valve (TEHV) that could be replaced by the patient's own tissue could allow the valve to grow with the patient and could preclude the need for multiple valve replacements during a patient's lifetime. The goal of a resorbable valve is for the tissue-engineered scaffold to serve as a template to direct tissue formation. As the scaffold degrades, the neotissue forms, ultimately creating a living autologous valve.

The central hypothesis driving this project is that a biodegradable TEHV will normalize the fetal hemodynamics in a way that the complexity and severity of the congenital heart defect formation may be mitigated or even eliminated. Further the highly regenerative potential of fetuses may serve as the perfect host and timing for intervention such that the neovalve takes over the function as a normal heart valve with the capacity to grow. Recent advancements from our group have demonstrated the efficacy of a fully resorbable fetal TEHV design [6] with the help of a fetal ovine model [5]. Due to the transcatheter nature of this valve deployment, the procedure may not be riskier than a traditional fetal valvuloplasty. However, restoration of normal valve function in utero holds the potential to restore biventricular anatomy and function.

## METHODS

**Valve design manufacturing.** We scaled down our adult valve design (after numerous computational simulations to establish an optimized design) to a fetal size of 5mm. A 2D drawing was developed from this 3D CAD design in order to laser-cut this design. A tube made of Cobalt-Chromium, specifically the L605 alloy (Vascotube, GmbH, Birkenfield, Germany) was used in this process. The stent was cut using an OPTEC Femtosecond laser (Optec Laser Group, Frameries, Belgium). To manufacture biodegradable resolvable leaflets, we created 0.75% wt/vol solutions of polycaprolactone (PCL) (Mn = 80,000 Da) (Sigma-Aldrich, St. Louis, MO) in chloroform. We used an in-house spray method to cast leaflets onto the laser cut stent prototype using 1.2mL of PCL solution.

**Valve testing.** A custom fetal flow loop was constructed to mimic right heart conditions. The flow loop consisted of a reservoir to simulate atrial function, a bladder pump controlled by compressed air that acted as the ventricle, a mechanical valve acting as a tricuspid valve and a pulmonary valve test chamber with a diameter of 7.5 mm, where the prototyped valve was deployed. A compliance chamber was connected in series with a resistance valve to simulate the compliance and resistance of the great arteries. The valve was tested in a working fluid of 60/40 water/glycerin (99% pure glycerin) at 0.5 L/min (cardiac output), 140 beats per minute (heart rate), 70/45 mm Hg (peak systolic/diastolic pulmonary artery pressure) for 100 consecutive cardiac cycles. Transvalvular pressure gradient (PG), regurgitation fraction (RF) and effective orifice area (EOA) were evaluated from this setup.

**Leaflet degradation studies**. Homogenous and heterogenous films were cast using the 0.75% wt./v. PCL/chloroform solution. Dried samples underwent accelerated degradation testing using a high-pH solution to understand the natural degradation of the PCL polymer. Samples were weighed to take the pre-degradation mass and then rinsed in dH2O. The samples were then submerged in 8M sodium hydroxide solution at room temperature. Samples were removed from the solution after 20, 30, 40, 60, 120 and 150 minutes. The sample films were rinsed in dH2O and placed in the oven to dry. Pre-degradation masses were

compared to the measurements taken after the samples dried to determine the remaining mass.

## RESULTS

**Valve design and manufacturing.** We successfully manufactured the valve stent from a 5mm tube of cobalt-chromium with our in-house adult stent design (as shown in Figure 1). The PCL was cast onto the laser cut stent and a trileaflet prototype was developed.

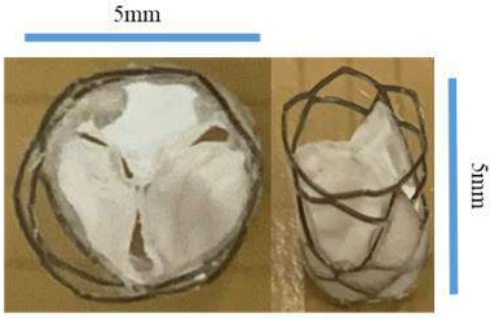

**Figure 1: Trileaflet fetal valve prototype**

**Valve testing.** Our prototype fetal valve was tested for 100 consecutive cardiac cycles in the fetal pulmonic conditions described in the methods. The valve had a regurgitant fraction of 3.9% with an effective orifice area (EOA) of 0.18 $cm^2$ and a mean transvalvular pressure gradient of 3.84mmHg, as shown in Figure 2. These values are in line with our previous studies and also show that the design and setup are robust, able to be tuned to varied fetal conditions.

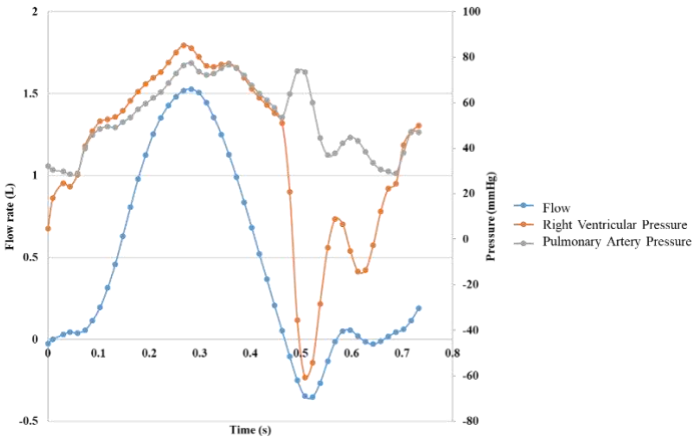

**Figure 2: Valve prototype performance characteristics**

**Leaflet degradation studies.** Our preliminary results did not show any significant differences in the 20 - 40 minute treatments, but we are currently running studies for the longer time periods in order to observe and document significant differences.

## DISCUSSION

This project is the first step to design, develop, and manufacture a fully biodegradable tissue-engineered valve for use *in utero.* Our current prototype, although developed from a non-resolvable metal alloy, provided the basis for design development and modifications. Our next iterations in the project will be using completely resolvable metal alloys. The current drawback in the lack of interventional techniques for cardiac anomalies can be overcome with the progress of such a replacement device. By establishing an in-house sutureless design, we are potentially alleviating the diastolic stresses on the leaflets and, therefore, premature failure of the device.

The ability to replace a stenotic fetal heart valve with a living autologous TEHV could, for the first time, enable the creation of a truly curative strategy for the complex cardiac anomalies that cause single ventricle physiology.

## INTRODUCTION

Aortic stenosis (AS) is one of the major causes of mortality, and its prevalence is estimated to increase in the next few years among the aging population. Bioprosthetic aortic valve replacement (AVR) procedures are currently the most efficient widely used approaches for aortic stenosis. AVR involves surgical aortic valve (SAV) replacement (SAVR) and transcatheter aortic valve (TAV) replacement (TAVR). While SAVR is highly invasive, TAVR is a less invasive therapy that recently has been approved for low-risk patients.

Although SAVR and TAVR procedures are effective, they are associated with adverse outcomes such as restenosis due to short durability, thrombus formation, coronary obstruction, among others. Several studies tried to predict (clinically, computationally, and experimentally) valve performance and implantation. For example, Yanagisawa et al.[1], through a clinical study, identified balloon-expandable valves as predictors of leaflet thrombosis. Simonato et al.[2] suggested that sub-annular deployments after TAVR are predictors of elevated pressure gradients. Hatoum et al.[3] derived a semi-empirical model to predict thrombus formation.

Despite the aforementioned efforts, a statistical model that can numerically estimate valve performance (without running extensive computational or experimental assessments) is still lacking. In this study, we aim to generate a data driven statistical predictive model based on experimental in-vitro data for valve performance (transvalvular pressure gradient (DP)) under different physiological conditions such as heart rate (HR) and blood pressure through the usage of a logistic regression method. The goal of this work is to provide a model where valve performance under different physiological conditions can be conveniently estimated using a simple equation obtained from logistic regression.

## METHODS

The hemodynamics of a 25mm Magna Ease (Edwards Lifesciences, Irvine, CA) SAV and a 23mm SAPIEN 3 (Edwards Lifesciences, Irvine, CA) TAV were assessed under different HRs, a constant cardiac output (5L/min), and systolic and diastolic blood pressure conditions (SBP and DBP, respectively) in a duplicating left heart simulator.

The left heart simulator consists of: (1) a reservoir where the blood analog (water/glycerin mixture 60 – 40% by volume) with properties similar to blood (density of 1060kg/m$^3$ and a kinematic viscosity of 3.5 cSt) was used, (2) a mechanical valve emulating the role of a mitral valve, (3) a custom-made bladder pump connected to compressed air and regulated by an in-house developed LABVIEW program, (4) an aortic valve chamber where the valves were deployed, (5) a compliance chamber, and (6) a resistance valve to control the flow rate. The pressure measurements were obtained using Millar Catheters (ADInstruments Inc., Colorado Springs CO) at the ventricular and aortic pressure ports. Instantaneous cardiac cycles of flow rate, aortic and ventricular pressures were collected and recorded at a sampling rate of 100 Hz for each condition (1,924 total cycles). In this study, we are looking at the DP to measure the performance of the valve.

Our reasoning is based on the fact that the performance of an aortic valve is affected by the output being greater or lower than a threshold such as stenosis criteria[4]. For such cases, the performance of the valve could be enumerated by a binary (0 or 1) event where 1 indicates the event of failure and 0 indicates the event of survival. The recommendations on the echocardiographic assessment of aortic valve stenosis define mild aortic stenosis as DP>20mmHg[4]. Therefore, DP values greater than 20mmHg indicate a failure event (1) in the valve, while values less than 20mmHg indicate a survival event (0) in the heart valve. For such binary events, when enough experimental or empirical data are available, a logistic regression model could be employed to estimate the probability of failure in the heart valve as a function of hemodynamic conditions of the valve. In this study, we employed logistic regression on a total of 1,924 input data for the conditions listed in Table 1, for each valve. The outputs were the probabilities of having

a DP, exceeding 20mmHg. The logistic regression model is computed using MATLAB.

To test the accuracy of the model with the original data that the logistic model was obtained from, one may have hardship in comparing probabilities with binary values. Since these probabilities cannot be directly compared with Zero and One values, a discrimination threshold is chosen such that any probability lower than the threshold is considered as Zero and any probability larger than the threshold is considered as One. To do so, in statistics, a confusion matrix is introduced.

| Valve | Cardiac Output (L/min) | Heart Rate (bpm) | Blood Pressure (mmHg) |
|---|---|---|---|
| 25 mm Magna Ease | 5 | 60, 120 | 100/60 |

**Table 1. List of experimental conditions used for each valve.**

A logistic model that results in more true Ones and true Zeros and less false Ones and false Zeros are more accurate[5]. Commonly, to test the accuracy of the logistic model using confusion matrix, a discrimination threshold of 0.5 is selected, providing bias in the evaluation[8]. To eliminate this bias, in statistics, a receiver operation characteristics (ROC) curve is used. ROC curves plot the Sensitivity versus the Specificity. To estimate the accuracy of the logistic model, the area under the ROC curve (AUC) is measured. AUC ranges from 0 to 1. The closer it is to 1, the better the performance of the logistic model is. In this study, ROC curves were adopted to test the accuracy of the logistic regression models. Additionally, we performed experiments at SBP conditions that were not input in the model (110/80 mmHg and 130/80 mmHg) for both valves, collected 57 cardiac cycles for each, and compared the probabilities of DP>20mmHg between the experiment and the model.

## RESULTS

Based on the employed logistic regression model, the probability of DP>20mmHg in the valve follows the following equation (1):

$$P(DP > 20\text{mmHg}) = \frac{1}{1+\exp[-(a_0+a_1\times HR+a_2\times SBP+a_3\times DBP)]} \quad (1)$$

where $a_0$, $a_1$, $a_2$, and $a_3$ are the regression coefficients for linear log odds. The estimated values for each of these coefficients are provided in **Table 2.**

| Valves | Output | a0 | a1 | a2 | a3 | AUC |
|---|---|---|---|---|---|---|
| SAPIEN 3 | Pressure Gradient (DP) | -21.1905941 | -0.024493659 | 0.054906659 | 0.189990387 | 0.947 |
| | P-Value | N/A | 1.14E-10 | 3.33E-26 | 3.15E-76 | |
| Magna Ease | Pressure Gradient (DP) | -15.83684824 | -0.028063161 | 0.047635196 | 0.109735857 | 0.905 |
| | P-Value | N/A | 2.87E-09 | 1.19E-07 | 2.27E-33 | |

**Table 1. Parameters of SAPIEN 3 and Magna Ease logistic regression model (Eq 1). AUC denotes Area under the curve of the ROC curve. A p-value less than 0.05 is considered to be significant.**

**Figure 1** shows the 3D map contour of the probability of DP>20 mmHg for the SAPIEN 3 (A) and Magna Ease (B). In both models, for both valves, the AUC was found to be close to 1 (>0.90) (**Table 2**), and the p-values for each of the input parameters were < 0.05 (**Table 2**), indicating that each input variable (HR, SBP and DBP) significantly influences the results. The contours in **Figures 1** were plotted at HR = 60bpm. The figures show that at a specific SBP, increasing the diastolic pressure will lead to an increase in the probability of DP>20mmHg for both valves, which is consistent with the experimental data used. The logistic model presented in Eq. (1) also allows us to estimate the probability of DP>20mmHg for any other pressure condition. For instance, we can now obtain a probability for any DBP, SBP, and HR between those used For Eq. (1). In Eq. (1), HR values are valid between 60 and 120 beats per min, SBP values are valid between 100 and 180 mmHg, and DBP are valid between 40 and 100 mmHg. The experiments performed with 110/80 mmHg and 130/80 mmHg showed probabilities that agreed with the values obtained with the generated model.

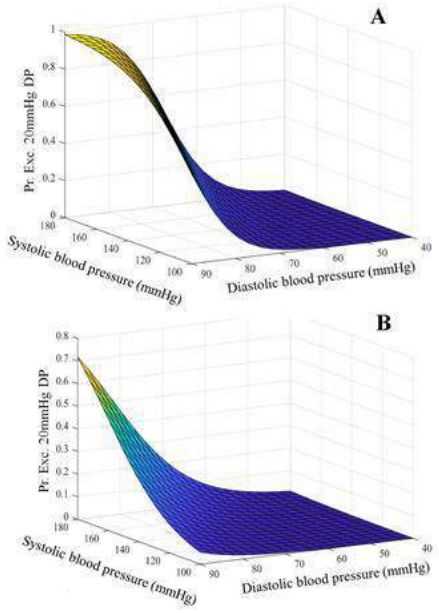

**Figure 2. Logistic regression plot of the SAPIEN 3 (A) and Magna Ease (B) shown in a 3D map contour format.**

## DISCUSSION

In this proof-of-concept study, we generated a probabilistic model that estimates the probability of a hemodynamic output (average DP) under different heart rates and blood pressure conditions (systolic and diastolic). The model was obtained based on logistic regression, and the results suggest that a logistic model with linear log odds function offers a good fit to the data. The importance of this model lies within its ability to quickly obtain an estimate of the hemodynamic parameters pertaining to the performance of aortic valves and to help in preprocedural clinical decision-making. Any testing condition within the limits of the input range based on which the model was generated can be interpolated. The model up to this point does not include numerous cardiac outputs or patient-specific variability in terms of various geometries and dimensions as previously mentioned. However, ongoing studies using clinical data aim at refining it. It should be also noted that the output parameters can be expanded to include a variety of desired outputs given enough experimental data are provided.

## INTRODUCTION

Endovascular thrombectomy (EVT) was recently proven to be an effective and safe treatment for a subset of patients with acute ischemic stroke (AIS) and is now the standard of care. However, improvement is needed since this treatment is not effective in 41% of the patients [1]. Studies on thrombi retrieved with EVT found that the main components are red blood cells (RBCs), fibrin, platelets, and white blood cells, and that the thrombus composition is an important factor influencing successful recanalization [2]. The exact reason for this is unknown, but it has been postulated that the thrombus composition and platelet-driven thrombus contraction affects the mechanical properties of thrombi, which in turn influences the interaction with the thrombectomy device [3, 4]. A pre-interventional estimation of the mechanical properties is hypothesized to aid in selecting the most suitable treatment on a case-by-case basis to improve success rates.

Computed Tomography (CT) imaging is the most commonly used imaging modality for diagnosis of AIS and could therefore potentially be useful in predicting the mechanical properties, composition, and contraction of cerebral thrombi [5]. While a link between mechanics and thrombus composition, as well as radiological imaging characteristics and thrombus composition have been determined, the direct relationship between thrombus mechanics, imaging characteristics, composition, and contraction has not been examined before [6].

## METHODS

Blood was drawn by venipuncture from four healthy human volunteers. Twenty thrombus analogs per donor were made by reconstituting the platelet rich plasma and RBCs in five different volumetric RBC percentages: 0%, 20%, 40%, 60% and 80%. To assess the extent of thrombus contraction, the weight of each thrombus was measured and expressed as a percentage of the weight of the original clotting mixture [4].

To determine the mechanical properties, unconfined compression tests were performed using a custom made compression tester [7]. For this, the thrombi were cut into 2 mm slices. The samples were 80% compressed, with a compression and retraction speed of 0,2 mm/s (10% strain/s). As a measure for the stiffness, the low strain (approximately initial 20%) and high strain (approximately final 2%) secant moduli were measured from the slopes of fitted straight lines of the non-linear nominal stress-strain curves [4].

Clinical CT was used to determine the thrombus imaging characteristics. First, a non-contrast computed tomography (NCCT) was made to study the density. Subsequently, an iodinated contrast agent was added and scans were made 5, 10, 15, and 20 minutes after administering the contrast in order to study the perviousness, which reflects the permeability of a thrombus. In each scan, three non-overlapping regions of interest with 1 mm diameter were defined in each thrombus, of which the mean density was measured in ImageJ [8].

The composition of the thrombi was analysed using histology. Hemotoxylin and Eosin (H&E) stain was used to identify the percentage of RBCs using Orbit Image Analysis software.

Spearman correlation tests and two-way ANOVA tests were performed to determine the relationship between the four thrombi characteristics. Within one thrombus composition group, t-tests were performed to assess differences in density between NCCT and contrast-enhanced CT imaging. A p-value lower than 0.05 was considered statistically significant.

## RESULTS

Figure 1 shows the histological results. Composition analysis showed that the initial volumetric RBC ratios of the clotting mixture of 0%, 20%, 40%, 60% and 80% produced thrombi with non-equivalent compositions of 0.0%, 91.0%, 93.5%, 95.1%, and 97.9% RBCs, respectively. This indicates that only 0% RBC and RBC-rich thrombi (>90% RBC) were produced.

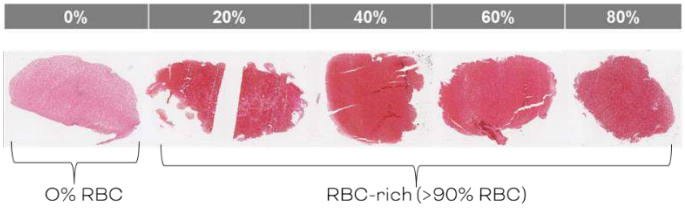

**Figure 1: Representative thrombus samples of the five volumetric RBC percentages of the clotting mixture, with resulting thrombus RBC content indicated at the bottom.**

Figure 2A and B show the thrombus mechanical properties. The mechanical tests showed that the low and high strain secant moduli decreased with increasing RBC content of the clotting mixture: e.g. for donor 1 we measured a high strain of 264, 84, 72, 27, and 13 kPa for increasing RBC content of the clotting mixture. Furthermore, a large variation between donors for thrombi with comparable composition was observed.

Figure 2C shows the results of the contraction measurements. A strong positive linear relationship was found between the degree of contraction and the volumetric RBC ratio of the clotting mixture ($r=0.98$, $p<0.001$). Furthermore, the relationship between the high strain stiffness and degree of contraction was observed, for which a strong negative correlation was found ($r=-0.68$, $p=0.006$).

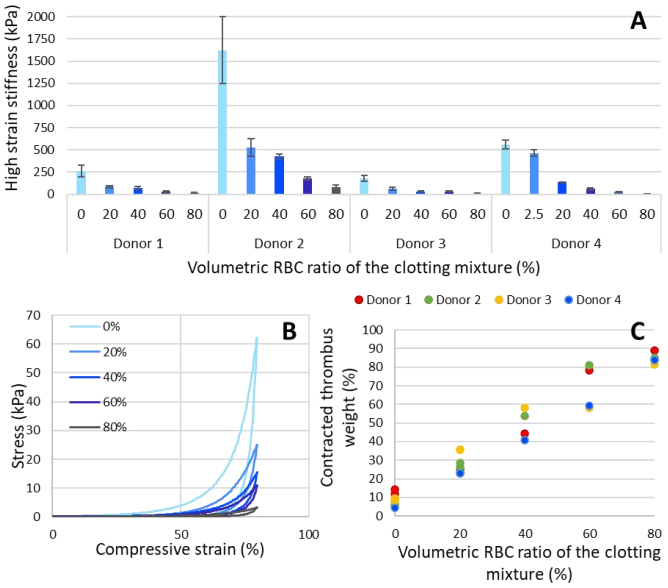

**Figure 2: Thrombus mechanics and contraction properties. (A) High strain stiffness of the five volumetric RBC ratios of the clotting mixture of the four donors. (B) Representative stress-strain loading and unloading curve for the five compositions. (C) Relative contracted thrombus weight (i.e. degree of contraction) per volumetric RBC ratio of the clotting mixture for the four donors.**

Figure 3 shows the CT imaging characteristics. On NCCT, the 0% RBC thrombi had a mean density of 34 HU, which was found to be significantly lower in density compared to the RBC-rich thrombi with a mean density higher than 78 HU ($p<0.001$). The increase in density, the perviousness, was significantly higher for the 0% RBC sample compared to the RBC-rich thrombi compositions after 10, 15, and 20 minutes ($p=0.002$, $p=0.001$, $p=0.005$).

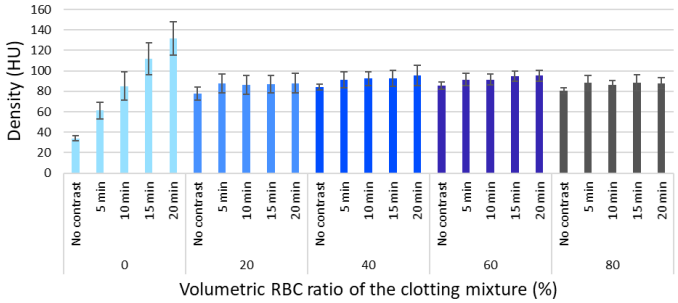

**Figure 3: Mean thrombus densities on NCCT baseline scans and 5, 10, 15, and 20 minutes after contrast administration.**

The relationship between thrombus mechanics (high strain stiffness), thrombus imaging characteristics (NCCT density and density increase after 20 minutes), and resulting thrombus RBC content was analysed. Stiffer thrombi were moderately correlated to a lower density and higher perviousness ($p=0.03$ and $p=0.02$, respectively). The density and perviousness were found to be more significantly correlated to the thrombus RBC content (both $p<0.001$).

## DISCUSSION

This is the first study to assess the thrombus mechanics of thrombi in conjunction with an analysis of CT density, contraction, and composition. Strong correlations were found between 1) the compressive high strain stiffness and the volumetric RBC ratio of the clotting mixture 2) the compressive high strain stiffness and the degree of thrombus contraction, 3) the degree of thrombus contraction and the volumetric RBC ratio of the clotting mixture, and 4) the CT density and perviousness, and thrombus RBC content.

Mechanics was not (strongly) associated with the imaging characteristics that were explored in this study, indicating that the thrombus mechanical properties cannot be directly predicted from CT imaging. However, thrombus contraction is hypothesized to be associated with perviousness [8]. Therefore, assessing the perviousness of thrombi and correcting for the RBC content through NCCT density may provide a measure for contraction on pre-interventional imaging. This could be clinically relevant since thrombus mechanics could then be predicted prior to the intervention.

Although the volumetric RBC ratios in the clotting mixture used in this study resulted in either RBC-rich or 0% RBC thrombi, the mechanical properties were different per volumetric RBC ratio. A possible explanation could be a difference in amount of fibrin or the degree of platelet-driven contraction. Future experiments will focus on creating clots with intermediate RBC and fibrin content and different levels of contraction in order to improve the understanding of the differences in mechanics.

## INTRODUCTION

Aortic stenosis (AS) is the most common valvular heart disease in developed countries, and is a major cause of heart failure[1]. A treatment approach for AS can be accomplished by replacement of the diseased valve with a bioprosthetic transcatheter aortic valve or surgical aortic valve. The performance and durability of these bioprosthetic valves have been related to postoperative mean transvalvular pressure gradient (ΔP). Echocardiography (ECHO) and catheterization (CATH) modalities are used to measure ΔP.

Discrepant differences in ECHO- and CATH-based measurements of ΔP have been reported. These discrepancies are a result of the different measurement locations for each modality in the pressure recovery zone. ECHO measurements do not account for pressure recovery unlike CATH measurements. Several attempts have been made (clinically, computationally, and experimentally) to quantify pressure recovery in these geometries and to understand its effect on postoperative ΔP measurements. Attempts have also been made to modify the simplified Bernoulli equation to account for pressure recovery as a function ascending aorta size[2]. Abbas et al.[3] investigated these modifications clinically. Samaee et al.[4] experimentally assessed the effects of the ascending aorta on ΔP by varying its diameter while keeping the annulus fixed. In a computational study by Keshavarz-Motamed et al.[5], pressure recovery in coarcted aortas was simulated in a U-shaped tube.

Despite the aforementioned efforts, pressure recovery assessment of physiological diameter, shape, and three-dimensional curvature of the ascending aorta and aortic arch is still lacking. In this study, we aim to assess pressure recovery in a physiological 3D aortic arch to determine its effects on valve performance and ultimately durability.

## METHODS

A 23mm SAPIEN 3 Ultra (Edwards Lifesciences, Irvine, CA) was hemodynamically assessed in a pulse duplicator left heart flow loop simulator under physiological flow and pressure conditions (cardiac output = 5L/min, heart rate = 60bpm, and systolic to diastolic pressures = 120/80mmHg). Briefly, the pulse duplicator was comprised of a reservoir for fluid storage, a mechanical mitral valve separating the fluid reservoir and pump, a bladder pump whose contraction is controlled by an in-house LabVIEW program, an aortic chamber (with arch and without), a compliance chamber to simulate arterial distensibility, and a gate valve to control the flow. The blood analog fluid used was a mixture of water-glycerin with a density of 1060kg/m$^3$ and a kinematic viscosity of 3.5cSt. Flow rate at the valve was measured using an ultrasound Clamp-on Flowsensor (Transonic Systems Inc., Ithaca, NY).

The rigid aortic chambers had two different geometries, curved and straight, but had the same aortic root dimensions. The curved chamber was designed using a physiological geometry detailed by Boufi et al.[6] Both chamber setups can be seen in **Figure 1**.

All pressure measurements were taken with Millar Pressure Catheters (Millar, Houston, TX). The measurements were made

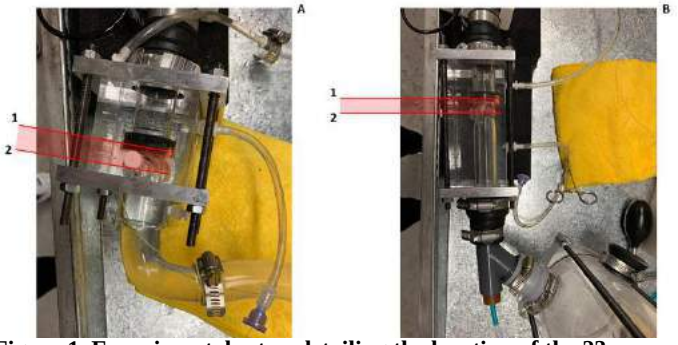

**Figure 1. Experimental setup detailing the location of the 23mm SAPIEN 3 Ultra in the curved (A) and straight (B) aortic root chambers. Locations 1 and 2 represent the valve entrance at 2.1mm and valve limit at 3.9mm, respectively.**

incrementally along the aortic model with intervals of 0.1cm, 0.2cm,

and 0.5cm downstream of the valve, at the valve, and upstream of the valve, respectively. In both models, the position 0cm corresponds to the most upstream measurement (ventricular) and the positions 12.2cm and 19.7cm are the last measurements made in the straight and curved models, respectively. Fifty consecutive cardiac cycles of pressure and flow data were recorded at a sampling rate of 100Hz. The mean pressure measurements were recorded at each incremental increase in catheter position. Peak flow was determined by the time point at which the flow was maximum (peak systole) in the generated curves. The mean transvalvular pressure gradient (ΔP) — defined as the average of positive pressure difference between the ventricular and aortic pressure curves during forward flow — was calculated for both aortic models. Values are presented as mean with standard deviations.

## RESULTS

The pressure measurements as a function of distance at different time points during systole in the curved model are plotted in The peak flow time point (peak systole) occurred at 0.28s into the cardiac cycle. Results from the pressure measurements are plotted starting from upstream (ventricular) of the valve and end downstream (aortic) of the valve. As the valve opens and flow begins, pressure decreases until the vena contracta (VC; 3.7cm). After passing VC, pressure gradually rises until the curvature of the aorta begins (3.7–11.2cm). This rise in pressure marks the beginning of pressure recovery. At the curvature of the aorta, pressure drastically decreases (11.2–14.7cm). After passing the curvature of the aorta (14.7cm), the pressure starts increasing gradually marking the beginning of a second pressure recovery zone. During peak flow, pressure was 118.66±4.49mmHg at the valve entrance, 121.83±4.75mmHg at VC, 129.04±3.86mmHg at the start of the curvature, and 127.852±3.47mmHg after the curvature (final measurement point). The final pressure measurement was taken at 19.7cm and the slope of the pressure curve indicates the pressure will continue recovering past this point.

The pressure measurements as a function of distance at different time points during systole in the straight model are plotted in **Figure 2B**. The peak flow time point (peak systole) occurred at 0.27s into the cardiac cycle. Results from the pressure measurements are plotted starting from the upstream (ventricular) of the valve and end downstream (aortic) of the valve. As the valve opens and flow begins, pressure decreases from the LVOT region until VC (3.1cm). After passing VC, pressure gradually rises (3.1–12.2cm). This rise in pressure marks the beginning of pressure recovery. The final pressure measurement was taken at 12.2cm.

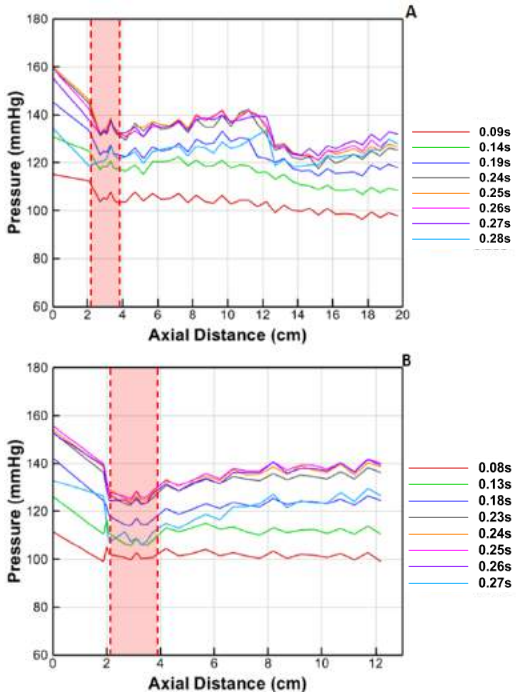

**Figure 2. Variation of pressure as a function of axial distance at the selected time points during systole for curved (A) and straight (B) aortas. The shaded regions represent the location of the valve.**

During peak flow, pressure was 107.04±5.07mmHg at the valve entrance, 108.62±4.05mmHg at VC, and 126.51±2.89mmHg at the final measurement point.

The ΔP as a function of axial distance in the curved model are shown in **Figure 3A**. ΔP is 7.71±1.03mmHg at the valve entrance, 13.08 ±0.27mmHg at VC, 21.15±0.31mmHg before the curvature, and 21.03±0.36mmHg after the curvature (final measurement point).

ΔP vs. axial distance in the straight model are shown in **Figure 3B**. ΔP is 12.08±0.67mmHg at the valve entrance, 17.45±0.41mmHg at VC, and 13.51±0.26mmHg from positions 3at the final measurement point.

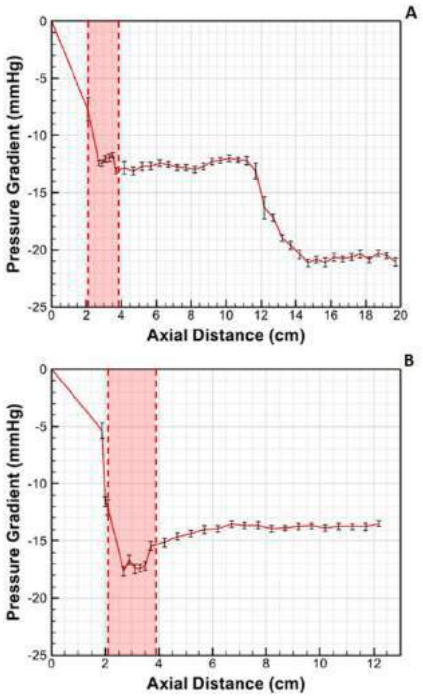

**Figure 3. Mean pressure gradient as a function axial distance with curved (A) and straight aortas (B). The shaded region represents the valve location, and the error bars represent standard deviation.**

## DISCUSSION

In this study, we measured pressure recovery in a physiological aortic arch in-vitro. The resulting pressure recovery curves for the straight model are consistent with those found in other studies[7]. In the curved model, we observed pressure recovery unlike the pattern seen in the straight model. This difference is due to minor losses associated with bending in internal flows. As the fluid passes through the bend, centrifugal forces cause a difference in pressure at the inner and outer bend, causing the formation of a recirculation zone containing Dean vortices[8]. These vortices cause the kinetic energy of the fluid to change, resulting in an energy loss downstream which is represented by pressure loss. Literature reporting ΔP in healthy aortic arch models is limited. However, some studies reported clinically significant pressure gradients in coarcted aorta models at the curvature[5]. This is consistent in our study, where we observe an increase in ΔP of about 9mmHg at the curvature. Clinically, where the catheter is positioned is important to assess accurately the pressure variation or the pressure drop. If the aorta curves where the tip of the catheter is located, the measurement may be influenced and the pressure drop may be overestimated. Based on the ΔP curves of this study, if a catheter measurement is made at the curvature, the resulting ΔP is going to be drastically higher than a measurement made in the recovery zone just after the valve. Ongoing work on other bioprosthetic valves and patient specific models assessing the effect of pressure recovery in the ascending aorta and aortic arch is underway.

## INTRODUCTION

The meningeal membrane is a critical composite tissue that protects the central nervous system. The incorporation of the meninges into finite element (FE) models of traumatic brain injury (TBI) is essential to ensure accurate injury prediction. Inaccurate modelling of the meninges can significantly impact FE model results [1]. There is a paucity of studies detailing the mechanical response of the cranial meningeal membrane. In particular, no mechanical analyses have been conducted on the falx cerebri tissue which projects between the two cerebral hemispheres. As a result of the anatomical location of the falx and its relatively large stiffness (approx. 1,000 fold the stiffness of the brain [2]), it is of significant importance when evaluating the mechanopathology of TBI. If efforts are to improve preventative measures of TBI and advance the design of protective equipment, an improved knowledge of meningeal tissue properties is required. Additionally, damage to the meninges is frequently incurred during both traumatic injuries and during surgical interventions [3]. In particular, angioplasty procedures are frequently conducted on the superior sagittal sinus (SSS) vessel of the meninges, with limited knowledge on how this circumferential stretch may damage the structure [4]. The study seeks to address these knowledge gaps by conducting biaxial tensile analysis of the meninges to characterise the tissues' stiffness and evaluating the sensitivity of the SSS structure to the effects of mechanical strain.

## METHODS

7 human meningeal tissues were acquired in collaboration with the Dublin Brain Bank at Beaumont Hospital, Ireland. Specimens from the dura mater, SSS and falx cerebri were prepared for biaxial tensile testing by first cutting specimens into square sections (of approx. 8 – 15 mm length). The thickness of specimens (for post-test stress calculation) was analysed using a noncontact photogrammetry technique [5]. Samples were then speckled in preparation for digital image correlation (DIC) analysis using an ABEST airbrush and a tissue-specific staining dye (Cancer Diagnostics Inc.). Samples were then placed in the biaxial tensile configuration, see Fig. 1 (A). Following 10 preconditioning cycles to 1% strain (preconditioning serves to allow test samples to settle into the testing apparatus and to return the tissue to its in situ stress configuration [6]), samples were stretched to a nominal strain of 20% for biaxial mechanical characterisation.

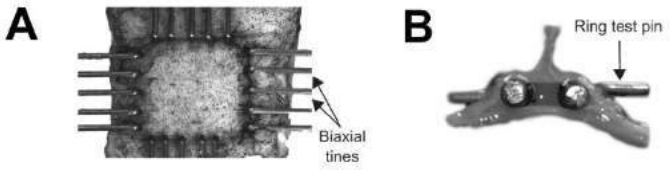

**Figure 1(A) Biaxial tensile setup with Cellscale BioRake system. (B) Ring test setup.**

Specimens from the SSS region were prepared for strain sensitivity analysis using a combination of uniaxial ring testing (to emulate the circumferential stretches the tissue may be subjected to during an angioplasty procedure, see Fig. 1 (B)) and a novel collagen hybridizing peptide (CHP) which enables detection of damaged collagen fibres [7]. Specimens were cut into rings of approx. 3 mm length. DIC was not possible for the SSS rings due to the limited cross-sectional thickness

for speckle application [8]. Samples were subjected to various magnitudes of subfailure stretch prior to structural analysis with CHP. Briefly, CHP analysis involved snap-freezing specimens, cryosectioning specimens into 20 µm sections, staining with CHP and imaging utilising immunofluorescent microscopy. Immunofluorescence images were quantified using CellProfiler software to quantify the extent of CHP binding in acquired images (indicative of the amount of collagenic damage in specimens [7]).

## RESULTS

Specimens from the SSS region were prepared for strain sensitivity analysis using a combination of uniaxial ring testing (to emulate the circumferential stretches the tissue may be subjected to during an angioplasty procedure, see Fig. 1 (B)) and a novel collagen hybridizing peptide (CHP) which enables detection of damaged collagen fibres [7]. Specimens were cut into rings of approx. 3 mm length. DIC was not possible for the SSS rings due to the limited cross-sectional thickness for speckle application [8]. Samples were subjected to various magnitudes of subfailure stretch prior to structural analysis with CHP. Briefly, CHP analysis involved snap-freezing specimens, cryosectioning specimens into 20 µm sections, staining with CHP and imaging utilising immunofluorescent microscopy. Immunofluorescence images were quantified using CellProfiler software to quantify the extent of CHP binding in acquired images (indicative of the amount of collagenic damage in specimens [7]).

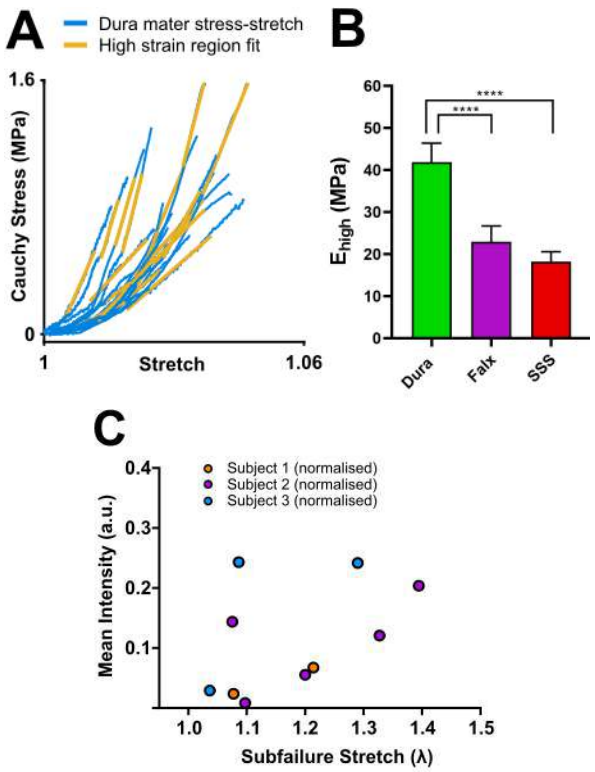

**Figure 2 (A) Stress stretch curves from dura mater region including linear fit for elastic modulus calculation. (B) Linear elastic modulus results. (C) Stretch sensitivity results for 3 human subject SSS tissues.**

## DISCUSSION

These results demonstrate that there are mechanical stiffness differences between the dura mater, falx cerebri and SSS tissues, in contrast to the assumption typically employed in FE head models that these tissues are mechanically homogeneous [2]. These results have important implications for FE head model design (particularly given the mechanopathological influence of these structures [9]) and may aid in improving FE biofidelity through direct implementation of the linear elastic values to head models. It is also demonstrated that the SSS undergoes circumferential strain-mediated damage at a relatively low value of subfailure stretch, at least when compared to cerebral arteries [7]. This finding suggests the structure may be particularly susceptible to angioplasty-mediated damage, which has the potential to induce permanent damage to targeted vessels [7]. Care should thus be taken during clinical procedures involving the SSS structure.

## INTRODUCTION

Breast cancer (BC) is the most frequent cancer in women and the second-leading cause of cancer deaths worldwide. Breast tumor development is the consequence of cell mutations manifested in the mammary glands that result in uncontrollable proliferation, and other properties such as survival strategies, invasiveness, and metastasis. New studies of cancer development are necessary to predict patient prognosis from the morphology of early-stage tumors and decrease cancer-related deaths. To this end, by taking advantage of 3D engineered culture models and computational models of breast tumors, we establish connections between morphology and dynamics of the primary tumor and cancer progression.

Considering all the above, we study the migratory behaviors and mechanical interactions between cancer cells that arise during tumor development. We also recognize the cellular mechanisms that promote tumor growth, cancer cell invasion, and cell dissemination from the primary tumor [1,2,3,4,5], which are necessary to clarify crucial aspects of cancer development **(Figure 1A**).

To help interpret our experimental findings, we consider a minimal continuum model that incorporates the main mechanisms driving cancer progression and escape.

## METHODS

We engineered 3D tumor spheroids of triple-negative breast cancer (TNBC) 4T1 murine mammary carcinoma cells. We embeebed the 3D spheroids in type I collagen to provide a physiologically relevant microenvironment in which to study cell behavior. Although spheroids can be generated using a variety of experimental techniques [6,7,8,9], we prepared the size-controlled 3D spheroids in agarose microwells. We fabricated PDMS masters with positive circular posts and stamped them on aqueous solution of 2% agarose. After gelation of the agarose, cells were seeded in the microwells and excess cells were removed by washing. Cells began to aggregate within a few hours and formed into spheroids within one day. After four days, we collected the spheroids and embedded them within collagen (**Figure 1B**).

## RESULTS

The 3D tumor spheroids allowed us to examine the dynamics of tumor-like anatomy and physiology. Using agarose microwells, our resultant spheroids were homogeneous in size and with a rounded shape. The size of the spheroids was controlled by the size of the well stamped into the agarose. Between days 4-6 we collected the spheroids and embedded them in collagen to study their growth rate and invasion.

We characterized the dynamical features of migratory response of individual cells within the tumor spheroids and analyzed the mechanical interaction between the cells to determine and

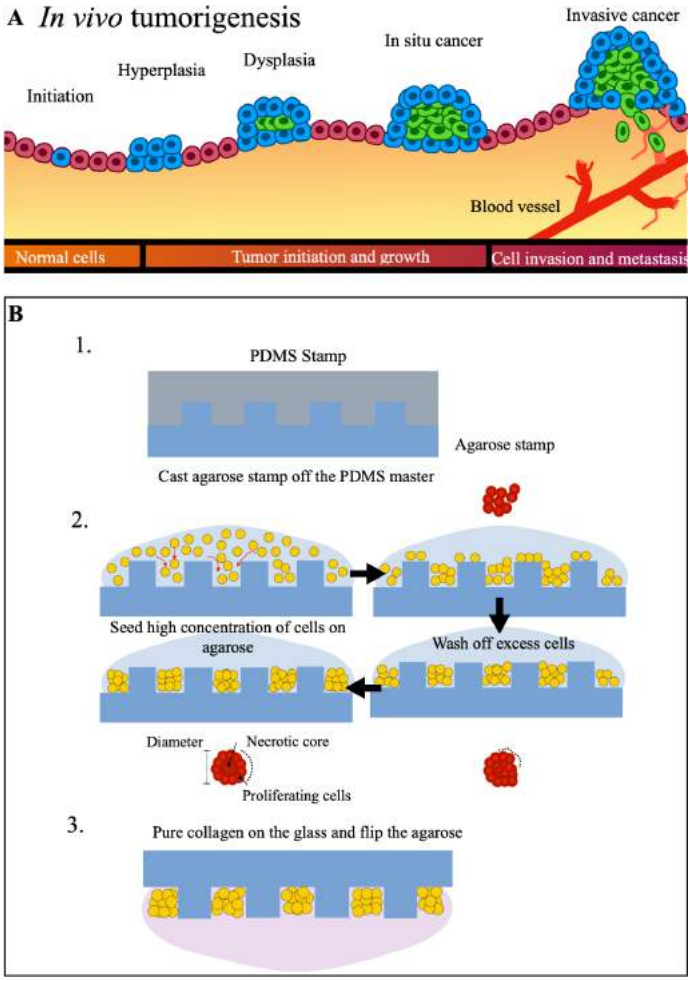

**Figure 1. A. Tumor development. B. Schematic of spheroid formation in agarose microwells.**

predict responses to therapeutic drugs. For this purpose, we studied the spreading of the spheroid by measuring its growth area and the effects of cellular forces. From the theory side, we propose a hydrodynamic active continuum model of the 3D growing tumor as an initial disordered network with embedded cells. We include growth and death, to understand the different types of stages during tumor development.

## DISCUSSION

Using agarose microwells, we were able to reproduce tumor spheroids that can be used to model tumor growth, invasion, and escape. Our approach allowed us to control the size of the spheroid, which is crucial to reproduce and analyze how the development of a tumor depends on its diameter, as well as to analyze how treatment with drugs affects the spheroids.

We investigate the growth rate of the spheroids by monitoring the area and volume over several days. These measurements provided the minimal parameters necessary to model the 3D spheroids using continuum theory. Overall, we performed experiments and simulations to study tumor growth, invasion, and the effects of cell-cell interaction. In addition, given that the mechanical properties of the tumor influence its morphogenesis, we were able to control the structural and shape evolution of the tumor through specific driving protocols that change during tumor growth or that are position-dependent.

## INTRODUCTION

The most widespread cause of heart disease is coronary artery disease (CAD) [1] , which manifests as narrowings, or stenoses, in the arteries that supply the heart muscle. The disease is diagnosed by visually inspecting X-ray coronary angiography images to estimate percent diameter reduction of the affected vessel. While diameter reduction is a useful metric, functional metrics of disease severity lead to better patient outcomes [2]. Fractional Flow Reserve (FFR) is a functional metric of CAD severity, defined as the ratio of pressures on both sides of the stenosis. FFR is typically measured via cardiac catheterization and traditionally requires the placement of coronary wires across stenoses; however, it can also be derived from CFD simulations in patient-specific 3D geometries.

Automatic geometric reconstruction of 3D coronary artery trees using a limited number of X-ray angiography images is a challenging task due to heart and respiratory motion, as well as angle orientation and calibration of the angiography system. Several approaches to reconstruct 3D coronary geometries have been developed, based on the principles of projective geometry. While these methods have demonstrated some success, their accuracy is limited, often requiring operator intervention or calibration of the angiography system [3]–[5].

In this work, we describe a calibration-free, angle-agnostic deep learning method to reconstruct 3D models of synthetically-generated vessel-like structures given two projection images. Furthermore, we present preliminary results on the effect of geometric reconstruction error on the pressure gradient, a surrogate measure for FFR.

## METHODS

A synthetic vessel generator was developed to produce 2,000 vessel-like structures with up to 3 random stenoses, informed by anatomical parameters (Fig 1). Stenosis geometry was determined by randomly sampling position, percent diameter reduction, and length from random uniform distributions. The generated ground truth vessel geometries mimicked the anatomy of the major branches of coronary vessels.

Each vessel was encoded as an Nx4 matrix, with N centerline points $(x, y, z)$ and radius $r$. Two projections of each synthetic vessel were created by randomly sampling spherical angles from uniform distributions. Finally, a Euclidean distance transform (EDT) was applied to the projection images to create a continuous array for neural network training. Of the 2,000 synthetically generated vessels, 1800 were used for training and 200 were used for validation.

Transformed projection images were input into a multistage neural network (Fig 1), which used features extracted by ResNet101 [6] to learn the corresponding vessel matrix. Mean squared error (MSE) was used as the loss function. The learned vessel matrix was used to reconstruct a NURBS-based centerline and an analytical vessel surface.

Steady-flow simulations were performed using CRIMSON [7] in two pairs of ground truth and predicted geometries, one with stenosis and one without (Fig 2). Each pair of vessels was modeled with identical boundary conditions: fixed inflow ($Q_{in}$ = 1200 mm$^3$/s) and fixed outlet resistance. The difference in pressure along the ground truth and predicted vessel centerlines were evaluated.

## RESULTS

The mean absolute error (MAE) of the $x$, $y$, and $z$ centerline coordinates for the 200 vessels in the validation set were 0.384±0.024mm, 2.219±0.039mm, and 1.196±0.030mm, respectively. MAE of the radius in the validation set was 0.0735±0.004mm.

For the two pairs of vessels chosen for CFD analysis, a comparison of the ground truth and predicted radii is shown in Fig 2A. In the stenotic

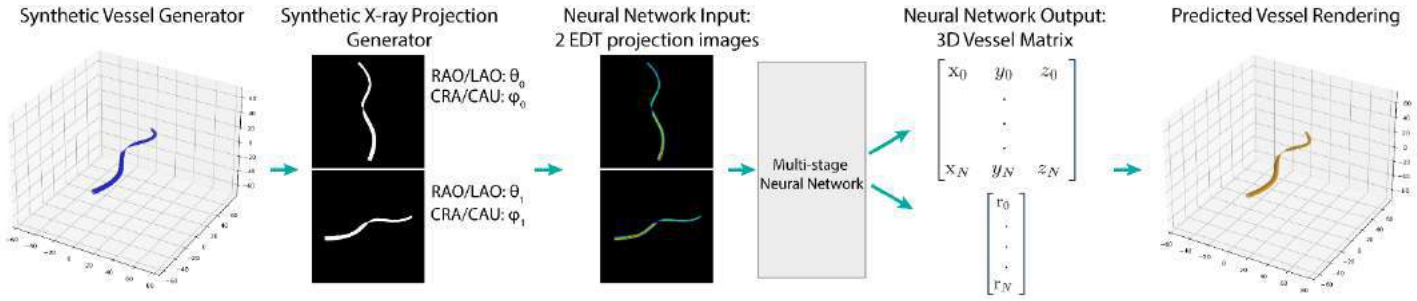

**Figure 1: Workflow of 3D vessel reconstruction. Ground truth synthetic vessels are generated and randomly projected to produce synthetic X-ray images. The images are transformed and input into a neural network, which predicts the 3D vessel geometry.**

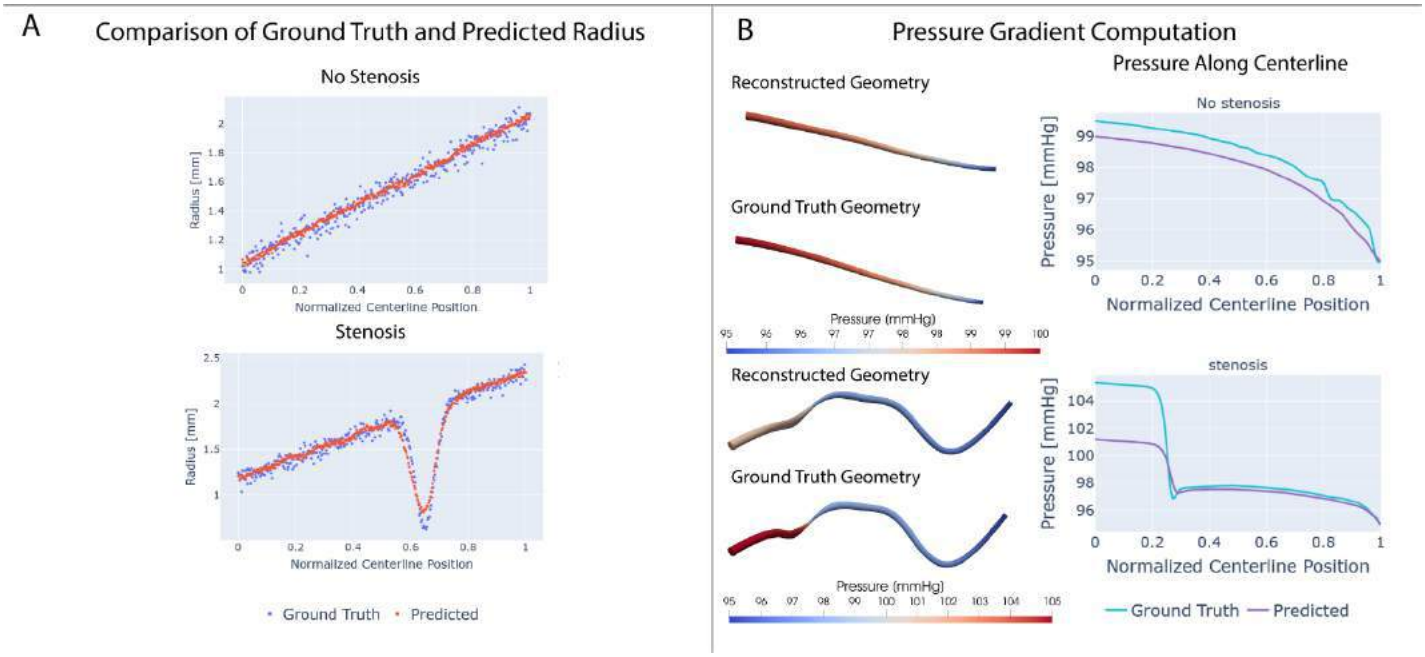

**Figure 2: Reconstruction results. 2A shows the radius along the centerline in the ground truth and predicted geometries. In 2B, the results of CFD simulations to measure the difference in pressure between ground truth and predicted vessel geometries are shown.**

case, the ground truth geometry had a maximum diameter reduction of 1.24mm or 66%, while the predicted geometry had a maximum diameter reduction of 1.09mm or 57%. In Fig 2B, the MAE of pressure along the centerline was 0.47mmHg in the non-stenotic case, with a maximum error of 0.58mmHg, and 1.17mmHg with a maximum error of 4.14mmHg in the stenotic case.

## DISCUSSION

This work is proof-of-concept that 3D vessel-like structures can be reconstructed from two projection images without any information about the geometry of X-ray image acquisition, including projection angle.

These results highlight that while the absolute error in the reconstructed path (0.384±0.024mm, 2.219±0.039mm, and 1.196±0.030mm for x,y, and z coordinates, respectively) was larger than errors in the reconstructed radius (0.0735±0.004mm), the impact of the radius error is (as expected) much larger on pressure gradient metrics. This is demonstrated by the CFD simulation results of the stenotic vessel. A 0.15mm difference in minimum vessel diameter at the region of stenosis leads to a 44% error in total pressure gradient. One major contributor to the error in radius is the discretization of the vessel radius into pixels on the projection images. One pixel typically represents 0.2-0.3mm in X-ray angiograms, thus limiting the accuracy of any reconstruction method, machine learning or otherwise.

Future work will focus on improving reconstruction accuracy by training on a larger and more varied synthetic vessel dataset. The synthetic vessel generator will also be improved to more closely resemble the geometry of coronary vessels, including the addition of branches.

# INTER-DONOR VARIABILITY IN THE TENSILE AND COMPRESSIVE BEHAVIOUR OF IN VITRO HUMAN THROMBI

## INTRODUCTION

Adequate reperfusion is still not achieved in 41% of endovascular thrombectomy (EVT) procedures [1]. These procedures are significantly influenced by the mechanical behaviour of the occluding thrombus [2], which is exposed to complex multi-axial loading conditions during retrieval [2]. While unconfined compression is commonly used to determine compressive thrombus mechanics, the difficulties in specimen handling has led to a shortage of data on thrombi in tension. In the limited tensile data available, there are conflicting reports of linear and non-linear stress-strain responses [3]. Moreover, composition alone cannot explain the observed variation in compressive stiffness values for thrombi retrieved from EVT procedures [4]. Although the majority of in vitro studies do not consider inter-donor variation in their design [5,6] or do not report it in their results [7–10]. data suggests that a mechanical variation exists between comparable thrombi from different donors [9,11,12]. Here, we report on the tensile and compressive behaviour of comparable thrombus analogues produced in a variety of compositions from the blood of human donors.

## METHODS

**In vitro Thrombi Production:** Thrombus analogues were prepared from the blood of 6 healthy human donors (3 males, 3 females). The different blood constituents were used to produce platelet-rich plasma (PRP), platelet-poor plasma (PPP), whole blood (WB) clots and clots with a range of red blood cell (RBC) concentrations (0%, 5%, 10%, 20%, 40%, 60% and 80% RBC volume with PRP in the clotting mixture). All specimens were formed under static conditions.

**Mechanical Characterisation:** Both uniaxial tensile and unconfined compression tests were performed using custom-built setups. Tensile stretching was conducted until failure. Compressive stretching was performed to 80% strain. Both tests were conducted at 5% strain per second. It was not possible to perform tensile testing on 80% RBC samples, as observed by the limits of specimen handleability in preliminary experiments. For both datasets, a low-strain stiffness value was acquired by applying a linear fit to the nominal stress-strain data between 0 and 10% strain. For tensile data, a high-strain stiffness value was acquired by applying a linear fit to the final 10% of the stress-strain curve (prior to sample failure). For compressive data, a high-strain stiffness value was acquired by applying a linear fit to the nominal stress-strain data between 70-80% strain.

**Composition, Microstructure, Contraction and Hemostasis:** Histology (hematoxylin & eosin [H&E], Martius Scarlet [MS] and CD42b) and scanning electron microscopy (SEM) were performed to determine the composition and microstructure of the thrombi, respectively. The degree of clot contraction was assessed gravimetrically. Complete blood cell counts and fibrinogen levels were also measured to appreciate the origin of any inter-donor variations.

## RESULTS

There is a strong negative (almost linear) relationship between the percentage of RBCs in the clotting mixture and the degree of clot contraction (Fig.1A). Additionally, the percentage of RBCs in the clotting mixture does not produce thrombi with a proportionate RBC content. The thrombus RBC content ranged from 0.03% (PRP [MS]) to 97% (40% RBC [MS]). Of note, a 5% RBC volume produces a thrombus with approximately 70% RBC content (Fig.1B).

There is pronounced asymmetry in the compression-tension behaviour of in vitro human blood clots for all compositions. A marked strain-stiffening compressive response is observed, in contrast to the approximately linear nominal stress-strain profiles under tension (Fig.2A). Of interest, there are overlapping behaviours for thrombi of different compositions from different donors (Fig.2B). Tensile low-strain stiffness values are approximately 15 times higher than compressive low-strain stiffness values (Fig.2C). Additionally,

compressive high-strain stiffness values are approximately 39 times higher than tensile high-strain stiffness values (Fig.2D).

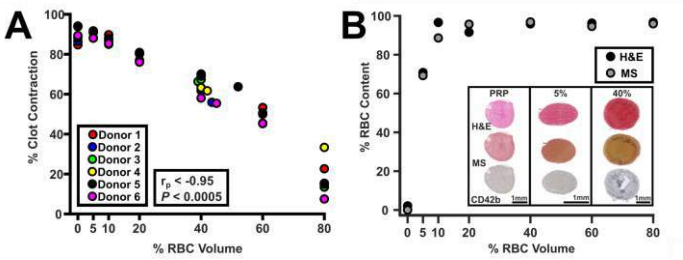

**Figure 1: Clot contraction and RBC content per RBC volume in the clotting mixture (or hematocrit for WB). (A) Clot contraction by weight. (B) Thrombus RBC content. Representative H&E, MS and CD42b stained section for PRP, 5% and 40% RBC clots.**

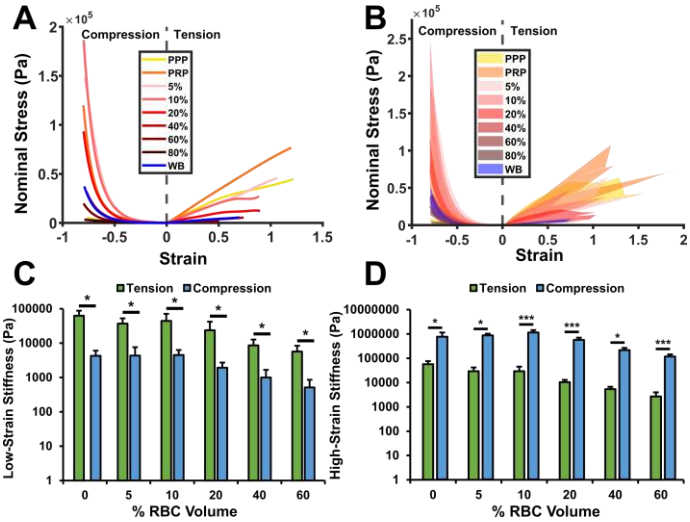

**Figure 2: (A) Nominal stress-strain midlines per composition. (B) Nominal stress-strain range per composition. (C) Tensile versus compression low-strain stiffness (log scale y-axis). (D) Tensile versus compression high-strain stiffness (log scale y-axis). Statistical significance: *$P$<0.05, ***$P$<0.0005.**

Thrombus tensile stiffness generally decreases for each increasing RBC volume (Fig.3A). In contrast, compressive stiffness increases from 0% to 5% and 10% RBC volumes, followed by a decrease in stiffness with subsequent RBC volumes (Fig.3B). By examining the microstructure of the samples with SEM, it is clear that PRP samples exhibit pores in the fibrin network (Fig.3C), while RBCs are tightly packed in the network for a 5% RBC sample (Fig.3D). The network becomes looser again for a 60% RBC sample (Fig.3E). Additionally, PRP clots are stiffer than PPP clots in compression (high-strain stiffness: 741 ± 359 vs. 31 ± 12 kPa, $P$ = 0.005). However, there are no significant differences in the tensile stiffness of PRP and PPP clots (high-strain stiffness: 57 ± 20 vs. 46 ± 12 kPa, $P$ = 0.28).

To further quantify the variations observed in Fig.2B we examined the coefficient of variances (CoV) for low- and high-strain stiffnesses of the WB clots between donors. High-strain compressive stiffness exhibited the lowest CoV (30%), followed by low-strain compressive stiffness (47%), low-strain tensile stiffness (48%) and high-strain tensile stiffness (49%). Pearson's correlation revealed trends towards significance between donor age, platelet cell counts and levels of fibrinogen with high-strain compressive stiffness. There was also a trend towards significance between the degree of clot contraction and low-strain compressive stiffness.

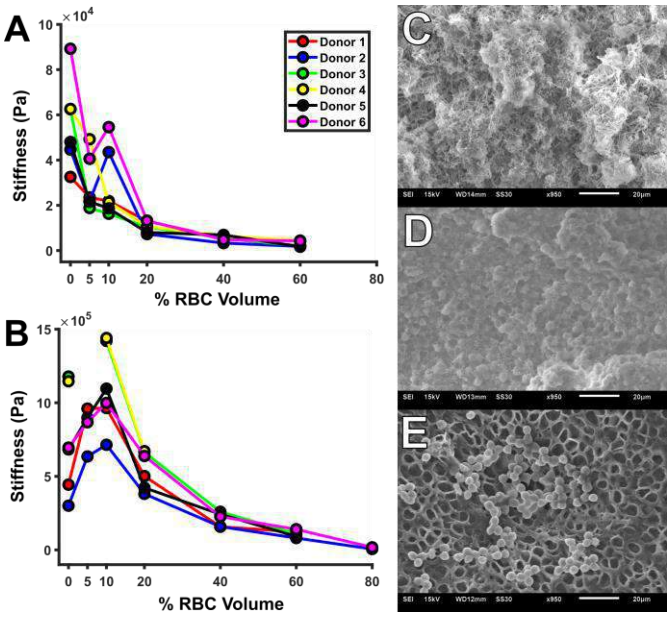

**Figure 3: Influence of composition on thrombus mechanics and SEM of microstructure. (A) Tensile and (B) compressive high-strain stiffness. (C) PRP, (D) 5% and (E) 60% RBC clot.**

## DISCUSSION

This is the first investigation of the stiffness properties of thrombus analogues made from the blood of healthy human donors in a range of compositions under both tensile and compressive loading. There is a distinct asymmetry in the tension-compression nominal stress-strain profiles of in vitro healthy human thrombi. Accordingly, different material models may be required to adequately capture the thrombus response to EVT. The effect of composition on stiffness also differs in tension versus compression. In line with previous findings [3,5], the tensile stiffness of clots decreases with increasing RBC content, but the compressive stiffness initially increases from 0 to 10% RBC content, then decreases with further amounts of RBCs. There is significant variation present in the stiffness of whole blood clots derived from different healthy human donors. Composition alone does not account for all the observed variation in retrieved clot mechanics [4]. Future studies should assess the utility of this mechanical variation in the prediction of EVT success in patients undergoing AIS treatment.

## INTRODUCTION

Two-thirds of people experience lower backpain during their lifetime, with herniated discs commonly occurring in patients 20-40 years of age.[1,2] The intervertebral disc (IVD) separates adjacent spinal vertebrae. IVDs consist of an outer annulus fibrosus (AF) and an inner nucleus pulposus (NP). Herniated discs occur when the inner NP region of an IVD extrudes through a full-thickness annular tear and impinges on spinal nerves, often resulting in debilitating back and leg pain. Despite the high prevalence of herniated discs, the mechanical factors that drive annular tears are still poorly understood. More specifically, knowledge of the relationship between the AF and NP in IVD degeneration is limited.[3] This highlights the critical need for both investigating the mechanisms of disc herniation and developing diagnostic methods for characterizing disease progression. Previous studies have used magnetic resonance imaging to assess IVD strains in human samples.[4] However, ultrasound may be advantageous over other imaging modalities because of its fast acquisition time, lower equipment costs, and improved resolution. We aim to integrate advanced high-resolution ultrasound imaging and texture correlation to quantify strain profiles in the IVD under dynamic loading conditions. This study establishes a methodology for measuring IVD strain in bovine caudal spine with high-frequency ultrasound and establishes the foundation for future work quantifying strain profiles with texture correlation.

## METHODS

### Bone-Disc-Bone Segment Preparation

Two bone-disc-bone (BDB) segments were used for this study. Bovine caudal spine was acquired from a local abattoir (age 18-24 months; West Lafayette, IN). Tissue surrounding the spine was removed with a scalpel to isolate the IVDs. Three cuts were made along the mid-transverse plane of the top three vertebrae (C1-C3), and spinous processes were removed to create BDB segments (Figure 1A). The ends of the BDB segments were then potted in polymethyl methacrylate (PMMA; 2.08 g powder per mL liquid; Bosworth Fastray Custom Tray and Acrylic Base Plate) (Figure 1B). Prepared BDB segments were wrapped in gauze dampened with phosphate-buffered saline and stored at -20 ºC.

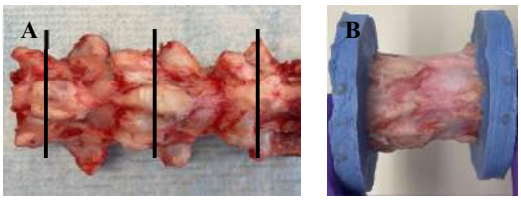

**Figure 1: A) Bovine caudal spine with tissue removed. Black lines demarcate vertebrae C1, C2, and C3 along which the sample was cut B) BDB segment with spinous processes removed and potted in PMMA**

### Loading System

A custom-built testing device was built to apply axial compression at one end of the BDB segments. The tester has five main components: a frame, motor, transmission, Arduino controller, and a power supply (Figure 2). The motor generates a rotational force which is converted into axial force by the transmission and applied to the potted BDB segment.

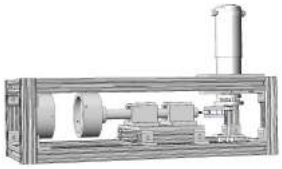

**Figure 2: Representative image of tester**

### Ultrasound Imaging

All data was collected using a 40 MHz center frequency ultrasound transducer (MX550D, Vevo3100, FUJIFILM VisualSonics) held in place by a linear step motor above the disc surface. Thawed BDB segments were loaded into the custom testing device. Ultrasound conductive gel was applied to the topside of the BDB segments. B-mode images and three-dimensional ultrasound volumes were collected along the transverse plane of the bovine caudal spine at 0 mm, 2 mm, and 4 mm of axial displacement. The transducer orientation relative to the sample is shown in Figure 3.

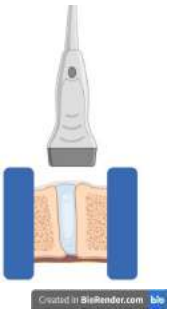

**Figure 3: Transducer orientation above potted sample**

### Disc Deformation

Disc height (distance between vertebral end plates) was measured 4 mm from the surface of the disc (VevoLab, FUJIFILM VisualSonics) with a linear measurement tool. Linear axial strain ($E_{Axial}$) was then calculated at 2 mm and 4 mm of compression using the linear definition of strain (Eq:1), where $\Delta H$ is change in height and $H_0$ is initial height of the disc:

$$E_{Axial} = \frac{\Delta H}{H_0} \quad (1)$$

## RESULTS

The vertebral end plates and IVD appeared clearly in the B-mode ultrasound images. The subcomponents of the IVD could be distinguished from one another, with visible striations in the AF. Vertebral end plates were black and contrasted against the white IVD. A labeled representative B-mode ultrasound image is shown in Figure 4.

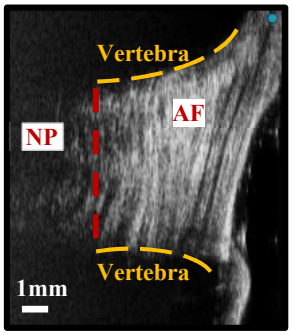

**Figure 4: Representative B-mode ultrasound image of BDB segment at 0 mm axial displacement, NP: nucleus pulposus, AF: annulus fibrosus**

Linear strain increased as axial displacement increased. The IVDs experienced an average compressive strain of 3.3% at 2 mm and 6.1% at 4 mm of displacement, respectively. Curvature of the disc also increased as axial displacement increased. The outward bulging of the disc is highlighted in Figure 5.

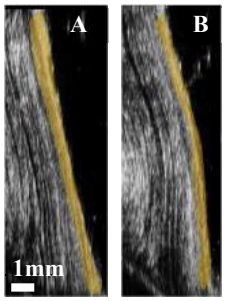

**Figure 5: BDB segment with visual evidence (yellow) of annulus fibrosus curvature increasing with axial displacement A) 0 mm displacement B) 2 mm displacement**

## DISCUSSION

Here we demonstrate the ability to measure axial IVD strain with high frequency ultrasound under dynamic loading. The results show that IVD axial strain increased by approximately two-fold with increased compression from 2 mm to 4 mm. IVD curvature also increased with compression. This method could be used to assess dynamic disc compression at varying frequencies and magnitudes to describe time-dependent behavior. The system is capable of cycling loading tissue up to 0.5 Hz. The clear delineation between the disc (white) and the adjacent vertebrae (black), as well as the clear striations in the AF, in the ultrasound images will be valuable when developing displacement fields.

One of the samples maxed out at 2 mm of axial displacement. Consequently, only one measurement could be taken at 4 mm of axial displacement by the tester. Non-uniform IVD anatomy throughout a given sample poses a limitation in measuring disc height. Therefore, determining or assigning a coordinate point to track within samples during compression would improve the accuracy of the calculated strains. After further validating this method in bovine specimens, the study will be expanded to assess human cadaveric-lumbar spine sections. We anticipate that the methods described in this work will lead to improved approaches for non-invasive image-based assessment of IVD herniation and add to our current understanding of herniation progression and treatment.

## ACKNOWLEDGEMENTS

The authors acknowledge Norvin Bruns at Purdue University for assisting in slicing the bovine caudal spine and sample preparation.

## INTRODUCTION

An abdominal aortic aneurysm (AAA) is a localized dilation of the aorta, which, in case of rupture, has a mortality rate of 80%. Current clinical guidelines for intervention are based on AAA diameter, which has been proven to be a non-optimal criterion for rupture risk prediction [1,2]. Biomechanical models can improve rupture risk prediction using patient-specific geometries obtained from imaging modalities such as computed tomography (CT) and ultrasound (US). US is safer than CT because of the lack of nephrotoxic contrast agents and radiation, especially when longitudinal studies are needed. Moreover, US imaging adds temporal information required for accurate mechanical characterization (elastography), which is important for rupture risk prediction. Those patient-specific mechanical properties can be used in combination with the patient-specific geometry for FE-based stress analysis for a more patient-specific rupture risk assessment [2].

Previous studies have shown that intraluminal thrombus (ILT) affects the rupture risk. Some studies showed that ILT attenuates oxygen diffusion from the lumen to the vessel wall, leading to increased inflammation, therefore weakening the vessel wall and increasing the rupture risk [3]. On the other hand, studies showed that ILT reduces the peak wall stress in the AAA, therefore decreasing the rupture risk [4]. Intraluminal thrombus should therefore be included in rupture risk assessment. Imaging thrombus using US is challenging, due to the limited contrast between lumen and thrombus.

Recently, a method was developed in-house to assess the geometry of ILT from 3D US images, for patient-specific measurements as well as modeling purposes. In this study, we investigate the feasibility of US-based mechanical characterization of both the thrombus and AAA vessel wall from 3D(+t) US data.

## METHODS

In this study 10 AAA patients were included, who all gave their informed consent. The 3D+t (volume rate 4-8 Hz) ultrasound images were acquired in the Catharina Hospital Eindhoven, The Netherlands. Time-resolved 3-D ultrasound data were acquired using a Philips iU22/Epiq system with X6-1 transducer. After the US exam, the brachial blood pressure was measured.

The thrombus and vessel wall geometries were segmented from the ultrasound images using an in-house developed fully automatic segmentation algorithm, which was validated using CT (Figure 1).

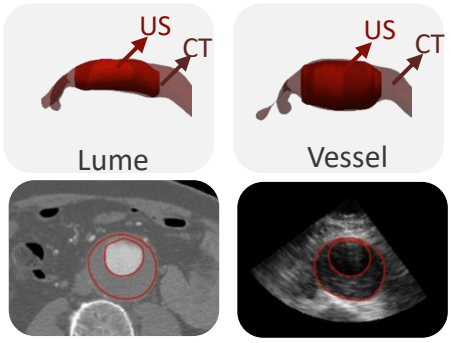

**Figure 1: US-based geometry of the lumen and the inner vessel wall and its comparison with CT**

Those time-varying geometries resulting from the US-based segmentations were used to determine the volume at each time-step using the Gibbon toolbox.

The volume-time curves resulting from those geometries (Figure 2) were used to calculate the in-vivo relative thrombus volume change

during the cardiac cycle using the systolic and diastolic thrombus volume ($V_{ILT,sys}$ and $V_{ILT,dia}$):

$$dV_{ILT} = \frac{V_{ILT,sys} - V_{ILT,dia}}{V_{ILT,dia}} \cdot 100\% i \qquad (1)$$

The circumferential stress can be calculated using Laplace's law with pressure (p), radius (a) and wall thickness (h). The radius was calculated from the volume and the length.

$$\sigma = \frac{p \cdot a}{h} \qquad (2)$$

The shear modulus can be calculated using the diastolic and systolic circumferential stress ($\sigma_{dia}$ and $\sigma_{sys}$) and Finger strain ($\varepsilon_F$).

$$Gi = i\frac{(\sigma_{sys} i - i\sigma_{dia})}{2 \cdot \varepsilon_F} \qquad (3)$$

## RESULTS

In Figure 2, the volume-time curves of the lumen, vessel and thrombus are shown. For the lumen and vessel a clear pulsatility is visible. However, for the thrombus volume no clear pulsation is seen.

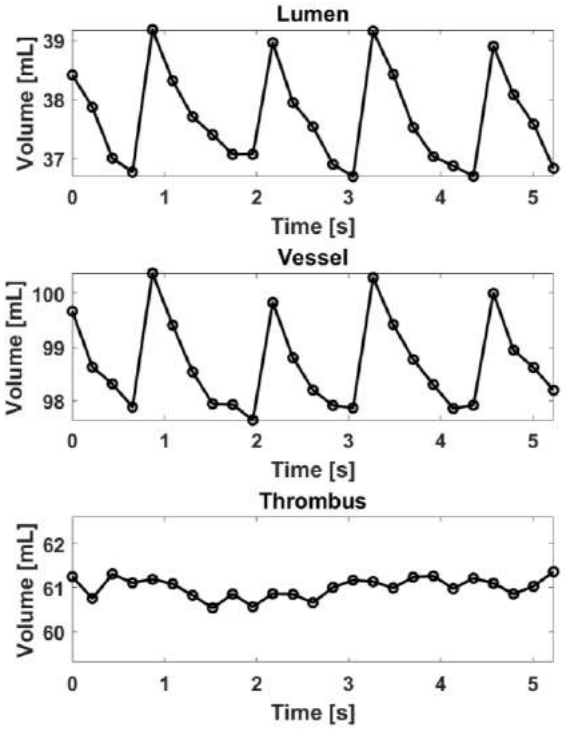

**Figure 2: Volume-time curves of the lumen, total artery, and intraluminal thrombus.**

In Figure 3, the volume change of the thrombus and shear modulus of the vessel wall are shown. The median thrombus volume change is 0.4 %, with an IQR of 1.5%. The median shear modulus of the vessel wall is 1.12 MPa, with an IQR of 0.8 MPa.

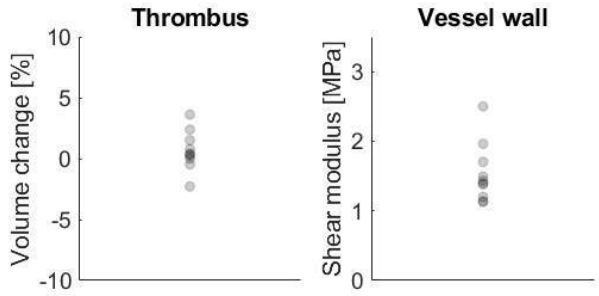

**Figure 3: Compressibility of the thrombus and shear modulus of the vessel wall resulting from the volume-time curves.**

## DISCUSSION

In this study the volume-time curves of the lumen, vessel and thrombus were acquired fully automatically from a 3D+t US acquisition. As shown in Figure 2, a clear pulsatility is seen for the lumen and vessel volume-time curve, which is promising for mechanical characterization. The volume-time curve of the thrombus was used to calculate the thrombus volume change. Kontopodis performed comparable measurements on 5 patients, using ECG-gated CT [5]. The results of the volume change (median 0.4% , IQR 3%), were comparable to the ones shown in Figure 3 [5]. Vorp et al. analyzed the thrombus area ratio using 2D-ultrasound (median 2%, IQR 2%) [6]. Those results were comparable to the volume-ratio obtained in this study. These and our results show that the assumption of incompressibility of the thrombus, which is often used in mechanical modeling, is valid.

In van Disseldorp et al [7], the shear modulus of the vessel wall was determined using 4D-ultrasound. In that specific study, 40 patients were analyzed and the displacements were determined using 3D speckle tracking. The stiffness was determined using inverse finite element analysis (FEA) and resulted in a median of 1.1 MPA (IQR, 0.7-1.4). The stiffness shown in Figure 3 are higher compared to the ones found in this study. Those deviations might be because of the assumptions made in Laplace's law for a thin-walled tube. However, this shear modulus is a good first estimate for the stiffness. In future, this shear modulus can be used as a first guess and input for inverse Finite Element Analysis.

This study showed that it is feasible to estimate mechanical parameters of the AAA and thrombus from 3D+t US using volume-time curves. The limiting factor remains the quality of the US data. Future research will focus on thrombus stiffness estimation using inverse finite element analysis. The patient-specific geometry in combination with the patient-specific stiffness of both thrombus and vessel wall can ultimately be used for FE-based stress analysis for more accurate, patient-specific rupture risk.

## INTRODUCTION

Intracranial aneurysms (IAs) are categorized into non-saccular and saccular (SIA) shapes. Counting to non-saccular types, fusiform intracranial aneurysms (FIAs) occur in 3-13% among all IAs [1]. Subsequently, blood flow parameters in FIAs are less examined than in SIAs and more difficult to make assumptions about the rupture risk, since parameters concerning the aneurysm neck reference cannot be taken into account [2].

In this study the focus is on the difference from FIA to SIA concerning the occurring hemodynamic parameters. To analyze the treatment effectiveness onto each aneurysm model's flow, the virtual implantation of a stent is considered. On top of that the creation and investigation of their healthy counterpart is added to analyze the impact onto the aneurysm formation.

## METHODS

### Patient data and IA models

In this study, three FIA models from different patients were captured with 3D digital subtraction angiography (Case 1 and 3) and computer tomographic angiography (Case 2). Case 1 was found in the left middle cerebral artery (MCA), case 2 in the left vertebral artery and case 3 in the basilar artery [3].

To further elucidate the flow, three SIAs each at a similar location as one fusiform IA were chosen to be analyzed as a comparable basis.

### Virtual stenting and healthy model creation

For each aneurysm model a virtual flow-diverter stent was applied and a healthy counterpart was created manually. Hence, the efficacy of treatment and the blood flow differences between an IA and an equal vessel model without IA could be investigated. The flow diverting devices were deployed with an in-house software [3]. The IAs were extracted from the vessel geometry within the open-source software Blender 2.9 (Blender Foundations, Amsterdam, Netherlands).

### Hemodynamic simulation

In total 18 patient-specific image-based blood flow simulations were carried out using the fluid dynamic solver STAR-CCM+ 14.04 (Siemens Product Lifecycle Management Software Inc., Plato, TX, USA). The same simulation settings were used for each IA model and a spatial resolution of 0.15mm mesh size was enabled. Incoming flow was set to representative flow rates [4] and adapted according to the vessels' inlet diameter. An advanced outlet flow splitting method was used to apply realistic outlet boundary conditions [5].

### Analysis

Blood flow inside the FIA and SIA models was analyzed qualitatively and quantitatively examining the time- and spatially averaged hemodynamic parameters velocity (VEL), vorticity (ω), kinetic energy (KE) and time averaged walls shear stress (AWSS).

To create a comparable basis of the pathological aneurysm model to the stented and the manually created healthy model, the energy loss (EL) for each vessel geometry was considered [6]. The EL describes the difference of the energy at all inlets to the energy at all outlets. For calculating EL, cut planes were set at the inlet and outlet areas for each model at equal locations. The energy appearing at these cut planes was calculated (equation (1)) and then summarized (equation (2)) using velocity (V), area (A), fluid density ($\rho$) and static pressure (P). For summarizing the appearing energy, the temporal and spatial mean over the cut planes was considered.

$$E = V * A * ((0.5 * \rho * V^2 + P) \quad (1)$$

$$EL = i\sum E_{inlets} - i\sum E_{outlets} \quad (2)$$

## RESULTS

Figure 1 represents qualitative results of the velocity streamlines inside the IA models colored with the temporal mean velocity. The three examined FIA models are compared line-wise, together with their saccular comparative case. The different conditions (pathological, treated, healthy – in this order from top to bottom) are stated column-wise for each model. The streamlines within the pathological IAs show a higher variation in temporal mean velocity and in formation than

within the healthy and treated cases. Within the treated cases, the velocity value gets lower inside the IA but follows straight lines compared to the healthy cases.

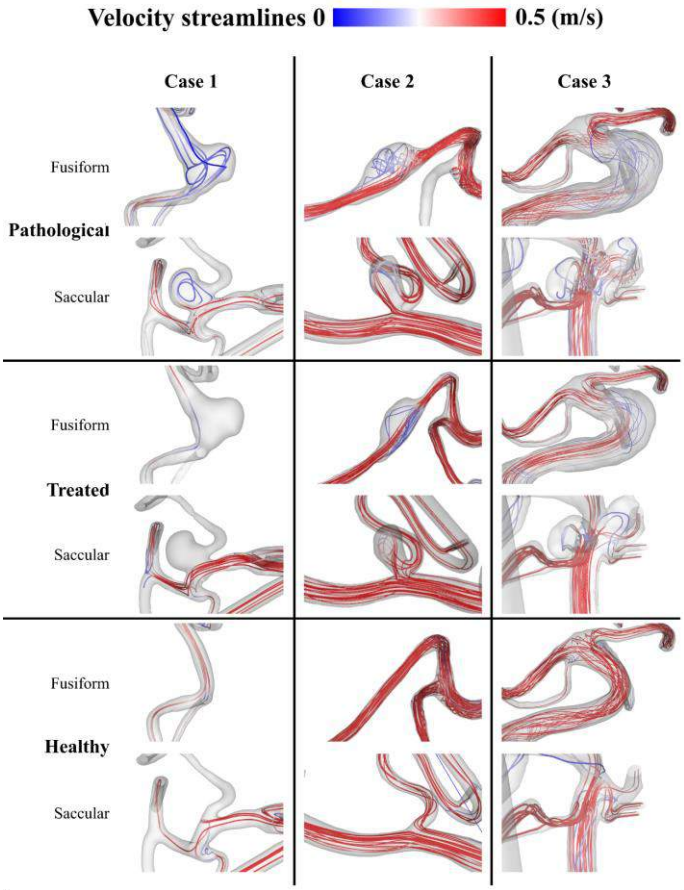

**Figure 1: Velocity streamlines of all aneurysm models.**

Concerning the aneurysm formation, the specific results for the parent vessel in the healthy and treated geometry are shown in Table 1 exemplary for case 1. The parent vessel is chosen to be the part of the vessel in flow direction before the aneurysm part. For the direct comparison, the results of the saccular comparative of case 1 are listed below the FIA results. The values show that the internal blood flow behavior (ω and KE) is decrease in the pathological model for FIAs and SIAs, respectively. Wall characteristics at the SIAs decrease as well and increase minimally FIA, respectively. The deviation from pathological to healthy is higher for SIA than for FIA.

**Table 1: Resulting hemodynamic parameters inside the parent vessel of case 1 (FIA and SIA) for the configurations pathological and healthy.**

| Hemodynamic parameter | | Pathological | Healthy | Pathological /Healthy |
|---|---|---|---|---|
| ω mean (1/s) | FIA | 798.27 | 803.37 | 0.994 |
| | SIA | 1505.43 | 1546.40 | 0.974 |
| KE mean (J) | FIA | 36.44 | 36.615 | 0.995 |
| | SIA | 158.04 | 164.51 | 0.961 |
| AWSS (Pa) | FIA | 6.24 | 6.23 | 1.001 |
| | SIA | 16.10 | 16.97 | 0.949 |

The visualization of the EL in figure 2 shows that especially the aneurysm treatment leads to a high loss of energy inside the vessel flow for all cases. The EL of the pathological compared to the healthy cases is slightly different in both directions (higher and lower).

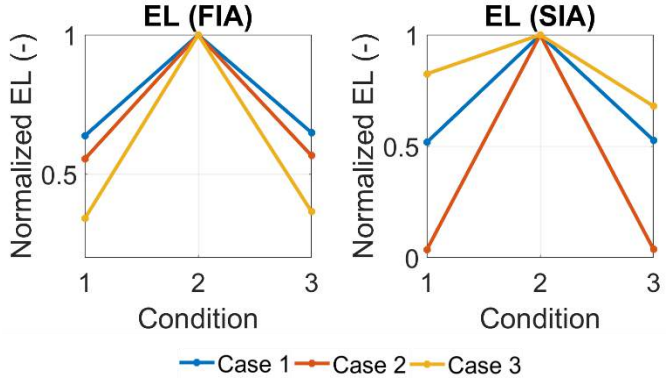

**Figure 2: Energy loss normalized by the highest value for each IA model shown for every condition (1- pathological, 2-treated, 3-healthy).**

## DISCUSSION

Models of FIA and SIA are chosen located at the vertebrobasilar system and MCA according to highest appearance in literature [1].

Qualitative results of the velocity streamlines reveal a high variation in flow structures and velocity value for both (FIA and SIA) compared to treated and healthy models [7]. Nevertheless, treated models show lower velocity values than the healthy ones. Comparing the healthy and pathological values in the parent vessel directly reveals that higher changes appear for SIA then for FIA which could indicate formation. Furthermore, the treatment shows undesirable effects onto the EL within each case [6]. Limitation of this study is the small number of cases analyzed. However, the amount of recorded and with computational fluid dynamics analyzed FIAs is yet rarely represented in the literature [8].

## INTRODUCTION

Chiari Malformation type I (CM-I) is a complex neurological disorder, which occurs in children and adults [1]. The typical diagnostic criteria is cerebellar tonsillar descent for at least 5 mm below the Foreman magnum in adults and 3 mm in children [2], along with the diagnosis of clinical manifestations, such as syringomyelia, neurological symptoms, headache, back and neck pain, blurry vision, or, in children, scoliosis or sleep apnea. However, it has been shown that a substantial number of patients expressed symptoms without severe tonsillar herniation [3]. On the other hand, there are underestimated numbers of asymptomatic patients who meet the radiographic diagnostic criteria of tonsillar herniation [4].

Therefore, the measurement of tonsillar descent may be a limited marker as the CM-I diagnostic criteria. Even though other hindbrain regions in CM-1 keep their normal position, they may be slightly deformed and changed in size. Several studies analyzed the 2D morphometric characteristics of the posterior fossa and studied the correlation with CM-1 syndromes [5, 6]. However, 2D analysis may not be sufficient to explain complicated morphometric abnormalities and associated diseases. For example, syringomyelia, which involves the collection of cerebrospinal fluid (CSF) in a small cavity in the parenchyma of the spinal cord, is usually associated with CM-1 syndromes. The obstruction of CSF outflow may be caused from the deformation of 4$^{th}$ ventricle or to disturbance of CSF fluid dynamics due to tonsillar herniation [7, 8].

Here, we studied anatomical correlations in CM-1 patients using 3D volumetric analysis of posterior fossa, along with 2D length, surface and angle measurements, in an attempt to improve the understanding of the morphological abnormalities of other hindbrain regions, and thus further promote CM-1 diagnosis and surgical treatment.

## METHODS

The retrospective MRI scans obtained from 72 adult CM-1 patients (58 females and 14 males between 19 and 74 years of age, mean = 43.71 ± 13.13 years), as well as 26 healthy adult volunteers (13 females and 13 males between 24 and 60 years of age, mean = 42.35 ± 11.71 years) at Icahn School of Medicine at Mount Sinai were analyzed through IRB approval. Whole brain segmentation was done by Freesurfer, a brain imaging software package, to extract the 3D rendering of the cerebellum, brainstem and 4$^{th}$ ventricle automatically, followed by manual corrections. Brainstem and cerebellum segmentations were then used to create masks for the cerebellar lobular parcellation by SUIT (Fig. 1), a SPM toolbox run by MATLAB 3D volumetric results of cerebellum, tonsil and 4$^{th}$ ventricle were analyzed by Freesurfer, while 2D surface area analysis, angle and tonsil length analysis were performed by Horos.

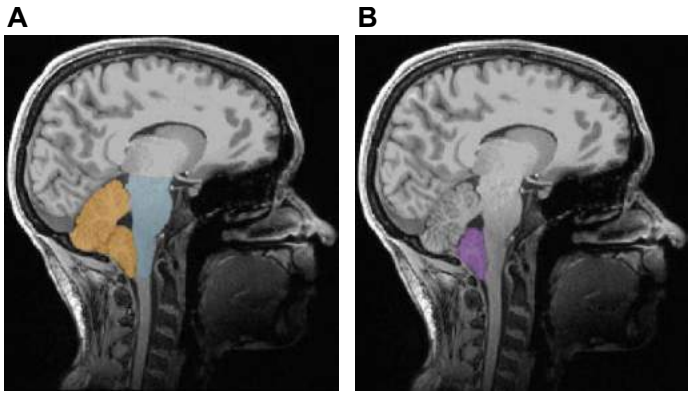

**Figure 1: Cerebellum and brainstem segmentation. Examples of (A) brainstem and cerebellum segmentation by Freesurfer, and (B) tonsil segmentation by SUIT.**

## RESULTS

We summarized some prevalent clinical symptoms in CM-1 patients (total $N$ = 72), and listed in Table 1. Most CM-1 patients experienced headache (72.2%), 2-fold higher than patients who experienced back or neck pain and burry vision. However, no significant age differences for patients exhibiting these symptoms.

**Table 1: Prevalence of symptoms in CM-1 patients.**

| | headache | back and neck pain | blurry vision |
|---|---|---|---|
| $N$ (%) | 52 (72.2%) | 28 (38.9%) | 22 (30.6%) |
| Mean age (σ) | 43.5 (12.8) | 46.2 (11.7) | 45.7 (10.8) |

In our 3D volumetric analysis of the posterior fossa, the mean cerebellar volume is lower in CM-1 patients than in healthy controls (133.19 ± 16.88 $cm^3$ vs. 144.17 ± 12.67 $cm^3$, $p$ = 0.003); while mean tonsillar volume is higher in CM-1 group (10.71 ± 2.71 $cm^3$ vs. 9.23 ± 2.11 $cm^3$, $p$ = 0.0099). The mean 4th ventricular volume was found to be significantly smaller in CM-1 patients (986.23 ± 422.31 $mm^3$ vs. 1433.86 ± 511.81 $mm^3$, $p < 0.0001$) (Fig. 2).

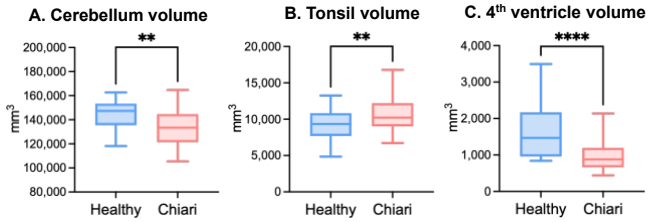

**Figure 2: 3D volumetric analysis of posterior fossa sub-regions. Volume comparison between Healthy subjects and CM-1 patients on (A) Cerebellum, (B) Tonsil, and (C) 4th ventricle.**

In 2D morphological measurements, we analyzed the mean length of tonsillar herniation length in CM-1 patients to be 9.48 ± 4.47 mm. The surface area of the foramen magnum ($A_F$), and areas of the cervicomedullary junction ($A_C$) and tonsils ($A_T$) at the foramen magnum (FM) were also analyzed. The ratio of neural tissue within the area of the FM $(A_C + A_T)/A_F$ was calculated. We found about 3-fold higher ratio in the CM-1 group (67.88 ± 9.73% vs. 18.44 ± 2.97%, $p < 0.0001$) (Fig. 3A), indicating more brain tissues occupied the FM in CM-1 patients.

To find the correlation between length of tonsillar herniation and crowding of the FM, we plotted tonsillar herniation length vs. the ratio of $(A_C + A_T)/A_F$, where we found a positive correlations ($p < 0.0001$) (Fig. 3B).

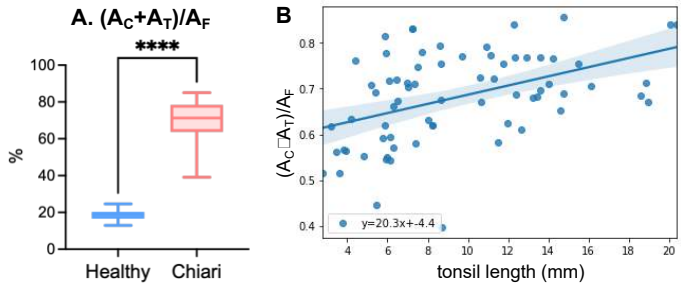

**Figure 3: 2D length and surface area analysis. (A) The comparison between healthy subjects and CM-1 patients of $(A_C + A_T)/A_F$ ratio. (B) A linear regression showing a positive correlation between $(A_C + A_T)/A_F$ ratio and tonsil length ($p < 0.0001$).**

## DISCUSSION

Various conditions can lead to CM-1 syndrome. One possible cause is incomplete development of the occipital bones and small posterior fossa resulting in overcrowding of the cerebellum, thus leading to tonsillar herniation [9]. These structural abnormalities may further cause volumetric changes not yet elucidated. Our 3D volumetric analysis demonstrated significantly larger tonsillar volumes in CM-1 patients compared to healthy controls. Additionally, CM-1 patients exhibited significantly smaller cerebellar volumes. Our 3D volumetric analysis found significantly smaller 4th ventricle volume and more brain tissue $(A_C + A_T)$ at the FM in the CM-1 group ($p < 0.0001$). In addition, a positive correlation between this ratio and tonsillar herniation length, indicates a correlation between tonsillar ectopic and the degree of brain tissue crowding at the FM. The results suggest that tonsillar herniation in CM-1 is also associated with other anatomical abnormalities in the posterior fossa.

Some studies suggest that abnormalities of CSF flow, such as reduced flow velocity, are present in CM-1 patients [10], and could be related to CM-1 symptomatology [3]. As a next step, we are currently investigating the relationships of morphometric characteristics with disturbance of CSF dynamics. The anatomic characteristics found in this study, namely smaller 4th ventricular volumes and increased crowding of the FM with greater tonsillar ectopia may contribute to irregular CSF flow. This may be an explanation for syringomyelia that is not infrequently found in CM-1 patients. Together, these factors may all compound to affect the clinical presentation of the CM-1 patient.

Follow on this research, we will expand more morphometric measurements, such as angle analysis of posterior fossa, to study more complicated morphometric correlations in CM-1 patients. In addition, we will explore more sophisticated correlations between CM-1 conditions and morphometric abnormalities of posterior fossa. This could improve the understanding of disease development, and could potentially build a more reliable model for CM-1 diagnosis.

# PRESSURE INJURIES AND WHEELCHAIR USERS: UNDERSTANDING THE ROLE OF FRICTION BETWEEN PANT FABRICS AND THE SEAT

**Archana Lamsal and Tamara Reid Bush, PhD**

Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

## INTRODUCTION

Wheelchair users spend a large amount of time seated, and because of this, have a high risk of developing pressure injuries (PIs) particularly on the bottom of the buttocks. The World Health Organization estimates that 1% of the global population requires wheelchairs for increased mobility [1]. In 2010, there were 3.7 million wheelchair users in the USA and 264,000 in Canada [2]. Annually over 2.5 million people suffer from PIs in the US, and nearly 1 million in the UK [3], [4]. PIs are a global problem. PIs can lead to infections, sepsis, and potentially death [5]. Shear forces acting on the seat interface have been linked to PI formation. Shear forces are parallel to person's tissue and occur at the person-chair interface. A larger friction coefficient correlates to a larger capacity of generating shear force between the person and chair. Higher friction leads to larger shear forces which are related to increased risk of pressure injuries [6]. Thus, reducing the coefficient of friction between the seat interface and clothing material (specifically pants) can be a beneficial strategy to reduce the shear forces in wheelchair seating and therefore the incidence of PIs. This same reduction of friction and shear forces can also be beneficial to patients who need to be frequently repositioned in bed or, have chronic muscle spasms, and are thus at an elevated risk of developing a PI [6].

Research showed that the coefficient of friction of fabrics depends on various factors, such as the yarn material, type of weave and surface finish[7], [8]. Yarn with higher frictional properties have been generally known to produce fabrics with higher frictional properties [9]. However, different structure and finish of the fabrics have also been found to affect the friction properties of the material [7]. Because of the interaction of various factors, predicting the frictional property of a fabric is a complex task. Further, little is known about the frictional interactions of commonly used pant fabrics with the seat cover of wheelchair. So, the goal of this study was to determine the coefficient of friction between a vinyl seat cover (common cover coating for wheelchair seats and cushions) and seven commonly used pant fabrics.

## METHODS

A wooden block with cross section of 15 cm x 15 cm and thickness of one centimeter, called the 'sled' was used to carry a test weight during trials. A 110 N weight was attached to the top surface of the sled, and segments of the pant fabric were cut out and attached to the bottom surface of the sled (Figure 1). These fabrics were wrapped around the wooden surface and secured so they were taut (Figure 1a). Seven commonly used fabrics were tested: men's jeans (100% cotton, woven fabric), men's khakis (100% cotton, woven fabric), women's jeans (75% cotton, 24% polyester, woven fabric), women's khakis (93% cotton, 7% spandex, woven fabric), sweatpants (60% cotton, 40% polyester, knit fabric), basketball shorts (100% polyester, knit fabric), women's pull-on pants (100% polyester, woven fabric). The woven fabrics were all twill weaves. The fabric structures of all fabrics are shown in Figure 2.

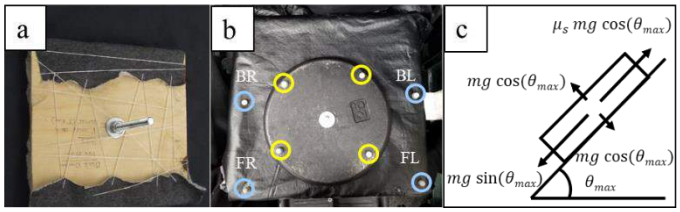

**Figure 1 (a) The top of the sled. Fabric was wrapped around the wooden surface and secured so they were taut (b) A round weight was positioned on top of the sled while on top of seat pan. Yellow circles denote the markers on the sled, and blue circles denote the seat pan markers. The seat pan markers were named front left (FL), back left (BL), front right (FR) and back right (BR). (c) Free body diagram for sled just before it starts to slide on the seat pan.**

Four reflective markers were attached to the weight on top of the sled (Figure 1b). A custom designed chair with a tilting seat-pan (0-45 degrees of tilt) was used. A vinyl seat cover was secured in the seat pan, and four reflective markers were attached to the articulating seat pan. The sled was placed on the seat pan, and the seat pan was tilted starting from 0 degrees (horizontal) until the sled started sliding. The data set was collected for 20 repetitions for each fabric.

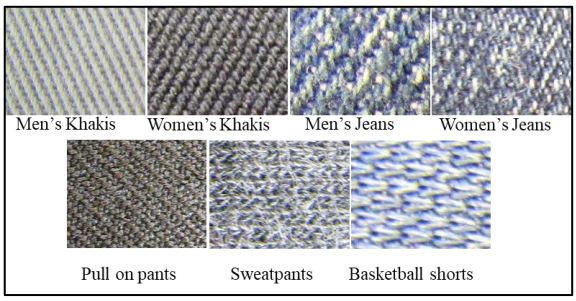

**Figure 2 Fabric structure of different pant fabrics tested. The sweatpants and basketball shorts were knit fabric, whereas the rest of the fabrics were woven with twill weave.**

A multi-camera motion capture system was used to capture the 3D positions of the markers at a sample rate of 100 Hz. The position of the sled ($\vec{s}$) was the average position of the four markers on the sled. The unit vector along the orientation of the seat pan ($\hat{e}$) was determined using two markers- front left (FL) and back left (BL). The position of the sled along the depth of the seat pan ($\vec{r}$) was calculated using Equation 1.

$$\vec{r} = \hat{e}i \cdot (\overrightarrow{FL} - \vec{s}i) \quad (1)$$

The angle of tilt of seat pan $\theta$ was determined using Equation 2.

$$\theta = \tan^{-1}\left(\frac{\hat{e}_z}{\hat{e}_y}\right) \quad (2)$$

The coefficient of static friction was determined using Newton's second law of motion. The free body diagram of the experimental setup just before the sled started sliding on the seat pan is shown in Figure 1c. Equation of motions to determine the coefficient of static friction are given in Equations 3 and 4.

$$\sum F_t = \mu_s mg\cos(\theta_{\max}) - mg\sin(\theta_{\max}) = 0 \quad (3)$$

$$\mu_s = \tan(\theta_{t,max}) \quad (4)$$

To determine the time point when the sled started to slide on the seat pan, a difference (d) between $\vec{r}$ and moving average of r (using 20 preceding data points) at each time point was calculated. The last point when the value of d was less than 1mm was determined as the point where the sled started to move. Thus, the coefficient of static friction was calculated at that point.

## RESULTS

The mean and standard deviations of the coefficients of static friction between the vinyl seat cover and seven different pant fabrics are presented in Table 1. Men's khakis and men's jeans, which were both 100% cotton twill weave fabrics, demonstrated small differences in their coefficients of friction. Women's jeans (75% cotton, 24% polyester) had a smaller friction coefficient compared to men's jeans. Women's jeans and sweatpants, both comprised of cotton-polyester blend, demonstrated similar coefficients. Women's pull-on pants and basketball shorts demonstrated large differences in their friction coefficient despite both being comprised of 100% polyester.

**Table 1 Means and standard deviations of static coefficients of friction ($\mu_s$)**

| Composition | Type of cloth | $\mu_s$ (Mean) | SD |
|---|---|---|---|
| 100% polyester | Women's pull-on pants | 0.46 | 0.01 |
| 93% cotton, 7% spandex | Women's khakis | 0.48 | 0.02 |
| 60% cotton 40% polyester | Sweatpants | 0.51 | 0.02 |
| 75% cotton, 24% polyester | Women's jeans | 0.53 | 0.02 |
| 100% cotton | Men's khakis | 0.54 | 0.03 |
| 100% cotton | Men's jeans | 0.57 | 0.01 |
| 100% polyester | Basketball shorts | 0.59 | 0.01 |

## DISCUSSION

This study determined the coefficient of friction between a vinyl, seat cover and seven common pant fabrics. Understanding the frictional properties of the seat interface is important, especially for wheelchair users who are seated the majority of the day and at high risk for PIs.

Since the reduction of friction and shear force is desired for wheelchair users, pure cotton fabrics such as denim and 100% cotton khakis are not the optimal choices due to their higher friction coefficient. Our data suggest that sweatpants and polyester pull-on pants may be better choices as they have lower frictional coefficients.

Our data have some interesting findings. For example, the basketball shorts and women's pull-on pants had large differences in their friction coefficients despite both consisting of 100% polyester. These differences between fabrics of the same composition could be due to the finish of the fabrics. There might also have been differences in the density and thickness of the yarn or tightness of the weave [10]. Literature has shown that the tighter fabric construction results in lower coefficients of friction [7].

Another interesting comparison was between women's khakis and the basketball shorts. Both fabrics were stretchy, but with a different composition. The stretch of the women's khakis was due to the material properties of spandex whereas the stretch of the shorts was due to the looser fabric construction. This could be one of the reasons behind higher friction coefficient of the shorts.

The results show that the coefficient of friction can vary with difference in content, construction, as well as finish. Pants normally chosen by the users might be producing high friction and increasing the risk of PI formation. Thus, there is a need for better guidelines and understanding of frictional behavior of pant fabrics for the wheelchair users. The results also indicate that pants designed for males (from our selection) mostly had higher friction coefficients than pants designed for females. So, the male wheelchair users might need to be more cautious in choosing their pants.

# SEATED SHEAR FORCES ARE AFFECTED BY PANTS AND CUSHION COVER MATERIALS

**J. Scott PhD and T.R. Bush PhD**

Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

## INTRODUCTION

Over 3 million wheelchair users live in the United States, over half of whom will develop a pressure injury (PI) in their lifetime [1,2]. PIs are painful and disrupt the lives of those experiencing them because treatment includes unloading the affected body region, disengaging people from their lives. Not only are PIs disruptive, but expensive, costing the United States an estimated $27 billion per year [3].

Shear forces have been consistently cited as a risk factor for the development of PIs, particularly in tissues deeper than the skin [4]. These forces are present on the buttocks and thighs while seated, creating risk for PI development in those regions. Although back recline is the most popular repositioning strategy to reduce the risk of PIs in the buttocks and thighs, some studies have suggested that it may actually increase shear forces in those areas [5,6]. Thus, there is a need to evaluate the effects of back recline on shear and potential alternative ways to reduce shear at the buttock and thigh-to-cushion interface.

One potential way that shear forces on the buttocks and thighs may be mitigated is by using cushion covers that have low coefficients of friction when contacting typical clothing materials. Examples of applications where low friction materials are already applied include transfer sheets in hospitals. As such, this type of material may be used to reduce shear forces experienced on the buttocks while seated.

Therefore, the goals of this work were to 1) evaluate three cushion covers' abilities to reduce shear on the buttocks and thighs while in reclined position and 2) determine coefficients of friction for pairs of three cushion cover materials and two clothing materials.

## METHODS

10 able-bodied individuals (5 male, 5 female) volunteered for this study (IRB #16-681). An articulating chair was built with independently rotating seat pan and chair back supports. The supports were mounted on six-axis load cells and covered by a 1-inch layer of foam. Cushion cover materials were attached on top of the foam and included vinyl, one-layer nylon, and two-layer nylon covers. Pants materials included denim and sweatpants. Two different experiments were conducted in a motion capture space, with markers on the corners of the seat pan, on the back of the chair, and on participants' lateral epicondyles (Figure 1).

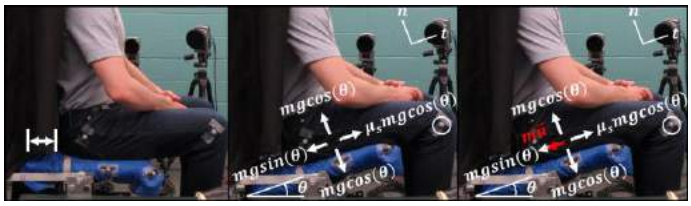

**Figure 1. A participant sitting on the chair without touching the back (left), a free body diagram of person before they begin sliding (middle), and while they are sliding (right). The coordinate system is in the top right and lateral epicondyle marker circled.**

The first experiment was to determine the effects of pants, cushion cover, and back recline angle on shear forces on the buttocks and thighs. Participants sat in the chair with their buttocks pushed back as far into the chair as possible. Motion capture and force data were collected while the back was reclined to 15° and then inclined back to 0° recline (vertical). Shear force data were collected at 5°, 10°, and 15° of back recline. The angle of the back recline was recorded by the markers on the back of the chair. A two-way repeated measures ANOVA and post-hoc Tukey tests were used to determine between-material pair and between-recline differences in shear forces.

The second experiment was to determine the coefficients of friction between the pants and cushion covers. The seat pan was covered with one of the cushion cover materials, and participants sat in the chair

wearing one of the pants materials with their back not contacting the back of the chair (Figure 1). The seat pan was tilted until the participant began sliding. Sliding along the anterior-posterior axis of the seat pan was tracked with markers on participants' lateral epicondyles and on the front and back left corners of the seat pan using Equations 1 and 2.

$$\hat{e_1} = \frac{\overrightarrow{FL} - \overrightarrow{BL}}{\|\overrightarrow{FL} - \overrightarrow{BL}\|} \quad (1)$$

$$\vec{q} = \hat{e_1} \cdot \left(\vec{k} - \overrightarrow{BL}\right) \quad (2)$$

Where $\overrightarrow{FL}$ was the front left marker on the seat pan, $\overrightarrow{BL}$ the back left, $\hat{e_1}$ the unit vector along the anterior-posterior axis of the seat pan, $\vec{k}$ the average position of the two markers on the lateral epicondyles, and $\vec{q}$ the position along the axis of the seat pan. The vertical and horizontal components of $\hat{e_1}$ were used to determine the angle of seat pan tilt ($\theta$), and $\vec{q}$ was used with the motion capture data collection frequency (60 Hz) to determine the acceleration of the participant by dividing the difference in $\vec{q}$ between frames by the frequency twice. The static and kinetic coefficients of friction were determined by Equations 3 and 4.

$$\mu_s = \tan(\theta_{max}) \quad (3)$$

$$\mu_k = i\tan(\theta_{max}) - \frac{|\vec{a}|}{g\cos(\theta_{max})} \quad (4)$$

Where $\theta_{max}$ was the maximum angle of tilt before the participant started sliding, and $|\vec{a}|$ was the magnitude of their acceleration.

## RESULTS

Shear forces at 5°, 10°, and 15° of back recline for all material pairs are displayed in Figure 2. Shear forces increased with back recline, regardless of cushion cover ($p < .0001$). Further, the largest shear forces occurred with sweatpants on vinyl. Though there were no significant between-pants differences in shear forces, shear forces on the two-layer nylon cover were reduced by 20% relative to the vinyl cushion cover.

The coefficients of friction for the material pairs including the one and two-layer nylon covers are displayed in Figure 3. Because of the large coefficients of friction for the material pairs that included the vinyl cushion cover, the participants never slid on the vinyl cover during coefficient of friction experiments. Instead, the seat pan tilt was too large for participants to keep their backs from contacting the chair. The coefficients of friction on the two-layer nylon cover were smaller than on the one-layer nylon cushion for both pants materials.

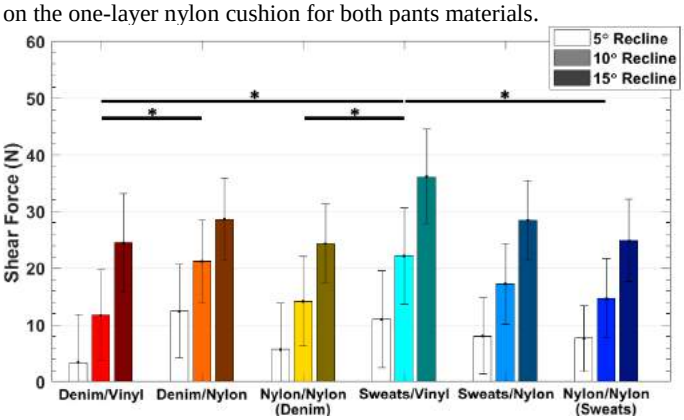

**Figure 2. Shear forces on the seat pan at three recline angles for all pairs of pants and cushion cover materials. Significant differences between shear on material pairs are indicated by asterisks (*).**

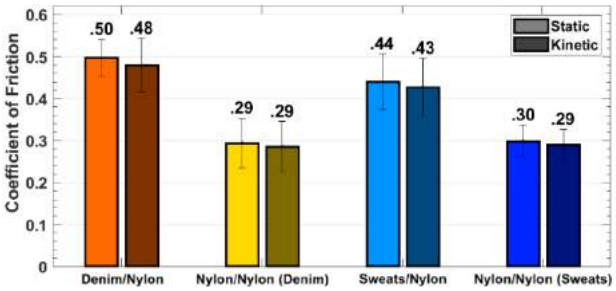

**Figure 3. Static and kinetic coefficients of friction between pants and cushion cover materials.**

## DISCUSSION

The goals of this work were to establish the coefficients of friction for material pairs that may be seen at the soft tissue-cushion interface and to evaluate their abilities to reduce shear forces on the buttocks and thighs while seated. This work is integral to mitigating the risk of developing PIs because it investigates a current repositioning method used to reduce PI risk and a potential method for reducing shear forces.

The data collected from this study indicated that increasing back recline angle increased the shear forces on the buttocks and thighs. This finding held true, regardless of the pants-cushion cover material pair. Moreover, this finding is of the utmost importance because of the ubiquity of using back recline as a pressure relief strategy. The data from this work suggest that increasing back recline angle may actually increase the risk of developing a PI instead of reducing it, which means that the most common repositioning strategy to relieve pressure might need to be reevaluated.

Our results also showed that the vinyl cushion cover had too large of coefficients of friction when paired with pants materials to be determined with the current method and that shear forces on the seat pan were larger with that cover than with the two-layer nylon cover. These findings suggest that materials used to make cushion covers are a potential mechanism by which shear forces can be reduced on the buttocks and thighs. Further, a specific material like the nylon material used in transfer sheets has the potential to reduce the shear forces on the buttocks and thighs. Such a strategy may be able to mitigate the increase in shear forces on the buttocks and thighs due to increases in back recline angle. Doing so may allow wheelchair users to continue using back recline with a smaller increase in risk in PI development.

Future work will need to consider the inclusion of wheelchair users in shear force studies and extension to real-world settings outside of the laboratory. These will be used to confirm that the results hold true in more realistic settings and applications.

## INTRODUCTION

The flow in 3D curved pipes is much more complicated compared to that in straight pipes. All biological systems are characterized by curvatures and bifurcations that make the geometry more challenging to model. For simplification, the majority of experimental flow assessment studies did not account for the physiological 3D spatial curvature and geometry of the ascending aorta as opposed to the efforts done computationally especially with patient-specific geometries.

The existence of secondary flows in curved pipes was noted by Eustice 1910[1], and a complete assessment of the flow features pertaining to vortices in the ascending aorta was performed by Dean 1927[2]. Additionally, the additional pressure drop imposed by the curvature is important to assess for a complete ventricular pumping energy understanding and evaluation[3]. The locations of maxima and minima in the wall shear stress (WSS) are also of utmost importance in the aorta because these may represent sites for plaque buildup on vessel walls, and thus may play a major role in atherogenesis[3].

The aim of this work is to (1) validate the computational framework using in-vitro particle image velocimetry (PIV) experiments and (2) assess the flow dynamics in a physiologically curved aortic arch. The importance of validated computational assessment in this body of work is to allow the visualization and quantification of the 3D flow features that 2D PIV in experiments cannot capture.

## METHODS

Large Eddy Simulation (LES) was adopted in our study with the capability to resolve the wall regions that contain a wide range of scales of flow motion from both temporal and spatial domains. It can directly resolve the large scales of turbulence everywhere in the computational domain and model those small-scale motions in the near-wall region. The wall-adapting local-eddy viscosity (WALE) sub-grid scale model was used to account for the effects of small eddies on the resolved flow. All simulations were calculated using STAR-CCM+ (Siemens, Inc., Germany) with all y+ treatment. The wall y+ treatment method combines the high y+ wall treatment for coarse meshes and the low wall y+ treatment for fine meshes, which gives similar results to the low y+ treatment as y+≤1 and to the high y+ treatment for y+≥30. In addition, it is also designed to produce reasonable results within the buffer layer (i.e., 1<y+<30) for intermediate meshes. The working fluid has a density of 1060 kg/m$^3$ and a kinematic viscosity of 3.5cSt.

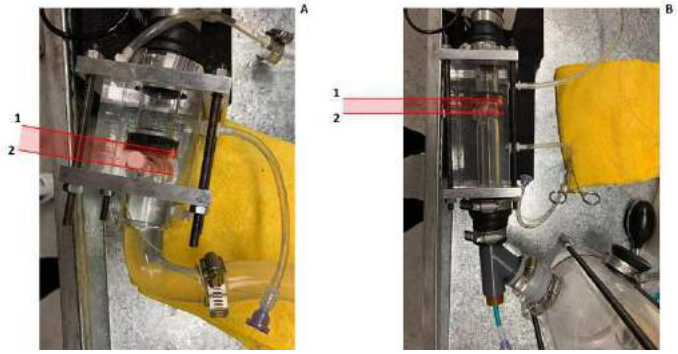

**Figure 1. Experimental setup detailing the location of the 23mm SAPIEN 3 Ultra in the curved (A) and straight (B) aortic root chambers. Locations 1 and 2 represent the valve entrance at 2.1mm and valve limit at 3.9mm, respectively.**

The boundary conditions adopted in this study were obtained from pressure and flow data obtained experimentally using an in-vitro model of the same computational one. Briefly, the experiments were performed using the curved aortic model along with a typical straight one under pulsatile physiological conditions. The cardiac output was 5 L/min, the heart rate was 60 beats per min and the pressures imposed were 120/80 mmHg in the presence of a 23 mm SAPIEN 3 Ultra valve. Several pressure measurements were taken using Millar catheters going from upstream to downstream of the valve. The velocity conditions right

at the valve leaflets were adopted as boundary conditions for the simulations. Figure 1 shows the experimental setup for both aortic models.

*Model Validation*

The model validation was performed between a straight aorta model experimentally through PIV experiments and computationally. Given the 3D complex geometry of the aortic arch, 2D PIV was not possible. Thus, in this study, we used the straight model for validation, and we show the results of the aortic curvature flow through computational modeling only. **Figure 2** shows the instantaneous velocity distributions in the central plane (i.e., z=0) at the acceleration, peak systole, and deceleration phases. The upper images are from experimental measurement and the lower ones are from simulation. Agreement was found between velocity magnitudes between the experiment and the simulation along with the overall general flow features.

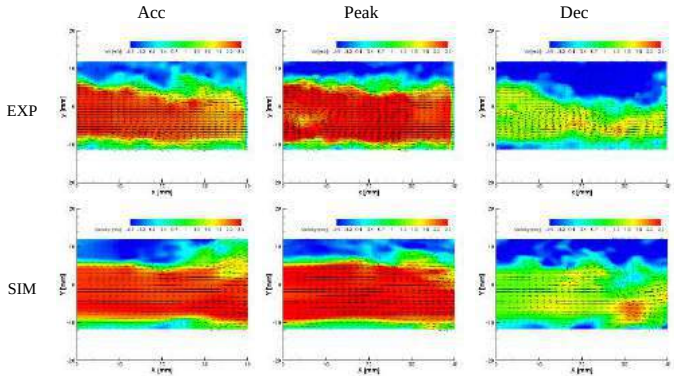

**Figure 2: Comparison of velocity contours at Acceleration (Acc), Peak Systole and Deceleration (Dec) phases: Experiment (upper row); Simulation (Lower row). The legend shows the velocity contours with magnitudes ranging from 0 to 2.5 m/s. EXP denotes experimental results and SIM denotes simulation results.**

## RESULTS

The velocity contours in the central plane of the curved aorta are shown

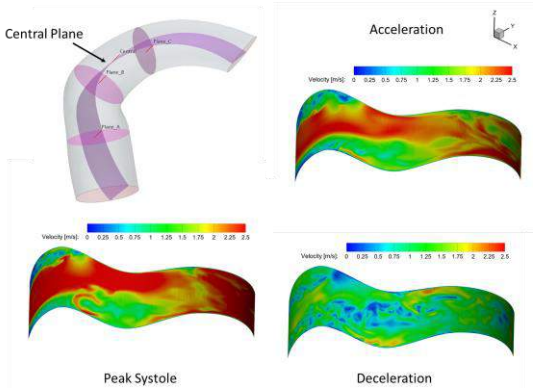

**Figure 3: Velocity contours at the center plane of the curved aorta at acceleration, peak systole, and deceleration phases of the cardiac cycle. Velocity legend ranges from 0 to 2.5 m/s.**

in Figure 3. The location of the maximum axial velocity is shifted toward the outer wall of the aorta. Figure 4 shows the velocity distribution in the cross section of each of the planes marked on the figure at peak systole. These planes indicate the locations where the curvature changes. With these geometric changes, different velocity patterns are seen as well. It is important to note that from construction

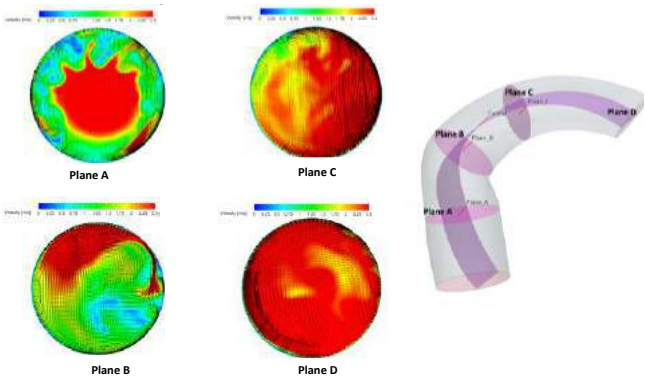

**Figure 4: Velocity contours and vectors in planes A, B, C and D at different curvatures of the ascending aorta during peak systole. The diameter at planes C and D is smaller than that in planes B and A, hence the increase in velocity magnitude. The velocity contours range from 0 to 2.5 m/s in magnitude.**

of the aortic arch[4], the diameter decreases as the descending aorta is reached. This decrease in diameter leads to an increase in velocity as shown in the figure. Additionally, on these planes, the shift in velocity maxima is also apparent. Figure 5 shows the WSS distribution in the straight and curved aortic arches. More concentrated WSS maxima are shown in the curved aortic model.

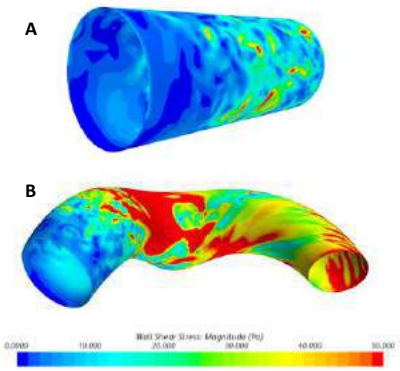

**Figure 5: Wall shear stress contours of the (A) straight and (B) curved aortic arches at peak systole.**

## DISCUSSION

In this study, we validated and established a computational framework to assess the flow dynamics in the ascending aorta with a 3D physiological curvature. We found great agreement with PIV results and CFD results in the straight aortic model and therefore, we extrapolated our computational framework to the aortic arch modeling. The results show the shift in axial velocity towards the outer wall, which is expected given the centrifugal effects induced by the aortic curvature[3]. The spatial and temporal effects of the 3D curvature leads to different velocity profiles. Additionally, the low velocities observed on one side of the aortic walls combined with the elevated non-physiological WSS results show are associated with atherosclerosis and plaque deposits[5,6].

## INTRODUCTION

Rotator cuff tears are common, affecting more than 50% of patients over the age of 65 and resulting in pain and loss of shoulder function [1]. Rotator cuff repair is one of the most common shoulder procedures performed clinically. Recent literature shows healing after rotator cuff repair to be very unpredictable, with reported failure rates as high as 94% [2]. In the current standard double-row suture bridge repair, the suture punctures through bone and tendon at only two anchor points, concentrating stress so that sutures can cut through the tendon and cause the repair to fail (Fig. 1) [3]. Previously, inspired by the remarkable grasping ability of python teeth on their prey, we showed a strong relationship between tooth curvature and tendon grasping, and determined the optimal tooth shape for grasping soft tissue [4]. Furthermore, we identified an optimal tooth array design for a grasping device to augment rotator cuff tendon-to-bone repair [4]. In this study, we applied this biomimetic approach to augment rotator cuff repair. We hypothesized that a clinically relevant tooth array device interposed between tendon and bone can enhance tendon-to-bone repair mechanics through better load distribution across the repair site (Fig. 1). We performed 3D finite element models (FEM) to study stresses near the tip of the tooth and to determine the effect of tendon thickness on tooth gripping strength. We extended the single tooth and the tooth array optimization to the design of a rotator cuff-specific device. To assess the efficacy of the device, we tested its strength in a cadaveric rotator cuff repair model.

## METHODS

*Device design:* To translate the idealized model and shear lag test results from prior studies for clinical tendon-to-bone repair, a rotator cuff-specific device was designed using SolidWorks (Dassault Systèmes, Waltham, MA, USA). The device consisted of the optimized array of teeth placed in a curved, flexible base that matched the curvature and dimensions of the human humeral head supraspinatus tendon attachment site (0.67" x 0.4" footprint area [5]). The fit and qualitative grasping ability of the device were evaluated in human cadaver shoulders for 3 different device prototypes. To optimize fixation of the device into bone, 9 cadaveric shoulder rotator cuff repairs were completed with various iterations of the device. A series of device design changes were implemented based on hands-on feedback from orthopedic surgeons.

*Finite element model (FEM):* 3D finite element simulations were performed to interpret how the shape of the teeth affected the peak stresses in the tendon and the contact area between the tendon and the bone (Abaqus, Dassault Systèmes, Waltham, MA, USA). Consistent with models of healing tendon, transversely isotropic material properties were used (Young's modulus $E_1$=450 MPa, $E_2$=$E_3$=100 MPa, shear modulus $G_{12}$ = 0.1 $E_1$, Poisson ratio $\nu$=0.55); the tooth and base were isotropic with E=100 MPa and $\nu$=0.3. Periodic boundary conditions were applied on the four lateral faces, and a master-slave algorithm with a penalty for interpenetration was used to enforce frictionless contact boundary conditions between the tendon, tooth, and bone; tooth and bone were fully adherent. The upper surface was traction free. The tendon was displaced in the direction opposite that of the tooth. Convergence studies were performed.

*Human cadaver rotator cuff repairs:* To assess the device in a clinically relevant rotator cuff repair setting, paired human cadaver rotator cuff samples were used (Anatomic Gift Foundation, Inc., Hanover, MD). Clinically relevant supraspinatus tendon tears were created with a scalpel and then repaired using a double-row suture bridge technique, in a paired fashion either with or without the device (n=5 per group). After repair, humerus-supraspinatus tendon-muscle samples were carefully isolated and stored at 4 °C overnight.

*Biomechanical testing:* The humerus was secured in a pipe with two orthogonal k-wires and Rockite cement. The pipe was secured close to the humeral head to prevent flexion. The rotator cuff muscle was secured in a freezing clamp using liquid $N_2$. The humerus was angled at

120° relative to the tendon so that muscle was pulled parallel to the tendon fibers at the insertion. Repaired supraspinatus samples were held in tension at 15 N for 20 s and then pulled in uniaxial tension to failure at 0.5 mm/s. Force and grip displacement data were recorded (MTS, Eden Prairie, MN, USA), and maximum force, stiffness, and energy to failure were determined.

*Statistical analysis:* All data are shown as mean ± standard deviation. Paired t-tests were used to evaluate the efficacy of the device with statistical significance set to $p < 0.05$ (GraphPad Prism 7).

## RESULTS

FEM results showed that stresses in the tendon were elevated in the region of the tip of the tooth (Fig. 2a). Peak stresses in the tooth were dominated by flexure, and occurred approximately midway up the tooth (Fig. 2a). Peak stresses increased as tendon thickness increased relative to tooth size, and decreased with tendon curvature (Fig. 2b). When iterating on the design of the device, the amount of tissue in contact with the bone increased with increasing base curvature and tooth length.

The final design of the rotator cuff-specific device consisted of an array of teeth placed in a curved, flexible base that matched the curvature and dimensions of the human humeral head supraspinatus tendon attachment site (Fig. 1). Fixation of the device onto bone was accomplished through 4 suture holes, placed in the 4 corners of the rectangular base. Mechanical testing results revealed that testing of the device led to 28%, 43%, 62%, 139% and 141% improvements in strength (i.e., maximum force) relative to the paired repair without the device (average strength improvement of 83%; Fig. 3b). Consistent with this, energy absorption was significantly increased with use of the device (Fig. 3c). The trend towards increased repair stiffness with the device was not significant statistically (p=0.07; Fig. 3c).

## DISCUSSION

Rotator cuff repair using current techniques and hardware has reached a limit. Therefore, there is a major clinical need to develop novel approaches for improving tendon-to-bone fixation and reducing failure rates after surgical repair.

Integrated experiments and modeling provided insight into how to adapt a concept based upon python teeth to tendon-to-bone reattachment. 3D modeling revealed that stresses in tendon were elevated in the region of the tip of the tooth, indicating that the tooth tip is crucial in maintaining maximum tendon grip. Modeling also showed that tooth size can be optimized to the thickness of a tendon to improve gripping strength. This is of particular interest as we apply these findings and adapt them to better repair other commonly injured tendons such as the patellar and Achilles tendons.

Human rotator cuff cadaver experiments indicated that the python-tooth-inspired device interposed between tendon and bone significantly enhanced rotator cuff repair mechanics. The base of the device must be made in various sizes to accommodate for variations in the size of the attachment footprints across patients.

The efficacy of the device was likely related to improvement of stress distribution. Instead of relying on a small number of suture anchor points, the device augmented the current repair through better load distribution by transferring stress between tendon and bone over the entire footprint area. Combined with current repair techniques, the proposed grasping device nearly doubled repair strength. Improving fixation of tendon to bone during rotator cuff repair by this amount would have a significant impact on outcomes after rotator cuff repair by reducing the high re-rupture rates currently observed.

## INTRODUCTION

Heart disease is the leading cause of death worldwide [1]. Because of this pressing societal challenge, cardiac drug discovery and cardiac tissue engineering are highly active areas of research. There is not only a pressing need to discover new treatments for cardiac disease, but also a pressing need to understand unintended cardiac-related adverse effects of drugs used for other purposes [2]. Recently, there has been a growing focus on human induced pluripotent stem cell derived cardiomyocytes (hiPSC-CMs). This technology presents a feasible approach to acquiring human cells and future patient-specific treatment plans [3]. These cells can be studied either in isolation, or as components of tissue engineered constructs (Fig. 1). For example, hiPSC-CMs can self-assemble into beating microtissue. However, despite this functionality, hiPSC-CMs are both morphologically and functionally distinct from the cells in mature cardiac tissue (Fig. 1).

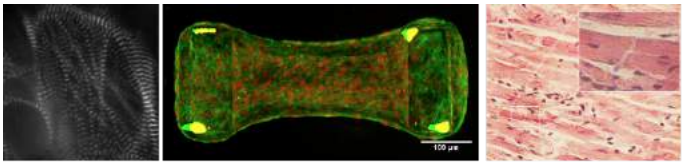

**Figure 1. Example of disordered myofibrils in hiPSC-CMs, a hiPSC-CM microtissue that formed between two flexible posts, and highly ordered mature cardiac tissue for contrast.**

The immature and non-linear structure of hiPSC-CMs makes it difficult to extract quantitative information from image-based assays. Recently, there has been significant work in this direction where z-disks in hiPSC-CMs are fluorescently labeled (Fig. 1) and advanced image processing and analysis software is used to segment and track sarcomeres and approximate their length with respect to time [3]. However, these state-of-the-art computational methods have room for improvement in both the efficacy of sarcomere segmentation and tracking under laboratory conditions, and strategies for comprehensive data analysis. Here we present our recent steps forward in automated quantitative analysis of beating hiPSC-CMs and cardiac microtissue constructs.

## METHODS

Here we introduce "Sarc-Graph," a computational framework to segment, track, and analyze sarcomeres in fluorescently tagged immature and non-linear hiPSC-CMs. Our framework includes functions to segment z-disks and sarcomeres, track z-disks and sarcomeres in movies of beating cells, and perform automated spatiotemporal analysis and data visualization. Here we briefly note a few key features of our framework. First, we created an algorithm to segment z-disks and sarcomeres (Fig. 2a). Of note, our algorithm does not require any input parameter tuning, and is able to reliably capture non-linear sarcomeres in the presence of noise. Then, we track z-disks and sarcomeres independently using the Python package trackpy which is based on the Crocker–Grier algorithm [4]. Finally, we use Gaussian process regression to interpolate data between lost movie frames when necessary and feasible [5]. The segmentation and tracking process take only a few minutes to run on a laptop computer.

Next, we introduce two novel analysis approaches. First, we treat tracked and segmented components (i.e., sarcomeres and z-disks) as fiducial markers and use them to compute the approximate deformation gradient of the entire tracked population. This represents a new quantitative descriptor of hiPSC-CM function (Fig. 2b). Second, we construct spatial graphs where z-disks correspond to nodes and sarcomeres correspond to edges. This makes measuring the network distance between each sarcomere straightforward and makes it possible to compute statistics that include information about the network structure (Fig. 2c). In addition, we provide additional analysis tools that compute descriptive metrics previously proposed in the literature such as the Orientational Order Parameter [6]. We showcase and validate our

approach with both synthetic and experimental movies of beating hiPSC-CMs. The Sarc-Graph software can be freely accessed through GitHub: https://github.com/elejeune11/Sarc-Graph [7]. Example data and code to generate and analyze synthetic data with a known ground truth are also included on GitHub.

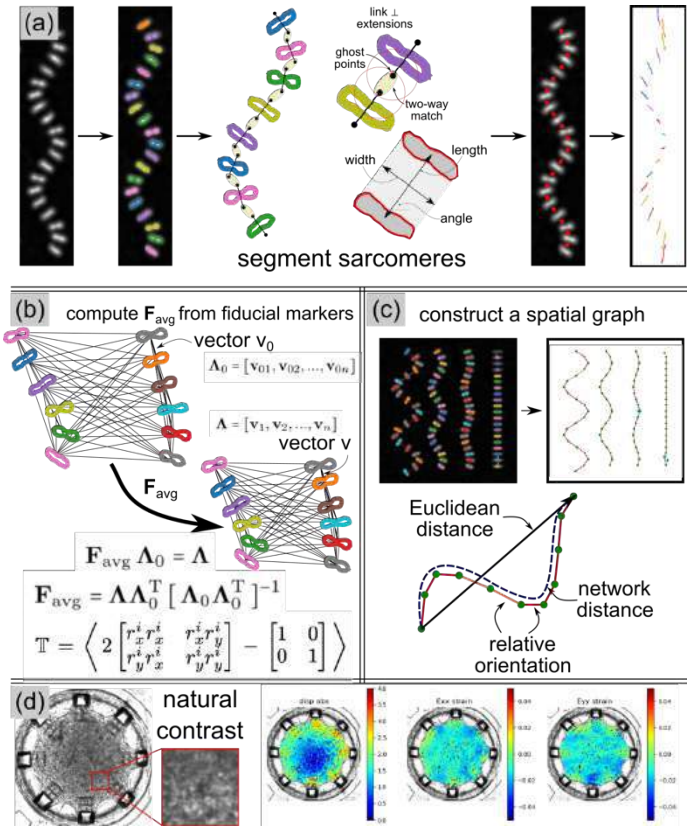

**Figure 2: Key aspects of our image analysis pipelines: (a) segmenting and tracking individual sarcomeres; (b) computing key quantities of interest such as average deformation and structure from images and movies; (c) constructing spatial graphs of myofibril structure; and (d) analyzing strain in movies of beating microtissue.**

Finally, we move up one spatial scale and create software to analyze cardiac microtissue. Specifically, we extend Sarc-Graph to analyze static 3D confocal images of hiPSC-CM based microtissue and we implement a digital image correlation approach to compute surface strains from movies of beating microtissue (Fig. 2d).

## RESULTS

Here we show one example of Sarc-Graph run on movies of beating hiPSC-CMs (Fig. 3, see also [7]). In this example, we are able to segment ≈800 sarcomeres per frame and successfully track 539 sarcomeres. The time series plot of normalized sarcomere length with respect to frame number show five distinct contraction events during the movie. Though the individual sarcomeres are clearly not perfectly in sync, there is enough of a unifying pattern for these peaks to emerge. These five distinct contraction events are also reflected in the average deformation plot. We also show the spatial graph representation of the example and a plot of normalized cross-correlation between pairs of individual sarcomere time series curves with respect to network distance. We note briefly that additional information, including movies, more experimental data examples, and validation examples on synthetic data, are available both on GitHub and in our manuscript [7].

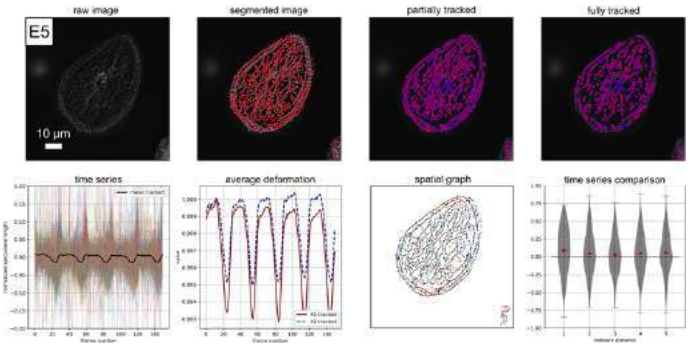

**Figure 3: Example set of results from running Sarc-Graph. For the corresponding movie, please see S5 Movie in [7].**

## DISCUSSION

These results clearly show the importance of developing computational tools and metrics to analyze this type of imaging data. From the raw data alone, it is not possible to either objectively discern collective sarcomere contraction in irregularly contracting hiPSC-CMs or quantify spatial and temporal patterns. With our software, we are able to both extract information about individual sarcomeres, and summarize mechanical behavior in a manner that is suitable for statistical comparison between groups.

The objective of this work was to provide an open source computational framework to quantitatively analyze images and movies of beating hiPSC-CMs on both the individual cell and microtissue spatial scales. With our framework, we are able to automatically segment and track a higher number of sarcomeres than other state of the art tools (see comparison in [7], appendix S4), and we introduce two important new approaches for the analysis of beating hiPSC-CM: a method for computing an average deformation gradient based metric, and a method for treating the hiPSC-CMs as spatial graphs. In addition, we have recently extended our Sarc-Graph software to 3D, where we can segment confocal z-stacks of regions of interest in cardiac microtissue (results forthcoming). Finally, we have created an open source digital image correlation pipeline for computing strain in movies of beating microtissue that relies solely on the natural contrast of bright field microtissue images (results forthcoming). Looking forward, we see this work as an important tool for substantial future study of hiPSC-CM behavior with applications ranging from drug discovery to tissue engineering. We encourage others to download and use our open source software for their own research purposes.

## INTRODUCTION

The global COVID19 pandemic has highlighted the lethality associated with the acute respiratory distress syndrome (ARDS) [1]. ARDS occurs when bacterial or viral infections cause excessive lung inflammation, disruption of the alveolar-capillary barrier and severe hypoxemia. ARDS patients often require mechanical ventilation (MV) and the mechanical forces generated during ventilation exacerbates lung injury and inflammation [2]. Since protective ventilation strategies are not able to eliminate the injurious mechanical stimuli, developing novel therapeutics that can prevent the mechanotransduction process responsible for ventilation induced lung injury (VILI) is a major area of research. Our group has used a novel combination of in-vitro organ-on-a-chip modeling, in-silico computational modeling and in-vivo animal and human studies to identify the biomechanical and molecular mechanisms responsible for VILI [3]. Specifically, we have identify mechanosensitive microRNAs and used nanotechnology gene delivery tools to demonstrated that over-expression of microRNA-146a (miR-146a) can be used to dramatically mitigate VILI.

## METHODS

As shown in Fig 1A, microfabrication technologies were used to develop a novel ventilator-on-a-chip (VOC) platform that incorporates co-cultures of primary human alveolar epithelial cells, endothelial cells and alveolar macrophages on an electrospun fibrous matrix. Specifically, primary cells obtained from human donors under IRB-2014H0367 or from commercial sources and/or human epithelial/endothelial/macrophage cell lines were seeded on electrospun matrices of collagen coated polyurethane. Platinum electrodes were used to monitor trans-epithelial electrical resistance (TEER) and fluorescent microscopy was used to quantify cell injury (plasma membrane rupture). In addition, ELISA was used to quantify pro-inflammatory cytokine levels in the apical and basal compartments. As shown in Fig 1B, cell were exposed to the major mechanical forces associated with MV, i.e. volutrauma (stretch), barotrauma (pressure) and atelectrauma (surface tension/shear). Standard lipofectamine transfection techniques were used to investigate how over-expression of miR-146a and miR-155 influenced the degree of barotrauma and atelectrauma respectively.

In-vivo animal studies utilized 7–9-week-old C57BL/6J wildtype and miR-146a knockout mice. Animals were subjected to an injurious ventilation protocol (12mL/kg tidal volume and 0 positive end expiratory pressure) for 4h [3,4]. The flexivent system was used to monitor changes in lung mechanics and bronchoalveolar lavage (BAL) fluid was analyzed for pro-inflammatory cytokine and total protein content. Cell pellets from the BAL as well as whole lung tissue were analyzed by PCR for miR-146a levels. Mice were pre-treated with a

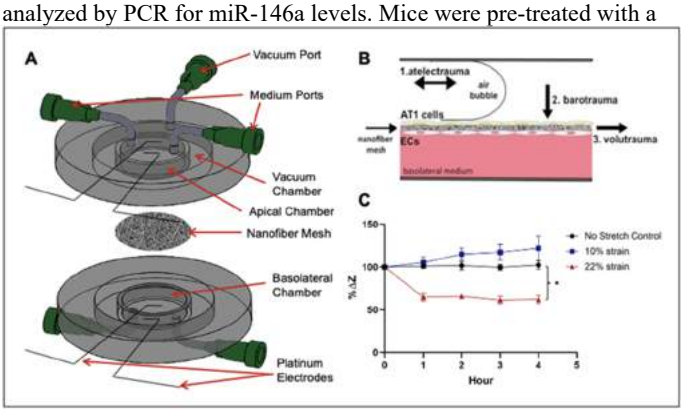

**Figure 1: A.** Schematic of ventilator-on-a-chip (VOC) **B**. Schematic of cell co-culture and application of injurious mechanical forces **C.** Effect of injurious strain (22%), physiologic strain (10%) and no stretch control (n=3/condition) on TEER measurements (data normalized to 0Hr. *p<0.05

solid lipid nanoparticle (LNP) containing a pre-miR-146a or scramble control construct 24h and 0h before ventilation. LNPs were prepared using an ethanol injection method [3].

Human studies were conducted by collecting bronchoalveolar lavage (BAL) fluid under an approved IRB protocol (IRB-2016H0009) from 15 control non-ventilated subjects, 11 ventilated subjects without ARDS and 10 ventilated subjects with ARDS. RNA was isolated from the cell pellet and PCR was used to quantify the expression of several microRNAs.

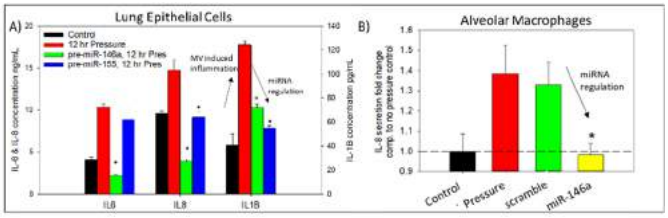

**Figure 2:** A) Over-expressing miR-146a (green) and miR-155 (blue) reduces pressure-induced IL-6, IL-8 and IL-1β cytokine secretion in primary human airway epithelial cells (EpC). *p<0.05 with respect to 12 hr pressure. B) Over-expressing miR-146a downregulates pressure-induced IL-8 secretion from AMs. *p<0.05 with respect to pressure control and scramble.

## RESULTS

As shown in Fig 1C, cyclic strain magnitude had a significant effect on barrier formation and disruption where low levels of physiologic strains (10%) promoted increased barrier resistance while large pathological strains (22%) promoted disruption of the barrier and reduced resistance. As shown in Figure 2, barotrauma experiments indicate that 12h of high transmural pressure results in increased pro-inflammatory cytokine secretion (IL-6, IL-8 and IL-1β) in both alveolar epithelial cells (Fig 2A) and alveolar macrophages (Fig 2B) and that over-expression of miR-146a in both epithelial cells and macrophages significantly reduces the inflammatory signaling caused by barotrauma. Atelectrauma experiments indicate that co-culture of AMs with EpCs exacerbates the cell injury/plasma membrane disruption caused during airway reopening (data not shown). Interestingly, overexpression of miR-155 in epithelial cells alters cytoskeletal structure and reduces atelectrauma but over-expression of miR-155 in macrophages exacerbates mechanically-induced inflammation and injury (data not shown).

Animal studies indicated that miR-146a knockout mice exhibit more inflammation (i.e. increased pro-inflammatory cytokine secretion, Figure 3AB) and lung injury (i.e. barrier disruption as measured by increased protein in the BAL, Figure 3C) during MV. Interestingly, wild-type mice exhibited a modest increase in miR-146a levels but still suffer from VILI as measured by increase pro-inflammatory cytokine secretion and barrier disruption (data not shown). Importantly, the use of a non-targeted LNP to delivery miR-146a resulted in a dramatic 100-1000x over-expression of miR-146a in both epithelial cells and macrophages (Figure 3D) and this resulted in a significant reduction in inflammation and injury during MV (Figure 3EF).

Finally, we investigated the expression of several miRs (miR-27b, miR-21, miR-33a, miR-144, miR-155 and miR-146a) in human patients and found that miR-146a and miR-155 levels were significantly higher in patients undergoing MV alone while the level of these miRs were not upregulated in patients suffering from ARDS. This data suggests that miR-146a/155 are mechanosensitive miRs in human subjects and that the failure to upregulate these anti-inflammatory miRs may play a role in the development of ARDS.

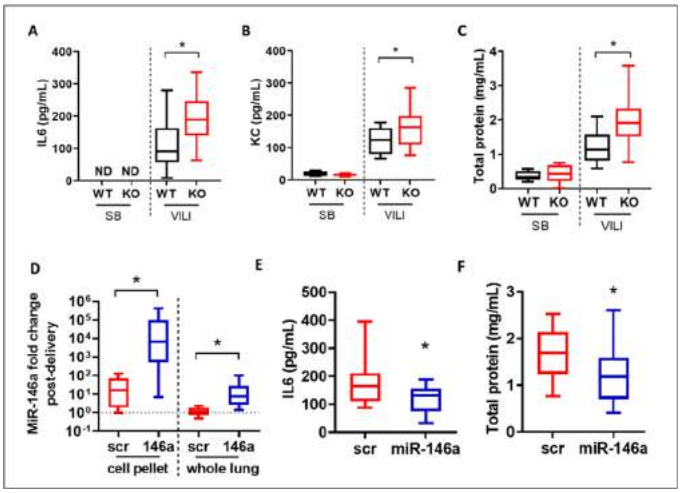

**Figure 3: Knock-out mice lacking miR-146a exhibit** AB) increased IL-6 and KC (IL-8 analogue) expression and C) increased barrier disruption as measured by BAL protein. Nanoparticle delivery of miR-146a resulted in A) dramatic over-expressing in cell pellet and whole long and E) reduced pro-inflammatory cytokine expression and F) reduced barrier disruption *p<0.05 with respect to wild-type and scramble controls.

## DISCUSSION

We have identified as set of mechanosensitive microRNAs (miR-146a and miR-155) in human subjects and have demonstrated using in-vitro and in-vivo animal models. Importantly, changes in miR expression during mechanical stress appears to be an insufficient compensatory response that doesn't mitigate VILI on its own. However, therapeutic over-expression of miR-146a to supra-physiological levels resulted in a significant reduction in lung injury and inflammation during MV. Therefore, nanoparticle mediated over-expression of miR-146a may represent a novel therapeutic way to reduce VILI during ARDS.

# EFFECTS OF MICROPIPETTE HANDLE DIAMETER AND INCLUSION OF FINGER REST ON BASILAR THUMB JOINT CONTACT MECHANICS

## INTRODUCTION

The use of manual micropipettes has been associated with a high prevalence of upper extremity and work-related musculoskeletal disorders in laboratory workers [1]. This may be due to a combination of repetitive motions during pipetting and the amplification of forces from the thumb tip to the basilar thumb joint [2] that lead to tendonitis, carpal tunnel syndrome, other musculoskeletal injuries, and may increase risk of osteoarthritis (OA). These pathologies cause substantial physical pain/discomfort, increase health care costs, and cause employees to miss time at work. An investigation into ergonomic micropipette design could help to reduce these musculoskeletal pathologies and their consequent negative impacts.

One method to investigate micropipette design parameter effects on stresses within joints is magnetic resonance imaging (MRI) based modeling. This offers a non-invasive *in vivo* approach to estimate joint forces, contact pressures, contact area and contact location(s), and tissue stresses in joints during functional activities. MRI-based modeling allows for good soft tissue visualization and subject-specific geometries. It also minimizes assumptions for model boundary and loading conditions. This is accomplished through the collection of higher resolution unloaded scans (i.e. with a relaxed hand) for finite element model building. Then lower resolution loaded scans (i.e. during simulated pipetting) are used with image registration to obtain displacement boundary conditions for the finite element analysis [5-6].

A modular MRI-compatible micropipette simulator enabled analyses of the effects of base design parameters on contact measures within joints of the hand through MRI-based modeling. In this pilot study, the effects of handle diameter and the inclusion or exclusion of a finger rest on contact measures within the basilar thumb joint were examined. We hypothesized that increasing handle diameter would decrease contact measures in the basilar thumb joint. We also hypothesized that the inclusion of a finger rest would decrease contact measures in the basilar thumb joint.

## METHODS

***Micropipette Simulator and Handle Designs –*** The micropipette simulator was divided into multiple parts: a button to be pushed by the thumb, a carbon fiber plunger/rod to transfer force through a handle, an O-ring on the far end of the rod to prevent the rod and button from falling out of the handle, a two-piece spherical base, and a pneumatic rubber bulb inside the base. Each handle set (with button and push-rod) can be screwed onto the spherical base (with rubber bulb). The rubber bulb was attached via plastic connectors and tubing to a pneumatic pressure system with pressure regulator to assure consistent pre-pressure (before the pipette plunger is pushed) and a precision pressure transducer to assure consistent plunger force. This system was designed for minimal friction and a had a pressure precision of 0.001 psi. A custom LabVIEW code provided visual feedback to the subjects and allowed them to attain and hold the pressure near a specified target during the MRI scan.

**Figure 1. From left to right: 40 mm handles with and without a finger rest, 25 mm handles with and without a finger rest, and 12 mm handles with and without a finger rest. Each handle also has the plastic button, carbon fiber rod, and O-ring (not visible)**

A combination of three handle diameters (12 mm, 25 mm, and 40 mm) and the inclusion or exclusion of a finger rest resulted in six handles that were tested per subject (Figure 1). All the handles had a length of 127 mm.

***Subject Information and Imaging Protocol*** – Three male subjects (average age = 30 years, range = 28-33 years) and two female subjects (average age = 27.5 years, range = 27-28 years) were recruited for the study. MR image sets for each subject were acquired for two types of conditions. One image set was collected while the hand was in a relaxed state where the wrist and thumb ray were imaged at a high resolution (in-plane voxels 0.22 mm by 0.20 mm and out-of-plane thickness 0.5 mm) over a duration of 4.5 minutes. This image set was used to create finite element model geometries. The second group of image sets was collected while a subject was using the micropipette simulator (loaded state). The loaded state images were collected at a reduced resolution (in-plane voxel 0.31 mm by 0.31 mm and out-of-plane thickness 1.0 mm) over a duration of 188 seconds. These images were used to create kinematic transformations that placed the trapezium into the loaded position for the finite element models. A total of six loaded state image sets were collected per subject (one for each micropipette handle variation). A simulator target pressure of 1.125 psi was used for consistent micropipette plunger depression force during image collection. Handles without a finger rest were tested first due to concerns about subject fatigue limiting the number of possible tests. The image set of the relaxed state was collected next. Finally, the handles with a finger rest were tested. Within each type of handle, they were tests from smallest diameter to largest diameter. Subjects wore an MRI-compatible wrist brace with 20º wrist extension during testing to assure consistent hand/wrist position (and thus more consistent data overall) between subjects.

***Finite Element Model Definition and Statistical Analysis*** – MR images for both the relaxed and loaded states were segmented using ScanIP 7.1. The metacarpal and trapezium were isolated in the loaded state images. The metacarpal, trapezium, and their respective cartilages were isolated in the relaxed state images. ScanIP was also used to generate tetrahedra meshes of the bone and cartilage geometries from the relaxed state scan. Kinematic transformations for the trapezium were defined using image registration between loaded and unloaded scans [5-6]. Once the trapezium was in the loaded position, contact was eliminated for the start of the simulation, through an initial separation displacement. Displacements were then applied to the trapezium during the simulation to restore the trapezium to the loaded position. The cartilage was assumed to be a Neo-Hookean material with an effective relaxation modulus of 1 MPa and a Poisson's ratio of 0.2 (due to the length of the scans) with frictionless contact. Bone was assumed to be a rigid body. Contact area, contact force, and contact pressure were primary simulation outputs. Two-way repeated measures analysis of variance (ANOVA) and one-way repeated measures ANOVA were used to test for statistical differences in contact measures. Statistical significance was set at $p < 0.05$.

## RESULTS

Images from one female subject had poor image quality could not be processed. For the remaining subjects, contact force decreased with increasing handle diameter, and it increased with the presence of a finger rest (Figure 2). Contact area and peak contact pressures followed the same pattern for changes in handle diameter and finger rest.

Two-way repeated measures ANOVA results indicated that there were no significant interactions between the diameter and finger rest factors for contact area ($p = 0.9$), contact force ($p = 0.9$), or peak contact pressure ($p = 0.8$). There were significant differences between the levels of diameter for contact area ($p = 0.01$), contact force ($p = 0.01$), and peak contact pressure ($p = 0.004$). There were also significant differences between levels of finger rest for contact area ($p = 0.007$) and contact force ($p = 0.02$). One-way repeated measures ANOVA results indicated that significant differences only between the 12 mm handle diameter and 40 mm handle diameter for contact area ($p = 0.002$), contact force ($p = 0.007$), and peak contact pressure ($p = 0.03$). Contact pressure location was consistent within subjects.

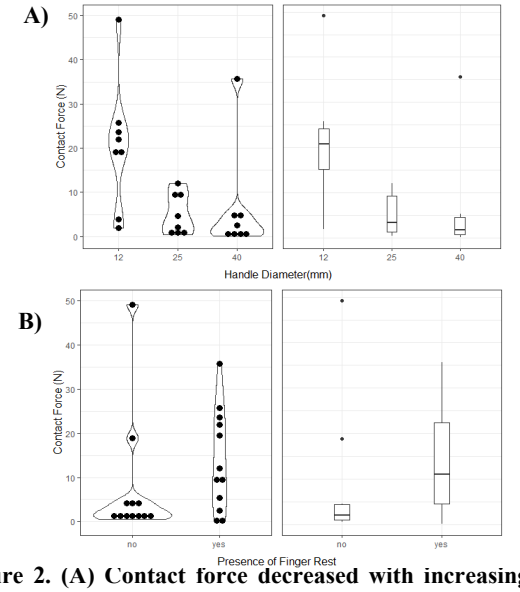

**Figure 2. (A) Contact force decreased with increasing handle diameter. (B) Contact force increased with the presence of a finger rest.**

## DISCUSSION

Decreasing contact measures with increasing handle diameter confirmed our first hypothesis. However, increased contact measures with the presence of a finger rest did not confirm our second hypothesis. This result likely resulted from the order of testing. All handles with a finger rest were tested after handles without a finger rest, so fatigue (which can increase co-contractions and overall force) may have contributed to increased contact measures. We expected that the finger rest would provide additional stabilization which would reduce the necessary grip strength and muscle tension. The chosen order put (assumed) easier handles later in the sequence, to help subjects complete tests with every handle. Future studies should randomize the order of micropipette handles and increase rest breaks between tests to reduce the effects of fatigue.

# EFFECT OF VENOUS VALVE MORPHOLOGY ON FLOW CONDITIONS CONDUCIVE TO THROMBOSIS

**Jacob T. Biesinger (1), Matthew S. Ballard (1)**

(1) Mechanical Engineering, Utah Valley University, Orem, Utah, USA

## INTRODUCTION

Venous valves serve a vital role in the proper return of blood from the lower extremities. These valves open and close with pressure oscillations to enable blood to return to the heart against the pull of gravity. Thrombi are known to form in the regions near the venous valves, referred to as deep vein thrombosis (DVT). Once DVT develops, the thrombi may release from the vein wall and travel toward the lungs to become a pulmonary embolism (PE). PE is a major cause of death in the U.S. responsible for approximately 200,000 deaths annually, a figure that likely underestimates the effect of PE since it can be difficult to detect and thus often goes unnoticed [1]. DVT and PE are especially concerning for individuals who are immobile for an extended period of time, such as during a hospital stay, or long plane ride.

This study is an investigation of the effect of valve morphology on disease-conducive flow conditions. Specifically, mechanical properties of the valve, as well as the three-dimensional shape are varied to identify the effect on shear stress, residence time and fluid stasis. Results of this study will help to establish an understanding of how doctors can better identify at-risk patients for whom to take preventative measures against DVT and PE.

## METHODS

A model of the venous valve region is made by creating a rigid sinusoidal vessel which is then intersected by two planar membranes. The portion of the planes internal to the vessel forms the elastic valve, and the valve tips are trimmed to a crescent shape, as shown in Figure 1. The intersecting lines of the vessel and valve are fixed, simulating connection of the valve to the vessel wall. The vessel is filled with a viscous fluid, which is driven by a dynamically-oscillating pressure gradient.

To effectively model the dynamics of the valve and fluid, a fully-coupled, three-dimensional fluid-solid-interaction model is used. Fluid mechanics are solved using a lattice Boltzmann method (LBM), an effective method for simulation of incompressible viscous flows interacting with complex and moving boundaries [2]. Solid mechanics are modeled using a lattice spring method (LSM), modeling the solid valve leaflets as a network of mass points connected by harmonic springs [3]. The LBM and LSM models are fully-coupled via appropriate boundary conditions [4,5].

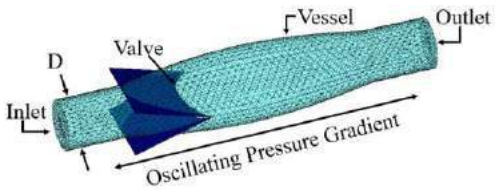

**Figure 1: Venous valve model with vessel and intersecting valve.**

Geometric parameters varied for this study are the valve length and the depth of the crescent at the valve tip. The stiffness of the valve is also varied using a dimensionless stiffness, K [5]:

$$K = \frac{4\,k_b}{\pi\,D^3 \Delta P} \tag{1}$$

## RESULTS

Flow in the vicinity of the valve can be seen in the normalized velocity magnitude plots given in Figure 2. Flow is driven past the valve by an oscillating pressure gradient. A favorable pressure gradient causes the valve to open and fluid to flow in the forward direction (left to right in Figure 2A). As the pressure gradient reverses, the valve closes (Figure 2B) and once fully-closed (Figure 2C) blocks any significant reverse flow from occurring. As seen in Figure 2D, this results in an overall flow rate waveform giving a significant amount of

forward flow followed by a short duration of negative flow when the pressure gradient is reversed but the valve has not yet closed, and finally very little flow once the valve has closed. Thus, a net positive flow effect is obtained.

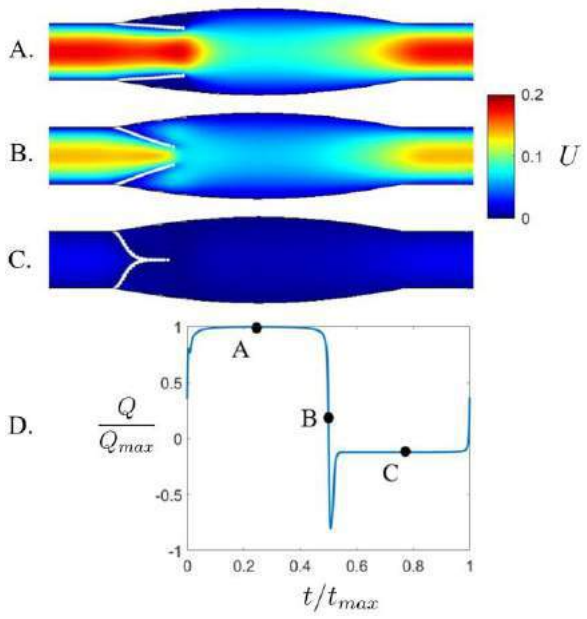

**Figure 2: Velocity profile of: A) fully open valve, B) closing valve, C) closed valve. D) flow rate versus time.**

Since shear stress is an important factor in thrombus formation, the fluid shear stress magnitude (normalized by the maximum shear stress in Poiseuille flow through a tube with diameter D) in the region of interest is plotted in Figure 3 for the same time snapshots as given in Figure 2.

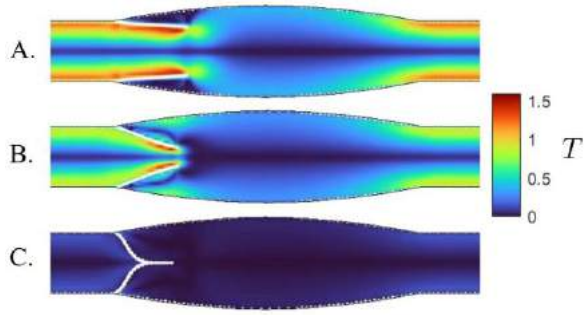

**Figure 3: Shear stress profile of: A) fully open valve, B) closing valve, C) closed valve.**

In this system, thrombi are likely to form in areas of low and oscillatory shear stress, high residence time, fluid stasis [6,7]. Figure 2 shows that the fluid behind the valve experiences low velocity, and presumably high residence time. Additionally, Figure 3 shows that the region behind the valve also experiences low shear stress, making this an area of concern.

While detailed quantification of shear stress, residence time and fluid stasis cannot be addressed in this abstract and will be addressed in the presentation, here we briefly show the effect of valve stiffness on the fluid shear stress distribution in the vicinity of the valve. Each column of Figure 4 represents simulation data with a different value of *K*, and gives the distribution of the fluid domain in the shear range given at left. Increasing valve stiffness gives a general decrease in shear stress. This increases the amount of the system that is at risk of thrombus formation due to low shear stress. This shift occurs due to the decrease in valve deflection allowing less flow, leading to reduced velocity and shear stress. Additionally, the region behind the valve is bigger for low deflection, as the valve cannot deflect as close to the vessel wall.

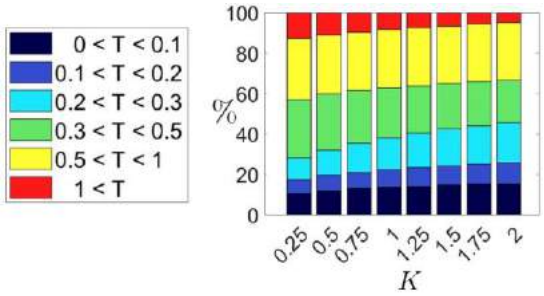

**Figure 4: Shear stress distribution with varying stiffness.**

## DISCUSSION

A fully-coupled FSI model was used to study the effect of venous valve morphology on resulting flow conditions. Low fluid velocity and low shear stress behind the valve indicate that it is an area likely to give conditions conducive to thrombosis. Further, valve stiffening reduces shear stress, also making thrombosis more likely. In the full version of this study, we investigate in more detail the effect of valve morphology on shear stress, as well as on residence time and fluid stasis. This study informs a deeper understanding of the effect of valve morphology on flow conditions conducive to thrombosis, and can help pave the way to improved risk analysis to inform measures for prevention of DVT and PE, especially in admitted hospital patients.

# WALL SHEAR STRESS TOPOLOGICAL SKELETON VARIABILITY PREDICTS ATHEROSCLEROTIC PLAQUE GROWTH IN HUMAN CORONARY ARTERIES

**Giuseppe De Nisco (1), Eline Hartman (2), Valentina Mazzi (1), Diego Gallo (1), Claudio Chiastra (1), Joost Daemen (2), Jolanda Wentzel (2), Umberto Morbiducci (1)**

## INTRODUCTION

Although low wall shear stress (WSS) has become the consensus hemodynamic mechanism for coronary atherosclerosis, the exact biomechanical stimulus affecting atherosclerosis evolution is still undetermined [1]. In this regard, recently there is a marked in the topological skeleton analysis applied to the WSS vector field [2,3]. The WSS topological skeleton consists of fixed points, where the WSS vector vanishes, and manifolds, namely the regions connecting them, where the WSS vector field contracts or expands. The interest in such an analysis is dictated by its ability to (1) identify flow features usually classified as "disturbed flow", linked to atherosclerosis onset and development, and (2) quantify the contraction/expansion action exerted by the WSS on the endothelium. Very recent findings have demonstrated a link between the WSS topological skeleton features and adverse vascular response [4-7], showing its capability to concur to the identification of the complex biomechanical stimulus affecting atherosclerosis evolution [6,7].

Based on these pieces of evidences this study tests the ability of WSS topological skeleton features to predict the temporal evolution of coronary artery plaque burden (PB), a hallmark of atherosclerosis development, in 49 patient-specific computational models of human coronary arteries. The final aim is to probe whether hemodynamic quantities giving a direct measure of the variability of the contraction/expansion action exerted by the blood flow on endothelial cells are capable to predict longitudinal local PB changes.

## METHODS

**Patient population.** An overview of the methods is provided in Figure 1. Forty-eight hemodynamically stable patients from the IMPACT study data set [8] were used in the analysis. The IMPACT study enrolled patients with acute coronary syndrome and with at least one non-stented non-culprit coronary segment accessible for intracoronary imaging. The presence of previous coronary artery bypass graft surgery, 3-vessel disease, renal insufficiency (creatinine clearing < 50 ml/min), left ventricular ejection fraction < 30%, and atrial fibrillation, were considered as exclusion criteria. All patients underwent percutaneous coronary intervention of the culprit coronary vessel. After successful treatment, a non-culprit coronary segment (right - RCA, left anterior descending - LAD, or left circumflex - LCX coronary artery) was imaged by coronary computed tomography (CCTA) angiography and intravascular ultrasound (IVUS) at the time of the intervention (T1) and at 1 year follow-up (T2).

**Computational hemodynamics.** The lumen geometry of 49 imaged coronary arteries (18 RCA, 18 LAD, and 13 LCX,) was reconstructed at T1 [8]. IVUS images were segmented into lumen contours and stacked upon the 3D CCTA centerline. Luminal regions proximal and distal to the IVUS segment were added using lumen segmentations from the CCTA images. Transient computational fluid dynamics simulations were performed by using the finite volume method (Fluent, Ansys Inc.). Blood was modelled as non-Newtonian Carreau fluid. Patient-specific inflow and outflow boundary conditions were derived from ComboWire Doppler flow velocity measurements. If velocity-based flow measurements were inaccurate or not available, a generalized flow rate [9] was prescribed as inflow BC, while a proper diameter-based scaling law [9] was applied to estimate the flow ratio at the outflow sections.

**Wall shear stress-based descriptors.** The most widely adopted descriptors of WSS magnitude, multidirectionality and topological skeleton features were tested. In detail, three canonical WSS-based descriptors of "disturbed flow", i.e., TAWSS, OSI, and RRT, were computed. Additionally, the transverse WSS (transWSS), representing the average WSS component acting orthogonal to the time-average

WSS vector direction, was considered [10]. Moreover, the contraction/expansion action exerted by hemodynamic shear forces on the endothelium was quantified according to a Eulerian-based method for the analysis of the WSS topological skeleton based on the divergence of the WSS unit vector field ($DIV_{WSS}$) [2]. Negative (positive) $DIV_{WSS}$ values at the luminal surface identify WSS contraction (expansion) regions. Here the quantity Topological Shear Variation Index (TSVI) was used as a measure of the variability of the local contraction/expansion action exerted by the WSS along the cardiac cycle. Technically, the TSVI is defined as [4,5]:

$$TSVI = i\left\{\frac{1}{T}\int_0^T [DIV_{WSS} - \overline{DIV_{WSS}}]^2 dt\right\}^{1/2} \quad (1)$$

where T is the cardiac cycle duration.

**Statistical analysis.** The analysis was focused at the IVUS imaged arterial segments. Each IVUS segment was divided into 3mm/45° sectors [8]. In all IVUS frames at T1 and T2, lumen and external elastic membrane contours were semi-automatically segmented, and PB was assessed as the ratio between plaque area and total vessel area, multiplied by 100. The mean values of the difference between PB measurements at T2 and T1 was evaluated for each sector and used for the analysis (PB growth). Hemodynamic descriptors were averaged over each 3mm/45° sector and divided into artery-specific low, mid and high tertiles to perform a statistical difference analysis on the associated PB growth measurements. Significance was assumed for $p < 0.05$.

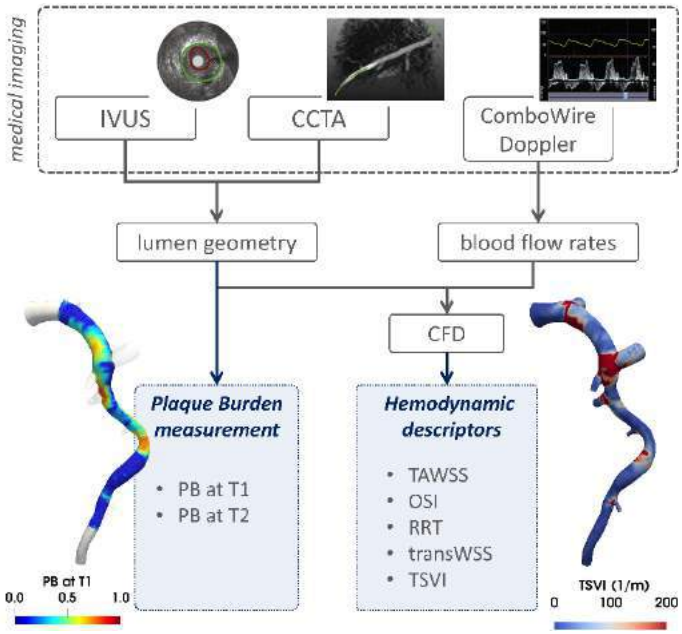

**Figure 1: Overview of study methods.**

## RESULTS

Figure 2 reports the (mean ± sem) PB growth values associated to low, mid, or high values of each hemodynamic descriptor. It clearly emerged that sector exposed to high TSVI values at T1 exhibited significantly higher PB growth in the T2-T1 time interval, compared to the exposure to low or mid TSVI at T1. As expected, a significant association emerged also for the exposure to low TAWSS at T1 and PB growth. Finally, an association between PB growth in the T2-T1 time interval and WSS multidirectionality at T1, quantified in terms of OSI and transWSS, emerged. However, the scarce multidirectional action of the WSS in the investigated coronary arteries (with OSI <0.01 and transWSS <0.15 Pa), suggests a secondary role for WSS multidirectionality in promoting aggravating biological events.

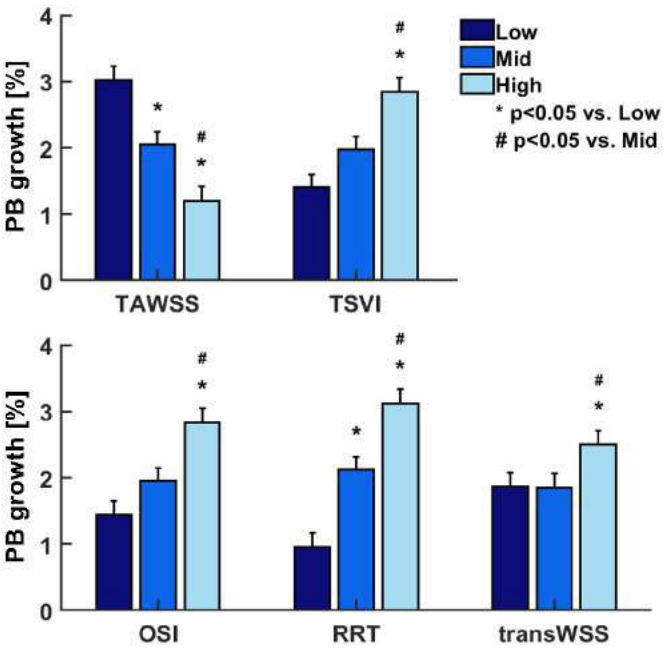

**Figure 2: Hemodynamic descriptors vs. estimated PB growth.**

## DISCUSSION

This study tested the capability of CFD-derived WSS topological skeleton features and canonical WSS-based descriptors of disturbed flow to predict local plaque burden temporal changes in human coronary arteries. The main results can be summarized as follows: (1) as confirmation, luminal sectors characterized by low TAWSS values at T1 exhibited significant plaque growth; (2) luminal exposure to high variability in the WSS contraction/expansion action was associated with significant PB growth. Physically, TSVI describes the variability of the contraction/expansion action exerted by WSS on the endothelium. Thus, it describes different features of the WSS vector field with respect to TAWSS and it represents a different hemodynamic stimulus to the endothelium. Translating this into mechanistic implications, the variability in the contraction/expansion action exerted by shear forces on endothelial cells reflects on intra- and inter-cellular tension variability that could lead to aggravating biological events. Recent results on a large dataset of 188 atherosclerotic coronary arteries confirm the effectiveness of TSVI as biomechanical biomarker able to identify intermediate coronary lesion site of subsequent myocardial infarction at 5-year follow-up [7].

In conclusion, high TSVI is a strong predictor of PB growth in the analyzed population, encouraging further clinical trials to enforce the presented results and translate this concept into clinical practice.

# PRELIMINARY MODELING AND EXPERIMENTAL STUDY OF THROMBOEMBOLISM: EFFECTS OF SHEAR STRESS ON THROMBUS BEHAVIOR

**Arash Azimi (1), Eathan S. DiTullio (1), Keefe B. Manning (1,2)**

(1) Department of Biomedical Engineering, The Pennsylvania State University, University Park, PA, USA
(2) Department of Surgery, Penn State Hershey Medical Center, Hershey, PA, USA

## INTRODUCTION

While thrombosis and thromboembolism in cardiovascular devices have been observed clinically, few studies related to thrombosis deformation and embolization are available. Thromboembolism can result in partial or full occlusion in blood vessels and implanted cardiovascular devices, which can be involved in life-threatening complications. Thus, to evaluate the stability of the thrombus and its behavior under different flow conditions, it is important to predict thromboembolism [1-4].

Coupled reactions among blood clot, flow regime, and surface increase the complexity of numerical modeling and require significant computational power. The shear stress can impact the thrombus and may result in partial or full embolization. Therefore, it is critical to understand the interplay between the thrombus and flow regimes. While the clot formation time is on the order of minutes, when embolization starts, it may occur on a time scale of seconds. Thus, any computational model must include this complex aspect. Furthermore, to assess the credibility of numerical simulations, *in vitro* experiments must be performed.

Taylor *et al.* [5, 6] introduced a continuum model to predict platelet adhesion and cardiovascular device-induced thrombosis. Fogelson and Guy [7] presented a continuum macroscale model of platelet aggregation and studied individual platelets and their interactions with fluid flow. This approach is used to model the thrombosis mechanics here using computational fluid dynamics (CFD). The principal objectives are to perform 3D numerical simulations and provide insight on thrombus behavior, deformation, and embolization under different flow conditions. Moreover, verification and calibration of the computational model are conducted by comparing to *in vitro* experimental data.

## METHODS

The governing equations to model thromboembolism include the equations of motion for fluid flow and cohesive stress equations to characterize the thrombosis viscoelasticity. To predict the turbulent motions, momentum equations for the fluid are modeled via large-eddy simulations (LES), which solves the spatially filtered Navier-Stokes (N–S) equations. Equations 1 and 2 represent the incompressible Newtonian flow governed by the continuum and N–S equations, respectively:

$$\nabla \cdot u = 0 \tag{1}$$

$$u_t + u \cdot \nabla u = -\frac{1}{\rho}\nabla P + \nu \nabla^2 u + \frac{1}{\rho}\nabla \sigma \tag{2}$$

where $u$ is flow velocity, $\rho$ is density, $t$ is time, $P$ is pressure, $\nu$ is kinematic viscosity, and $\sigma$ is cohesive stress tensor.

The thrombosis and thromboembolism mechanics are modeled in a way similar to [7]. This model incorporates two sets of evolution equations for the cohesive stress tensor $\sigma$ (Equation 3) and the cohesive link density $z_c$ (Equation 4).

$$\sigma_t + u \cdot \nabla \sigma = \sigma \nabla u + (\sigma \nabla u)^T + \alpha_2 \phi_a^2 I - \beta[Tr(\sigma)/(z_c)]\sigma \tag{3}$$

$$\frac{\partial z_c}{\partial t} + u \cdot \nabla z_c = \alpha_0 \phi_a^2 - \beta(Tr(\sigma)/(z_c))z_c \tag{4}$$

where $\alpha_0$ and $\alpha_2$ are constant growth rate coefficients, $\phi_a$ is activated platelets, $\beta$ is breakage rate, and $I$ is an intensity factor. To halt fluid flow in areas with thrombus, the divergence of the cohesive stress tensor is added as a body force. Figure 1a shows the computational domain and boundary conditions using OpenFOAM.

*In vitro* experimental validation is performed by using a tube geometry as depicted in Figure 1b. This geometry is designed to validate different aspects of the numerical simulations. The experimental flow loop is filled initially with phosphate buffered saline (PBS) solution with viscosity of 1 cP. The PBS is circulated using a peristaltic pump (Cole-Parmer, Vernon Hills, IL, USA) in the range of $1500 < Re <$

20000. The dimensions of the tube are 100 mm with inner diameter of 12.7 mm and made of clear polycarbonate (PC). Fresh whole bovine blood, collected through an approved IACUC protocol, is used to form a clot by adding 6.45% b/w calcium chloride ($CaCl_2$). We used this recalcified blood to inject into the tube and allowed it to form a clot for 1 hour, then slowly filled the loop with PBS. In both numerical simulations and experiments, a constant pressure boundary condition is set on the outlet of the tube, while a constant inlet velocity is set for the inlet boundary. After the loop is filled with PBS, the pump is set to a constant speed, and the embolization captured using high speed videography.

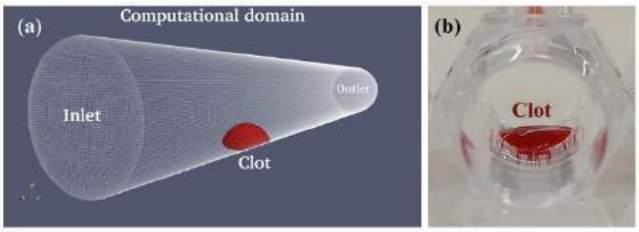

**Figure 1: The circular tube and blood clot: (a) the computational domain and (b) a clot formed in the tube.**

## RESULTS

For both numerical simulations and experiments, the results are presented for the mechanical interaction of pre-existing thrombus and fluid flow at different Reynolds number. Figure 2 shows the results for a 100 µL blood clot. The clot starts to separate from the surface due to the high inertial force induced by the fluid flow, resulting in embolization. The velocity and pressure contours along with the streamlines are presented for better graphical understanding of embolization.

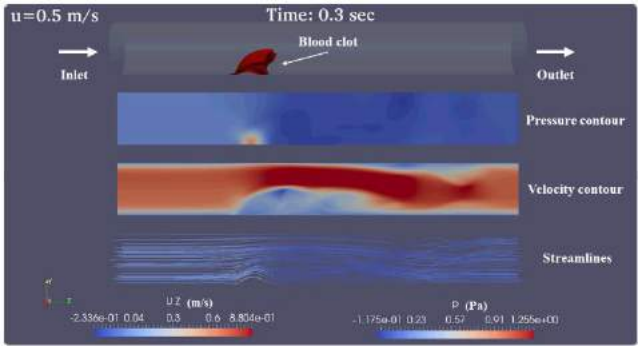

**Figure 2: The numerical results in terms of streamlines and contours for a pre-existing clot in a circular tube.**

Figure 3 shows the *in vitro* experimental validation of thromboembolism. The results show good agreement between simulations and experiments. Due to the high Reynolds number, the leading edge of the clot separates from its anchor point (Figure 3a-c) and then from the surface (Figure 3d). The same phenomenon can be observed experimentally.

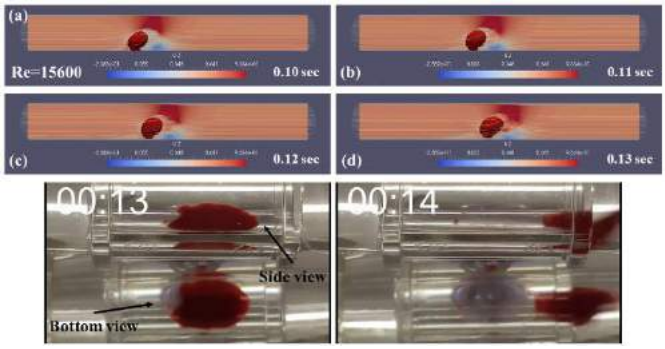

**Figure 3: The comparison of numerical simulations with experimental data at a Reynolds number (*Re*) of 15600.**

For the flow at Re=2000, the upstream flow kinetic energy dissipated during the impact with the leading edge of blood clot. This impact can cause a small separation of clot from the surface. Once this separation between the clot and surface is initiated, the wall shear stress amplifies the separation and results in full embolization. When the clot fully embolized, the downstream flow becomes chaotic due to perturbations induced by the clot. Therefore, our model is designed to capture this chaotic motion.

## DISCUSSION

In this study, a computational model has been improved to consider thromboembolism under different flow conditions. These numerical simulations provide a foundation to predict the embolization risk and physical behavior of the thrombus under different Reynolds numbers. The dynamic process of embolization is extremely brief ($< 0.3$ s), and thus, the numerical model can be used to understand the complexity of turbulent flow and physical behavior of thrombus, deformation, and embolization. Parameters for the numerical simulations such as fluid viscosity, density, Reynolds number, and clot volume can be provided with controlled experiments. The impact of shear stress is extremely important in turbulence regimes, which are considered in our CFD model. In addition, our simulation results can predict the chaotic motions and complex interplay between turbulent flow and physical behavior and characteristics of blood clots. Our simulations showed good agreement of clot embolization compared to experiments.

# THUMB METACARPAL KINEMATICS: A VOLUMETRIC PERSPECTIVE

**Adam J. Chrzan (1), Nicole D. Arnold (1), Kevin Chan, M.D. (2), Tamara Reid Bush, PhD (1)**

(1) Mechanical Engineering, Michigan State University, East Lansing, MI, USA
(2) Orthopedic Hand and Upper Extremity Surgery, Spectrum Health, Grand Rapids, MI, USA

## INTRODUCTION

Radiographic osteoarthritis (OA) of the hand is a condition characterized by radiographically visible damage to a joint's articular cartilage and underlying bone. Among Americans ages 50-54, more than 27% show signs of OA. The prevalence steadily increases with age to a rate of more than 84% when 70-74 years old [1].

OA in the thumb carpometacarpal (CMC) joint, located at the interface of the thumb metacarpal and trapezium, is of particular concern (Fig. 1). The thumb CMC joint is the most likely joint in the hand to develop OA (~32%) and the most likely to cause symptoms, such as decreased pinch strength, joint stiffness, and pain, which render daily tasks difficult (i.e. open jars, writing, etc.) and hinder the ability to live independently [1, 2].

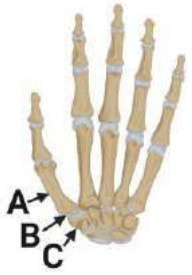

**Figure 1: A) Thumb metacarpal, B) CMC Joint, and C) Trapezium.**

Standard assessments of thumb kinematics include qualitative and goniometric measures, which are limited due to their subjective nature and single plane measurements, respectively. Some work has been conducted to characterize 3D kinematics of the healthy thumb, but these studies are bounded by small sample sizes, small age ranges, and by describing the thumb as a whole [4]. Thus, there is a need for research with a more detailed kinematic analysis of each bone in the healthy thumb, particularly the metacarpal where CMC OA surgeries occur.

A thorough understanding of healthy thumb kinematics will inform treatment options for OA patients and may lead to new treatment approaches. In severe cases of thumb CMC OA, loss of function and constant pain require surgical intervention [2]. Current standard-of-care treatments involve partial or complete removal of the damaged cartilage and bone in the CMC joint. While this and other available surgical procedures have been shown to reduce pain and increase thumb mobility, there is little evidence identifying which procedure, if any, yields superior postoperative thumb kinematics [3]. The goal of this work is to provide a more detailed 3D characterization of healthy thumb metacarpal kinematics as a point of comparison to better understand and improve the kinematic outcomes of thumb CMC OA surgeries.

## METHODS

Recruited participants had no history of significant hand injury, hand surgery, or diagnosis of arthritis, were right-hand dominant, and not pregnant. This work was approved by the university (IRB #00006111), and all participants gave written consent.

The 52 participants were segmented into the following groups, each containing 13 participants: young males (avg. age = 28.8 ± 5.6), young females (avg. age = 25.8 ± 5.1), older males (avg. age = 60.2 ± 11.4), older females (avg. age = 58.0 ± 9.3). 'Young' groups had individuals ages 18-39, and 'Older' groups ages ≥40. The lengths of

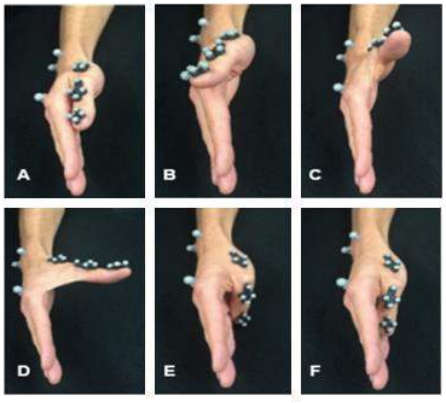

**Figure 2: Movement steps used to gather the metacarpal volume. A) starting position, B) adduction towards dorsal palm, C) maximum 'thumbs-up', D) largest arc to oppose to the pad of the fifth digit, E) completed opposition, F) sliding thumb laterally along finger pads. Rigid marker pods, each containing 4 markers, were fixed to the dorsal surface of the thumb metacarpal, proximal phalange, and distal phalange.**

participants' thumb bones were measured before testing. Thumb metacarpal (MC) kinematics were gathered using a six-camera motion capture system (Qualysis, Gothenburg, Sweden), which collected the positions of reflective markers at 100 Hz. Rigid marker pods and individual markers were used to identify thumb and hand movements (Fig. 2).

Participants performed the movement described in Figure 2 to scribe out the largest volume around which the thumb MC could move, or the MC volume. Each participant performed the motion three times.

Spherical coordinates were used to plot the outer surface of the MC volume, where the r-coordinate was the length of the MC (Fig. 3). The two angular coordinates were perpendicular to each other, and defined relative to the palm. Both angles were calculated for each time point during the motion and plotted to obtain the outer perimeter of the MC volume, or the path of the distal end of the MC during the motion. The MC volume was completed by sweeping from one side of the perimeter to the other and plotting angles internal to the perimeter.

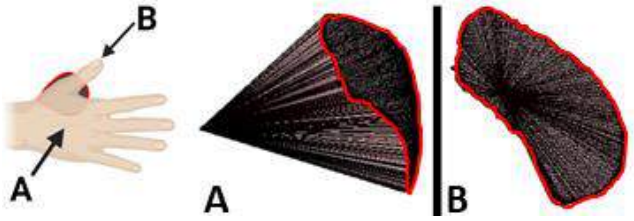

**Figure 3: A) Representative MC volume viewed from the back of the palm. The leftmost tip is the thumb CMC joint. B) The same volume viewed from the distal thumb. The outermost edge shows the MC perimeter.**

The MC volume was determined using the 'boundary' function in MATLAB (MathWorks), which calculates the volume enclosed by the plotted spherical coordinates. To normalize for MC length, each volume was divided by the participant MC length cubed. A two-way ANOVA and Brown-Forsythe tests were used to determine differences in normalized MC volume means and variances between groups, respectively.

## RESULTS

Normalized MC volume data showed no significant change due to age ($p = 0.88$) or sex ($p = 0.60$) (Fig. 4). In both younger and older groups, females had a slightly larger normalized MC volume than males. In both male and female groups, older participants had a larger normalized MC volume. Variances were similar across all groups ($p > 0.80$). Average perimeters for all groups were visually similar (Fig. 5).

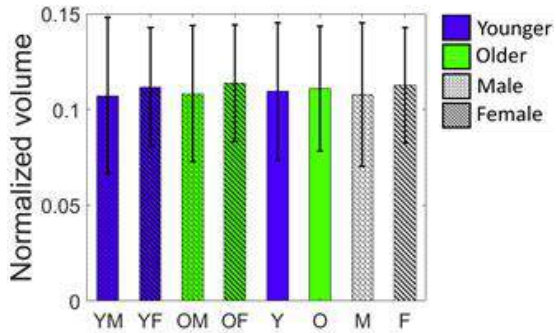

**Figure 4: Mean normalized metacarpal volume and standard deviation. Y = young(18-39), O = older(40+), M = male, F = female. Raw volume data was normalized by dividing by the cube of the MC length.**

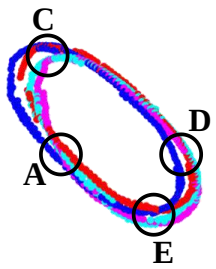

**Figure 5: Average metacarpal volume perimeter for each group viewed from the distal thumb. Red = YM, blue = YF, magenta = OM, cyan = OF. Letters correspond to Figure 2.**

## DISCUSSION

This work used the normalized metacarpal volume to characterize the complex 3D kinematics of the thumb metacarpal. Establishing baseline healthy kinematics using methods that offer more information than those typically seen in clinical settings is key to understanding and optimizing patient outcomes for CMC OA surgeries.

Our data suggest that, in a healthy population, age has a minimal effect on normalized MC volume, or may even increase it, while females show larger MC volumes than males. Increased CMC mobility may be of concern because it is linked to joint laxity, a known risk factor for CMC OA [5]. This increased risk in females and in older populations is consistent with increased prevalence among the same populations [1].

Average MC perimeters for all groups are comparable in size, which is consistent with volume numbers, shape, and position. Shape and position similarity implies groups have access to the same 3D space of movement.

This is the first work to use a volumetric approach to thumb kinematics that is normalized for thumb size. This is a vital step, as it enables comparisons between individuals, across groups, and provides the foundation for the MC volume to be a tool to evaluate the effects of surgical interventions. This is also the first work to use the volume of just the thumb metacarpal, instead of the whole thumb. Breaking down the volume of the entire thumb by each bone is key to identifying regions where therapeutic and surgical components can be targeted to provide optimal function post-surgery.

Future expansions of this work will include the normalized volume of the other bones of the thumb, and the thumb as a whole. Testing participants before and after a CMC OA surgery will also be conducted to gain a better understanding of post-operative thumb kinematics. Increased understanding will inform adjustments to surgical and therapeutic methods to optimize patient outcomes.

# IMAGE-BASED DYNAMIC STRAIN ESTIMATION OF ALVEOLAR MICROSTRUCTURES DURING EX VIVO MECHANICAL VENTILATION

## INTRODUCTION

Breathing and mechanical ventilation cause deformation of lung tissues and cyclic strain fluctuations in alveolar ducts and septal walls. Injurious ventilation may induce or worsen lung injury associated with mechanical trauma via alveolar overdistension and/or repetitive collapse and reopening. Mechanical ventilation settings applied across the entire lung—such as positive end-expiratory pressure and driving pressure—result in heterogeneous alveolar dynamics due to regional variations in the mechanical properties of lung tissue. Thus, microscale investigations of alveolar dynamics during mechanical ventilation may reveal mechanisms of ventilator-induced lung injury associated with heterogeneity in alveolar mechanics and deformation.

Previous approaches to laser-scanning confocal microscopy of alveolar dynamics have relied on quasi-static conditions (i.e., holding the inflation pressure constant during imaging) to characterize the change in lung structure between an end-expiratory and end-inspiratory state [1,2]. However, quasi-static conditions may not accurately reflect dynamic conditions, especially if the lung does not reach mechanical equilibrium within the time allowed for inspiration or expiration. Videomicroscopy techniques allow rapid imaging of alveolar dynamics [3], but interpretation of specific alveolar structures is fraught with difficulty [4]. Optical coherence tomography enables volumetric imaging with high temporal resolution, but comes at the expense of a reduced signal-to-noise ratio and lower spatial resolution [5].

In this study, we developed a retrospectively gated laser-scanning confocal microscopy technique [6] that enabled us to reconstruct a sequence of two-dimensional images of alveolar deformation within a cross-section of lung tissue (Figure 1A). From these reconstructed images, we were able to quantify the dynamics of alveolar septal wall strain during pressure-controlled mechanical ventilation.

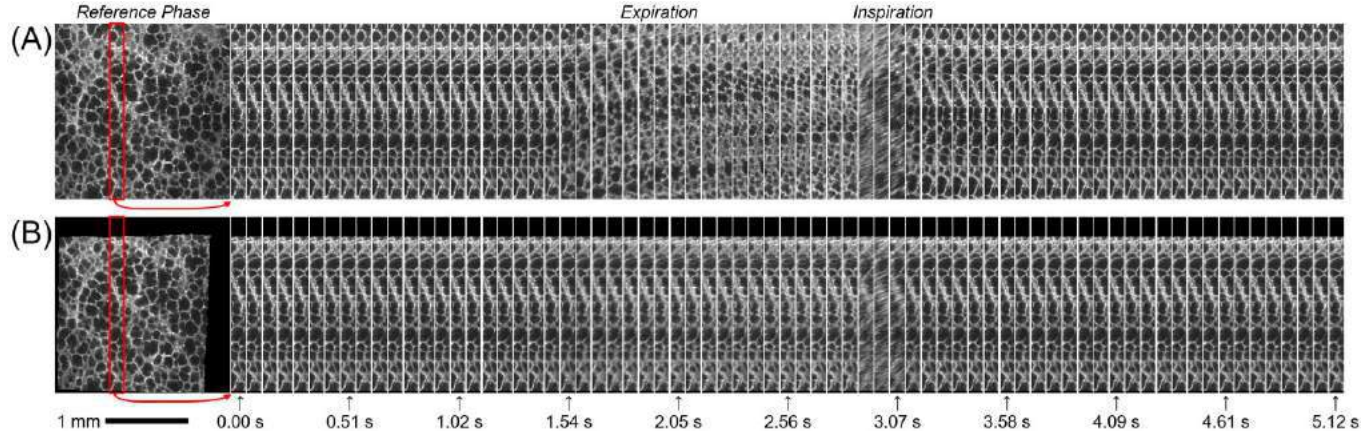

**Figure 1. (A) Slices of a reconstructed image sequence showing alveolar deformation throughout ventilator cycle. (B) Corresponding slices from the deformed image sequence after image registration, showing alveolar structures aligned with those of the reference image.**

## METHODS

Subsegmental regions of porcine lung tissue were dissected, carefully preserving intact airtight structure. Periodic pressure-controlled mechanical ventilation was simulated by a microcontroller-timed solenoid valve that switched the airway opening pressure between high and low states determined by adjustable pressure relief valves.

Imaging was performed on a Nikon A1 laser-scanning confocal microscope, using 561 nm excitation and 595 nm emission. Image frames were acquired continuously over a 2.12-mm field of view, without interrupting mechanical ventilation, and with a fixed 3-second time delay between the start of each frame's acquisition. Image reconstruction was performed retrospectively according to the ventilator rate [6]. Each pixel was associated with a phase of the periodic respiratory cycle. Pixels with the same respiratory phase but different spatial locations were assembled into phase-binned frames. Each frame thus described the structure of the lung sample at a single phase in the ventilation cycle, with minimal motion artifact. A sequence of these phase-binned frames was constructed to describe the dynamic motion of the lung sample throughout the ventilation cycle (Figure 1A).

Image registration was performed to estimate periodic spatial transformations that describe alveolar deformations during the ventilator cycle. A sequence of B-spline transformations between each frame and a common reference frame were estimated using the Elastix registration library [7]. All frames could then be deformed to align alveolar structures with those of the reference frame (Figure 1B). The resulting spatial transformations were queried to assess regional expansion and contraction at each ventilation phase.

Linear strain in each alveolar septal wall was approximated by first segmenting alveolar walls in the end-inspiratory reference frame, and then computing the change in distance between the endpoints of each wall after applying the spatial transformations corresponding to each ventilation phase. Exponential regression was performed to estimate time associated with relaxation of septal wall strain in response to step changes in airway opening pressure during expiration.

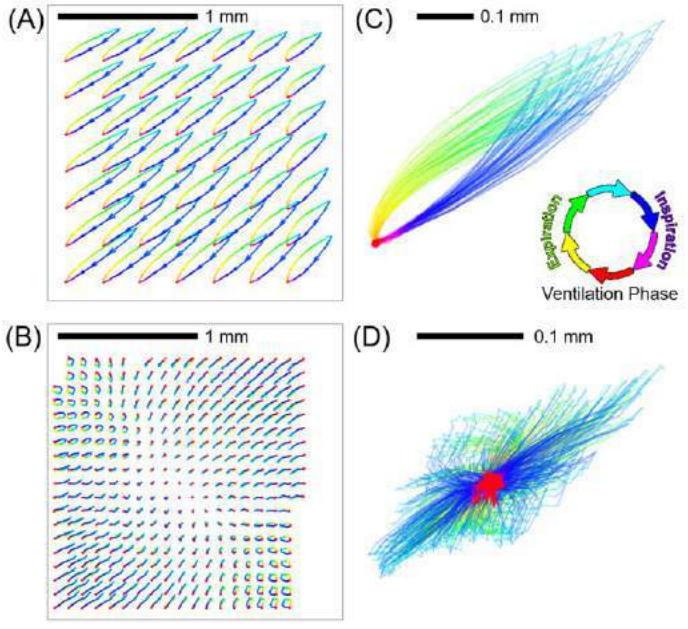

**Figure 2. Trajectories of tracked points within the 2.12-mm field of view before (A) and after (B) subtracting the mean translation at each phase. Superimposed trajectories (C, D) magnified for clarity. Color indicates phase of ventilation cycle.**

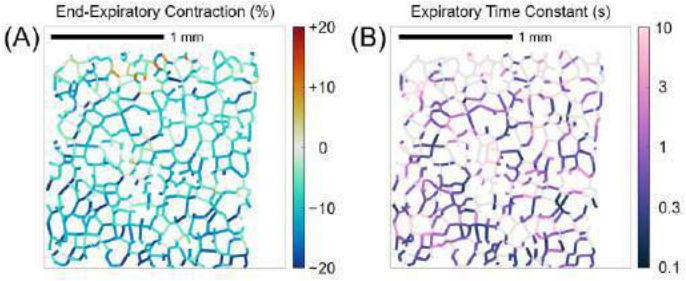

**Figure 3. (A) End-expiratory alveolar wall strain (relative to end-inspiratory state). (B) Exponential time constant associated with relaxation of alveolar wall strain after a stepwise decrease in airway pressure (gray indicates $R^2 < 0.8$ for exponential regression).**

## RESULTS

The reconstructed image sequence (Figure 1) contained 71 images throughout the 5.19-second ventilator cycle, for an effective temporal resolution of 73.1 ms. Image registration revealed hysteresis of spatial trajectories that varied throughout the sample (Figure 2). Substantial heterogeneity was observed even after subtracting the mean translation component of displacement, indicating nonaffine deformations (Figure 2C,D). Linear strain within alveolar septal walls demonstrated substantial heterogeneity, both in end-expiratory contraction (strain mean ± standard deviation: -9.1% ± 6.3%) (Figure 3A), and in the rate at which strain equilibrated to a step change in airway pressure (time constant percentiles 50$^{th}$ [25$^{th}$, 75$^{th}$]: 0.7 [0.4, 1.6] seconds) (Figure 3B).

## DISCUSSION

This study presents a microscale investigation of alveolar dynamics using retrospectively gated image reconstruction and image registration. Substantial mechanical heterogeneity of alveolar deformation and septal wall strain occurred even within a well-aerated region of the lung, consistent with previous findings in quasi-static conditions. However, imaging under dynamic conditions revealed that many alveolar structures are not in mechanical equilibrium by end-inspiration or end-expiration, but rather exhibit a wide range of relaxation time constants. There is also a large degree of hysteresis in the spatial trajectories of alveolar deformation. These findings underscore the importance of imaging alveolar dynamics without interrupting ventilation, especially for specialized modalities that rely on high respiratory rates or low exhalation times. Furthermore, these findings suggest the possibility of characterizing viscoelasticity for individual alveolar structures. The techniques developed herein enable future investigations to assess interactions between expiratory time, driving pressure, and end-expiratory pressure on heterogeneous microstructural dynamics in normally and poorly aerated lung tissues.

# A NOVEL MACHINE LEARNING-BASED FRAMEWORK TO PREDICT THE ANISOTROPIC MECHANICAL PROPERTIES IN SOFT MATERIALS USING ANISOTROPIC INDENTATION

**Habibeh Ashouri Choshali (1, 2, 3), Juanyong Li (2), Taylor Paradis (2), Nima Rahbar (3), Kristen L. Billiar (2)**

## INTRODUCTION

Characterizing the mechanical properties of soft tissues and biomaterials is of intense interest as changes in mechanical properties in these materials can be a sign of disease and abnormalities. Many biological materials are anisotropic due to the alignment of the fibers in their internal structure which increases the difficulty in characterization (1, 2).

Characterization of anisotropic mechanical properties in soft materials is challenging due to the difficulties that exist in the nature of biological material, applying and measuring the mechanical loads, and the need to combine the data from multiple experimental protocols (3). Indentation is widely used to determine the local mechanical properties of soft materials due to the ability to test samples in their native state without harvesting (4, 5). However, a single indentation experiment with a symmetric (conical or spherical) probe is not sufficient to estimate the anisotropic mechanical properties; the force-displacement data need to be combined with other experimental and computational techniques such as tracking 3D deformations and inverse finite element model fitting (3, 4, 5).

Here, we develop a machine learning (ML)-based framework to predict the local anisotropic mechanical properties of anisotropic soft materials using two orthogonal indentation protocols with a novel anisotropic indenter. We demonstrate the applicability of the proposed framework using the experimental data for chicken breast and develop a normalization process and workflow which makes the approach applicable for a wide range of anisotropic materials from micro to macro scale.

## METHODS

Frozen chicken breasts were defrosted in air until they were able to be sliced into reproducible-sized slabs. The samples were cut to an average width and length of 25-40 mm and thickness of ~10 mm. Typical samples are shown in (Fig. 1a). Indentation experiments were performed with an anisotropic indenter made from a curved metal wire of major radius 3.5 mm and minor radius 0.5 mm at 0.1 mm/s to a maximum depth of 2 mm using an Instron EP1000 with 1N load cell (±1mN) (Fig. 1b). The maximum load was set between 0.15 N-0.3 N. The direction of fibers was determined visually for each sample. At each site, indentations were performed for two directions: 0-degree (the long axis of the indenter aligned with the fiber direction) and 90-degree. The indentation sites were chosen away from the sample edges to avoid the edge effects.

Finite element (FE) modeling (Abaqus) was used to generate a labeled dataset using the indentation simulation for different material property sets. The size of the sample is 40 by 30 mm with a thickness of 10 mm. Mesh convergence and optimization was performed. The elements were modeled as transversely isotropic material with values in Table 1. The whole process was automated.

We then extracted features for our ML model using the resultant normalized pair of force-displacement curves for each data point. For this purpose, each pair of curves was transformed to a feature vector which is constructed as follows: the range of the indentation for each pair of curves was split to a certain number of knots (the number of knots is a hyper-parameter that can be tuned to improve the performance of the model). The indentation value, the force corresponding to 0-degree alignment, and the force corresponding to 90-degree alignment were then extracted at each knot. These values were finally concatenated for all knots to construct the feature vector. To train the ML model, 80 percent of the dataset was used, and the remaining 20 percent was used for testing the model after shuffling. Linear regression, random forests, and fully connected neural networks were used to develop the ML models per aspect ratio, R. A max depth of 40 was used to build the random forests model. For the fully connected neural network model, we used 3 layers in which the first, second, and third layers had 20, 10, and 20 nodes respectively. Our activation function was ReLU.

## RESULTS

A total of 37 sets of orthogonal indentations were completed on 17 different chicken samples. The average of the results for each indentation angle was then measured, and the results are shown in (Fig. 1c). The results of indentation experiments as well as FE simulation with two different property sets are shown in Fig. 1d (black: $E_1 = 20$, $E_2 = 10$, $G_{12} = G_{23} = 10$; blue: $E_1 = 30$, $E_2 = 5$, $G_{12} = 15$, $G_{23} = 2.5$; $\nu = 0.47$ for both and moduli in kPa) showing an obvious difference for the predicted force-displacement curves in 0-deg and 90-deg for anisotropic elastic constants in agreement with the experimental results.

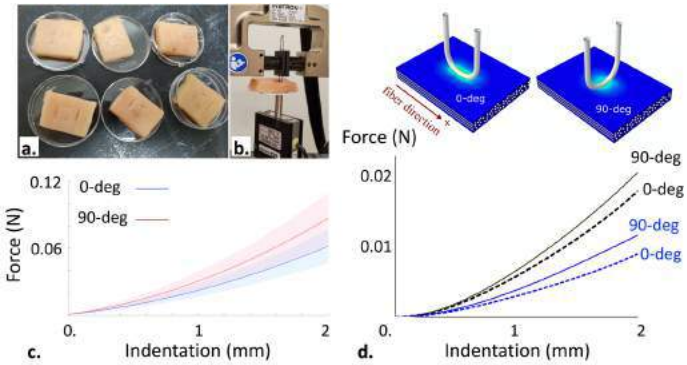

**Figure 1: a) Chicken breast samples post indentation. b) Experimental setup for indentation experiments. c) Average indentation results ± 1 SD with a shade of similar color for each direction. d) The results of FE simulation for two example material property sets, for 0- and 90- degree alignment (see text).**

After validation of the FE model using the Hertz contact theory for a spherical indentation into an isotropic material, 3568 pairs of orthogonal force-displacement (F-d) curves were simulated for each combination of the material properties presented in Table 1. The values of the material properties are taken from the literature as representative of a broad range of biological tissues (3, 5, 6). The F-d data were normalized to remove the scale dependency by dividing the displacement by the maximum indentation, $d_{max}$ and the force values by $d_{max}^{3/2}\sqrt{r}$ according to the Hertz contact rule where r is the smaller radius of the indenter.

**Table 1: Transversely anisotropic material properties and indenter geometry values for grid generation with $E_1 > E_2 = E_3$.**

| parameter | values |
|---|---|
| $E_1\ (kPa)$ | [1, 5, 10, 30, 50, 70, 90, 100] |
| $E_2 = E_3\ (kPa)$ | [1, 5, 10, 30, 50, 70, 90, 100] |
| $\upsilon_{12} = \upsilon_{13}$ | [0.3, 0.47] |
| $\upsilon_{23}$ | [0.3, 0.47] |
| $G_{12} = G_{13}\ (kPa)$ | [0.1, 0.5, 1, 5, 10, 20, 30, 40] |
| $G_{23}$ | $E_2\ /(2(1+\upsilon_{23}))$ |
| R (large:small indenter radius ratio) | [3.25, 5, 7, 10] |

The best overall performance achieved for the linear regression, random forests, and fully connected neural networks models are 0.63, 0.76, and 0.9 respectively. The performance of the ML framework in predicting the elastic constants for the training and test set using the fully connected neural networks for R=3.25 is presented in Fig. 2. The neural networks model shows the highest $R^2$ among all the ML techniques with the lowest overfitting meaning that it achieved the best performance. Random forests tended to over-fit the training set and the linear regression model achieved a very poor performance due to the complex pattern that exists between the dependent features and the response (elastic constants).

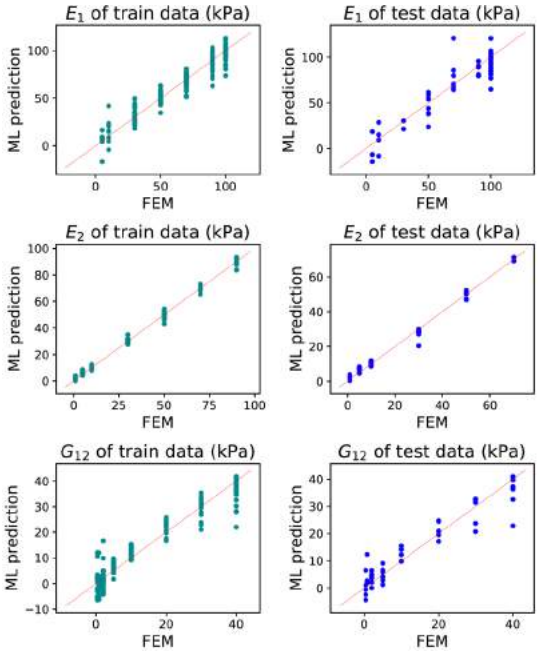

**Figure 2: Predictions on the training and test sets using neural networks. $R^2$= 0.94 for the training set and $R^2$= 0.9 for the test set.**

## DISCUSSION

For an anisotropic material, indentation with an anisotropic indenter along and perpendicular to the preferred mechanical axis (i.e., fiber direction) will result in different force-indentation behavior. Here, we proposed a novel ML-based methodology to predict the anisotropic mechanical properties of biological material using the difference between the force-displacement curves resulting from two asymmetric orthogonal indentations parallel and perpendicular to the fiber directions. The main application of the proposed framework is to determine anisotropic properties for biological materials for which performing multiple experiments such as biaxial testing and shear testing is not straightforward (e.g., living cells, in situ tissues). We built a computationally effective model that can determine the anisotropic mechanical parameters for a given material in just a few seconds on a standard desktop computer by using just one set of two indentation test results as input. This result is more significant if we compare it with the average time for running a single forward FE simulation for a pair of indentations (more than half an hour on a standard computer). Solving the inverse problem and finding the properties using the force-displacement curves using the available techniques requires multiple simulations and an optimization protocol e.g., genetic algorithm taking many hours. The proposed framework has the potential to be a powerful tool for quickly determining the anisotropic properties of biological materials with application in disease diagnosis.

# PERFORMANCE OF SKIN COOLING DEVICE IN COOLING PENETRATION IN TISSUE – EXPERIMENTS AND SIMULATIONS

**Manpreet Singh (1), Jacob Lombardo (1), Alexander Caporale (1), Liang Zhu (1)**

(1) Department of Mechanical Engineering, University of Maryland Baltimore County, Baltimore, Maryland, USA

## INTRODUCTION

Placing a cooling device on the skin of a surgical site is one of the recommendations for patients after surgery to reduce inflammation and to alleviate pain.[1-2] Cooling may temporarily reduce nerve activity via disrupting the transmission of pain signals.[1-2] Unfortunately, unknown cooling penetration depth and uneven cooling on the surgical site are factors contributing to the discontinuous use of the cooling device by patients. Those patients often turn to take pain-killer medications to relieve pain, and this has led to the opioid epidemic in the country. Theoretical simulation is a valuable tool to predict cooling extent in targeted tissue region, however, its accuracy depends on physiological and physical parameter inputs. In this study, we performed experiments on healthy volunteers to record temperatures on skin surface under a cooling pad and then developed a whole-body heat transfer model to simulate the temperature field in the body tissue before and during cooling. Physiological parameters such as local blood perfusion rate and metabolism and heat transfer parameters such as lumped heat transfer coefficients will be extracted first. Then temperature field underneath the cooling pad will be simulated to evaluate both cooling penetration and the time duration needed to achieve the penetration.

## METHODS

A commercially available cooling device was evaluated in this study. Shown in Figure 1, it consists of a container with good insulation, a pump to induce water circulation, and a cooling pad suitable for cooling the lower extremities. The cooling pad was wrapped on both the thigh and leg of a human volunteer in a sitting position. An elastic belt was used to ensure good physical contact to the skin and an aluminum sheet was attached to the cooling pad to generate even cooling to the skin surface.

Two healthy volunteers were recruited to this study with local IRB approval. The baseline temperatures of the thigh were recorded by an infrared camera (TIS45, Fluke Corporation, Everett, WA), shown in Figure 1. Then the cooling pad was wrapped on the thigh and leg of the volunteer. A thermistor bead sensor with a nominal resolution of 0.001°C (0.8 mm dia., T-View system, Alpha Technics, Irvine, CA) was attached to the center of the cooling pad on the thigh to measure the temperatures before and during the cooling experiment. Water at approximately 1-2°C was circulating through the cooling pad and the total cooling time was 20 minutes. The oral temperature of the volunteer was also recorded before and after the cooling.

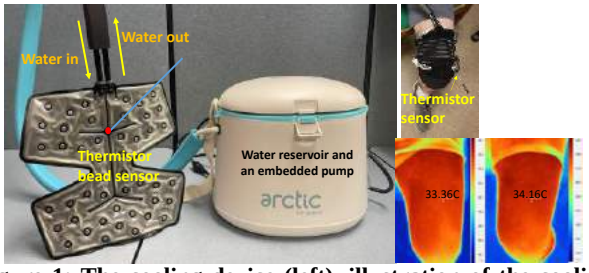

**Figure 1: The cooling device (left), illustration of the cooling pad wrapped on the thigh and leg of a volunteer (upper right), and recorded infrared images of two volunteers (lower right).**

A physical model based on realistic measurements of the volunteer was generated. As shown in Figure 2, the body (79 kg and 1.75 m tall) consists of three components: the brain, the rectangular column of the internal organ, and the muscle for the rest of the body. Each component has its own thermal and physiological properties. The Pennes bioheat equation[3] is used to model both the steady state and the transient temperature fields of the body as

$$\rho_t c_t \frac{\partial T_t}{\partial t} = k_t \nabla^2 T_t + \omega_t \rho_b c_b (T_a(t) - T_t) + Q'''_{met,t} \quad (1)$$

where $\rho$ is density, $c$ is specific heat, $k$ is thermal conductivity, $\omega$ is local blood perfusion rate, and $Q'''_{met}$ is volumetric heat generation rate due to metabolism. Initially, the body is exposed to an ambient environment, and the thermal resistances due to clothing layers and convection/radiation with the air are lumped as an overall heat transfer coefficient $h_{air}$. The boundary condition of the cooling pad is also lumped as an overall heat transfer coefficient $h_{water}$.

$h_{air}$ was determined considering free convection and radiation as 9.57 W/m$^2$K. We first adjusted the blood perfusion rate and metabolism in the muscle component (including the lower extremities) so that the recorded temperatures in the infrared image matched that predicted by the steady state simulation (Eq.1) before wrapping the cooling pad. Then the transient temperatures predicted by Eq. 1 during cooling were compared to that measured by the thermistor bead sensor, and $h_{water}$ was adjusted until the match between predictions and experimental data was achieved. Finally, local blood perfusion rate and metabolism, $h_{water}$, and other parameters were used to simulate temperature distribution inside the thigh and leg using the cooling pad with a water temperature at 0°C, a setting as recommended by the manufacturer.

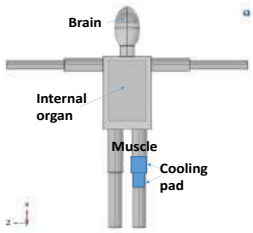

**Figure 2: Schematic diagram of the whole body model and location of the cooling pad.**

## RESULTS

Table 1 gives the physical and physiological properties needed in the model. The air temperature in the lab ($T_{air}$) was recorded as 22.1°C. The local blood perfusion rate and the metabolism of the muscle were determined and shown in Table 1, based on the infrared temperature recording (the emissivity was selected as 0.94). One notes that the two volunteers have similar $\omega$ and $Q'''_{met}$ values, with variations < 10%.

**Table 1 Physical and physiological properties[4,5], *: fitted results**

| **Properties** | Brain | Internal organ | Muscle | Blood |
|---|---|---|---|---|
| $k$, W/mK | 0.52 | 0.52 | 0.52 | 0.50 |
| $\rho$, kg/m$^3$ | 1060 | 1060 | 1060 | 1060 |
| $c$, J/kg K | 3800 | 3800 | 3800 | 3800 |
| $\omega$, 1/s | 0.009 | 0.0021 | **0.00054*,0.00050*** | |
| $Q'''_{met}$ W/m$^3$ | 9225 | 2198 | **543*, 498*** | |

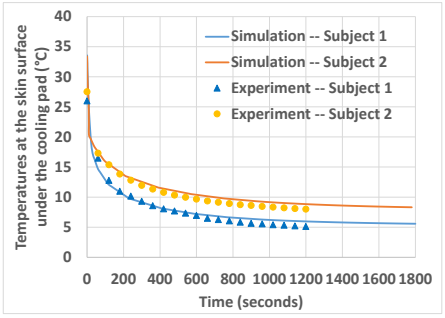

**Figure 3: Recorded temperatures by the thermistor bead sensor (symbols) and the simulation using the finalized $h_{water}$.**

The oral temperature of the volunteer changed slightly, as ±0.1°C from the baseline to that after the cooling. The transient temperatures recorded by the thermistor bead in both volunteers are shown by the symbols in Figure 3. Note that water temperatures in the reservoir did not change very much during the cooling (subject 1: 0°C-1.36°C; subject 2: 1.36°C-2.32°C). In the simulation, an average water temperature (0.68°C or 1.84°C) was used for each subject. While adjusting the overall heat transfer coefficient $h_{water}$ (subject 1: 223 W/m$^2$K, subject 2: 138 W/m$^2$K), one obtains the best match between the experimental data and simulation predictions, shown in Figure 3. The variation of $h_{water}$ from one subject to another may be due to how tight the elastic belt and/or measurement uncertainty.

The final task of this study is to simulate the transient temperature distribution based on the recommended cooling setting by the manufacturer. The water in the reservoir should be ice-water mixture ($T_{water}$=0°C) and the cooling time is set as 30 minutes. Figure 4 illustrates the baseline temperature contours, showing the maximal temperature of 37.3°C occurring in the brain and internal organ. After 30 minutes of cooling by the cooling pad ($T_{water}$=0°C), one can see significant cooling penetration to the deep tissue of the thigh and leg.

The transient temperature distribution along the horizontal line in the right panel of Figure 4 is plotted in Figure 5. The results show a relatively uniform temperature distribution inside the thigh before the cooling, varying from ~33°C at the skin to 37°C at the center. Once the 0°C water is circulating in the cooling pad, temperature decreases rapidly. Temperature profile in the tissue does not change very much after cooling of 20 minutes. Cooling penetrations of both volunteers are similar, even if the thigh diameter of the two volunteers are slightly different (0.12 m vs. 0.129 m). If the cooling front is defined as 33°C, the penetration depth is appropriately 28 mm.

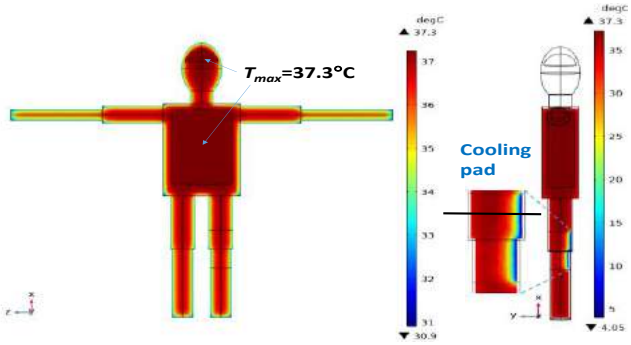

**Figure 4: Contours of the temperature field of the body before (left) and 30 minutes after surface cooling, $T_{water}$ = 0°C (right).**

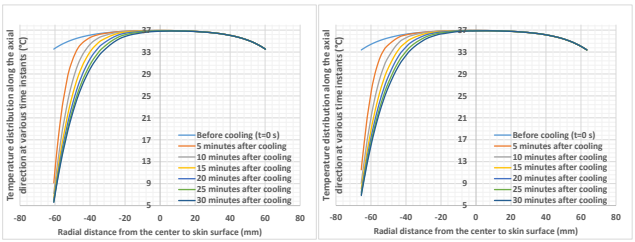

**Figure 5: Temperature distribution along a middle horizontal path (shown in Figure 4) at various time instants of cooling (left: subject 1; right: subject 2).**

## DISCUSSION

The current study shows feasibility of extracting physical and physiological parameters from measured temperatures at the skin surface of targeted cooling region using a cooling pad. The extracted parameters are within the range of normal physiology. The accuracy of theoretical model should be significantly improved with those extracted parameters. Based on the data, the model predicts a cooling penetration depth (<33°C) as 28 mm from the skin surface to the deep region. Further, the cooling penetration is almost unchanged after 20 minutes, suggesting possible shortened cooling duration for patients.

## INTRODUCTION

Systemic delivery of therapeutics to the spinal cord is restricted by the blood-spinal cord barrier (BSCB), which regulates the molecular transport from the blood into the spinal cord parenchyma via transcellular and paracellular pathways, only allowing small molecules crossing (<500 Da), such as oxygen, glucose, and water molecules [1-2]. BSCB represents a critical challenge in therapeutics delivery for treating various diseases/disorders affecting the spinal cord in humans. Innovative approach for effective and safe modulation of the BSCB is highly demanded for improving the drug delivery to the spinal cord [3-4]. Herein, we present a novel optical approach (refer as Opto-BSCB, Figure 1) for transiently modulating the BSCB permeability (works for the blood-brain barrier -BBB modulation in the brain as well) [5] and its utility for localized drug delivery with high spatial resolution into the spinal cord in a rodent model [6].

## METHODS

Opto-BSCB approach relies on the optical stimulation of spinal cord vascular tight-junction (TJ) protein, junction adhesion molecule-A (JAM-A) targeted plasmonic gold nanoparticle (AuNP) by ultrashort picosecond laser pulses (Figure 1A). AuNPs conjugated with vasculature protein targeted antibodies are administrated intravenously and stimulated by 532 nm picosecond laser [5]. An optimal method for delivering laser light to reach the spinal cord surface for modulating the BSCB permeability is developed by using an intrathecal injection cannula with an ultrasmall optic fiber inserted through the inner channel at the mouse lumbar region. The efficacy is evaluated by systemically delivering tracers including Evans blue (EB), 660 Da EZ-link biotin, 70 kDa FITC-dextran, and a small molecule peptide-bombesin through intravenous injection. Laser is delivered to lumber L4-5 though the intrathecal device. Behavior studies are carried out to assess the impact of bombesin, an itching causing peptide, after BSCB opening. The safety is examined by analyzing cell specific protein expression in spinal cord tissue after BSCB modulation and bombesin delivery.

## RESULTS

Significantly increased BSCB permeability were observed in the laser stimulated region as compared to region without laser (Figure 1B-E). Opto-BSCB enabled the transient opening of the BSCB within 24 hours for local delivery of biologics with sizes ranging of 660Da – 70kDa in mice.

To demonstrate whether the Opto-BSCB approach can be used for delivering therapeutics/biologics to the spinal cord without significant adverse effect, we used an itch-inducing peptide, namely bombesin (BBS, MW: 1.62 kDa), as a model molecule. After systemic administration following the BSCB modulation (Figure 2A), a rapid and transient itching behavior was observed in the mice with BSCB opening (Figure 2B). In contrast, only a slow and much lower itching behavior (due to the IT injection itself) was observed in the mice with intact BSCB (Figure 2B, $p<0.05$ at 5-10 minutes post-injection of BBS). The increased itching score lasted up to 10 minutes, consistent with the peptide clearance profile. These results suggest that small peptide drugs can be delivered to the spinal cord to introduce behavior-specific changes in rodent models. We then compared the major cellular activities by staining NeuN, IB4, and CGRP post-bombesin delivery in the mice with BSCB intact versus BSCB open (Figure 4C-F, and 4G-J, respectively). We observed no significant changes to IB4, CGRP, and NeuN (Figure 4K, no significance), reflecting the minimal invasiveness of Opto-BSCB-enabled drug delivery. Additional staining suggested no significant increase in GFAP (data not shown).

## DISCUSSION

With this integrated optical nanotechnology, BSCB can be opened efficiently as indicated by the enhanced EB distribution in the laser stimulated region in the mouse spinal cord. BSCB nonpermeable

molecules with sizes ranging from 600 Da to 70 kDa can be delivered into the spinal cord within a 24-hour time window post-laser stimulation. The rapid and transient increase to the itching behaviors is observed in mice upon systemic administration of bombesin within the optimal delivery window after local Opto-BSCB modulation. Opto-BSCB causes minimum impact on the protein expression on the major cell types in the spinal cord (neuron, astrocyte, and glial cells) and does not significantly alter animal behaviors (motor function, inflammation, and pain relevant behaviors, data not included).

Opto-BSCB as a novel minimally invasive BSCB modulation approach is promising for delivering a wide range of therapeutics to the spinal cord, and may have potential applications in improving the local concentration of therapeutics for facilitating the treatment of many diseases/disorders in the spinal cord. Opto-BSCB shows great potential for integrating with the intrathecal devices for bypassing issues of the ultrasound-BSCB opening approach, such as impact of the complicated vertebrae, overheating of bone, and standing waves generated in the narrow spinal canal [3].

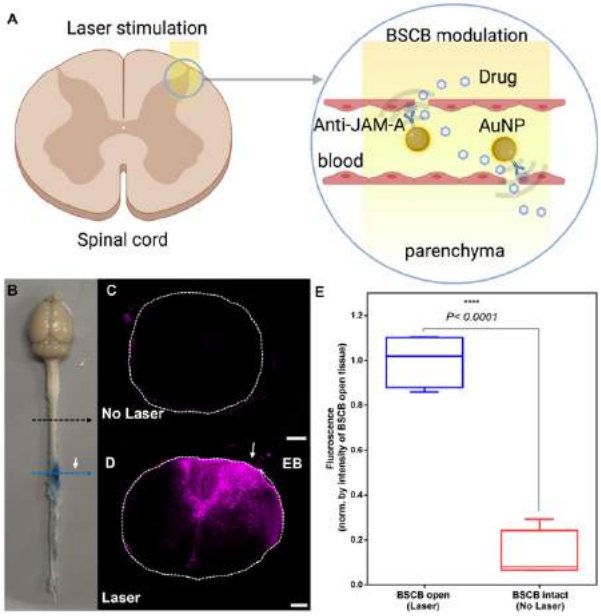

**Figure 1: Opto-BSCB modulation with the bulk laser beam (beam size of 6 mm in diameter).** (A) Schematic representation of the BSCB modulation via TJ protein (JAM-A)-targeted plasmonic AuNPs under laser pulse stimulation for drug delivery into the spinal cord. AuNPs are intravenously (I.V.) injected into the tail vein at a volume of 90 µL dispersed in PBS 1x at a final concentration of about 8.5 nM. 532 nm ps laser stimulation is applied by penetrating the intact tissue on top of the spinal cord to excite nanoparticles targeted to the TJ protein in the blood vessel. Tracer molecules or therapeutics will be I.V. administrated following BSCB opening for delivery to the spinal cord. (B) A macroscopic image of the mouse CNS shows the EB dye penetration in spinal tissue regions with (blue color) and without (natural color) laser stimulation. Laser pulse number of 10 at an intensity of 35 mJ/cm$^2$ measured at the fiber tip. (C) Fluorescence imaging of the cross-section of spinal cord tissue collected from the BSCB intact tissue (no laser), and (D) with BSCB open tissue (laser). Scale bar: 200 µm. (E) Quantitative comparison of the fluorescence in the spinal cord with BSCB open vs intact, showing a 7.7-fold higher fluorescence in the BSCB open tissue as compared to BSCB intact tissue (fluorescence is indicated as mean ± SD, normalized by the mean intensity at BSCB open tissue N=4, ****p<0.0001).

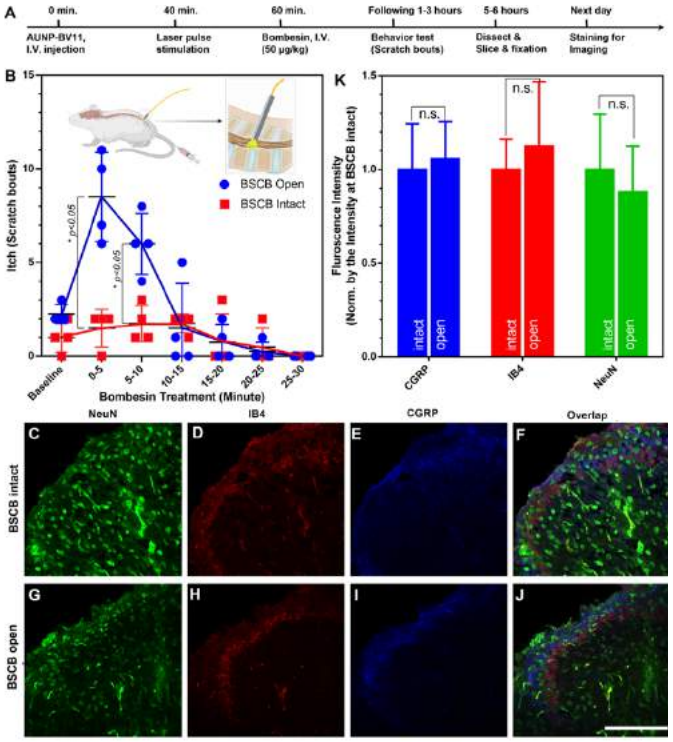

**Figure 2: Local drug delivery into the spinal cord post-Opto-BSCB modulation with the integrated intrathecal device.** (A) Schematic of Opto-BSCB modulation and stepwise experimental methods. (B) Increased itching behavior in mice with BSCB open (blue scatter/line) in comparison with control mice with BSCB intact (red scatter/line). Bombesin (BBS) is I.V. injected at the dose of 50 µg/kg body weight in mice tail vein at a volume of 100 µL. BSCB is opened by using an optic fiber injected through intrathecal injection in vivo at lumbar L4-L5, N=4 per group, $p<0.05$ at 0-5 and 5-10 minutes. Immunohistochemistry (IHC) staining of tissue from spinal cord regions with BSCB intact by (C) NeuN (green), (D) IB4 (red), (E) CGRP (blue), (F) Overlay; and tissue from regions with BSCB open by (G) NeuN (green), (H) IB4 (red), (I) CGRP (blue), (J) Overlay. (K) Quantification of NeuN, IB4, and CGRP on IHC images. Laser pulse number of 10 at an intensity of 35 mJ/cm$^2$ measured at the fiber tip. Scale bar: 100 µm.

## ACKNOWLEDGEMENTS

This research was supported by grants funded by the Department of Defense (DOD: W81XWH2110219, to Z. G), National Institutes of Health (NIH: NS065926, to T. P.), American Hospital Association (AHA: 19CSLOI34770004, to Z.Q.), and Cancer Prevention and Research Institute of Texas (CPRIT: RP190278, to Z.Q.).

## Conflict of interest

Z.G., E.D., T.P., and Z.Q. co-invented the system and method of Opto-BSCB. A US patent application (No. 63/253,543) has been filed through The University of Texas at Dallas.

# IN SILICO FATIGUE OPTIMIZATION OF TAVR STENT DESIGNS WITH PHYSIOLOGICAL MOTION IN A BEATING HEART MODEL

## INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive therapy used to treat severe aortic valve (AV) stenosis resulting from progressive calcific aortic valve disease (CAVD). With recent advances in the TAVR procedure and device design generations, TAVR is becoming a standard therapy that is rapidly expanding to younger and lower risk patients. This new patient cohort highlights the importance of long-term fatigue resistance of the device leaflets and stent frame as the device must remain safe and functional for a longer time or else risk the patient with repeat replacement surgeries.

The testing standards for TAVR devices, chiefly the ISO 5840-3 (2021) standard [1], was created by combining the hydrodynamic accelerated wear leaflet testing standards of surgical valves and the stent frame fatigue analysis of stent and graft devices. The leaflet structures are evaluated with various pressure loading conditions and various deployment configurations (under and over expanded, elliptical) at an accelerated frequency ensuring proper full opening and closing for a minimum of 200M cycles. Whereas the stent frame is required to withstand 400M cycles with the manufacturer subject to "identify and justify appropriate *in vivo* loading conditions" [1]. Some researchers have focused on induced strain on the stent frame from the flexure of the diastolic leaflets [2]. Others will use a similar protocol to stent grafts with *in vitro* testing the stent deployed within a compliant tube (representative of the vessel deployed against) with a cyclic pressure waveform inducing the cyclic strains within the stent frame. Others will select a uniform radial displacement that is measured with *in vivo* observations. Since TAVR devices are not deployed against only an artery, with potentially part of the stent in contact with ascending aortic artery, the calcific valve, and the dynamic aortic annulus, the TAVR stent is subject to the cardiac motion as well as the pressures.

Currently there is a paucity of longer term clinical studies data indicating the risk of stent fracture within patients, with most of the research focus on the structural valve degeneration of the leaflet tissues. In the following study, we present a more accurate stent fatigue analysis by utilizing the motion and interaction of the device with a full electro-mechanical coupled beating heart model to determine the *in vivo* loading conditions. The lack of this clinical focus is likely a result of yet to be established durability in these younger., longer-term patients. We additionally posit that the devices may be over engineered and their design iterated in order to achieve similar fatigue life of that acceptable in high-risk and shorter-term elderly patients – aimed at fewer other clinical complications (e.g. cardiac conduction abnormalities). Extended stent fatigue lifetimes will become more critical with the rapid development of polymeric TAVR

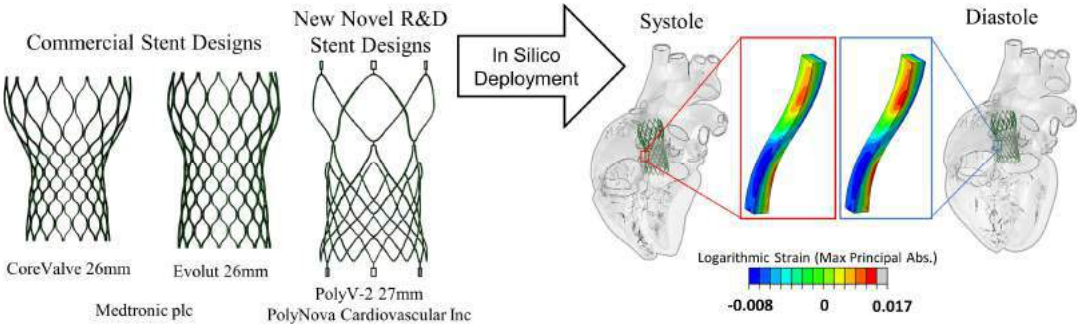

**Figure 1: Commercial stent models and experimental stent designs (left) are simulated deployments within a beating heart model (right). Inset features the change in strain on a single strut over the cardiac cycle.**

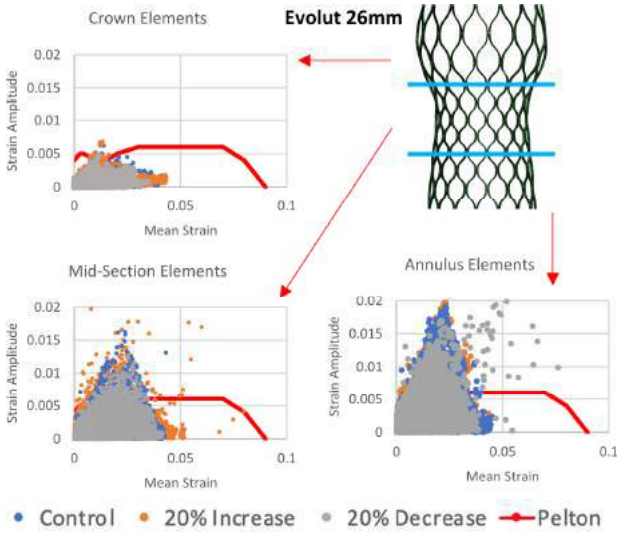

**Figure 3: Fatigue analysis of the Evolut model compared to 20% increase and decrease in strut width and split into different stent sections for comparison**

devices where SVD of tissue valves will not be present resulting in longer leaflet lifetimes [3].

**METHODS**

Commercial stent models were generated for self-expandable nitinol CoreValve 26mm and Evolut 26mm (Fig 1, Medtronic plc, Dublin, Ireland) devices. These models were generated with variable stent circumferential thicknesses as measured on the physical devices. In order to validate the models, finite element analysis (FEA) of the radial force and crush resistance of each model was compared to *in vitro* results. The nitinol material properties at 37°C were adjusted to achieve similar curves and mesh sensitivity/convergence was completed to optimize the simulations. Additionally, the novel polymeric PolyV-2 (Fig 1, 27mm, PolyNova Cardiovascular Inc, Stony Brook, NY) stent frame was analyzed in this study.

These models were deployed inside the Living Heart Model v.2019 (The Living Heart Project, Simulia, Dassault Systemes, Velizy, France) and simulated with ABAQUS Explicit v.2019. The stents are crimped to the appropriate diameter and the outer sheath is retracted with the device is deployed into the native aortic valve (simulating the deployment procedure). After the device is stabilized, the heart is allowed to beat and the deformation of the stent is tracked over 3 cycles until the deformation is repeatable.

In this study FEA is utilized to determine the fatigue resistance of the stent models with an analysis for nitinol materials defined by Pelton et al [4]. Given the unique hyperelastic material properties of self-expanding nitinol stents, both the mean strain (over the loading cycle) and the strain amplitude (change in strain over the cycle) of each element node is tracked. Pelton defines a unique curve (Fig 2 and 3) with limits of mean absolute principal strains over 8% failing and strain amplitudes over 0.4% (below the curve is considered no risk of fatigue failure).

**RESULTS**

The fatigue analysis of the Evolut model (Fig 2) is compared to modified Evolut models with 20% increase and decrease in circumferential strut thickness. Pelton et al indicate that an increase in strut width should result in larger strains in the standard fixed radial displacement analysis [4], however the opposite is observed in our analysis. The thinner strut models apply lower radial force against the contracting myocardium of LHM, thus displacing more and having a higher strain. In all the models, there were elements that would fail (above the Pelton curve) an indefinite fatigue lifetime.

The PolyV-2 design (Fig 3) was iterated to optimize achieving the highest radial force with a lower crimping volume of the stent (total volume must be reduced due to the incompressiblity of the polymer). The larger oversizing of the valve in comparison to the Evolut 26mm, resulted in higher mean strains in the analysis. The PolyV-2 struts were optimized to reduce the strain in stent joints and thus achieving better fatigue resistance in the top and mid element compared to the Evolut and similar fatigue in the annulus region.

**DISCUSSION**

This study demonstrates the utility of advanced *in silico* analysis of devices with the electro-mechanical coupled beating LHM. This analysis is able establish a more realistic study of the interaction of the device and the cardiac structure, as well as the resulting cardiac motion and stent motion. This offers a unique tool to analyze close to *in vivo* loading – bypassing the need for risky human or animal trials to obtain this motion, as well as establish a platform to study the impact of device design features on these results. There may be a discrepancy between this analysis that indicates a limited fatigue life of the commercial stents which has not been observed yet in current clinical reports. It may indicate an over estimation of strain amplitudes due to the explicit analysis or may highlight a clinical complication that may eventually develop as younger, lower-risk TAVR patients age. However, this protocol and analysis does establish a platform to iterate device designs with limited research cost to reduce other clinical complications while maintaining the expected fatigue lifetime. Additionally, with advancements in the LHM, in the future this analysis could be performed on patient-specific models to study the fatigue life in more extreme anatomies.

# THE EFFECT OF FLUID FLOW ON THE LEPTOMENINGEAL CELLS OF THE SUBARACHNOID SPACE

**Mannthalah Abubaker (1,2), David Newport (1,2,3), John Mulvihill (1,2,3)**

## INTRODUCTION

The Leptomeningeal cells (LMC) are cells that are part of the meninges and line the subarachnoid space (SAS). They function to form membranes that protect and support the brain, and barriers that ensure separation of the cerebrospinal fluid (CSF) from blood found in the vessels of the brain and the dura mater. Emerging evidence has started to show that these cells, previously only thought to have a supportive role in the CNS, are much more complex [1].

Research has so far focused on the role of LMC's developmentally and have shown that they are major sources of extracellular matrix components, growth factors and proteins which in turn make them integral to the formation of basement membranes such as the glial limitans, integral to the migration of the Cajal-Retzius cells, proliferation of cerebellar radial glial progenitor cells, cortical layer formation, cortical neurogenesis, and cerebrovascular development [2-6]. Thus, cells with such complex roles developmentally, should also retain some importance in the adult brain, especially as the LMC's cover the entire CNS and are in constant contact with CSF flow.

This preliminary study aims to understand the importance of the LMC's and their relationship with flow by characterizing the morphological changes of the LMC's. The LMC's will be examined under different flow conditions, imitating the SAS environment in homeostatic and pathophysiological instances, and their responses analysed. This study aims to give a deeper understanding of the potential consequences of altered flow in the CNS and the roles LMC's provide.

## METHODS

**Cell culture and flow experiments:** Primary Human Leptomeningeal Cells were obtained from Sciencell (SC1400, USA) and cultured per recommendations. For the preliminary rocker flow experimentation (Figure 1), 6 well plates were used with no coating and grown to confluence in normal LMC medium (SC1401, Sciencell, USA). A day before experimentation, serum-free medium was applied to minimise cell growth. Four 6-well plates were used, two plates for dynamic flow application and two plates for static control. The magnitude of shear applied was calculated using the peer reviewed ShearFast application [7]. A shear stress of 0.02 Pa was applied by setting the rocker to 30 RPM at a rocking angle of $\pm$ 7°. The wells were filled with 2 mL serum free medium. Flow was applied to the cells for 24 hours and 48 hours respectively in an incubator (37°C, 5%$CO_2$). This was a preliminary study to assess if cells reacted to the stimulus of flow.

**Immunofluorescence experiments:** To verify LMC's identity cells were stained for Vimentin (ab45939, Abcam, Netherlands), CRABP2 (NB100-2590, Bio-techne Ltd, England), S100a6 (NBP1-89388, Bio-techne Ltd, England) and E-cadherin (data not shown) (NBP2-19051, Bio-techne Ltd, England) [2]. Appropriate secondary antibody was used, either anti-mouse (ab150115, Abcam, Netherlands) or anti-rabbit (ab150077, Abcam, Netherlands). Cells were fixed in 4% paraformaldehyde (PFA) in 1x PBS for 15 minutes at room temperature followed by an hour incubation in blocking buffer made up of 1% fetal bovine serum (FBS) and 0.3% Triton x-100 in 1x PBS. Primary antibody diluted in blocking buffer was applied and left over-night at 4°C. The secondary antibody diluted in blocking buffer was applied the next day and left for an hour at room temperature in the dark. 1x PBS was applied to prevent drying and plates were covered to prevent light exposure. Samples were imaged using an IMX confocal high-content imaging system (Molecular devices, USA) at 20x widefield magnification.

## RESULTS

**Flow experiments:** A preliminary test run was performed to optimize the rocker experiment and to determine whether the LMC's were responsive to flow stimulus. This test showed that there could be

a potential response to flow. Two plates underwent a shear of 0.02 Pa. Their response to this shear (flow) was assessed using trypan blue cell counting. Figure 2 below shows the cell count and viability of the dynamic and static controls plates in this preliminary test. A p-value < 0.001 was observed between the 24 hour and 48-hour results for both dynamic and static results. The 48-hours run yielded a larger cell viability than the 24-hour run while the opposite was seen for the controls.

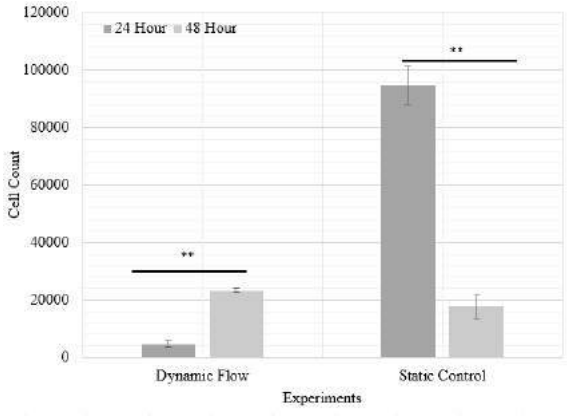

**Figure 2: The viability of the cells in the dynamic plates and static control plates after undergoing flow for 24 hours and 48 hours. **p<0.001**

**Immunofluorescence experiment:** Immunofluorescence staining for Vimentin, CRABP2, S100a6 were performed to characterise the cells and validate that they are LMC's (Figure 3). The cells stained positively for the three proteins which confirms that these are LMC's. Figure 3D highlights the elongated morphology of the LMC's under a static environment. This was also found in the immunofluorescent images with some cells displaying flat and large cell bodies (e.g., Figure 3A). CRABP and S100a6 stained as expected, as cytoplasmic protein, with CRABP2 staining with greater intensity around the nucleus in comparison to S100a6.

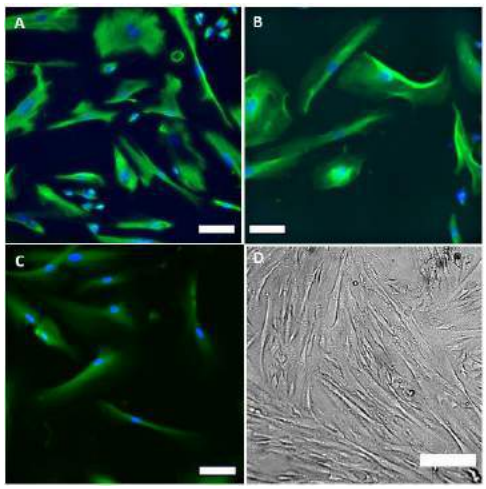

**Figure 3: (A) Vimentin (green) and DAPI (blue) immunofluorescence staining of LMC, scale bar 100µm. (B) CRABP2, scale bar 100µm. (C) S100a6, scale bar 100µm. (D) Brightfield of LMC at full confluency, scale bar 100µm.**

## DISCUSSION

We hypothesize that the LMC's play an important role in maintaining a functional CNS. For this preliminary study, we examined the response of the LMC's to a flow stimulus by inspecting the change in cell viability and performed immunofluorescence staining to confirm cell identity. It is hoped that this research will provide information that will aid in understanding the neurological environment more in-depth to be able to diagnose disease and offer better treatments.

In the preliminary rocker experiment, cell response to flow was observed by comparing cell viability in a flow applied dynamic plate to a no flow static control. The cells showed a higher viability after 48 hours of flow application in comparison to 24 hours but an opposite response in the static controls. This was hypothesised to be indicative of cell adaptation to the flow over time and that the cells may require a stimulation to retain viability as can be seen by comparing the 24-hour static plate to the 48-hour static plate which saw a large drop in cell number. However, the abrupt addition of serum-free media a day in advance of the test may have propagate cell death in both plates and thus influenced the overall results. To confirm this, more testing is required which will be achieved in the next stage of flow experimentation. Serum-free medium will be applied more gradually to the cells to ensure cells will only be impacted by flow. The next stage experimentation will also examine protein expression and cell morphology changes under different flows compared to the static.

The immunofluorescence experiment confirmed that the LMC's stained for three of the five proteins of interest that this study will focus on [1-2]. Figure 3A demonstrated vimentin protein structure of the LMC, showing the typical morphological structure expected of the LMC's. Figure 3B and 3C, CRABP2 and S100a6, both cytoplasmic proteins with functional roles in the LMC, were used to identify whether the LMC's originated from the arachnoid mater or pia mater. However, due to the LMC's staining for both, there is a possibility that these LMC's originate from both. To further confirm this, flow cytometry will be used to detect cell type. Similarly, further staining will be completed to fully characterise the cell morphology using GFAP, Cytokeratin, Claudin-11 and Nestin [1][8].

# CARRIER SOLUTION COMPOSITION AFFECTS RECOVERY OF CPA-PERFUSED RAT HEARTS

## INTRODUCTION

Heart cryopreservation would revolutionize cardiac transplantation and regenerative medicine applications[1]. The only approach that can achieve indefinite cryopreservation is vitrification or cooling the organ into a glassy state[2]. While vitrification solutions have been developed that can be delivered to organs such that they can be successfully vitrified, the exposure to these solutions often causes injury[3], hindering recovery of organ function. Our group is focused on reducing toxicity and improving the delivery of these solutions in an isolated rat heart model thereby allowing functional recovery sufficient for both cryopreservation and eventual transplantation. A vitrification solution is a mixture of cryoprotective agents (CPAs) and a carrier solution which contains different salt, sugars, buffers, antioxidants and/or metabolites. A key finding is that while the carrier solution is a fraction of the overall osmolality of the cryoprotective solution, it has an oversize impact on toxicity. Through manipulation of the carrier solution we are able to demonstrate dramatic functional improvements that suggest recovery of contraction following vitrification and nanowarming will be possible.

## METHODS

To answer the research question of which vitrification solution is least toxic, we implemented two perfusion stages. In the "toxicity" stage, the rat heart was perfused with the test vitrification solution. In the "recovery" stage, the rat heart was perfused with a physiological solution, wherein any recovery of beating was observed. Perfusate was flowed retrograde into an aortic cannula[4], causing perfusion of the heart tissue via the coronary vasculature. To assess edema, the heart was weighed before and after each perfusion stage. To assess vascular resistance, flowrate was recorded at constant perfusion pressure. Every twenty minutes, samples were taken from the organ bath and analyzed for lactate dehydrogenase (LDH), a biomarker of injury. Afterwards, biopsies from each chamber were procured and analyzed for ATP, our key quantitative metric of viability. Other details are shown below (Fig. 1).

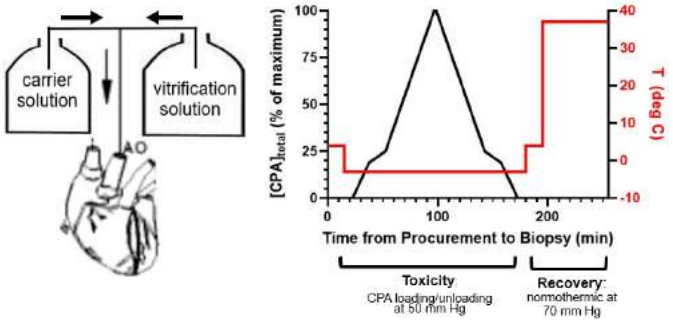

**Figure 1: To limit osmotic damage, CPA concentration was gradually increased until all flow originates from the vitrification solution reservoir at 83 min of hypothermic perfusion, then gradually decreased until all flow originates from the carrier solution reservoir at 158 min of hypothermic perfusion. Qualitative recovery of contractions was assessed at 37 °C during perfusion with Tyrode's, a blood-mimicking solution.**

Our study focused on four different carrier solutions: LM5[5], Euro-Collins (EC)[6], University of Wisconsin (UW)[7], and

Celsior[8]. Though these solutions have been investigated by others[9] as perfusates for hypothermic preservation, our study is the first to our knowledge to compare their utility as CPA "carriers" for vitrification.

## RESULTS

Our major result is that carrier solution selection is important. So important, in fact, that we found it made the difference between recovery of beating versus no recovery at all.

This "carrier solution screening" was conducted using VEG, a CPA cocktail consisting of 2.7 M ethylene glycol, 3.1 M dimethyl sulfoxide, and 3.1 M formamide[10]. The total CPA concentration in this cocktail is 8.9 M, and we found that this high concentration was extremely toxic if LM5 or EC was the chosen carrier (Fig 2.). For LM5, in fact, two rat hearts did not even recover beating at half the listed CPA composition (4.45 M). Both UW and Celsior, by contrast, enabled recovery of beating at the full 8.9 M.

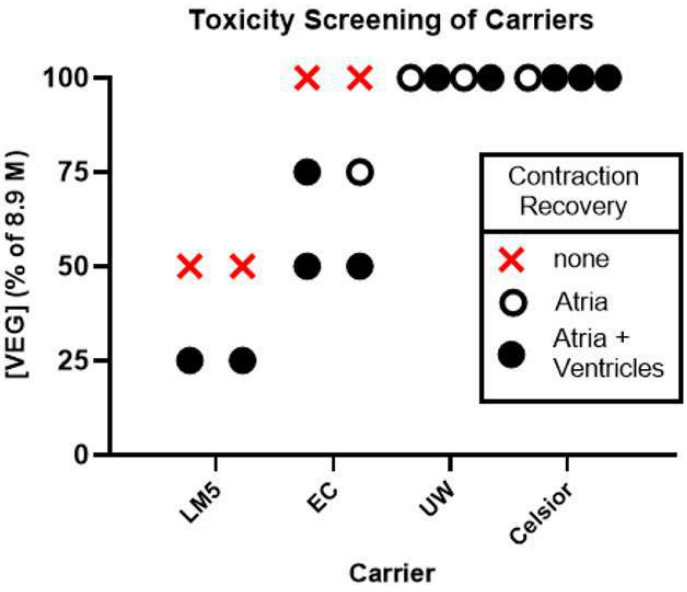

**Figure 2: The carrier solutions UW and Celsior confer better tolerance to VEG than LM5 and EC. Each data point represents one heart, and contraction recovery was ascertained visually.**

## DISCUSSION

In clinic, donor hearts are preserved by ischemic immersion in either UW or Celsior. One study in rats found that Celsior is slightly better[11], while another study in humans found that UW is slightly better[12]. These results extend this understanding of hypothermic perfusates to CPA-containing vitrification solutions. While a mechanistic explanation for the superiority of these solutions is incomplete, some insight may be gleaned by comparing the compositions of these solutions (Table 1).

**Table 1: Compositions of Tested Carrier Solutions**

| component | EC | UW | LM5 | Celsior |
|---|---|---|---|---|
| sodium | 10 | 25 | 10 | 100 |
| potassium | 115 | 125 | 35.4 | 15 |
| magnesium | | | | 13 |
| chloride | 15 | 20 | 29.2 | 41.5 |
| calcium | | | | .26 |
| glucose | 195 | | 90 | |
| lactose | | | 45 | |
| lactobionate | | 100 | | 80 |
| raffinose | | 30 | | |
| mannitol | | | 45 | 60 |
| glutathione | | 3 | 5 | 3 |
| allopurinol | | 1 | | |
| adenosine | | 5 | | |
| adenine | | | 1 | |
| glutamate | | | | 20 |
| phosphate | 50 | 25 | 7.2 | |
| bicarbonate | 10 | | 10 | |
| histidine | | | | 30 |
| HEPES | | | | |
| properties | | | | |
| pH | 7.4 | 7.4 | 7.4 | 7.3 |
| osmolality (mOsm/kg) | 365 | 320 | 283 | 340 |

We speculate that the low cation content of LM5 interfered with the transmembrane potential, leading to worse recovery. Perhaps UW and Celsior outperformed EC because of the inclusion of glutathione, a free radical scavenger. A better mechanistic understanding could be achieved by a cellular/molecular investigation.

Although Celsior and UW hearts did recover beating, their contractility was very low. Therefore, future work could involve improving these perfusates for the application of vitrification, or shift focus to minimizing CPA toxicity by adjusting temperature and/or exposure time, as well as preconditioning the heart to tolerate ischemia and CPA damage.

# A DISCRETE-FIBER MODEL FOR UNDERSTANDING CELLULAR MECHANOADAPTATION

**Ryan R Mahutga (1), Patrick W Alford (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

Cells are the living component of tissues and are responsible both directly and indirectly for how tissues grow and remodel [1]. We know that cells actively adapt to their extracellular environment by changing both their morphology and their cytoskeletal architecture both of which affect the cellular mechanics as well as overall tissue mechanics. Particularly, cells tend to be at the initiation of mechanical dysfunction in disease like aortic aneurysm [2–4]. Thus, being able to understand how mechanical cues affect cells, and how cells adapt to those cues is important for predicting disease progression and assessing intervention outcomes.

Most models of tissue growth and remodeling (G&R) either treat the cells quite coarsely or neglect them altogether. In this work, we develop a multiscale model of cellular mechanoadaptation to simulate cellular microbiaxial stretching (CμBS) [5]. This model allows us to track the changes within the cell and the influences such changes have on the substrate. With this model system, we can readily alter actin dynamics simulating pharmacological treatments as an in-silico disease-on-a-chip model. This framework is also easily adapted to investigate cells in 3D environments, which can include both experimental gel-based systems and in vivo mimicking fibrous extracellular matrix.

## METHODS

Computational Model:

*Cell Mechanics:* We developed a model using a discrete actin stress fiber network that lies within a membrane domain (Fig. 1A). The actin stress fibers are defined as linear springs with modulus 150kPa. The membrane itself is a surface upon which hydrostatic pressure acts from within the cell. The cellular hydrostatic pressure is given by $P = k\phi$ where $k$ is 1kPa and $\phi$ is the fiber volume fraction of actin. The cell's homeostatic state is then calculated by finding the equilibrium between the hydrostatic pressure on all free surfaces and the force within constituent stress fibers using Newton iteration. We derive the Cauchy stress within the cell of arbitrary shape using volume-averaging theory [6] as

$$\sigma_{ij} = \frac{1}{V}\int \sigma'_{ij}\,dV = \frac{1}{V}\sum_f \sigma^f V^f n_i^f n_j^f = \frac{1}{V}\sum_f t^f l^f n_i^f n_j^f \quad (1)$$

where V is the cell volume, $\sigma'_{ij}$ is the local stress at any point within the cell, $f$ is an index for each fiber, $\sigma^f$ is the fiber stress, $V^f$ is the fiber volume, $n^f$ is the normal vector along a fiber, $t^f$ is the fiber force, and $l^f$ is the fiber deformed length. We can see from this relation that the cell can be any arbitrary shape, and the only geometric quantity we need from the cellular domain is the volume. Simply, we can define the membrane surface using triangular surface elements from which we can calculate an enclosed volume for the surface mesh. We define the edges of the membrane surface mesh to be intermediate filaments, serving the primary role of maintaining cellular structure. We prescribe these fibers as linear with modulus 15kPa.

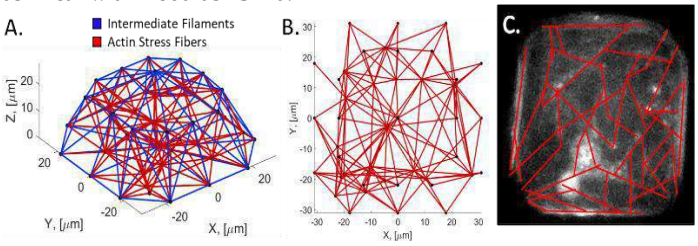

**Fig. 1. A.** 3D cell cytoskeletal network architecture immediately after substrate attachment. **B.** 2D projection of the actin stress fiber network. **C.** SIR live actin image of representative VSMC with overlay of identifiable fibers (red).

*Remodeling:* Actin fibers within cells are dynamic and assumed to exhibit tensional homeostasis, so we prescribe the remodeling law

$$dL^f/dti = 1/T^f\left(\sigma^f - \sigma^\infty\right)ïL^f \quad (2)$$

where $L^f$ is the fiber undeformed length, $T^f$ is the remodeling time constant (150 kPa h), and $\sigma^\infty$ is the fiber homeostatic (target) stress (35kPa). This remodeling equation is solved using a forward Euler

method to obtain the fiber lengths at each time point during remodeling. Because intermediate filaments are relatively stable in nondividing, nonmotile cells [7], we do not remodel them in this model system. Further, we prescribe a minimum fiber length of 3μm to prevent fibers from being removed (or becoming very short) which lead to instabilities in the computation.

Experimental Validation:

Human umbilical artery vascular smooth muscle cells (VSMCs) were cultured using standard methods [5], and were tested at passage six. Fibronectin micropatterns of aspect ratio one (L=62um,W=62um) were created on a fluorescent bead-doped 13.5kPa polyacrylamide gel affixed to a silicone membrane construct [5]. After gelling, the constructs were seeded with VSMCs, and incubated for 24h. The media was then changed to serum-free equivalent, and the constructs were incubated for 24h prior to experimentation.

The constructs were loaded into a custom apparatus mounted to a confocal microscope consisting of four high-resolution linear actuators. The actuators were used to stretch the construct to 30% grip strain. The construct was then imaged for a 0h timepoint. The construct was then placed in a custom bracket to maintain the stretch and moved to incubate until the next time point. At the next timepoint, the construct was imaged at the stretched state then returned to the incubator for the next time step. This process was repeated for time steps 2h and 4h. At 22h the sample was again placed in the scope in the stretch configuration and imaged. After this imaging, the sample was returned to zero grip strain where its position was recorded. The construct was then stretched back to 30% grip strain, and the cells were lysed from the construct using SDS. The sample was then imaged for a stretched, cell-free state. The construct was returned to the zero-strain state and imaged again for the undeformed, cell-free state.

Displacements and tractions were measured from the fluorescent bead images using ImageJ [5]. With displacements and tractions measured, stressed were calculated using a custom Matlab routine integrating the traction fields over the cellular cross-sections.

**RESULTS**

In this model system, we perform two stages of remodeling. In the first we apply no deformation to the cell, and simply let it equilibrate according to Eq. 2 taking the network from the initial state to the basal state. Next, we apply an instantaneous stretch to the cell and allow it to re-equilibrate taking it from the basal state to the stretched, remodeled state. The experiment we attempt to recapitulate with this model gave the local substrate stretch determined from the bead displacements (strains of 0.263±0.017 in X and -0.077±0.019 in Y). Fig. 2 shows the experiment compared to the model. The basal state is shown in the black box, and the remodeling comparison shows the model as dashed lines and the experiment as data points.

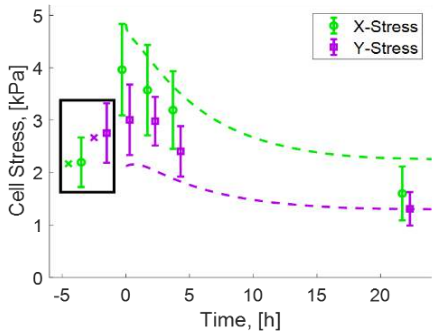

**Fig. 2.** Cellular mechanoadaptation comparison between experiments (circles and squares) and model (x's and dashed lines). The black box shows the basal state. (experiment: n=9, error bars: 95% confidence interval)

This model system further allowed us to investigate cellular morphology and individual fiber changes. For example, in Fig. 3A and 3B, we show the changes in fiber lengths and in fiber orientations respectively in the initial, basal, and stretched cases. The fiber length evolution (Fig. 3A) tends to form two populations: short fibers and long fibers. The stretched remodeled case shows a shift of the short fiber family to the right, indicating lengthening of these fibers. The fiber orientations in the plane of stretch (Fig. 3B) show realignment toward the X-direction in the stretched state as compared to the basal state.

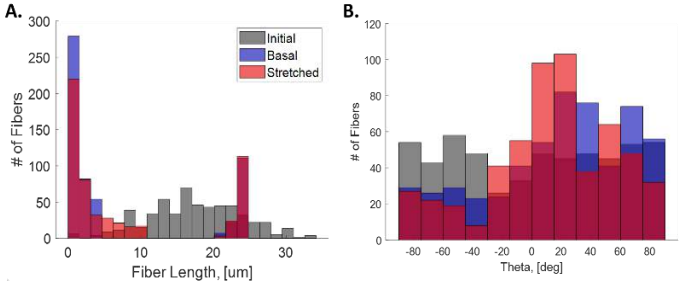

**Fig. 3. A.** Fiber length histograms showing initial state (grey), basal state (blue), and stretched state (red). **B.** Fiber orientation in the plane of stretch relative to the X-direction showing initial state (grey), basal state (blue), and stretched state (red).

**DISCUSSION**

The model described above is a new method for understanding cell mechanobiology. We show very good agreement in the cellular basal state between the experiment and the model (black box in Fig. 2) and match the qualitative trend of cell stress progression post-stretch (data points vs. lines in Fig. 2). The X-direction stress in the model is slightly elevated compared to the experiment, but the slopes of the evolution curve match quite well. The Y-direction stress in the model is slightly depressed as compared to the experiment, but we show similar behavior including an initial phase of relatively little change over the course of the first two hours, and a lower overall homeostatic stress state at the end of remodeling. Further, this model gives us increased structural insight into the cell such as the fiber orientations and growth of individual fibers (Fig. 3A, B). We see general lengthening of fibers in the stretched case as one would expect, as well as reorientation of the fibers toward the direction of stretch consistent with experimental observation [5].

*Limitations:* In its current state, the model assumes a rigid substrate. We mitigate the issues with this assumption by precisely prescribing the deformations the cell undergoes, but it will be important to include the substrate stiffness moving forward as we know there is an influence between stiffness and mechanoadaptation of cells. We have a framework developed to couple this discrete model to a finite-element mesh of the substrate where one can control the substrate behavior more accurately. We also neglect other fiber types (such as microtubules) and exclude the cell nucleus in the model in its current form. We could prescribe any number of different fiber constituents, as well as prescribing the nucleus in a method similar to the cell itself. The purpose of this study was to investigate the actin remodeling in cells, so we omit these structures for simplicity. Future work with this model will use the nucleus as a structural element that drives mechanoadaptation based on the stress experienced by the nucleus itself.

## INTRODUCTION

The facet capsular ligament, which is primarily composed of collagen fibers arranged in the extracellular matrix (ECM) network with afferent neurons embedded in that ECM [1,2], is a common source of pain in both the cervical and lumbar spines [3,4]. Injury and/or damage to the capsular ligament has been shown in animal models to result from excessive stretch of the ligament, which induces laxity and collagen disorganization in the ligament [5,6] and induces pain and injury responses in afferent nerve fibers via mechanotransduction [4,7-8]. Those neuronal responses are rate-dependent [9]. Further, the local biomechanical environment surrounding afferents has been shown to alter their neuronal response [10] for systems like the capsular ligament. In addition, the biomechanical response of ligaments is also known to vary with loading rate [11-14]. Although the effect of loading rate has been studied for ligament injuries [12,13] and neuronal injury is rate-dependent [15-18], little is known about the effects of loading rate on neuronal activity and pain signaling.

Our lab has developed a neuron collagen gel construct (NCC) in vitro system that enables the integrated investigation of macroscale and local mechanics, along with neuronal responses, to better understand joint pain and injury [19-22]. That NCC system has been used to define relationships between local mechanics, collagen fiber responses and neuronal mechanisms relevant to nociception. In fact, collagen realignment, which likely modulates neuronal responses [10], occurs to a lesser extent when the rate of uniaxial tension is increased by 7-fold [19,20]. While that work suggests loading rate to be important, most work with the NCC system has been limited to a slow strain rate (i.e. 1%/s) [21,22]. However, ligament trauma is known to occur at much faster rates [13]. As such, this study aimed to define the macroscale biomechanical response and corresponding microscale regional strains for NCCs undergoing stretch at a high rate of loading (10.5mm/s), corresponding to an order of magnitude greater than previous work [19,22].

## METHODS

NCCs (n=11) were prepared using 2.0mg/mL of rat tail collagen I solution cast in 12-well plates as previously described [19-22]. Briefly, collagen gels self-assembled at 37°C in 5% $CO_2$ for at least 45 minutes and were seeded with DRG neurons ($3x10^5$ cells/mL) dissociated from embryonic day 18 rats [19]. After 3 days in vitro, more collagen was added to encapsulate the neurons and the NCCs.

On day-in-vitro 7, NCCs were transferred to sterile phosphate buffered saline (PBS) and cut into a strip (21mm x 8mm). A marker grid was drawn on each NCC surface to define smaller regions, allowing elemental strain analyses (Figure 1). Gels were submerged in a 37°C PBS bath, and each arm was fastened to microclamps of a planar testing machine (TestResources) that was integrated with a high-speed camera (Phantom-v9.1; Vision Research; Inc.) [19-22]. NCCs were stretched to failure uniaxially with each arm distracted at 10.5mm/s. Force and displacement data were recorded at 500Hz and synchronized with imaging data (500fps).

Force and displacement data were filtered using a 25-point moving average filter [19-22]; failure was defined as the maximum point of the force-displacement curve for each loading arm (Figure 1A). Stiffness was calculated as the slope of the force-displacement curve between 20% and 80% of maximum force [23] (Figure 1A). Each of the failure force and displacement, as well as stiffness, was averaged across both arms for each NCC. Elements of each NCC were defined using the fiducial markers as elemental nodes (Figure 1). Nodal displacements were measured using ProAnalyst software (Xcitex) and input into LS-DYNA (LSTC) to compute both the peak maximum principal strain

(MPS) from any element in each NCC and also the mean MPS across all elements for each NCC (Figure 1) [19-22].

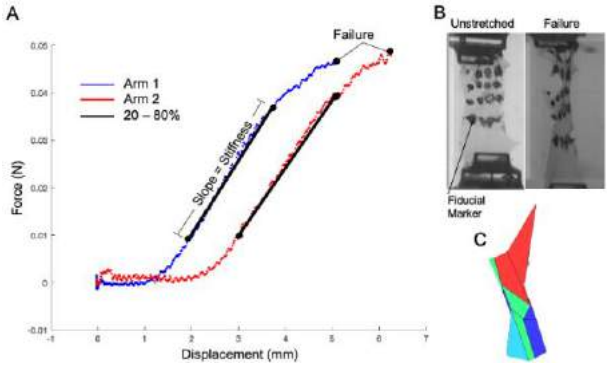

**Figure 1: (A) A representative force-displacement curve. (B) Representative images at reference (unstretched) and failure, with the (C) corresponding MPS map of the sample at failure.**

## RESULTS

The measured displacement rate across all NCCs is 9.7±0.6mm/s, corresponding to an imposed strain rate of 92.4±5.6%/s. At this rate of applied stretch, the NCCs fail at a force of 25.6±14.6mN and a displacement of 4.5±1.2mm. The corresponding stiffness for loading at this rate is 10.2±5.6mN/mm. Image data were available for strain analysis from only 6 of the total 11 NCCs due to poor image quality or asynchronous acquisition during the applied distraction. The mean elemental MPS in those NCCs is 0.47±0.20 and the peak MPS is 0.81±0.43 at failure (Figure 2). Failure was observed to occur at either the top or bottom edge of the gel in the majority (5 of the 6) of the NCCs with imaging, corresponding to the location where the peak MPS was calculated (Figure 1C).

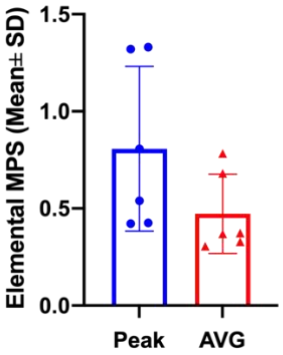

**Figure 2. Peak and average elemental MPS at failure, showing individual gel data points in circles and triangles for each outcome.**

## DISCUSSION

This is the first study to our knowledge defining the macro-scale biomechanical responses and microscale regional strains of NCCs. The force at failure is double, and the stiffness is nearly 3-fold greater than, corresponding values at failure with the same NCC system (12.6±7.3 mN; 3.1±1.1mN/mm) at a measured strain rate of approximately one-tenth (1%/s) of the rate used here [22]. This increase in macroscopic mechanical metrics is consistent with other work supporting increases in both force and stiffness with increasing loading rate for ligaments in the knee and spine stretched to failure [12,13].

However, the displacement (4.5±1.2mm in current study) at failure is similar despite the difference in loading rates (4.68±1.6mm for 1%/s).[22]. Interestingly, both the peak and average MPS are at least 3-4 times greater than the average MPS (0.12±0.07) found using a 1%/s distraction rate [22]. This difference is in contrast to reports that strain is independent of strain rate [12,13,19]. Also notable is that the standard deviation of both strain metrics (Figure 2) in the current study are relatively larger than those reported in prior studies using slower loading rates. That variability, together with the small group size for strain data may suggest the need for both more testing and more detailed investigation to define the collagen responses and micro-level mechanics.

The stiffening and strengthening of ligament tissues has been attributed to the stiffening of collagen fibrils and a reduction in fibril strain associated with matrix-debonding of inter-fibillar sidechains [24]. It is possible to integrate polarized light imaging during testing to simultaneously measure collagen kinematics in this test system [19-22], which would help not only to define reorganization of collagen but also help to better understand the strain response magnitude and regional variability. In addition, studies defining the neuronal responses in this system would help characterize the effects of traumatic loading on nerve injury, pain transmission and mechanotransduction in this unstudied high-rate loading paradigm. Nevertheless, this study demonstrates that the macroscale and microscale mechanics of NCCs is altered with increasing strain rate, exhibiting similar response to that observed in ligaments, and given the known relationship to cellular and neuronal mechanotransduction likely has implications for pain and injury.

## INTRODUCTION

Ventricle dysfunction is the most common cause of heart failure, which leads to high mortality and morbidity in the United States. However, compared to the left ventricle (LV), there is a lack of right ventricle (RV) treatment due to the poor understanding of the RV. In order to have a comprehensive view of the RV, thorough experimental and computational studies of the RV under physiological conditions are required. Our previous experimental data showed that the LV and RV exhibit different viscoelastic behaviors and the RV exhibited fully non-linear viscoelastic (NLV) behavior [1]. However, due to the complex nature of myocardium biomechanics, most computational models are hyperelastic and there is a lack of nonlinear viscoelastic models for the RV. Previous viscoelastic models on the LV adopted the quasi-linear viscoelastic (QLV) assumption and a formulation originally established by Fung [2,3]. To date, there is no computational study for the RV passive viscoelasticity using either QLV or NLV assumptions.

Therefore, the goal of the study was to characterize the RV passive viscoelastic behavior by computational modeling. We applied both QLV and NLV models to the biaxial experimental data from healthy adult ovine. Our results suggest that the NLV model is a more appropriate formulation to model the RV viscoelastic behavior, and the RV had strain–dependent, anisotropic relaxation behavior. The findings will assist the development of RV simulation to capture both energy storage and energy dissipation functions, which can help to reveal the RV failure mechanism and inspire new treatment development.

## METHODS

Details of our experimental work described in our previous study [1]. Briefly, eight fresh RVs from adult female ovine with no known cardiac disease were included. The outflow tract direction was marked as the longitudinal (L) direction and its perpendicular direction was the circumferential (C) direction. All samples underwent equibiaxial stress relaxation tests at different strain magnitudes (3, 6, 9, 12 and 15%).

We applied two viscoelastic models to the experimental data. 1) In the QLV model, stress relaxation data were fitted to Eq. 1. The instantaneous elastic stress $\sigma^e$ was derived from an anisotropic Ogden strain energy density function $W$ (Eq. 2). The reduced relaxation function ($G(t)$) with the Prony series and constraint was used to describe the relaxation response (Eq. 3), which is associated with the time constants $\tau_n$ fixed at decadal values and different $G_n$ represent the strength of the relaxation at the corresponding time constant [4,5]. A two-step fitting strategy was used in which we fitted the relaxation phase first, then fitted the entire data including the ramp phase. 2) To test the strain-dependence of the viscoelastic response, we first adopt a power law model previously used to describe tissue's NLV behavior (Eq. 4) [4,5]. A power law fitting procedure was used for the log-log scale of stress relaxation curves at different strain magnitudes [4]. From the fitting line, the initial stress ($\sigma_0$) (ordinate intercept) and the relaxation rate m (slope) were determined [4]. All fits were performed using MATLAB software.

$$\sigma(\varepsilon,t) = \int_0^t G(t-\tau)\frac{d\sigma^e(\varepsilon)}{d\varepsilon}\frac{d\varepsilon(\tau)}{d\tau}d\tau \quad (1)$$

$$W = \frac{2\mu}{\alpha^2}(\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3) + \frac{2k\mu}{\alpha^2}(I_4^{\alpha/2} + 2I_4^{-\alpha/4} - 3) \quad (2)$$

$$G(t) = G_\infty + \sum_{n=1}^{3} G_n e^{-t/\tau_n}$$

and $G_1 + G_2 + G_3 + G_\infty = 1$ (3)

$$\sigma(\varepsilon,t) = \sigma_0(\varepsilon)t^{m(\varepsilon)} \quad (4)$$

where $\varepsilon$ is strain, $\tau_n$ are time constants, $G_1$, $G_2$, $G_3$ and $G_\infty$ are relaxation coefficients, $\mu$ is the infinitesimal shear modulus, $\alpha$ is nonlinearity parameter, $k$ is anisotropy parameter, $I_4$ is anisotropic invariance, $\sigma_0$ is the initial stress, and $m$ is the relaxation rate.

Data are presented as mean ± SE. Paired Student's t-test was performed and $p \leq 0.05$ was considered significant.

## RESULTS

**The relaxation function *G(t)*, shear modulus and nonlinearity were strain dependent.** At each individual strain magnitude, the QLV model fitted the experimental data well (Fig. 1). Next, we examined the effect of strain on relaxation function. We found in both directions $G(t)$ was strongly dependent on the strain magnitude (Fig. 2A&B). Furthermore, the RV's shear modulus increased with increased strain level and had altered nonlinearity as strain increased (Fig. 2C&D).

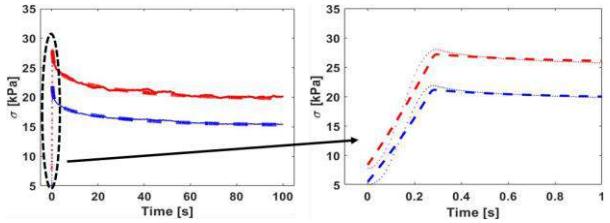

**Fig 1.** Representative fitting results of the QLV model.

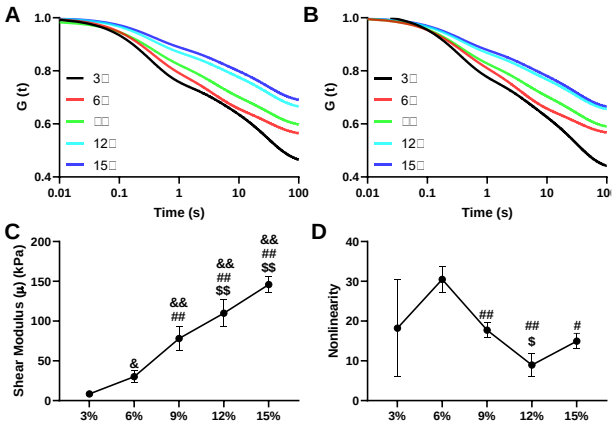

**Fig 2.** Averaged fitted reduced relaxation function *G(t)* in longitudinal (A) and circumferential (B) directions. (C&D) show the strain-dependent shear modulus and nonlinearity of the RV. $^{\&}$<.05, $^{\&\&}$<.01, $^{\#}$<.05, $^{\#\#}$<.01, $^{\$}$<.05, $^{\$\$}$<.01, vs 3, 6 and 9%, respectively.

**The *G(t)* coefficients were strain-dependent and $G_1$ and $G_3$ *i*differently contribute to relaxation response at low and high strains.** In both directions, the *G(t)* coefficients were strongly dependent on strain magnitudes (Fig. 3A&B). Interestingly, the $G_\infty$ was monotonically increasing with increased strains whereas the opposite behavior was observed for the $G_1$. At most strain levels, the relaxation coefficients did not differ between directions, except that at 15% of strain there was a larger $G_\infty$ in the L than C direction (Fig. 3A). Furthermore, we also observed that in both directions, $G_1$ and $G_3$ were both prominent at low strain (3%), whereas at high strain (15%) only $G_3$ was more prominent (Fig. 3C&D). This indicate that the dominant $G_n$ varied at different strain levels.

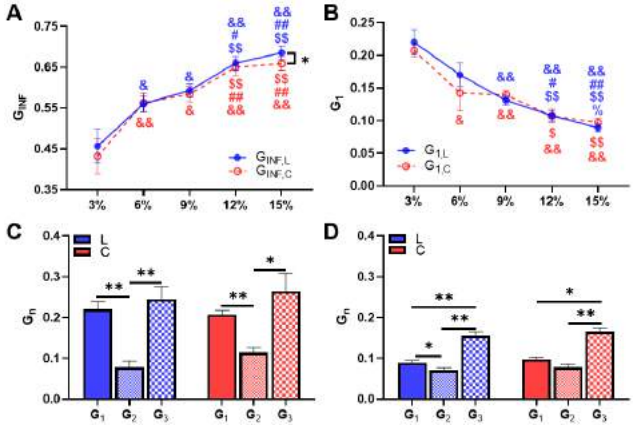

**Fig 3.** (A&B) $G_\infty$ (shown as $G_{INF}$) and $G_1$ vary with strain levels in both directions. At the fixed strain of 3% (C) and 15% (D), $G_n$ show varied values and the trends are similar between two directions. $^{\&}$<.05, $^{\&\&}$<.01, $^{\#}$<.05, $^{\#\#}$<.01, $^{\$}$<.05, $^{\$\$}$<.01, $^{\%}$<.05 vs 3, 6, 9 and 12%, respectively and $^{*}$<.05, $^{**}$<.01.

**The relaxation rate and initial stress were different between directions.** In both directions, with increased strain, the RV had a slower relaxation rate with larger initial stress (Fig. 4), this suggests fully nonlinear viscoelastic behavior. These relations were well fitted by a 2nd polynomial function, indicating a dependence on the square of strain [4]. Furthermore, the RV had different relaxation rate at 15% of strain and different initial stress at 6-12% of strain between L and C directions, which indicate an anisotropic relaxation behavior.

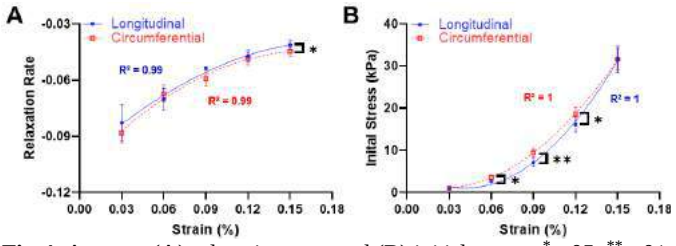

**Fig 4.** Average (A) relaxation rate and (B) initial stress. $^{*}$<.05, $^{**}$<.01.

## DISCUSSION

To best of our knowledge, this is the first study to model the RV passive viscoelastic behavior. In this study, we applied both QLV and NLV theories to the biaxial experimental data. Our results suggest that the relaxation function *G(t)* was strain-dependent and had a diverging behavior in both directions (Fig. 2A&B). Therefore, despite a good fitting of the QLV model at individual strains, an NLV constitutive formulation should be more appreciate to model the RV viscoelasticity.

Nevertheless, we found some interesting characters of the RV viscoelasticity based on the QLV model. As the strain increased, the RV had a larger shear modulus and initially increasing and then decreasing nonlinearity (Fig. 2C&D). This behavior may be linked to the recruitment process of the collagen fibers and different contributions of myofiber and collagen to RV viscoelasticity at different strains. When the collagen becomes gradually recruited from low to high strains, the monotonically increasing shear stress indicates an increasing contribution of collagen in load bearing. But the nonlinearity may be affected by collagen and myofiber orientation and inter-fibril sliding patterns, and thus the change was biphasic. We also observed anisotropic RV relaxation response at end-diastole (15% of strain), which is evidenced by a larger $G_\infty$ (Fig. 3A) and a slower relaxation rate (Fig. 4A) in the L direction. Since more collagen fibers are recruited at high strain, the anisotropic viscoelastic behavior may be attributed to collagen rather than myofibers. Furthermore, we observed that, at small strain (3%), the $G_1$ and $G_3$ had similar strength of the relaxation, whereas at the high strain (15%), $G_3$ had the largest strength of the relaxation than other coefficients (Fig. 3C&D). This implies different dominant $G_n$ at different strain levels. Overall, $G_1$-$G_3$ were reduced as the strain increased, and this agrees with the reduced relaxation response of RV at higher strains shown in Fig. 2A&B. We postulate that the dominant role of myofibers at low strains may explain the enhanced viscoelasticity at low strains. The potential molecular mechanisms that determines these $G_n$ awaits further investigation. Lastly, from the NLV model, we observed that the relaxation rate and initial stress were strongly correlated with the square of the strain rather than the strain (Fig. 4). These findings merit further study into RV structure-function relations responsible for the nonlinear viscoelasticity.

# A HYBRID DISCRETE-CONTINUUM ANALYSIS OF REMODELING IN ARTERIES: AN ASSESSMENT OF MICROSCOPIC FEATURES FROM MACROSCOPIC OBSERVABLES

**Ryan R Mahutga (1), Elizabeth Gacek (1), Victor H Barocas (1)**

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

The study of tissue growth and remodeling (G&R) remains an open question. Of particular interest in the biomedical space is predicting how a tissue will grow and remodel in response to various therapeutics. Traditional continuum-based computational growth and remodeling frameworks are an excellent and efficient method for understanding macroscopically observable phenomena (e.g. aneurysmal growth, cardiac hypertrophy) [1,2]. However, such frameworks lack the robustness to evaluate microstructural characteristics including fiber-by-fiber evolution within the extracellular matrix (ECM) and constituent cells, local mechanical heterogeneity in the tissue, and overall tissue strength in various physiological loading scenarios. Such factors are of particular importance in the evaluation of aortic aneurysm, where growth rate and overall size have historically been the only markers of risk, and have been shown to be inadequate in many cases [3]. In this work, we detail a technique using a discrete-microstructural network of the ECM to inform a continuum-based finite-element (FE) G&R model. We apply this model to aortic remodeling and assess clinically and experimentally observed phenomena including growth, tissue stiffness, and fiber volume fraction. We relate these features to microstructural evolution providing insight into the remodeling process.

## METHODS

We utilize microstructural discrete-fiber networks to represent a tissue's ECM (collagen and elastin), and cellular stress fibers (actin), as shown in Fig 1A. The networks are generated from a periodic Delaunay tessellation using the tetrahedron edges as fibers. Fibers are linked at the nodes of the tessellation tetrahedra via a pin joint. We define collagen fibers to have a nonlinear behavior based on a helical spring model, elastin fibers to be linear, compliant springs, and actin to be slightly stiffer, linear springs (for full details see [4]). To solve for the internal equilibrium of the network subject to a deformation, we use Newton-Raphson iteration to minimize the forces on all nodes.

Each fiber in each network remodels separately based on its own fiber stress. The assumption is made that the cells remodel the microstructure to approach a defined target stress for each individual fiber (local application of tensional homeostasis), which, in turn, results in a net tissue equilibrium state. This remodeling model is given by

$$\frac{dR^p}{dt} = \frac{1}{\tau}\left(\frac{\sigma^p}{\sigma_\infty} - 1\right) R^p i; \frac{dL^p}{dt} = k\frac{dR^p}{dt} \quad (1)$$

where $R^p$ is the fiber radius, $t$ is time, $\tau$ is the remodeling time constant, $\sigma^p$ is the fiber stress, $\sigma_\infty$ is the homeostatic fiber stress, $L^p$ is fiber initial length, and $k$ is a parameter relating fiber lengthening to fiber thickening. For our study, we used $\tau_{collagen} = 90 days$, $\sigma_{\infty,collagen} = 200 iMPa$, $\tau_{actin} = 4.5 idays$, $\sigma_{\infty,actin} = 750 kPa$, and $k = 60$. The elastin fibers do not remodel.

As the fibers remodel, the network zero-stress state is updated by finding a new deformation such that the average stresses in the network are zero. More precisely, we reduce the problem to finding the diagonal terms of $F^g_{kN}$, which are the growth stretches $\lambda^g_i$, such that the stresses on the diagonal of the volume-averaged Cauchy stress $\sigma_{ij}$ are zero, since the shear stresses are relatively small throughout the remodeling process and thus neglected. Further, to maintain network stability, we enforce an osmotic (or hydrostatic) pressure to prevent the network from collapsing. The expression for the osmotic pressure is

$$c_{fcd} = c_0 \phi i; P = RT\left(\sqrt{c_{fcd}^2 + 4c_*^2} - 2c_*\right) \quad (2)$$

where $c_{fcd}$ is fixed charge density, $c_0$ is a fixed charge scaling factor (70 mM), $\phi$ is the fiber volume fraction, $P$ is the osmotic pressure, $R$ is the universal gas constant, $T$ is the tissue temperature (310K), and $c_*$ is the external osmolarity (150 mM). Thus, the total stress in the fiber network system can be expressed as

$$\sigma_{ij}^{total} = \frac{1}{v}\sum_p f^p l^p \alpha_i^p \alpha_j^p - P\delta_{ij} \quad (3)$$

where $v$ is the volume of the network, $f^p$ is the force in fiber p, $l^p$ is the deformed length of fiber p, $\alpha^p$ is the direction vector of fiber p, and $\delta_{ij}$ is the Kronecker delta.

Using Eq. 3, we fit the behavior of our network using a continuum material 3-fiber family model with a strain-energy density

$$W = c_1(I_1 - 3) + \frac{K}{2}(ln(J))^2 + \sum_{i=1}^{3} \frac{c_2^i}{2c_3^i}\left[exp\left(c_3^i(I_4^i - 1)^2\right) - 1\right] \quad (4)$$

where $c_1$ is the modulus of the ground matrix, $I_1 = tr(C_{ij})$ is the first strain invariant of the right Cauchy-Green tensor C, $K$ is the bulk modulus, $c_2^i$ is the fiber modulus of family i, $c_3^i$ captures the nonlinearity of fiber family i, $I_4^i$ is the fourth strain invariant of C. This technique is further outlined in [5]. We take the fiber families to align with the axes of the microstructural element which are aligned as R, Θ, Z in the cylindrical case (Fig 1).

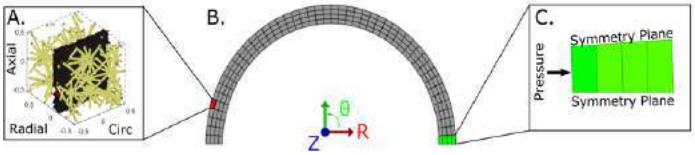

**Fig. 1: A.** Fiber network consisting of actin (yellow), elastin (black), and collagen (red) for **B.** vessel mesh element with **C.** applied boundary conditions.

The network growth and fitted material properties are model inputs into *FEBio 2.9.1* using the *Prestrain plugin* [6] where compatibility is enforced onto the macroscopic geometry based on the microstructural growth. The coupled hybrid process is shown in Fig. 2. Utilizing symmetry planes, a small wedge of the cylindrical mesh (Fig. 1) with an inner applied pressure of 100mmHg is remodeled for 235 days before pressure is increased to 150 mmHg. Circumferential stress, network fiber volume fraction, and growth stretches are analyzed throughout the 320 days of remodeling.

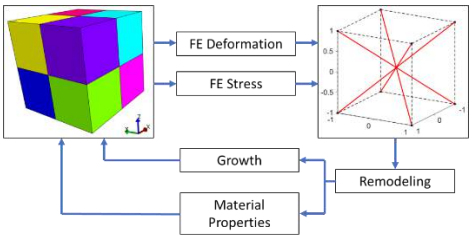

**Fig. 2:** Flowchart of coupling the finite element model of arterial inflation with the growth and remodeling scheme.

## RESULTS

We apply the model to remodel a thick-walled cylinder representing an arterial blood vessel. The vessel initially contracted going from its initial configuration (Fig 3A) to its homeostatic, normotensive (100mmHg) arterial pressure state (Fig. 3B). The vessel was then prescribed a 50% increase in pressure (150 mmHg), and allowed to re-equilibrate, where it grew in response (Fig. 3C).

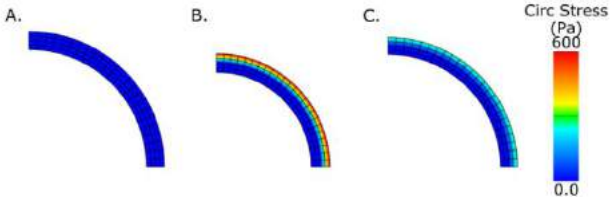

**Fig. 3:** Circumferential residual stress at **A.** t = 0, **B.** t = 235, and **C.** t = 320 days.

The main feature that makes this modeling technique so valuable is that one can observe the fiber network throughout the remodeling period. We monitor the growth of individual element networks shown in Fig. 4A where we observe through thickness variation in network growth. We also monitor the composition of the tissue shown in Fig. 4B. We note that elastin, while not being remodeled, increases in volume fraction because the tissue is compacting (Fig. 3A vs Fig. 3B). Upon the application of increased pressure, we note that the vessel grows (Fig. 3C) and, therefore, the elastin content decreases. We also see a drop in actin content and an increase in collagen content associated with this hypertensive remodeling scenario.

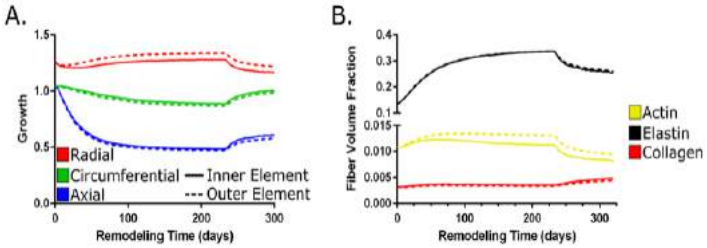

**Fig. 4: A.** Growth in the radial (red), circumferential (green), and axial (blue) direction at the inner (solid) and outer (dashed) radius. **B.** The fiber volume fraction for actin, elastin, and collagen. Pressure increased from 100 mmHg to 150 mmHg at t = 235 days.

## DISCUSSION

This technique is the marriage of two powerful and insightful computational strategies, one of which is extremely efficient (FE analysis) and one of which gives a high degree of structural detail (discrete microstructural analysis). The hybridizing of the two allows us to maintain structural detail without loss of computational efficiency by coarse graining the microscale mechanics in the macroscale simulation, but maintaining the detail in the actual remodeling process.

We analyze a standard problem in the G&R field in this work, and have a qualitative agreement with previously published models [7], as we see circumferential growth in response to increased pressure (Fig. 3C, Fig. 4A), and a decrease in actin and elastin content with an increase in collagen content (Fig. 4B).

This model not only captures the G&R behavior, but will allow us to investigate other pertinent properties that are often lost in standard continuum G&R approaches. For instance, we are particularly interested in tissue strength and the modes of failure in physiological loading. This approach is readily adapted to local failure assessment following [4], which will be insightful for analysis of therapies and surgical intervention.

## ACKNOWLEDGEMENTS

## INTRODUCTION

Cartilage tissue engineering (TE) is a promising osteoarthritis treatment strategy whereby chondrogenic cells are embedded in scaffolds to generate cartilage replacement tissues. TGF-β is prominent cartilage TE growth mediator due to its efficacy in accelerating extracellular matrix (ECM) biosynthesis. An assortment of TGF-β delivery platforms are currently in development, varying by delivery mode (e.g. media supplementation, scaffold loading) and administered dose (0.3-2000ng/mL) [1]. Cells are highly sensitive to TGF-β dose—low doses may be insufficient to induce ECM enhancements and excessive doses can lead to fibrosis [2], hyperplasia [3], or biosynthetic suppression [4] As such, TGF-β delivery optimization may be critical for TE outcomes.

Methodology to optimize TGF-β exposure in delivery systems remain limited. Optimization predominantly consists of empirical measures of TGF-β desorption from acellular scaffolds with the goal of maximizing scaffold retention durations [1]. However, these assessments provide limited predictive capabilities and do not provide quantitative insights into TGF-β activity levels to which cells are exposed. As an alternative approach, reaction-diffusion modeling frameworks that account for chemical reaction kinetics in TE cartilage (e.g. scaffold/ECM binding, cell-mediated internalization, enzymatic degradation) can potentially be used to predict temporo-spatial distribution of different states of TGF-β in TE constructs that are important for clinical outcomes, including: 1) scaffold-bound TGF-β, 2) available free TGF-β, 3) cell-internalized TGF-β, and 4) TGF-β desorbed into synovial joint tissues. As such, modeling can be used to optimize scaffold design parameters to improve TE growth outcomes.

Here, we advance the development of predictive reaction-diffusion modeling frameworks by characterizing chemical reaction constitutive relations that can be influential of TGF-β delivery outcomes, including TGF-β-scaffold/ECM reversible binding and TGF-β cell-mediated internalization reactions. Characterizations are performed over the range of TGF-β doses used in TE applications (0.3-2000 ng/mL) and assessed in the absence or presence of intracellular TGF-β signaling processes. Lastly, finite element (FE) models are implemented to examine the impact of chemical reactions on the spatiotemporal distribution of TGF-β in TE constructs for media supplementation and scaffold loaded delivery platforms.

## METHODS

**Tissue source**: Immature bovine chondrocytes were seeded in 2% agarose ($45\times10^6$ cells/mL) to form ∅2×1mm TE constructs [5]. Freshly-cast constructs were maintained live in chondrogenic media (CM) [5] or subjected to an initial freeze-thaw cycle to induce rapid devitalization for reaction kinetic characterizations.

**Binding kinetics:** Devitalized constructs were exposed to a range of TGF-β3 doses (0.3-2000ng/mL) for 48h (n=3/dose). Bound TGF-β3 was extracted and measured via ELISA as performed previously [5]. Binding models were curve-fit to experimental data: 1) Langmuir isotherm (Eq.1)—accounting for reversible binding to construct binding sites, and 2) BET isotherm (Eq.2)—accounting for additional aggregation of TGF-β bound to binding sites:

$$C_{B_T} = \frac{C_F N_T}{C_F + K_o} \quad (1) \qquad C_{B_T} = \frac{N_T c x[1-(M+1)x^M + Mx^{M+1}]}{[1-x][1-x+cx-cx^{M+1}]} \quad (2) \qquad c = K_o/K_c \;\; x = C_F/K_c$$

where $C_{B_T}$ and $C_F$: bound and free TGF-β dose, respectively, $N_T$: surface binding site density, $M$: maximum number of aggregated TGF-β molecules at a binding site, $K_o$ and $K_c$: dissociation constant for scaffold-to-TGF-β binding and TGF-β-to-TGF-β binding, respectively. Uptake ratio, $R_U$, was calculated as the ratio of total TGF-β dose ($C_B$+$C_F$) within the construct to free TGF-β dose ($C_F$).

**Internalization rate kinetics**: Live constructs were exposed to TGF-β3 in CM (100 μL) at the aforementioned doses. The cell-mediated internalization rate, $V_i$, of TGF-β3 in constructs was determined by

monitoring the transient TGF-β3 concentration decrease in the bath over 48h and curve-fitting the response with our reaction-diffusion model, which accounts for TGF-β diffusion (Eq.3), scaffold/ECM reversible binding and TGF-β aggregation (Eq.4&5, respectively), and cell-mediated internalization (Eq.6) of TGF-β in constructs:

$$\frac{\partial C_F}{\partial t} = D\nabla^2 C_F \quad (3) \qquad \frac{\partial C_F}{\partial t} = k_r C_B - k_f C_F N_T \quad (4)$$

$$\frac{\partial C_F}{\partial t} = k_{r_1} \sum_{i=1}^{M-1} C_{B_{i+1}} - k_{f_1} C_F \sum_{i=1}^{M-1} C_{B_i} \quad (5) \qquad \frac{\partial C_F}{\partial t} = R_i C_F \quad (6)$$

where $D$: TGF-β diffusivity, $k_r$&$k_f$: reverse and forward binding constant, respectively, $R_i$: internalization rate constant. The transient TGF-β3 bath decrease was curve fit for $R_i$ using our measured binding parameters as performed previously [5]. The influence of intracellular TGF-β signaling dynamics was further assessed by repeating $R_i$ measurements in the presence of a TGF-β receptor kinase inhibitor (5μg/mL, LY364947). Subsequently, $V_i$, (internalized TGF-β molecules per cell per second [mol/cell/s]) was calculated as $R_i \times C_F$.

**TGF-β transport modeling: Media-supplemented delivery:** FE simulations were implemented using measured reaction kinetics parameters to predict the uptake of media-supplemented TGF-β in constructs (∅6×3mm) at a 10 or 800 ng/mL dose ± TGF-β internalization kinetics and ± intracellular TGF-β signaling.

**Affinity-scaffold-loaded delivery:** FE simulations were implemented to predict the retention of scaffold-loaded TGF-β (800ng/mL) in heparin-affinity scaffold constructs using previously measured heparin -to-TGF-β binding parameters ($k_r$:$9.2\times10^{-3}s^{-1}$&$k_f$:$1.0\times10^{5}(M.sec)^{-1}$)[6] and measured internalization rate ± TGF-β internalization kinetics.

## RESULTS

**Binding kinetics:** The TGF-β uptake ratio increased with dose, ranging from $R_U$=11.4 at 0.9 ng/mL to $R_U$=32.1 at 1400 ng/mL. While this binding response could not be described by the Langmuir model ($R^2$<0.01), it could be faithfully described by the BET isotherm model ($R^2$=0.99, Fig 1A).

**Internalization rate kinetics:** In the low dose regime (0.3-100ng/mL), $V_i$ exhibited a Michaelis-Menten relationship ($R^2$=0.96; Fig 1B), saturating at a rate of 2mol/cell/s. In the high dose regime (100-2000ng/mL), $V_i$ increased linearly with dose ($R^2$=0.96), reaching a rate of 504mol/cell/s at 2000ng/mL. For all doses in the high regime, TGF-β signaling inhibition induced a significant decrease in $V_i$ ($p<0.05$, Fig 1C).

**TGF-β transport modeling: Media-supplemented delivery:** Media-supplemented 10ng/mL TGF-β exhibited pronounced steady-state gradients in constructs in the presence of cell-mediated internalization whether or not TGF-β signaling dynamics were present (Fig 2). In contrast, 800ng/mL supplemented TGF-β exhibited pronounced steady-state gradients but gradients were mitigated upon TGF-β signaling inhibition (Fig 2). For both doses, gradients were greatly mitigated in the absence of cell-mediated internalization.

**Affinity-scaffold-loaded delivery:** Cell-mediated internalization led to a rapid loss of loaded TGF-β, exhibited by an 80% loss in the constructs after 2 days. In the absence of internalization, over 40% of TGF-β was retained in the construct after 20 days (Fig 3A&B).

## DISCUSSION

This work establishes novel quantitative relations of dose-dependent TGF-β chemical reaction kinetics and provides expanded insights into its biochemical behavior in TE systems. For characterizations of TGF-β binding kinetics, we observe that TGF-β binding to constructs increases with dose. This response contrasts with behavior predicted by Langmuir, in which the uptake ratio is expected to decay to a value near unity as tissue binding sites saturate, thus suggesting the occurrence of TGF-β aggregation events at tissue binding sites. This aggregation phenomenon is consistent with prior examination of TGF-β binding events [7] and can be predicted by a BET isotherm model, that accounts for multiple layers of aggregated TGF-β at each tissue binding site. For characterizations of TGF-β cell-internalization kinetics, we observe an intriguing interplay between TGF-β dose and intracellular TGF-β signaling dynamics. The internalization rate exhibits a unique biphasic response, following Michaelis-Menten kinetics at low doses (<100ng/mL), saturating as a value $V_i$=2.4 mol/cell/s, but increasing further with a linear relationship at higher doses (>100ng/mL). A striking aspect of this characterization is the remarkably high TGF-β internalization rates measured at high doses—reaching 500 mol/cell/s at 2000 ng/ml—particularly when considering the documented limited number of TGF-β receptors at the cell surface (~10k receptors) [8]. These elevated TGF-β internalization rates can be suppressed at high doses by blocking intracellular TGF-β signaling, thus suggesting a role of TGF-β signaling in upregulating internalization machinery to clear high doses of TGF-β from the extracellular space. Reaction kinetics are predicted to have a significant impact on the spatiotemporal distribution of delivered TGF-β to TE constructs. For conventional 10ng/mL media-supplemented delivery, TGF-β internalization kinetics give rise to pronounced steady state gradients in TE constructs with TGF-β penetrating less than 500μm into the tissue—remarkably, gradients are also present with an 800ng/mL dose due to elevated internalization rates resulting from intracellular TGF-β signaling. For scaffold delivery, while heparin affinity domains can promote long term TGF-β retention, retention is far reduced in the presence of TGF-β internalization kinetics as affinity domains compete for TGF-β with cell internalization machinery. Overall, this work demonstrated the potential significant impact of chemical reactions on the delivery of TGF-β in TE applications and sets the foundation for using reaction-diffusion frameworks to modulate delivery platform parameters to optimize TGF-β delivery to TE constructs.

## INTRODUCTION

Coordinated collective cell migration is a fundamental biological process particularly important for the proper formation of tissues and organs during embryonic development[1]. During vertebrate gastrulation, mesoderm and endoderm precursor cells associate to form a mesendodermal mass. Mesendoderm cells maintain adhesions to one another and exert tension between C-Cadherin complexes and integrin-dependent contacts with a fibrillar fibronectin matrix at the inner surface of the blastocoel roof (BCR), which serves as a migratory substratum[2]. Mesendoderm cells migrate collectively with front row leader cells polarized in the direction of travel and with follower cells dragged along by leader cells[2-3]. Leader cells extend monopolar protrusions forward on the fibronectin matrix and generate significant traction stresses, while follower cells form random transient attachments to the BCR substrate below them[4]. Prior studies of these movements utilized the Dorsal Marginal Zone (DMZ) explant from developing *Xenopus laevis* embryos[2]. However, these movements and mechanisms remain challenging to observe and measure *in-vivo* while *in-vitro* explants (e.g., DMZ) may not demonstrate the full range of behaviors that occur in the embryo. Because these mechanisms of cell migration and resultant tissue formation are difficult to investigate experimentally, computational methods may provide insight into the contributions of the multiple morphogenic mechanical mechanisms present as they drive embryonic development.

In-silico experiments have the potential to predict and/or reveal cellular dynamics that are difficult to observe in wet bench analysis and lead to new hypotheses that drive further *in-vivo* and *in-vitro* experimentation. In this work, we introduce a computational multicellular model developed in the Cellular-Potts framework to represent the mechanics of a tissue of collectively migrating cells, built to recapitulate observed behaviors of the *Xenopus laevis* DMZ explant. Our model represents a computational tool with which to perform in-silico experiments to further investigate fundamental mechanics of collective cell migration.

## METHODS

The Cellular-Potts Model framework (CPM, also known as the Glazier-Graner-Hogeweg model) as implemented in the open-source simulation environment Compucell3D was chosen to approximate the behavior of the DMZ explant because the method effectively captures the inherently stochastic behavior of biological cells and tissues. In the Cellular-Potts formulation, single cells are represented as a collection of pixels on a square lattice. These computational "cells" are given properties of predefined volume, contact affinity with surrounding cells and substrate, and spring-like mechanical objects called "links" representing properties of cell adhesion and formation of lamellipodia. These properties are defined mathematically in the Effective Energy function *H*, which is evaluated for every cell during each computational timestep[5]. To approximate the DMZ explant, a bilayer of tissue was created by pre-defining a tissue 8 cells in width, 4 cells in length, and 2 cells in height where each cell occupied 5x5x5 voxels (to represent approximately 30x30x30μm). Cells were placed upon a two-dimensional substrate consisting of 1x1x1 volumes of material so that simulated cells could form links to the simulated substrate to represent experimental cell-substrate attachments. The front row of cells was defined to be of the "leading edge" cell type. Equation (1) represents the Effective Energy function which imposes the physical properties of each cell in the model.

$$H = \sum_{i,j,neighbors} J\left(\tau_{(\sigma(i))}, \tau_{(\sigma(j))}\right)\left(1 - \delta_{\sigma(i),\sigma(j)}\right) + \lambda_{volume}\left(V_{cell} - V_{target}\right)^2 + \left(\sum_{i,j,cell\ neighbors} \lambda_{ij}\left(l_{ij} - L_{ij}\right)^2\right) \quad (1)$$

The first term models cell affinity for neighboring cells and surrounding medium governed by the contact coefficient *J* where *i*, *j*, denote neighboring lattice sites, $\tau$ denotes cell types, and $\sigma$ denotes individual cell ID's in the simulation. The second term imposes a

volume constraint $\lambda_{volume}$ on each cell. The third term represents the forces of elastic links which represent persistent cell-cell adhesion within the tissue, where $\lambda_{ij}$ represents the Hookean spring constant of a link between neighboring cells *i* and *j*, *l* represents the distance between the centers of mass of neighboring cells, and *L* is the target length of the spring-like link. Additional elastic links model the random attachments that passive cells form with their substrate. Leading edge cells have an additional term detailed in equation (2) to represent the constant-tension traction force between the cell's lamellipodium and the substrate.

$$Hi = \lambda_{Lamellipodia} * l \quad (2)$$

Lamellipodial extension and retraction behaviors are modeled as a Poisson process whereby the probability $P_\tau$ of an extension/retraction event occurring per timestep is approximated by equation (3)

$$P_\tau = 1 - e^{\lambda} \quad (3)$$

We calibrated the Poisson parameter λ to reflect observed mesendoderm lamellipodial cycling rates obtained from video data collected for the development of the model.

## RESULTS

The migration speed of leading-edge cells was calibrated to match literature migration speeds of 107 μm/hr[2]. The model recapitulates migrating mesendoderm at a temporal resolution of 5 seconds per Monte Carlo Step (MCS, the intrinsic timestep of the model's CPM methodology).

We applied our model to perform an in-silico experiment simulating the *in-vitro* experimental disruption of fibronectin binding by computationally disrupting lamellipodial links after 100 minutes. Our experiments reproduced observed "hold-fast" retraction behavior of living mesendoderm tissue after application of a function-blocking monoclonal antibody (mAB) directed against the "synergy site" of fibronectin as reported by Davidson et. al[2]. This behavior implies that migrating mesendodermal tissue is under anisotropic tension in the direction of migration during development. Figure 1. shows the "hold-fast" behavior whereby tissue retracts approximately one cell diameter both from a representative simulation and as observed *in-vitro*.

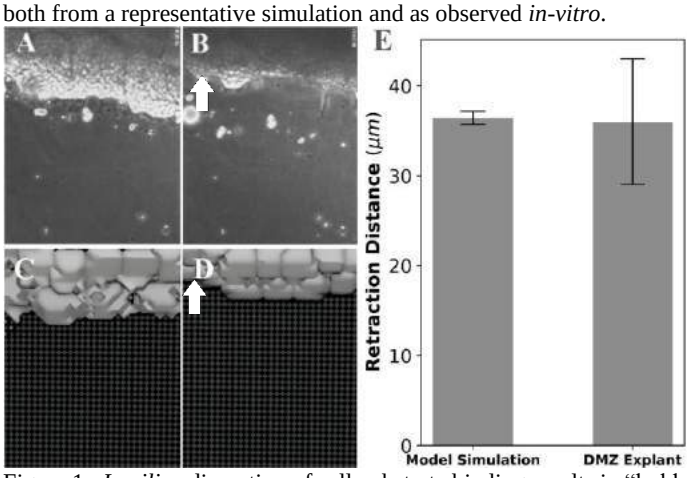

Figure 1: *In-silico* disruption of cell-substrate binding results in "hold-fast" behavior that has been observed in experiments. Top-down images from a representative experimental DMZ explant before (A) and after (B) disruption of cell-substrate binding via function-blocking mAB. Similar top-down images from a representative simulation before (C) and after (D) disruption of cell-substrate binding. White arrows represent the simulated (B) and experimentally observed (D) retraction direction. Quantitative comparison of measured retraction distances from 10 experiments each shown in (E).

## DISCUSSION

In this work, we present a novel multi-layered model of collective cell migration calibrated to experimental data of explant tissue removed from developing *Xenopus laevis* embryos. Our model employs the Cellular-Potts methodology to represent the multiple mechanical mechanisms underlying gastrulation movements in development as well as the stochastic nature of biological cells. The model reproduced experimentally measured migration speeds (data not shown). We also applied our model to observe the snap-back behavior previously demonstrated experimentally by blocking binding to the synergy site of fibronectin thus reproducing similar directional tissue tension characteristic of migrating mesendoderm tissue.

Few three-dimensional models characterize collective cell migration during early development. Prior efforts to investigate the mechanics contributing to collective cell migration often describe two-dimensional monolayers during important physiologic phenomena such as wound healing, re-epithelialization, or cancer metastasis[6-7]. Three-dimensional models are better suited to studying tissue morphogenesis as they can capture the mechanics of multiple layers of cells and developing cell types.

Our initial model recapitulates elements of physical cell and tissue mechanics and at present, offers limited insight into biochemical mechanisms of migration such as chemotaxis in response to morphogen gradients. Additionally, our model does not fully capture the complex geometry of the tissue when present in the embryo such as the toroidal shaped tissue that forms during late gastrulation in the *Xenopus laevis* embryo[2,4]. Future models will investigate how cellular mechanics give rise to tissue-level behaviors characteristic of these more complex geometric configurations. Modeling more elaborate tissue geometries will yield new insights into the emergence of complex tissue-scale dynamics occurring during development and morphogenesis.

## INTRODUCTION

Traumatic brain injury (TBI) is a leading cause of death and disability[1,2] that results from a direct impact or blast when the force applied to the head exceeds the protection provided by the skull-brain interface[3]. Despite the prevalence and severity of TBI, the brain's response to trauma and the mechanisms involved with injury remain unclear. Quantifying the relative motion between the brain and skull at this interface can help researchers better understand how skull acceleration leads to brain injury. Data on skull-brain coupling can be used to improve computational TBI models that will elucidate these mechanisms and aid in the design of protective equipment[4]. Magnetic resonance elastography (MRE) can measure brain deformation noninvasively to estimate brain mechanical properties but can also be used to measure the relative motion of the skull and brain *in vivo*[5,6]. Previous work introduced a method to separately measure the relative motion of the skull and brain by isolating signal from fat in the bone marrow[3]. In this study, we expand on that approach using a modified multishot spiral MRE sequence to simultaneously measure both skull and brain motion to ultimately quantify the transmission of motion from the skull to the brain.

## METHODS

**Imaging:** MRE displacement data of the brain and skull was acquired using a modified 2D multishot spiral MRE sequence[7]. We used a 12-shot constant-density spiral sequence with no fat suppression to see the fat signal while minimizing blurring through short data readout times. All scanning was conducted using a Siemens 3T Prisma MRI scanner and a 64-channel head coil. Vibrations were generated at 50 Hz and 100 Hz using a Resoundant pneumatic actuation system (Rochester, MN) and a passive pillow driver (Figure 1). Low motion encoding gradient strength (5 mT/m) was used to capture rigid body motion of both the skull and brain while avoiding temporal phase wrapping[3,5].

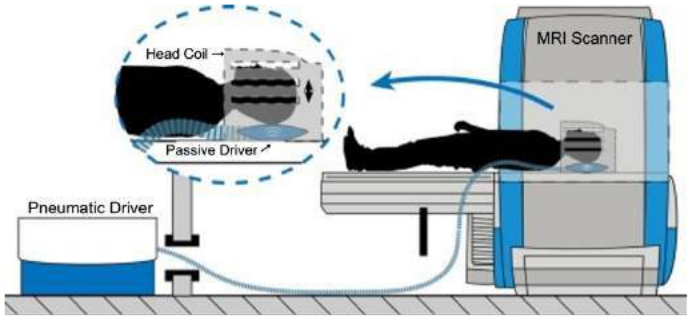

**Figure 1: Overview of MRE setup and acquisition showing the external mechanical driver inducing shear waves into the brain through inflation of the passive driver.**

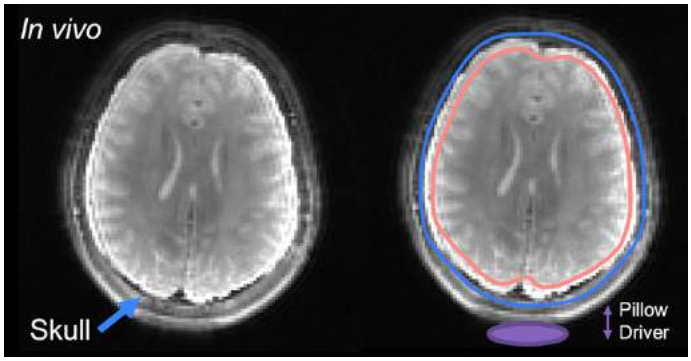

**Figure 2: Magnitude images from an adapted 2D multishot spiral MRE sequence. Both water and fat components are visible, and masks of the brain and skull are overlayed.**

***In vivo* Testing:** A single human subject (female, age 23) was scanned using the fat-water MRE sequence at both 50 Hz and 100 Hz vibration frequencies.

**Analysis:** Imaging data was iteratively reconstructed[8]. Phase images were processed to obtain maps of complex motion with sensitization in the x (left-right), y (anterior-posterior), and z (superior-inferior) directions. Representative masks were created at the interface of the skull and brain (Figure 2). Points around the circumference of the skull were defined in terms of polar coordinates and described by their polar angle, $\theta$. Displacement amplitude and relative phase of the harmonic motion was quantified for each point in both skull and brain.

## RESULTS

Our *in vivo* analysis of brain and skull motion showed an overall lower displacement amplitude of the brain relative to the skull, indicating reduced transmission of motion to the brain in all three directions (Figure 3). The skull motion amplitude appears to follow a sinusoidal pattern for each individual direction starting from the site of actuation and represents the rigid body motion in three dimensions. The brain shows a similar pattern but at a lower amplitude than the skull.

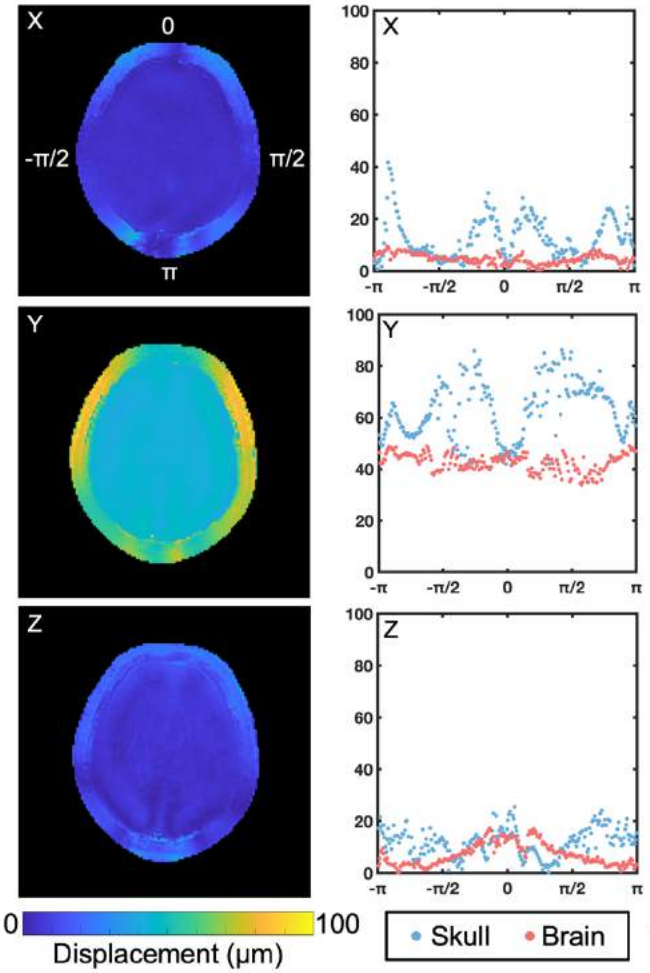

**Figure 3: Motion amplitude in the x, y, and z directions at 50 Hz.**

The phase plots show that the skull and brain are moving out of phase in both the x (left-right) and z (superior-inferior) directions while the brain and skull in the y direction (anterior-posterior) appear to remain in phase (Figure 4).

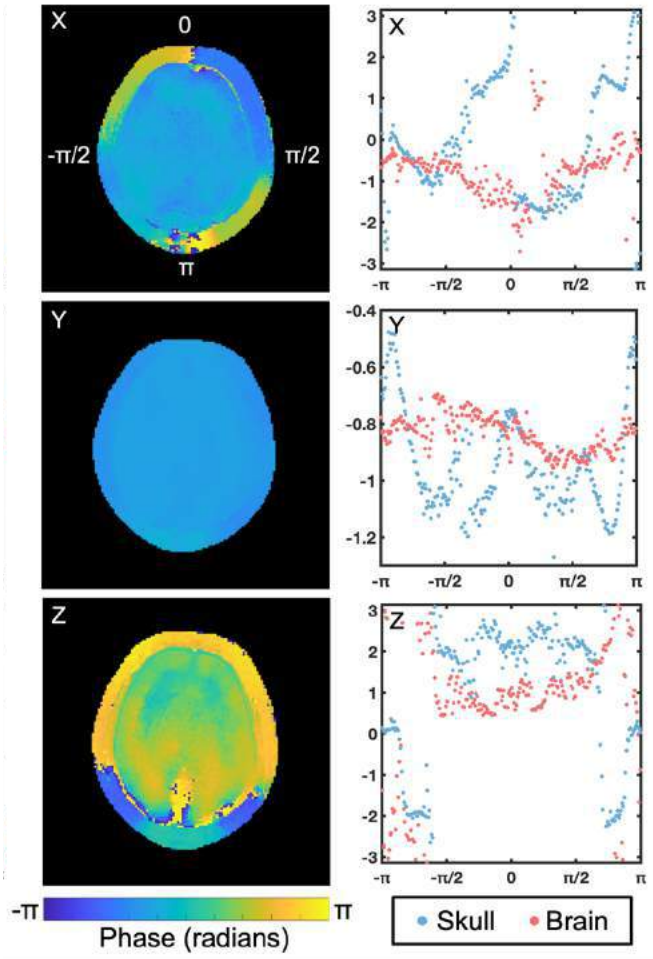

**Figure 3: Phase of x, y, and z motion at 50 Hz.**

## DISCUSSION

These preliminary results support the hypothesis that the brain moves out of phase with the skull as captured by our modified fat-water spiral MRE sequence. Further sequence developments will seek to optimize the skull signal and reduce artifacts caused by the scalp[6]. An increased range of actuation frequencies with multiple excitation directions will allow us to comprehensively quantify skull-brain transmission. Understanding this relationship will allow researchers to improve TBI models by accounting for the skull-brain interface and evaluate how this relative motion changes in patients with a history of mild TBI.

# A NOVEL MATLAB SCRIPT FOR THE ANALYSIS OF MECHANICAL CHARACTERIZATION DATA

**Emily R. King (1), Michael T.K. Bramson (1), David T. Corr (1)**

(1) Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, New York, USA

## INTRODUCTION

Mechanical characterization is an important component of biomedical research focused on the development of engineered tissues and biomaterials. Although a robust experimental design and data collection process is an important preliminary step, a robust data analysis process is also critical. Specifically, balancing objectivity and sensitivity within the data analysis process allows for meaningful conclusions to be drawn from the data. Thus, we sought to develop a MATLAB script to objectively identify key material and failure properties from tensile testing data, with the flexibility to enable characterization of a wide variety of material behaviors.

The aims of this project were (i) to develop a script that determines key material parameters from collected raw experimental data and sample geometries, and (ii) demonstrate its ability to extract key characterization parameters from tensile pull-to-failure data of mouse tendons, engineered tendon fibers, and engineered biomaterials exhibiting a range of characteristic behaviors [1, 2]. Eight parameters of interest were selected to be extracted from the experimental data: peak stress, failure strain, toe-in strain, toughness, pre- and post-yield modulus, and yield stress and strain.

## METHODS

Load-displacement-time data collected from uniaxial tensile pull-to-failure characterization experiments of engineered tendon fibers, mouse hind-limb tendons, and engineered biomaterials (i.e., Lipase-catalyzed Poly(Glycerol-1,8-Octanediol-Sebacetate; or PGOS) were used as input data for our analyses. Mechanical testing was performed using a materials testing system (TestResources Inc., MN) for mouse tendon and engineered biomaterials, and a custom tensile bioreactor system (Admet Inc., MA) for engineered tendon fibers. Force-displacement data were exported from the testing software as an Excel file. Sample geometries were acquired prior to testing.

When initialized, the program prompts the user to select the Excel data file for analysis, and loads the collected force-displacement data. The user is then prompted to input the sample geometries: gauge length and cross-sectional area, which the program uses to calculate values for strain and stress. Strain is then normalized by determining the strain that corresponds to the start of sample deformation, and subtracting this offset from the raw strain values to get an adjusted strain where zero corresponds to the start of tensile strain in the material. From this normalized data, peak stress is determined as the maximum stress value. The index corresponding to this peak stress is then used to define the failure strain. Toughness is determined as the integration of the stress-strain curve from the start of sample deformation until failure strain.

Determination of Young's elastic modulus is initiated through user input of upper and lower strain percentage boundaries, to accommodate a variety of material behaviors. These boundaries are used as the range over which the modulus is calculated, determined as the slope of the line of best fit via linear regression. Subsequently, a stress-strain plot of the data is generated with the range for modulus calculation highlighted (Figure 1A), for visual confirmation that the selected range captures the specimen's linear elastic response.

Should the selected range not reflect an appropriately-linear region, the user can select new strain boundary inputs, and run the code block again. A new figure will be generated to provide immediate visual feedback on the selected range for modulus determination. This process is mirrored for calculation of a post-yield modulus, as necessary.

Calculation of toe-in strain is accomplished by fitting the adjusted stress-strain data with a spline, from the onset of loading until sample failure. The first derivative of the spline fit is calculated, and the program iteratively compares values of the derivative to determine the strain at which it equals the modulus determined in the prior block. This approach identifies the transition between the strain-stiffening and linear regions, which is indicative of the toe-in strain. Noise within the

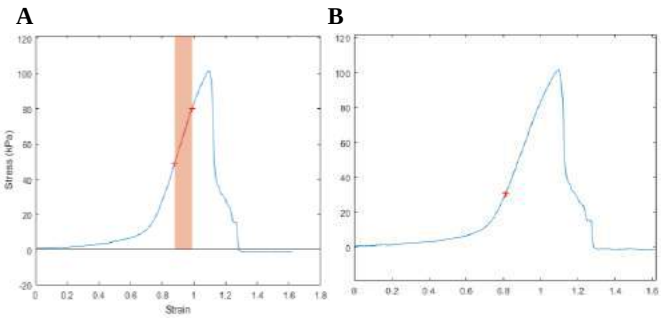

**Figure 1: A: Modulus is calculated from user-prescribed upper and lower strain boundaries, and plot provides visual confirmation. B: Representative image of stress-strain plot with toe-in region marked (red asterisk) for user verification.**

data, most notable in low-stress regions of smaller-scale samples (e.g., single fibers), creates the potential for the condition to be triggered prematurely within the initial strain-stiffening response. To account for and address this possibility, the program generates a plot with the calculated toe-in strain marked on the strain-strain curve with a red asterisk (Figure 1B). The user is prompted to verify (Y/N) that the toe-in strain appears reasonable, and reflects the transition from strain-stiffening to linear response. Should the user indicate no, the program undergoes another iteration, selects the next data point that satisfies this criterion, and generates a new figure. In this manner, the feedback loop allows the program to balance sensitivity with objectivity by accommodating for noise in the data while maintaining a numerical basis for the toe-in strain selection.

For materials that exhibit yield behavior, yield strain is determined by constructing linear equations from the pre- and post-yield moduli and determining their respective intersection point. The strain and stress corresponding with the index of this intersection defines the yield strain and the yield stress, respectively.

## RESULTS

Calculated values of interest and generated figures are exported automatically, including a figure with key values marked (Figure 3). When applied to experimental tensile data of engineered single tendon fibers and mouse tendons, which exhibit a characteristic strain-stiffening, linear response to failure, the MATLAB script was able to objectively identify the key parameters of interest, including the toe-in strain (Fig. 2). Additionally, this program was applied to pull-to-failure

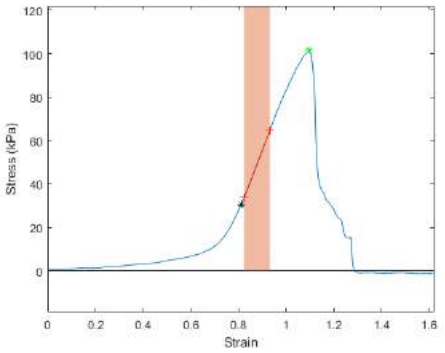

**Figure 2: Representative stress-strain curve of an engineered fiber, as generated by code. Modulus is the slope calculated within the red shaded region, and asterisks denote the end of the toe-in region (black) and point of failure (green).**

data of various engineered PGOS biomaterials exhbiting a wide range of tensile behaviors, demonstrating its ability to extract the key parameters of interst for tensile characterition from diverse material responses, including bilinearly-elastic, elastic-perfectly plastic, and elastic-softening, (Figure 3).

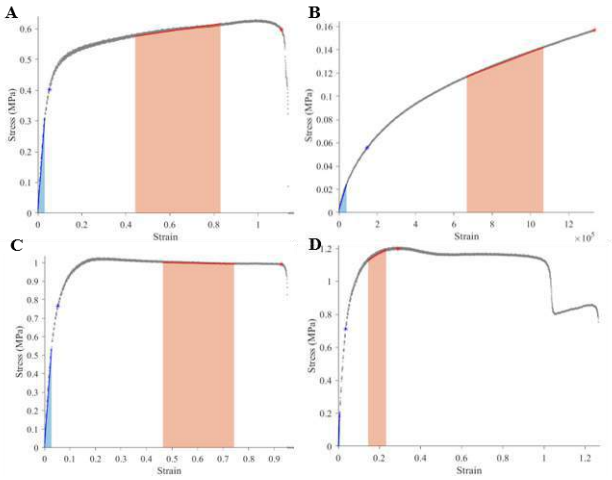

**Figure 3: Representative figures of engineered biomaterials exhibiting different characteristic behaviors. A, B: bi-linearly elastic C: elastic-perfectly plastic D: elastic-softening**

## DISCUSSION

This novel MATLAB script streamlines the process for mechanical characterization data analysis, and reduces subjectivity in parameter determination. Visualization of the data and extracted parameters during the analysis process creates a functional tool for objective analysis with visual confirmation, that can be applied across multiple length scales (engineered single tendon fibers vs. whole tendon and engineered biomaterials), and for a variety of material behaviors.

In the future, this code can be expanded to include additional parameters of interest and to accommodate other modes of mechanical characterization, such as viscoelastic parameters from stress-relaxation or creep testing.

# PARAMETERS TO MODEL CARTILAGE AS OSTEOARTHRITIS PROGRESSES

**Xiaogang Wang (1), David M. Pierce (1,2)**

(1) Department of Mechanical Engineering, University of Connecticut, Storrs, CT, USA

## INTRODUCTION

The remarkable mechanical function of healthy cartilage derives from interactions among proteoglycans, networked collagens (in three through-thickness zones: superficial, middle, and deep), and electrolytic fluid. Osteoarthritis (OA) is a pervasive disease involving failure of the synovial joint and deleterious changes in composition and micro-structure (e.g. loss of zones) of cartilage. Changes in cartilage properties correlate with tissue composition and thus with OA severity [1-3].

During normal movement, healthy cartilage provides load transfer between bones and near-frictionless joint articulation, compressing as much as 30% under pressures up to 20 MPa [1,4,5]. These large *in vivo* deformations of the tissue, where shear is critical in both failure and cell death, mean mechanical analyses of cartilage should employ large-strain, nonlinear mechanics. Moreover, research shows tensile properties of the collagen network dominate the shear response [1,6].

Finite element (FE) modeling plays a well-established and increasingly significant role in analyses of cartilage at organ, tissue, and cell scales. An accurate FE model requires an experimentally calibrated and validated constitutive model; however, research literature features few calibrated large-strain constitutive models for healthy human cartilage, and even fewer for osteoarthritic human cartilage [2,3].

We established a finite-strain constitutive model of cartilage addressing both solid (reinforcement) and fluid (permeability) dependence on the network of collagen fibers, and which admits patient-specific organizations of collagen via diffusion tensor MRI [7]. We also included osmotic swelling and the osmotically prestretched/prestressed state of cartilage determined from medical images [8]. In this study, we aimed to advance our constitutive model by leveraging our novel experimental data [9,10] to establish parameters with respect to structurally defined OA progression quantified by OARSI scoring [11].

## METHODS

*Experimental Evidence.* We previously harvested 106 3×3 mm, full-thickness specimens of healthy and progressively osteoarthritic cartilage from 17 donors [9,10]. Using standard histological scoring we determined the OARSI grade of each specimen [11]. Briefly, we applied cyclic simple-shear displacements at a rate of 75 μm/min for six cycles, and at maximum displacements corresponding to shear strains of 5%, 10%, 15%, 20%, and 25%. Many mechanical tests failed at 20% shear strain and we used data only up to 15%. We grouped specimens based on OARSI grade: Healthy ($n = 42$) contains healthy specimens with OARSI score of 0-1; OARSI-1 ($n = 11$) with OARSI grade $\in [0,2)$; OARSI-2 ($n = 20$) with OARSI grade $\in [2,3)$; OARSI-3 ($n = 17$) with OARSI grade $\in [3,4)$; and OARSI-4 ($n = 10$) with OARSI grade $\geq 4$.

*Constitutive Model.* We described cartilage as a biphasic continuum $\varphi = \varphi^{\mathrm{S}} + \varphi^{\mathrm{F}}$ of a porous solid phase $\varphi^{\mathrm{S}}$ saturated with a fluid phase $\varphi^{\mathrm{F}}$. We calculated the total Cauchy stress as [7,8]

$$\boldsymbol{\sigma} = -p\mathbf{I} + 2\rho^{\mathrm{S}}\mathbf{F}_{\mathrm{S}}\frac{\partial \Psi^{\mathrm{S}}}{\partial \mathbf{C}_{\mathrm{S}}}\mathbf{F}_{\mathrm{S}}^{\mathrm{T}} = -p\mathbf{I} + \boldsymbol{\sigma}_{\mathrm{E}}^{\mathrm{S}}, \tag{1}$$

where $p$ is the fluid pressure, $\mathbf{I}$ is the identity, $\rho^{\mathrm{S}}$ is the partial density of solid, $\mathbf{F}_{\mathrm{S}}$ is the solid deformation gradient, $\mathbf{C}_{\mathrm{S}} = \mathbf{F}_{\mathrm{S}}^{\mathrm{T}}\mathbf{F}_{\mathrm{S}}$, and $\boldsymbol{\sigma}_{\mathrm{E}}^{\mathrm{S}}$ is the effective Cauchy stress. We used an additive decomposition of the solid Helmholtz free-energy $\Psi^{\mathrm{S}}$ into contributions from Donnan osmotic pressure $\Psi_{\mathrm{OP}}^{\mathrm{S}}$, an isotropic matrix $\Psi_{\mathrm{IM}}^{\mathrm{S}}$, and a fiber network $\Psi_{\mathrm{FN}}^{\mathrm{S}}$ as [8]

$$\Psi^{\mathrm{S}} = \Psi_{\mathrm{OP}}^{\mathrm{S}}(J_{\mathrm{S}}) + (1-\nu)\Psi_{\mathrm{IM}}^{\mathrm{S}}(J_{\mathrm{S}}, I_1) + \nu\Psi_{\mathrm{FN}}^{\mathrm{S}}(\mathbf{C}_{\mathrm{S}}), \tag{2}$$

where $J_{\mathrm{S}} = \det\mathbf{F}_{\mathrm{S}}$, $\nu$ is the volume fraction of collagen to total solid, and $I_1 = \mathrm{tr}\mathbf{C}_{\mathrm{S}}$. We modeled the Cauchy stress from osmotic pressure as

$$\boldsymbol{\sigma}_{\mathrm{OP}}^{\mathrm{S}} = -R\Theta\left[\sqrt{4(\bar{c}_{\mathrm{m}})^2 + (c_{\mathrm{m}}^{\mathrm{fc}})^2} - 2\bar{c}_{\mathrm{m}}\right]\mathbf{I}, \tag{3}$$

where $R = 8.314 \times 10^3\,\mathrm{mJ/(K\cdot mol)}$, $\Theta$ is the absolute temperature, $\bar{c}_{\mathrm{m}}$ is the ion concentration of the external solution, and the concentration of the fixed charge depends on the deformation as [8]

$$c_{\mathrm{m}}^{\mathrm{fc}} = c_{0\mathrm{S}}^{\mathrm{fc}}\left(1 - n_{0\mathrm{S}}^{\mathrm{S}}\right)\left(J_{\mathrm{S}} - n_{0\mathrm{S}}^{\mathrm{S}}\right)^{-1}, \tag{4}$$

where $c_{0\mathrm{S}}^{\mathrm{fc}}$ is the initial concentration of fixed charge (within the tissue) and $n_{0\mathrm{S}}^{\mathrm{S}}$ is the initial solid volume fraction. We modeled the (largely)

proteoglycan solid matrix $\Psi^{S}_{IM}$ using a neo-Hookean function extended with compaction effects. We modeled the dispersed network of collagen $\Psi^{S}_{IM}$ using and orientation distribution function calibrated with diffusion tensor MRI. We considered the viscoelasticity of both the proteoglycan and collagen solids using two parameters: $\beta$ [-], a magnitude factor, and $\tau$ [s] the associated relaxation time, cf. [12].

*Inverse Finite Element Analyses.* We modeled the center slice of specimens under plane strain (**Fig. 1(a)**) using 20-node hexahedral elements to simulate the shear tests in FEBio (U. of Utah). We validated our mesh, using an *h*-refinement test [9,12]. In light of the available data we leveraged previous studies to establish some of the parameters (**Table 1**). We started the parameter optimization using a homogeneous constitutive model where we used $z^*$= 0.5 to obtain the averaged parameters and the diffusion tensor $\mathbf{D} = \mathbf{I}$ for an isotropic distribution of fibers. With this model we optimized the fiber stiffness parameter $k_1 \in$ [0.3,10], initialized with $k_1$= 3.0, using the "interior-point" algorithm. For healthy samples, we then fitted a heterogeneous model consisting of a superficial zone (SZ, 15%), middle zone (MZ, 55%), and deep zone (DZ, 35%) based on the tissue thickness (**Fig. 1(b)**) to refit $k_1$. To investigate the contribution of prestress resulting from Donnan osmotic pressure we repeated the parameter optimization without osmotic pressure and without the backward displacement method (BDM) to determine initial equilibrium [8].

*Statistical Analyses.* We tested whether the fitted $k_1$ was normally distributed by the Jarque-Bera test. We used the two-sample *t*-test to establish if two data sets were significantly different (with $p$ = 0.05).

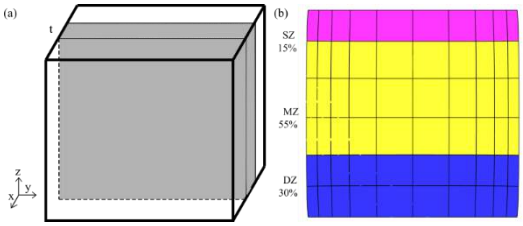

**Figure 1: FE model of the shear experiment: (a) schematic with center slice in plane strain; (b) mesh with three distinct zones.**

**Table 1: Model parameters from previous studies, where z* ∈ [0,1] is the normalized tissue thickness (zero refers to the articular surface and one to the interface with subchondral bone) [7,8].**

| Parameter | Value | Unit |
|---|---|---|
| $\boldsymbol{\Theta}$ | 310 | K |
| $\boldsymbol{\mu}$ | 0.23 | MPa |
| $\boldsymbol{k_2}$ | 8.0 | – |
| $\boldsymbol{\beta_{IM}, \beta_{FN}}$ | 2.7, 1.5 | – |
| $\boldsymbol{\tau_{IM}, \tau_{FN}}$ | 360, 1500 | s |
| $\boldsymbol{c^{fc}_{0S}}$ | $2.0 \times 10^{-7}$ | mol/mm$^3$ |
| $\boldsymbol{\bar{c}_m}$ | $1.5 \times 10^{-7}$ | mol/mm$^3$ |
| $\boldsymbol{n^{S}_{0S}(z^*)}$ | $0.15 + 0.15(z^*)$ | – |
| $\boldsymbol{\nu(z^*)}$ | $0.43(z^*)^2 - 0.60(z^*) + 0.85$ | – |
| $\boldsymbol{J^{S}_{cp}(z^*)}$ | $0.36 + 0.11(z^*)$ | – |
| $\boldsymbol{k_{0S}(z^*)}$ | $(1 - 0.9(z^*)) \times 10^{-3}$ | mm$^4$/(N · s) |
| $\boldsymbol{m(z^*)}$ | $3.0 + 5.0(z^*)$ | – |

## RESULTS

Fitting results of the healthy samples with both homogeneous and heterogeneous models are normal distributed. There is no significant difference between the bulk responses of the two models with the BDM approach. Without osmotic pressure and BDM, the optimal fiber stiffness parameter $k_1$ is larger in the homogeneous model **(Fig. 2(a))**. Starting from OARSI-1, $k_1$ decreased as OARSI grade increased. The most significant changes occurred between OARSI-1 and OARSI-2 in both BDM and Non-BDM approaches. Since OARSI-3 in BDM and OARSI-4 in both BDM and Non-BDM did not pass the JB-test, we show median and interquartile ranges for these three cases instead of mean and standard deviation **(Fig. 2(b))**. We also plot the bulk stress-strain response of representative specimens for comparison **(Fig. 3)**.

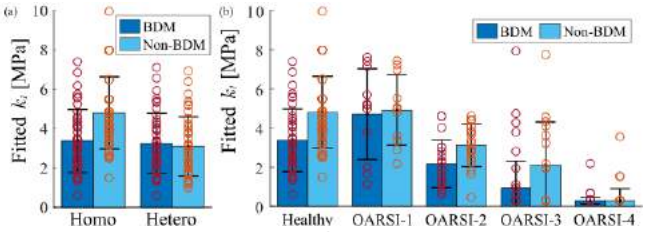

**Figure 2: Fitted fiber stiffness $k_1$: (a) healthy specimens with different methods and models, (b) specimens from OARSI grades.**

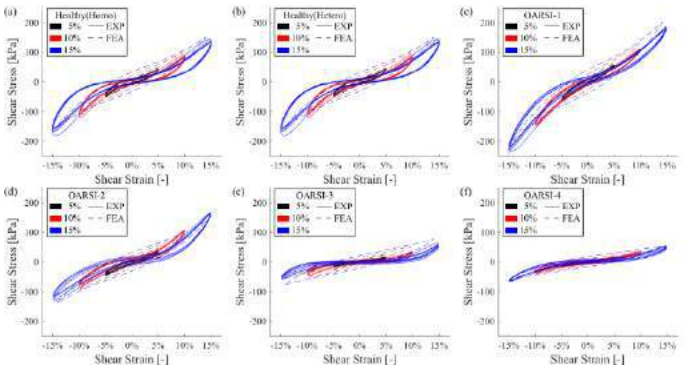

**Figure 3: Representative stress-strain responses of OARSI grades.**

## DISCUSSION

In this study, we calibrated our constitutive model with experimental data from healthy and progressively osteoarthritic human articular cartilage undergoing large-strain shear. Since many of the parameters we require are directly measureable and well established (e.g. the permeability of healthy cartilage) we focused our fitting under shear on the stiffness of collagen fibers, particularly since the properties of the collagen network dominate the shear response of cartilage. With advancing OA, the fiber stiffness parameter $k_1$ progressively reduces indicating progressive loss of collagen integrity. We can further improve our cartilage model by leveraging more experimental data.

We also established a general method to better calibrate our cartilage model using experimental data. Our methods can be expanded for fitting multiple parameters simultaneously or different constitutive models, or leveraging other types of experimental data. With our models and modeling methods, we hope to improve the fidelity of FE-based, patient-specific biomechanical simulations of joints and cartilage.

# A NOVEL APPROACH FOR MAPPING 3D EXTRACELLULAR MATRIX MECHANICS AT THE CELLULAR SCALE USING MAGNETIC MICROPARTICLES

**Adil Khan (1), Jacopo Ferruzzi (1)**

(1) Department of Bioengineering, The University of Texas at Dallas, Richardson, TX, USA

## INTRODUCTION

Mechanical interactions between cells and their microenvironment have been shown to regulate important biological processes such as adhesion, proliferation, and migration [1]. However, cell-matrix mechanical interactions are neither simple nor unidirectional. As cells responds to biomechanical cues from the extracellular matrix (ECM), they actively restructure and remodel this surrounding micro-environment, thereby altering its mechanical properties [2]. Over the past several decades, there has been an increased effort towards understanding the complexity of cell-ECM dynamics, and the inherent role played by mechanical forces in regulating cell behavior. The ECM derives its tensile strength from collagen, its predominant protein constituent. Because collagen also provides the scaffolding for cell adhesion in vivo, it is often the substrate of choice for three-dimensional (3D) cell culture studies. Traditional characterization of collagen mechanics has either relied on global methods such as uniaxial tension, compression, and shear rheometry, or on nano- and micro-scale manipulation techniques such as atomic force microscopy [3]. While these tests have led to important insights on the impact of factors such as protein concentration on collagen network mechanics, they do not provide an accurate representation of the forces that are experienced by resident cells in a 3D ECM. In addition, they commonly fail to address spatial heterogeneities that emerge during the cell-driven remodeling of complex 3D fibrous networks.

In this study, we introduce a novel approach to characterize the mechanics of the ECM at a scale best representative of the cellular microenvironment. Our method uses ferromagnetic beads, embedded in collagen hydrogels during polymerization, which experience a torque from the application of two orthogonal magnetic fields. By measuring the deformation field in the fibril structure that surrounds these microscopic force probes, we quantify the local mechanical properties of the collagen network. While a similar technique has been used previously to capture changes in mechanical properties with changes in collagen concentration in two dimensions (2D) [4], our study is the first to use magnetic bead stimulation to explore spatiotemporal aspects of collagen mechanics in a full 3D setting.

## METHODS

Acellular networks of type I collagen (Corning), of concentrations between 1 and 4 mg/mL, were prepared using established protocols [5]. Custom ferromagnetic microparticles, with an average diameter of 8.37 μm and at a density of $10^6$ particles/mL, were distributed evenly throughout the gels during polymerization. Intrafibrillar and interfibrillar cross-links were generated by adding a solution of glutaraldehyde diluted in deionized water. Following the protocol of Doyle et al. [6], an Atto 488 NHS ester dye (Sigma-Aldrich) was used for fluorescent labeling of collagen fibrils. In brief, 2 moles of fluorescent dye per mole of collagen protein were added to a borate buffer solution and allowed to bind with fully polymerized collagen. The dye conjugated with collagen for 1 hour (at room temperature and protected from light), after which the solution was replaced with a 50mM TRIS buffer to quench the dyeing reaction. Finally, excess dye was washed out thrice with 1x PBS before testing.

The micro-structural organization of the collagen network around selected beads was assessed using a Nikon AX confocal microscope equipped with a 20× water immersion objective lens (0.95 N.A., 950 μm working distance). The unit for 3D magnetic twisting includes a microscope insert with three perpendicular coils [7]. The embedded microparticles were stimulated by the application of a strong magnetic pulse followed by a weak magnetic field in a perpendicular direction to generate a torque about one of the coordinate axes (*z*-axis in Figure 1). Confocal stacks were acquired both before and after magnetic stimulation. In order to capture how deformations propagate into the matrix surrounding the beads, the collagen network was imaged using

both reflection and fluorescence modes. An augmented Lagrangian digital volume correlation algorithm [8] was used to quantify the induced 3D deformation fields. These displacement maps were then recreated in an iterative finite element framework to estimate the unknown material parameters of the collagen network, which was modeled as a locally homogenous neo-Hookean material. To demonstrate the ability of the proposed approach to capture spatially and temporally evolving mechanical properties of remodeled ECMs, we monitored the local properties of gels surrounding highly contractile MDA-MB-231 breast cancer spheroids (Figure 1a).

## RESULTS

Ferromagnetic beads were found to localize around collagen fibrils, and to induce measurable deformations in the collagen matrix upon magnetic stimulation (Figure 1b). Experimental and simulated displacement fields show a pattern of deformation that is consistent with the twist of a spherical inclusion (Figure 1c-d). Radial profiles of absolute matrix displacement display decays that are sensitive to collagen concentration and degree of cross-linking. Iterative simulations allowed us to match experimental and computational displacement fields thereby extracting the unknown material parameters under the assumption of neo-Hookean material behavior (Figure 1e).

MDA-MB-231 post-metastatic breast cancer cells are highly contractile and are known to remodel the surrounding ECM as they invade either as single cells or as collective multicellular strands [9]. Embedded MDA-MB-231 spheroids actively remodel the collagen matrix, resulting in a characteristic increase in collagen density and alignment at the spheroid-ECM interface. These structural changes were captured by our mechanical measurements, thereby demonstrating the feasibility of quantifying the mechanical effects of remodeling due to cell-matrix interactions.

## DISCUSSION

Changes in ECM structure and mechanics via cell-mediated matrix remodeling have important implications for tissues in both physiological and pathological states. To understand the complex roles played by ECM remodeling in health and disease, accurate quantification of 3D tissue mechanics is of the essence, though not currently possible with high spatial and temporal resolution. Previous studies have used magnetic forces largely to study cytoskeletal mechanics of cells adhering to a 2D substrate [7, 10, 11]. The micromechanics of collagen gels has been analyzed using optical tweezers [12, 13], standard magnetic twisting cytometry [14], 2D optical magnetic twisting cytometry [5], and more recently using 3D twisting of magnetic micro-rods [15]. To the best of our knowledge, our study is the first to use magnetic forces to investigate the mechanics of collagen networks fully in a 3D setting, combining the effects of concentration and degree of cross-linking. The recent study by Asgeirsson et al. [15] proposed a similar framework but examined only the effect of collagen concentration and limited their analysis within the context of linear elasticity. Instead, our approach has the potential to define the local structure-function relationship in collagen networks by stimulating thousands of covalently bound microbeads at the same time via an external magnetic field, imaging local matrix displacements, and modeling ECM mechanics. Future work will focus on incorporating the nonlinear anisotropic properties of the fibrous ECM by means of a constitutive model that accounts for both structural and material features of collagen fiber networks.

## ACKNOWLEDGEMENTS

The authors acknowledge Professor Jeffrey J. Fredberg and Dr. Chan Y. Park (Harvard T.H. Chan School of Public Health) for their support with ferromagnetic beads, and Professor Christian Franck and Dr. Jin Yang (University of Wisconsin-Madison) for their expert assistance with Digital Volume Correlation.

# SIMULATION OF THROMBUS FORMATION IN MICROFLUIDIC CONSTRICTION AT SUPRAPHYSIOLOGIC SHEAR RATE

**R. Méndez Rojano, G. W. Rowlands, S. Schirmacher, J. F. Antaki**

Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY, USA

## INTRODUCTION

Excessive blood clot formation, also known as thrombosis, is one of the leading causes of mortality worldwide accounting for one out of four deaths [1]. Thrombosis can impact the cardiovascular, neurovascular, and pulmonary systems. In addition, blood wetted medical devices are frequently affected by abnormal thrombus formation [2].

To better understand the hemostatic process that leads to thrombosis, microfluidic flow experiments and mathematical models have been developed over the past decades [3]. Microfluidic chambers are often designed to mimic a vascular injury and characterize thrombogenesis. This is achieved by coating surfaces with collagen, Tissue Factor (TF), or von-Willebrand Factor (vWF) to capture platelets and trigger coagulation reactions. While microfluidic experimental studies provide useful insight for thrombus formation dynamics, their data are limited to fibrin polymerization and platelet aggregation [4], and do not capture intermediate steps in the coagulation cascade. This is one of the motivations for mathematical models of thrombosis: to simulate the hemostatic steps at different spatial and temporal scales.

In the current study, a parallel plate microfluidic chamber with a constriction was developed to study the thrombus formation at supraphysiologic shear rate (>6000 s-1). Microfluidic experiments were conducted with healthy human whole blood. Commensurate numerical simulations were performed to reflect platelet and vWF activity. The main objective of this work is to replicate experimental observations with our multi-constituent thrombosis model.

## METHODS

An acrylic parallel plate flow chamber was constructed using a polydimethylsiloxane (PDMS) microfluidic chip with a constriction to generate large shear stresses (>6000 s-1.) The PDMS channel was sealed with a glass slide that was partially coated 1 mm downstream and upstream of the constriction with Collagen type 1 from calf skin to promote clotting. Flow was introduced via syringe pump. (See Fig 1A and 1B.)

The channel was passivated with 0.5 % Bovine Serum Albumin (BSA) solution for 10 minutes at a flow rate of 75 µL $min^{-1}$. Subsequently, citrated whole blood was perfused at 75 µL $min^{-1}$ for 10 minutes. Blood was collected from healthy adults, following the Helsinki declaration and approved by Cornell University IRB. Citrated blood collection tubes were used, the first tube was discarded to avoid introducing activated platelets to the channel from the venipuncture procedure. Hematocrit and platelet count were measured with a hematology analyzer. Hematocrit and platelet count were maintained at approximately 30-45% and 150,000-300,000 plt $\mu L^{-1}$ respectively. Platelets were labeled with a Phosphate-Buffered Saline-mepacrine solution in a 1:9 ratio. Platelet aggregation was observed with an inverted fluorescence microscope equipped with a. color CCD Camera at 10 fps.

Computational fluid dynamics was performed to estimate the scalar shear rate field, considering the blood as a Newtonian fluid. (See Fig. 1C.) The Reynolds number of the flow under these conditions was 8 considering the asymptotic value of the kinematic viscosity ($3.5\times10^{-6}\ m^2\ s^{-1}$), the bulk velocity before the constriction (0.2 m $s^{-1}$), and the constriction width as characteristic length (140 µm). This ensured the absence of recirculation downstream of the constriction. (See Fig. 1D.)

Thrombus formation was simulated using the mathematical models of Wu et al. [5] that considers platelet mechanical activation by shear, platelet chemical activation by thrombin, thromboxane (TxA2), and adenosine diphosphate (ADP). In addition, vWF activity and its effect on platelet recruitment and embolization is modeled following Zhussupbekov et al. [6]. Briefly, the Navier-Stokes (NS) are coupled with Convection-Diffusion-Reaction (CDR) equations for seven biochemical species involved in platelet activation and aggregation. As the thrombus grows, a resistance term is introduced in the conservation of momentum equations hindering the blood flow within the thrombus.

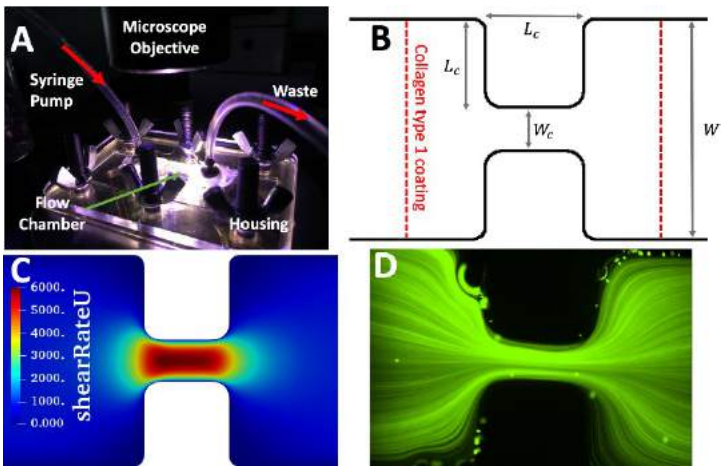

**Figure 1: A) Microfluidic experiment set up. B) Top view of chamber at constriction with dimensions ($W = 540\mu m, W_c = 140\mu m$ and $L_c = 200\mu m$) the depth is 180 µm. C) Shear rate field ($s^{-1}$.) D) Flow path lines visualized with fluorescent microspheres.**

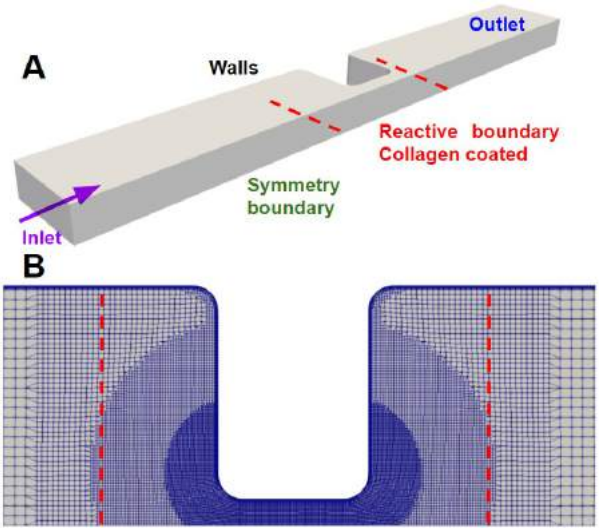

**Figure 2: A) Computational domain considered in the simulation. B) Mesh refinement near the constriction; red dashed lines indicate the regions where the reactive boundary conditions were applied (platelet deposition flux due to collagen.)**

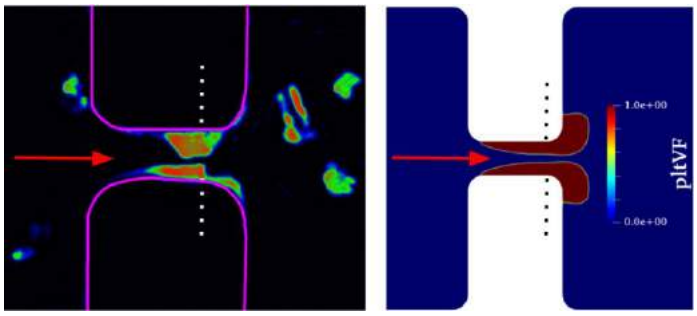
## RESULTS

In both experiments and simulation, thrombus formed preferentially within the constriction of the channel, initiating along the lateral wall edges of the channel, growing towards the center of the constriction, and propagating downstream. (See Fig. 3.) In the experiment, embolization impeded occlusion of the channel, and large aggregates were observed downstream of the constriction. The location of the thrombus experimentally was somewhat variable, sometimes in the leading edge of the constriction and some others in the downstream edge; in contrast in the deterministic simulation, wherein the thrombus always forms in the downstream edge of the constriction. Figure 4, which presents the time course of the percent occlusion over 10 minutes, illustrates overprediction of the rate of occlusion by the numerical model, although the general trend was well captured with similar lag times and sigmoidal growth rate.



Experiment Thrombosis Simulation

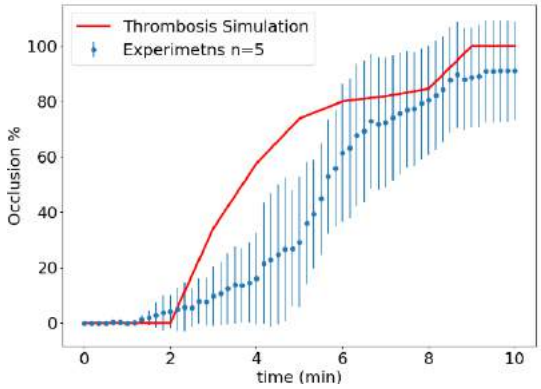

**Figure 4: Thrombus occlusion percentace evolution in time computed at the middel plane along the white and black dotted lines of Fig 3 for experiments n=5.**

## DISCUSSION

The current study presents both numerical and experimental results of thrombus formation under high shear rate conditions within a microfluidic constriction. The thrombosis model considers a mechanistic description of platelet aggregation and vWF activity. The model predicted reasonably well the thrombus formation at the constriction and the occlusion dynamics. The main limitation of the model was the omission of thrombus fracture and embolization. The present model represents embolization through a constant "shear cleaning" term as a function of the local shear rate, therefore does not capture the sudden and prevalent embolization of large platelet aggregates. Ongoing development of the model is incorporating fibrin production, which is important in capture of red blood cells – which may contribute significantly to the volumetric growth of a thrombus.

# EVALUATION OF TACHYCARDIA PACING THERAPY RESPONSE IN A WHOLE HEART HFpEF MODEL: THERAPY DESIGN IMPLICATIONS

**Kevin L. Sack (1), Joshua Blauer (1), Richard Cornelussen (2), Troy Jackson (1)**

(1) Cardiac Rhythm Management, Medtronic, Mounds View, Minnesota, USA
(2) EMEA CS&T Therapy Innovation, Bakken Research institute, Medtronic, Netherlands

## INTRODUCTION

Heart failure with preserved ejection fraction (HFpEF), which affects over half of the patients diagnosed with heart failure [1], is a vast, underserved patient population. While pharmacological therapies are marginally useful, there is no approved therapy to lower cardiovascular morbidity and mortality. Tachycardia induced remodeling is a new therapy concept whereby high-rate pacing delivered by a dual-chamber pacemaker would promote remodeling and subsequent normalization of the diastolic failing heart. In recent preclinical studies, moderate to high increased heart rates (to 125/min and 175/min) could be used to increase left ventricular (LV) volumes and lower mass-to-volume ratios in concentrically hypertrophied LVs without reducing the EF [2]. This change in LV structure is reversible, can be titrated, and is not associated with HF. To burn down risk and identify optimal therapeutic protocols, finite element computer modeling was employed to simulate the effects of high pacing rates in virtual hearts and under a wide range of applicable conditions.

## METHODS

**Geometry:** CT scan data of a human subject were imported and processed in Simpleware ScanIP (Synopsys, Mountain View, USA). Detailed geometric segmentations of the atria and the ventricles at end diastole were created and meshed into 10-node tetrahedral elements.

**Myofiber orientation:** Myofiber orientation in the ventricular structure has been well described in the literature [3]. Accordingly, we assumed that the ventricular myofiber orientation could be represented through a linearly varying helix angle from −60° on the epicardium to +60° on the endocardium. Myofiber orientations of papillary structures and the extending pulmonary trunk were assigned manually to run parallel and circumferential to anatomical structures respectively. Myofiber orientations in the atria are characterized by overlapping, joining and separating fiber bundles that are critical for both electrical and mechanical function [4]. Accordingly, we assigned atrial myofibers aligned circumferentially with the native orifices and atrioventricular valve annuli. Distinct fiber bundles representing Bachman's bundle, pectinate muscle and atrial free wall were prescribed following the morphology of atrial anatomy.

**Constitutive properties:** The passive material response for myocardium is governed by an anisotropic hyperelastic description [5]. Contractile function is coupled to the solution of simulated electrophysiological activation, which is initiated when the calcium transients exceed a resting threshold. Active tension development following initiation is governed by a time varying elastance law [6].

**Excitation contraction coupling:** The electrical activation of the heart was simulated using CARPentry electrophysiology simulation software. The geometry was refined to a tetrahedral mesh with approximately 400 μm edge length resolution. The cardiac activation was simulated in a pseudo-bidomain mode for atrial and ventricular [7] cell models. The calcium transients for 4 consecutive cycles of activation at rates between 77-150 BPM were exported from the cell models to drive the timing of atria and ventricular contraction which was simulated in ABAQUS (Dassault Systèmes Simulia Corp, Providence, USA.)

**Circulatory system**: Our electromechanical four-chamber heart is coupled to a closed loop circulatory model adapted from simple lumped parameter representations of the cardiovascular system [8]. Unidirectional fluid exchange, driven by pressure difference between two connected chambers, allow for a meaningful representation of the entire circulatory system and the cyclic performance of a beating heart. To simulate natural baroreflex response of the systemic arteries, systemic vascular resistance was adjusted (i.e., resistance reduced with increasing rate to allow more flow in the system). This was done under the assumption that the mean arterial pressure (MAP) was maintained within 5% of values at baseline.

**Disease state modeling**: Severity of pathophysiology was simulated by adjusting myocardial constitutive properties and

circulatory parameters to produce graded deterioration of cardiac function representative of HFpEF. Ventricular myocardial stiffness was scaled linearly by a factor of 1.5, 2.0, 2.5 and 3.0 in HFpEF prototypes HF25, HF50, HF75 and HF100 respectively [9]. Lusitropic impairment, the inability of the myocardium to adjust contraction and relaxation with rate effects [9], is also considered by slowing the rate of active tension development and lengthening the relaxation of contractile function. Global contractility appears normal in HFpEF patients due to remodeling. When contractile properties are normalized by wall thickness [10] the contractile capacity (per unit volume) is diminished. To reflect this, all HFpEF prototypes have a peak contractile capacity set at 80% of normal. Normal physiological response to rate includes increased contractility (often referred to as "functional reserve"), which HFpEF patients lack to varying degrees. In HFpEF prototypes this reserve was diminished by degree of pathology (see **Table 1**). A prominent symptom of HFpEF is elevated left-sided pressure and pulmonary congestion. To simulate this, the circulatory parameters for the pulmonary circuit were raised to a higher-pressure state as part of new "pathological" initial conditions which creates higher LV preload, resulting in increased mean left atrial pressure (mLAP) and the LV end diastolic pressure (EDP) [11]. (see **Table 1**). The clear majority of HFpEF patients present with hypertension [11]. To represent this, elevated mean arterial pressure (MAP) was included to elevated degrees in the HFpEF prototypes by severity of pathology.

**Table 1: Summary of disease state modeling in the HFpEF prototypes compared with normal cardiac properties.**

| HF prototype | Normal | HF25 | HF50 | HF75 | HF100 |
|---|---|---|---|---|---|
| Myocardial stiffness | baseline | 150% | 200% | 250% | 300% |
| Peak tension capacity (kPa) | baseline | 80% | 80% | 80% | 80% |
| Lusitropic capacity | baseline | 79% | 53% | 26% | 0% |
| Contractility reserve | baseline | 75% | 50% | 25% | 0% |
| LV EDP (mmHg) | 9.3 | 17.3 | 21.7 | 27.5 | 30.7 |
| mLAP (mmHg) | 6 | 12 | 16 | 22 | 27 |
| MAP (mmHg) | 93 | 93 | 96 | 99 | 103 |

**Modeling scenarios:** Each patient prototype simulation was explored over a range of heart rates and atrioventricular intervals:

- Heart Rate (bpm) – 77, 90, 100, 110, 120, 130, 140, 150
- AV Interval (ms) – 80, 100, 120, 140, 160, 200 (over a reduced range of HRs: 77, 100, 110, 120 and 130)

The combination of 77 bpm and 120ms is considered the baseline (default) state of the patient.

## RESULTS

Over the full set of scenarios, the reduction of LV end diastolic pressure with increased heart rate was observed regardless of the AV delay. All HFpEF prototypes had significant unloading of the LV with increases in rate, with 130bpm being a general inflection point of diminishing unloading at higher rates. This achieved ~ 30% decrease in LV end diastolic pressure suggests that if unloading helps with remodeling, it can be established, at least acutely in all patient prototypes. Analysis of chamber wall stress also showed general improvements relative to the 77bpm baseline with increased rate in all prototypes. Maximum stress reduction of ~50% was achieved in some prototypes due to increased rates (22.0 vs 10.5 kPa, from 77 to 130bpm). However, with more severe pathology, adverse or undesirable wall stress results emerged as AV intervals extended to 160ms and beyond (see **Figure 1**).

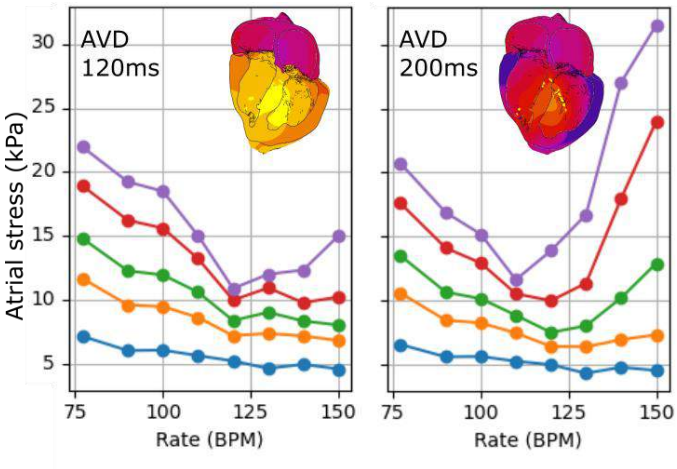

**Figure 1: Effects of rate and AV interval on LA stress at peak atrial activation. Colors of data represent the different patient prototypes of increasing severity: Normal, HF25, HF50, HF75, HF100. Colors across full heart model insert represent calcium transient concentration from high to low, illustrating AV delay.**

## DISCUSSION

Computational modeling of the interactions of rate and atrioventricular delay has provided mechanistic insight into the emerging therapy of high-rate induced remodeling. While there are unanswerable questions around tachycardia remodeling due to the lack of definitive concepts on the drivers of remodeling, the modeling effort has allowed us to systematically examine the therapy space. A key discovery was that AV delay could reduce and even reverse the positive effects of rate unloading (see **Figure 1**). Consequently, dual-chamber pacing modes with careful selection of AV interval may be needed to ensure patient safety and efficacy of future trial designs. These insights would otherwise have been impractical to obtain through clinical means, costing >$2M, spanning multiple years and with vastly limited operating procedures.

## INTRODUCTION

Patient-specific computational fluid dynamic (CFD) models have enabled a greater understanding of the role of fluid mechanics in various systems' physiology and pathophysiology. However, these models are limited by the segmentation of the patient geometries and the prescribed boundary conditions [1]. Time resolved 3D phase-contrast MRI (4D Flow MRI) can address these limitations by providing *in vivo* measurements of biofluid flow non-invasively [2]. While 4D Flow MRI has been applied to a range of vascular territories, recent work has extended its application to cerebrospinal fluid (CSF) flow in study patients with normal pressure hydrocephalus [3].

While 4D Flow MRI provides *in vivo* measurements of flow, there exist tradeoffs between acquisition time, resolution, field of view, and velocity-to-noise ratio. Given that CSF flow is slow moving and traverses through narrow passageways, *e.g.,* the cerebral aqueduct, the application of 4D Flow MRI can result in particularly noisy measurements. This high noise complicates deriving reliable flow metrics such as wall sheer stress (WSS) that rely on near-wall velocity gradients and may be related to pathologies in the cerebrospinal fluid systems.

Recently, Ferdian *et al.* proposed using convolutional neural networks for super-resolution and denoising of 4D Flow MRI data within aortic geometries [4]. This network uses a gradient-based loss constraint and a mean square error loss. Additionally, Rutkowski *et al.* proposed using convolutional neural networks for denoising 4D Flow MRI in cerebral aneurysms using a traditional mean square error loss function [5]. We extend on this work by (1) adapting a densely connected super-resolution network (DCSRN) architecture previously utilized for denoising MRI [6] to 4D Flow MRI data and (2) utilizing a divergence-based regularization constraint.

## METHODS

Herein, we assess the ability of a physics-guided neural network (PGNN) to super-resolve and denoise synthetically generated 4D Flow MRI within a stenotic pipe geometry. The velocity field in the stenotic pipe was simulated with an opensource software SimVascular [7]. Four simulations were run: (1) physiological pulse wave inflow with a peak Reynolds number ($Re_{peak}$) of 250, (2) physiological pulse wave inflow with $Re_{peak}$ equal to 500, (3) sinusoidal pulse wave inflow with $Re_{peak}$ equal to 250, and (4) sinusoidal pulse wave inflow with $Re_{peak}$ equal to 500. Each inflow condition had a period of one second and all simulations were run for four seconds with data from 1.0 – 4.0 seconds being utilized.

The velocity distributions computed in the four simulations were interpolated onto a high-resolution grid with isotropic voxels of 0.5 mm to serve as the network target data. To obtain synthetic 4D Flow MRI measurements, these data were converted to a complex MRI signal which was downsampled in space and time by a factor of 2 and 3 respectively. Gaussian noise of 10% and 20% was also added to the signal. The resulting synthetic MRI signal was then transformed back into a low-resolution velocity field with an isotropic voxel size of 1 mm. This created a total of eight full geometry paired high-resolution low-resolution datasets with 20 timesteps for each case. Each of the eight paired datasets was sub-divided into 72 patches to decompose the dominant flow features into smaller-scale flow features that may be conserved across varying geometries. The entire dataset included 11,520 patches. The dataset was split using a 6:1:1 ratio for training, testing, and validation. The physiological pulse wave inflow condition with a $Re_{peak}$ of 500 at 10% and 20% noise levels was reserved for testing and validation.

The neural network architecture, shown in Figure 1, is based on the DCSRN network architecture that was previously used for denoising MRI data [6]. The network was trained using the traditional mean square error loss function and a divergence regularization term. Pytorch was

used for implementation [8]. The Adam optimizer was used for training [9].

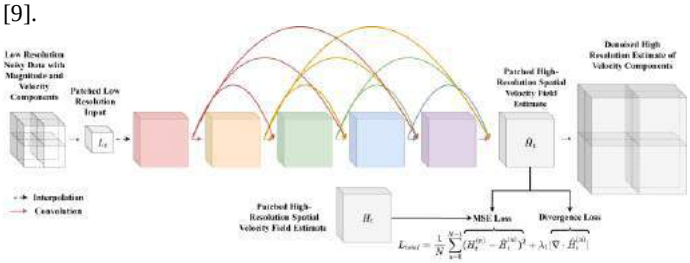

**Figure 1: Physics-guided neural network (PGNN) utilizing patching and a divergence-based regularization term.**

## RESULTS

For validation, we assessed the trained network's performance in the case of flow through a stenotic pipe with a physiological pulse wave resulting in a peak Reynolds number of 500. The synthetic 4D Flow MRI data with 10% noise and 20% noise was the input for the trained model. We observed a temporally averaged mean square error of 1e-4 between our network's reconstruction of the high-resolution velocity field and the high-resolution structured CFD data. Qualitative results are shown below in Figure 2 and illustrate the network's ability to resolve flow recirculation and near-wall velocities.

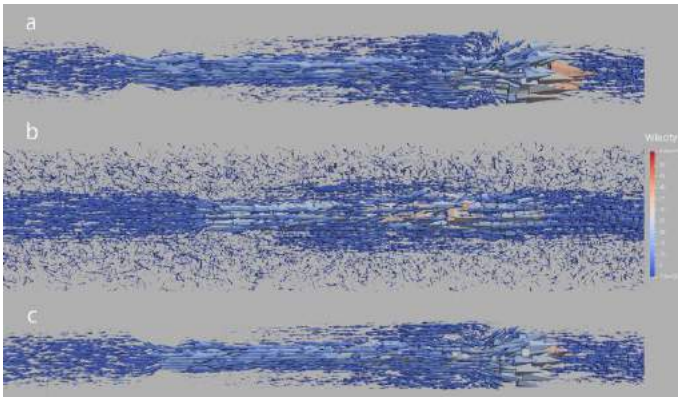

**Figure 2: PGNN shows the ability to denoise and super-resolve synthetic 4D Flow MRI. (a) High-resolution target data derived from CFD simulations, (b) synthetic 4D Flow MRI downsampled in time and space with 10% added noise, and (c) network estimation of the high-resolution, denoised velocity field.**

Upon examining the reduction of the mean square error and divergence error, we observed temporally dependent characteristics of the error terms. Figure 3 demonstrates the cumulative dimensionless divergence error increases as diastole progresses.

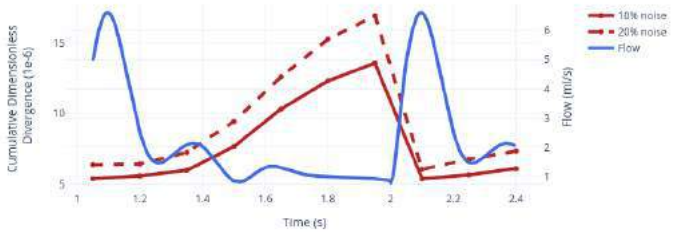

**Figure 3: Temporally dependent cumulative dimensionless divergence error with 10% added noise (solid red) and 20% added noise (dashed red) with the superimposed pulse wave (blue).**

## DISCUSSION

These preliminary results indicate that our physics-guided neural network can denoise and estimate the high-resolution velocity field for stenotic pipe flow. By using a divergence-based metric as a regularization term, the mass conservation of the flow is enforced, which aids in generating more physically consistent results. This will enable more reliable derivation of flow metrics including WSS. Interestingly, we observe a temporally dependent divergence and mean square error profile, which is in accordance with observations by Ferdian *et al.* [4]. Utilizing temporal dependence of the flow may enable greater performance and will be the focus of future work. Additionally, a dataset of CSF flow within varying cerebral ventricle geometries will be created and paired synthetic 4D Flow MRI with varying noise levels will be generated as performed in the current work. Once trained on CSF flow within the cerebral ventricles, we will apply this network to in-vivo and in-vitro 4D Flow MRI cases.

# PCR-BASED APPROACH TO MEASURE INTRAVASATION AND METASTASIS OF MOUSE CANCER CELLS IN THE CHICK CHORIOALLANTOIC MEMBRANE ASSAY

**Molly C. Brennan (1), Susan E. Leggett (1), Celeste M. Nelson (1,2)**

(1) Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ, USA
(2) Department of Molecular Biology, Princeton University, Princeton, NJ, USA

## INTRODUCTION

Metastasis is responsible for the majority of cancer-related deaths. Understanding the risk of metastasis is necessary when determining a patient's prognosis and deciding upon the appropriate treatment. Animal models are often used to study the metastatic cascade. Tumor formation, intravasation, and metastasis can be studied in the chick chorioallantoic membrane (CAM) assay. When compared to other animal models, the CAM assay has several advantages, including the brevity of the assay and natural immunodeficiency in chick embryos. To measure intravasation, low numbers of cancer cells must be detected in samples from the lower CAM and various organs. Previously, PCR-based approaches using primers that bind to Alu repeat sequences have been used to amplify human DNA and detect human cancer cells in the CAM assay (*1*). However, many mouse cell lines are used in cancer research and, as Alu sequences are not present in the mouse genome, another method was needed to detect mouse cancer cells. Using primers that bind to B1 repeat sequences found in the mouse genome, we developed a quantitative PCR-based approach to measure intravasation and metastasis of mouse cancer cells in the CAM assay. As an application of this method, we are investigating the relative intravasation and metastasis of epithelial-like and mesenchymal-like populations derived from a mouse cancer cell line.

## METHODS

We performed PCR with primers that bind to the B1 repeat sequences in the mouse genome (*2, 3*) to detect 4T1 triple-negative mouse breast cancer cells in the CAM assay. A window was created above the upper CAM on embryonic day 3. On embryonic day 9, the mouse cancer cells were xenografted onto the upper CAM. On embryonic day 18, the embryo was sacrificed, and the tumors formed on the upper CAM were imaged. The areas of the tumors on the upper CAM were measured to determine tumor burden. A sample from the highly vascularized lower CAM was extracted and used to measure intravasation. Samples from the liver and lung were extracted to measure metastasis (**Figure 1**). Genomic DNA was isolated from the samples and processed for PCR.

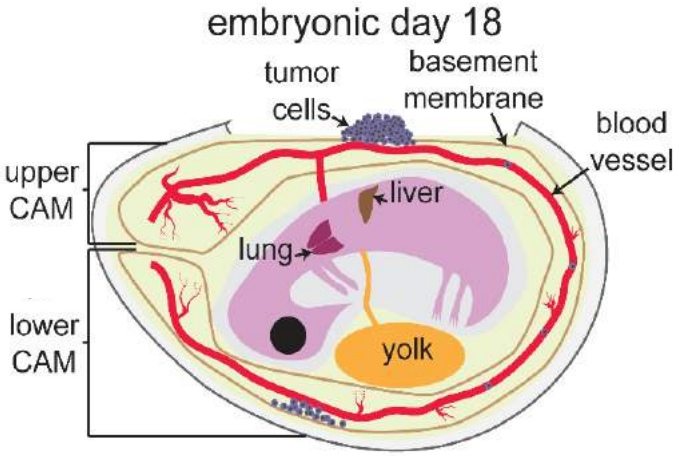

**Figure 1: Schematic of the chick CAM assay.**

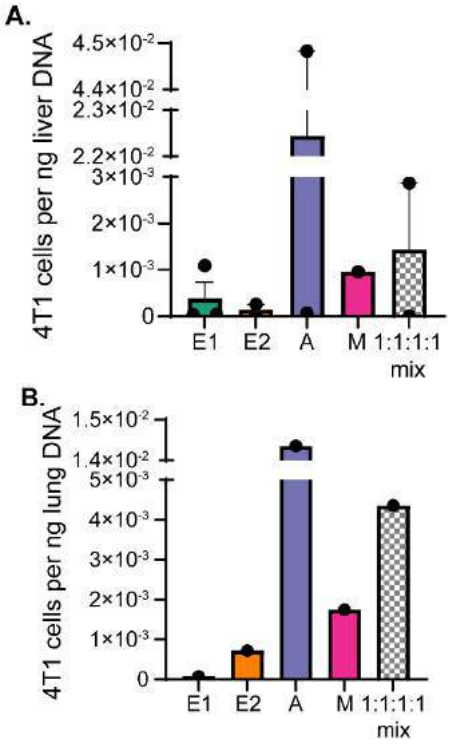
## RESULTS

Using quantitative PCR, we were able to detect mouse cancer cells in samples from the lower CAM, liver, and lung. Primers bound to B1 repeat sequences in the mouse genome and amplified mouse DNA in the samples. The B1 repeat threshold cycle for each sample was then compared to a standard curve relating B1 repeat threshold cycles to the number of mouse cells per nanogram of DNA. The number of mouse cells per nanogram of DNA was used as a measure of relative intravasation and metastasis.

We have begun to investigate intravasation and metastasis by epithelial-like clonal populations, mesenchymal-like clonal populations, and mixes of clonal populations of 4T1 mouse breast cancer cells. Epithelial-like clonal populations (E1 and E2) and mesenchymal-like populations (A and M) were derived from single cells in the parental 4T1 cell population. The expression of E-cadherin and vimentin by these populations was measured to verify their phenotypes as epithelial-like and mesenchymal-like. Homogeneous clonal populations and a 1:1:1:1 mix of the populations were xenografted onto the chick embryo and samples were extracted on embryonic day 18 to measure relative intravasation and metastasis. All populations formed tumors on the upper CAM, and cancer cells from several populations could be detected in the lower CAM, liver, and lung. Relative metastasis was measured as the number of 4T1 mouse cancer cells detected per nanogram of DNA from the liver and lung (**Figure 2**).



## DISCUSSION

Using quantitative PCR, we established a method that permits the use of mouse cancer cells in the CAM assay. Using primers that bind to B1 repeat sequences, the amplification of mouse DNA allows for the detection of low numbers of cancer cells in a sample. Mouse DNA detected in samples from the lower CAM is used to measure intravasation, while that from the liver and lung is used to measure metastasis.

This quantitative PCR-based method enables the use of the CAM assay to investigate metastasis of mouse cancer cells. For example, the relative intravasation and metastasis of epithelial-like, mesenchymal-like, and heterogeneous mixtures of mouse cell lines can be examined in this model. We have used this approach to investigate potential differences in intravasation and metastasis as a function of epithelial/mesenchymal phenotype. Overall, the quantitative PCR-based method enables researchers to use any of the many common mouse cancer cell lines in this animal model to study metastasis.

# RADIOFREQUENCY ABLATION OF THE MEDIAL NERVE FOR FACET JOINT PAIN ALTERS THE BIOMECHANICS OF THE SPINE - A COMPUTATIONAL STUDY

## INTRODUCTION

Lower back pain affects the lives of an increasing number of individuals, deteriorates their movement and lifestyle, and hinders their capability of performing daily-life tasks. Back pain is related to facet joint in approximately 31% of the cases [1]. The first line of treatment for facet joint pain is physical therapy. However, if physical therapy is not effective, radiofrequency ablation (RFA) of medial nerve is prescribed. Although RFA provides pain relief to the patients, it also denervates the multifidus muscle (MF). The multifidus is one of the most essential muscles for the stability of the lumbar spine [2]. By activating psoas major (agonist) and multifidus muscles (antagonist), stability is increased in lateral bending and torsion [3]. Multifidus contraction also influences intradiscal pressure in the lumbar joints [4]. Therefore, denervation of multifidus after RFA may affect the biomechanics of the spine. In fact, an increase in degeneration of the intervertebral disc has been reported after RFA [5]. However, the changes in spine biomechanics after RFA are not well known. The objective of this study is to quantify changes in joint angle and loading of the intervertebral disc after RFA of the medial nerve using computer simulations. We hypothesize that RFA ablation of the medial nerve affects the loading of the intervertebral joint in the different directions of reaction forces and joint angles.

## METHODS

This study used the force-dependent kinematics (FDK) module of AnyBody Modelling Software (Version 7.3, AnyBody Technology A/S, Aalborg, Denmark) that have been previously validated in different conditions [6,7]. Intervertebral joint forces (mediolateral, proximodistal and anteroposterior) and angles in the lumbar spine were calculated for the following movements: 50º flexion, 20º lateral bending, and 20º torsion. The range of motion for those body movements were chosen to represent common daily activities [8]. Both unilateral (MF Red Unil) and bilateral ablations (MF Red BiL) were compared to intact multifidus muscles (MF ON). The reduction of force production of the multifidus fascicles after RFA was simulated by reducing the physiological cross-sectional area (pCSA) of the fascicles similar to other studies [9]. The spine levels analyzed in this study were the L3L4-L4L5-L5S1 joints. The reduced cross-sectional area (rCSA) for each fascicle of the multifidus was calculated as:

$$rCSA = (\#\ joints\ spanned - \#\ joints\ ablated) / (\#\ joints\ spanned) \times pCSA$$

where # *joints spanned* is number of intervertebral discs between the proximal and distal insertion point of the fascicle, and # *joints ablated* corresponds to the number joints ablated within the insertion points.

## RESULTS

Figure 1 shows the joint angle and forces for different motions and treatments. As the flexion angle of the torso increased, the difference in disc joint angle between MF ON and MF Red UniL, and MF ON MF Red BiL also increased. The maximum differences among the joint angles were seen in the L5S1 disc: 1.4º for unilateral, and 2.93º for bilateral ablation. A similar change in the disc lateral bending angle of the disc was observed during lateral bending of the torso, with maximum differences of 1.7º and 2.07º in the L5S1 joint for unilateral and bilateral ablations respectively. Meanwhile in torsion, the maximum differences in the disc torsion angle (0.35º for unilateral, and 0.74º for bilateral RFA) were found in L4L5 joint.

The proximodistal reaction forces differences in flexion were highest between MF ON and MF Red UniL and MF Red BiL in the L5S1 disc (33.12 N and 59.75 N respectively). The general trends for lateral bending reaction forces showed that the largest absolute maximum difference for mediolateral force was in L3L4 in both unilateral (28.71 N) and bilateral reduction of MF (27.99 N). Regarding torsion, the absolute maximum difference for mediolateral reaction

forces where highest in L4L5 in unilateral (11.1 N) and bilateral reductions (14.73 N). Meanwhile, L4L5 had the highest difference anteroposterior reaction forces unilaterally (14.26 N) and bilaterally (31.26 N).

## DISCUSSION

The simulations of spine deformations shown differences in joint angles and forces after RFA. Some differences are more pronounced in the case of bilateral RFA compared to unilateral. For instance, the increase in joint angle in flexion as it changes from MF ON to unilateral then to the maximum mean in bilateral ablation. In this motion, the action multifidus from both sides of the spine is cumulative. Therefore, larger differences can be expected for bilateral ablation. However, for other motions like lateral bending and torsion, the fascicles of the multifidus from both sides of the multifidus experience different activation and elongation. Therefore, the differences between unilateral and bilateral ablation are not as pronounced.

There was considerable angular difference in flexion between the angle of L5S1 with intact and with bilateral reduction (maximum difference= 2.93º). Also, in lateral bending of the L5S1 joint, the maximum difference between intact and bilaterally reduced MF was 2.07º. These changes in disc angle can be considered large relative to the normal values (up to 30%) and can have significant effects in the mechanobiology of the spine. An increase in angles during flexion with bilateral ablation can lead to larger deformations in the intervertebral disc, which can lead to altered cell behavior and structural damage. Therefore, these changes may lead to the increase in disc degeneration after RFA reported in a previous study [5].

The largest absolute difference in proximodistal joint forces for flexion in the L5S1 joint (59.75 N) is relatively small compared to the total value of the force (~1400 N). This is expected since the contribution of the force generated by the multifidus is relatively small compared to the force generated by other muscle like the erector spinae and the weight of the upper body. The changes in reaction forces in lateral bending and torsion are also small (10-20 N), but represent a large percentage of the normal force.

Modification of pCSA have been used by other studies to change the force production of the spine muscles. For example, a previous study altered the pCSA of deep muscles to change the maximum force. This study found that joint shear forces were decreased with the increase of maximum force of the muscles. [9] Another study used different pCSA values of the transversus abdominis muscle to study their strength. They found that, by altering PCSA, the spinal loading was detrimentally affected by changing the strength of this muscle. [10]

One of the limitations of this study is that the model was only for the spine, not including arms and lower limbs, to simplify FDK calculations. Another limitation is that model represents an average size male body. However, it is expected that similar results would be obtained for bodies with other anthropometric characteristics.

It can be concluded that modifying the MF muscle by RFA leads to changes in loading and angles of intervertebral joints, leading to more susceptibility to disc degeneration and facet joint pain. The findings from this research can help in treating facet joint pain which is caused by load alteration.

## INTRODUCTION

Platelet adhesion to blood vessel walls and platelet-platelet aggregation in shear flow is essential in initiating the blood coagulation cascade and prompting clot formation in prosthetic cardiovascular devices and vascular disease processes. In adhesion and aggregation, which lead to thrombus formation, platelets undergo complex and rapid receptor-ligand binding such as GPIbα-von Willebrand factor (vWF) and αIIbβ3-Fg-αIIbβ3 bond association and breakage.

We have developed a combined Dissipative Particle Dynamics (DPD) - Coarse Grained Molecular Dynamics (CGMD) multiscale model (MSM) to continuously evolve platelet structures, to describe the platelet mechanotransduction process induced by blood flow and synergistically activate platelets, aggregate, and adhere to the blood vessel wall [1-2]. In addition to describing flipping and adhesion of a deformable platelet, we modeled a thrombus interacting with flowing platelets consisting of 250 platelets, the first of such effort to integrate multi-physics of thrombus formation at multi-scales [3].

Due to the vast spatial and temporal scales involved in this multi-component system, we developed a novel artificial intelligence (AI) inference algorithm that adaptively adjusts multiple timestep (MTS) sizes to underlying biophysical dynamics, with the overall modeling accuracy and speed are largely improved [4], achieving 500× speedup over fixed timestep sizes. To overcome a major challenge of analyzing flowing in vitro platelet images and generating accurate inputs for the MSM platelet simulations, we applied a semi-unsupervised learning system (SULS) [5], trained and fine-tuned with in vitro platelet morphological changes under flow shear. We describe the kinematics of platelet adhesion and thrombus formation, illustrate the implementation details of the AI-MTS algorithm, and summarize the biophysical insights our system provides.

## METHODS

Two simulation systems were used in this study. For platelet adhesion, we adapted our deformable CGMD multiscale platelet model to describe flipping over vWF in a channel with DPD particles at 30 dyne/cm$^2$ (Fig. 1A). The platelet's bilayer membrane has a total of 67,004 particles, with 16,751 particles designated as GPIbα receptors, with a particle density of 585/μm$^2$. The vWF, with 506/μm$^2$ density, is fixed on the blood vessel wall, binds to a platelet GPIbα receptor, and initiates platelet adhesion.

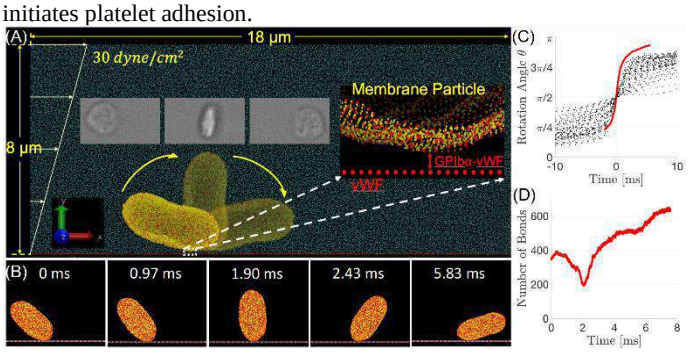

**Figure 1. (A) MSM platelet adhesion model. (B) Simulated platelet flipping. (C) Rotational angle of MSM platelet (red curve) and in vitro results (black dots) and (D) GPIb*α*-vWF bonds over time.**

Additionally, a large-scale multiscale system of a flow-mediated forming thrombus with 102 million particles, representing 70 flowing and 180 aggregating platelets under shear flow, was simulated and integrated with our AI-MSM framework (Fig. 2). A microchannel is simulated by a rectangular channel (302.3×21.3×19.9 μm), with periodic boundary conditions. Two thrombi are attached to the blood vessel wall, each consisting of 90 aggregated platelets and form a

stenosis of 14.3 μm in the microchannel. The blood vessel walls are modeled with a no-slip boundary conditions with a pressure-driven fully developed Poiseuille blood flow between the top and bottom plates.

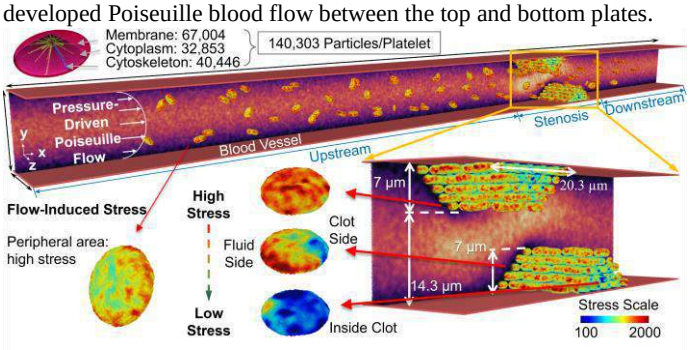

**Figure 2. Simulated thrombosis with 102,300,840 particles, involving 70 flowing platelets and 2 thrombi, each with 90 aggregated platelets.**

The force field between the platelet GPIbα receptor and the vWF ligand is described by a hybrid force field combing Morse and Hooke potentials:

$$E_{Adhesion} = E_{Morse} + E_{Hooke} \quad (1)$$

$$E_{Morse} = D_0\left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)}\right) \quad (2)$$

$$E_{Hooke} = k_1(r-r_b)^2 + k_2(r-r_b)^4 \quad (3)$$

The aggregation between receptors of the platelets is mediated by the membrane GPIIb-IIIa receptors and fibrinogen (Fg), governed by a force field [2]:

$$\boldsymbol{F}_{ij} = D_0\left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)}\right)\boldsymbol{e}_{ij} + f^A(t_{ij})\left(1-\frac{r_{ij}}{d_c}\right)\boldsymbol{e}_{ij} \quad (4)$$

The hybrid force field was parameterized, and the GPIbα receptor distribution was modified based on the curvature of the platelet, to reproduce flipping kinematics as the rotation angle $\theta$ during adhesion. We validated our numerical method by correlating simulations (Fig. 1B) and model predictions with in vitro results [6].

Our MTS algorithm splits the system into two subsystems based on the spatial scales of the underlying components [5]: the fluid at the macroscopic scale and the platelet at the microscopic scale. A three-level MTS time integrator is developed to handle the two subsystems and the interface using different timestep sizes. The characteristic $\Delta t_{\mathrm{f}}$ is employed to integrate the fluid subsystem aggressively, and a variable $\Delta t_{\mathrm{p}}$ attuning the dynamics is applied to the platelet subsystem for capturing molecular-level details while an intermediate $\Delta t_{\mathrm{m}}$, where $\Delta t_{\mathrm{f}} > \Delta t_{\mathrm{m}} \geq \Delta t_{\mathrm{p}}$, handles the fluid-platelet interface bridging the energy exchange. By collecting the multiple time series properties which describe the platelet dynamics, we were able to predict the adaptive timestep sizes and number of jumps by a deep learning framework consisting of (a) a 2-stage denoising by moving average and wavelet transform filters to cleanse high-frequency noise in raw data and (b) two RNN-based autoencoders to extract latent features.

## RESULTS

Our multiscale model successfully described the biophysical properties for platelet adhesion and thrombus down to *nm*-length and *ps*-time scales.

The progression of the simulated flipping angle $\theta$ during platelet adhesion follows the in vitro observations well, with slightly higher peak flipping speed – as compared with the ML-guided in-vitro analysis of the flipping (Fig. 1C). The model further distinguishes between the distinct lift-off and reattachment periods of the flipping. GPIbα-vWF bond number is variable during the flipping, ranging from 200 to 650 (Fig. 1D). The total GPIbα-vWF bonds force, ranging from 1 to 1.5 nN, primarily acts in the y-direction, and is positively correlated with the number of bonds. Ongoing simulations and in vitro experiments will expand our predictive capability over the 15-45 dyne/cm$^2$ range.

In the thrombus formation system, the position of individual platelets impacts the accumulation of flow-induced stresses: the closer to the blood vessels, the larger stress accumulation as expected (Fig. 2). The periphery zone of the platelets (red) experiences larger stresses than its central area (green/blue). Platelets that have aggregated have relatively larger stresses than those of flowing platelets. For the two thrombi, surface platelets exposed to flow experienced larger stresses than those at the core layers of the thrombus (Fig. 2). Fluid particles approaching the stenotic section strongly accelerated downward, the redirected upwards after passing the first thrombus, slowing down downstream of the stenotic section (Fig. 3). Shear stresses of blood flowing in this system corresponded to its velocity profile, where high shear stress was observed near the blood vessel wall and declined gradually in the center of the microchannel, with the highest stresses generally observed upstream of the thrombi.

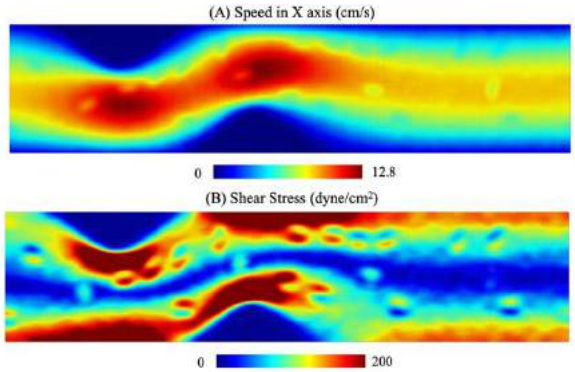

**Figure 3. (A) Flow speeds and (B) shear stress through the stenosis.**

## DISCUSSION

We simulated the adhesion process of a flowing marginated platelets in a flow channel, where our results converging towards high-fidelity prediction of flipping dynamics. We modeled a multi-physics MSM of flow- and platelet-mediated thrombus formation involving 102 million particles and integrated an AI-MTS algorithm for splitting the system and adapting timestep sizes to varying dynamics. This MSM approach enables computationally affordable, highly resolved, and validated granular studies of flow dynamics in stenoses, accumulated stress-induced platelet activation, platelet adhesion to vWF-coated vessels, and recruitment aggregation of flowing platelets with activated platelets adhered to the vessel walls. Nanoscale-level depictions of the biophysical properties of deformable platelets allows mapping of hemodynamic stresses on membrane and intra-platelet components. This approach will be expanded to simulate thrombosis processes involving several hundred platelets under pathological flow conditions.

# SUBJETS WITH CAROTID WEBS EXHIBIT DIFFERENT HEMODYNAMIC FLOW PATTERNS THAN SUBJECTS WITH ATHEROSCLEROTIC LESIONS

**A. Sharifi (1), R. El Sayed (1,2), C. Park (2), D. Haussen (3), J. W. Allen (1,2,3), J. N. Oshinski (1,2)**

## INTRODUCTION

Carotid webs (CaWs) have previously been associated with stroke and they may account for up to one-third of cryptogenic strokes in younger patients between the ages 30-48 without vascular risk factors [1,2]. CaWs are intraluminal shelf-like projections in the internal carotid artery bulb that cause focal luminal narrowing of 20-50%. Unlike carotid atherosclerosis, CaWs are not characterized by inflammation, wall thickening, or plaque deposition. CaWebs are primarily characterized by intimal hyperplasia. The shelf/pyramidal shape of the CaW may result in significant hemodynamic disturbance resulting in flow separation, recirculation, stagnation, and ultimately thrombus formation. Understanding the hemodynamic alterations caused by CaWs is essential for determining the risk of thrombus formation and subsequent stroke. The ***goal*** of this study is to understand the effect of CaW geometry on local hemodynamic parameters, which may lead to the formation of clots.

Shear rate is considered an important hemodynamic parameter in clot formation, and low shear values have been linked to activation of the coagulation cascade [3,4]. We compared the area of low shear rate in the carotid bifurcation in subjects with CaW and subjects with mild atherosclerosis using computational fluid mechanics (CFD) simulations based on 3D patient specific imaging-based geometries. We ***hypothesized*** that CaWs will be associated with a larger area of low shear rate than mild atherosclerosic lesions.

## METHODS

This was an IRB-approved study. The study population included patients with CaWs (n=5, 4 female, age 48.3±10.8) with history of stroke or TIA and mild luminal narrowing near the web, and subjects with mild atherosclerosis (n=5, 2 female, age 71±14.60) with mild stenoses. All CaW subjects has computed tomography angiography (CTA) of the carotids available. All subjects were imaged on a 3T system (MAGNETOM Prismafit, Siemens Medical Solutions). Multi-slab, transverse, 3D time of flight (TOF) images were acquired to cover the bifurcation ($0.5mm^3$, TR=23ms, TE=3.1ms). 2D, ECG-gated, cine phase contrast (PCMR) images were acquired 10mm below and 10mm above the bifurcation (1x1x5mm3, VENC=80 cm/sec, TR=43.6, TE=7). Mimics and 3-Matics (Materialise, 2019) were used to create the smoothed 3D geometry based on segmentation of TOF images for subjects with atherosclerosis, and CTA images for patients with CaW. Fluent (ANSYS, 2021 R1) was then used to mesh the geometry and conduct transient flow simulations based on 2D PCMR at the inlet and constant pressure at the outlet with the assumption of rigid walls and the no-slip conditions. Outlet 2D PCMR data was used for validation of our CFD method (**Figure 1**).

Based on literature review, when the shear rate is below a value of 10 $s^{-1}$ it has been linked to coagulation and clot formation [3,4]. Therefore, the *fractional area of low shear rate* was quantified using the surface area of the computational domain that was below the threshold of 10 $s^{-1}$ divided by the surface area of the entire computational domain (carotid bifurcation starting from 10mm below the bifurcation to 10mm above the bifurcation). An unpaired t-test was performed for

statistical analysis comparing the areas of low shear between CaW subjects and atherosclerosis patients.

**RESULTS**

the *fractional area of low shear rate* was 0.33±0.24 for the 5 CaWs, and 0.05±0.05 for the 5 atherosclerotic lesions (**Table 1**). The difference was statically significant (p~0.05). The results are also presented visually (in **Figure 3**) with an example of each of the cases. The areas with low shear rate are shown with blue color. The results show that CaWs with similar degree of luminal narrowing to atherosclerosis are associated with a larger area of low shear rate and with more complex flow patterns.

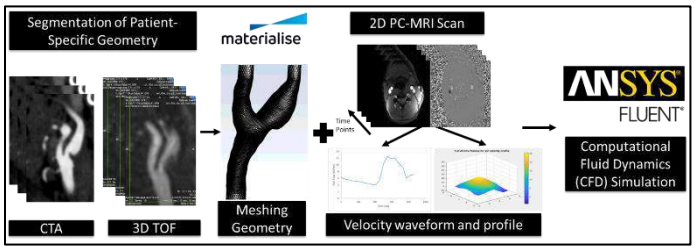

**Figure 1**.Overview of methods. Patient specific MRA geometry segmentation and smoothing using Materialize Mimics and 3-Matic. Fluent was used for the meshing and simulation of flow (ANSYS, 2021 R1). Velocity data from patient specific PCMR data.

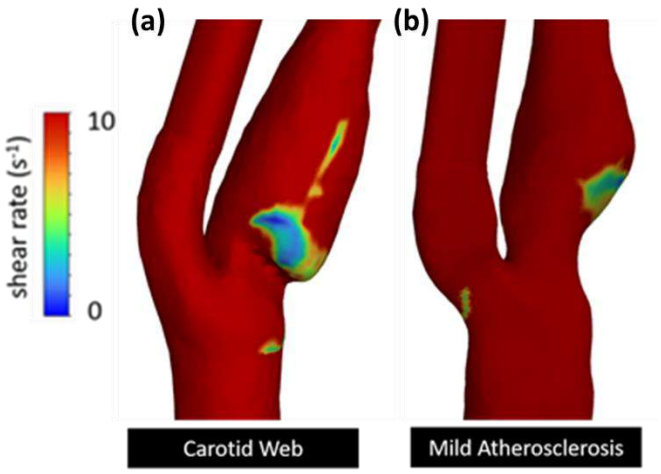

**Figure 3**. Area of low shear rate (<10 $sec^{-1}$) are shown in two example geometries: carotid web and mild atherosclerosis.

**DISCUSSION**

Carotid webs (CaWs) have been linked to cryptogenic strokes and therefore quantifying different hemodynamic parameters is essential to understand the mechanism of clot formation in patients. CFD modelling based on patient-specific geometry and PCMR inlet flow conditions was conducted on five subjects with CaWs and five subjects with mild atherosclerosis (with a similar degree of luminal narrowing. The total area within the carotid bifurcation that contained low shear rate values associated with clot formation is significantly larger in CaW subjects compared to subjects with atherosclerotic lesions or healthy subjects. The results indicate that CaW caused a greater degree of flow disturbance, recirculation, and stagnation in comparison to atherosclerosis with similar degree of stenosis.

In conclusion, CaWs showed a statistically significant larger area of area of low shear rate compared to atherosclerotic lesions and healthy carotid.

## INTRODUCTION

Carotid atherosclerosis is a leading cause of ischemic stroke and is characterized by inflammation, wall thickening, plaque build-up, stenosis, and thrombus formation. However, atherosclerosis is not the only cause of strokes as carotid webs (CaWs) account for up to one-third of cryptogenic strokes in younger patients without vascular risk factors [1]. CaWs are intraluminal shelf-like projections in the ICA bulb, which cause local lumen narrowing of only 20-50%, but can cause significant hemodynamic disturbance resulting in flow separation, recirculation, stagnation, and ultimately thrombus formation [2,3]. Low shear rate produces an environment enabling development of red clot that can embolize to produce strokes intracranially and this may occur distal to CaWs.

The ***goal*** of this study was to find the shear values in the thrombogenic areas where the specific area that a clot has formed in patients with CaWs. We identified a set of patients with CaWs who had a computed tomography angiography (CTA) scan *with a clot present* and another CTA study *without the presence of a clot*. Computational fluid dynamics (CFD) was used to simulate the blood flow in these patients *before* clot formation to determine a quantitative critical value for shear rate in the location that clot formed.

## METHODS

CTA images were acquired from six patients with CaWs with history of stroke or transient ischemic attack who had images *with* and *without* clot separated by less than one year. Images were segmented to create a smoothed 3D geometry using Mimics and 3-Matics (Materialise, 2019). As CTA is a static study without flow information, we conducted CFD simulations using the mean flow inputs from five patients with CaWs, who had undergone a 2D cine phase contrast magnetic resonance (PCMR) scan below and above the bifurcation. Fluent (ANSYS, 2021 R1) was used to mesh the geometry and conduct transient flow simulations based on 2D PCMR at the inlet and constant pressure at the outlet with the assumption of rigid wall and the no-slip condition. Outlet PCMR data was used for validation of our CFD method. Time averaged shear rate and particle residence time (PRT) over the cardiac cycle was determined for each case in the area where clot formed (**Figure 1**). The exact location of the formed clot was determined based on the images with the clot.

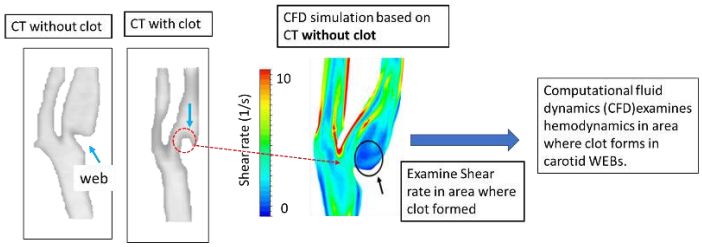

***Figure 1****. Overview of methods. Patient specific CTA geometry with and without clot. Examining the shear rate in the exact location of the formed clot shows the relation between the hemodynamic parameters in the Web patients and clot formation.*

## RESULTS

For the CaWs, the shear rate in the area inside the thrombogenic area is lower 10 $s^{-1}$. The areas with critical low shear rate are shown with blue color. It is known that low shear

rate values can cause red clot forming in some patients [2-4]. The other hemodynamic parameters including the particles residence time is also larger than 4 s in this section. (**Figure 2**). Moreover, the velocity values are very close to zero (stagnation) in the area of where the clot formed.

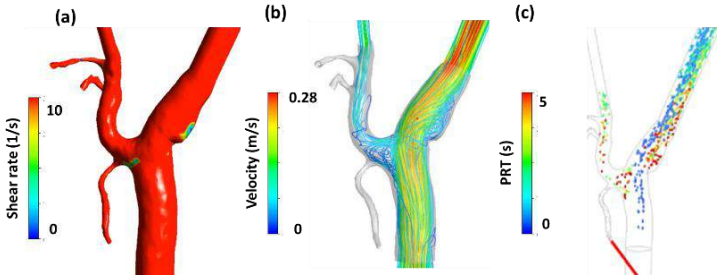

***Figure 2****. The hemodynamic parameters in a patient with CaW. (a) time averaged shear rate in a cardiac cycle, (b) streamlines during the systole, and (c) time averaged particle residence time in a cardiac cycle*

## DISCUSSION

While carotid webs (CaWs) have been associated with cryptogenic strokes, the mechanism of thrombosis is unknown. Therefore, we quantified different hemodynamic parameters such as shear rate directly in the area where a clot was known to have formed. Computational fluid dynamics (CFD) based on patient-specific geometry and PCMR inlet flow conditions was conducted on six subjects with CaWs. The area within the carotid bifurcation where the clot formed demonstrated low shear rate values (less than 10 $s^{-1}$), high PRT (longer than 4 cardiac cycle) and very low flow velocity (close to 0 m/s).

In conclusion, there exists and area of shear rate below 10 $sec^{-1}$ shear rate associated with the area of clot formation in CaW patients.

## INTRODUCTION

Breast cancer is the most common malignancy and the leading cause of cancer-related death in women worldwide **[1]**. Triple-negative breast cancer (TNBC), which accounts for 10-20% of all breast cancers, is the most aggressive breast cancer subtype with an overall 5-year relapse of 40% owing to metastatic spread of cells from tumor sites **[2]**. As metastatic cancer cells detach from a tumor site and acquire a highly migratory phenotype **[2]**, their successful progression to distant organs relies, in part, on membrane trafficking pathways to uptake and secrete factors that assist them in navigating within their surroundings **[3]**. Notably, endocytic membrane trafficking, responsible for the cellular uptake of key cell migration-promoting factors, has been shown to be easily disturbed by tension at the plasma membrane **[4,5]**. While tension gradients assist in maintaining a front-to-rear polarity of the cell during migration **[6]**, recently it has been shown that these gradients create an asymmetry in endocytic dynamics across the plasma membrane **[4,5]**, termed as polarized membrane trafficking. However, questions remain about whether this asymmetry is intrinsic to migratory TNBC cells and what its role is in cell migration.

We aim to develop experimental and analytical approaches that will allow us to monitor clathrin-mediated endocytosis (CME) and the force required to deform the plasma membrane in migrating TNBC cells, which can be used to quantify membrane tension **[7]**. This involves utilizing a microfluidic platform that simultaneously allows the leading and trailing edge of a cell to be separately treated during migration and enables the application of inputs native to the cellular microenvironment. To establish the role of asymmetric membrane trafficking in cell migration, we will separately apply small molecule CME inhibitors at the leading and trailing edges of migrating TNBC cells. Here, we discuss initial results showing an inverse relationship between CME dynamics and the force required to deform plasma membrane in stationary TNBC cells and our optimization of the microfluidic platform.

## METHODS

Our TNBC cell line, SUM-159 was genome-edited to express a fluorescently tagged component of CME, AP2-EGFP. AP2-EGFP expressing SUM-159 cells were maintained in an enclosed glass slide in environmental-controlled conditions overnight. Endocytic dynamics were then captured with laser scanning confocal microscopy **(Fig 1A)** and the force required to deform the plasma membrane was measured with optical tweezers shortly after **(Fig 1B)**. Precise locations to perform force measurements were selected by noting the varying thicknesses of plasma membrane around a cell body via brightfield microscopy. Both microscopy modules and the optical tweezers apparatus were housed within the same system, allowing fast exchanges between the different cell analysis modules.

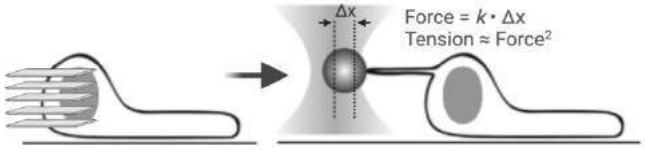

**Figure 1:** *Left*: Each cell is imaged for 7 min along 5 axial planes. *Right*: After an average delay of 3 minutes after confocal imaging, a tether is created at the plasma membrane 3 μm above the glass slide, where the force can be calculated from a bead's displacement, Δx and trap stiffness, *k*. Figure adapted from **[6]**.

Custom Python scripts were used to create the membrane tether and extract the force measurements performed on each cell. The maximum intensity projection of the imaged axial planes was processed for each cell over time with a custom MATLAB script to generate the slopes corresponding to the formation and dissolution of endocytic coats from the normalized fluorescence intensity curve of each endocytic event. These slopes were then used to obtain a distribution consisting of the rates of formation and dissolution of endocytic coat components during the entire timespan of cell tracking, termed the growth rate

distribution **(Fig 2)**. The smaller the standard deviation of the growth rate distribution, the larger the population of low magnitude slopes, or equivalently, the slower the formation and dissolution phases, and represents impeded endocytosis **[4,5]**.

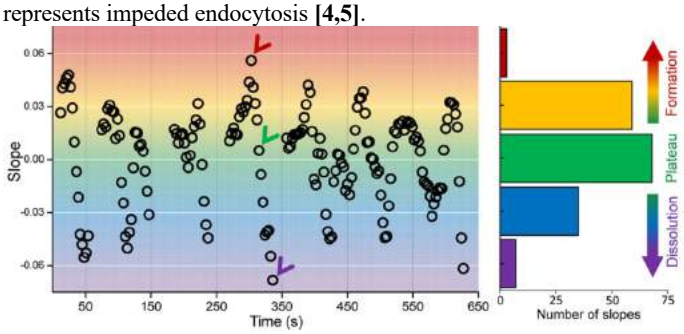

**Figure 2:** The growth rate distribution. *Left*: Slopes extracted from temporal windows centered at each timepoint of the fluorescence intensity curves of AP2-driven endocytic events. *Right*: Binning these slopes gives the growth rate distribution at a single AP2/CME hotspot over time. Figure adapted from **[5]**.

Our proposed microfluidic device will allow for unidirectional tracking of cells subject to mechanical stimulation by the microchannel walls and chemical stimulation by inducing steady-state gradients of epidermal growth factor (EGF) to induce chemotactic cell migration (*see Results section*). The device was designed with these considerations in AutoCAD and computationally modelled in COMSOL. FITC-dextran, a fluorescent molecule with a similar molecular weight to EGF, and its properties were used as input parameters. As activation of non-CME pathways is enhanced when high doses of EGF are used to induce chemotaxis compared to low EGF doses **[8]**, a low concentration (2 ng/ml) of FITC-dextran was additionally used as an input parameter in the simulations. A scalar mixing analysis was used to obtain the concentration distribution of FITC-dextran in the device by solving the steady-state Navier-Stokes and 1D advection-diffusion equations.

## RESULTS

Relating the tether force measured at areas of varying plasma membrane thickness to the standard deviation of the growth rate distribution obtained from the same SUM-159 cell, we find that the tether force is inversely related to CME efficiency **(Fig 3)**.

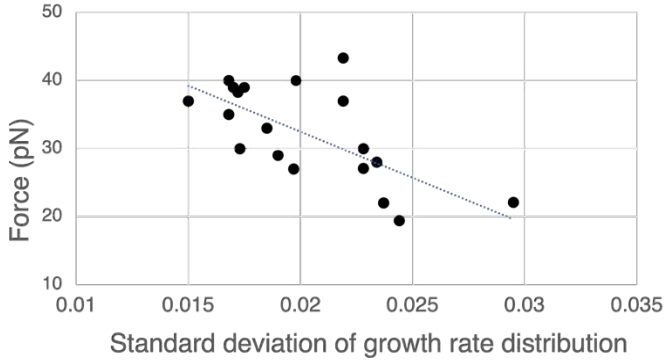

**Figure 3:** Inverse relationship between CME dynamics and the force required to deform plasma membrane in SUM-159 cells (n = 19).

The theoretical time for steady-state gradient establishment is 2.9 minutes (calculation not shown). In addition, endocytic dynamics may be recorded for periods up to 30 minutes without obvious signs of photoxicity. Thus, we concentrate our analysis of the computational model between the timespan of 3-30 minutes after introduction of FITC-dextran into the microchannels **(Fig 4A)**. We observe minimal loss of the gradient during this time **(Fig 4B)**, obtaining a maximum percent error in concentration differences between the 3- and 30-minute timepoints of 4% for a channel located at the edge of the device and 6% for a channel located in the middle of the device (at the location of each microchannel that is furthest from the FITC-dextran source).

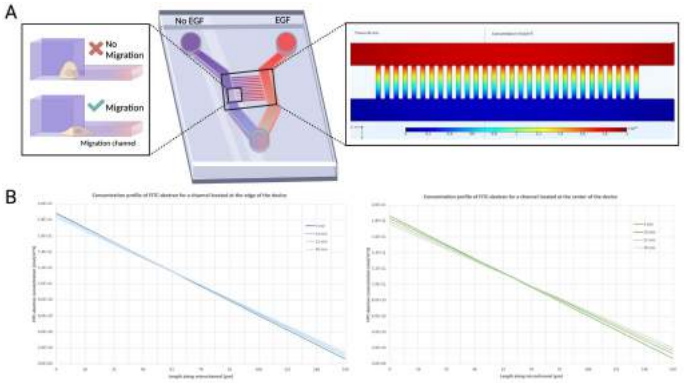

**Figure 4:** Simulated concentration profile of FITC-dextran, used to simulate the diffusive properties of EGF. **(A)** *Left:* Cells enter the microchannel only once they are well-spread i.e., less than 5 μm in height. *Right:* Concentration profile at 30 minutes. **(B)** Concentration profile along the distance of the microchannel for a channel located at the edge of the device (*left*) or at the center of the device (*right*).

## DISCUSSION

Although tether forces were performed on stationary, adherent cells, our results can be compared to force measurements performed on the plasma membrane of migrating cells, where membrane tension at the leading edge of cells is significantly greater than tension at the trailing edge **[4,6]**. As a cell polarizes towards a direction of migration, a heterogeneity in the thickness of the membrane becomes apparent, where the trailing edge of the cell appears thicker than the leading edge due to the localization of the nucleus to this area. We provide the first results connecting the spatial characterization of CME dynamics to the tether force, which may lead to the generalization that CME dynamics are reduced at leading edge with additional studies in migrating cells.

Fast establishment of a linear chemogradient and minimal loss of the gradient during the short timespan for measuring CME dynamics shown here will be desirable for future optimization, which will include experimental confirmation of the gradient by fluorescently imaging FITC-dextran (i) in the absence of cells and (ii) in the presence of cells with the addition of EGF. The completion of these studies will further allow us to connect the spatiotemporal distribution of endocytosis and membrane tension to the directionality of cell migration by performing force measurements and measuring endocytic dynamics in cell lines of varying levels of malignancy migrating in the microfluidic platform.

## INTRODUCTION

The concerted expression of genes sets, cross-referenced with the expertly annotated Kyoto Encyclopedia of Genes and Genomes (KEGG), [1] can illuminate the influence of an intervention on both a host and its microbiome. KEGG BRITE hierarchy files list pathway-organized KEGG orthologs (denoted by KO identifier, aka K number) and corresponding NCBI-GeneID. Metabolic pathway modeling and complex microbiome mapping can be used to examine human disease through the lens of microbial circuitry. However, a simple visual method could provide succinct clarity. The KEGG Mapper Color Tool (KCMT) visualizes the extent of differentially expressed host genes and the affected microbiome.

Merging host and microbiome pathway maps in ImageJ can clarify the host and microbiome boundaries, with specific focus on treatment changes. The goal of this study was to assess hypertension-induced cardiac gene expression in association with microbiome alterations following treatment of hypertensive rats with a proprietary muscadine grape extract. The muscadine grape (*Vitis rotundifolia*) is native to the Southeastern United States and muscadine grape seed and skin products are marketed as dietary supplements, based upon their antioxidant properties. Bioactive phenolic compounds found in grapes can serve not only as signaling molecules but also as fuel sources for the endogenous microbiome.

## METHODS

Sprague-Dawley rats (male, 8 weeks old, n=8/group) were treated for four weeks with drinking water, muscadine grapeseed extract (MGE, 0.2 mg phenolics/mL in drinking water), angiotensin II (Ang II, 24 µg/kg/h via osmotic minipump) to induce hypertension, or both Ang II and MGE (Ang II/MGE). Heart and fecal samples were flash frozen to -80°C for RNA sequencing (RNA seq) and bacterial identification from sequenced 16Sv4 amplicons, respectively. Genus proportions [Operational taxonomic unit (OTU), n=122, Microbiome Insights; Vancouver, BC, Canada] or 32,754 RNA seq counts (Bioinformatics Shared Resource of the Wake Forest Baptist Comprehensive Cancer Center) for the control group 25th (Q1) and 75th (Q3) percentiles [limits for the interquartile range (IQR)] [2] were calculated. All subjects in the four groups scored 0 (within IQR), -1 (< Q1) or 1 (> Q3).

$$\text{IQR score} = n_0*(0) + n_{-1}*(-1) + n_1*(1) \qquad (1)$$

An IQR score of 4 and OTU control Q3 $\geq$ 100 ppm, or for RNA seq control counts Q3 $\geq$ 64 was needed to assert change for treatment group. Only Swiss-Prot genes were searched for rat heart. 6350 bacterial species existed on the KEGG site on at the time of study. Each gene (by K number) found in > 25% of the species of a genus was included for this analysis. For visualization purposes, OTU gene hits as well as cardiac RNA seq were combined for changes by Ang II alone and both Ang II and the combination of Ang II and MGE [A∪(A∩AM)]. Similar analysis was also performed for changes by MGE alone and both MGE and the combination of Ang II and MGE [M∪(M∩AM)]. All OTUs were considered as the baseline bridge. First to fifth neighbors, for 33 KEGG pathways were explored for receiver operator conditions to show the relationship between cardiac and bacterial microbiome genes regulated by [A∪(A∩AM)] or [M∪(M∩AM)] treatments [3].

To investigate the affected metabolome, SMILES (Simplified Molecular Input Line Entry System) and KEGG pathway memberships via cardiac [A∪(A∩AM)] gene-connected compounds and gut [M∪(M∩AM)] gene connected compounds were tabulated from 9 pathways (F-AUC-3) with a 1-specificity and sensitivity area under the curve (AUC) of at least 0.7 or F-measure (2/[1/precision+1/recall]) of

at least 0.7 and at least 3 directly adjacent compounds to (adjC) cardiac [AU(A∩AM)] genes were fifth neighbor to adjC microbiome [MU(M∩AM)] genes.

## RESULTS

**Figure 1** is the fifth neighbor map for arginine and proline metabolism KEGG pathway as a representative of the 33 KEGG metabolic pathways analyzed. For 4109 cardiac [AU(A∩AM)] genes detected, 1075 genes (orange) were identified in KMCT. For 240 cardiac [MU(M∩AM)] genes detected, 50 genes (purple) were identified in KMCT. A total of 5718 microbiome genes and 670 compounds (pink) were identified in KMCT. For 7 microbiome [AU(A∩AM)] genera, 2714 genes (magenta) and 9 microbiome [MU(M∩AM)] genera, 4368 genes (cyan) were identified in KMCT.

For F-AUC-3, contingency tests of specific SMARTS (SMILES arbitrary target specification) or not that specific SMARTS vs. rat network adjacent or bacterial network adjacent compounds was analyzed. Arenes were predominantly found adjacent to cardiac [AU(A∩AM)] genes (odds ratio [OR] = 7.941; Fisher exact [FE] $p < 0.0001$), and carbonyls were generally located adjacent to microbiome [MU(M∩AM)] genes (OR = 2.980; FE $p < 0.01$). The extent of the rat genome and connected compounds is found in **Figure 2** (depicted by green edges and nodes). Thirty-five (35) microbiome [MU(M∩AM)] gene adjacent compounds, that were carbonyl and not arene, were mapped on the KEGG metabolic pathway map in black.

Aggregate correlate summation (ACS) [4] clustering performed on all of the Euclidean distances between the 35 microbiome [MU(M∩AM)] gene adjacent compounds on the KEGG metabolic pathway map yielded an arginine and proline metabolism cluster (yellow ellipse, **Figure 2**) and a galactose metabolism cluster. The compounds related to putrescine degradation in the ACS cluster are components of the arginine and proline metabolism KEGG pathway. Six putrescine to 4-amino-butanoate gut genes found in species in the genus Escherichia were downregulated by MGE. Analysis of the other ACS cluster was further explored for the galactose metabolism KEGG pathway and showed similar gene alterations.

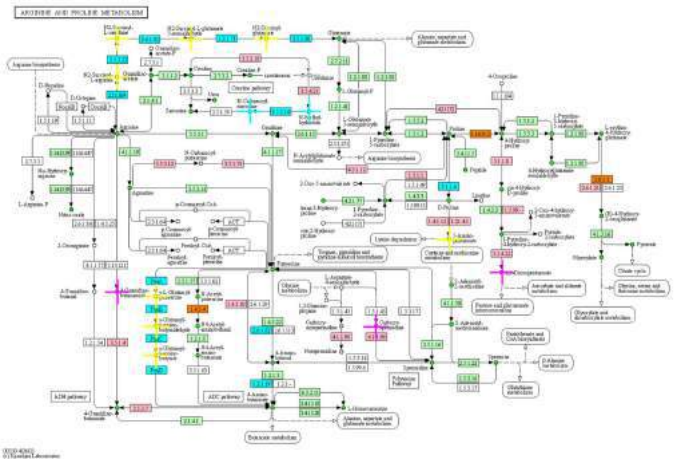

**Figure 1: Arginine and proline metabolism KEGG pathway; gene coloring- [AU(A∩AM)] cardiac (orange), ∉*i*[AU(A∩AM)] rat (green), [MU(M∩AM)] microbiome (cyan), ∉*i*[MU(M∩AM)] microbiome (pink).**

## DISCUSSION

The results of the ACS clustering suggest more scrutiny of arginine and proline metabolism KEGG pathway is warranted. Putrescine may be shunted toward spermidine in the host. Spermine and spermidine administration can be beneficial for general metabolic health and positively correlated to healthy clinical parameters in cardiac tissue, through reactive oxygen species scavenging. N-acetylputrescine is converted to N4-acetylaminobutanal amine oxidase [flavin-containing] A (MAOA) which is upregulated by Ang II in the rat heart, possibly shunting putrescine away from spermidine in cardiac tissue.

In galactose metabolism, D-glyceraldehyde 3-phosphate is processed through an open circuit via D-tagatose 6-phosphate to galactitol by gut genes found in species in genus Escherichia, which is downregulated by MGE. MGE could restrict galactitol to exploit the prebiotic properties of D-tagatose. Galactitol is converted to D-galactose by aldo-keto reductase family 1 member B, which is downregulated by both Ang II and Ang II/MGE in rat heart. Galactitol is toxic at high levels and is reduced during intermittent fasting. Reduced conversion of D-tagatose 6-phosphate to either D-tagatose or galactitol 1-phosphate and further to galactitol in MGE gut indicates that tagatose 6-phosphate levels may play a role in MGE beneficial effects.

The results of this analysis suggest that microbiome metabolic network expansion could provide a useful tool for the investigation of complex biological systems.

# DEVELOPMENT OF POROUS, MINERALIZED COLLAGEN-CHITOSAN SCAFFOLDS TO RECREATE THE 3D CANCELLOUS BONE MICROENVIRONMENT

**Sandra Stangeland-Molo (1), Kathryn L. Benedict (1), Jacqueline H. Cole (1)**

(1) Joint Department of Biomedical Engineering
University of North Carolina-Chapel Hill and North Carolina State University

## INTRODUCTION

Three-dimensional (3D) *in vitro* platforms (microdevices and on-a-chip systems) are becoming more common in research, as they allow decoupling of local and systemic effects on cell behavior, recapitulate cell microenvironments, are more physiologically relevant compared to 2D culture, and have fewer ethical concerns [1,2]. A limitation of current 3D *in vitro* platforms of bone microenvironments is that they do not provide a model for studying the cancellous bone environment [3,4]. Highly porous and load-directing, cancellous bone is particularly susceptible to mass loss during disease [5] and thus important for assessing utility of therapeutic interventions. A challenge in creating 3D *in vitro* cancellous bone is development of a scaffold to support the cells and provide cues that best recreate the microenvironment.

Cells behave more favorably when they are cultured on a substrate that is similar to their native extracellular matrix [6]. Cancellous bone is a highly porous composite of type I collagen and hydroxyapatite mineral. Previous work on bone scaffolds have prioritized either protein mineralization [7,8] or increasing porosity [9,10], despite both being key components of the cancellous bone environment. Previous mineralized collagen scaffolds have included chitosan to provide additional structural support to achieve a desired mechanical stiffness but were limited for this application by low porosity [8]. Previous porous bone scaffolds have either not contained any protein [9] or not incorporated mineralization [10]. The goal of this study was to create porous, mineralized collagen-chitosan scaffolds that promote mesenchymal stem cell activity.

## METHODS

Scaffold Fabrication. Commercially available type I collagen (3 mg/mL) and chitosan were homogenized in desired ratios (10:0, 8:2, and 6:4 wt% collagen:chitosan) and then mixed with 20 vol% phosphate buffered saline (10x). To create large pores, a two-step freeze-drying protocol was used. Protein solutions were pipetted into Teflon molds that were placed on a copper block chilled to below -30 °C to induce ice crystal formation and growth. Once frozen, pellets were removed from the mold and lyophilized to remove water, leaving a porous cylindrical protein scaffold. Scaffolds were crosslinked in a 2:1 molar ratio of EDC:NHS with 98% ethanol as solvent to prevent protein dissolution and covalently bind proteins to retain the porous structure. Two mineralizing solutions, modified simulated body fluid (mSBF) and polymer-induced liquid precursor (PILP), were made using methods described previously [7,11]. Crosslinked scaffolds were rinsed 3x in deionized water and submerged in 20 mL of mineralizing solution for 14 days. After mineralization, scaffolds were rinsed 3x in deionized water, lyophilized, and prepared for characterization.

Characterization. Scaffold pellet pore size distributions and approximate porosity were determined by thresholding scanning electron microscopy (SEM) micrographs (n=4 per collagen:chitosan/ mineralizing formulation) and measuring pore size in ImageJ. Scaffold composition was evaluated using Fourier transform infrared (FTIR) spectroscopy, labeling characteristic peaks for collagen and chitosan.

Biocompatibility. Scaffolds (n=3 per formulation) were trimmed to 1 mm thick, biopsy-punched to fit in a 96-well plate, and then sterilized in ethylene oxide. Scaffolds were placed in a 96-well plate and immersed in cell growth medium comprised of Dulbecco's Modified Eagle Medium supplemented with 10% fetal bovine serum and 1% penicillin-streptomycin. Bone-derived rat mesenchymal stem cells (rMSCs) were plated in growth medium in a separate 96-well plate and allowed to attach overnight. Beginning at experimental day 0, scaffold-conditioned media or control growth media was added to rMSCs with daily media changes for 6 days. Cell-conditioned media was collected on experimental days 0, 3, and 6 for fluorometric measures of alkaline phosphatase (ALP) activity to assess rMSC function. Live/dead staining and fluorescence imaging of rMSCs were performed as an endpoint measure on experimental day 6. For quantitative viability measurements, fluorescence images were

processed in ImageJ to remove background and converted to a greyscale image for thresholding. The processed images were then analyzed using the built-in particle analysis tool in ImageJ, in which number of counted particles were exported for both live and dead cells.

Statistics. Differences between formulations were assessed using one-way ANOVAs with Tukey tests for multiple comparisons ($\alpha$=0.05, Graphpad Prism 9).

## RESULTS

Characterization. The two-step freeze-drying protocol produced porous scaffolds that retained the bulk of their structure through the crosslinking and mineralization steps. Some protein dissolution was present, but over 80% of the protein remained. Pores for each formulation ranged 2-230 μm in size, with mean pore sizes of 30 ± 35 μm despite differing formulations. Approximate porosity measures indicated low surface-level porosity for each formulation, with 10% porosity near the outermost face of the scaffold pellets. Preliminary data of interior scaffold pore architecture suggest pore size distribution of 6-290 μm, mean pore size of 85 ± 75 μm, and approximate porosity of 50%. SEM micrographs showed mineral deposition, appearing as cuboid crystalline deposits between 1-2 μm in length, on the exterior scaffold surface and on surfaces within the pores. FTIR spectra for all scaffold formulations displayed strong peaks characteristic of collagen for amides A, B, I, II, and III at ~3300, 2900, 1650, 1550, and 1200 $cm^{-1}$, respectively. The 8:2 and 6:4 collagen:chitosan formulations also had the chitosan out-of-plane C-O bending peak at ~560 $cm^{-1}$.

Biocompatibility. Culturing rMSCs in scaffold-conditioned media was not detrimental to cell health, evidenced by no statistical differences in cell viabilities between the scaffold formulations and the control (**Figure 1A**). All groups had average viabilities above 70%, and 10:0 mSBF and both 6:4 formulations had viabilities of 84%. ALP activity was clustered around 2 mU/mL and did not differ between each scaffold formulation or compared to the control at each timepoint (**Figure 1B)**.

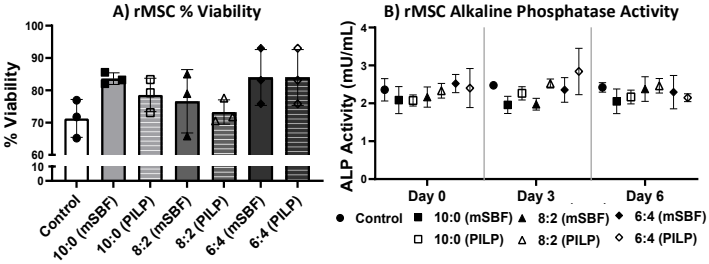

**Figure 1: A) % viability and B) alkaline phosphatase activity of rMSCs cultured for 6 days in scaffold-conditioned media.**

## DISCUSSION

The freeze-drying protocol was successful in producing porous collagen-chitosan scaffolds of varying wt% protein. The entire fabrication scheme produced mineralized biomimetic cancellous bone scaffolds that retained porosity through multiple processing steps. The varying weight % of collagen and chitosan proteins was reflected in FTIR spectra, which contained characteristic peaks for collagen and chitosan for the 8:2 and 6:4 ratio samples, in line with previous data [8]. While our mean scaffold pore sizes were lower than what has been reported previously for this freeze-drying method of unmineralized collagen:glycosaminoglycan scaffolds (150 μm, -40°C freezing temperature) [12], we presume that this is largely due to the location of our analysis. Measures in previous studies analyzed samples near the innermost region, while our initial analysis was taken from a more exterior location. Our preliminary data of interior scaffold porosity measures showed pore size distributions that skewed larger and a higher % porosity than the exterior measures. Further evaluation of interior scaffold porosity is ongoing. Additionally, we presume that the diminished pore architecture in our mineralized scaffolds relative to the previous study in unmineralized scaffolds is due in part to our fabrication method; when exposed to aqueous mineralization solutions, a small amount of protein dissolution likely occurs on the exterior scaffold surface, and this slow removal of uncrosslinked protein and subsequent scaffold drying likely leads to pore collapse. Despite the exterior protein loss and pore collapse, we are still able to retain pore structure and create mineralized biomimetic bone scaffolds.

Cell viabilities were not impacted by scaffold-conditioned media, and all formulations had average viabilities greater than or equal to 70%. The neutral effect of scaffolds on rMSC viability was not surprising and aligns with previous data [8]. Surprisingly, ALP activity was constant over the 6-day experimental window, and similar across all formulations and the control, indicating a lack of increased osteoblast differentiation. This finding differs from previous work showing higher ALP activity for mineralized scaffolds compared to controls [13]. ALP activity is usually measured for cells plated directly on the scaffolds, which likely is a key contributor to the differences in ALP activity observed here compared to past work. Cells are sensitive to the substrate they are cultured on and behave differently with varied stiffness and surface topology [6]. Since the rMSCs were cultured on treated tissue culture plastic and not the scaffolds, our results suggest that soluble factors in the scaffold-conditioned media are not sufficient to promote osteoblastic differentiation, at least on this timescale.

Limitations of this study include incomplete characterization of the mineral phase in scaffolds and plating of cells on tissue culture plastic rather than the scaffolds for biocompatibility analysis. Mineral composition and % mineralization are important metrics, as they influence the scaffold stiffness and cell responses [7,8]. Understanding cell responses when cultured on the scaffolds is also important, as their behavior is influenced by the substrate. While these metrics of mineral characterization and cell responses to culture on scaffolds were not included here, they are currently being collected as part of our study.

Overall, these results show that porous, mineralized biocompatible cancellous bone scaffolds can be fabricated using a two-step freeze-drying protocol and subsequent mineralization. This work is a first step in creating 3D *in vitro* environments to better study interactions within the cancellous bone niche.

## INTRODUCTION

Our goal is to develop vascular models of the tumor microenvironment (TME) in microfluidic devices to observe interactions between multiple cell types in 3D and to investigate factors that drive tumor growth, metastasis, and resistance to therapy. In this study, we have focused on the role of cancer-associated fibroblasts (CAF) in shaping the phenotype of the TME. Many other groups have developed 3D organoid or microphysiological to replicate the TME more fully than in 2D culture, but the majority of these lack functional vasculature, making studies of angiogenesis and immune cell extravasation from circulation into the tissue impossible [1,2]. This work overcomes this limitation by using CAF to support self-assembled vascular networks in microfluidic devices. To this end, tissue was dissociated from thyroid and oral cavity cancer specimens, and CAF were expanded. CAF or normal fibroblasts (lung, dermal, thyroid) were embedded in microfluidic devices, either with endothelial cells applied as a monolayer to assess sprouting or co-mixed to generate vascular networks. In these studies, we have quantified several ways in which CAF remodel the TME: induction of angiogenesis, secretion of cytokines and chemokines, production of extracellular matrix, recruitment of immune cells, and immunosuppression.

CAF are a heterogeneous cell type, defined by their function, and generally classified as myofibroblast CAF (responsible for fibrosis and extracellular matrix (ECM) remodeling), inflammatory CAF (secrete immunogenic and immunosuppressive cytokines), or the newly identified "antigen-presenting CAF" [3]. Recent results by other groups using CAF from head and neck cancers showed they induced lymphangiogenesis in a microphysiological model [4]. However, the work described here focuses on vascular angiogenesis, the secreted factors and extracellular matrix (ECM) responsible for modifying the TME, as well as subsequent immunosuppression through recruitment and polarization of macrophages.

## METHODS

Under IRB approval, tumor resection specimens were dissociated into single cells, and fibroblasts were isolated and expanded. CAFs or normal fibroblasts (lung, dermal, thyroid) were embedded in microfluidic devices with a single hydrogel channel. Endothelial cells were either applied as a monolayer to assess sprouting or co-mixed to generate vascular networks. For sprouting experiments, fluorescent human umbilical vein endothelial cells (HUVEC) were applied as a monolayer and allowed to sprout into the fibroblast-laden gels for 4 days before imaging and quantification of sprout area, length, and density (in FIJI). To generate microvascular networks for immune cell recruitment experiments, endothelial cells and fibroblasts were combined in fibrinogen and injected into microfluidic devices. Over 7 days, microvascular networks self-assembled. Then, T cells and monocytes were fluorescently labeled with cytoplasmic dyes and perfused through the microvasculature for 1 hour before washing out unbound cells with fresh cell culture medium. All imaging was performed on a confocal microscope. Secreted factors were quantified using bead-based cytokine arrays, angiogenesis protein profiler arrays, and ELISA for VEGF and CAF. All microfluidic devices were maintained in endothelial-specific culture medium (Vasculife VEGF, Lifeline Cell Technology) changed daily.

## RESULTS

Endothelial cells sprouted more readily into gels with CAFs than those containing normal fibroblasts, with 2.35-fold higher sprouting area ($p = 3 \times 10^{-18}$) in CAF devices (see fig. 1). Cytokine arrays and ELISA revealed that secretion of VEGF ($p = 0.02$) and CCL5 ($p = 0.006$) by CAFs was much greater than by normal fibroblasts, and CCL5 exhibited a significant positive correlation with sprout area ($p = 0.003$, $R^2 = 0.74$). Treating devices with neutralizing antibodies against VEGF and CCL5 nearly eliminated sprouting. Figure 1 summarizes the experimental design for sprouting quantification, example images, plots

of sprouting area comparing normal fibroblasts vs CAF or CAF controls vs CAF + blocking antibodies, CCL5 production by normal fibroblasts vs CAF, and the correlation between CCL5 and sprouting area.

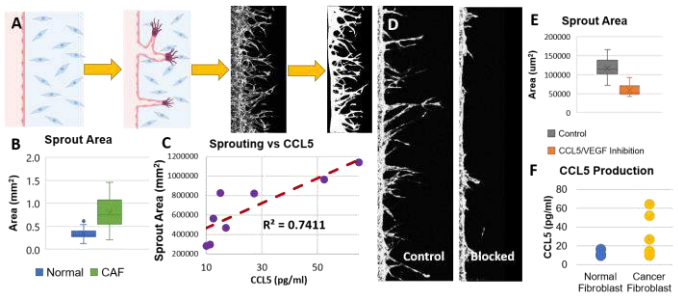

**Figure 1: A) Workflow to quantify angiogenic sprouting, B) sprout area in gels with normal fibroblast vs CAF, C) linear regression showed a positive correlation between sprouting and CCL5 concentration, D-E) sprouting is inhibited when VEGF and CCL5 are blocked with neutralizing antibodies, F) Secreted CCL5 in normal fibroblasts and CAF, quantified with ELISA.**

Additionally, CAFs supported generation of self-assembled microvascular networks, which were perfused with T cells and monocytes. The goal of this experiment was to observe their retention in the microvasculature to compare differential recruitment of these cell types in 3D microvascular culture systems mimicking healthy tissue or the TME. Perfusion of equal numbers of THP-1 monocytes and Jurkat T cells demonstrated that both cell types are retained more abundantly in microvascular devices containing CAF than in control devices made with fibroblasts from healthy tissue. Figure 2 shows example images of microvasculature from these devices shown in blue, with clear visible differences in the number of immune cells present in each case.

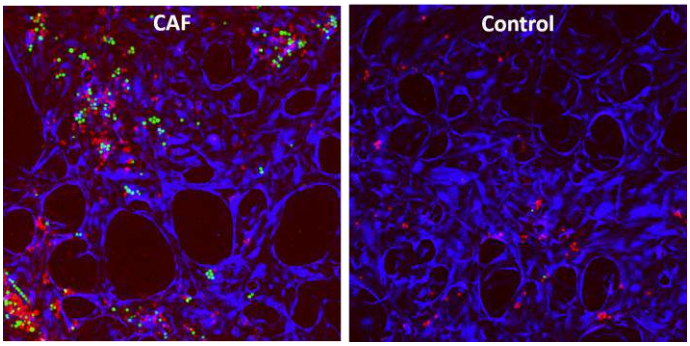

**Figure 2: Monocytes (red) and T cells (green) retained in microvascular networks (blue).**

The TME is typically immunosuppressive rather than immunogenic, despite the ability to recruit immune cells (as seen in figure 2). Therefore, we also examined the ability of CAF to polarize macrophages to the M2/tumor associated macrophage (TAM) phenotype. We generated non-polarized macrophages (M0) via differentiation from primary monocytes and M-CSF treatment for 6 days. M0 macrophages were then treated with CAF supernatant from 5 different patients, and RNA was collected for gene expression analysis with qPCR. Table 1 summarizes the relative expression of markers for M2 (CD206) and TAM (TGF-β) phenotype, as well as M1 (CD80) type. CAF from all five donors strongly polarized macrophages to the M2 type, and also generated significant expression of TGF-β, an immunosuppressive growth factor.

**Table 1: Gene expression of markers of M1/M2 polarization for macrophages incubated with CAF supernatant.**

| | M0-ctrl | CAF 1 | CAF 2 | CAF 3 | CAF 4 | CAF 5 |
|---|---|---|---|---|---|---|
| CD206 (M2) | 0.145 | 0.459 | 0.354 | 0.241 | 0.280 | 0.444 |
| TGF-b (TAM) | 0.116 | 0.170 | 0.179 | 0.130 | 0.152 | 0.150 |
| CD80 (M1) | 0.003 | 0.002 | 0.002 | 0.001 | 0.001 | 0.002 |

In addition to the stimulation of angiogenesis and the immunosuppression promoted by cancer associated fibroblasts, they are also involved in remodeling the extracellular matrix (ECM). Therefore, CAF promote metastasis both through direct interactions with tumor cells leading directed migration [5], as well as through pro-metastatic ECM modifications [3]. Devices were fixed with 4% paraformaldehyde and stained with an antibody for collagen 1 and a conjugate for hyaluronic acid, two ECM components related to CAF and the TME. See figure 3, below.

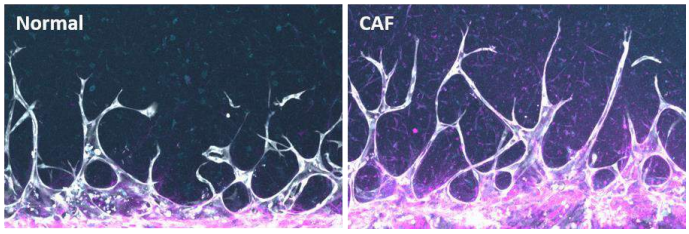

**Figure 3: Images of ECM in sprouting devices (normal vs CAF), with endothelial cells in gray, hyaluronic acid in cyan, and collagen 1 in magenta. Collagen 1 is notably more apparent in the device containing CAF, as expected.**

## DISCUSSION

This work represents the first demonstration of *in vitro* 3D microvascular networks formed with patient-derived cells for immuno-oncology studies. The overarching goal is to determine how CAF reshape the phenotype of the TME, including processes such as remodeling of the ECM, neovascularization via sprouting angiogenesis, secretion of cytokines and chemokines, recruitment of immune cells and subsequent polarization to immunosuppressive phenotypes. In this project, we generated vascular networks by combining cancer associated fibroblasts with endothelial cells, which allowed us to perfuse T cells and monocytes through the vasculature *in vitro*. In another configuration, sprouting was quantified by adding the endothelial cells as a monolayer on one side of the fibroblast gel and showed higher angiogenesis in devices containing CAF, likely due to VEGF and CCL5, which were identified to be secreted in significantly higher concentrations by CAF than by normal fibroblasts. Ongoing studies will increase the number of specimens included in this work, incorporate tumor spheroids, and quantify immune cell migration with primary and patient-derived immune cells.

# FABRICATION AND CHARACTERIZATION OF 3D-PRINTED ANISOTROPIC, HYDROGEL LATTICES

**Margrethe Ruding (1), Daniel Yoon (1), Charlotte A. Guertler (1), Annabella Mascot (1), Philip V. Bayly (1)**

## INTRODUCTION

Many fibrous biological tissues are structurally and mechanically anisotropic. Mechanical anisotropy plays an important role in normal tissue function and is affected by injury and disease. In modeling and fabricating synthetic biomaterials, it is thus important to include anisotropy [1-3]. Furthermore, fibrous materials may exhibit anisotropy in both tension and in shear. One way to incorporate anisotropy is via a reinforcing fiber network or lattice structure. Others have characterized isotropic 3D-printed lattices [4,5] but ignored anisotropy. This previous work has also focused on materials that are much stiffer than soft tissue.

The objective of this study is to design, 3D-print, and characterize isotropic and anisotropic hydrogel scaffolds of various lattice types. These 3D-printed, hydrogel lattices will allow us to create tunable, structures of desired shape, stiffness, and anisotropy (shear and tensile), to advance research in the field of soft biomaterials and biomechanics.

## METHODS

Lattice and sample design: Samples were designed using Rhino7 (Robert McNeel & Associates, Seattle, WA) [6] and plugins Grasshopper and Intralattice. (ADML, Montréal, QC) [6,7]. Unscaled (isotropic) and scaled (anisotropic) versions of three lattices (cubic, diamond, and vintile) were created. Unscaled lattices had a unit cell spacing of 1.25 mm; strut diameter was 0.4 mm for cubic and diamond lattices, 0.2 mm for vintile lattices. To create anisotropic lattices, the lattice was scaled by a ratio of 2 in one direction. In this abstract the direction of scaling (elongation) is denoted as the "X"-direction.

Samples for two mechanical tests: compression (cube, 10×10×10 $mm^3$) and dynamic shear testing (DST; disc 15 mm dia × 4 mm thick) were designed for each lattice, for a total of 12 samples (Table 1).

Sample fabrication: A LumenX+ bioprinter (CellInk, Boston, MA) stereolithography (SLA) was used to print samples. PEGDA Start™ (polyethylene (glycol) diacrylate < 2000 Da, CellInk), a photocurable bioink, was cured at 100-µm resolution at a light intensity of 20 $mW/cm^2$. Each slice was illuminated for 5 sec when in contact with the print bed; first and last layers were illuminated for 25 sec. CAD models and photographs of samples are shown in Figure 1.

**Table 1: Summary of 12 hydrogel lattice samples used in the study**

| y<br>x | Cubic | Diamond | Vintile |
|---|---|---|---|
| Unit Cell [8] |  |  |  |
| Compression (cube)  | Unscaled (isotropic) | Unscaled (isotropic) | Unscaled (isotropic) |
| | Scaled 2× in X direction | Scaled 2× in X direction | Scaled 2× in X direction |
| DST (disc)  | Unscaled (isotropic) | Unscaled (isotropic) | Unscaled (isotropic) |
| | Scaled 2× in X direction | Scaled 2× in X direction | Scaled 2× in X direction |

Compression testing: Samples were tested in compression on an HR-20 rheometer (TA Instruments, New Castle, DE). The top platen (20 mm, flat) was lowered until contact was reached with an axial force of 0.05 N. A displacement ramp of 1 mm/min to 5% compression was then applied; axial load and displacement were recorded. For all tests, samples were held at ~23°C and submerged in DI water until testing. Each cubic sample was tested twice. Scaled samples were compressed parallel ("X") and perpendicular ("Y") to the scaling direction, unscaled samples were loaded in two arbitrary directions ("1", "2").

Shear testing: Disc samples were tested using DST procedures established previously [9]. Briefly, samples were placed in a chamber

on the platform of a flexure connected to a voice-coil actuator. A top platen instrumented with dynamic load cells was lowered until contact was achieved. Horizontal (shear) displacement of ~ 100 µm over a frequency range of 20-100 Hz was applied by driving the voice-coil actuators with a "chirp" signal. Shear testing was repeated at 4%, 8%, and 12% compressive strain, achieved by lowering the platen to the appropriate height. Each sample was tested twice. Scaled samples were sheared parallel ("X") and perpendicular ("Y") to the scaling direction (Fig. 2), unscaled samples were sheared in arbitrary directions (1 & 2).

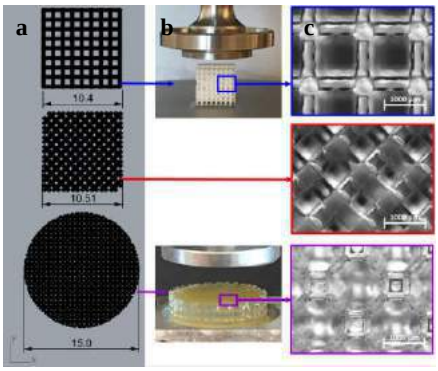

**Figure 1. (a) Cubic, diamond, and vintile lattices. (b) Compression (cube) and shear (disc) samples. (c) Photographs of samples at 2.5X (Scale bar: 1 mm).**

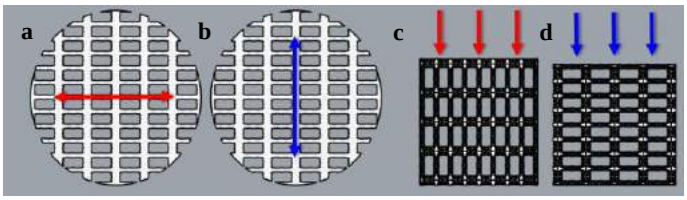

**Figure 2. (a) Diagram of scaled cubic lattice discs loaded in shear parallel to scaling direction (X) for DST; (b) Scaled sample loaded in shear perpendicular to scaling direction (Y); (c) Cube samples loaded in compression parallel to scaling direction (X); (d) Sample loaded in compression perpendicular to scaling direction (Y).**

## RESULTS

Compression: Stress was estimated from the ratio of force to sample area ($\sigma = F/A$) and strain from the ratio of displacement to sample height ($\varepsilon = \Delta L/L$). Apparent Young's moduli ($E$) were found by linear fits to stress-strain curves (Fig. 3) and summarized in Fig. 5.

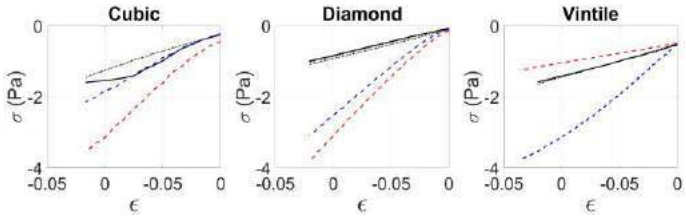

**Figure 3. Stress-strain curves for cube samples of cubic, diamond, and vintile lattices loaded in compression. Unscaled samples: black (solid: 1, dotted: 2). Scaled samples: dashed; red: X, blue: Y.**

Shear: Apparent shear modulus,$iG$, was estimated from the ratio of apparent shear stress (shear force/area; $\sigma = F/A$) to shear strain ($\varepsilon = \Delta X/h$, e.g.). Apparent shear moduli and ratios for 20-60 Hz at 8% normal strain are shown in Fig. 4, and summarized in Fig. 5.

Anisotropy: Ratios of apparent moduli are shown in Table 2. For isotropic (unscaled) lattices, the loading directions are denoted as 1 and 2, respectively. All scaled samples exhibited mechanical anisotropy. Unscaled diamond and vintile lattices exhibited similar moduli in different loading cases; the unscaled cubic lattice exhibited different moduli in each direction, possibly due to test order.

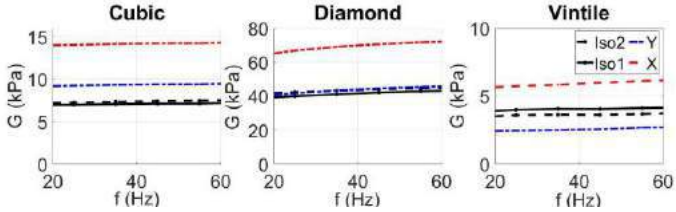

**Figure 4. Magnitude of apparent shear modulus, $G$, over 20-60Hz in different loading directions by DST at 8% normal compression, in unscaled lattices (Iso1 and Iso2) and scaled lattices (X, Y).**

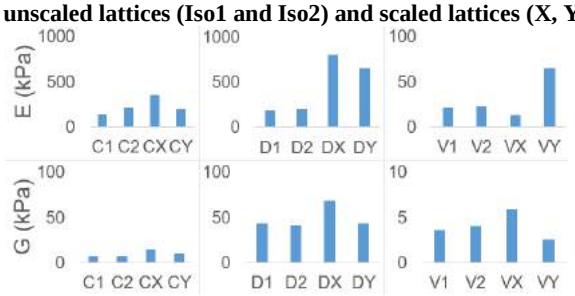

**Figure 5. Summary of apparent Young's modulus, $E$, and shear modulus, $G$, in cubic (C) diamond (D), and vintile (V) lattices under in loading in different directions (1, 2, X, Y).**

**Table 2. Ratios of apparent moduli in unscaled and scaled lattices.**

| | Cubic | | Diamond | | Vintile | |
|---|---|---|---|---|---|---|
| | C1/C2 | CX/CY | D1/D2 | DX/DY | V1/V2 | VX/VY |
| $E_X/E_Y$ | 0.65 | 1.80 | 0.98 | 1.22 | 0.93 | 0.21 |
| $G_X/G_Y$ | 1.04 | 1.52 | 1.05 | 1.59 | 0.90 | 2.31 |

## DISCUSSION

Geometrically scaled hydrogel lattices 3D-printed in tunable, soft biomaterial (PEGDA Start™) exhibited mechanical anisotropy in both tension and shear. The type of lattice strongly influenced the magnitude of effective Young's moduli and shear moduli, with the diamond lattice being the stiffest and vintile lattices the softest. The effects of scaling on anisotropy differed in different lattice types: the diamond lattice appeared stiffer in compression when loaded along the scaling axis (X), while the vintile lattice appeared softer when compressed along the scaling axis. Relative changes in lattice mechanical properties due to scaling were different in shear and in tension.

In future work, it will be important to increase sample numbers and to better characterize and control the properties of the PEGDA material. Future work will explore additional lattice types and scaling strategies.

## INTRODUCTION

Each year, the number of orthopaedic implant-related procedures in the U.S. rises, as does implant associated infections [1]. Current standard treatments rely on a two-stage revision arthroplasty which involves surgery to remove the implant, followed by antibiotics to eradicate the bacteria [2]. While this approach has a high cure rate [3], it involves a highly invasive procedure with a significant effect on the patient's quality of life [1]. Furthermore, this treatment is very expensive [4], with a projected annual cost for patients in the U.S. at $1.6 billion in 2020 [5]. The primary obstacle to effective antibiotic treatment is the formation of biofilm, a thin (< 1 mm) [6] extracellular polymeric substances (EPS) layer, on the implant surface [7]. The EPS forms a barrier to the surrounding environment, rendering more resistance to antibiotics [8]. Inadequate biofilm eradication is the main reason for the standard procedure of replacing the infected implant [9]. A minimally invasive means of eradicating biofilm would be a positive step towards effective infection treatment. High frequency alternating magnetic fields (AMF) can generate heat on the surface (skin effect) of the metal implants [10] which provides a non-invasive approach for the eradication of biofilms on implanted devices. The goal of this project is to design a high throughput *in vivo* medical induction heating system to facilitate heating of multiple metal coupons simultaneously. The system should be able to uniformly heat multiple metal coupons.

## METHODS

### a. Induction Coil

To achieve uniform heating, the coils were custom designed to current system specifications. The coil must be able to hold and heat three metal coupons uniformly, reaching a target temperature of ≥ 85°C within 10 sec. Several coil designs were considered, and the design specifications were listed in a selection criteria table. Ultimately, an open coil design (pancake) and closed coil design (flat solenoid) were chosen (*Figure 1*) to facilitate a future monitoring and control system based on non-contact temperature measurement. The two designs were modelled in a 3D CAD design software (SOLIDWORKS®). Coil dimensions were optimized to hold three metal coupons.

**Figure 1: Models of (a) Flat solenoid coil, and (b) Pancake coil.**

### b. Finite Element Analysis (FEA)

A commercial finite element software, COMSOL Multiphysics, was used to evaluate the magnetic field and coupon temperatures for the flat solenoid and pancake coils. In the simulations, each coil holds three equally spaced metal coupons. The coupons were modelled following laboratory grade disc coupons for biofilm-related studies (12.7 mm diameter, 3.8 mm thickness). Three industry standard orthopaedic implant materials were tested–316L Stainless Steel, Cobalt Chromium, and Ti-6Al-4V Titanium–to compare heating performance. The thermophysical properties of the materials used in the simulations are as listed in Table 1.

**Table 1: Thermophysical Properties of Metal Coupons**

| Materials | k [W/mK] | σ [S/m] | c [J/kg.K] | ρ [kg/m3] | δ [μm] |
|---|---|---|---|---|---|
| 316L Steel | 15.0 | $1.32*10^6$ | 500 | 8050 | 0.875 |
| Cobalt Chromium | 9.4 | $1.18*10^6$ | 390 | 10000 | 0.925 |
| Ti64 | 7.2 | $2.38*10^6$ | 560 | 4450 | 0.652 |

The computer-generated simulations were used to help estimate and compare the magnetic field strength, surface temperature of the coupons and the heating performance of the pancake and flat solenoid coil on the various coupon materials. Based on our induction system's specification, the induction heating simulations were carried out at 200 A current and frequency of 315 kHz. The coupons were initialized at room temperature, 20°C.

## RESULTS

The magnetic field strength and distribution of the flat solenoid and pancake coil can be seen in Figure 2. The magnetic field amplitude is higher for the pancake coil based on simulation results. The magnetic flux streamlines in Figure 2 also indicate a uniform magnetic field around the coil and coupons on both coil designs.

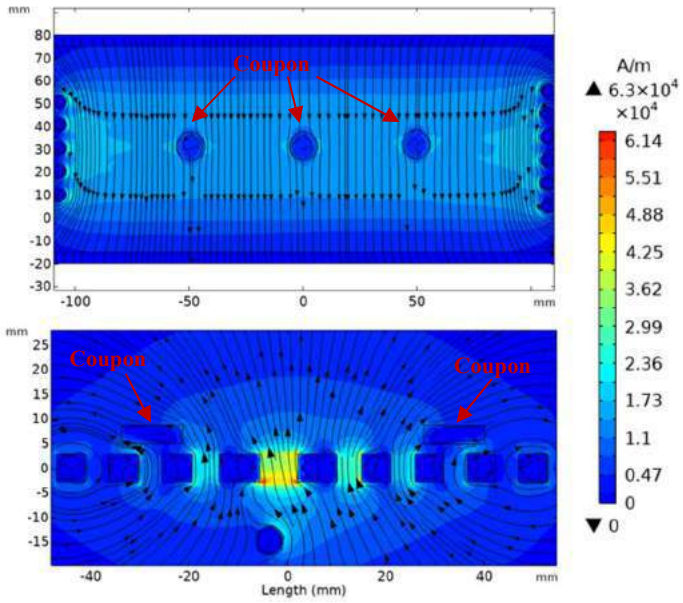

**Figure 2: FEA simulations of magnetic field strength of (a) Flat solenoid coil, and (b) Pancake coil with metal coupons.**

The temperature contour plots (*Figure 3*) and distribution with time (*Figure 4*) from the simulation results show the heating capability of the coils. The surface temperature of the metal coupons was measured at 10 sec. Both coils achieved similar temperatures (134°C) at 10 sec for the 316L stainless steel coupons that were used for the simulation results in Figure 3. The temperature distribution of each coupon material (*Figure 4a*) shows that the Ti64 coupon heats the quickest and achieves the highest surface temperature at 10 sec, which is consistent with its thermophysical properties. Equally spaced coupon placement on the pancake coil (*Figure 4b*) also helped with relatively uniform heating. Coupon #3 showed a higher temperature rise due to its coupon placement being slightly closer to the center of the pancake coil.

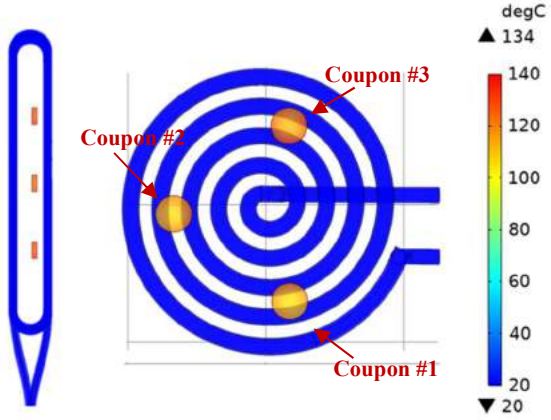

**Figure 3: FEA simulations of coupon surface temperature on (a) Flat solenoid coil, and (b) Pancake coil at 10 sec.**

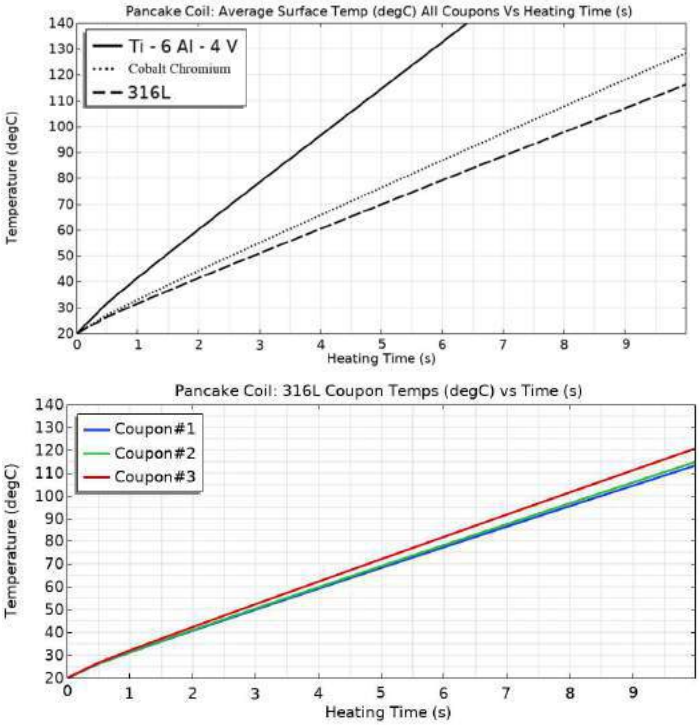

**Figure 4: Surface temperature with time of (a) Various coupon materials, and (b) Coupon placement of 316L on pancake coil.**

## DISCUSSION

The simulation results show that the flat solenoid and pancake coil can successfully heat the coupons to setpoint temperature within the specified time. The metal coupons models simulated at 200 A and 315 kHz for 10 sec resulted in surface temperatures of 134°C on both coils for the example 316L coupon test. Although the pancake coil displayed a higher magnetic field amplitude, the flat solenoid still managed to reach similar temperatures, showcasing the effectiveness of a closed coil design. Simulation results also show relatively uniform heating with proper coupon placement for the pancake coil. Future studies will explore more open coil designs, and a temperature controller to maintain coupon temperature at the target temperature.

## INTRODUCTION

Incidences of Alzheimer's disease (AD) and other dementias increase with age and are linked to the reduced clearance of the toxic waste products (such as amyloid-β (Aβ)) accumulating in the brain [1]. Cerebrospinal fluid (CSF) entering and leaving the brain is integral to this clearance. CSF is propelled into the brain along perivascular spaces, mixes with the brain's waste-laden interstitial fluid (ISF) and then drains these toxins predominantly via the cervical lymph vessels of the neck. This transport of fluid deteriorates with age, presumably because lymphatic function is compromised [1]. However, the dominant physiological mechanisms that drive cervical lymphatic flow (or fail in aging) remain unclear as most studies assess fluid transport using isolated lymph vessels. These conditions do not accurately represent physiological transport, where a network of vessels undergoes coordinated pulsations to transport fluid. In this talk, we present measurements of fluid flow in the cervical lymph vessels of mice in vivo. We use these first-of-their-kind measurements to explore the failure mechanisms impacting fluid clearance in mouse models of aging.

## METHODS

Intravital two-photon microscopy was used to visualize and quantify CSF flow in the cervical lymph vessels of both young (2-month) and aged mice (18 – 22-month, n>5). The mice were anaesthetized using ketamine/xylazine, and the cervical lymph vessels were surgically exposed. We simultaneously visualized vessel diameter fluctuations and the motion of 1 µm fluorescent microspheres (injected in the cisterna magna) flowing in the vessels. Detailed velocity measurements from particle motion and correlations to the changes in vessel diameter were performed using custom particle tracking and vessel wall detection algorithms in MATLAB [2]. All experiments were approved and conducted in accordance with the relevant guidelines and regulations stipulated by the University Committee on Animal Resources of the University of Rochester Medical Center, certified by the Association and Accreditation of Laboratory Animal Care.

## RESULTS

Figure 1 shows typical particle tracking measurements in lymph vessels. Particle tracking revealed significantly impaired clearance in the cervical lymph vessels of aged mice (Figure 2). The reduced speeds (Figure 2a) and lower volumes cleared (Figure 2c) were strongly correlated to the decrease in the contraction frequency (intrinsic rate, Figure 2b)) of the lymphatic vessels – the dominant driving force of fluid transport. Additionally, valve function is compromised in aged vessels, leading to stronger retrograde flows that reduce the net fluid volumes cleared.

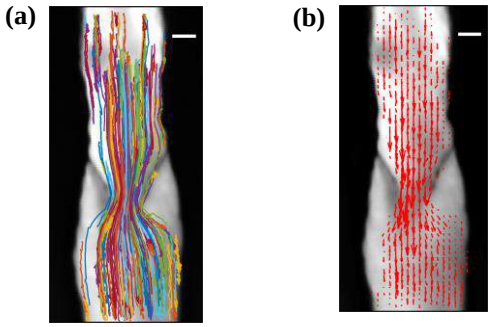

**Figure 1: In vivo particle tracking in cervical lymph vessels. (a) Rainbow colored lines represent the super-imposed tracks of the injected 1µm particles flowing in the lymph vessel. (b) The arrows represent the velocity vector field of the net particle motion. The downward pointing arrows indicate that net direction of fluid clearance away from the brain. Scale bars = 50 µm.**

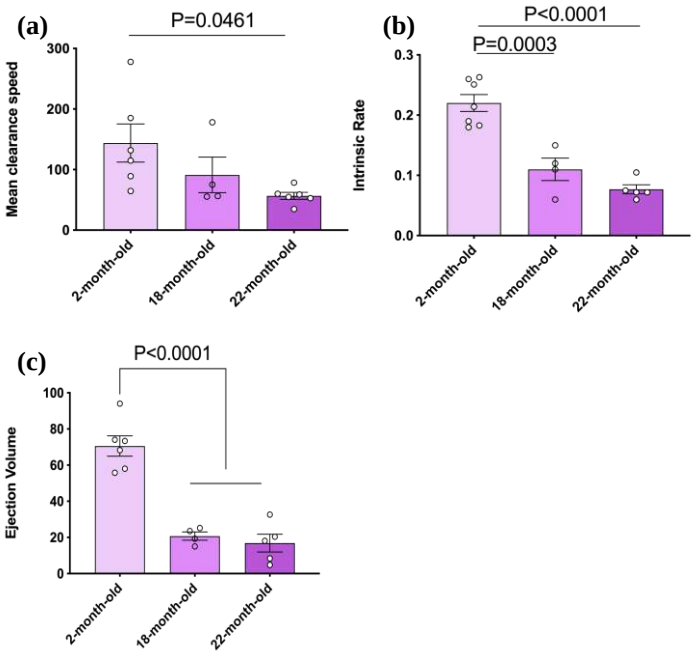

**Figure 2: Derived flow characteristics. (a) Mean clearance speed (µm/s) was calculated by first spatially averaging the measured speeds of particles flowing in the imaged lymphangion, and then performing a temporal average over one minute. (b) The intrinsic rate (Hz) represents the number of contractions per second in each of the data sets. The decrease in frequency with age indicates the weakening of the active pumping mechanism with age. (c) The volume flow rate (µL/min) was calculated as the product of the spatially averaged mean flow speed of particles exiting the vessel and cross-sectional area of the lymph vessel computed using a median value of the diameter.**

## DISCUSSION

The techniques and results presented here allow for the first in vivo investigation of fluid dynamics and vessel function in the cervical lymph vessels – a dominant exit pathway draining CSF from the brain. With simultaneous particle tracking and vessel contraction measurements, we present mechanistic evidence that the severely reduced volumes of CSF cleared through these vessels is strongly correlated to the decrease in vessel function with age. Our measurements bolster the hypothesis that the cervical lymph vessels are a bottleneck in the aged brain's fluid transport and restoring their function could be a powerful therapeutic target.

# MODELING MACROPHAGE-REGULATED PULMONARY FIBROSIS WITH ENGINEERED MEMBRANEOUS LUNG MICROTISSUES

**Ying Xu (1), Ruogang Zhao (1)**

(1) Department of Biomedical Engineering, State University of New York at Buffalo, Buffalo, USA

## INTRODUCTION

Idiopathic pulmonary fibrosis (IPF) is a chronic, progressive disease that affects around 3 million people worldwide [1, 2]. The exact pathological mechanisms underpinning the initiation and progression of pulmonary fibrosis are poorly understood [3], but postmortem examination shows that IPF involves significant inflammatory cell infiltration, fibroblast activation and massive destruction of the normal alveolar structures. Despite the recent introduction of novel drugs that slow disease progression (namely pirfenidone and nintedanib), IPF remains a deadly disease, and the benefits of these new drugs differ markedly between patients [4,5]. A major roadblock in the understanding of IPF mechanism and the development of novel therapies is the lack of suitable in vitro models that can model the pathogenesis of the disease. Although existing Lung-on-chip devices can simulate flow-mediated inflammatory responses, the use of synthetic polymer (PDMS)-made membranes made it unsuitable for the study of tissue remodeling such as fibrosis induced alveolar destruction. Here we developed a co-cultured fibrotic microtissue system that can model macrophage-induced fibrogenesis of the lung interstitial tissue and tested the effect of fibroblast activation on tissue remodeling using a collagen-elastin (CE) fabricated alveolar-like thin membrane system.

## METHODS

To model macrophage-induced fibrosis initiation and progression, human peripheral blood mononuclear cell (PBMC) derived monocytes were isolated and polarized into profibrotic M2a macrophages (MΦ) using IL4 and IL13, then dropped onto a normal human lung fibroblasts (NHLF) - populated microtissue which was created on micropillar array (**Fig. 1A**) [6]. The co-cultured system was maintained for three days and was co-stained for the fibrotic marker α-smooth muscle actin (α-SMA) and macrophage marker CD206. To recapitulate the ECM remodeling and alveoli destruction found in progressive fibrotic disorders, a thin collagen-elastin membrane was fabricated on a gold mesh (250 μm hole diameter and 18-μm-thin) via surface tension to mimic the alveolar structures. NHLFs were seeded on the thin membrane and were treated with fibrosis inducer TGF-β to examine the effect of fibroblast activation on the remodeling of alveolar-like thin membraneous tissues.

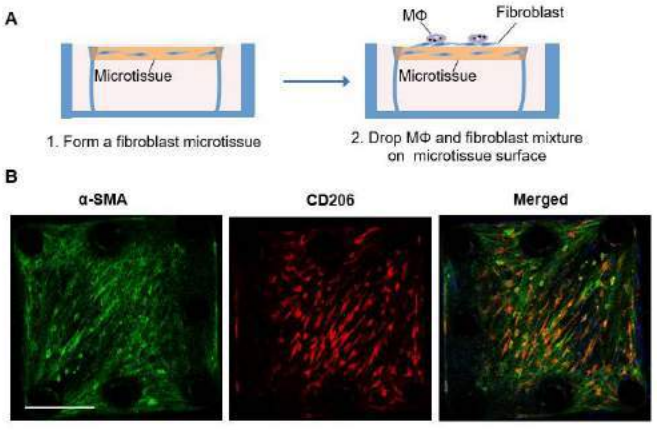

**Figure 1: Macrophage co-cultured lung microtissue model. (A) Schematic showing that lung fibroblasts and polarized M2a macrophages (MΦ) were directly dropped onto the 3D microtissue surface. (B) Representative immunofluorescence images of α-SMA (green) and CD206 (red) of the co-cultured microtissue. Note the macrophages became elongated and aligned with the fibroblasts along the diagonal direction of the microtissue. Scale bar is 200 μm.**

## RESULTS

Human PBMC derived monocytes were successfully polarized into M2a MΦs using IL4 and IL13, as characterized by the expression of CD206. After loading M2a MΦs onto the surface of NHLF- populated lung microtissue, M2 MΦs adhered well to the tissue surface in large numbers (**Fig. 1B**). After three days of co-culture, strong expression of α-SMA was observed in the co-cultured microtissue, indicating the differentiation of fibroblasts to myofibroblasts. There is significant alignment formation in the differentiated myofibroblasts along the diagonal direction of the microtissue, suggesting the generation of contractile forces. Surprisingly, the macrophages adopted an elongated morphology and aligned along the fibroblasts (**Fig. 1B**), implying the strong interaction between these two cell types that affected the morphology and phenotype of both cell types. Quantitative analysis of fluorescence intensity shows much higher expression of α-SMA in co-cultured microtissue as compared to mono-cultured fibroblast-populated microtissue, confirming myofibroblast differentiation.

Alveolar-like CE membrane was formed successfully on gold mesh. Macroscopic examination shows intact CE membrane with smooth surface. Phase contrast images showed that NHLFs distributed uniformly on the CE membrane and spread well, suggesting the good biocompatibility of the CE membrane. While quiescent NHLFs (untreated, **Fig. 2A)** didn't cause significant remodeling of the CE membrane, TGF-β treated NHLFs tore open many CE membrane units and caused significant destruction of the membrane with holes (**Fig. 2B)**. Since TGF-β has been shown to induce NHLF differentiation to myofibroblasts, the destruction of the CE membrane is likely caused by elevated contractile forces generated by differentiated myofibroblasts. Significant level of cell alignment was also observed in TGF-β treated condition, further confirming the generation of high contractile forces by the myofibroblasts.

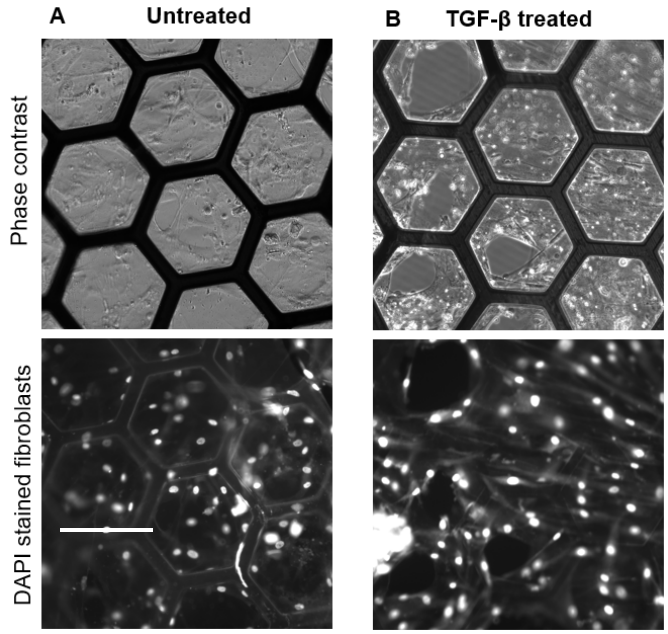

**Figure 2: Collagen-elastin (CE) membrane remodeling by activated lung fibroblasts. Phase contrast image and fluorescent image (DAPI stained) showed NHLF cultured on CE membrane formed on a gold mesh without (A) or with (B) the presence of TGF-β. Note significance tearing of the CE membrane in TGF-β treated condition. Scale bar: 200 μm.**

## DISCUSSION

In this work, we modeled MΦ induced lung fibrogenesis using a micropillar-based 3D microtissue system. PBMC-derived MΦs adhered well to the NHLFs, became elongated and aligned with the fibroblasts. With co-cultured MΦs, NHLFs differentiated to myofibroblasts. The simultaneous changes of phenotypes in both cell types suggest they interact and affect each other. Such interaction is likely facilitated by the close physical contact between the two cell types, as suggested in previous publications. Notably, the immunostaining results (**Fig. 1B**) demonstrated that a large number of M2a MΦs on the lung microtissue co-expressed MΦ marker (CD206) and myofibroblast marker (α-SMA), implying these MΦs acquired both myofibroblast and MΦ phenotypes. It is possible that these PBMC-derived MΦs underwent MΦ to myofibroblast transition in the current model system. Furthermore, since PBMC sub-populations such as fibrocytes have been reported to infiltrate fibrotic tissue and differentiate to the myofibroblast, fibrocytes can also contributed to the results observed in the current study. Compared with conventional 2D culture model, the force sensing capability of the microtissue system, contributed by the micropillar force sensors, allows measurement of the changes in tissue mechanics occurred during fibrosis progression. Together, this co-cultured model system provides a useful platform for the investigation of the disease mechanism of IPF including the MΦ-fibroblast interaction and the testing of potential anti-fibrosis drugs that targets inflammatory pathways.

Additionally, the CE membrane formed on the gold mesh recreated the structure, composition and mechanical properties of the alveolar tissue. Its membranous structure allows the modeling of alveolar destruction caused by the contractile myofibroblasts in the fibrotic tissue. Compared to the existing synthetic polymer based lung-on-chip devices, this model offers new opportunity to examine the mechanism of pathogenesis in the fibrotic lung. It is expected that the adoption of these new models in the field of pulmonary fibrosis will help the understanding of the disease mechanism and the development of novel anti-fibrosis therapies.

# UNDERSTANDING THUMB JOINT MOVEMENT AND HOW AGE CONTRIBUTES TO ITS CHANGES

**Nicole D. Arnold (1), Adam J. Chrzan (1), Kevin Chan, MD (2), and Tamara Reid Bush, PhD (1)**

## INTRODUCTION

Osteoarthritis (OA) of the hand is a debilitating musculoskeletal disease that can severely impact one's ability to carry out activities of daily living, such as opening a bottle or food packages. Almost 70% of women and 55% of men over the age of 55 will develop hand OA in at least one joint [1]. People diagnosed with thumb OA, regardless of severity, benefit from conservative treatment methods such as strengthening or stretching exercises, non-steroidal anti-inflammatory drugs, splinting, and/or corticosteroid injections [2,3]. Conservative treatment options can provide pain relief for a few days to several months. However, a limitation to all these treatments is that their effects weaken over time, and the disease may continue to progress to where surgery may be required to improve strength and function.

Clinical assessments (i.e., patient questionnaires and range of motion using goniometers) are not sufficient to quantify complex, dynamic motions. On the other hand, motion capture systems can obtain both standard clinically measured ranges of motion and more complex multi-planar motions, which provide an accurate assessment of joint motions [4]. Thus, motion capture systems can provide quantitative and comprehensive baselines of healthy function so that impairments and restoration of function during rehabilitation can be identified. The purpose of this research was to determine and compare the maximum flexion angles of the interphalangeal (IP) and metacarpophalangeal (MCP) joints of the thumb in populations of younger and older individuals to establish baselines of healthy function.

## METHODS

10 young healthy (YH) (5 female, 5 males, and ages 26 ± 4 years) and 10 older healthy (OH) participants (8 females, 2 males, ages 63 ± 10 years) were included in this study. All participants had no prior injury or disease (including osteoarthritis), were not pregnant, and were right hand dominant. Three-dimensional kinematic data of the thumb's movements were captured using three reflective marker pods attached to the distal phalange, proximal phalange, and metacarpal of the thumb (Fig. 1 left). Additionally, four single markers were attached to the sides of the wrist. (Note: Tracking movement of the thumb was our primary goal, but as seen in the figures, markers were also placed on the index finger to accommodate other tests not discussed in this abstract.) Participants sat in a chair with their hand and forearm resting in the testing device on a table (Fig. 2). This system prevented movement of the forearm and wrists permitting individuals to focus on thumb motions. Participants were instructed to flex their thumbs three times to the best of their ability. Thumb flexion was defined as increasing the angle between the two bones around the IP or MCP joints (Fig. 1 right).

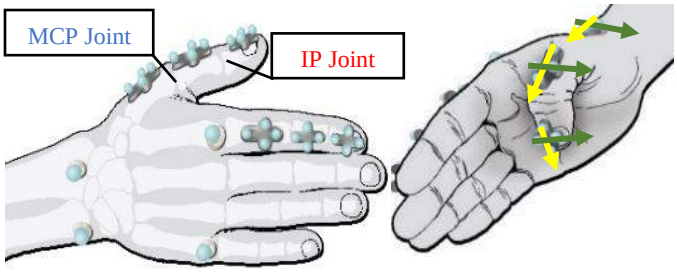

**Figure 1: Marker pods on the thumb and single markers located on the base of the 2nd and 5th metacarpophalangeal joints and the medial and lateral sides of the wrist (left). X- and Y -axes of the local coordinate systems on the distal, proximal, and metacarpal phalanges (right). Flexion of the IP and MCP joints occurs about the green axes.**

## RESULTS

The maximum flexion IP and MCP joint angles are presented in Table 1 and Figure 3. The averages of the maximum IP and MCP flexion values for the younger healthy group were 69º and 59º, respectively. The averages of the maximum IP and MCP flexion values for the older healthy group were 66º and 56º, respectively. Additionally, the averages for the flexion angles were reduced in the OH group by 4.3% for the IP joint and 5.1% for the MCP joint relative to the YH group.

**Figure 2: A participant's hand resting in the testing device performing maximum flexion of the IP and MCP joints**

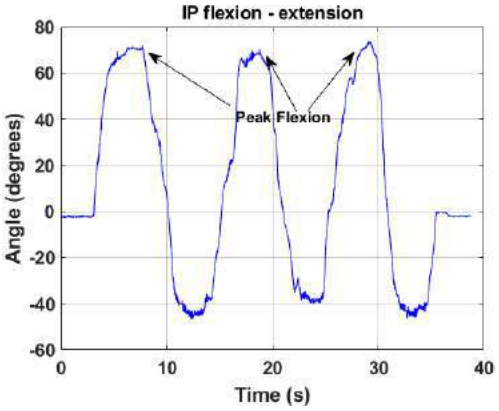

**Figure 3: IP thumb flexion, with maximum flexion identified at three time points for a single participant.**

## DISCUSSION

The goal of this study was to investigate IP and MCP ranges of flexion in the thumbs of young and old healthy groups. As expected, the older group had a reduction in the average ranges of flexion. On average, those older in age had a decrease of 4-5% range of motion of the IP and MCP joints. However, what has not been evaluated by other studies is the comparison of IP flexion to that of the MCP flexion. 70% of the YH participants had larger motion at the IP joint with the difference between the IP and MCP averaging 20º. However, in the OH group, the IP and MCP maximum flexion values had similar movement angles. The max IP and MCP flexions for 6 of 10 OH participants were less than 5º apart, and the average difference was only 11º. Similarly, the IP joint had the larger magnitude for most participants in the OH group, but as noted, it was only slightly larger than the MCP flexion. The similar contributions of the IP and MCP joints to thumb movements in the OH group relative to the YH group could be explained by several mechanisms. These mechanisms include inflammation, stiffness, strength loss, joint alignment changes, or muscle imbalance. All of these have been shown to be present in patients with doctor diagnosed OA. So, a question for future consideration is whether or not this decreased differential between IP and MCP flexion is a pre-cursor to OA. Further, if our OH participants sought out hand therapy now (prior to pain), could the contributions of the IP and MCP joints be restored to that of the YH group?

**Table 1: Maximum individual and group values of thumb IP and MCP flexion. n= 20 (10 younger and 10 older)**

| Subject | YH | YH | OH | OH |
|---|---|---|---|---|
| | Max IP (º) | Max MCP (º) | Max IP (º) | Max MCP (º) |
| 1 | 56 | 62 | 81 | 39 |
| 2 | 80 | 41 | 75 | 65 |
| 3 | 72 | 50 | 57 | 60 |
| 4 | 74 | 90 | 72 | 45 |
| 5 | 66 | 45 | 75 | 77 |
| 6 | 67 | 58 | 59 | 55 |
| 7 | 74 | 40 | 49 | 47 |
| 8 | 72 | 60 | 52 | 51 |
| 9 | 59 | 79 | 78 | 61 |
| 10 | 74 | 65 | 60 | 55 |
| Average | 69±7 | 59±15 | 66±10 | 56±10 |

Such reductions in joint ranges of motion have an impact on thumb function when carrying out activities of daily living. Examples of activities that require larger degrees of thumb joint flexion are buttoning and/or zipping up pants/shirt, putting on a shoe and tying shoelaces [5]. Because of the large range of motion needed to do these activities, they may be the first impacted by a reduction in range of motion. As a result, many individuals will experience a loss of independence to some degree. Our work suggests that these reductions in motion may appear prior to pain, or other signs of OA, and are occurring in our OH group.

This research provides information on the range of motion of healthy thumbs. Understanding healthy function is important when monitoring treatment effects or designing therapies for thumb OA and identifying when older individuals may need to seek out therapy. Our work indicates that even older individuals who are pain-free may benefit from hand therapy to preserve their ability to conduct daily activities.

These data from healthy thumbs will be used to define healthy baseline values for those treatments and therapies. Our future goals include testing participants with thumb OA pre- and post- surgery. It is important to quantify healthy movement of the thumb to further assess the deficits in those with OA.

## INTRODUCTION

Fibrosis is a critical way in which a body heals itself from injury. While this is a necessary process, many diseases have an aspect of pathological fibrosis which can lead to long-lasting effects and organ damage. In the lung, fibrosis can be extremely debilitating and is seen in a range of diseases, such as Idiopathic Pulmonary Fibrosis (IPF) and in coronavirus infections of SARS-CoV2 (COVID-19)[1]. Lung fibrosis stiffens the otherwise malleable lung tissue and decreases the airspace that is necessary for gas exchange. It is well established that activated fibroblasts, or myofibroblasts, are critical for healing damaged tissue by secreting and remodeling extracellular matrix (ECM) proteins, such as collagen. However, if this process is unregulated, pathological fibrosis can ensue. The mechanisms that regulate fibroblast-to-myofibroblast transitions and aberrant ECM remodeling are active areas of research. Here, we have developed a novel method to quantify fibroblast activation and measure stiffness changes in the surrounding ECM. We present a 3-dimensional (3D) *in vitro* cell culture model that allows for histologic endpoint analysis of cell phenotypic transitions and allows us to dynamically measure physical stiffness of the matrix using a novel, sensor-based method[2,3].

## METHODS

We have developed a novel method to culture fibroblasts in a 3D type I collagen gel and visualize and quantify how they interact with and remodel their ECM over a period of days, while allowing the addition of pro-fibrotic stimulants, such as transforming growth factor beta (TGF-β), tumor necrosis factor alpha (TNF-α), and interleukin one beta (IL-1β). At the terminal endpoint of the study, cells can be labeled with NucBlue (nuclei), as well as immunostained for F-actin and alpha-smooth muscle actin (α-SMA) to assess fibroblast activation and fibroblast-to-myofibroblast phenotypic transitions. The cell-laden gel is also instrumented with a piezoelectric milli-cantilever sensor, which allows for real-time measurements of ECM stiffening (Fig 1a, 1b). Custom MATLAB software allows continuous tracking of the sensors' resonant frequencies and phase angles, which are then calibrated to provide the ECM storage modulus. The change in viscoelastic properties reported by the sensor over time correlate with the Young's modulus of the gel. We validated this *in vitro* culture system by seeding $3.5x10^5$ human lung fibroblasts (CCL-210 ATCC) per mL in 2.7 mL of type I collagen (from bovine skin) and in the presence or absence of transforming growth factor-beta (TGF-β), a growth factor known to induce fibroblast-to-myofibroblast differentiation and collagen synthesis and remodeling. 3.5 mm thick cell-laden collagen gels were cultured in 8-well and 12-well plates, and were fed with DMEM media supplemented with 10% fetal bovine serum for 55 hours and maintained in standard culture conditions (37 ºC, 5% $CO_2$). Negative control wells contained collagen gels without cells. Thirty hours after the initiation of the experiment, half of the wells containing cell-laden collagen gels were supplemented with exogenous TGF−β (20 ng/mL), while the other half were supplemented with vehicle (Fig 1c).

## RESULTS

Cells labeled with NucBlue were assessed for viability at 55 hours (Fig 1d). Immunohistochemical staining for F-actin and α-SMA enabled visualization of markers of fibroblast activation between TGF−β stimulated and un-stimulated groups (Fig 1e). Samples that received TGF−β stimulation exhibited increased levels of F-actin and α-SMA protein expression, indicating that more cells had undergone fibroblast-to-myofibroblast transitions. Additionally, collagen stiffness in each well was able to be quantified over time using our mechanical force sensor, and the sensors embedded in the cell-laden gels that received TGF−β stimulation reported altered stiffness values over time relative to cell-laden gels that received vehicle control or gels without cells.

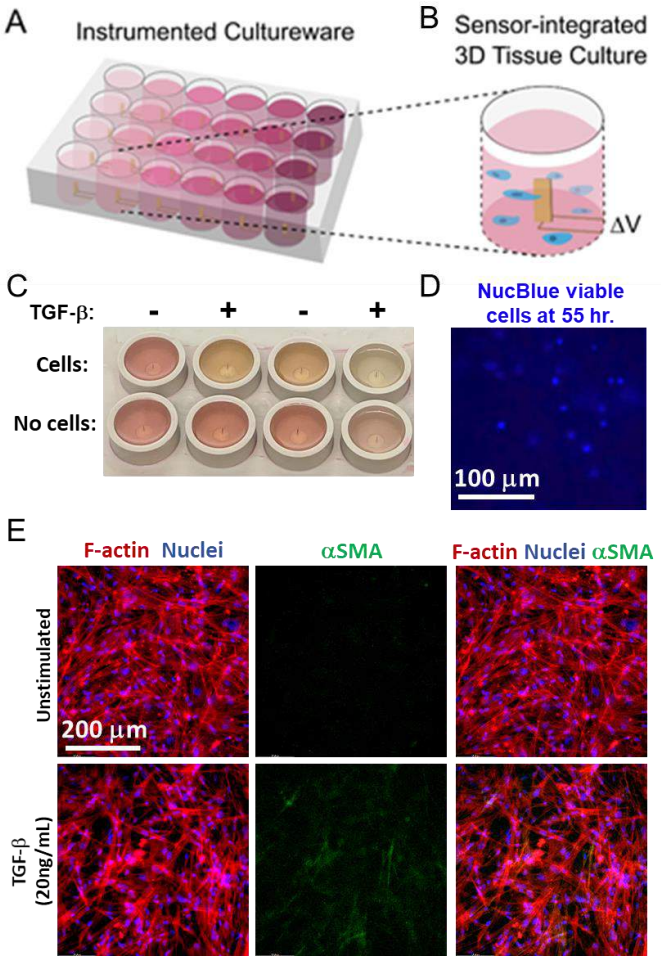

**Figure 1: Schematic of the multi-well culture plate (A) instrumented with a force sensor protruding from the bottom of the well containing the cell-laden gel (B). The sensor measures changes in voltages (ΔV) corresponding to changes in matrix stiffness. (C) Experimental image of cell-free and cell-laden gels with and without TGF-β in a custom-made tissue culture plate instrumented with sensors. (D) Cells labeled with NucBlue nuclei stain visualized at 55 hours to confirm viability. (E) Immunohistochemical staining of unstimulated fibroblasts in gels (top row) and fibroblasts in gels stimulated with TGF-β (bottom row) to visualize nuclei (blue), F-actin (red) and α-SMA (green).**

## DISCUSSION

Our novel fibroblast culture model incorporates a method for quantifying both cell phenotypic differentiation and the mechanical properties of the ECM in a real-time and non-destructive manner. To validate our model, we immunohistochemically assessed human lung fibroblast activation and differentiation, and quantified type 1 collagen matrix stiffening over time. Our model can be extended to interrogate how co-cultures of different cell types (e.g. endothelial cells and fibroblasts) interact with each other and impact the mechanical stiffness of the ECM. Other natural ECM constituents (e.g. fibronectin) and synthetic ECM mimics (e.g. elastin-like peptides[4]), in addition to collagen, can also be assessed in our system. Our model facilitates the incorporation of different biochemical activators of fibrosis (or inducers of other cell differentiation processes to a myofibroblast phenotype, such as Endothelial to Mesenchymal Transition (EndoMT)[5]), as well as the exploration of pharmaceutical agents to therapeutically alter these processes. Model systems that report metrics of both cell activation/differentiation and ECM remodeling non-destructively are not yet commonplace in fibroblast research, and studying them could inform new therapeutic intervention strategies for fibrotic diseases, such as lung fibrosis.

# FEATURE TRACKING MICROFLUIDIC ANALYSIS REVEALS DIFFERENTIAL ROLES OF VISCOSITY AND FRICTION IN SICKLE CELL BLOOD

## INTRODUCTION

Sickle Cell Disease (SCD) is a hematological disorder affecting millions of people worldwide [1]. The disease can manifest in various vascular pathologies such as vaso-occlusions, acute chest syndrome and organ damage. As a result, patients experience a decreased life expectancy and reduce quality of life [2]. SCD is caused by a genetic mutation to the oxygen carrying hemoglobin molecule resulting in a sickle hemoglobin (HbSS) molecule which can polymerize under reduced oxygen conditions and subsequently cause changes in red blood cell properties and alter whole blood rheology [3,4].

Altered blood rheology has been defined as a driver of the pathophysiology and progression of the disease as seen by the increased likelihood of vaso-occlusive crisis with increased blood viscosity [5]. Therefore, therapies such as transfusions and anti-sickling drugs aim to prevent disease complications by restoring normal blood flow [6]. Thus, the main goal of this work is to further the understanding of the rheological properties of SCD blood as it relates to disease severity and therapeutic effectiveness. Previous studies have characterized macroscopic rheological properties of SCD blood such as average velocity or effective viscosity but blood is a complex suspension that exhibits non-Newtonian flow behavior such as shear-thinning and frictional effects arising from wall interactions, all of which depend on the properties of the red blood cells [7]. Therefore, a deeper understanding of the physical determinants of SCD blood rheology is needed.

Herein, we present a method which quantifies the unique properties of SCD blood as it flows in a microcirculatory geometry under reduced oxygen conditions by tracking individual red blood cell velocities in bulk blood flow. This approach allows us to quantitatively interpret the observed non-Newtonian rheological behavior and further investigate the role of frictional and viscous resistance on the overall effective fluid resistance while including oxygen dependent effects. This increased understanding of SCD blood rheology extends beyond previous macroscopic measurements and may provide insight into features of the disease to therapeutically target. Additional work will be aimed at assessing rheological properties of SCD blood prior to and following treatments to investigate therapeutic effects.

## METHODS

All studies were conducted using a bifurcating microfluidic device previously described [8]. Blood samples from healthy donors and donors with SCD were collected at the Massachusetts General Hospital under Institutional Review Board approved protocols (2006P000066). For all measurements, sample plasma was replaced with phosphate buffered saline (PBS) and the hematocrit was fixed at 25%.

To estimate red blood cell velocity using computer vision, the Kanade-Lucas-Tomasi (KLT) algorithm was used as a sparse feature-tracking method to identify object features such as corners and edges based on image intensity gradients [9]. The pixel coordinates of identified features were initialized and tracked among a set of consecutive frames and their positions saved. Using this method, red blood cell (RBC) velocity fields across the width of the microfluidic channel were reproduced from experimental image sets.

To quantify the non-Newtonian flow behavior, the observed RBC velocity profiles were modeled as an effective power-law fluid in which the velocity ($V$) depends on the distance from the channel center ($r$).

$$V(r, O_2) = V_{max} * \left(1 - \left(1 - \frac{V_{wall}}{V_{max}}\right) * \left|\frac{R}{W}\right|^B\right) \quad (1)$$

$V_{\text{wall}}$ is the slip velocity at the channel wall, $V_{\text{max}}$ is the maximum velocity, and $B$ is the bluntness index. $V_{\text{wall}}$ , $V_{\text{max}}$ and $B$ are fitted parameters to the empirical values for both $V$ and $r$ from the experimental setup, and $W$ is a fixed parameter based on measurements of the channel width.

We then calculated the frictional resistance and viscous resistance as follows

$$R_{friction} = {\Delta P}/{Q_{slip}} \quad (2)$$

$$R_{viscous} = {\Delta P}/{Q_{bulk}} \quad (3)$$

The pressure drop $\Delta P$ in the blood channel was found using a linear network model [10] . The flow rate $Q$ in the experimental channel was found using the average velocity and device geometry previously determined. The total flow rate was separated into a bulk component $Q_{bulk}$ and a slip component $Q_{slip}$ by conservation of mass.

## RESULTS

To characterize the effect of oxygen on SCD blood rheology, velocity profiles at a fixed pressure drop were sampled for both HbSS blood and healthy blood (HbAA) at different oxygen tensions. SCD blood demonstrated a strong dependence on oxygen compared to healthy blood as seen by the decrease in velocity with decreasing oxygen (Fig. 1A-B). Additionally, SCD blood exhibited both a change in red blood cell velocity near the channel walls along with a transition in the profile from parabolic to plug flow as oxygen decreased (Fig. 1A-B). These changes in physical properties were quantified using Eq. 1 and the results indicated a large RBC slip velocity factor (${V_{\text{wall}}}/{V_{\max}}$) and increased bluntness index ($B$) in response to hypoxia (Fig. 2E-H). Our results suggest that as oxygen decreases, SCD blood flow experiences a larger shear stress transition near the wall along with a more blunted flow profile; both of which describe the physical changes of SCD blood properties from that of healthy blood.

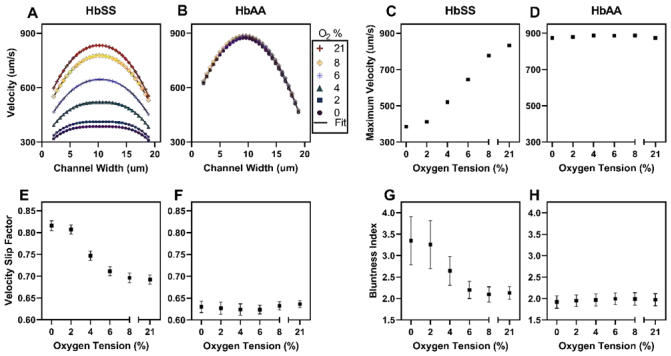

**Figure 1: Qualitative and quantitative oxygen dependence of representative samples of healthy (HbAA, n=1) and SCD (HbSS, n=1) blood flow.**

To gain a deeper understanding of how the macroscopic rheological properties of SCD blood differ from healthy blood for a cohort of patients, effective flow resistances were computed, and the results demonstrated statistically significant differences even at normoxic conditions (Fig 2A). Effective flow resistances were separated into their viscous and frictional parts (see Methods) to determine their contribution to the overall resistance (Fig. 2C-D). The results revealed sharp increases in effective viscous and frictional resistance at lower oxygen tensions in SCD blood which was consistently differentiable from healthy blood. The large increase in viscous resistance suggests that as SCD blood becomes more deoxygenated, the bulk viscosity increases. In contrast, the frictional resistance shows an oxygen dependent effect, but the magnitude is significantly less than the viscous resistance. This result suggests that the overall resistance of SCD blood at low oxygen tensions becomes increasingly dependent on frictional effects to maintain flow.

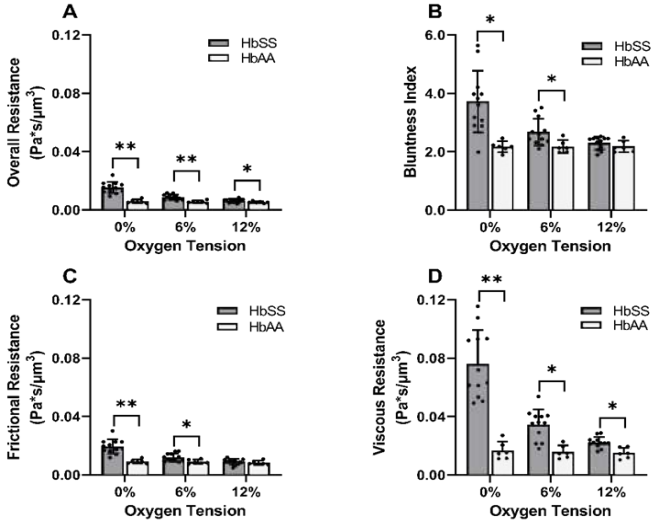

**Figure 2: Evaluation of effective material properties of SCD blood across a range of samples. 12 HbSS samples, 6 HbAA samples. P values correspond to p* < 0.05 and p** < 0.001 using a Mann-Whitney U test.**

## DISCUSSION

We have presented a new method that combines microfluidic, optical tracking, and modeling approaches that can quantify and decouple multiple macroscopic characteristics of SCD blood, including effective viscous and frictional resistances. It is not yet known how the combination of these resistances determines the risk of a vaso-occlusive crisis *in vivo*, and further work is needed to understand how heterogeneity in red blood cell properties determines these emergent properties. Future work will also be aimed at combining our results with clinical outcomes which will allow the determination of vaso-occlusive risk and the prediction of optimal transfusion ratios and treatment regimens that reduce acute and chronic pathology in SCD.

# ROLE OF THERMAL CONTACT RESISTANCE IN INDUCTION HEATING OF IMPLANTS

**A. Ahmad (1), N. Werkheiser (1), M. Abu-Ayyad (1), M. Garner (2), A. Attaluri (1)**

(1) Department of Mechanical Engineering, The Pennsylvania State University Harrisburg, Harrisburg, PA, United States

## INTRODUCTION

Preclinical studies have shown that non-contact induction heating can be a useful tool to eradicate biofilm infections[1-4]. Exposure to alternating magnetic field (AMF) induces eddy currents in the metal implants and causes the implant to heat up. One concern regarding this method is the heating of the bone which could cause tissue necrosis. Early studies are addressing patient safety and the overall viability of the treatment method[5]. Experimental data from previous test indicates limited heat conduction to the bone during induction heating of the implant[6]. We explore the role of thermal contact resistance between implant and bone in the context of patient safety.

## METHODS

### a. Finite Element Analysis of Thermal Contact Resistance

Figure 1 shows the 3D CAD model used in the thermal contact resistance analysis. The model was obtained from a CT scan of a cadaver that was sliced using 3DSlicer program and converted into a SOLIDWORKS(R) file.

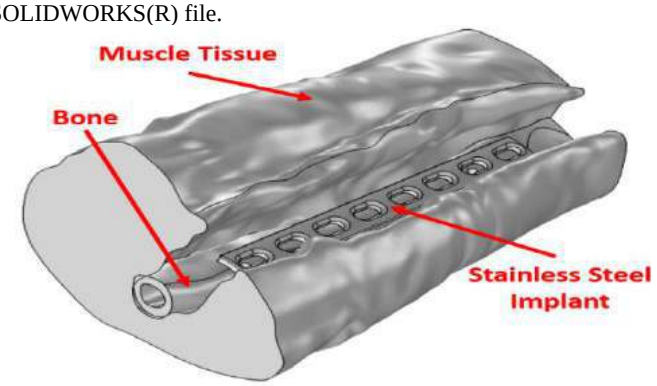

**Figure 1: Simplified CAD model of a cadaver used for thermal contact resistance simulation.**

The heat transfer analysis was done using a commercial finite element software, COMSOL Multiphysics. The model was situated inside and air domain at 20$^{O}$C while the muscle, bone, and implant were given an initial temperature of 37 $^{O}$C. The material properties are shown in Table 1.

**Table 1: Material properties used for bone, muscle, and implant for the thermal contact resistance analysis.**

| Properties | Bone | Muscle | Implant |
|---|---|---|---|
| **Heat Capacitance** | 1313 $\frac{J}{kg-K}$ | 3421 $\frac{J}{kg-K}$ | 500 $\frac{J}{kg-K}$ |
| **Density** | 1908 $\frac{kg}{m^3}$ | 1090 $\frac{kg}{m^3}$ | 7990 $\frac{kg}{m^3}$ |
| **Thermal Conductivity** | 0.32 $\frac{W}{m-K}$ | 0.49 $\frac{W}{m-K}$ | 16.2 $\frac{W}{m-K}$ |
| **Relative Permeability** | 1 | 1 | 1 |
| **Relative Permittivity** | 191 | 5230 | 1 |
| **Electrical Conductivity** | 0.0214 $\frac{S}{m}$ | 0.407 $\frac{S}{m}$ | 1.35E5 $\frac{S}{m}$ |

To simulate the heating condition of the implant from previous cadaver test, a temperature function was created using the step function shown in Figure 2. This condition was applied to the top surface of the implant.

A parametric sweep for the surface roughness was conducted for the values between 0.5 – 2 µm with an increment of 0.5 µm. A parametric study was also done on the contact pressure for the value of 100 – 1000 kPa with an increment of 100 kPa.

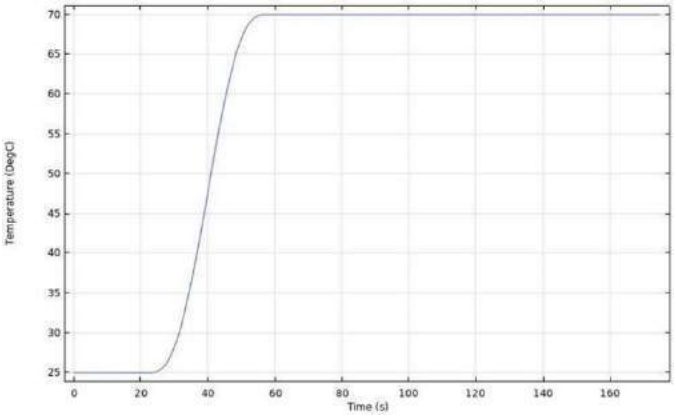

**Figure 2: Temperature function simulating the implant heating during the previous cadaver test.**

## RESULTS

Figure 3 shows the results of the implant and bone temperature for with and without thermal contact resistance. Contact pressure and surface roughness of 400 kPa and 1 µm respectively was assumed as it yielded similar results to previous experimental data[6].

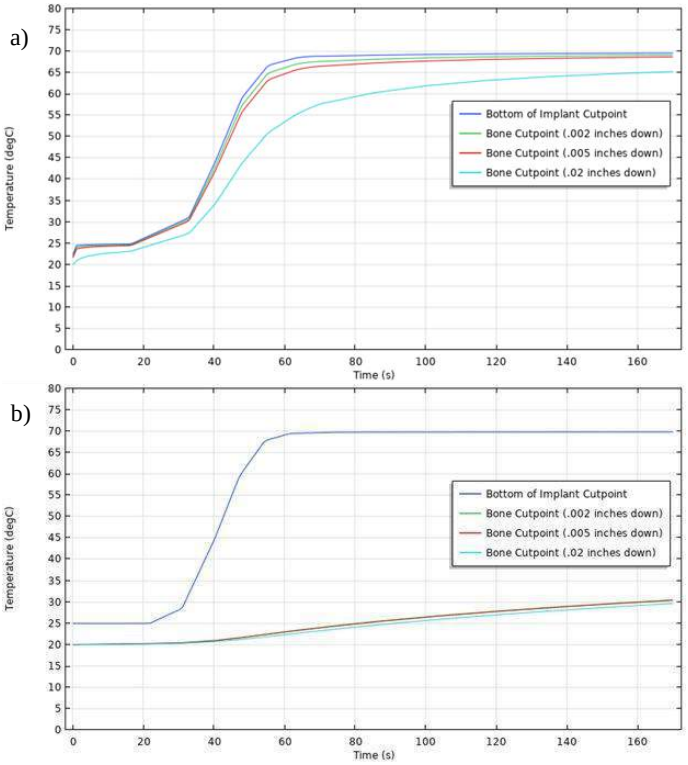

**Figure 3: Temperature of the bottom surface of the implant and the bone at different depth for without (a) and with (b) thermal contact resistance.**

Figure 4 shows the individual effect of surface roughness and contact pressure on the temperature of the bone. The relationship between surface roughness and bone temperature is inversely proportional while the relationship between contact pressure and bone temperature is directly proportional.

## DISCUSSION

Thermal contact resistance plays a crucial role in the heating of the bone. As seen in Figure 3a, the surface of the bone almost reached 70$^{O}$C. Even at a bone depth of 0.02 inches, the temperature rises to a harmful level. Modeling the thermal contact resistance, as seen in Figure 3b, the bone temperature is approximately 54% lower - well below the thermal damage threshold and safe for patients undergoing the treatment.

Note that the results from Figure 3 are specific to contact pressure and surface roughness of 400 kPa and 1 µm respectively. More studies must be done to determine the bone temperature based on different combinations of contact pressure and surface roughness.

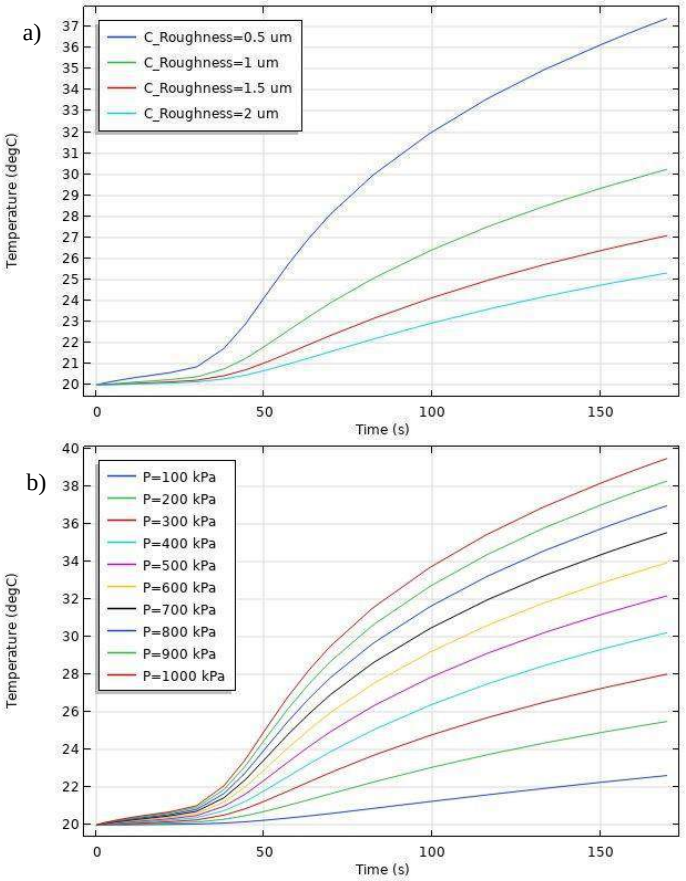

**Figure 4: a) Effect of varying surface roughness on bone heating at a depth of 0.002in assuming 400KPa for contact pressure. b) Effect of varying contact pressure on the bone heating at the same point and assuming surface roughness of 1µm.**

# RECENT UPDATES ON THE GHBMC HUMAN HEAD FINITE ELEMENT MODEL – NEW VISCO-HYPERELASTIC BRAIN MATERIAL MODEL AND BRAIN STRAIN VALIDATION

**Ding Lyu (1), Runzhou Zhou (1), Liying Zhang (1)**

(1) Department of Biomedical Engineering, Detroit, MI, United States

## INTRODUCTION

In the United States, approximately 2.5 million Traumatic Brain Injury (TBI)-related emergency department visits, 280,000 TBI-related hospitalizations, and 56,000 TBI-related deaths occurs each year[(1)]. The postmortem human subjects (PMHS) experiments have been conducted to obtain the biomechanical responses relevant to injury production. The Finite Element (FE) model evolve in complexity and improve our understanding of mechanisms of brain injuries far beyond what could be learnt from experimentation. The Global Human Body Models Consortium (GHBMC) human body model is a well-developed FE model for predicting crash-induced injury in an effort to advance crash safety technology.

White matter injury is one of the key features of diffuse brain injury ranging from cerebral concussion to diffuse axonal injury (DAI) of various severities. A variety of experimental studies on the directional properties of gray and white matter tissues revealed transverse isotropy for some of the white matter structures, notably the brainstem, corpus callosum and internal capsules[(2,3)]. This work described the refinement of the GHBMC 50$^{th}$ percentile adult male (M50) head model by the development and incorporation of a new anisotropic hyper-elastic material into the white matter tissues. The material properties were then optimized to best correlate the prediction of brain strain response to the measured strain from PMHS tests. This improved head model v6.0 enables the model capability of predicting directional dependent responses and associated type and severity of the neurotrauma.

## METHODS

*Anisotropic hyper-elastic material model*

All prior versions of the GHBMC M50 head model including v5.0 defined the brain as an isotropic viscoelastic material. To model the anisotropic property of hyper-elastic material, the reinforced fiber may be embedded in the ground Mooney-Rivlin matrix. The strain energy of the material is formulated as:

$$\boldsymbol{W = C_1(I_1 - 3) + C_2(I_2 - 3) + F(\lambda) + \frac{1}{2}[Kln(J)]^2} \quad (1)$$

in which $C_1$ and $C_2$ are the Mooney-Rivlin coefficients; $I_1$ and $I_2$ are the two principal invariants of left Cauchy-Green deformation tensor; $F(\lambda)$ is the function to depict the mechanical properties of axonal fibers; $K$ is the effective bulk modulus of the material. The fiber is assumed to be unable to resist compressive loading and its mechanical behavior was described as

$$\frac{\partial \boldsymbol{F(\lambda)}}{\partial \boldsymbol{\lambda}} = \begin{cases} \boldsymbol{0} & \boldsymbol{\lambda < 1} \\ \boldsymbol{\frac{C_3}{\lambda}\left[e^{C_4(\lambda-1)} - 1\right]} & \boldsymbol{1 < \lambda < \lambda^*} \\ \boldsymbol{C_5 + C_6/\lambda} & \boldsymbol{\lambda > \lambda^*} \end{cases} \quad (2)$$

The deviatoric and volumetric decay coefficients $\beta_s$ and $\beta_p$ are introduced to present the viscoelasticity of soft tissue.

$$\boldsymbol{s_I^\nabla = s^\nabla - \beta_s s_I; \dot{p}_I = \dot{p} - \beta_p p} \quad (3)$$

where s and p can be understood as the deviatoric stress and pressure from the last iteration results. In this new version head model (v6.0), a transversely anisotropic material model (*MAT_SOFT_TISSUE) coupled with *MAT_ADD_INELASTICITY was developed and defined for subcortical white matter, corpus callosum, and brainstem (LS-DYNA R12.0). The direction of the neuronal fiber architecture in each of the structures was defined via MAT_COORDINATES and related to the location of the white matter elements.

*Brain Strain Validation and Optimization of Material Properties*

A multiple-objectives optimization model was built to find the optimal parameters of anisotropic material model for various brain

components in order to improve the validity of brain strain prediction by the model. Seven PMHS head impact cases (C380-T1, T2, T3, T4, T6, C288-T3, and C393-T3)[4, 5] were simulated. The average Green maximum principal strain (MPS) of 12 triad-elements simulated for each case were compared with the experimental curves to derive the validation score (Fig.1). To optimize the properties for test results, the optimization target score was defined as the averaged validation score from all 7 simulations. The higher the target score, the better the model was which reflecting the overall predictive ability of MPS response.

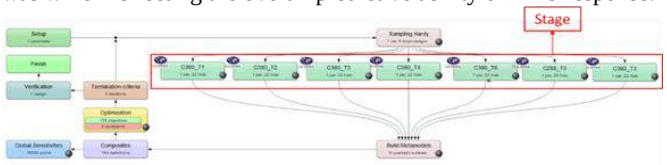

**Figure 1: The optimization model used to optimize the match of the MPS prediction with the PMHS experimental data**

*Intracranial Pressure Validation*

The GHBMC head model v6.0 was subjected to validation against intracranial pressure (ICP) measured from frontal head impact test[6] as well as ICP and ventricular pressure from facial impact[7].

*Facial and Skull Impact Validation*

The skin of the head model v6.0 was updated with a new Ogden material model consistent with the skin model used in other body regions. The model was validated against force-deflection (F-D) responses from 8 skull impacts (frontal, temporal, tempo-parietal, occipital)[8,9] and 6 facial impacts (nasal, zygomatic and maxilla)[10].

## RESULTS

*Brain Response Validation*

Overall, the simulated MPS curves matched well with the experimental curves (Fig. 2). The peak MPS of the experiment and model were 0.076±0.02 and 0.067±0.015, respectively. The average CORA (CORelation and Analysis, v4.0.4) rating was 0.58 (0.48 - 0.74).

The model predicted ICPs matched well to test data[6]. The phase of the simulated pressure curves showed the highest match to the test whereas the magnitude score was the least. The CORA score was 0.60 for coup ICP and 0.63 for contrecoup ICP.

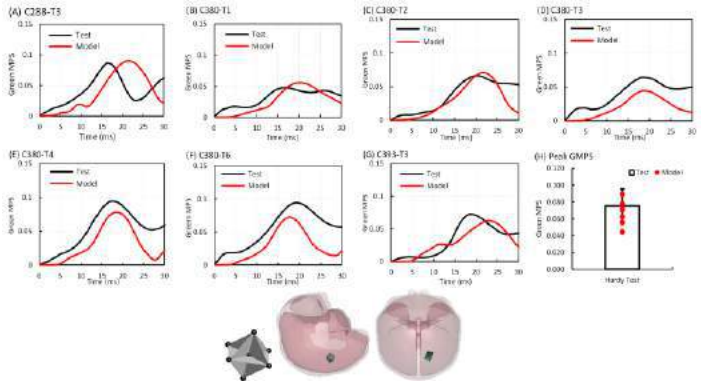

**Figure 2: Validation of time-histories and peak green MPS responses in the brain and 12 null-triad elements for MPS output**

*Skull and Facial F-D Response Validation*

The model predicted F-D, stiffness, and peak fracture force matched well with test results for various facial and skull impact (Fig. 3).

(b) Skull impact

**Figure 3: Comparison of F-D responses in facial and skull impacts**

## DISCUSSION AND CONCLUSIONS

An advanced anisotropic material model was developed, optimized, and incorporated to improve bio-fidelity of the GHBMC M50 head model v6.0. These improvements enable the model to simulate directional properties of the white matter and predict realistic directional dependent impact response in the brain and associated injury severity. The head model v6.0 has been subjected to rigorous validations against a total of 60 PMHS experiments to ensure the accuracy of the model in predicting kinematic, kinetic, stress and strain responses in a variety of loading conditions. The current model showed good biofidity in MPS prediction. The error of peak MPS compared with the test data, was 15% in the current v6.0 model and was 31% in the head model published[5].

To the authors' best knowledge this is the first FE head model that has been rigorously validated against responses in the skull, face and the brain of various regions. This validated head model has been used to develop Crash-induced Injury Indices (CIIs) for predicting facial bone fracture, skull fracture, cerebral contusion, acute subdural hematomas and diffuse brain injury through the reconstructing PMHS and real-world injury cases and the findings are reported in a separate communication.

## INTRODUCTION

Degeneration of the spinal facet joints is a primary cause of pain, and occurs with aging or trauma [1,2]. The capsular ligament that encases the facet joint is comprised of collagen fibers with afferents that innervate it and have their cell bodies in the dorsal root ganglion (DRG) [3]. After a ligament injury, a complex combination of biomechanical, biochemical, and inflammatory cascades alters the extracellular matrix (ECM) and initiates responses in the afferents, resulting in pain [4]. The matrix metalloproteinases (MMPs) are one such regulator and are responsible for modifying the ECM. The interstitial collagenase MMP-1, in particular, digests type I collagen fibers and has been implicated in pain by acting on neuronal receptors involved in nociception [5,6].

Phospholipase $A_2$ ($sPLA_2$) is involved in inflammation and is an enzyme that hydrolyzes glycerophospholipids, releasing active molecules that induce inflammation and tissue damage [7]. Although $sPLA_2$ is present at a basal level in joint tissue, it is upregulated in degenerated joints [8,9]. Thiotheramide-PC (TEA-PC) is a competitive inhibitor of $sPLA_2$ and has been shown to mitigate degeneration when introduced in the joint space [10]. Further, targeted TEA-PC loaded micelles mitigate neuronal injury in neuropathy, and attenuate spinal neuronal hyperexcitability and pain [11]. Although TEA-PC helps retain joint tissue and relieves pain, it is unclear whether or how that inhibitor alters neuronal activity and/or injury.

In this study an in vitro culture model of the facet capsular ligament was used to begin to evaluate the effect of the $sPLA_2$ inhibitor TEA-PC on neuronal dysfunction and injury following exposure to a collagen-digesting agent. Our neuron-collagen construct (NCC) that models the microstructural environment of the facet capsular ligament was exposed to MMP-1 to simulate the early effects of the degenerative cascade [1,6]. Calcium activity in the afferent DRG neurons was recorded in a time-lapse study before and after MMP-1 exposure and again after treatment with the inhibitor, to serve as a proxy for neuronal dysfunction. NCCs were also assayed for expression of activating transcription factor-3 (ATF-3) 24 hours after treatment to assess injury.

## METHODS

NCCs (n=4) were fabricated from a 2mg/mL collagen solution with dissociated DRG neurons ($3x10^5$cells/mL) from embryonic day 18 rats [12-14]. After plating, neurons were cultured with neurobasal medium supplemented by 1% GlutaMAX, 2% B-27, 1% fetal bovine serum, and 10ng/mL 2.5S nerve growth factor (ThermoFisher). On day in vitro (DIV) 2, neurons were transduced with an AAV expressing GCaMP6f in the media (1:5000), which causes them to transiently fluoresce at 488nm with calcium influx [15,16]. At DIV6, additional collagen (150µL) was added to encapsulate the NCC. At DIV9, NCCs were placed on glass-bottomed dishes in 1.2mL of culture media.

Gels were imaged on a Leica inverted spinning disc confocal microscope under a 20X water-immersion objective. Fields of view (FOVs; n=4) were selected for each NCC and their x-y stage positions were stored using the microscope software to enable making repeated measurements from the same FOV. Images were captured at 3 timepoints for each gel: baseline (BL) before any exposure to MMP-1, immediately after 20mins of exposure to MMP-1, and then 20mins after the treatment. Image series were captured (1024 x 1024 pixels$^2$) at each timepoint at 20fps for 60s to capture transient calcium events (Fig. 1). Baseline images were captured before replacing the culture media with human recombinant MMP-1 (30µg/mL; SRP3117; Sigma Aldrich) [5]. Gels were exposed to MMP-1 and the media was removed after 20mins. A subset of gels (n=2) received 1.2mL of culture media with 10mM of the $sPLA_2$ inhibitor, TEA-PC. The other subset of gels (n=2) received 1.2mL of the media only and served as a vehicle control. Images were taken again after 20mins of treatment and gels were transferred to fresh culture media supplemented with 1% penicillin/streptomycin. After

24hrs, they were fixed with 4% paraformaldehyde for 2hrs, transferred to 30% sucrose in saline solution, and stored at 4°C.

Fixed gels were triple-washed with 3X PBS and incubated with blocking buffer for 2hrs at room temperature. Gels were incubated at 4° overnight with primary antibodies ATF-3 anti-Rabbit (1:200) and collagen anti-Mouse (1:200). The next day, gels were washed with PBS and incubated for 2hrs at room temperature with secondary antibodies Goat-anti-Rabbit 555 (1:500) and Goat-anti-Mouse 647 (1:500). Gels were also labelled with DAPI (1:1000) for 10mins and washed again before being cover-slipped and stored at 4°C.

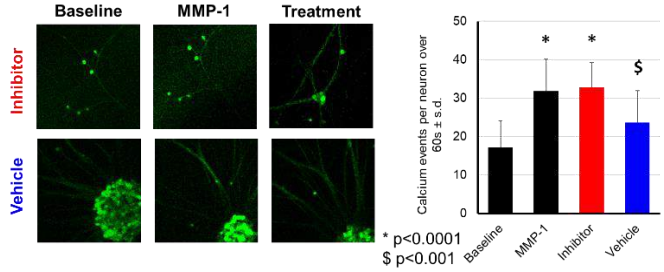

**Figure 1: Calcium activity was imaged before (baseline) and 20mins after exposure to MMP-1, and 20mins after treatment (inhibitor or vehicle). Calcium activity increases with MMP-1 exposure (*) but decreases with vehicle treatment ($).**

Neuronal activity was measured using the custom MATLAB script, FluoroSNNAP, to segment and quantify the number of calcium events for each neuron ($n_{inhibitor}$=122; $n_{vehicle}$=81) [16]. The same neurons were identified and segmented across timepoints using the images of each FOV. A grader blinded to the treatment and exposure time segmented each neuron by drawing around the soma. The frequency of calcium events for each neuron was captured by a template-matching algorithm [16,17]. The mean number of calcium events for each neuron at each timepoint was calculated and compared using a one-way repeated measures ANOVA, with treatment as the factor.

Gels were imaged on a Leica inverted spinning disc confocal microscope under a 20X water-immersion objective with12 FOVs (1024 x 1024 pixels$^2$) acquired for each gel. A separate set of labeled, unexposed gels was also imaged to serve as a control for basal ATF-3 expression levels. Images were analyzed in ImageJ and ATF-3 expression was quantified by measuring the average intensity of the pixels positive for ATF-3 signal, and compared between treatment groups using a t-test.

## RESULTS

Exposure to MMP-1 for 20mins increases the calcium activity from 17.2±6.8 events/min at baseline to 31.8±8.4 events/min in each neuron (p<0.0001) (Fig. 1). Of the two treatment groups, both groups have similar BL activity (18.7±6.4 inhibitor, 16.2±7.0 vehicle events/min/neuron; p=0.68) and activity after MMP-1 exposure (inhibitor 29.9±6.9, vehicle 33.1±9.1 events/min/neuron; p=0.76) but before treatment. Although treatment with TEA-PC does not lower calcium activity (32.8±6.5 events/min/neuron; p=0.925), exposure to culture media alone in the vehicle group does lower activity (23.6±8.3 events/min/neuron; p<0.001) (Fig. 1).

Contrary to the calcium activity responses at 20 minutes after treatment (Fig.1), ATF-3 expression at 24 hours later does appear to be reduced with TEA-PC treatment (Fig. 2). Expression of ATF-3 decreases (p=0.047) after treatment with the sPLA$_2$ inhibitor (25.7±10.3 pixel intensity units) compared to expression levels observed with the vehicle treatment (35.9±8.1 pixel intensity units). Both of these groups exhibited ATF-3 expression levels higher (p<0.01) than those in the control gels (16.8±4.9 pixel intensity units).

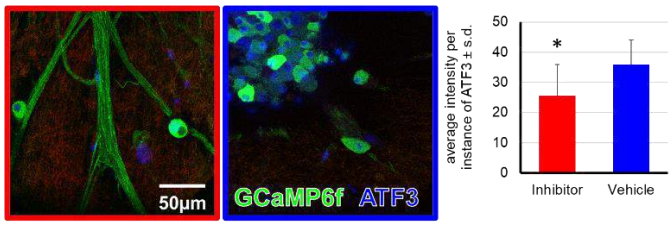

**Figure 2: ATF3 expression 24hrs after MMP-1 exposure and treatment decreases with inhibitor treatment (*p=0.047).**

## DISCUSSION

Although a 20min treatment with the sPLA$_2$ inhibitor, TEA-PC, following exposure to MMP-1 does not reduce neuronal calcium activity, it *does* reduce expression of the injury marker ATF-3 (Figs. 1 & 2), though not to control levels. In fact, ATF-3 levels were approximately 1.5-fold higher than control in the TEA-PC-treated gels. MMP-1 directly binds to protease-activated receptors (PARs), inducing signaling cascades that modulate the inflammatory cascade [18]. The fact that TEA-PC does not appear to fully return ATF-3 to normal suggests that the sPLA$_2$ inhibitor either acts on specific signaling pathways that attenuate, but not wholly prevent, downstream transcriptional changes [19], or that there is a temporal effect in which the TEA-PC is more effective hours after the initial insult.

TEA-PC loaded micelles (at a dose of 0.25 mg/mL) applied immediately after a painful nerve root injury to reduce neuronal hyperexcitability in vivo when injected at the injury site [11]. That concentration of TEA-PC is much higher than the one used in the current study (10mM; which is approximately 30-fold less), which could also explain why calcium activity after MMP-1 stimulation was not attenuated by the TEA-PC. Furthermore, in the micellar delivery the TEA-PC is retained for much longer due to the inhibitor's controlled release, which enables them to also sustain the absence of any pain - related behavior after injury [11]. MMP-1 inhibitors, such as tissue inhibitors of metalloproteinases (TIMPs), may be more effective in mitigating neuronal dysfunction and nociception from degeneration since they directly target the enzymes that are upregulated in the degenerative cascade and that contribute to neuropathic pain [20]. Nevertheless, although the sPLA$_2$ inhibitor does not alter neuronal dysfunction at the concentration used here, it does affect transcriptional changes that underlie neuronal injury and central sensitization [21].

## INTRODUCTION

Stroke is commonly initiated by rupture of the atherosclerotic plaque fibrous cap in a carotid artery. However, cap rupture mechanisms are not well understood yet. Collagen is the main load-bearing component in caps. [1] Understanding its impact on local cap mechanics may provide critical insights into plaque rupture. Various limitations within studying the real animal and human plaques in vivo and ex vivo highlight the need for additional methods to investigate rupture mechanics. Therefore, we created a tissue-engineered collagenous plaque cap analog model, with controllable collagen architecture, that can be imaged and mechanically tested [2]. In the current study, we present our pipeline for visualizing collagen orientation and obtaining local mechanical properties in these analogs to analyze the relation between collagen architecture and local cap mechanics.

## METHODS

*Development of fibrous cap analogs*

Ten cap analogs were created by seeding human vena saphena cells (HVSCs) in 1 x 1.5 cm-sized fibrin gels (Fig 1A).

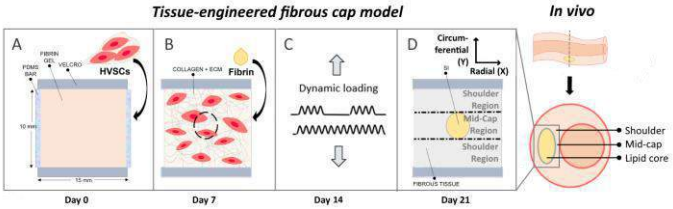

**Figure 1: Protocol for developing fibrous cap analogs.**

After seeding, the samples were cultured for 7 days under static loading, whereafter a 2 mm Ø soft inclusion (SI) was created by punching a hole in the center of each analog and filling this core with fibrin (Fig 1B). This fibrin inclusion mimics the soft lipid core of atherosclerotic plaques. The analogs were statically cultured for 7 more days, after which they were exposed to 7 days of dynamic loading (Fig 1C) using the Flexcell FX-4000T (Flexcell Int, 196 McKeesport, PA).

*Collagen imaging*

On day 21, the samples were exposed to multiphoton microscopy (MPM) with second harmonic generation (SHG) to visualize the collagen architecture. First, a tile scan was made of the entire sample (Fig 2A). From the tile scan, two horizontal lines of adjacent tiles were selected for further analysis. One line of the selected tiles overlaid the shoulder region of the sample while the other overlaid the mid-cap, including the soft inclusion (Fig 2B). For each tile, z-stack imaging in the depth direction was performed (728x728 µm, 512x512 pixels, 3-µm steps).

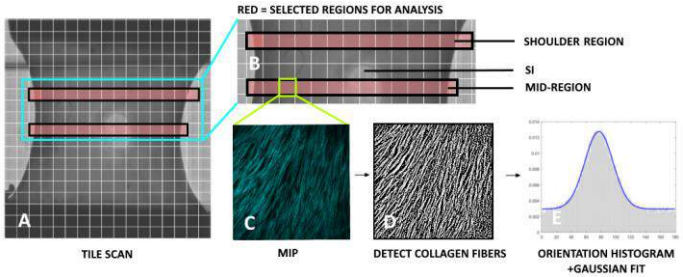

**Figure 2: Collagen imaging and fiber orientation analysis pipeline.**

After imaging, maximum intensity projection (MIP) images were created of each z-stack (Fig 2C). Finally, a MATLAB based fiber orientation analysis tool (FibLab) was used to calculate the orientation of individual collagen fibers in the MIP (Fig 2D). A Gaussian distribution was fit to the histogram of all detected collagen fiber orientations (Fig 2E). From this gaussian distribution, the predominant

fiber orientation (θ in degrees) and standard deviation (SD) of the fiber orientations in the tile, which indicates the degree of fiber anisotropy, were determined.

*Uniaxial tensile tests and DIC*

After imaging, the samples were mechanically tested. A speckle pattern for digital image correlation (DIC) was applied to the top surface of each sample using an airbrush and a tissue dye. After pre-stretch (15 mN) and preconditioning (10 cycles of 10% strain), the samples were uniaxially strained until complete failure at a speed of 100%/min. The samples were strained in the y-direction, which biologically corresponds to circumferential strain (Fig 1D). To obtain local strains (Green-Lagrange), DIC analysis was performed in MATLAB using the open-source software Ncorr [3].

## RESULTS

*Collagen imaging*

The predominant fiber angles (θ) and standard deviations within the tiles of a representative sample are presented in Fig 3. The figure shows that the fibers in both the shoulder and mid-cap region are mostly oriented in the y-direction. Similar results are found in the other samples. The average fiber orientation (θ ± SD) of the ten analyzed samples is 91±22° in the shoulder region and 89±22° in the mid-cap region.

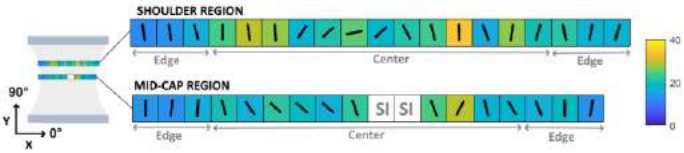

**Figure 3: Mean predominant fiber angle (black line) and SD (background color) in both the mid-cap and shoulder region of an analog. A larger SD indicates greater fiber dispersion. Z-stacks located in the SI were excluded from analysis.**

The figure also indicates that the fibers at the edges of the sample (defined as the 3 most left and right tiles) are oriented closer to the y-direction than the fibers in the center of the sample. This holds for both shoulder and mid-cap regions. The difference of the predominant fiber orientation with the y-axis (Δθ) averaged over the ten analyzed samples is 13° at the edges and 35° in the center. The minimum and maximum Δθ found in the ten samples are 0 and 54 at the edges and 0 and 89 in the center of the sample, respectively. Finally, the center sections indicate a more dispersed fiber distribution, indicated by the high SD values (background color in Fig 3), compared to the edge sections of the samples (Average SD values 10 samples: 24 vs 18).

*Uniaxial tensile tests and DIC*

Of the ten samples, five ruptured at the clamping site and were therefore excluded from further strain analysis. The rupture in all analyzed samples (n=5) initiated in the SI, in the mid-cap region (Fig 4A.1). After rupture initiation, the rupture propagated in a -slightly tilted-horizontal direction (Fig 4A.2). Once the rupture arrived at the SI-fibrous tissue interface, the rupture propagation paused for a short period (Fig 4A.3). Finally, the rupture propagated to the fibrous tissue, resulting in a crack over the full width of the analog (Fig 4A.4).

Fig. 4B shows the DIC-derived local strain measurements in the tensile direction ($E_{yy}$) at the time point of rupture initiation in the SI. The figure shows a region of elevated tensile strain near the rupture location. The maximum tensile strain ± SD found in this high-strain region averaged for all five analyzed samples is 60% ± 20%. This maximum strain is four times higher than the average tensile strain in the entire sample (15±5%). This clearly indicates that the average tissue strain commonly used for plaque tissue rupture characterization underestimates the real, local rupture strain.

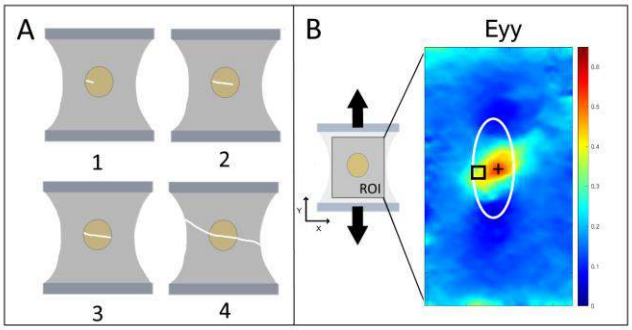

**Figure 4: A) Phases of rupture identified in cap analogs. B) DIC-derived local strains (tensile ($E_{yy}$)). The white oval shape marks the edge of the soft inclusion, the black rectangle the location of rupture initiation and the plus sign the maximum strain location.**

## DISCUSSION

We successfully created tissue-engineered collagenous plaque cap analogs to study the atherosclerotic plaque cap rupture characteristics. We used MPM with SHG to obtain information about the collagen architecture of these analogs and obtained local strain data using uniaxial tensile tests with DIC.

The results from MPM showed that the collagen fibers in the analogs are mainly oriented in the y-direction, which corresponds to the circumferential direction in the real plaque tissue. This predominant fiber orientation is in line with the predominant fiber orientation in human plaques [4]. Despite the overall circumferential orientation, MPM results demonstrated larger deviations of the predominant fiber orientation from the circumferential direction and indicate more dispersed fiber architecture in the center sections compared to the edges.

The DIC measurements showed elevated tensile strains in the SI, representing the necrotic core of the real plaques. Rupture initiated near this region of elevated tensile strains. The maximum strain found in this region is similar to the local rupture strain found in a previous DIC-analysis of ex vivo human plaque tissue [5]. After rupture initiation near the high-strain region within the SI, the rupture in the analogs propagated towards the luminal surface of the fibrous cap. The directionality (from SI to lumen) observed in this study differs from the hypothesis that proposes plaque rupture starts at the lumen.

As the next step, with a larger sample set, we will investigate the intra- and inter-sample variations in the fiber orientations in more detail and study the association of this local structural information to the rupture propagation path and to the local strain pattern. Furthermore, we will further study our new hypothesis proposing rupture initiation in the SI to gain better understanding of the underlying plaque rupture mechanisms.

## INTRODUCTION

Concussions continue to be a prevalent safety concern in contact sports due to their potential short-term and long-term neurodegenerative effects. Studies suggest that repetitive, non-concussive head impact exposure may lead to similar pathologies as those caused by concussion.[1,2] With approximately 3.5 million youth athletes (age 6-13) participating in football each year, it is essential to minimize head impact exposure to prevent future brain injury.[3-6] Football head acceleration data has been quantified using the Riddell Head Impact Telemetry (HIT) System. Advancements in sensor technology has allowed for head acceleration measurement with greater accuracy using mouthpiece-based sensors.[7,8] however, there is little information on head acceleration events in youth football with mouthpiece-based sensors.[9] Therefore, the objective of this study was to characterize head acceleration in middle school football using mouthpiece-based sensors.

## METHODS

Thirty athletes on two middle-school-level (ages 11-14) football teams were instrumented with a mouthpiece-based sensor, containing a gyroscope and tri-axial accelerometer. Mouthpieces were custom fit to each athlete's upper dentition using a TRIOS intraoral scanner (3Shape, Copenhagen, Denmark). The mouthpiece sensors were set to a threshold of 5g: if any axis exceeded 5g for at least 3 milliseconds, the mouthpiece would record an event for 15 ms pre-trigger and 45 ms post-trigger.[7] Head acceleration exposure was quantified by number of head acceleration events (n), linear acceleration (LA), rotational velocity (RV), and rotational acceleration (RA). Data were collected for each session (e.g., practice, scrimmage, game) during which a participating athlete was present. One time-synchronized camera was placed on the sideline at sessions to collect video data. Members of the research team were present to monitor all data collection.

All head acceleration events were individually video-verified by the research team so that false-positive events could be identified and excluded from analysis. True-positive events were categorized by several variables, including session type and impact type (Table 1). Analysis and results from athletes participating on one of the enrolled youth football teams (n=15 athletes) are presented herein.

**Table 2: Overall values for biomechanical parameters.**

| Impact Type | Description |
|---|---|
| Blocking | Collision with closing distance of <10 ft. |
| Running | Collision between athletes while running |
| Passing | Collision while attempting to catch/block a pass |
| Tackling | Athlete is taken to the ground by another player |
| Isolated Fall | Athlete falls without contact from external source |

## RESULTS

A total of 23,605 recordings were collected over 34 sessions (25 practices, 1 scrimmage, and 8 games). After video verification of individual recordings was completed, 21,773 false-positive events were excluded; the remaining 1832 recordings were determined to be true-positives, 752 (41%) of which exceeded 10g. False-positive recordings were often a result of an athlete interacting with their mouthpiece. The total number of head acceleration events (i.e., events) per athlete ranged from 7 to 436, with an average (± standard deviation) of 122±128 events (i.e., events) over the duration of the season. Summary statistics for peak resultant LA, RV, and RA for the sample are provided in Table 2.

**Table 2: Summary statistics for biomechanical parameters.**

| Event Threshold | Sensor Output | Mean ± St Dev | Median | 95$^{th}$ Percentile |
|---|---|---|---|---|
| ≥5g (n=1832) | LA (g) | 11.7 ± 10.2 | 8.9 | 28.2 |
| | RV (rad/s) | 8.9 ± 4.5 | 8.0 | 17.4 |
| | RA (rad/s$^2$) | 925.6 ± 1029 | 655.0 | 2477 |
| ≥10g (n=752) | LA (g) | 18.4 ±13.0 | 14.1 | 42.6 |
| | RV (rad/s) | 11.2 ± 4.91 | 10.3 | 20.1 |
| | RA (rad/s$^2$) | 1439 ± 1439 | 966.0 | 4231 |

All data, exceeding 5g, were analyzed by session type and impact type. Summary statistics of head acceleration data grouped by session type are provided in Table 3. Games had the greatest magnitude median LA, RV, and RA. Scrimmages had the lowest median LA, RV, and RA.

**Table 3: Biomechanical parameters by session type.**

| Session Type | Sensor Output | Mean ± St Dev | Median | 95th Percentile |
|---|---|---|---|---|
| Practice (n=1273) | LA (g) | 11.9 ± 11.3 | 8.8 | 30.0 |
| | RV (rad/s) | 8.8 ± 4.4 | 7.9 | 16.9 |
| | RA (rad/s$^2$) | 945.6 ± 1157 | 637.7 | 2770 |
| Scrimmage (n=110) | LA (g) | 10.6 ± 7.4 | 8.5 | 22.3 |
| | RV (rad/s) | 8.8 ± 4.7 | 7.6 | 17.3 |
| | RA (rad/s$^2$) | 825.4 ± 679.4 | 651.0 | 1836 |
| Game (n=449) | LA (g) | 11.2 ± 6.9 | 9.4 | 24.1 |
| | RV (rad/s) | 9.3 ± 4.6 | 8.5 | 18.3 |
| | RA (rad/s$^2$) | 893.4 ± 641.9 | 723.7 | 2006 |

Summary statistics of head acceleration data by impact type are provided in Table 4. Running collisions had the greatest median LA, RV, and RA. Isolated falls had the lowest median LA and RA. Blocking collisions had the lowest median RV. A sample running event collected by an instrumented athlete, engaging in helmet-to-helmet contact during a game, is shown in Figure 1.

**Table 4: Biomechanical parameters by impact type.**

| Impact Type | Sensor Output | Mean ± St Dev | Median | 95th Percentile |
|---|---|---|---|---|
| Blocking (n=1157) | LA (g) | 10.7 ± 8.9 | 8.6 | 20.8 |
| | RV (rad/s) | 8.1 ± 4.0 | 7.3 | 15.0 |
| | RA (rad/s$^2$) | 817.1 ± 916.6 | 601.7 | 1780 |
| Running (n=269) | LA (g) | 14.7 ± 11.7 | 11.3 | 33.9 |
| | RV (rad/s) | 10.7 ± 5.1 | 9.8 | 19.9 |
| | RA (rad/s$^2$) | 1210 ± 1146 | 857.8 | 3435 |
| Passing (n=21) | LA (g) | 13.4 ± 11.1 | 8.7 | 41.9 |
| | RV (rad/s) | 9.6 ± 4.3 | 9.3 | 15.6 |
| | RA (rad/s$^2$) | 1453 ± 1702 | 790.8 | 5937 |
| Tackling (n=319) | LA (g) | 13.1 ± 12.6 | 9.4 | 33.0 |
| | RV (rad/s) | 10.3 ± 5.0 | 9.3 | 20.8 |
| | RA (rad/s$^2$) | 1078 ± 1238 | 762.8 | 2770 |
| Isolated Fall (n=66) | LA (g) | 8.7 ± 6.1 | 6.8 | 18.0 |
| | RV (rad/s) | 9.0 ± 3.9 | 8.2 | 16.9 |
| | RA (rad/s$^2$) | 764.5 ± 549.0 | 598.2 | 1976 |

## DISCUSSION

The objective of this study was to characterize head acceleration events in middle school football athletes using mouthpiece-based sensors. Events with LA greater than 10g generally had lower median LA values and higher RA values, when compared with past studies utilizing the HIT System.[5,7,9] This may result from differences in the coupling of sensors (i.e. mouthpiece, HIT System) to an athlete's skull.

All head acceleration data were categorized and analyzed by session type and impact type. Games had the greatest magnitude median LA, RV, and RA; however, two-thirds of the head acceleration events were attributed to practices. This aligns with prior youth football research with the HIT system.[6,9] The higher head acceleration events in games might result from athletes engaging in more intense contact than they would experience in practices. Practices involve repetitive contact across multiple days per week, resulting in a greater proportion of head acceleration events over the course of the season.

Running collisions had the highest magnitude LA. Higher LAs could result from athletes building up high speeds before the event. This is consistent with past studies, which found that events involving fast contact speeds had greater linear acceleration.[10] Running collisions also had the greatest median RV and RA. This might result from athletes running in from oblique field positions.

One limitation of this study was that several research team members completed video verification of acceleration events. To ensure consistency in film review, inter-rater-reliability was analyzed and determined to be acceptable. The results of this study represent a single football team and the results of this study may not be generalizable to every team youth football across the country. This research utilized mouthpiece-based sensors to collect head acceleration data in youth football and demonstrate kinematic differences by session and impact type. The data collected in this study will be utilized in the future development of an evidence-based intervention for youth football.

## ACKNOWLEDGEMENTS

The authors thank the youth football organizations for participating in this research. The authors also thank the project manager, Tina Strates, and the undergraduate interns for assisting with this study. NIH NICHD (K25HD101686) provided funding for this study.

# IMAGE-BASED TEMPORAL QUANTIFICATION OF AORTIC COARCTATION WITHIN THE RANGE OF SEVERITIES AND DURATIONS SEEN CLINICALLY

**Jamasp Azarnoosh (1), Arash Ghorbannia (1), John F. LaDisa Jr. (1,2)**

## INTRODUCTION

Coarctation of the aorta (**CoA**) is one of the most common congenital cardiovascular defects. CoA often presents at birth as a narrowing that is most frequently treated surgically [1], [2]. Even after successful treatment, life expectancy is still lower than normal due to long-term morbidity, most often caused by refractory hypertension (**HTN**) [3]. The contributors to persistent HTN in CoA after treatment are not well understood [1], which is the primary focus of our research. The current treatment guideline of a peak-to-peak blood pressure gradient (**$BPG_{pp}$**) ≤20 mmHg implemented clinically has revealed irreversible changes in arterial structure and function, yet revised $BPG_{pp}$ guidelines have not been proposed [4]. Prior studies of pathologic aortic remodeling have neglected the temporal evolution of mechanical stimuli at younger ages that may contribute to HTN in CoA [1], [3]–[5]. As a step towards quantifying temporal alterations in mechanical stimuli and changes in arterial properties for the range of CoA severities and durations seen clinically, the current study proposes a methodology using ultrasound images and magnetic resonance imaging (**MRI**) data to develop computational geometries of the aorta. Investigation into the temporal evolution of coarctation in human patients is technically challenging due to a relatively low number of heterogeneous patients at each center. Therefore, we used a novel rabbit model that has served as a clinically representative model of CoA in humans [4], [5].

## METHODS

Following IACUC approval, rabbits were exposed to $BPG_{pp}$ severities ≤10, 11-20, and >20 mmHg for 1, 3, or ~20 weeks by varying the severity and duration of coarctation using permanent (**CoA**), dissolvable (**dCoA**), and rapidly dissolvable (**RdCoA**) sutures tied around the aorta at the location CoA most often presents clinically [4], [5]. The CoA group replicates untreated condition while the coarctation is corrected in dCoA and RdCoA groups within 1 and 3 weeks, respectively. This rabbit model includes data from a control group and nine CoA groups that mimic the morphology seen clinically in humans with CoA.

The general approach to develop computational geometries over ages is shown in **Figure 1**. Bodyweight for the rabbits was measured during the experimental duration, which aligns with data from Masoud et al. [6] (**Figure 1A**). Data were fit to the allometric (power-law) equation, which is wildly used for scaling in biology [7], [8]. A subject-specific geometry was reconstructed using SimVascular (simvascular.github.io) from 3-D MRI at the final week (MRI week marked in **Figure 1A**) and used as the baseline to create geometries at younger ages. A series of ultrasound images across all regions from the proximal to distal aorta including the coarctation were collected during

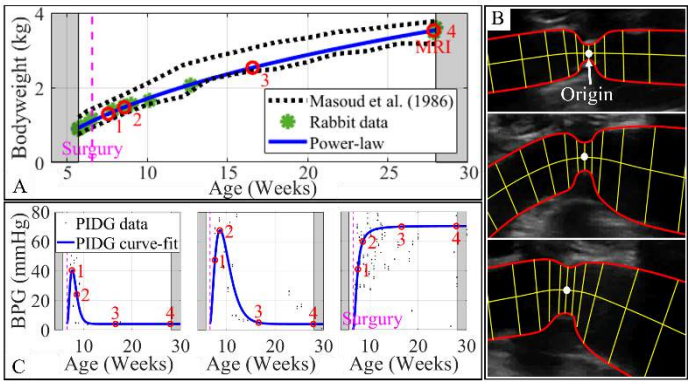

**Figure 1: (A) To replicate geometries at younger ages, MRI data are adjusted based on body size using allometric scaling (e.g. bodyweight vs. age for the dissolvable 20mmHg BPGpp rabbit at 4 time points). (B) A series of ultrasound images at the diastolic phase for three time points in a representative rabbit. (C) Temporal peak instantaneous Doppler pressure gradient (PIDG) for RdCoA, dCoA, CoA from left to right, respectively.**

the experimental duration. Images during the diastolic phase for all available series of ultrasound were imported for image processing (ImageJ) to quantify diameters. **Figure 1B** shows segmentations assigned perpendicular to the centerline to measure the temporal evolution of CoA shape from initial to final weeks. The longitudinal length of each segmentation was measured from the coarctation. Diameters and longitudinal length measurements were imported to MATLAB to predict the shape of the aorta using interpolation (Piecewise Cubic Hermite Interpolating Polynomial). The allometric equation was then used again to determine temporal changes of diameters at any longitudinal locations from proximal to distal. A similar procedure was performed during the systolic phase to determine arterial wall deformation (i.e. percentage radial strain) that will be used for quantifying elastic modulus in FSI simulations. The CoA shape based on longitudinal ultrasound images was determined at four time points of interest. The critical time points at younger ages are selected based on peak velocities seen in each group by Doppler-based estimates of BPG. Briefly, the first time point represents the age when peak BPG is observed in the rapid dissolvable group i.e. one week after surgery date (time point 1 in **Figure 1C**). Similarly, the second time point is two weeks after the surgery date when peak BPG occurs in the dissolvable group (time point 2 in **Figure 1C**). The third time point is the middle age of the rabbits (i.e. ~10 weeks after surgery date) to evaluate the evolution of mechanical stimuli at this age from early weeks (time point 3 in **Figure 1C**).

## RESULTS

**Figure 2** provides example results from the methods above by showing temporal changes in the CoA shape at four time points for a dissolvable CoA with the severity of 20 mmHg. **Figure 2A** shows diameter variation over ages at three selected locations (proximal, CoA, and distal), during the diastolic phase (solid black line) that was used to develop geometries and systolic phase (dotted blue line) used to determine arterial wall deformation for quantifying elastic modulus in future FSI simulations. Corresponding models for each time point are shown in **Figure 2B** with the final week reconstructed model from MRI. The other three time points scaled from the geometry of the final week based on the bodyweight curve shown in **Figure 1A** and the coarctation region adjusted corresponding to the shapes as depicted in **Figure 2C**.

Similar to the results presented in **Figure 2**, imaged-based quantification of computational geometries was conducted for other CoA groups as well as a control group. A complete summary of aortic deformation at four time points is presented in **Table 1**. The results in the control group indicate that radial strain seems to remain consistent with age (i.e. ~11%). In all CoA groups, radial strain in the proximal region above the coarctation was generally more than was seen in control measurements. Conversely, less deformation was seen distal to the coarctation as the severity and associated pressure drop across the coarctation increased. The proximal region of dissolvable CoA groups appeared to be exposed to smaller deformation with age compared with permanent CoA. The radial strain variation in the final week of dissolvable groups was similar between proximal and distal regions, but more pronounced in the rapid dissolvable groups since the suture dissolves in the first few weeks and the narrowing is enlarged with age.

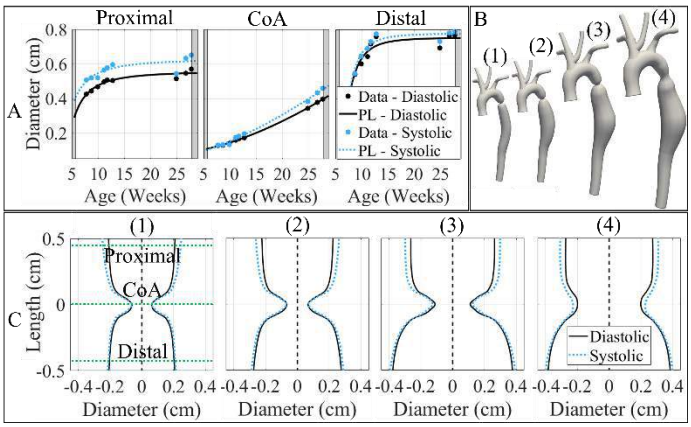

**Figure 2: (A) Diastolic and systolic diameters with age at proximal, CoA, and distal locations were measured and fit to the power-law model. (B) The 3-D geometries at four selected time points. (C) Temporal evolution of the CoA shape measured using longitudinal ultrasound images (e.g. dissolvable 20mmHg BPGpp at 4 time points) and incorporated into computational models.**

## DISCUSSION

The temporal evolution of aortic coarctation is absent in the literature. We proposed a novel approach to quantify image-based computational models of the aorta exposed to severities and durations seen clinically. This method provides quantitative information on the temporal evolution of regional aortic deformation (i.e. radial strain from the proximal to distal regions of the coarctation). Subject-specific geometries for nine CoA groups and a control group were developed at four time points that can now be used in FSI simulations to determine the range of mechanical stimuli that correlate with irreversible vascular impairment [4]. We will conduct longitudinal FSI simulations using the developed geometries and boundary conditions measured empirically for each group to characterize mechanical stimuli including blood flow velocity patterns, medial tension, and wall shear stress (WSS) indices. The radial strain across all regions (i.e. from proximal to distal) measured using longitudinal ultrasound images as well as 2-D phase-contrast magnetic resonance imaging (PC-MRI) sequences at the final week allows for quantification of elastic modulus at younger ages in the FSI simulation tuning process, which is our ongoing work.

## INTRODUCTION

Mechanical circulatory support devices (MCSDs) have been widely used to improve a patient's transplant candidacy and act as a bridge-to-heart transplantation for end-stage failing Fontan [1]. However, a healthy pulmonary circulation requires physiological pulsatility [2] while most of the standard MCSDs proposed for Fontan circulation are continuous flow [3]. Furthermore, due donor shortage novel approaches and devices are desired for this vulnerable patient population [4]. Therefore, a novel Fontan-support modification which can provide the desired pulsatile pulmonary flow is proposed in this study. It hypothesizes that in combination with a conventional left MCSD, sparing the native single ventricle (SV) for pulmonary circulation would result the physiological hemodynamics. Our previously developed multi-compartmental lumped parameter cardiovascular model (LPM) [5] was modified to simulate a realistic Fontan circulation to investigate the feasibility and performance of the proposed modification. The LPM was also validated via our established pediatric pulsatile *in vitro* Fontan mock-up flow loop [6].

## METHODS

*In silico* analyses were performed for an optimal Fontan circulation representing the baseline, i.e. the functional hemodynamic state, of the patient before the Fontan failure (*Case-1*). A ventricular dysfunction Fontan failure mode is simulated next (*Case-2*), which is treated through the proposed MCS configuration by delegating the SV to the right-side and a clinical ventricle assist device (VAD) (*Case-3*), Figure 1.

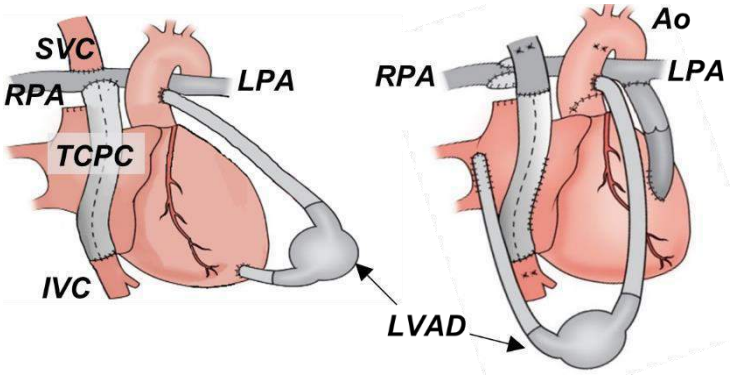

**Figure 1: *Left:* Conventional mechanical support of failed Fontan circulation with a left ventricle assist device (LVAD). *Right:* The proposed support alternative where the single-ventricle is spared as a right heart. Ao: aorta, IVC: inferior vena cava, SVC: superior vena cava, LPA: left pulmonary artery, RPA: right pulmonary artery TCPC: total cavopulmonary connection**

*Case-1* was reproduced based on the clinical data reported for optimal Fontan hemodynamics [7]. In *Case-2*, stroke volume was reduced by 40% to initiate the SV failure through decreasing ejection fraction (EF). In the proposed modification, a small portion of the common atrium is separated to form a posterior pulmonary venous (PV) chamber, while the remaining part serves as a right atrium. The systemic return was detached from the total cavopulmonary connection and directly connected to the newly created right atrium. Thus, systemic and pulmonary

circulations become parallel, similar to a native biventricular system. Finally, SV was connected to pulmonary arter (PA) to maintain the pulmonary circulation while the systemic circulation was governed by an MCSD. Its inlet was connected to the newly created posterior PV chamber and its outlet was placed to the aorta enabling it to act like a native left ventricle.

Numerical computations were validated through our *in vitro* Fontan mock-up loop. For both *in silico* and *in vitro* analyses as a clinical VAD the Heartware, HVAD (Medtronic)$^{TM}$ was used.

## RESULTS

***In vitro* Validation of LPM.** Mean values and percent differences between *in silico* and *in vitro* results for the selected clinical circulation states are provided in Table 1. It shows that LPM demonstrated acceptable agreement with the *in vitro* measurements in terms of compared hemodynamic parameters.

**Table 1: Difference between *in silico* and *in vitro* results for the key hemodynamic parameters. $P_{AO}$: aortic pressure, CI: cardiac index, $P_{SV}$: single ventricle pressure, $P_{CV}$: central venous pressure and $P_{PV}$: pulmonary venous pressure. *In silico* results of pressure and CI values in *Case-1* are given in *mmHg* and *l/min*, respectively**

| *Parameter* | *Case-1* | *Case-2* | *Case-4* |
|---|---|---|---|
| **$P_{AO}$ (70)** | No disparity | 1.5% | No disparity |
| **CI (4)** | No disparity | No disparity | 3% |
| **$P_{SV}$ (50.5)** | 1% | 6% | 5% |
| **$P_{CV}$ (16)** | 13% | 4% | 6% |
| **$P_{PV}$ (11.5)** | 11% | 8% | 3% |

**Ventricular Dysfunction Model.** In *Case-2*, reducing stroke volume decreased the EF from 44% to 26%, which led to a decrease in cardiac index (CI) and mean aortic pressure by 1.7 l/min/m$^2$ and 5 mmHg, respectively. The proposed modification was implemented in *Case-3* to support the failing SV. In systemic circulation, MCSD directly reflects the pulmonary flow. In pulmonary side, EF of the SV remained constant although the stroke volume was doubled. Mean SV pressure was simulated as 18.5 mmHg. Mean PA pressure increased from 10.7 mmHg to 17.5 mmHg (39%). Central venous pressure (CVP) was decreased by 2 mmHg (13%). As expected, MCSD suction caused a decrease in PV pressure to -1.2 mmHg, almost collapsing the chamber. Nevertheless, CI and aortic pressure increased by 1.7 l/min/m$^2$ (doubled) and 25 mmHg (38%), respectively, compensating the low EF as particularly aimed. Figure 2 shows the hemodynamic waveforms observed via implementation of proposed modification on ventricular dysfunction Fontan failure.

## DISCUSSION

In this study, a novel support modification for failing Fontan circulation states is proposed and investigated. In *Case-3*, mean PA pressure and flow waveforms were observed as very similar to a native pulmonary circulation. Additionally, simulated mean

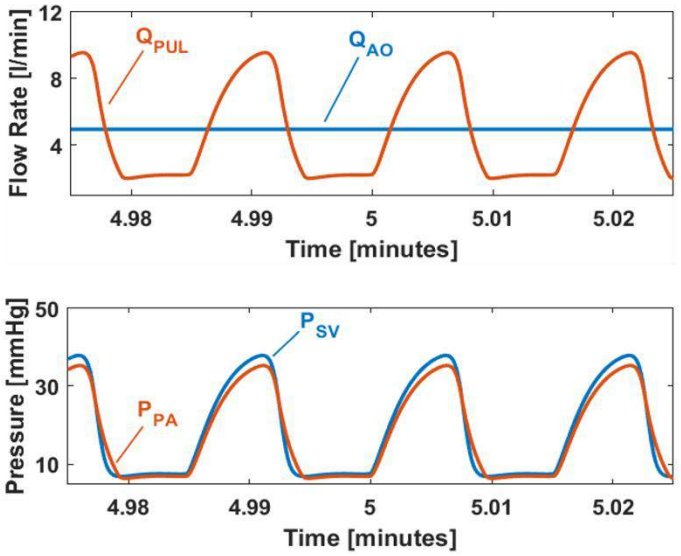

**Figure 2: Ventricular dysfunction Fontan failure with proposed modification (Case-3). Top: Aortic ($Q_{AO}$) and pulmonary ($Q_{PUL}$) flow waveforms. Bottom: Single ventricle ($P_{SV}$) and pulmonary artery ($P_{PA}$) pressure waveforms**

pressure value of the SV in pulmonary circulation was calculated to be very similar to a native right ventricle. As such, in addition to providing systemic support the proposed modification also assists the cavopulmonary connection through a decreased CVP. These observations showed that a failing SV, which might be insufficient to govern the systemic circulation can be enriched in the pulmonary side.

Only the ventricular dysfunction associated Fontan failure mode was analyzed in this study and the high pulmonary vascular resistance (PVR) failure mode will be presented during the meeting. Likewise, utilizing an SV having mildly reduced or normal EF may lead to pulmonary hypertension due to excessive stroke work over even a considerably high PVR, as previous studies demonstrated [2,3]. The hemodynamic benefit of the proposed modification likely to be more prominent for patients with severely failing SV. Considering the low resource settings with limited access to VAD systems, the proposed modification utilizing the native ventricle might lead to a novel perspective for MCSD implantation in failed Fontan patients.

# TIME-DEPENDENT MATERIAL PROPERTIES OF NONPREGNANT AND PREGNANT HUMAN UTERUS UNDER SPHERICAL NANOINDENTATION

## INTRODUCTION

The uterus plays a critical role in the establishment and maintenance of pregnancy, undergoing dramatic growth and remodeling from the time of embryo implantation to labor and birth. The uterus is composed of three distinct tissue layers: (i) the endometrium, the innermost mucosal layer that proliferates, differentiates and sheds throughout the menstrual cycle and transforms into the decidua in pregnancy, (ii) the myometrium, the middle smooth muscle layer, and (iii) the perimetrium, the outermost serosal layer (Fig.1a). Although the uterus performs critical biomechanical functions and is known to be mechanosensitive, remarkably few studies have investigated the mechanical and structural properties of the human uterus and how they change throughout pregnancy [1-3]. Yet, this knowledge is essential for developing physiologically accurate *in vitro* and *in silico* models of the uterus to better understand the pathophysiology of different gynecological and obstetric disorders.

Therefore, the purpose of this study is to characterize the spatial variance of time-dependent micromechanical properties of the human uterus across the endometrium, decidua and myometrium between nonpregnant and pregnant individuals, respectively. We then investigated how distinct viscoelastic and poroelastic mechanisms contribute to the time-dependent behavior of uterine tissues by evaluating the differences in individual versus combined model fits.

We therefore hypothesize that stiffness of the myometrium will be significantly greater than the endometrium and decidua in both nonpregnant and pregnant states, respectively. Furthermore, we expect the intrinsic permeability of the uterus to be greater in the endometrium than the myometrium and to increase in pregnancy.

## METHODS

In accordance with Columbia University Irving Medical Center (CUIMC) IRB approval, nonpregnant human uterine samples (n = 4) were collected from women undergoing hysterectomies, while pregnant samples were collected from biopsies of Caesarian sections (healthy, n = 2) and hysterectomies for abnormal placentation (placenta accreta, n = 2). Hysterectomy and biopsy samples were collected at the fundus and anterior regions of the uterus, respectively, and subsequently stored at -80°C. Prior to testing, samples were sectioned into myometrial and endometrial/decidual layers (Fig.1a) and subsequently thawed at 4ºC overnight in Opti-Free contact lens solution (Alcon, Fort Worth, TX, USA) and equilibrated at room temperature for 30 min. Spherical nanoindentation (Piuma, Optics11Life, Amsterdam, NL) was utilized to characterize the time-dependent mechanical properties of the samples at three distinct regions sized 1mm x 1mm with 200µm resolution between points and a probe radius of 57.5 $\pm$ 1 µm. Samples were indented to fixed depth of 4 µm, corresponding to a 5% strain rate, for 15s to achieve equilibrium load relaxation. Load relaxation curves were fit in Matlab (1) individually with a two-parameter viscoelastic model and poroelastic model, as described by Mattice et al. 2006 and Hu et al. 2010, respectively, and (2) with a combined poro-viscoelastic (PVE) model, described by Islam et al. 2021 [4-6]. Parameters of stiffness ($E_\infty$), viscoelastic ratio ($E_\infty/E_0$), and intrinsic permeability ($k$) were determined (Fig.1b) [4-6]. Normality of the data was first assessed with a Shapiro-Wilk normality test. The Mann-Whitney test was then utilized to analyze two groups of data with statistical significance of $p < 0.05$.

## RESULTS

Regardless of the time-dependent model employed for data analysis, uterine stiffness was determined to be in the range of $10^2 – 10^3$ Pa for all tissues evaluated (Fig.1c). Supporting our hypothesis, the myometrium is significantly stiffer than the endometrium for nonpregnant samples, however, surprisingly, no distinction in stiffness exists between decidua and myometrium layers in 3rd trimerster pregnancies (Fig.1c). Interestingly, the myometrium is significantly stiffer in placenta accreta patients as compared to healthy pregnancies, however additional samples are needed to confirm this trend (Fig.1c).

Viscoelastic ratio and permeability were subject to the greatest changes between the two models employed. Viscoelastic ratio ranges from 0 to 1, whereby 0 indicates a perfectly viscous material and 1 a perfectly elastic material. Measurements for viscoelastic ratio determined by the individual viscoelastic model yielded a larger degree of variation with many infinitesimally small values indicating a poor model fit (Fig.1d). This issue was subsequently resolved with the PVE model whereby the mean viscoelastic ratio increased from approximately 0.4 to 0.5 (Fig.1d). Viscoelastic ratio differed marginally across uterine layers for both nonpregnant and pregnant samples, suggesting all uterine tissues exhibit viscoelastic properties to an extent (data not shown).

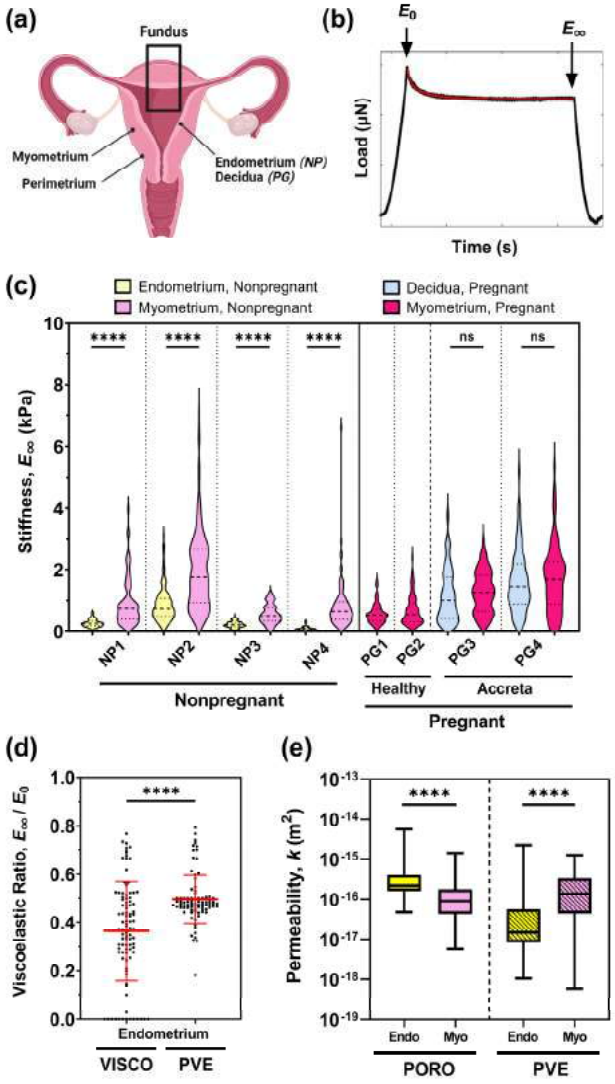

***Figure 1*: (a) Schematic of the human uterus. Nonpregnant (*NP*) endometrium / pregnant (*PG*) decidua, myometrium, and perimetrium are shown for the frontal plane. (b) Representative load versus time plot used for model fitting. (c) Stiffness of all patient matched endometrial, decidual, and myometrial layers determined by the combined PVE model. (d) Representative endometrial sample data analyzed with the viscoelastic and PVE models. (e) Representative patient-matched permeability measurements of the endometrium and myometrium analyzed with the poroelastic and PVE models.**

Interestingly, analysis with the poroelastic model reveals that the intrinsic permeability of nonpregnant endometrium is significantly greater than that of the myometrium, supporting our original hypothesis (Fig.1e). Notably, this distinct trend is not only eliminated, but reversed in the majority of nonpregnant samples when the same data in analyzed with the combined PVE model, exhibiting a greater degree of variability (Fig.1e). No clear distinctions exist across the pregnant decidual and myometrial tissues, which, contrary to our hypothesis, does not dramatically increase in relation to nonpregnant samples (data not shown). All samples had a mean permeability in the range of $10^{-17}$ to $10^{-14}$ $m^2$, corresponding to pore sizes on the nanometer scale.

## DISCUSSION

Here, a novel dataset representing the time-dependent mechanical properties of the human uterus at small length scales is presented, including the first reported measurements of uterine permeability and viscoelastic ratio, distinguishing between the endometrial, decidual and myometrial layers in nonpregnant and pregnant states. The data correspond to stiffness measurements previously reported in the literature as evaluated with AFM, spherical indentation, and small-strain tensile testing [2-3].

Fundamental differences in the evaluated time-dependent material properties exist between the individual and combined poroelastic-viscoelastic models, however this finding suggests that neither theories of viscoelasticity or poroelasticty alone are sufficient to fit the uterine nanoindentation data. Furthermore, given current understanding of uterine structure, it is likely that both poroelastic and viscoelastic mechanisms act in concert to yield the observed time-dependent behavior of these tissues, which can be confirmed using a similar approach employed by Wang et al. 2014 and Strange et al. 2013 [7-8]. The sensitivity of the permeability data to the two models further highlights the need for additional analysis to determine the exact contribution of poroelastic and viscoelastic mechanisms to the observed time-dependent response in nonpregnant and pregnant uterine tissue.

Key limitations of the current data set include the small sample size, inherent pathological nature of the nonpregnant hysterectomy samples, and the absence of the outermost layer of the uterus, the perimetrium. Moving forward, we plan to address these issues with the inclusion of additional samples.

Yet, despite these limitations, the data presented here yield key insights into the mechanobiology of the uterus, providing foundational knowledge for advancing models of pregnancy, particularly in relation to embryo implantation and placentation. Furthermore, the distinct differences in healthy and pathological uterine tissue at term reveals a fundamental question about the role mechanics plays in the initiation and progression of placenta accreta.

## ACKNOWLEDGEMENTS

We would like to thank Drs. Joy Vink, George Gallos, and Arnold Advincula from CUIMC for their assistance in the collection of uterine tissue. Research was supported financially by the NSF GRFP, Iris Fund, and Eunice Kennedy Shriver National Institute of Child Health & Human Development Grant (R01HD091153).

# INFLUENCE OF VASCULAR STASIS BASED BLOOD PERFUSION ON MAGNETIC NANOPARTICLES MIGRATION USING MODIFIED THERMAL DAMAGE MODEL: AN ILLUSTRATION OF THERMAL BY-STANDER EFFECT

**Manpreet Singh**

Department of Mechanical Engineering,
University of Maryland Baltimore County,
Baltimore, MD, USA

## INTRODUCTION

MicroCT imaging assisted *in-vivo* animal studies have suggested possible change in nanoparticle distribution after heating[1]. The redistribution of nanoparticles from the region of higher concentration to the region of lower concentration is described as *"Thermal By-Stander Effect"*[1,6].

One hypothesis[7] suggests the possibility of continuous regeneration of living human tissues due to meeting of oxygen demands through arterial blood. Hence, due to this regeneration process, the biological tissues shows an accelerated tissue repair and recovery with an evident rise in blood perfusion levels. Previous studies[2-3] implemented regeneration term into Arrhenius formulation; however, effect of hyperemic region through vascular stasis (non-linear perfusion change[4-5]) is missing for such regeneration based model.

This study incorporates vascular stasis based blood perfusion for magnetic nanoparticle assisted thermal therapy to model the thermal by-stander effect using modified thermal damage model with regeneration.

## METHODS

Pennes Bioheat Transfer Equation[6] (PBHTE) is used to compute the temperature field distribution in both the healthy, *h* and cancerous, *c* tissue domains respectively as per equations (1a) and (1b);

$$\rho_h c_h \frac{\partial \mathrm{T}_h}{\partial \mathrm{t}} = k_h \nabla^2 \mathrm{T}_h + \omega_{h,0} \rho_b c_b (\mathrm{T}_b - \mathrm{T}_h) + Q'''_{met,h} \quad (1a)$$

$$\rho_c c_c \frac{\partial \mathrm{T}_c}{\partial \mathrm{t}} = k_c \nabla^2 \mathrm{T}_c + \omega_{c,0} \rho_b c_b (\mathrm{T}_b - \mathrm{T}_c) + Q'''_{met,c} + Q'''_{source} \quad (1b)$$

Here, the subscripts *b* and *met* represents blood and metabolic heat generation respectively. The thermophysical properties for biological tissue domains are shown in Table-II. Contribution of heterogeneously distributed magnetic nanoparticles are extracted from MicroCT images from pixel value information known as Specific Absorption Rate (SAR) mapped at different tumour locations. This source term[6] is coupled with Concentration as $Q'''_{source}(x,y,z,t) = 2266.67 \times C(x,y,z,t)$. The governing equation for nanoparticle diffusion is given as;

$$\frac{\partial C(x,y,z,t)}{\partial t} = \nabla \cdot \left[ \phi D_n \nabla \left( \frac{C(x,y,z,t)}{\phi} \right) \right] \quad (2)$$

where, the diffusion coefficient $(D_n)$ relates to interstitial space $(\phi)$ and diffusion coefficient in unbound interstitial fluid $(D_{n,f})$ as;

$$D_n = D_{n,f} \left[ \frac{2\phi}{3-\phi} \right] \quad (3)$$

The interstitial space tends to increase with the cell-necrosis as;

$$\phi = \phi_o + (80\% - \phi_o)\left(1 - e^{-\Omega(\mathrm{x,y,z,t})}\right) \quad (4)$$

Spatio-temporal thermal cell-death, Ω (dimensionless) can be computed as per first-order traditional Arrhenius equation;

$$\Omega(x,y,z,\tau) = \int_0^\tau A e^{-E_a / R_u T(x,y,z,t)}\, dt \quad (5)$$

The Arrhenius kinetic rate equation is recently modified[1-3] to account for regeneration of healthy cells. The modified thermal damage is;

$$\frac{d\Omega(\mathrm{x,y,z,t})}{d\mathrm{t}} = A\left(1 - \Omega(x,y,z,t)\right) \exp\left(\frac{-E_a}{R_u T(x,y,z,t)}\right) - B\omega_{c,0}\Omega(x,y,z,t) \quad (6)$$

where, $R_u$ is the universal gas constant 8.314 J/(mol·K), $\tau$ is the duration of exposure(s), T is the temperature (K), B is a dimensionless coefficient[2] $(9 \times 10^{-3})$. The thermal damage parameter, $\Omega = 1$ represents 63.21% of denaturation of proteins sufficient to initiate coagulation. It should be noted that the induced thermal damage is zero before the onset of nanoparticle assisted heating.

It is well known that during heating, the blood perfusion rate, $\omega_{c,0}(t)$ first increases at hyperthermic temperature due to vasodilation of vessels and then starts decreasing due to total collapse of vasculature[5]. This phenomenon is known as "*degree of vascular stasis*" or "*vascular collapse*" or "*fractional injury*" or "*vascular stasis*". The functional dependence of $\omega_{c,0}(t)$ on VS is shown in fig. 2 and Eq. 7 as;

$$\omega_{c,0}(t) = \begin{cases} \omega_{b,o}(1 + 30 \cdot \mathrm{VS}); \text{if ori} 0 < \mathrm{VS} \leq 0.02 \text{if ori} \\ \omega_{b,o}(1.86 - 13 \cdot \mathrm{VS}); \text{if ori} 0.02 < \text{if VS} \leq 0.08 \\ \omega_{b,o}(0.884 - 0.79 \cdot \mathrm{VS}); \text{if ori} 0.08 < \text{if VS} \leq 0.97 \\ \omega_{b,o}(3.87 - 3.87 \cdot \mathrm{VS}); \text{if ori} 0.97 < \text{if VS} \leq 1.00 \\ \text{if} 0; \text{if ori VS} > 1.00 \text{if} \end{cases} \quad (7)$$

VS can be mathematically expressed as

$$\mathrm{VS}(x, y, z, t) = 1 - \exp(-\Omega(x, y, z, t)) \quad (8)$$

Here, the baseline value of blood perfusion, $\omega_{b,o}$ is extracted from the thermal infrared imaging by adjusting the metabolic heat generation rates and blood perfusion values using inverse heat transfer analysis[6]. The Arrhenius kinetic coefficients used to evaluate the vascular stasis (VS) and thermal damage ($\Omega$) are summarized in Table-I.

**Table-I**: Arrhenius coefficients considered in this study[1-5].

| Parameters | Symbol [Units] | Vascular Stasis | Thermal damage |
|---|---|---|---|
| Frequency factor | $A$ [$s^{-1}$] | $1.98 \times 10^{106}$ | $3.1 \times 10^{98}$ |
| Activation Energy | $E_a$ [$Jmol^{-1}$] | $6.67 \times 10^5$ | $6.28 \times 10^5$ |

*#bulk tissue consideration*.

**Table-II**: Thermophysical properties[6].

| Property | Symbol [Units] | Healthy Tissue | Cancerous Tissue | Blood |

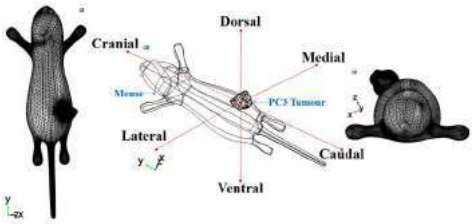

**Figure 1.** Wireframe and meshed model of mouse and PC3 tumour.

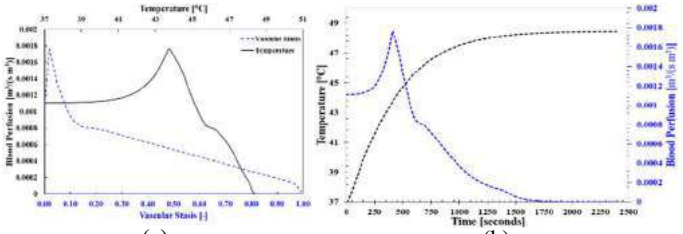

(a) (b)

**Figure 2.** Blood perfusion variation on vascular stasis and temperature at minimal temperature location.

## RESULTS AND DISCUSSION

Fig.1. shows the wireframe and meshed model of PC3 tumour attached to the flank position of mouse. In this problem formulation, the blood perfusion of cancerous lesion is defined as a piecewise function of vascular stasis as per equation 7 and pictorially represented in fig. 2(a). It can be inferred from fig. 2(a) that the maximum peak of perfusion is achieved at 43.5°C. From fig. 2(b), perfusion collapse occurs at minimal temperature location takes 1750 sec. Fig. 3 illustrates temperature ($T_{max}$=83.13°C, $T_{min}$=48.46°C, $T_{avg}$=67.23°C), modified thermal damage with healthy tissue regeneration ($\Omega_{modified}$=1), diffusion coefficient ($4.87\times10^{-11}$m$^2$/s), vascular stasis (VS=1), and porosity (80%) after 2400 sec. The probe is located at minimum temperature location to monitor these parameters. It is noticeable from fig. 3 that there is 39.62% increase in redistribution volumes of nanoparticles and five-fold increase in diffusion coefficient after heating of 2400 sec. The implementation of equation 4 is verified through fig. 3(e) that maximum interstitial space of 80% inside PC3 tumour can be achieved after thermal cell-death of 63.2%. The physical interpretation of this regeneration term implies that thermal damage would not propagate deep inside the healthy tissue fringes. Thus, it can inferred that regeneration phenomenon prevents and suppress the collateral thermal damage spread at the interface within bounds of $\Omega \leq 1$ which is in agreement with the findings of literature[3-5].The implication of this work would help design better heating protocol designs in future. However, more experimental exploration is needed in this context.

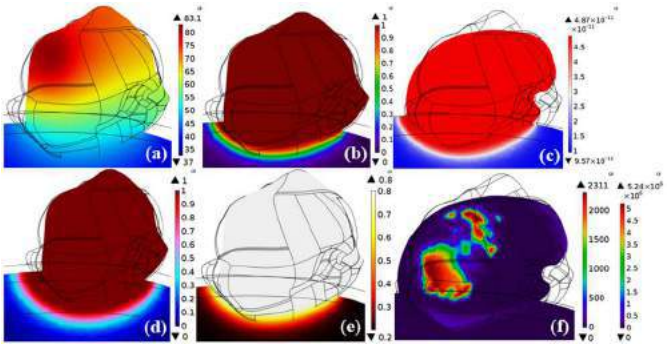

**Figure 3.** (a) Temperature [°C], (b) Modified thermal damage [-], (c) Diffusion coefficient [m$^2$/s], (d) Vascular stasis [-], (d) Porosity [-] at 2400 sec and (e) Initial concentration distribution [mol/m$^3$] and Nanoparticle heat generation rate [W/m$^3$].

# PROGRESSIVE DISC AND BONE ADAPTATIONS DUE TO POSTEROLATERAL TETHERING IN A PORCINE MODEL OF SCOLIOSIS

## INTRODUCTION

Scoliosis is a multi-planar spine deformity that presents predominantly as a lateral curve in the coronal plane >10°. In children and adolescents the etiology of scoliosis is most often idiopathic. Stokes hypothesized that spinal deformities progress as a "vicious cycle" in which asymmetric stresses and strains applied to the growing spine induce deformity of both osseous and non-osseous tissues, causing growth modulation in agreement with the Hueter-Volkmann Principle (i.e., tension applied to the physis stimulates growth, compression inhibits growth) [1]. This concept was validated clinically, demonstrating that spine deformity progresses as a function of skeletal age: during periods of high growth, spine deformity evolves primarily through the intervertebral disc (IVD), whereas towards the end of growth, the deformity increases primarily through the vertebrae (VB) [2]. Interventions to correct scoliosis that preserve spinal growth and motion are based on predictably modulating spine growth. Currently, it is unknown how asymmetric loading alters the growth of IVD relative to the VB. The goal of this study is to identify progressive spinal deformity transitions (i.e., initiation of VB wedging and attenuation of IVD wedging) under asymmetric loading. In this proof-of-principle study we investigate the influence of mechanics in spinal deformity progression by applying a bending moment to a straight spine in an otherwise healthy, growing pig. Our long-term goal is to apply this controlled model of skeletal deformity to determine the effect of the mechanical environment on mechanotransduction through molecular and mechanical analyses and to evaluate clinical interventions for correcting the scoliotic spine.

## METHODS

With IACUC approval, 3 Yorkshire pigs were instrumented with a CoCr cable spanning the thoracolumbar junction and lumbar spine; this offset tether created a lateral bending moment and an initial scoliosis that progressed as the pig matured (**Fig 1**). Two un-instrumented Yorkshire pigs were used as controls. Anatomical changes to the IVD and VB as a function of time were measured with serial CT scans at -2, 0, 4, 6, 8, 12, and 19 weeks post-op and MRI at 5, 19, and 22 weeks post-op. CT scans were used to quantify lateral wedging and longitudinal growth along the line of curvature between the instrumented levels. Two MRI sequences were utilized, a T1-weighted FLASH sequence to evaluate IVD volume and a T2-weighted CPMG echo sequence to evaluate IVD T2 relaxation time. The T2 relaxation time, which is positively correlated with hydration

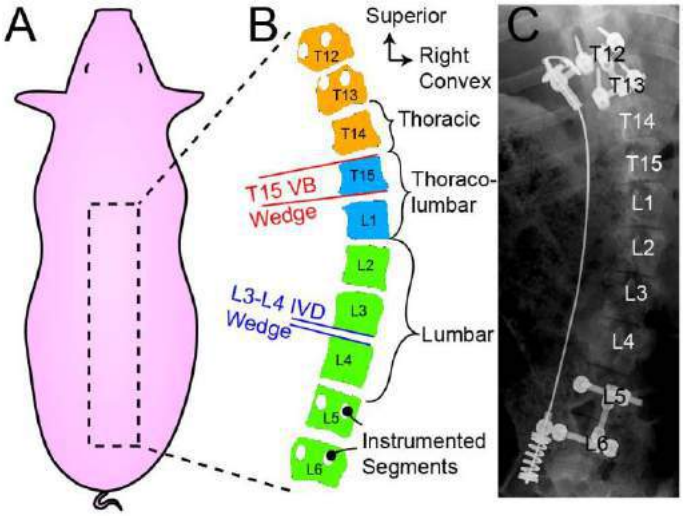

**Figure 1: (A) Pig model, (B) schematic, and (C) radiograph showing instrumentation and curvature at 6 weeks post-op. Avoiding instrumented levels, analysis was conducted from the inferior side of T13 to the superior side of L5. Color coding indicates the thoracic (orange), thoracolumbar junction (blue), and lumbar (green) regions.**

and is decreased in IVD degeneration, was calculated for the IVD nucleus pulposus.

## RESULTS

3D CT reconstructions demonstrate progression of spinal deformity and vertebral growth modulation due to the tether (**Fig 2**).

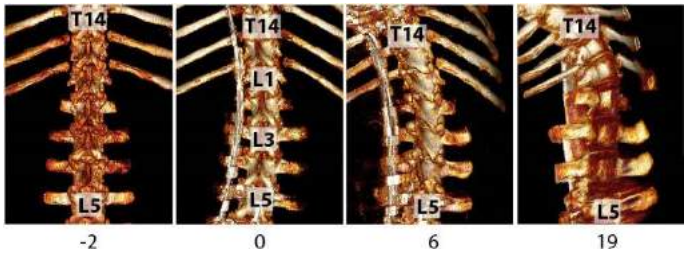

**Figure 2: CT reconstructions in weeks post-op demonstrating progressive curvature.**

At the time of surgery, a 17° Cobb angle was produced via IVD wedging (**Fig 3A,B**). At 6 weeks, deformity progression was approximately equally distributed between the thoracolumbar (45%) and lumbar (41%) regions (**Fig 3A**) with VB wedging accounting for 60% of the total deformity (**Fig 3B**). From 12 to 19 weeks post-op, the spine deformity transitioned from nearly equal contributions of IVD and VB to only VB (**Fig 3B**). At 19 weeks post-op, the spine developed a 41° Cobb angle.

The longitudinal growth of the VBs progressed overtime (**Fig 3C**) with tethering which is an important outcome as it demonstrates growth modulation rather than simply remodeling. However, the VB growth at 19 weeks post-op was less than the control at 18 weeks post-op indicating possible impaired growth. A larger sample size is required to confirm this observation. Reduced spinal height is a typical feature of scoliosis [3]. On the other hand, the IVDs did not undergo a clear change in the longitudinal growth between the instrumented levels or relative to the controls (**Fig 3C**). The IVDs did however grow in the lateral dimensions as demonstrated by an increase in IVD volume (**Fig 4**). When compared to the controls the volumetric growth is impaired. Despite this growth modulation of the IVDs, the T2 times (290 ± 40 ms) were similar to a control (340 ± 10 ms) suggesting that the tether did not induce degeneration over the time course assessed, but rather geometric alterations.

## DISCUSSION

In this preliminary study, asymmetric spine loading in a porcine model using a tether provoked asymmetric spine growth. Early-stage deformity was shared between the IVDs and VBs. However, from 12 to 19 weeks the deformity transitioned to be primarily located in the VBs. The growth of the IVDs and VBs appear to be impaired when compared to controls.

(C) Sum of VB and IVD height between instrumented segments. Controls at equivalent age are shown at 3- and 18-weeks post-op. Data from one representative pig shown.**

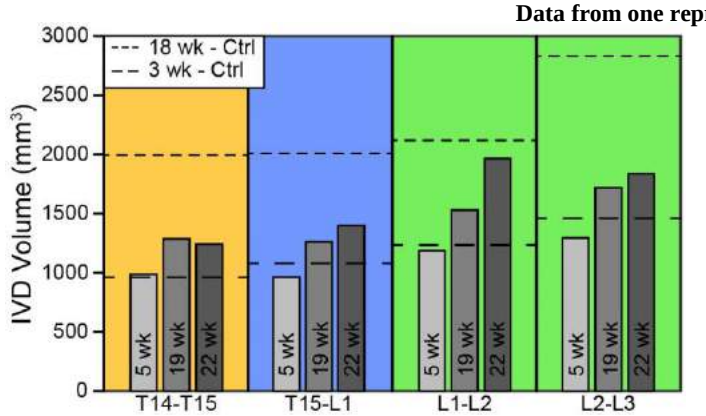

**Figure 4: IVD volume by level and post-op time. Control pigs at equivalent age are shown at 3- and 18-weeks post-op. Data from one representative pig shown.**

## SIGNIFICANCE

We have developed a clinically relevant in vivo animal model to mimic scoliosis. Serial CT and MRI imaging allowed differentiation of mechanical deformation of the soft tissues from modulated growth which manifest as changes in the composition, structure, and geometry. This model will allow biomechanical, biochemical, and biological adaptations to be studied. Moreover, this model is being developed to predictably apply corrective treatments for scoliosis.

## INTRODUCTION

The human brain is one of the most important and complex organs in our nervous system. It consists of an intricately folded outer layer of grey matter part and an inner white mater part saturated with axon tracts. It is also one of the most vulnerable organs in our body because it is affected by various neurological diseases and disorders, like Autism Spectrum Disorder, Anxiety Disorder, Alzheimer's Disease, etc. These neurological diseases and disorders are associated with abnormal white matter connectivity [1]. However, the complexity of the brain cortex and subcortex impeded the early diagnosis and treatment of brain diseases.

In recent years, there are renewed interests in assessing the axonal tension hypothesis [2]. From the biological perspective, Van Essen proposed that axon tension pulls surrounding tissue closer together. From a mechanistic standpoint [3], Holland suggested that the heterogeneous orientation of white matter connections leads to more physiological, less regular brain morphologies [4]. Garcia proposed that brain connectivity plays a significant role in inducing folding [5]. These recent discoveries draw our attention to connectivity-driven cortical folding.

Historically, many subcortical models have been based on a purely elastic subcortex and an isotropic stretch-driven growth model. These limitations conflict with the real distribution of axon tracts and the induced material heterogeneity. If the axon tracts are considered, there are still gaps to be filled. What's the level of tension provided by single axon tracts? How much of this level of tension affects the cortical morphology? Would this level of tension result in global wiring efficiency?

To address these questions, we built a novel computational model to explicitly simulate brain tissue growth with embedded axon tracts. We hypothesize that axonal tension could serve as a slight perturbation and trigger global tissue surface instability in the subcritical state.

## METHODS

We first build a bilayer system of an elastic thin film on a soft elastic substrate (Fig. 1). The top layer is the grey matter with a thickness of $h_g = 2\ mm$. The substrate is the subcortical white matter with a thickness of $h_w = 8\ mm$. The length of the system is $l = 20\ mm$. The simplified axon connectivity pattern located in the center, composed of three axon tracts.

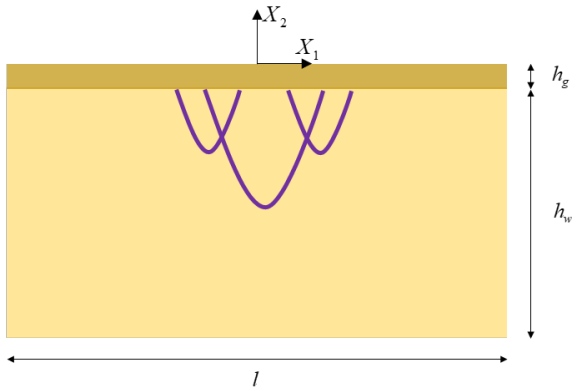

**Fig. 1 Schematics of the bilayer system**

We model brain development using the finite growth theory [6], with the deformation gradient $\boldsymbol{F}$ split into an elastic part $\boldsymbol{F^e}$ and volume growth part $\boldsymbol{F^g}$

$$\boldsymbol{F} = \boldsymbol{F^e F^g} \tag{1}$$

Next, we model the cortical growth as isotropic growth and assume a pure elastic normal response. The growth tensor is defined as

$$\boldsymbol{F^g} = \sqrt{\vartheta^g}\mathbf{1} + \left(1 - \sqrt{\vartheta^g}\right)\boldsymbol{n_R}\otimes\boldsymbol{n_R}, \quad (2)$$

where $\vartheta^g$ is the growth parameter and $\boldsymbol{n_R}$ is the unit vector normal to the surface [7].

The bilayer system is implemented numerically in the standard finite element package Abaqus by writing user-defined material subroutine (UMAT) [8]. Both the grey matter and the white matter substrate are modeled as compressible neo-Hookean materials. The energy density function is

$$\phi = \frac{G}{2}[tr(\boldsymbol{b}) - 3 - 2\ln(J^e)] + \frac{L}{2}\ln(J^e)\ln(J^e), \quad (3)$$

where $G$ and $L$ are Lamé constants, $\boldsymbol{b}$ denote left Cauchy-Green tensors. $J^e$ denote volumetric change due to the elastic deformation.

$$\boldsymbol{b} = \boldsymbol{F^e}\cdot\boldsymbol{F^{eT}},\ J^e = \det(\boldsymbol{F^e}). \quad (4)$$

The corresponding Kirchhoof stress $\tau$ is obtained as

$$\boldsymbol{\tau} = 2\frac{\partial\phi}{\partial\boldsymbol{b}}\cdot\boldsymbol{b} = [L\ln J^e - G]\boldsymbol{I} + G\boldsymbol{b}, \quad (5)$$

where $\boldsymbol{I}$ denotes the second-order unit tensor [9].

It was reported that neurites growing on the substrate generate substantial mechanical tension around 150 μdyn for 1μm diameter sensory neurons [2], with a relationship between force and length change. Scientists also model a typical axon fiber tract as an elastic spring with spring constants of 10-30 μdyn/μm [10].

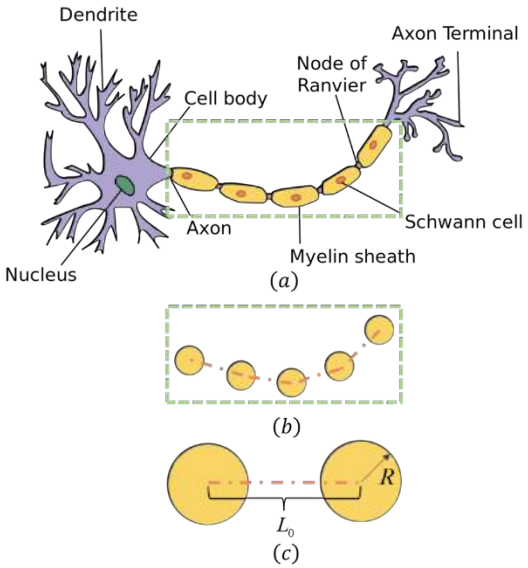

**Fig. 2 Schematics of simplified neuron and axon tracts. (a) Structure of neuron [11] (b) Connector element chain mimics the axon tracts (c) A connector element with two coupling nodes**

Axon is composed of multiple myelin sheaths connected with nodes of Ranvier(Fig. 2(a)). To explicitly model the axon fiber tracts in the Abaqus Standard [8], we adopt 1D connector elements with connection type Axial (Fig. 2(c)). We define the $n_{th}$ connector has an original length $L_0^n$ of 9.2e-3 mm and its reference length $L_r^n$ of 4.6e-3 mm. The generated axonal tension is

$$f_n = \boldsymbol{D}(L_0^n - L_r^n) \quad (6)$$

where $\boldsymbol{D}$ denote the axonal spring constant, and $f_n$ is the axonal tension on the $n_{th}$ connector element [8].

Each connector node is uniformly coupled with the subcortical substrate with an influence radius $R$ of 5e-4 mm. Together, these nodes from chains (Fig.2 (b)) of varying orientations.

## RESULTS

Fig. 3 shows the simulation results of bilayer brain tissue. The interaction between the isotropic tissue growth and anisotropic axon tensions leads to the progressive wrinkled surface. The global instability is induced by physical axon tension.

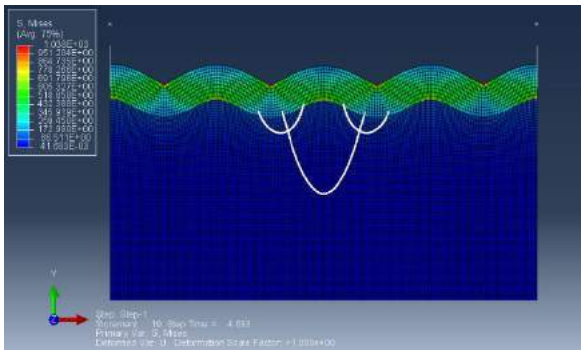

**Fig. 3 Deformed configuration and stress distribution in the brain slices**

## DISCUSSION

Here, we have established a connectivity-driven cortical folding model, which represents the heterogeneity in the subcortical region by incorporating the microstructure of varying axonal orientations. Our model suggests the axon tension leads to global instability by replacing the added imperfection perturbations in most finite element modeling of brain folding. Furthermore, the simulated surface becomes more physiological meaningful with different connectivity or tension levels. In the next step, we will study the influence of various densities of axon tracts and the effects of varied orientation and different levels of tensions on brain morphology. We also plan to fuse the experimental image data with our computational model to integrate a high-fidelity white matter simulation platform for helping the diagnosis and treatment of neurological disabilities.

## INTRODUCTION

Examining human movement and gait mechanics provides insight into the underlying mechanisms of injuries. For example, degenerative diseases, such as osteoarthritis, are thought to stem from asymmetrical loading in which one limb bears more load and moves differently than the other. This may result in changes in stability and balance that are crucial for reducing fall risk. Therefore, fundamental knowledge about movement allows us to create mobility solutions in our community to prevent disability and improve the integrity of care we provide by using a holistic and multi-disciplinary approach**.**

Balance is the ability to maintain the vertical line of gravity of the body within the base of support with minimal postural sway. It is a function of the vestibular, somatosensory and visual systems and provides insight into musculoskeletal mobility issues. Postural sway measurement may be a predictor of falls to identify those at risk for falling (1). Assessing postural stability aids in understanding underlying movement mechanisms that correlate to fall risk (2).

Previous research has consistently used small experiment populations to identify the conditions which cause excessive sway. Which often concludes with ambiguous or inconclusive data alluding to the presence of underlying mechanisms such as age, gender, race, and social/economics factors affecting sway outcomes.

To identify what, if any, known or unknown conditions are influencing postural sway, developing a large repository of human movement data is key. With a large data set we can begin to understand to how underlying factors affect the postural sway of diverse populations.

Therefore, an in-clinic data collection protocol was created, modified, and followed to achieve the purpose of expanding the dataset on this topic. The objective of this study was to design a sustainable data collection and analysis protocol to establish a new clinical vital sign as to better understand fall risk in the diverse populations surrounding the HSC community.

## METHODS

Sustainability Plan: Third year medical students rotating in the OMM clinic collected sway data for one half day during their month-long rotation. Data collectors were presented a video demo of the protocol and a didactic video explaining the importance of the visual, auditory, and proprioceptive systems in helping maintain balance before collecting data. Medical assistants (MA) in the clinic brought patients to students before the appointment time or when the patient's physician was seeing another patient, to avoid delays in clinic schedule. MAs roomed the patients afterwards. The total time for data collection is approximately 2 minutes.

Sway Data Collection: Postural sway was evaluated in patients seen in the Osteopathic Manipulative Medicine (OMM) clinic at University of North Texas Health Science Center between 6/7/2021 and 12/31/2021. Patients with mobility assist devices and children under 65 lbs. where excluded. Patients were instructed to take off their shoes and put on disposable shoe

covers. Patients then stood on footprints attached to the Bertec Force Plate (Bertec Columbus, Ohio). Patients were asked to stand straight, hands by their sides, body facing and looking at a target in front of them for 10 seconds with their eyes open (EO). Patients then repeated the same procedure on the Force Plate with their eyes closed (EC). Three trials of each condition were performed. A rest period of 3 seconds took place between each trial. Data was merged with the electronic medical record in a de-identified data warehouse and retrospectively analyzed from the clinic data collection (UNTHSC IRB# 2013-102)

## RESULTS

Sway Data: Postural sway variables were evaluated for 701 patient encounters (total of 511 patients) between June and December 2021. Figure 1 shows the positional trajectory of the center of pressure between the feed in a typical sway plot.

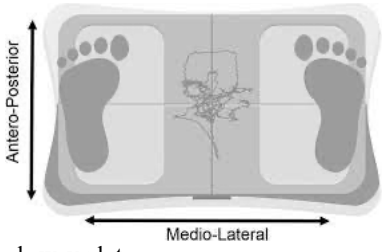

Figure 1 typical sway plot.

Dashboard creation: Data from the Bertec force plate were uploaded to a data warehouse and merged with the electronic medical record. Figure 2 shows the high-level data flow diagram. A Power BI dashboard (Figure 3) was created to visualize data characteristics.

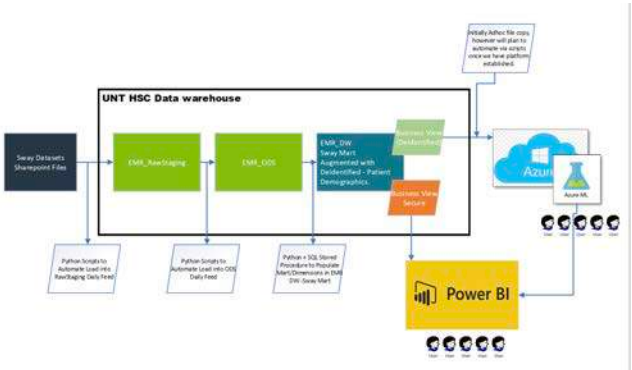

Figure 2 High level data flow diagram

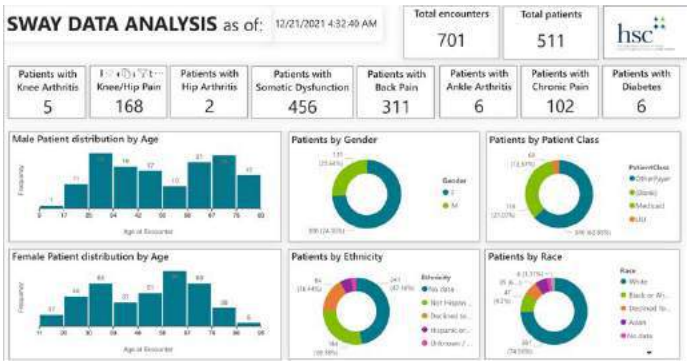

Figure 3 current dashboard of data collected.

## DISCUSSION

As a result of creating a sustainable data collecting model by incorporating third-year medical students in their rotations as data collectors, 701 postural sway measurements were achieved in approximately 7 months. This achievement was possible due to the continuous improvement of the protocol from the first week of data collection and onward. This improvement included a quality control protocol to assess human errors in data entry by matching patient encounter data with the electronic medical record demographic data. Further improvements will include placing students to collect data only on days with a higher patient census based on the past month's patient appointments. Additionally, this data collection protocol can be modeled in other clinics to further expand the database, such as UNTHSC's family medicine and internal medicine clinics.

Other future steps will be to allow healthcare providers secure access to their patient's data so they can discuss changes in sway with their patients during clinic visits. Furthermore, it is our goal to deliver the healthcare providers baseline sway data that is specific to possible differentiating factors (such as age, gender, race, socioeconomic factors) that can allow for more precise and targeted data for their clinical practice. For example, we may be able to provide precise fall prediction parameters that are more precisely designed for each patient encounter.

Finally, we are partnering with in-house experts in artificial intelligence and statistics to analyze sway parameters. Specifically, we will be focusing on machine learning through utilizing Microsoft Azure to analyze the repository to obtain information on human movement for diverse patient populations as to encourage Precision Medicine.

## ACKNOWLEDGEMENTS

We would like to thank HSC Health for providing space and access to their patient populations.

# HANDRIM BIOMECHANCS AND WHEELCHAIR FIT MEASURES IN PEDIATRIC AND EMERGING ADULT MANUAL WHEELCHAIR USERS

**Samantha R. Schwartz (1), Alyssa J. Schnorenberg (1), Hannah R. Frank (1), Matthew M. Hanks (1), Shubhra S. Mukherjee (2), Brooke A. Slavens (1)**

(1) Rehabilitation Sciences and Technology, University of Wisconsin- Milwaukee, Milwaukee, WI, USA

## INTRODUCTION

Approximately 124,000 people in the United States under the age of 21 primarily use manual wheelchairs for mobility [1], however, most studies of manual wheelchair users (MWU) focus on adult populations [2]. These studies contribute to the development of adult recommendations for manual wheelchair propulsion that aim to reduce pain and pathology development in the upper extremity [3]. Recommendations include minimizing force and rate of force application to the handrim of the wheel, maximizing time in the contact phase, and reducing push frequency. Importantly, these recommendations cannot be accurately scaled to children because children are not anthropometrically proportional to adults, are still developing their musculoskeletal system [4], and spend more of their lifetimes using a manual wheelchair.

Additionally, recommendations for wheelchair fit settings such as the position of the wheel axles with respect to the shoulder and elbow have been developed for adults [3], but not specifically for pediatric MWU. The implications of applying adult wheelchair fit recommendations to children have not been tested in an evidence-based clinical setting [5, 6]. Pediatric MWU have a difficult time following adult wheelchair fit recommendations due to rapid growth and the need to reassess fit and alter settings regularly with limited funding and insurance for clinic visits and obtaining new wheelchairs [6].

Because children cannot be treated as proportionally scaled down versions of adults, research on wheelchair fit settings and propulsion recommendations for younger MWU are warranted. The purpose of this study was to determine if pediatric and emerging adult MWU followed adult recommendations for wheelchair fit and handrim biomechanics during propulsion, as well as investigate correlations among wheelchair fit and biomechanics metrics.

## METHODS

**Participants:** This study was approved by the UW-Milwaukee Institutional Review Board. Ten pediatric and emerging adult manual wheelchair users (age range: 6-21yr, mean: 15.2yr, 5 females, 5 males) were recruited from Shriner's Hospital for Children- Chicago. All participants had a spinal cord injury at least 1 year prior (time since injury: 3-18yr, mean: 8.9yr, level of injury: T1-L3) and used a manual wheelchair for the majority of their mobility. Consent and/or assent forms were signed prior to data collection.

**Data Collection**: Reflective markers were placed on selected positions on the participant's personal wheelchair and on bony anatomical landmarks of the upper body. Three-dimensional (3D) marker positions were obtained in Vicon Nexus software using a 14-camera Vicon MX motion capture system (Vicon Motion Systems, Oxford, UK). Static trials were obtained of the participant seated in their wheelchair with their hands placed at the top dead center of the wheelchair handrim.

Next, a size matched SmartWheel (Outfront, Pasco, WA) replaced the wheel on one side of the participant's wheelchair to obtain the 3D forces applied to the handrim during propulsion. Participants propelled their wheelchairs along a 15m path at a self-selected speed for multiple trials. SmartWheel data were collected at 240 Hz while simultaneously, kinematic data were collected in Vicon Nexus at 120 Hz. The SmartWheel was then switched to the other side of the wheelchair and the process was repeated.

**Data Processing:** The SmartWheel and kinematic data were imported to custom MATLAB codes. The marker positions obtained during the static trials were used to calculate the elbow angle, and wheel axle position (Table 1). The SmartWheel data and kinematic data obtained during the dynamic trials were used to calculate the maximum resultant force, maximum rate of rise of resultant force, percent contact phase, frequency, and velocity during 10 stroke cycles, using 5 cycles from each side (Table 1). Force measurements were normalized by dividing by the participant weight. All handrim metrics were calculated per cycle and averaged for each subject.

Exploratory Spearman correlations were run on all wheelchair fit and handrim biomechanics metrics with significance set at $p < 0.05$.

**Table 1: Descriptions of wheelchair fit and handrim metrics**

| Metric | Description |
|---|---|
| Elbow angle (degrees) | Sagittal plane angle between ulnar styloid, olecranon process, and acromion while hand is positioned at the top of the handrim |
| Axle position (mm) | Fore (-)/aft (+) position of the wheel axle with respect to the acromion. |
| Maximum resultant force ($F_r$) (N/kg) | Maximum force applied to the handrim during stroke cycle divided by weight of participant. |
| Maximum rate of rise of $F_r$ (N/s/kg) | Maximum value of the derivative of the force applied to the handrim during the stroke cycle divided by weight of participant. |
| Percent contact phase (%) | The percent of the stroke cycle that the hand was in contact with the handrim. |
| Frequency (strokes/s) | Number of complete stroke cycles in one second. |
| Velocity (m/s) | Distance traveled in one second. |

## RESULTS

Wheelchair fit metrics are reported as the number of participants who did or did follow the adult recommendations and their resulting group averages (Table 2). Five participants had elbow angles between 100 and 115 degrees, which fall within the recommended range of 100-120 degrees for adults [3], while four had elbow angles smaller than recommended and one had an elbow angle greater than recommended. Axle position measurements were only processed for 9 of the 10 participants, but of these, only two had their wheelchair axle positioned anteriorly to the shoulder, as is recommended for adults [3]. No participants followed both of the adult recommendations for wheelchair fit and three followed neither of the adult recommendations. Average and range of values for the handrim biomechanics metrics, as well as values from the adult literature are presented in Table 3.

**Table 2: Wheelchair measure averages and number of participants who did and did not follow adult recommendations**

| | Followed Adult Rec. | | Did Not Follow Adult Rec. | |
|---|---|---|---|---|
| **Metric** | Number | Average | Number | Average |
| Elbow angle | 5 | 105.8° | 5 | 96.5° |
| Axle position | 2 | -26.5 mm | 7 | 97.2 mm |

**Table 3: Handrim Biomechanics Metrics for study participants and reference adult values from literature**

| | Pediatric & Emerging Adults | | Adults |
|---|---|---|---|
| **Metric** | Average | Range | Average |
| $F_r$ (N) | 61.2 | 16.7-133.4 | 67.3 [7] |
| Max rate of rise of $F_r$ (N/s) | 2602.7 | 941.9-5732.8 | 915.2 [7] |
| Percent Contact Phase (%) | 37.0 | 27.4-41.4 | 47.2 [8] |
| Frequency (strokes/s) | 1.3 | 0.78-2.0 | 0.84 [9] |
| Velocity (m/s) | 1.63 | 1.0-2.4 | 0.87-1.1 [8, 9] |

Preliminary results of the Spearman tests suggest the $F_r$ was highly correlated to normalized rate of rise of $F_r$ ($r = 0.964$, $p << 0.01$). Both the $F_r$ and the rate of rise of $F_r$ also had strong positive correlations with the propulsion frequency ($r = 0.891$ and $0.952$; $p = 0.001$ and $p < 0.001$, respectively) and velocity ($r = 0.770$ and $0.697$; $p = 0.009$ and $p = 0.025$). Additionally, frequency and velocity were moderately correlated ($r = 0.624$ and $p = 0.054$).

There was a moderate negative correlation between elbow angle and percent contact phase ($r = -0.624$ and $p = 0.054$) and a moderate correlation between the axle position and velocity ($r = 0.650$ and $p = 0.058$). Additionally, elbow angle and axle position were positively correlated ($r = 0.850$ and $p = 0.004$).

## DISCUSSION

Only 50% of participants had elbow angles that followed adult recommendations. Elbow angles between 100-120 degrees are recommended for adults to help increase time spent in the contact phase, which typically reduces push frequency and therefore reduces repetitive motion [3]. In this young population of MWU, however, only a moderate correlation was found between elbow angle and time spent in contact phase and no correlation with frequency, suggesting that this adult recommendation may not improve propulsion technique in children the same as it does in adults. Only two of nine participants followed adult recommendations to place the axle anterior to the acromion which has been shown to reduce rolling resistance and therefore reduce the force required to propel the wheelchair in adults. Interestingly, the participant who had the axle placed most anteriorly to the acromion also had the lowest normalized force, however the other who followed the recommendation was in the midrange of normalized force values. The lack of correlation between axle position and force may indicate that this adult recommendation does not perfectly translate to pediatric and emerging adult manual wheelchair users.

Overall, the average values of handrim metrics for our participants did not fall near adult averages. Notably, the maximum rate of rise of $F_r$ was more than twice the adult average reported in previous literature [7]. Reducing the rate of rise of $F_r$ is recommended for adult MWU because higher values have been associated with median nerve damage and carpal tunnel syndrome [7]. The average percent contact phase was more than 10 percentage points shorter than adult averages and even the participant with the largest percent contact phase did not meet the adult average [8]. Increased time in the contact phase is recommended to decrease the necessary frequency required to propel the wheelchair.

Current work is underway to collect data for more participants to investigate this question further. Currently, no strong correlations were found between wheelchair fit measures and handrim metrics. The wheelchair fit measures used in this study are derived from recommendations for adult manual wheelchair users that are intended to prevent pain and pathology development by providing ideal ergonomics and reducing repetitive joint dynamics of the upper extremity. Since no participants followed both adult recommendations, we cannot conclude that the recommendations do or do not work for pediatric and emerging adult MWU. It is important to continue to investigate this question to determine if the adult recommendations are applicable to younger MWU populations.

# EFFECTS OF GEOMETRICAL AND MICROSTRUCTURAL REMODELING ON VENTRICULAR MECHANICS IN HYPERTROPHIC CARDIOMYOPATHY

**Joy Mojumder (1), Lei Fan (1), Thuy Nguyen (2), Julius Guccione (3), Theodore Abraham(2), Lik Chuan Lee (1)**

## INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a genetic heart disease that is associated with sudden cardiac death. This disease is often classified based on whether the left ventricle (LV) outflow tract is obstructed or not (non-obstructive). The clinical features associated with HCM include a reduction in longitudinal and circumferential systolic strains (shortening) in the LV, alterations in contractility, myofiber disarray and asymmetrical septal hypertrophy. While these features are well established in HCM, the contribution of each remodeling feature (such as a change in contractility and myofiber disarray) to LV dysfunction is not clear. Besides, it is also not clear how differences in remodeling between obstructive and non-obstructive HCM affect LV function. To address these issues, we developed patient specific computational LV models to investigate the isolated effects of myofiber disarray, contractility and asymmetrical hypertrophy in these two types of HCM.

## METHODS

Clinical data from 2 patients with obstructive and non-obstructive HCM and a control subject were acquired. These data include the blood pressures, global longitudinal strain estimated from 3D echocardiography and magnetic resonance (MR) images. Left ventricle cavity volume waveform of each subject was derived by segmenting the endocardial wall from the MR images over the cardiac cycle with MeVisLab (MeVis Medical Solutions AG). Together with the pressure waveforms of HCM patients reported in published data, we obtained the pressure-volume (PV) loop of each subject. Finite element (FE) LV geometry of each subject was reconstructed from the MR images associated with end-diastole (ED) (**Fig. 1a**). Regional thickness of each subject was measured from the reconstructed geometry (**Fig. 1b**),

In the LV, mean myofiber direction, $\boldsymbol{e}_{f_0}$ was prescribed to vary transmurally from $+60^0$ at endocardium to $-60^0$ at epicardium (**Fig. 1c**). Myofiber disarray was described by applying a structural tensor to the constitutive models of the cardiac tissue. The structure tensor, **H,** is defined as[1]

$$\boldsymbol{H} = \kappa \boldsymbol{I} + (1 - 3\kappa)\boldsymbol{e}_{f_0} \otimes \boldsymbol{e}_{f_0} \quad . \qquad (1)$$

This tensor describes a conical dispersion of myofibers about a mean direction $\boldsymbol{e}_{f_0}$. The degree of myofiber disarray is parameterized by a dispersion parameter $\kappa$, which varies between 0 (perfect alignment or no dispersion) to 1/3 (complete disarray).

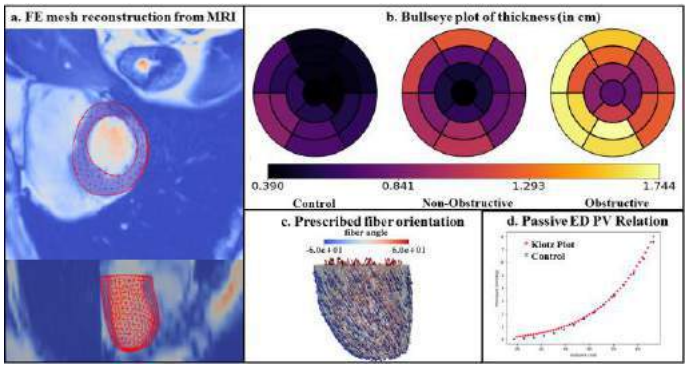

**Fig 1: Construction of LV Finite Element model.**

Left ventricular mechanics were described by an active stress formulation based on prescribed active and passive material laws. The passive mechanical behavior was described by the Holzapfel-Ogden constitutive model, whereas the active mechanical behavior was described using the Guccione model[2]. Simulation of LV mechanics in a cardiac cycle was performed in 2 steps for each subject-specific model. First, the unloaded LV geometry was estimated from the reconstructed ED LV geometry using a backward displacement

method, in which model parameters of the Holzapfel-Ogden model was calibrated so that the model-predicted end-diastolic pressure-volume relationship (EDPVR) matches the "Klotz" curve[3] that holds also in HCM (See **Fig. 1d** for the control subject). Following that, the unloaded LV FE model was coupled to a closed-loop lumped parameter model of the circulatory system to predict the cardiac hemodynamics and mechanics. Peak tension in the active contraction model, resistances and compliances in the circulatory model in each subject-specific model were first calibrated without myofiber disarray (i.e., $\kappa$ = 0) to match the corresponding measured LV PV loop, pressure and volume waveforms, blood pressure and longitudinal strain. Thereafter, based on published data of fractional anisotropy (FA), a different degree of myofiber disarray (i.e., $\kappa$ in **Eq. 1**) was determined, and was imposed globally into the HCM LV models. The peak tension in the active contraction model was adjusted to match results with the clinical data.

## RESULTS

The calibrated models' predictions were close to the measurements (see **Fig. 2a** for a representative case of the control subject). Left ventricular geometry and function were greatly different in the HCM patients compared to the control. Specifically, compared to the control subject, in both types of HCM patients end diastolic volume (EDV) were larger, whereas end systolic volume (ESV) was larger only in obstructive HCM patient (obstructive HCM: EDV 114.5 ml, ESV 37.9 ml; non-obstructive HCM: EDV 82.1 ml, ESV 12.1 ml vs. Control: EDV 63.1 ml, ESV 18.9 ml). Global longitudinal strain was reduced in the HCM patients: (obstructive HCM: 13%; non-obstructive HCM: 19% vs. Control: 20%). Thickness at septum was highest in the obstructive HCM patient (17.4 mm) followed by the non-obstructive HCM patient (12.3 mm) and the control (9.1 mm) (**Fig. 1b**).

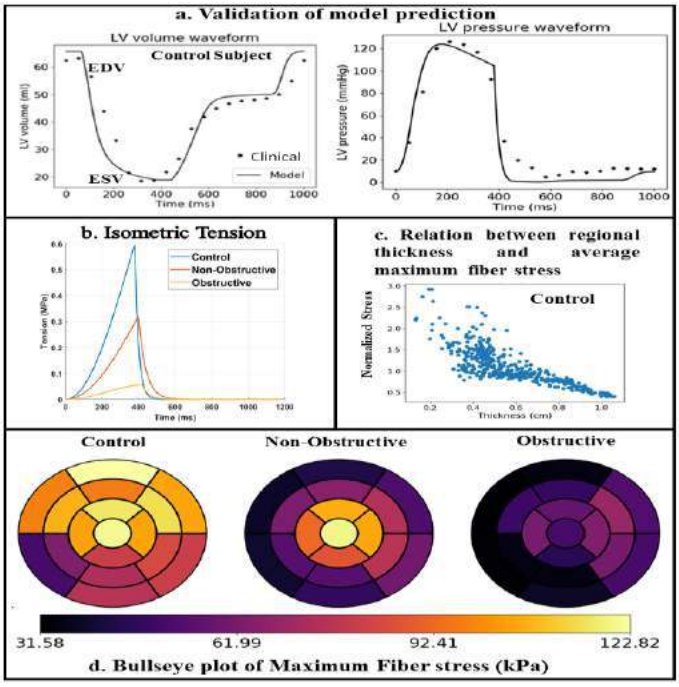

**Fig 2: Validation of hemodynamics results and prediction of mechanics data by model.**

Resultant isometric tension curve based on the calibrated active stress model parameters shows that the peak tension was lowest in the obstructive HCM patient (60 kPa) followed by the non-obstructive HCM patient (320 kPa) and the control (600 kPa) (**Fig. 2b**). Regional stress and stretch in the 3-material directions (i.e., fiber, sheet and sheet-normal) have good correlation with the regional thickness. The average maximum fiber stress showed a very good linear correlation with the variation in thickness in each subject (**Fig. 2c**). At the septum, maximum fiber stress was lowest in the obstructive HCM patient followed by the non-obstructive HCM patient and the control (**Fig. 2d**).

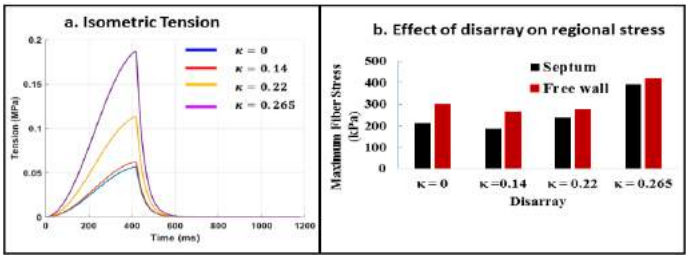

**Fig 3: Effect of myofiber disarray in Obstructive HCM**

With increasing $\kappa$, the resultant peak tension in the obstructive HCM patient needs to be increased to match the measured hemodynamics and strains. Specifically, when $\kappa = 0.265$ that is equivalent to a fractional anisotropy FA of 0.38, peak tension needs to be increased from 60 kPa (without disarray) to 200 kPa (**Fig 3a**). The increase in myofiber dispersion led to an increase in the maximum fiber stress at the septum and free wall. The change in fiber stress with respect to myofiber dispersion is monotonic (**Fig 3b**).

## DISCUSSION

Ventricular wall stress is an important determinant of myocardial oxygen consumption and ventricular remodeling. Because regional myofiber stress (or load on the myocytes) cannot be directly measured in the intact LV, we have estimated stress in HCM patients with different phenotypes (obstructive vs. non-obstructive) using computational modeling to gain insights of this disease.

We found that myofiber stress and contractility are all reduced in HCM patients compared to the control without consideration of myofiber disarray. The reduction is greatest in the obstructive HCM patient than the non-obstructive HCM patient. We also found that the reduction in myofiber stress is caused by the increased in wall thickness due to asymmetrical hypertrophy in the HCM patients. In the obstructive HCM patient, we found that an increase in myofiber disarray resulted in an increase in peak tension that is necessary to match the measured cardiac hemodynamics and function. With a substantially large degree of disarray FA = 0.38 that has been reported previously, peak tension of the myocyte, however, is still lower than that found in the control subject. This result suggests that it is likely that the myofiber contractility is reduced in HCM patient. __

There are some limitations associated with this study. First, the analysis was performed only on 2 HCM patients. Second, the degree of myofiber disarray is varied globally in this study. Future work on variation of the degree of myofiber disarray on non-obstructive HCM patient and incorporating spatial variation of disarray parameter will be helpful to understand the effect of different remodeling features in different HCM patients.

## INTRODUCTION

Matrix fibril anisotropy and density are gaining recognition for their mechanoregulatory roles in cellular growth and guidance. During angiogenesis, for instance, matrix density contributes to durotaxis while fibril orientation contributes to haptotaxis in an anisotropy dependent manner. The configuration of matrix density and fibril alignment are thought to affect the success of establishing new vasculatures during pathologic and homeostatic angiogenesis [1]. Computational simulation is emerging as a tool to determine how the integrated effects of mechanical and biochemical stimuli coordinate cell guidance depending on the relevant matrix architecture. Current 3D frameworks generally calculate guidance cues from discrete vector fields which represent general orientation but fail to reflect the degree of alignment [2-4]. We propose a deformable continuous 3D ellipsoidal fibril distribution (EFD) representation of collagen fibril orientations during simulations of collective migration phenomena. Our simulations accounts for matrix anisotropy and realignment due to cellular traction. We find that a continuous distribution is needed to model strongly polarized guidance. Further, our distributions encode the local degree of alignment, which is known to affect a range of cellular behaviors.

## METHODS

*In vitro alignment studies of angiogenesis:* The effects of matrix anisotropy on microvessel guidance using rat fat microvessels were embedded in type I collagen. Collagen was stretched along the axial direction just before polymerization finished to induce low, medium, or high levels of anisotropy (n > 6 ea.). The gel edges were cut from stretch anchors and then gels were cultured free-floating for 10 days before fixation, staining, and imaging. Avascular gels were imaged via second harmonic generation (SHG) to extract collagen fibril orientation distribution functions (ODFs) as inputs to simulations.

*Simulations of microvascular guidance*: Finite element mechanical models in FEBio were coupled with AngioFE, a plugin that simulates neovessel growth from parent microvessels [4]. Our prior approach to neovessel guidance represented the local fibril direction at each finite element node as a discrete vector. In this work, we developed a new method that represents fibril ODFs as EFDs stored as symmetric positive-definite (SPD) tensors at the integration points. The SPD criteria are critical as it allows us to interpolate local ODFs using DT-MRI methods [5].

Certain deformations morph SPDs into asymmetric shapes. Thus, we developed a pseudo-deformed EFD, $\boldsymbol{P}$, that accounts for scaling and rotation while maintaining the SPD criteria:

$$\boldsymbol{P} = \boldsymbol{Q}\boldsymbol{D}\boldsymbol{Q}^{-1} \tag{1}$$

Here, $\boldsymbol{Q}$ is a 3x3 matrix whose columns contain the directions of the EFD semiprincipal axes rotated by $\boldsymbol{R}$ (the rotational component of the deformation gradient). $\boldsymbol{D}$ is a diagonal matrix containing the lengths of the semiprincipal axes scaled by the deformation gradient $\boldsymbol{F}$. This approach was tested using simulations of uniaxial extension of a biphasic, hyperelastic material containing initially isotropic fibril distributions.

The direction of fibril guidance, $\boldsymbol{\theta}$, is sampled from EFDs using a Monte-Carlo approach. A randomly sampled vector is accepted if it lies within the surface of the EFD given by:

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}<1 \tag{2}$$

where $x$, $y$, and $z$ are the components of the random vector, and $a$, $b$, and $c$ are the lengths of the semiprincipal axes.

The new direction that a vessel grows, $\boldsymbol{\psi}_{new}$, depends on the persistence (prior) direction, $\boldsymbol{\psi}$, and the fibril guidance direction $\boldsymbol{\theta}$. This direction is calculated by partially rotating the persistence direction towards the fibril guidance direction via

$$\boldsymbol{\psi}_{new} = \boldsymbol{R}(\boldsymbol{\psi}, \boldsymbol{\theta}, \alpha)\boldsymbol{\psi} \quad (3)$$

where $\boldsymbol{R}(\boldsymbol{\psi}, \boldsymbol{\theta}, \alpha)$ is the matrix that completely rotates $\boldsymbol{\psi}$ to $\boldsymbol{\theta}$**.** The factor $\alpha$ scales the fibril contribution so that when $\alpha = 0$, directional control is governed by the persistence direction $\boldsymbol{\psi}$**,** while when $\alpha = 1$, directional control is governed by the fibril direction $\boldsymbol{\theta}$.

Simulations of guidance in low, medium, or highly anisotropic collagen were performed using both the discrete fibril and the continuous EFD approaches. Initial conditions and microvessel growth over time were prescribed based on in vitro data. Experimental collagen fibril ODFs were extracted from SHG images and fit to EFDs. Discrete fibril directions were sampled from a global EFD. A parametric study was performed on the fibril contribution scale $\alpha$ between 0 and 1 to determine how well each approach could simulate guidance for each level of anisotropy. A total of 10 simulations with unique initial random seeds (and thus initial conditions) were performed for each case. We focused on the 2D ODF in the XY plane was evaluated because the majority of collagen alignment was in this plane.

## RESULTS

Pseudo-deformed EFD fibril distributions undergo tension, compression, and shear while maintaining the qualities of an SPD (Fig **A**). This is crucial to allow approximation of the local ODF at all locations within the simulation domain.

A vector-field approach was unable to reproduce the experimentally measured 3D fibril guidance for medium and high anisotropy simulations (**Fig B,** blue lines). The continuous EFD approach, however, was able to replicate guidance to the degree seen experimentally (orange lines). These results are observable when comparing confocal imaging to simulation results (**Fig C**).

## DISCUSSION

In vitro and in vivo, cells continuously probe the matrix for cues. Discrete fibril approaches only sample the ODF once during model initiation while EFDs can be sampled as cells grow and move, much like is seen experimentally. Further, discrete fibril approaches are more sensitive to meshing constraints.

The contribution of fibril guidance required to match experimental data increased with anisotropy, which may reflect changes in the balance of persistence and guidance signaling.

Another crucial benefit of the continuous distribution approach is that it inherently encodes information about the degree of alignment. Anisotropy has previously been shown to affect cellular proliferation and growth rate, and may be mechanoregulatory in numerous other signaling pathways involved in homeostasis, healing, and pathology.

The presented approach is extensible to other guidance phenomena such as chemotaxis where cytokine gradients are anisotropically distributed.

# MOLECULAR DESIGN OF POLYELECTROLYTE COMPLEX MICELLES FOR NUCLEIC ACID DELIVERY

**Alexander E. Marras (1), Jeffrey R. Vieregg (1), Matthew V. Tirrell (1)**

(1) Pritzker School of Molecular Engineering, University of Chicago, Chicago, IL, USA

## INTRODUCTION

Developing effective non-viral methods for delivery of nucleic acids and other macromolecular therapeutics is one of the most pressing challenges in nanomedicine. The immense potential of engineered nucleic acids as therapeutic agents is limited by the difficulty of overcoming physical and biological barriers. A solution to this critical problem is using hydrophilic charged block polymers to condense nucleic acids, driving nanoscale phase separation to form polyelectrolyte complex micelles (PCMs) (Figure 1A). These core-shell nanoparticles sequester and protect nucleic acids from nucleases and immune response. Still, few systematic studies have been conducted on how parameters such as nucleic acid backbone chemistry, polymer charge density and polymer length influence PCM properties, despite evidence that these strongly influence complexation behavior. Here, we present an investigation of the impact of physical and chemical properties on PCM assembly and stability.

## METHODS

We used light scattering, small angle X-ray scattering (SAXS), and electron microscopy to investigate the relationship between oligonucleotide PCM properties and the properties of the nucleic acids and block copolymers that form them. Materials were synthesized by aqueous reversible addition-fragmentation chain transfer (RAFT) polymerization [1] or ordered from Alamanda Polymers or Integrated DNA Technologies. PCMs were prepared using a salt-annealing method [2] where dissolved complexes in 1M NaCl are slowly dialyzed into low salt conditions. SAXS measurements were made at the Advanced Photon Source at Argonne National Laboratory and analyses were performed using the Irena software package for Igor Pro as detailed in Marras et al. [2]. PCMs were imaged using transmission electron microscopy (TEM) at University of Chicago. Phase and morphology of homopolymer complexes were observed by bright field optical microscopy. To assess the stability against salt, samples were titrated with NaCl and light scattering intensity was measured.

## RESULTS

We found the molecular details of the cationic charged group and nucleic acid backbone strongly influence complexation behavior and stability. Briefly, nucleic acid hybridization drives PCM shape, where single-stranded nucleic acids formed spheres and double-stranded formed cylinders [3,4]. DNA, RNA, and common chemically modified nucleic acids also exhibited drastically different assembly behavior (Figure 1B) and phosphorothioate backbone modifications radically increase complex stability (Figure 1C). Furthermore, polymer lengths in the block copolymer control size and aggregation number while nucleic acid length is independent of these physical properties [5]. Experimental scaling laws (Figure 1D) were developed for numerous physical parameters and show consistency with previous studies and theoretical predications [6].

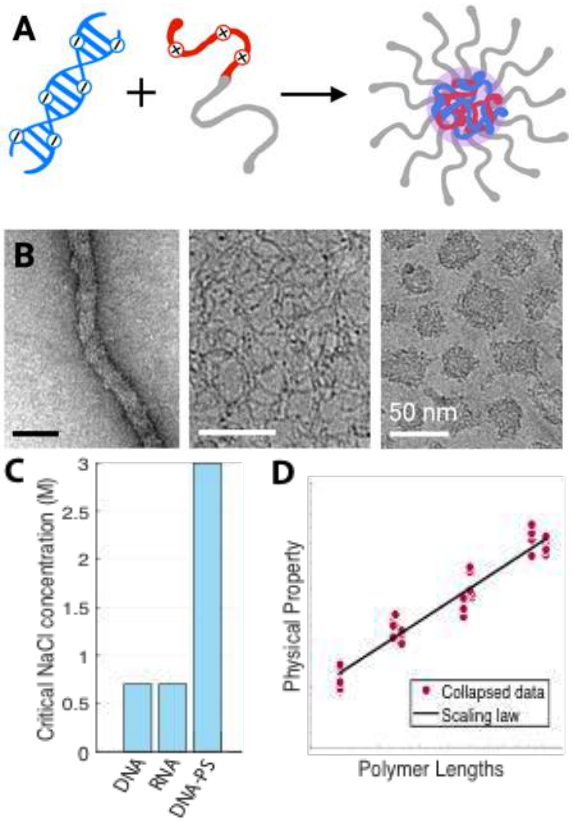

**Figure 1: (A) Charged polymers sequester therapeutic nucleic acids for protection and delivery. (B) Molecular details of both components control the shape, size, and stability of these particles. All scale bars = 50 nm. (C) Stability vs. NaCl show drastic differences with phosphorothioate (PS) modifications to nucleic acid backbones. (D) Scaling laws for physical parameters of PCMs were developed**

## DISCUSSION

Molecular details of nucleic acids and cationic polymers drastically influence PCM assembly and stability and should be considered when designing therapeutic delivery systems. These observations narrow the design space for tailored therapeutic micelles, promoting efficient design of delivery devices for therapeutic payloads.

# CHANGES IN CD44 AND DRUG RESISTANCE IN OVARIAN CANCER CELLS WITH DIFFERING MECHANICAL PRESENTATIONS OF HYALURONIC ACID

**Maranda E. Tidwell (1), Gillian Huskin (1), Molly Buckley (1), Joel Berry (1,2), M.K. Sewell-Loftin (1,2)**

## INTRODUCTION

Ovarian cancer is the deadliest and third most common gynecological cancer with a 5-year survival rate less than 30% [1]. However, little research has been done in understanding the role of the biomechanical tumor microenvironment (TME) in the metastasis of ovarian cancer. Previous studies have shown a link between hyaluronic acid (HA) in the TME and cancer progression and metastasis, through its receptor CD44 [2]. CD44 can activate many cell-signaling pathways including the cancer pathogenic pathway, Ras-MAPK. In the clinical setting, ovarian cancer is treated with surgical removal and chemotherapy, with cisplatin and paclitaxel being the primary drugs of choice. A higher presence of HA in the TME is associated with a more drug resistant phenotype of ovarian cancer and increases in CD44 levels in cancer cells correspond to more metastatic behaviors [3]. We hypothesize that biomechanical signaling in the HA-CD44 axis alters ovarian cancer growth and metastasis and increases chemo-resistance. The objective of this study was to evaluate changes in CD44 expression with differing presentations of HA. Further, the effects of HA and CD44 signaling on ovarian cancer cell response to cisplatin in 2D and 3D environments were quantified.

## METHODS

Human ovarian cancer cell line OVCAR8 was used as the model for the studies. OVCAR8 cells are non-serous and exhibit highly invasive behaviors [4,5]. HA (Sigma-Aldrich, 41897, 1MDa) was introduced to the cells in two methods: in the media as a soluble factor (SOL HA) or plated on tissue culture plastic (PLT HA). Concentration of HA was maintained across exposure groups at 1 μM. The HA plated dishes were made by coating HA to the tissue culture plastic with HA in HBSS overnight at 4C [6]. No treatment controls (0μM) only received HBSS. The cells were fed every 2-3 days and lysed after 7 days. Another study used collagen-I coated FlexCell plates coated with HA (FLX+PLT HA). OVCAR8 cells seeded on these plates and were allowed to adhere over night before straining at 10% and 0.3% Hz frequency for 24 hours. For analysis, all cells were lysed in RIPA buffer plus 1:100 HALT solution prior to a Western Blot for CD44 expression β-actin or GAPDH as a loading control. Densitometry was performed using FIJI, and CD44 expression was normalized first to the loading control, then to the appropriate no treatment control group.

For 3D studies, PDMS rings with an ID of 8mm and height of 1mm were used as microtissue models [7]. The rings were loaded with 25K cells in fibrinogen plus thrombin that quickly form a fibrin gel. The rings were fed with control media or 1 μM soluble HA (F+SOL HA). A separate set of samples were made with HA mixed in the fibrinogen (F+GEL HA). The rings were fed every 2 days for 7 days before the gels were digested with nattokinase; remaining cells were lysed for protein analysis as mentioned previously.

To evaluate the role of CD44 signaling in OVCAR8 chemo-resistance, we generated genetically-modified cell lines with lentivirus to knock down CD44 (shCD44) or a scramble was used as a control (shSCR). Knockdown was verified via Western Blot, and shCD44 cells show ~50% decrease in CD44 protein levels. These cells were seeded in fibrin only or F+GEL HA gels and treated with 50μM cisplatin (Cis) or vehicle (Veh) control for 24h. A live/dead imaging assay (ThermoFisher, L32250) was performed on the cells and co-stained with Hoescht 33342. For each gel, a 100um z-stack was collected and processed in FIJI.

## RESULTS

The results for the 2D experiments show that, CD44 expression decreased by ~30% in the SOL HA samples and increased by ~10% in the PLT HA samples compared to the no treatment controls (Figure 1). When the PLT HA samples were further mechanically stimulated in the

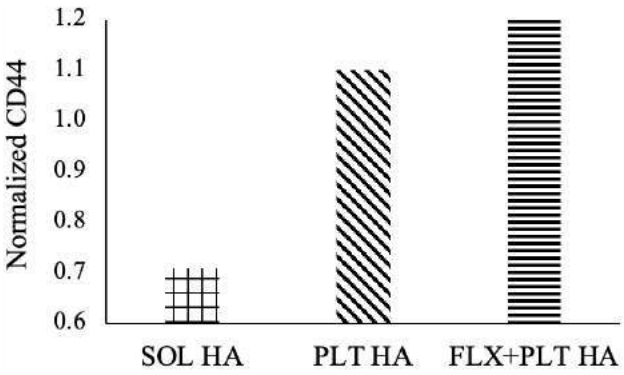

**Figure 1 Results from Western blot for 2D OVCAR8 with different exposures to HA. Values are double normalized first to a loading control protein, then to the appropriate no treatment control sample.**

FLX+PLT HA studies, CD44 increased by another 10% making the total increase ~20% compared to the no treatment control (Figure 1). We observed similar increases in CD44 when HA is incorporated into

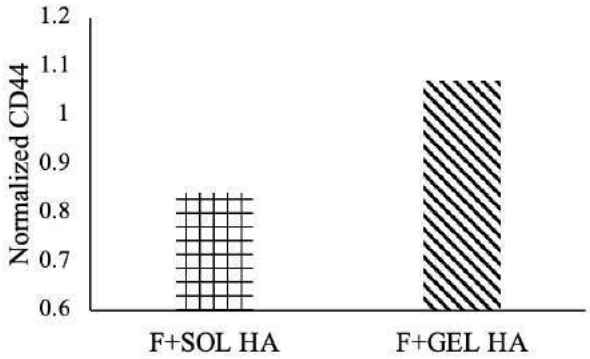

**Figure 2 Results from Western blot for 3D OVCAR8 with different exposures to HA normalized to 0 μM**

the 3D environment, compared to when it is supplied to OVCAR as a soluble factor in 3D studies. Overall, CD44 expression decreased by ~15% when the cells were presented with F+SOL HA (Figure 2). When the HA was incorporated in the gel in the F+GEL HA samples, CD44 was increased by ~7% (Figure 2).

The results from the chemosensitivity studies suggest that F+HA gels are somewhat protective for OVCAR8 cells with reduction in cell death for all lines when treated with cisplatin compared to cells grown in fibrin only gels (Figure 3). For cells with high levels of CD44 expression, WT and SCR, the effect is small. However, in the shCD44 cells there is a significant decrease in cell death for cisplatin-treated cells grown in the combination gels compared to fibrin only.

## DISCUSSION

The results show that the mechanical presentation of HA, whether in a 3D gel or coated on a 2D surface, increases CD44 expression more than when HA is a soluble factor in the media. This suggests a mechanobiological role for the HA-CD44 signaling pathway and could impact our understanding of ovarian cancer metastatic growth.

In our drug sensitivity studies, results indicate that HA embedded in the fibrin prevents or inhibits cell death compared to controls for cells treated with cisplatin. This effect was even observed in the shCD44 line which suggests the combination of HA in the matrix and limited CD44

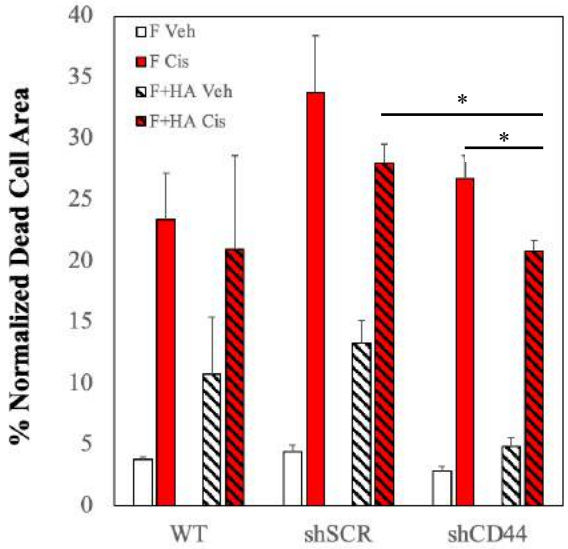

**Figure 3. Percentage of dead cells in 3D studies with OVCAR8 cell lines. All values are normalized to total nuclear area. Averages ± SEM; N=3-4. * p < 0.05.**

expression decreases the sensitivity of the cancer cells to cisplatin. Another potential explanation for this is that the large HA molecules in the microenvironment prevented the cisplatin from fully diffusing to cells; future studies will optimize delivery of chemotherapeutic agents in the 3D microtissues. Additionally, while the shRNA was designed to knockdown the standard splice variant of CD44, alternative splice variants such as CD44v6 may not be decreased in the shCD44 line. Studies are ongoing to evaluate the differential expression of CD44v6 in the shCD44 cells. Overall, our studies support that HA is associated with a worse prognosis of ovarian cancer and that this may be due to mechanobiological signaling.

Our studies demonstrate proof of concept that biomechanical stimulation of OVCAR8 cells with HA can cause changes in cell behaviors. We will further study this phenomenon by investigating factors downstream of CD44 such as Src And p38. Additionally, we will leverage 3D microtissue models developed in our lab to examine OVCAR8 migration and invasion in vascularized tissue mimics. These systems can also be used to evaluate how CD44 levels regulate response to cisplatin treatment. These proof-of-concept studies help explain the role HA plays in mechanically stimulating CD44. Ultimately, this project will help elucidate proliferation, metastasis, and drug resistance observed in ovarian cancer and open the doors for researching new diagnostics and therapeutics.

# A HYBRID PARADIGM TO DEVELOP REGIONAL THORACO-ABDOMINAL CRITERIA FOR BEHIND ARMOR BLUNT TRAUMA

**Narayan Yoganandan (1), John Humm (1), Brian Stemper (1), Cameron Bass (2), Robert Salzar (3), B. Joseph McEntire (4)**

## INTRODUCTION

Injury criteria are critical in the development of standardized tests and surrogates for evaluating injury risk and the efficacy of devices such as personal protective equipment (PPE), and to improve the overall safety of our Warfighters/Service Members. Protective body armor is ubiquitous to military and civilian law enforcement personnel. It reduces the risk of penetrating injury while decreasing the energy transferred to the body [1]. However, any deformation of the armor can lead to trauma to the underlying organs and tissues through momentum transfer. Tissue response, anatomy, geometry, and loading conditions all play a role in any resulting injuries, injury patterns, and injury mechanisms. The composition and mechanical properties such as stress-strain responses of cortical and cancellous bones of the ribcage and spinal column will lead to different injury responses. A similar analogy applies to the thoraco-abdominal organs because they are viscoelastic and loading rate sensitive. In addition, skin and subcutaneous fat plays a role. The heterogeneity of the human system anatomy should be considered during the development of biomedical injury criteria for behind armor blunt trauma (BABT). Many studies have been conducted using different types of animal models to develop injury metrics; however, the focus on regional tolerance differences is largely ignored in current injury assessment (residual clay penetration) [2]. The objective of this study is to examine the rationale for current clay-based injury criteria used in the military, identify recent studies and advancements in experimentation, analysis, and statistical modeling, and develop a hybrid paradigm that can be used to determine thoraco-abdominal regional injury criteria for BABT.

## METHODS

Studies focusing on live animal experiments to different body regions and metrics to develop current injury assessments and criteria were analyzed. Original studies conducted by the military that formed the basis of testing standards included impacts to goat thoraces (lungs) and liver [2]. Lethality in the former and liver injuries in the latter experimental model were used as the main injury outcome measures. Studies were also conducted using the swine and dog models with similar impacting locations and projectiles. Goat studies were used to develop the original probability curve for lethality using a binary regression model. Impacts to the midsternum were delivered to swine in another study that focused on heart impacts. Later studies used more sophisticated techniques for measuring deformations and adding other metrics such as viscous criterion, and post-mortem human subjects. A summary of some of these studies are presented to achieve the objectives of this project.

## RESULTS

Impacts were delivered to the lateral region of the thorax of goats with projectile diameters ranging from 40 to 63 mm, masses from 50 to 125 g, and velocities from 25.2 to 85.7 m/s in a group of 30 animals, out of which 12 resulted in fatal injuries. In another series of nine animals, a 63 mm diameter and 125 g projectile impacts resulted in four fatal injuries, with velocities ranging from 55.8 to 80 m/s. With diameters of 40 and 80 mm and masses of 50 and 200 g, respectively, none out of two and one out of five animal sustained fatal injuries, where velocities ranged from 78.3 to 82.1 m/s and 34.3 to 51.3 to 61.8 m/s, respectively. With diameters of 76.2 and 36.5 mm and mass of 132 and 210 g, respectively, none out of 15 and all 5 animals sustained fatal injuries. The velocities for this group ranged from 18.3 to 47.1 m/s and 24 to 28 m/s, respectively. Swine tests included 79 mm and 196 g impacts at 21.3 to 36 m/s with four out of six animals sustaining fatal injuries, and 27.7 mm and 11.7 g impacts resulting in three out of 15 animals sustaining fatalities, with velocities ranging from 21.3 to 36 m/s and 80.8 to 148.1 m/s, respectively. Dogs were subjected to 63 to 70 mm diameter and 43 to 382.2 g mass impacts with velocities from 18.9 to 80.2 m/s, and greater mass was associated with greater velocities.

**Table 1: Summary of thorax impacts to different animals.**
Fatal ratio refers to the percentage of animals in the specific group

| Animal | Dia. (mm) | Mass (g) | Velocity (m/s) | Specimen mass (kg) | Fatal Ratio |
|---|---|---|---|---|---|
| Goat | 36.8-80 | 43-210 | 18.3-85.7 | 27.8-52.8 | 23% |
| Swine | 79 | 196 | 21.3-36.0 | 13.1-17.4 | 67% |
| Swine | 27.69 | 11.7 | 80.8-148.1 | 12.6-18.2 | 20% |
| Dog | 70 | 63-383 | 18.9-80.2 | 14.8-23.1 | 21% |

Impacts were delivered to goat livers with projectile diameters from 40 to 63 mm and mass from 50 to 125 g in a group of 38 animals, out of which all sustained liver injuries, from velocities ranging from 44.8 to 81.2 m/s. In another group, projectile diameters of 36.5 and 63.5 mm with mass of 210 and 43 g, and velocities from 28 to 38 m/s and 50 to 80.8 m/s, resulted in liver injuries in 14 out of 16 animals and six out of 21 animals, respectively. In another group, projectile diameters from 83.9 to 90.7 mm with mass from 21.4 to 59.66 g, and velocities from 85.1 to 182.4 m/s and 50 to 80.8 m/s, resulted in no liver injuries in 14 animals and six out of 21 animals, respectively. As in the case of the thoracic impacts, greater mass was associated with greater velocities. In the swine model, projectile diameters of 79.4 and 27.8 mm with mass of 196 and 11.7 g, and velocities from 15.5 to 36 m/s and 58.2 to 147.2 m/s, resulted in liver injuries in one out of 13 animals and three out of seven animals, respectively. In the baboon model, projectile diameters from 76.2 mm and 132 g mass, and velocities from 16.3 to 52.3 m/s and 41.0 to 48.4 m/s, resulted in 13 and four liver injuries in 24 and four animals, respectively. In another series of tests, projectile diameters from 76.2 mm and 132 g mass, and velocities from 16.4 to 52.3 m/s and 41.0 to 48.4 m/s, resulted in 13 and four liver injuries in 24 and four animals, respectively (Table 2). Heart impacts using the swine model with a 140 g and 3.7 mm diameter impactor at velocities from 37 to 72 m/s produced cardiac injuries in 21 out 25 animals, whereby 20 to 34 m/s injured all six animals. The same study reported injuries to all six animals with a 10 mm diameter and 140 g impactor at velocities from 50 to 64 m/s.

**Table 2: Summary of liver impacts to different animals.**
(Injury ratio refers to the percentage of animals in the specific group)

| Animal | Dia. (mm) | Mass (g) | Velocity (m/s) | Specimen mass (kg) | Injury ratio |
|---|---|---|---|---|---|
| Goat | 40-80 | 50-200 | 44.8-85.7 | 26.4-46.8 | 100% |
| Goat | 36.5 | 210 | 28-38 | 45-68 | 93% |
| Goat | 63.5 | 43 | 50-80.8 | 28.8-46.4 | 29% |
| Swine | 79.4 | 196 | 15.5-36 | 13.1-17.4 | 92% |
| Swine | 27.7 | 11.7 | 58.2-147.2 | 13.6-17.0 | 43% |
| Baboon | 76.2 | 132 | 16.4-52.3 | 31.1-52.8 | 54% |
| Baboon | 76.2 | 132 | 41-48.4 | 19.0-25.6 | 100% |

## DISCUSSION

Studies incorporating body armor were specific to the type and design of the armor prevalent at the time testing, some dating to the 1970s. The Angora goat served as the baseline animal for which the mean lethality injury probability curve was developed based on the data from the impactor/indentor. The peak deflection metric was used in the logistic regression model. While numerical data were not reported for the mean/estimated risk curve and confidence intervals, indentor deformation depths of 44 and 50 mm were associated with 10% and 15% risk of fatal injuries in the original study [2]. The corrected analysis showed that the actual risk for soft armor for a 44 mm goat deformation is approximately 4% [3]. It should be noted that no animals sustained fatal injuries at this risk level. The current standard backface deformation (BFD) test is conducted with Roma Plastilina clay [3]. Based on clay and goat model tests at a velocity of 55 m/s, with a 200 g and 80 mm diameter solid hemispherical impactor, clay-goat response was linear, with a slope of 0.28 at deformations from 3 to 60 mm. This results in 56 and 44 mm for the clay corresponding to 44 and 34 mm for the goat model and associated with 10% and 4% risk of fatal injuries to the goat [3]. These data are based on impactor tests without body armor and is not region specific. Human cadaver studies have shown poor correlation ($R^2$=0.054) between penetration depth and velocity [1].

Based on subjective assessments from clinicians, the goat was justified in the original studies and was based on the assumptions that a 40 to 50 kg total body mass of the animal represents a typical 70 kg male, damage levels are similar between the goat and human, with both species experiencing the same course of ageing and disease process, etc. It should be noted that organ orientations in the goat are not the same as the axial anatomy in the human. While recognizing that no available animal model mimics the in vivo human in terms of anatomy, structure, and biomechanical response to impacts, swine models are extensively used in recent studies spanning from automotive to military. They include varying breeds, Sus Scrofa, Swedish Landrace, Yorkshire, cross between Yorkshire and Hampshire domestic breed, etc. The development of the swine model has been related to the onset of human puberty in the automotive safety field in the development of injury criteria. Human respiratory and circulatory systems are like the swine, as are human metabolic properties such as muscle perfusion. Studies have correlated/used swine anthropometry to thorax and organ injuries. Automotive injury biomechanics studies have shown that the responses between are comparable live and cadaver swine tests. From these perspectives, the swine is appropriate for BABT injury prediction and injury criteria research and development.

One important factor is the scaling between the animal and human. Subjecting live swine to BABT impacts yields important information on the resulting physiology and pathologies over time and allows the collection of biomedical and injury biomechanical measures; however, translating this information to the living human needs another set of experiments with the human as a surrogate. Because it is not ethical to apply potential injury producing impacts to any human subjects, human cadavers are required. Conducting matched pair tests with the human and swine cadavers, while not yielding pathophysiological outputs, allows structural scaling relationships to be developed for BABT scenarios. Equal stress-equal velocity and impulse momentum approaches are available [4]. Conducting parallel impact experiments with human and swine cadavers, and longitudinal live swine studies is an effective means to correlate injuries from the swine to human via scaling to develop human injury criteria. As impacts can be controlled with indentor designs that replicate the BFD and focused on regional areas of the human and swine anatomy, this hybrid paradigm can be effectively used to develop throacoabdominal region-specific BABT criteria.

From a statistical modeling perspective, the only risk curve reported is the mean/estimated curve with no associated confidence intervals. It is important to determine the confidence interval bounds, as an assessment can be made of the quality of the injury probability curve. Another issue is the use of the logistic regression model that ignores data censoring. More sophisticated methods such as parametric and Bayesian survival models are available to overcome this limitation [5]. They are used in recent military injury biomechanics studies for human injury criteria and developing advanced manikins. Thus, it is important to incorporate these developments to the outcomes from the hybrid paradigm using matched pair cadaver swine and human, and live swine experiments to develop improved BABT injury criteria and standards.

# REGULATION OF WHOLE-BODY ANGULAR MOMENTUM IN PERSONS WITH PARKINSON DISEASE WHEN TRANSITIONING FROM A REGULAR TO AN IRREGULAR SURFACE

**Nicholas G. Gomez (1), Kelton K. Gubler (1), Andrew S. Merryweather (1)**

(1) Department of Mechanical Engineering, University of Utah, Salt Lake City, Utah, USA

## INTRODUCTION

Whole-body angular momentum in relation to the body's center of mass (COM) is highly regulated in overground walking [1] and is invariant to walking speed in healthy adults [2-3]. These conclusions have been found to not be generalizable to other conditions beyond level, overground walking such as negotiating 90-degree turns [4] as well as stair ascent and descent [5]. Furthermore, it is unknown whether conclusions regarding regulation of whole-body angular momentum in healthy individuals extend to populations that are neurologically impaired, such as those with Parkinson disease (PD). A recent investigation found that in stair descent, persons with PD regulated whole-body angular momentum differently than a healthy control population [6]. This finding, in addition to the growing body of literature showing that Persons with PD alter their kinematics and kinetics in the presence of irregular terrain [7] as well as surface transitions [8], prompted us to investigate whether persons with PD regulate their whole-body angular momentum differently when transitioning from a regular surface to an irregular, potentially destabilizing surface compared to level, overground walking. Impaired regulation of whole-body angular momentum is significant because rotational momentum that is not cancelled can lead to the COM exceeding the base of support, and thus potentially leading to a fall [9].

This study seeks to determine how persons with PD and healthy, age-matched controls regulate their whole-body angular momentum when ambulating from a regular to an irregular surface compared to their normal, steady-state gait. We hypothesized that each health group would adjust their sagittal, frontal, and transverse whole-body angular momentum when overcoming a transition from regular to irregular terrain compared to level, overground walking. Furthermore, we also hypothesized that the Parkinson group would adjust their angular momentum when transitioning differently than the healthy group.

## METHODS

Ten persons that had been diagnosed by their primary treating neurologist with mild-to-moderate PD (6 male, 4 female; 67.7±6.7 years; 1.74±0.10m; 83.4±12.2kg) and five healthy, age-matched controls (2 female, 3 male; 66.6±6.8 years; 1.70±0.07m; 74.2± 13.0kg) were recruited for this study. This study was IRB-approved, and all participants provided informed consent. Participants wore tight-fitting clothes upon which 57 reflective markers were applied according to the Biomech 57 marker set [10,11]. The protocol asked participants to ambulate on a custom 9.75m long and 0.92m wide walkway that had two different surfaces, each covering half of the walkway: 1) Regular: oriented-strand board (OSB) covered in BEHR premium slate gray paint and premium NonSkid floor finish and 2) Irregular: OSB covered in faux rock panels (Model R3-RV-PN-MT, Regency River Rock, FauxPanels.com) (Fig. 1) until they expressed familiarity with the terrain. Once participants were comfortable, they ambulated from regular to irregular at least three times. A 14-camera motion capture system (OptiTrack; NaturalPoint Inc., Corvallis, OR) recorded marker trajectories at 120 Hz. Trajectory data were filtered using a 4$^{th}$ order, low-pass Butterworth filter at 6 Hz. The Parkinson group completed trials having taken their medication approximately 1 hour prior to data collection and expressed they felt to be in an "ON" medication state. A successful trial consisted of five consecutive steps (2 gait cycles) with the first two steps occurring on the regular surface and the final three steps occurring on the irregular surface. Following data collection with the surface transition present, participants ambulated on the same walkway with the surfaces removed as a control condition. Again, participants ambulated at least three times and the gait cycles used were those that began and ended at approximately the same start and end location on the walkway as if the transition had been present.

A 15-segment model was created for each participant (2 feet, 2 shanks, 2 thighs, pelvis, trunk, head, 2 arms, 2 forearms, 2 hands) in Visual3D (C-Motion Inc, Germantown, MD) to calculate the whole-body angular momentum about the three principal axes over the course

of a trial. The segmental contributions of inertia were summed together according to (1), where $\boldsymbol{L}$ is whole-body angular momentum, $\boldsymbol{I_i}$ and $\boldsymbol{\omega_i}$ are the moment of inertia and angular velocity of the i-th segment, respectively, $\boldsymbol{r_{COM}}$ is the distance from the body COM to the COM of the i-th segment, $m_i$ is the mass of the i-th segment, and $\boldsymbol{v_i}$ is the translational velocity of the i-th segment.

$$\boldsymbol{L} = \sum_{i=1}^{n}[\boldsymbol{I_i\omega_i} + \boldsymbol{r_{COM}} \times m_i\boldsymbol{v_i}] \quad (1)$$

We defined positive sagittal $\boldsymbol{L}$ as rotating forward, positive frontal $\boldsymbol{L}$ as rotating left with respect to the direction of travel, and positive transverse $\boldsymbol{L}$ as rotating left. All trials were normalized to participant body mass, height, walking velocity, and 100% of 2 gait cycles. Trials were reflected as necessary to have the left leg always lead across the transition and three trials from each participant for both the transition trials and control trials were averaged together to create an ensemble average. The results for sagittal, frontal, and transverse $\boldsymbol{L}$ were compared between surface conditions for each health group using non-parametric, two tailed, statistical parametric mapping paired t-tests. To compare health groups the sagittal, frontal, and transverse $\boldsymbol{L}$ for the transition condition were compared using a non-parametric, two tailed, two sample, statistical parametric mapping t-test (alpha=0.05).

**Figure 1: Overhead view of walkway, 5 steps used for analysis, and walking direction of trials. The control condition (not pictured) consisted of exposed, oriented-strand board.**

## RESULTS

The comparison between health groups for the transition condition revealed no significant differences in $\boldsymbol{L}$. When comparing each health group separately to the control condition, the healthy group did not exhibit significant differences between the transition and control condition while the Parkinson group did (Fig. 2). The Parkinson group significantly altered their sagittal $\boldsymbol{L}$ from 54-68% and 84-100% of the first gait cycle. They also altered their transverse $\boldsymbol{L}$ from 52-60% of the first gait cycle.

## DISCUSSION

This study provides evidence that persons with PD regulate their whole-body angular momentum differently than healthy, age-matched controls when transitioning from a regular surface to an irregular surface. Our study indicates that persons with PD adopt a distinct and consistent strategy to cross the surface transition. This strategy consisted of temporally arresting their sagittal $\boldsymbol{L}$ the step prior to the transition (25% Fig.2) followed by an immediate increase in sagittal $\boldsymbol{L}$ as the leading limb crossed the transition to step onto the irregular surface (50% Fig.2). The reduction was facilitated by early cancellation if the transverse $\boldsymbol{L}$ that began just prior to the second step of the trial (25% Fig.2). These findings coincide with the recent literature [8] that found persons with PD regulate their sagittal $\boldsymbol{L}$ differently than healthy, age-matched controls in alternative conditions, such as stair ascent and descent, but not in level, overground walking. Consequently, the results of this study support that investigations of momentum regulation in persons with PD should focus on scenarios and activities of daily living outside of level, overground walking to better understand where the impaired ability to regulate movement and gait in persons with PD may be most significant in terms of safety.

The present study has several strengths and limitations. It is the first to investigate regulation of whole-body angular momentum in persons with PD when ambulating from a regular to an irregular terrain. Furthermore, it investigated differences over two gait cycles, which gives a more complete picture of how momentum regulation changes over time. However, this study is limited by the small number of participants, which reduced the statistical power. We suspect this is why there were no significant differences between health groups even though the Parkinson group was significantly different than the control surface while the healthy group was not. Further work should investigate a larger study population as well as steady-state gait on different surfaces to confirm if the results we observed at the beginning and end of the trials are generalizable.

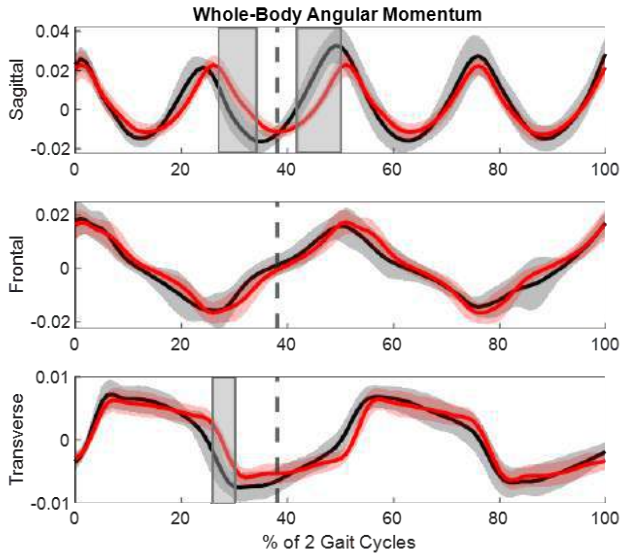

**Figure 2: Mean and standard deviation whole-body angular momentum results for the Parkinson group about the three principal axes for the Transition(BLACK) and Control(RED) conditions. Vertical dashed line represents when they crossed the transition and the grey boxes indicate significance at an alpha level of 0.05.**

# DISTORTIONAL STRAIN DEFINITION FOR FINITE ELEMENT FRACTURE HEALING ALGORITHM

**George Morgan (1), Hana Fox (1), Lucas Low (1), Arul Ramasamy (1,2,3), Spyros Masouros (1)**

## INTRODUCTION

Fracture healing is a complex process involving various mechanical and biological parameters, and failed or delayed healing can lead to additional surgeries and mortality risk. The ability to predict accurately fracture healing can inform surgical planning and fracture fixation device design. Fracture healing algorithms, such as the Ulm Fracture Healing Model [1], simulate healing times and outcomes and can be used to compare different fixation methods and configurations. These algorithms model callus ossification based on the mechanical strain environment at each location in the callus. Volumetric and distortional strains are used to represent the strain environment as each governs mostly separate biological processes. A finite-element (FE) model of the fracture and fixator calculates the strains due to expected external loading, and the healing algorithm calculates updated material properties for each callus finite element, and the simulation is repeated in an iterative process.

Despite the generally accepted good performance of healing algorithms when axial loading is applied, there is a significant limitation in the ability to predict the effect of torsional loading on healing; they often predict non-union even for low levels of torsion, for which the clinically observed outcome is usually delayed union [2]. Torsional loading creates high levels of distortional strain, which healing algorithms classify as 'destructive' levels, leading to the prediction of non-union. However, one variation of a healing algorithm successfully predicted delayed union under torsional loading by arbitrarily raising the threshold for 'destructive' distortional strain within the model [2].

Distortional strain is often defined in healing algorithms as octahedral shear strain (Equation 1) [1,2]. An alternative distortional strain definition (Equation 2) is derived similarly to von Mises equivalent stress and includes a dependence on material properties; this definition, therefore, is relevant in situations where material properties change over time, such as in fracture healing algorithms. The coefficient of the alternative strain definition is set such that the two strain definitions are equal at a Poisson's ratio of 0.3, representing the initial soft tissue callus [1]. However, as healing progresses and the callus differentiates into cartilage and bone, and as the Poisson's ratio increases, the alternative strain decreases, effectively raising the threshold for 'destructive' distortional strain.

$$\varepsilon_{oct} = \sqrt{\frac{1}{2}[(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_2 - \varepsilon_3)^2 + (\varepsilon_3 - \varepsilon_1)^2]} \quad (1)$$

$$\varepsilon_{alt} = \frac{1.3}{1+\nu}\sqrt{\frac{1}{2}[(\varepsilon_1 - \varepsilon_2)^2 + (\varepsilon_2 - \varepsilon_3)^2 + (\varepsilon_3 - \varepsilon_1)^2]} \quad (2)$$

This study compares effect of octahedral and alternative strains, as well as an arbitrarily raised 'destructive' strain threshold, on fracture healing algorithms simulating torsional loading.

## METHODS

An FE model was developed in MSC.Marc (v2021, MSC.Software) of a simple transverse mid-diaphyseal tibial fracture secured with an intramedullary nail with a pre-defined callus region. The tibia was represented as a hollow cylinder 100 mm in length, with outer diameter and thickness of 17 and 3 mm, respectively, with a 3 mm fracture gap. The intramedullary nail was modelled as an axial-torsional spring [2]. A mesh of 151,628 linear tetrahedral elements was used with an average callus element size of 1 mm. The material properties for each tissue type in the model are given in Table 1 [1].

**Table 1: Material properties of model tissue types [1].**

| Tissue Type | Young's Modulus (MPa) | Poisson's ratio |
|---|---|---|
| Lamellar bone | 10,000 | 0.36 |
| Woven bone | 4,000 | 0.36 |
| Cartilage | 200 | 0.45 |
| Connective tissue | 3 | 0.30 |

A fracture healing algorithm was developed based on the Ulm Fracture Healing Algorithm [1], which assumes maximum callus perfusion [2]. The algorithm was run with: (a) a 400 N axial compressive load case, a combined axial-torsional load case with a 1 Nm moment about the medullary axis using the (b) octahedral and (c) alternative strain definitions, and (d) a combined axial-torsional load case using octahedral strain with an arbitrarily raised threshold for 'destructive' distortional strain. Each simulation was run for 30 iterations, representing 30 days.

Callus torsional rigidity was quantified at each iteration by removing the fixator from the FE model and applying a pure torsional load. Fracture healing progress was quantified by the torsional rigidity at each iteration normalized to the rigidity of a fully-ossified callus [2].

## RESULTS

The normalized torsional rigidity over 30 iterations for each of the cases (a-d) is shown in Figure 1. The number of iterations required to reach 20% normalized torsional rigidity was 20, 27, 27, and 26 iterations for cases a-d, respectively. The normalized torsional rigidities at iteration 30 were 40.4%, 28.6%, 29.1%, and 35.1%, for cases a-d, respectively.

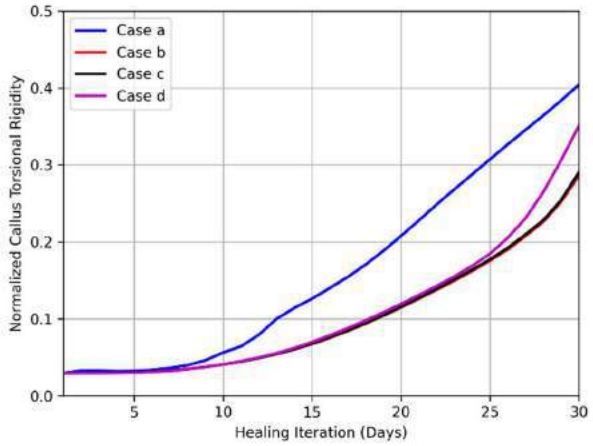

**Figure 1: Normalized callus torsional rigidity for healing algorithms with case: (a) axial loading and octahedral strain, (b) axial-torsional loading and octahedral strain, (c) axial-torsional loading and alternative strain, (d) axial-torsional loading and octahedral strain with a modified threshold for 'destructive' distortional strain.**

## DISCUSSION

The algorithm using an axial compressive load (case a) predicts the fastest fracture healing rate, as expected for an 'uncomplicated' loading regime. The algorithm with combined axial-torsional loading and an arbitrarily raised threshold for 'destructive' distortional strain (case d) predicts a delayed healing, as expected physiologically for low levels of torsional loading, and agreeing with similarly modified algorithms [2].

The algorithms using octahedral (case b) and alternative (case c) strain definitions with combined axial-torsional loading predicted the slowest healing rates and yielded the same healing rate at day 30. This is expected, as the two strain definitions are equivalent in the initial stages of healing when the callus is composed of connective tissue. However, as the torsional rigidities, and therefore the material properties, of the two cases diverge, the values of the two strain definitions will diverge, leading to a greater difference in algorithm outputs in the following iteration, thereby forming a positive feedback loop. Therefore, future works should examine the difference between these two strain definitions for simulations with a greater number of total iterations.

Elements with high distortional strains are primarily located at the bone-callus interface in the fracture gap region. This is caused by the glued contact model used at the bone-callus interface and the load transfer from a 'hard' material (cortical bone) to a 'soft' material (callus tissue). It is possible that a non-glued contact condition is more physiologically accurate and can reduce these distortional strain artifacts. Alternatively, a separate healing algorithm formulation could be used for a boundary layer model at the bone-callus interface.

This study compares an alternative definition for a distortional strain scalar against the commonly used octahedral shear strain for use in fracture healing algorithms. These results show minor differences between the strains in the outputs of the algorithm, however, a greater number of iterations in future simulations is likely to lead to greater differences between the two strain definitions.

# HOW SIGNAL-TO-NOISE RATIO IMPACTS THE APPARENT STIFFNESS OF BRAIN TISSUE IN MR ELASTOGRAPHY AT 7T

**Emily R. Triolo (1), Oleksandr Khegai (2), Jelle Veraart (3) Akbar Alipour (2), Priti Balchandani (2), Mehmet Kurt (1,2)**

## INTRODUCTION

Magnetic resonance elastography (MRE) is a technique for determining the mechanical response of tissues using applied harmonic deformation and motion-sensitive MRI[1]. Studies using MRE to investigate the mechanical properties of the human brain are most commonly performed at conventional field strength (3 Tesla (T) or 1.5T), although there have been a few attempts at the ultra-high field strength, 7T[2,3]. Aiming for higher resolution scans of the human brain at 7T, MRE presents unique challenges of decreased signal-to-noise ratio (SNR) and lower shear wave motion sensitivity. Additionally, it has been shown that quantitative values of MRE, i.e., the magnitude of the complex shear modulus estimate (|G*|), are sensitive to changes in SNR[4], so 7T MRE can present a challenge of not only quality, but accuracy. While applying commonly-used filtering techniques (e.g., Gaussian, Median) to MRE phase data can increase SNR (to combat low SNR in high-resolution scans), this can also blur fine physiological features, decrease the effective resolution[5], resulting in artificially increased |G*|[4]. We increase the SNR of our MRE acquisition without comprising the anatomical accuracy and spatial resolution by utilizing a Marchenko-Pastur Principal Component Analysis (MP-PCA) denoising algorithm[5]. In this technique, we are exploiting the intrinsic redundancies in MRE acquisition to identify and remove noise-only principal components[5].

In the most recent studies comparing 1.5T, 3T, and 7T MRE of the human brain, MRE at 7T and 1mm resolution resulted in significantly lower stiffness values than MRE at 1.5T and 3T at 2mm resolution[3,6]. However, one study indicated that when down sampled to 2mm, the 7T MRE results matched the traditional MRE field strength results, but in a second study, the difference remained[3,6]. In the past, we have shown that changes in resolution and field strength do not inherently change the value of |G*| in a linear elastic phantom[7]. However, MRE of phantoms typically have very high SNR, even at high resolutions, so this decrease in SNR as resolution increases may not have a large effect on scans with inherently high SNR. For MRE of the human brain however, SNR drastically drops with increasing resolution, very likely causing an artificially low |G*| calculation.

In this abstract, we will be investigating the effect of SNR on calculated |G*| in both a linear elastic phantom and the human brain using 7T MRE. We will therefore also be investigating how increasing SNR using MP-PCA denoising will change |G*| in scans that have inherently high SNR (phantom) and scans that have low SNR (human brain).

## METHODS

Full brain coverage MRE was performed on one healthy human subject at 1.7mm, 1.3mm, and 1.1mm isotropic resolutions at 50Hz vibration frequency, using a 32-channel head coil (Nova Medical) on a 7T Siemens Magnetom MRI Scanner. MRE was also performed on a custom silicone MRE phantom (CIRS 049) at 2.5mm, 1.3mm, and 1.1mm isotropic resolutions. The designed MRE sequence was a modified single-shot multi-slice spin-echo 2D-EPI sequence with trapezoidal flow-compensated motion encoding gradients (MEGs)[8], synchronized with the pneumatic acoustic actuator (Figure 1)[7] by TTL triggering at the beginning of every TR (TR/slice=140ms, TE=65ms,

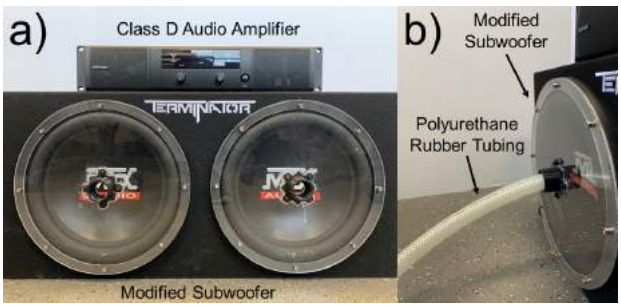

**Figure 1: Custom pneumatic actuator**

GRAPPA=3). Human brain images were masked using BET (Brain Extraction Tool) of FSL package[9] while phantom images were manually masked, denoised using a MP-PCA algorithm[5], and unwrapped using a Laplacian-based technique[10]. Curl filtering, Fourier decomposition, and a quartic smoothing kernel (scaled for resolution based on our previous investigation[7]) were used to acquire wavefield images, before Algebraic Inversion of the Helmholtz Equation was used to calculate the complex shear stiffness[11]. For the human brain, whole brain average stiffness was calculated (Figure 2), while for the phantom scans the mean of each stiffness map of five homogeneous slices per scan were calculated and compared using a one-way ANOVA. We then calculated the average octahedral shear strain-based SNR (OSS-SNR) for both original and denoised displacement data at each resolution[12].

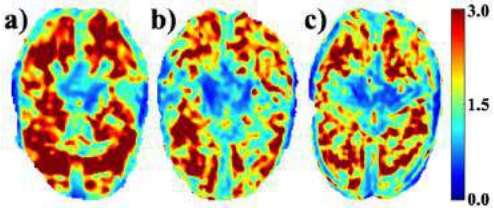

**Figure 2: Elastograms showing |G*| in kPa at (a) 1.7mm, (b) 1.3mm, and (c) 1.1mm isotropic resolution.**

## RESULTS

Looking at our average |G*| for the phantom results, we find no statistically significant difference between any resolution, nor between original and denoised. We also find that while denoising does increase the average OSS-SNR for a specific resolution, the average OSS-SNRs for all data sets are above 100 (Table 1).

**Table 1: Average |G*| and OSS-SNR in Phantom**

| | | 2.5mm | 1.3mm | 1.1mm |
|---|---|---|---|---|
| **|G*| (kPa)** | **Original** | 1.425±0.007 | 1.430±0.005 | 1.423±0.012 |
| | **Denoised** | 1.425±0.005 | 1.430±0.005 | 1.423±0.110 |
| **OSS-SNR** | **Original** | 953.7±248.1 | 195.8±39.8 | 115.9±23.9 |
| | **Denoised** | 980.6±274.5 | 247.5±50.0 | 153.7±20.9 |

For the human brain, on the other hand, average OSS-SNR ranges from 3.5 through 11.5. Once again, applying denoising increases the average OSS-SNR for each resolution. Also different from the phantom results, the average |G*| differ both between resolutions and between original and denoised data. Generally, |G*| increases with increasing OSS-SNR, but it appears to not be a perfectly linear relationship between resolutions (Figure 3).

## DISCUSSION

Based on the whole-brain stiffness estimates (|G*|) and SNR values, within-resolutions, denoising using the MP-PCA algorithm substantially increases the OSS-SNR and therefore increases |G*|. It also appears, based on the results of the phantom experiments, that increasing OSS-SNR only increases |G*| to a point, at which point additional increases in OSS-SNR using denoising will not significantly affect the |G*|. The benefit of using PCA-based denoising as opposed to other filtering techniques is that denoising maintains the physiological structures within the human brain and helps prevent over-smoothening/overfitting (Figure 4). This increased accuracy and sensitivity is of particular importance for smaller brain features, for example, the hippocampus when investigating changes due to Alzheimer's disease or dementia.

However, there appears to be a more complex relationship between OSS-SNR and |G*| between resolution likely due to the post-processing

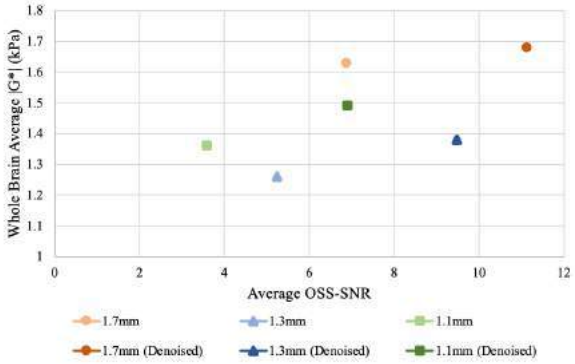

**Figure 3: The relationship between whole brain stiffness (kPa) and average OSS-SNR**

steps taken between displacement calculation and stiffness estimation. Additionally, the 1.7mm resolution scan appears to have an overall higher average |G*| than the 1.3mm and 1.1mm resolution scans, somewhat matching the increase in OSS-SNR values, which can be confirmed with further replicates. This potentially implies that additional fine viscoelastic features are detected at higher resolutions, decreasing the wavelength-based stiffness estimate, supporting the hypothesis of Barnhill, et al.[3]. Overall, to better understand these trends,

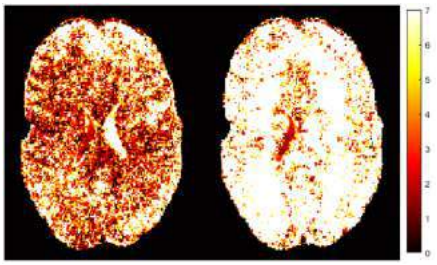

**Figure 4: OSS-SNR map comparison between original (left) and MP-PCA denoised (right) data at 1.1mm resolution**

we will continue to perform MRE at 7T on healthy human subjects at these three representative resolutions to better characterize the effects of both differing resolutions, change in field strength (3T versus 7T), and denoising on complex stiffness estimations of the human brain. Additionally, we will also implement a more complex segmentation algorithm to both investigate stiffness of specific subregions of the human brain.

In conclusion, our pilot study has shown a substantial increase in OSS-SNR after the use of MP-PCA denoising algorithm on the complex displacement data generated during MRE at 7T, and has shown a relationship between resolution, OSS-SNR, and |G*| that requires further investigation with a larger cohort of subjects.

# INTERVERTEBRAL DISC GEOMETRY AND HYDRATION ARE ALTERED FROM IN VIVO TO SEGMENT PREPARATION FOR MECHANICAL TESTS

**Harrah R. Newman (1), Natalie A. Thurlow (2), Kyle D. Meadows (1), Adriana Barba (3), Thomas P. Schaer (3), Edward J. Vresilovic (1), Dawn M. Elliott (1)**

## INTRODUCTION

Numerous studies have quantified cadaveric intervertebral disc structure, composition, and mechanical behavior. Cadaveric disc mechanical tests are frequently interpreted in the context of *in vivo* disc function for research related to back pain, degeneration, surgery, implants, computational models, engineered discs, and mechanobiology. However, there are substantial differences in the physical constraints and boundary conditions between *in vivo* and *ex vivo* multiple and single segment discs, which alter disc size, shape, hydration, pressure, residual stress, and mechanical behaviors. In many *ex vivo* studies, segments are pre-loaded in an attempt to mimic *in vivo* axial compression and are kept in a buffered bath solution to mimic *in vivo* hydration and fluid exchange. However, the differences that arise between the *in vivo* and *ex vivo* conditions are unknown, limiting our ability to mimic them experimentally, and complicating our ability to interpret cadaveric study outcomes for the *in vivo* disc. The objective of this study is to assess geometric and hydration differences between *in vivo* and *ex vivo* conditions using repeated magnetic resonance imaging (MRI) in the porcine spine. The *in vivo* condition will be represented by the Physiological group and the *ex vivo* condition will be represented by the Multilevel group and Segment group (**Fig 1**).

## METHODS

Repeat 3T MRI were acquired at room temperature on the L1-L2, L3-L4, and L5-L6 discs from Yucatan minipigs in three conditions (**Fig 1**): P**hysiological** (intact torso within two hours of sacrifice, n = 4 pigs, 12 discs), **Multilevel** (fresh-frozen intact excised spine extending from mid-thoracic to caudal, n = 8 pigs, 24 discs), and **Segment** (fresh-frozen vertebra-disc-vertebra motion segments with facets intact, n = 8 pigs, 24 discs).

Following the MRI of Physiological condition, the spine was dissected out to the Multilevel condition. The sample was wrapped in PBS-soaked gauze and frozen. The Multilevel was thawed, imaged, then dissected down to the Segment condition. Each segment was wrapped in PBS-soaked gauze and frozen, then later thawed and imaged.

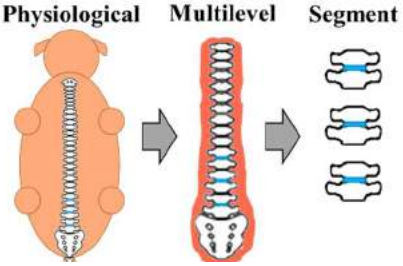

**Figure 1:** Spine condition groups shown with discs of interest in blue.

The variation in sample size, particularly for the Segment condition, required several changes for MRI acquisition. A methodology check was performed to ensure that changes in image resolution and MRI reception coil did not independently induce changes in $T_2$ relaxation time. Discs (n=2) were imaged across a variety of conditions (**Table 1**) in the same scanning session and the $T_2$ times were evaluated.

**Table 1:** T2 CPMG MRI changes between the Multilevel scan (#1) and Segment scan (#4). Change from previous case highlighted.

| # | Condition | MRI Coil | Image Resolution (mm) |
|---|---|---|---|
| 1 | Multilevel | Table/Spine | 0.47 x 0.47 x 3 |
| 2 | Multilevel | Table/Spine | 0.39 x 0.39 x 3 |
| 3 | Multilevel | Knee | 0.39 x 0.39 x 3 |
| 4 | Segment | Knee | 0.39 x 0.39 x 3 |

Two MRI sequences were used to evaluate differences between the conditions: a $T_1$-weighted FLASH sequence with in-plane resolution of at least 0.47 mm and slice thickness of 3 mm for assessing geometry, and a $T_2$-weighted CPMG sequence with in-plane resolution of 0.3-0.6

mm, TE = 13.6, 27.2, … 340 ms and TR = 3000 ms for quantifying $T_2$ relaxation time. Total scan time was less than an hour per condition.

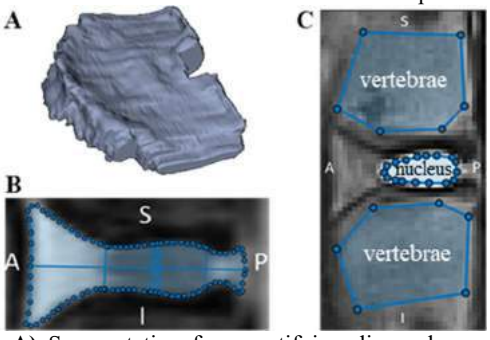

**Figure 2: A)** Segmentation for quantifying disc volume. **B)** MRI FLASH scan with outline for disc area, horizontal line for anterior-posterior disc width, and vertical lines for showing nucleus boundary and central vertical lines for calculating central NP height shown. **C)** MRI $T_2$ scan, nucleus and vertebrae ROIs shown.

The disc volume was calculated from segmentations of the $T_1$ images using ITK-SNAP (**Fig 2A**). The disc mid-sagittal height, anterior-posterior width, and area were calculated using a custom MATLAB code (**Fig 2B**). The $T_2$ relaxation times, which are positively correlated with hydration, were evaluated in the nucleus pulposus (NP) and adjacent vertebral bodies (VB). The $T_2$ times were calculated from the $T_2$-weighted echoes by fitting the intensity decay in the regions of interest (ROIs) to noise-corrected exponential fits [1] (**Fig 2C**). For statistical assessment, mixed model fits with fixed effect of condition, random effect of specimen, and post-hoc pair-wise Tukey tests were conducted. The significance was set at $p < 0.05$.

## RESULTS

From the altered scanning methods check, the $T_2$ relaxation time was within 10 ms for the nucleus ROIs and within 3 ms for the vertebrae ROIs (**Fig 3**), therefore the change in scanning coil and resolution did not impact study findings.

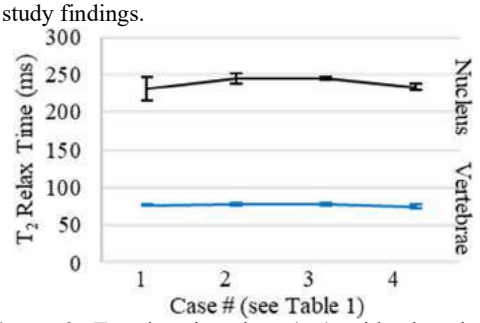

**Figure 3**: $T_2$ relaxation time (ms) with altered scan conditions. Average +/- standard deviation

For the conditions of interest, the disc volume increased 19% from Physiological to Segment (Fig 4A). The mid-sagittal NP height increased by 6% from the Physiological to Multilevel and by 17% from the Physiological to Segment (Fig 4B). The mid-sagittal width decreased 11% from Physiological to Segment (Fig 4C). There were no significant changes in mid-sagittal area (not shown). The NP $T_2$ time decreased by 7% from Physiological to Multilevel and by 13% from Physiological to Segment, while in the adjacent vertebrae the $T_2$ time increased 63% from Physiological to Multilevel and Segment (Fig 4D).

## DISCUSSION

Although a live, *in vivo* MRI was not performed, the Physiological condition is reasonably represented by the immediate post-mortem torso because *in vivo* MRI is generally performed in a relaxed supine position which minimizes axial load, and *in vivo* MRIs in animal models of the spine are performed under anesthesia which further eliminates active muscle contraction [2].

The Segment condition had substantially less surrounding tissue compared to the other conditions and required MRI scan modifications; however, they did not significantly alter the $T_2$ time of the NP (**Fig 3**).

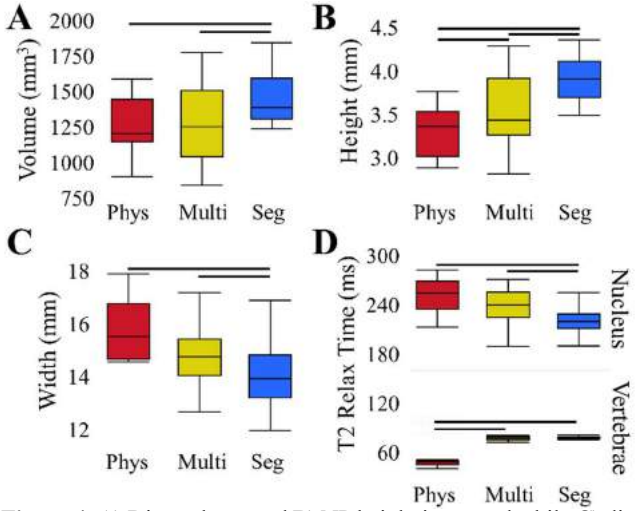

**Figure 4**: **A)** Disc volume and **B)** NP height increased while **C)** disc width decreased across conditions. **D)** NP $T_2$ time decreased but VB $T_2$ time increased across conditions.

*In vivo* spines are constrained and loaded by the surrounding muscles, ligaments, and body forces, causing pressurization and residual strain in the disc tissues. These *in vivo* constraints and loads are progressively removed when spines are dissected for *ex vivo* testing. This study showed that dissection alters disc geometry, leading to increased disc volume without changes in mid-sagittal area, increased mid-sagittal height, and decreased mid-sagittal anterior-posterior width. The driving cause of the significantly increased volume is likely the increased disc height resulting from a larger reduction of the loading constraints in the axial direction with soft tissue dissection. The reduced sagittal width could be related to release of annulus fibrosus circumferential residual strain. Future work will evaluate the changes between conditions in both the sagittal and coronal planes to enable a multi-dimensional perspective for understanding the geometric changes that arise between conditions. $T_2$ time is known to correlate with water concentration [1] and measurable changes in water content were not expected in the NP. This reduction in T2 time suggests a decrease in water concentration, likely from water redistribution within the larger volume disc. Alternatively, the disc could have lost water to the adjacent vertebrae, which had an increased $T_2$ time, though no previously understood mechanism underlying this fluid exchange is known. Collectively, these geometric and hydration changes will alter segment mechanical behaviors. While the effects of spinal dissection have been quantified here, further study is ongoing to restore cadaveric spinal segments to the *in vivo* state for testing and modeling.

# THE LONG HEAD OF THE BICEPS TENDON UNDERGOES MULTIAXIAL DEFORMATION DURING SHOULDER MOTION

**S. Cyrus Rezvanifar, PhD (1), JJ Lamb (2), Miles F. Wing (2), Arin M. Ellingson, PhD (1), Paula M. Ludewig, PhD (1), Victor H. Barocas, PhD (2)**

(1) Department of Rehabilitation Medicine, University of Minnesota, Minneapolis, MN, USA
(2) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

## INTRODUCTION

The shoulder joint is one of the most complex joints in the human body, and within this joint, the long head of the biceps tendon (LHBT, Figure 1) is a common source of injury and pain. In a study of 141 shoulders with complete rotator cuff tears, 36.1% also had LHBT pathology [1]. Despite LHBT common pathologies such as tendon rupture, tendinopathy, instability, and superior labrum anterior and posterior (SLAP) lesions and tears [2], diagnosis and treatment remain relatively poorly understood and controversial [1, 3]. While many shoulder and LHBT pathologies are thought to be symptomatic, a study of 21 asymptomatic Major League Baseball pitchers revealed that 11 pitchers had a rotator cuff tear, 10 had a SLAP tear, and it was unclear whether there were pitchers who had both [4]. Therefore, a deeper understanding of the LHBT mechanical environment and underlying mechanisms of its pathologies is of great importance. The purpose of this study was to develop a subject-specific finite element (FE) model of the shoulder joint to investigate the stress/strain response of the LHBT across the simulated range of motion.

**Figure 1. Demonstration of glenohumeral anatomy; LHBT passes under the THL and through the bicipital groove [5].**

## METHODS

*Geometry and mesh*

MRI scans of a right shoulder (48-year-old female) were reconstructed using Mimics (Materialise, Leuven, Belgium) to create the 3D model of the shoulder joint. An initial 3D mesh was assigned to the 3D models using HyperMesh (Altair, Troy, MI) and the humerus, scapula, LHBT, and transverse humeral ligament (THL) were imported into FEBio [6]. Four-node tetrahedral elements (TET4) were used for all bony and soft tissue components of the model (Figure 2).

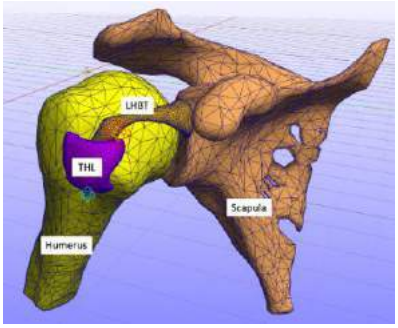

**Figure 2: Present FE model with bony and soft tissue structures**

*Boundary Conditions*

The scapula was fixed in place for all translational and rotational degrees of freedom, and all other motion happened relative to the scapula. The glenohumeral joint was defined via a "spherical joint rigid connector". The THL was fixed over the bicipital groove of the humerus. A frictionless sliding contact was defined between the LHBT and both the THL and the bicipital groove of the humeral surface to replicate in vivo conditions. The proximal end of the LHBT was rigidly connected to the superior rim of the glenoid, and a force with a

magnitude of 76.3 N was applied to the distal end of the LHBT to simulate native tension in the tissue.

*Material Properties*

The humerus and scapula were defined as rigid bodies, given the orders of magnitude greater stiffness compared to the soft tissues. The THL was modeled as a Neo-Hookean material with a bulk modulus of 600 MPa and a Poisson's ratio of 0.47. The material properties of the LHBT, as the tissue of focus in this study, was obtained by fitting a fiber-reinforced transversely isotropic Mooney-Rivlin model (Eq. 1) to previously published experimental data of uniaxial tensile tests on LHBT cadaveric tissues [7, 8].

$$W = C_1(I_1 - 3) + C_2(I_2 - 3) - 2(C_1 + 2C_2)\ln J + \frac{1}{2}k(\ln J)^2 + W_{fib} \quad (1)$$

where $C_1$, $C_2$, and k are material parameters, $I_1$ and $I_2$ are first two deviatoric invariants of the Cauchy Green deformation tensor (C), and J is the Jacobian of the deformation gradient tensor F [6]. The fiber contribution $W_{fib}$ is used to describe the mechanics in terms of three regimes (compressed, uncrimping, and uncrimped). Writing in terms of the first Piola-Kirchhoff stress $P_{fib}$,

$$P_{fib} = \begin{cases} 0 & \lambda_{fib} \le 1 \\ C_3\left(e^{C_4(\lambda_{fib}-1)} - 1\right) & 1 < \lambda_{fib} \le \lambda_{unc} \\ C_5\lambda_{fib} + C_6 & \lambda_{unc} < \lambda_{fib} \end{cases} \quad (2)$$

where $\lambda_{fib}$ is the fiber stretch ratio, the parameter $\lambda_{unc}$ is the stretch ratio at which the fiber is fully uncrimped, and the parameters $C_3$ - $C_6$ describe the mechanical behavior and are specified so that $P_{fib}$ is continuous and differentiable at $\lambda_{unc}$. The acquired material parameters were imported into FEBio software to study LHBT mechanical behavior during simulated glenohumeral motion.

*FE Simulated Motion*

In vivo joint kinematics during arm elevation acquired through our previous study [9] were used to drive the simulation. With the scapula fixed to the global reference frame, humeral motion started from a neutral arm position at side and ended at 90° of scapular plane abduction with 90° external rotation to represent a wider range of motion.

## RESULTS

The material properties obtained from the two curve fittings are listed in Table 1.

**Table 1. Results of curve fit for the Mooney-Rivlin Model**

| Parameter | Kolz [7] | McGough [8] |
|---|---|---|
| **$C_1$ (MPa)** | 1.00 | 1.00 |
| **$C_2$ (MPa)** | 1.00 | 1.00 |
| **$C_3$ (MPa)** | 0.0503 | 2.83 |
| **$C_4$ (unitless)** | 112.5 | 42.7 |
| **$C_5$ (MPa)** | 190.9 | 358.6 |
| **$C_6$ (MPa)** | -195.2 | -361.8 |
| **$r^2$ of model fit** | 0.999 | 0.998 |

Maximum von Mises (effective) stress occurred at nearly 70° of glenohumeral abduction, with magnitudes of 85.2 and 152.6 (MPa) with parameters from Kolz and McGough data, respectively. At this joint position, both sets of parameters resulted in von Mises strains of approximately 1.3, as demonstrated in Figure 3. Interestingly, a plateau (indicated by black arrow in Figure 3) was observed in the stress despite the continual increase in the strain measures.

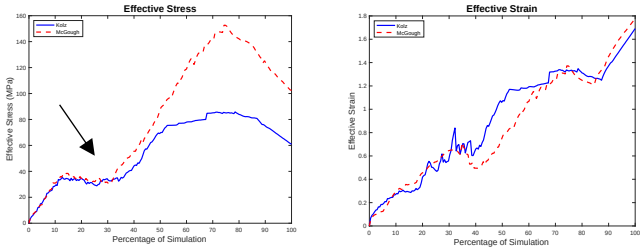

**Figure 3. Maximum von Mises stress (left) and strain (right) within the LHBT throughout the simulated range of motion**

Figure 4 demonstrates large stress and strain magnitudes occurring near the midpoint of LHBT where it is constrained with the THL and enters the bicipital groove.

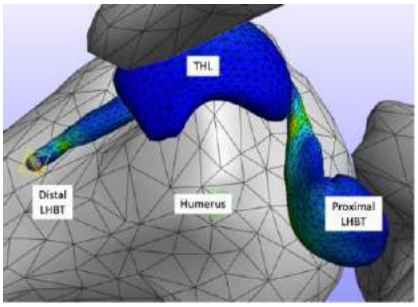

**Figure 4: Deformed LHBT near end range of motion.**

## DISCUSSION

This study was conducted to assess the viability of using uniaxial tension data to understand mechanisms of LHBT injury during FE simulated glenohumeral motion. The aforementioned plateau in stress concurrent with an increasing strain is evidence of complex multiaxial deformation within the LHBT during typical shoulder motion. Further experimental tests on cadaveric specimen, including bi-axial tension and combinations of tension and torsion, are needed to acquire realistic material properties. Our ongoing work will obtain and implement these material properties to provide a deeper understanding into the mechanisms of LHBT injury.

## ACKNOWLEDGEMENTS

The authors acknowledge the support from Carly Donahue for running and troubleshooting FE simulations.

# USING SMART PHONES TO SELECT HOUSEHOLD FABRIC FOR MAKING FACE COVERINGS: A CASE STUDY BY FDA, NIST AND HIGH SCHOOL STUDENTS

**Alexander Herman (1), Matthew Staymates (2), Salvatore Trupia (3), Victoria Guerrier (3), Glenda Garcia (3), Gloria Guerrier (3), and Suvajyoti Guha (1)**

(1) Division of Applied Mechanics, Office of Science and Engineering Laboratories, U.S. Food and Drug Administration (FDA), Silver Spring, MD, USA
(2) Material Measurement Science Division, National Institute of Standards and Technology (NIST), Gaithersburg, MD, USA
(3) West Hempstead High School (WHHS), West Hempstead, NY, USA

## INTRODUCTION

Face coverings are a critical tool in the fight against the spread of airborne pathogens such as SARS-CoV-2, the virus behind the COVID-19 pandemic [1]. These face coverings have been shown to reduce transmission of viral aerosol particles both in the laboratories as well as in clinical settings [2]. However, effectively testing these face coverings for filtration efficiency (FE) and breathability, as seen in most studies testing face coverings, require sophisticated aerosol instruments in the range of $10,000 - $100,000 or more. In addition, lack of consistency across techniques also precludes the user from making clear choices on fabrics they can use to make their own face coverings. Very few studies to date have offered simple, and cheap means of characterizing FE of fabrics [3, 4]. These studies, however, have still been conducted in controlled environments by experienced researchers. To our knowledge, no studies have been conducted in real world settings by non-experts for characterizing FE of fabrics. The objective of this study is to report a cost-friendly (< $1000) method to characterize the performance of household fabrics against viral droplets that can be accomplished using handheld cell phones and the expertise of sophomore-level high school students within a public school system and compare it to traditional quantitative particle counting techniques and semi-quantitative fog visualization system.

## METHODS

Three different experimental setups at the FDA, NIST and WHHS were developed. A quantitative setup was used at the FDA, and semi-quantitative fog visualization system at NIST & WHHS. Each of these setups tested the same three fabrics: silk, flannel, and cotton pillowcase (PC) materials.

**Quantitative Measurements.** The experimental testing for the quantitative measurement was performed by the researchers at the FDA and based of a study by Guha et al. [5]. To minimize protocol differences across the various institutes, some notable differences from the previous study included use of a heater coil (Nickel 200) with a cotton wick instead of a nebulizer and water was replaced with 1% glycerin water. The remaining equipment used, such as the Aerodynamic Particle Sizer (APS, Model # 3321, TSI Inc.), was the same. A schematic of the setup is shown in Figure 1. For consistency with NIST set up, the orifice was designed to achieve 42 cm/s fluid velocity across the material under test. The APS was set up for four scans per sample, with the droplet source triggered for 3 seconds at 18-20 Watts during the 2nd scan. This was done with and without a do-it-yourself (DIY) coupon in the holder.

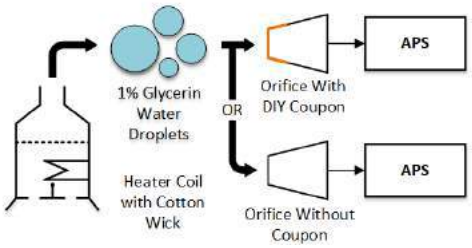

**Figure 1: Schematic of FDA's Lab experimental setup including the heater coil with wick and APS system.**

**Semiquantitative Measurements.** A pipe fog flow visualization system, shown in Figure 2, was developed at NIST to visualize fog droplets penetrating these fabrics. Specific details of this system can be found in Staymates [6]. High speed videography used to visualize fog droplets penetrating through various fabrics, and the video data was then processed with a custom image processing script in LabVIEW®. The experimental setup consisted of a 5 cm straight-walled pipe and a custom mounting flange. Flexible tubing connected the pipe system to a custom in-line fog generator that consisted of a cotton plug (soaked in an aqueous solution of 1% glycerin) wrapped with 20-gauge nichrome wire. A custom flow regulator system with 2 1.75 L accumulators controlled the flow to the fog generator. The particle size distribution of these droplets was measured with an APS (Model # 3321, TSI Inc.). A solid-state timer (Model # TMM-0999M-466, AMETEK Inc.) was used to pulse current into the fog generator for 2 seconds and provided a reasonably repeatable plume of fog droplets for each visualization experiment. Video data was collected with a high-speed camera (Model # NOVA S9, Photron USA, Inc.) at 125 frames per second.

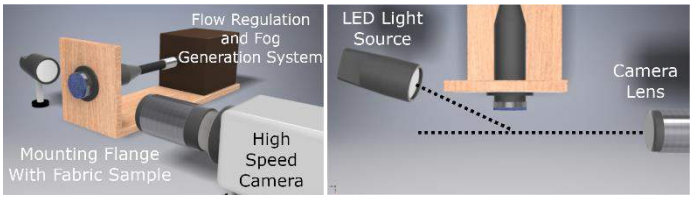

**Figure 2: Schematic diagram showing the NIST flow visualization system. (left) 3D rendering showing the highspeed camera, light source, flow regulation and fog generation system, and fabric mounting flange. (right)**

**High School Setup.** High school students in a sophomore-year science research class at WHHS built a set up like the NIST system (Figure 3 below). Water droplets were created with a commercially available ultrasonic nebulizer (Philips Respironics, InnoSpire Essence), while a light source (Model # Qualite 300, Impact Studio Lighting) was used to illuminate the droplets emerging through the fabric samples. A smartphone (Galaxy Note 20, Samsung Electronics Co., Ltd. and iPhone XR, Apple, Inc.) or digital single-lens-reflex (dSLR) camera (Model # T6i, Canon USA Inc.) was used to collect flow visualization footage. The fabric samples were tightly taped to the end of the 243mm tube connected to the ultrasonic nebulizer. The camera/phone was positioned such that the fabric sample was visible and located near the bottom of the field of view. A black curtain was used as a backdrop. The ultrasonic nebulizer was connected to a programmable timer (Model # AC 85V - 265V Cycle Timer Module, Pemenol) that ran the ultrasonic nebulizer for 4 seconds. Best results were obtained when the auto-exposure of the phone's camera was disabled.

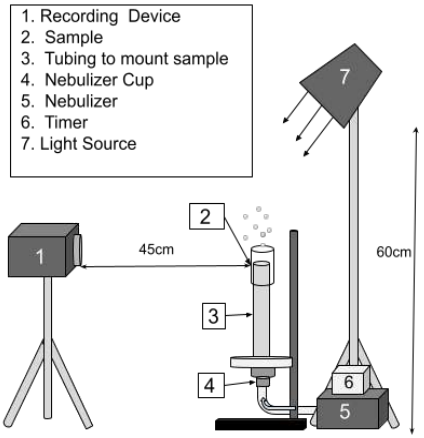

**Figure 3: Schematic diagram showing the High School flow visualization system.**

## RESULTS

**FDA Quantitative Analysis.** The size averaged FE shows the following order: Cotton PC > Flannel > Silk with the FEs aiming around 97.9%, 91.6%, and 65.4% respectively (Table 1). These results are consistent with prior findings for the same fabrics performed with water droplets [5].

**NIST and WHHS Semi-Quantitative Analysis.** When doing an image analysis of the data, all fabric samples produced smaller pixel intensities compared to the "open" scenario, so pixel intensity was normalized to the open case. Silk shows a roughly 20% decrease compared to open, the flannel shows a 60% reduction, and the pillowcase shows almost 90% reduction in pixel intensity. Qualitatively, when comparing the results from the 3 cameras from WHHS, the results show a similar trend in image intensity compared to the NIST data even in a less controlled environment (Figure 4).

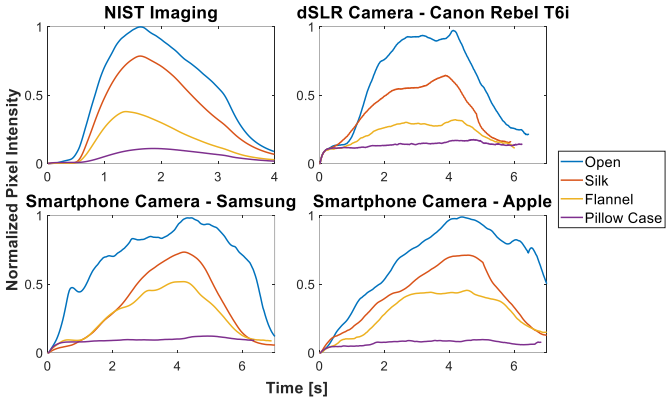

**Figure 4: Semi-quantitative image processing results from the WHHS and NIST flow visualization measurement system.**

An estimated FE can be derived by integrating the pixel intensity of each fabric and normalizing them to the pixel intensity with no sample (Open) and subtracting 1 from them (Table 1). There is a clear and observable trend between the correlation considering all the differences between experimental setups between the data sets (camera types, fog distributions, zoom, lighting, etc.) with no significant difference in the results between the visualization techniques (2 Factor ANOVA, $p<0.74$, $\alpha$-0.05). Inclusion of the FDA data into ANOVA analysis however, yielded $p<0.0233$ implying difference amongst the groups. The higher FEs reported with the FDA data across all three fabrics could have been because of electrical charges in the droplets at the time of aerosolization that may have enhanced dipole induced capture of the droplets on the fabrics, or from the over saturation of the smaller coupons used.

**Table 1: Estimated FE from the Image Analysis Data. Quantitative Data from the FDA shown as a comparison.**

## DISCUSSION

The flow visualization and imaging analysis method outlined here provides an easy and budget friendly method of determining the relative effectiveness of fabrics for homemade face masks, comparable to more professional methods. While there are significant differences in filtration efficiency values between the NIST and WHHS and laboratory FDA methods, the fabric-to-fabric trends overlap. These results suggest that anyone with a commercially available items that can be purchased for < $1000, can conduct these experiments and generate meaningful data that helps with the selection of fabrics for DIY face coverings and masks.

# EXERCISE THERAPY IMPROVES GLENOHUMERAL JOINT FUNCTION WHEN REACHING BEHIND THE BACK IN INDIVIDUALS WITH ROTATOR CUFF TEARS

**Luke T. Mattar (1), Rachel P. McLoughlin (1), Adam J. Popchak (3), William J. Anderst (2), Volker Musahl (1,2), James J. Irrgang (2,3), Richard E. Debski (1,2)**

## INTRODUCTION

Individuals with rotator cuff tears are generally prescribed non-operative treatment to improve pain and their ability to complete activities of daily living including personal hygiene and dressing that require one to reach behind their back. A tear involving the supraspinatus tendon may cause pain during these activities as the hand behind the back position has been shown to maximally stretch the supraspinatus[1]. Furthermore, posterior capsule tightness commonly seen in individuals with rotator cuff tears may contribute to experienced pain as the capsule is stretched during internal rotation when reaching behind the back. In regard to joint motion, reaching behind the back is a complex movement involving motion at the scapulothoracic, glenohumeral and elbow joints, where it is believed that the majority of internal rotation at the shoulder complex occurs before reaching the sacrum in healthy individuals[2].

Due to the movement's complexity and pain experienced by individuals with rotator cuff pathology, it is important to understand the effects of exercise therapy on one's ability to reach behind the back. Thus, the objective of the study was to assess changes in glenohumeral kinematics and arthrokinematics during a reaching behind the back movement in individuals with isolated supraspinatus tears before and after a 12-week structured and individualized exercise therapy program.

## METHODS

Eighty-three individuals (60.2 ± 9.3 years of age, BMI 28.4 ± 5.0) with a symptomatic rotator cuff tear isolated to the supraspinatus tendon were recruited after providing IRB-approved written informed consent prior to performance of any research procedure. Each individual participated in a 12-week structured and individualized exercise therapy program focused on restoring range of motion and strengthening of the rotator cuff and scapular muscles. To assess function, the individuals were asked to perform a behind the back task. Individuals began with their hand placed on their thigh and reached as far as they could behind their back. No specific instructions were given resulting in the individuals completing the task in their own manner. Glenohumeral kinematics and arthrokinematics were measured using a previously described and validated model-based tracking technique with images acquired from a synchronized biplane radiography system at 50 images/second[3].

Individuals underwent a computed tomography scan of the involved shoulder, and images were segmented to create individual specific bone models of the humerus and scapula. Digitally reconstructed radiographs of the bone models were created from the known geometry of the biplane radiography system. The bone models were then manipulated to match the digitally reconstructed radiographs to the corresponding bones in the biplane radiographic images in all 6 degrees of freedom for each pair of synchronized images throughout the movement. The local coordinate system for each humerus was constructed based on the International Society of Biomechanics recommendations with the origin located at the center of the humeral head. The scapula coordinate system was modified to create a glenoid based system to describe humeral motion with respect to the center of the glenoid. A X-Z-Y Euler angle rotation sequence was used to quantify translation and rotations with accuracy of ± 0.4mm and ± 0.5° for dynamic motion[3].

For each data frame, a 3D distance map was calculated between the humeral head and glenoid surfaces. The centroid of the 3D distance map was then quantified as the weighted average of the closest 200mm$^2$ region between the humeral head and glenoid surfaces and acted as an estimate of the contact center location. A contact path length was calculated as the change in frame-by-frame position of the contact center providing a quantification of the distance the humeral head articulated on the glenoid surface during the movement. A larger contact path length may indicate less joint stability as there is more movement of the humeral head on the glenoid surface. Three trials of the reaching behind the back movement were performed before and after exercise therapy. The trial on each day where maximum glenohumeral internal rotation was attained was used for all analyses. To compare glenohumeral kinematics and arthrokinematics, the common range of motion within each individual between testing days was utilized.

Outcome parameters include maximum glenohumeral anterior-posterior and superior-inferior translations (normalized to glenoid width and height, respectively), maximum glenohumeral internal rotation, and contact path length (normalized to glenoid size). Paired t-tests of Wilcoxon Sign Ranked tests were utilized to determine changes in maximum glenohumeral translations, maximum glenohumeral internal rotation, and contact path length following exercise therapy. Significance was set at $p<0.05$.

## RESULTS

All individuals completed the 12-week structured and individualized exercise therapy program. Maximum glenohumeral internal rotation significantly increased by 3.2° (12.5% in respect to before treatment) after exercise therapy (Table 1, $p=0.001$). Contact path length significantly decreased by 6.0% glenoid size (13.6% in respect to before treatment) after exercise therapy ($p=0.018$). No changes in maximum anterior, posterior, superior, or inferior translations occurred after exercise therapy ($p>0.05$).

**Table 1: Glenohumeral kinematics and arthrokinematics before and after a 12-week exercise therapy program.**

| | Before | After | p |
|---|---|---|---|
| Max. Internal Rotation (°) | 25.7 ± 13.9 | 28.9 ± 13.3 | 0.001 |
| Max. Ant. Trans. (% glenoid width) | 3.3 ± 4.0 | 3.7 ± 4.8 | 0.333 |
| Max. Post. Trans. (% glenoid width) | 3.2 ± 3.6 | 3.3 ± 3.8 | 0.823 |
| Max. Sup. Trans. (% glenoid height) | 2.7 ± 2.6 | 2.4 ± 2.4 | 0.068 |
| Max. Inf. Trans. (% glenoid height) | 2.4 ± 2.9 | 2.1 ± 2.4 | 0.709 |
| Contact Path Length (% glenoid size) | 44.0 ± 24.5 | 38.0 ± 21.2 | 0.018 |

## DISCUSSION

The primary findings of the study were that a 12-week structured and individualized exercise therapy program led to 1) improvements in maximum glenohumeral internal rotation and 2) decreased contact path lengths when reaching behind the back. The first finding suggests that individuals may be able to reach further behind their back due to increases in internal rotation after exercise therapy. Increases in maximum internal rotation likely occurred due to the prescribed stretching and exercise targeting passive range of motion[4]. The second finding may suggest that individuals have more joint stability when reaching behind the back after exercise therapy due to more control of the humeral head on the glenoid surface. The observed decrease in contact path length most likely occurred due to increases in compensatory muscle strength of the infraspinatus, teres minor, and subscapularis which are components of the transverse and coronal plane force couples of the glenohumeral joint, which have been shown to maintain joint stability in the presence of an isolated supraspinatus tear[5].

A previous study investigating glenohumeral kinematics in 15 healthy individuals using a dual fluoroscopy system found that individuals utilized 29.5° of glenohumeral internal rotation to reach L4-L5 when reaching behind the back[6]. Following exercise therapy in the current study, individuals utilized 28.9° of glenohumeral internal rotation, indicating that exercise therapy improved these individuals' internal rotation to levels comparable to that of healthy individuals. It has also been reported that during a reaching behind the back movement the majority of internal rotation at the shoulder complex occurs before reaching the sacrum[2]. After reaching the sacrum, reaching up the back is mostly comprised of elbow motion. Thus, since the individuals' glenohumeral internal rotation in the current study were comparable to healthy individuals, exercise therapy may improve one's ability to reach behind and up their back.

During our protocol, quantitative data on how far behind or up the back the individuals reached was not collected. This data may be important as vertebral level reached is commonly evaluated clinically. However, the current study provides novel information regarding glenohumeral kinematics and arthrokinematics in individuals with isolated supraspinatus tears before and after a 12-week exercise therapy program. Future studies will aim to quantify how far behind and up the back individuals in the current study reached.

# COMPUTATIONAL MODELING OF BRAIN BILAYER UNDER CEREBROSPINAL FLUID PRESSURE

## INTRODUCTION

The cerebral cortex is folded in some mammals, in contrast to others with a smooth brain surface. Folding patterns are a significant feature associated with the functionality of the brain, especially in humans. Lissencephaly, polymicrogyria, and microcephaly are among the various abnormalities that have been observed in folding patterns. Furthermore, these folding malformations have been linked to many neurological disorders, such as schizophrenia and autism spectrum disorder. The folding process is mainly known to result from mechanical instabilities induced by compressive forces and mechanical stresses. Several theories explain the folding mechanisms with respect to internal and external factors [1].

Focusing on the extrinsic constraints, early on researchers hypothesized that cortical folding happens during the embryogenesis period because the skull adds a constraint over the brain, which resists the tangential growth of the cortex. However, after the experimental results of a 1950s study showed the brain continued to normally develop after removing a piece of a sheep's cranium, researchers have lost their interest in this theory [2]. Therefore, most models consider the brain tissue without any external constraint and model gray and white matter as an isolated bilayer system. This approach has led to a comprehensive understanding of internal factors which form the gyri and sulci and addressed the importance of cortical growth, cortical thickness, and stiffness ratio between gray and white matter in brain folding [3, 4].

However, excluding the skull, other external constraints might contribute to brain instability and influence folding patterns. Here, we will focus on the cerebrospinal fluid (CSF) pressure as a non-zero stress boundary condition over the brain surface. CSF is a body liquid that circulates in the space between the brain surface and meninges, protecting the brain from external damage. The normal CSF pressure is between 0.2 kPa to 0.8 kPa on an infant's brain and 1.3 kPa to 2 kPa on an adult brain. In severe abnormal cases, the pressure might increase up to 6 kPa. The effect of CSF pressure on brain development and function has been proved in various studies, but its influence on the gyrification process of the brain has been understudied [5, 6].

## METHODS

We used the commercial software ABAQUS/Explicit to implement a three-dimensional finite element model of a bilayer with non-zero stress boundary conditions on the top and front faces, as shown in Figure 1. The whole model is subjected to a uniform compression imitating the growth-induced forces from the right side. CSF pressure is added as a follower surface traction on the top surface of gray matter, and the front face of the two layers is subjected to an in-plane pressure, replicating the influence of neighboring tissue boundaries on the bilayer system. The remaining sides are fixed due to the symmetry of the problem [7].

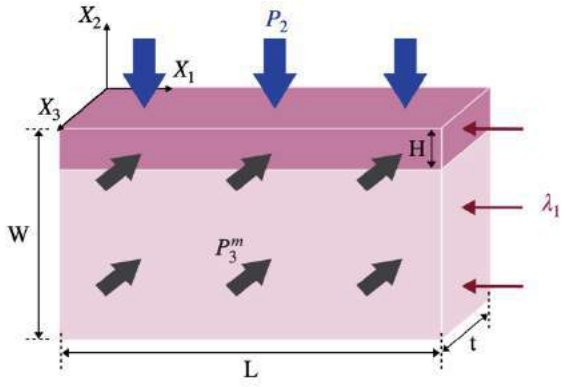

**Figure 1. Schematic of the bilayer system. The blue and black arrows imitate the CSF and the in-plane pressure, respectively, and the red arrows are uniform compression.**

Both gray and white matter are assumed to be nearly incompressible neo-Hookean hyperelastic materials with strain energy:

$$\Psi = \frac{1}{2}\lambda ln^2(J) + \frac{1}{2}\mu[tr(\mathbf{C}) - 3 - 2\ln(J)] \quad (1)$$

where $\mu$ and $\lambda$ are Lamé constants ($\lambda \gg \mu$) and $\mathbf{C}$ is the right Cauchy green tensor. We defined the stiffness ratio as the ratio between gray and white matter shear modulus, $\beta = \mu_f/\mu_s$, and the in-plane pressures are assumed to be a factor of surface pressure [8]:

$$P_3^f = 1.3P_2 \quad (2)$$

$$P_3^s = P_3^f/\beta \quad (3)$$

## RESULTS

We ran a total of 242 simulations, covering combinations of $\beta$ from 1.5 to 50 and CSF pressure from 0 to 2 kPa. The simulation results are presented, with an emphasis on the critical compressive strain and thickness variations. The critical buckling strain is identified by monitoring the total elastic strain energy in the cortex region; a sudden decrease in energy is assumed to indicate the buckling point. Then, the thicknesses of gyri and sulci regions are measured at this point and compared for multiple cases of pressure and stiffness ratios.

To investigate the effect of surface pressure on the stability of our bilayer system, we compared zero pressure cases for different stiffness ratios with non-zero pressure cases (Fig. 2). Adding pressure reduces the system's stability and makes the bilayer system buckle at smaller compressive strains, especially for stiffness ratios smaller than 4. Additionally, when we expand the range of stiffness ratios to $1.5 < \beta < 50$, the influence of applied pressure on the instability seems to vanish. This shows that the effect of pressure is only relevant for sufficiently low stiffness contrast, $\beta < 10$, and as the stiffness contrast between layers increases, it becomes very unstable regardless of the stress boundaries of surface pressure.

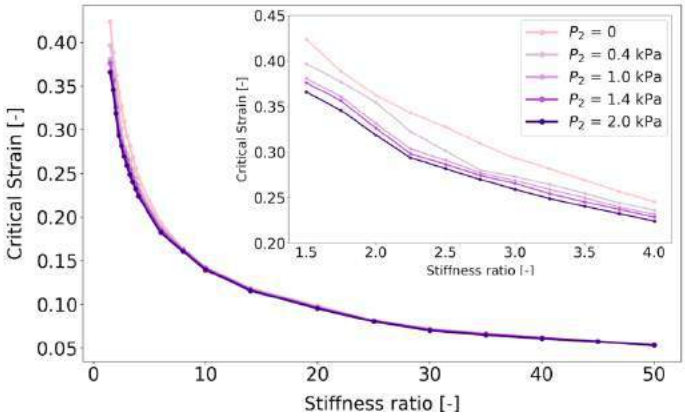

**Figure 2. Influence of pressure on stability for different stiffness ratios.**

Cortical thickness is a biomarker indicating the healthy and diseased condition of the brain. Generally, gyral regions are thicker than sulcal regions in the brain [9]. Here, we sought to find the influence of CSF pressure on thickness ratio throughout the folds of the brain. We compared the thickness of the cortex in gyrus and sulcus areas for four different pressure values, along with the zero-pressure case (Fig. 3). Here, we considered a region consisting of five elements along the between them. We defined the thickness ratio as the ratio between gyri and sulci thicknesses, $TR = t_g/t_s$, and measured the average ratio depending on the number of gyri and sulci for each simulation. We can see that adding surface pressure significantly influences thickness ratio, and when the amount of pressure is larger, the difference between sulcus and gyrus thicknesses increases. Also, we found that when the stiffness ratio between the layers increases, the thickness ratio decreases, which is in line with the previous data [9].

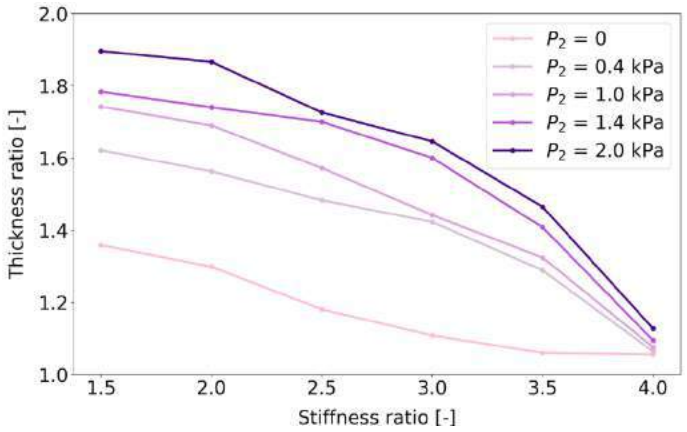

**Figure 3. Influence of pressure on thickness ratio for different stiffness ratios.**

## DISCUSSION

In this study, we investigated the wrinkling response of an inhomogeneous bilayer system, consisting of a dissimilar film and a substrate, under varying amounts of surface pressure. We focused on bilayer materials with similar mechanical properties to brain tissue, as we intended to investigate the influence of cerebrospinal fluid pressure on the instabilities of the brain. We showed that pressure plays a role in the system's instability, and a system under uniform compression with surface pressure is always more unstable. In our simulations, we could capture the instability behavior for stiffness ratios of 1.5 to 50, but our model could not converge for predicting buckling behavior of softer films, $\beta < 1$, which is closer to the brain tissue properties.

In the future, we plan to improve this study by incorporating tissue growth into our simulations, which would enable us to imitate the actual condition of brain tissue development. As the first step, we could repeat our simulations with an isotropic growth model and compare the results for both zero stress and non-zero stress boundary conditions. This will allow us to capture critical strain and thickness variations at the buckling point in a situation closer to the human brain.

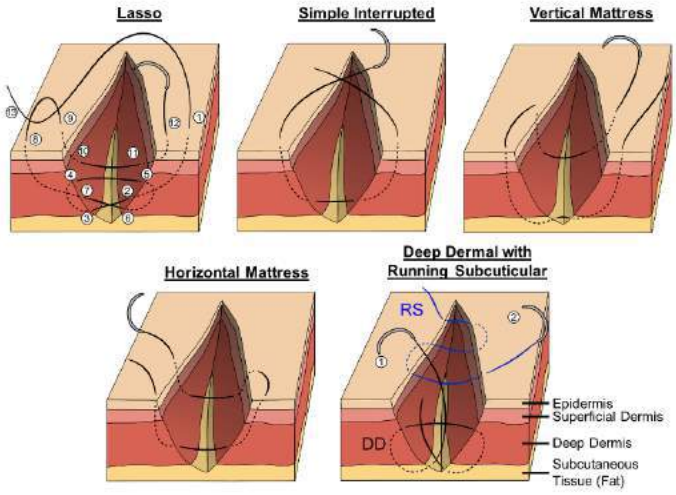
## INTRODUCTION

The skin is a three-layered structure consisting of the outer epidermis, the dermis (with a superficial and a deep component), and the subcutaneous layer. In the case of skin damage, surgical correction may be required. The optimum method of skin repair reduces the risk of adverse events and wound complications, such as wound dehiscence, infection or cosmetic scarring. Skin repair is often performed with staples, tissue adhesives, and sutures. With specific regard to sutures, there are several techniques that can be used.

The most commonly used suturing techniques include the simple interrupted (SI), vertical mattress (VM), horizontal mattress (HM), and deep dermal with a running subcuticular (i.e., "plastics stitch") (DDR) (**Fig. 1**) [1]. The ideal stitch is one that minimizes tension on the skin edges, is fast to perform, and, especially in the case of high-tension wound areas has a minimal risk of wound dehiscence. Previous research works have evaluated the various stitch patterns using uniaxial tensile testing of excised skin samples until suture failure. From these investigations, the following observations have been made: (i) the SI withstands greater tension than a subdermal stitch [2]; (ii) the VM can hold a greater load than the HM before failure [3]; (iii) the DDR is optimal for high-tension wound repair. Although these studies have elucidated the functional advantages of each pattern, there is still an emerging need for a stitch that is faster to perform and with a much better tensile strength.

In this study, we propose a new suturing technique for full thickness skin repair – the "Lasso" stitch (**Fig. 1**). This new method consists of a modified combined deep dermal and vertical mattress stitch, which has a superior mechanical strength and a faster time-to-repair than the existing suture patterns. If this new technique is used in the clinic, it could reduce the overall operating time and reduce wound complication rates due to dehiscence.



## METHODS

***Suture Procedure*:** The procedure to perform the proposed Lasso stitch is depicted in **Figure 1**, with the step breakdown herein. (Step 1) Starting 7 mm from the wound edge, a full thickness pass of the needle is performed, exiting at the dermal-subcutaneous fat transition. (Step 2) Going through the contralateral dermis, a complete deep-to-superficial pass is made, followed by a superficial-to-deep pass through the ipsilateral dermis. (Step 3) Starting at the contralateral dermal-subcutaneous fat transition, perform a full thickness pass, exiting the

skin 7 mm from the wound edge. (Step 4) A dermal-partial thickness pass is performed 4 mm from the wound edge, crossing the wound superficial to the buried deep dermal suture, and exiting 4 mm from the wound edge on the contralateral side. (Step 5) Finally, the tail end of the suture is pulled through the loop, the suture is made taut, and a knot is securely tied.

***Uniaxial Tensile Failure Mechanical Characterization*:** To characterize the tensile properties of the Lasso, we performed uniaxial load-to-failure testing of suture-repaired skin samples according to the previous literature [4-5]. Briefly, caprine skin was sectioned into 10x10 cm sections and further bisected to create a pseudo-wound. The divided skin specimens were then repaired with the Lasso, SI, VM, HM, or DDR stitch, and with either nylon (NYL) or polydioxanone (PDS) sutures, with 5 implanted sutures at a 1-2 cm spacing ($n$=6 for each subcategory). Thickness measurements were made for each specimen before mounting to a commercial uniaxial testing device (TestResources, Model #100-36) (**Fig. 2a**). Then, the specimens were loaded until suture failure, with the force and strain ε readings recorded throughout the test.

***Suture Operation Time Assessment*:** To assess the time-to-repair, we also enrolled $n$=6 medical residents to perform each of the five suture types on 10 cm wound incisions, and the time to repair with each stitch was recorded.

***Data and Statistical Analysis*:** For data analysis, the first Piola-Kirchhoff tissue stress $\sigma$ was calculated using the cross-sectional area of the specimen (from the measured thickness and width). Then, we determined the stresses and strains at the first suture rupture, and the stored elastic energy before the first suture rupture (**Fig. 2b**). For gaining better insights into the mechanical properties of the suture types, we also performed constitutive modeling of the stress-strain behaviors by prior to the first suture rupture using an exponential model form:

$$\sigma = \begin{cases} A(e^{B\varepsilon} - 1) & \text{for } \varepsilon \le \varepsilon_{ub} \\ A[(e^{B\varepsilon_{ub}} - 1) + Be^{B\varepsilon_{ub}}(\varepsilon - \varepsilon_{ub})] & \text{for } \varepsilon > \varepsilon_{ub} \end{cases}.$$

Herein, $A$ is a constant representing the material stiffness, $B$ represents the level of nonlinearity in the stress-strain behaviors, and $\varepsilon_{ub}$ is the upper bound of strain for the linearization of the stress-strain response.

For statistical analysis, a Kruskal-Wallis one-way analysis of variance was used with a Tukey's (normal data) or Dunn's (non-normal data) post-hoc test, and $p$<0.05 was considered statistically significant.

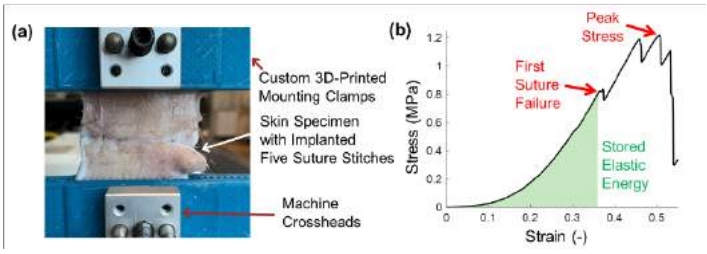


**Figure 2: (a) Uniaxial testing setup for the repaired skin samples. (b) Quantified failure mechanics from the stress-strain behaviors.**

## RESULTS

The results from the uniaxial failure testing of the sutures with the PDS and NYL materials are shown in **Figure 3**. In the PDS-repaired samples, for the first suture rupture stress, the Lasso reached a higher stress than all other patterns: 59% greater than SI ($p$=0.007), 51% greater than VM ($p$=0.022), 74% greater than VM ($p$=0.002), and 60% greater than DDR ($p$=0.039). This finding was further reflected in the stored elastic energy, where the Lasso outperformed all other patterns. Similar trends were also observed in the NYL-repaired specimens (bottom panel of **Fig. 3**). Additionally, from the time-based trials we found that the Lasso was significantly faster to perform than the DDR (264±21 s vs. 349±25 s, $p$=0.027); however, the SI (125±10 s), HM (164±16 s), and VM (182±18 s) were all significantly faster to perform than the DDR and Lasso stitches.

Finally, from the constitutive model fitting $\varepsilon_{ub}$ was largest for the Lasso specimens, indicating a longer low-tension regimen before transitioning into high-tensile behaviors. For the PDS-repaired specimens: $\varepsilon_{ub}$=0.33±0.16 (Lasso), 0.33±0.07 (SI), 0.29±0.08 (VM), 0.25±0.04 (HM), 0.24±0.04 (DDR), whereas similar trends in the estimated parameters were found with nylon sutures.

## DISCUSSION

In this work, we have shown that our proposed novel stitching technique was quantifiable demonstrated as superior or comparable to the suturing patterns classically employed in the clinic through uniaxial tensile testing and time-based operational trials. The Lasso is slower to perform than other traditional low-tension wound options such as the SI, VM, and HM, but provides a substantially superior tensile strength. Thus, it becomes clear that the choice of suturing pattern is a trade-off between a faster operational time and the suture strength, based on the requirements of the specific wound. Further, comparing the Lasso to the current standard for high-tension wound repair, the DDR, we have found that the Lasso has a superior first rupture stress and stored elastic energy with the PDS material, and comparable failure mechanics using the NYL material. These findings suggest the Lasso may have a lower rate of wound dehiscence. At the same time, the Lasso has a 28% faster time-to-repair than the DDR, which could lead to reduced operational times in the clinic for plastic and reconstructive surgeries.

## INTRODUCTION

According to the Center for Disease Control (CDC), 1 in 7 American adults are affected by disabilities that affect mobility [1]. Assistive devices, such as exoskeletons, may be able to assist affected individuals. Though these devices may be helpful, constant assistance can create dependence on the device. We hypothesize that an assist-as-needed control system can be developed to aid the wearer only when necessary. We hypothesize that an artificial neural network (ANN) can be used to predict user-intended torque outputs of joints. The user-intended torque can be compared to actualized torque outputs, with the difference of these torque values contributed by the assistive exoskeleton.

## METHODS

It has been shown by Coker et al. that future joint angles can be predicted from observing current joint angles, torques, and surface Electromyography (sEMG) data of pertinent muscle groups through the implementation of a Nonlinear Input-Output Time Series Neural Network [2]. We sought to evaluate the capability of this method in predicting knee joint angles and torques at varying walking speeds with a dataset supplied by the works of Moriera et al. [3].

This dataset is comprised of gait data for 16 subjects. Each participant performed 7 trials at 7 walking speeds: 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0 km/h. An 8-channel sEMG system, sampling at 2000 Hz, recorded EMG signals from four lower limb muscles, comprising the quadriceps and hamstring groups of both lower limbs. EMG signals were band-pass filtered using a 4$^{th}$ order Butterworth filter with cutoff frequencies at 20 Hz and 450 Hz. Motion capture information from the lower limb joints and pelvis were also sampled at 200Hz. Visual3D was used by the researchers to extrapolate joint angles and torques. Joint angle data was also low-pass filtered through a 4$^{th}$ order Butterworth filter with a 6 Hz cutoff frequency. 1001 EMG, joint angle, and torque measurements were logged for each stride [3].

For our purposes, 10 subjects were selected from this cohort (5 males, 5 females, with average age = 25 +/- 2 years, average height = 1.67 +/- 0.16 meters, average weight = 64.4 +/- 12.4 kg). Filtered quadriceps and hamstring sEMG data, X-axis knee joint angles, and X-axis knee torque measurements were extracted for each trial, individual leg, and stride of each participant. 1-in-7 trials were removed to produce a separate validation data set. The remainder were used as a training data set. A separate neural network was trained for each independent lower limb of each subject. To evaluate the networks' ability to predict joint mechanics, each network was trained to predict knee joint kinematics 50, 100, and 150 ms into the future. To obtain these time-shifted datasets, the entry offset was calculated (1).

$$\text{entry offset} = \frac{\text{time shift} * 100}{\text{stride time}} \quad (1)$$

The number of entries equal to the entry offset was then removed from the front of the matrix to be time-shifted and removed from the rear of the ground-truth matrix. This maintains equal matrix lengths and data synchronicity. One training set was produced for each person, limb, and time shift by horizontally concatenating the associated training data. Targets were set to the time-shifted joint angle and torque. A Nonlinear Input-Output Time Series Neural Network utilizing Bayesian Regularization, a singular hidden layer, and two delays was then trained for each set. 70% of the data was allocated for training, 15% for testing, and 15% for validation. A total of 60 networks were trained (10 subjects, 2 limbs, and 3 time shifts). Networks trained on left strides were trained on half as much data as networks trained on right strides. This was due to each trial containing 2 right strides and 1 left. All networks were validated by entering the validation data into the trained model and comparing the output to the ground-truth validation target. The Root Mean Squared Error (RMSE) was computed between the predicted knee

joint torque and the ground-truth, and the knee joint angle and ground-truth.

## RESULTS

The RMSE of the knee joint torques is shown in Table 1 and the RMSE of the knee joint angles is shown in Table 2.

**Table 2: RMSE of Predicted Knee Joint Angles (deg)**

| | 50 ms | | 100ms | | 150ms | |
|---|---|---|---|---|---|---|
| Subject | Left (deg) | Right (deg) | Left (deg) | Right (deg) | Left (deg) | Right (deg) |
| 1 | 1.8282 | 2.0503 | 3.3278 | 4.1263 | 5.6861 | 5.7360 |
| 2 | 1.7483 | 1.7429 | 4.1857 | 3.8520 | 5.8970 | 5.1469 |
| 3 | 2.0244 | 1.7405 | 4.3545 | 5.3600 | 5.2839 | 3.6910 |
| 8 | 1.4512 | 2.1675 | 3.2952 | 3.7357 | 5.3014 | 6.0310 |
| 9 | 1.3249 | 1.2519 | 3.0568 | 2.7714 | 4.5638 | 6.6518 |
| 10 | 1.6743 | 1.7126 | 4.2026 | 4.1058 | 6.3127 | 5.2424 |
| 11 | 2.4286 | 2.4970 | 5.0475 | 3.9368 | 6.4483 | 5.9241 |
| 12 | 1.6222 | 1.5239 | 3.6338 | 3.0996 | 4.7769 | 5.2960 |
| 13 | 1.8068 | 1.9775 | 3.3983 | 4.0182 | 5.1366 | 4.4932 |
| 14 | 2.9253 | 1.6462 | 6.9693 | 3.6557 | 5.5523 | 5.4481 |
| Average | 1.8834 | 1.8310 | 4.1472 | 3.8662 | 5.4959 | 5.3660 |

The average data is plotted in Figure 2, below. As one would expect, there is a consistent increase in error as our time shift increases and, interestingly, a slight increase in error as we compare right and left legs. It was also found that the right side has much lower standard deviation. These interesting observations were likely due to its much larger training data set available for the right side.

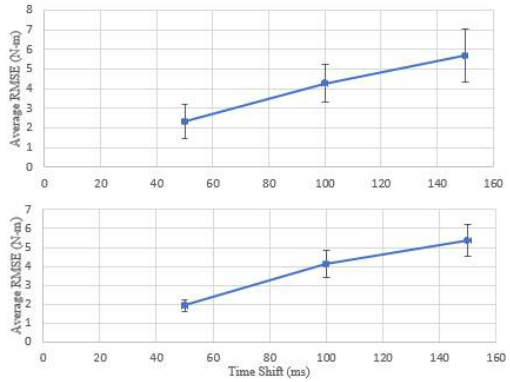

**Figure 2: Average RMSE of joint torque for left (top) and right (bottom) limbs across the three time shifts (50, 100, 150 ms).**

When predictions from our model are overlayed with the ground-truth, as in Figure3, it can be seen that future knee joint kinematics can be predicted with reasonable accuracy, even at a time shift of 100 ms.

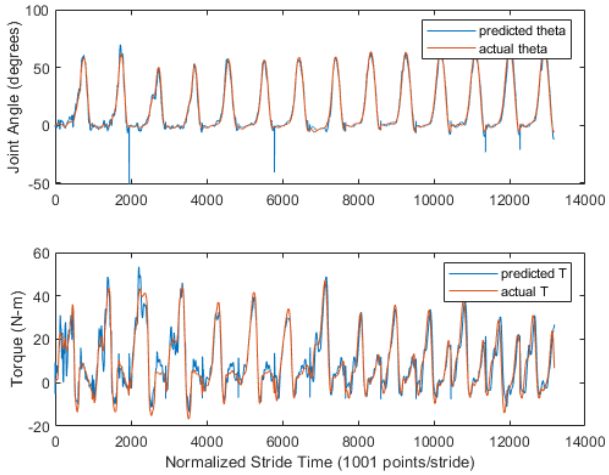

**Figure 3: 100 ms offset knee joint angle and torque prediction vs. ground-truth.**

## DISCUSSION

Similar work conducted by Coker et al. demonstrated lower RMSE for joint angle prediction at each of the time shift intervals [2]. This discrepancy is likely a result of our dataset having varying walking speeds for each subject, rather than a consistent walking speed.

Our work demonstrates an accurate system for estimating knee joint torque and knee joint angle out to at least 150 ms of offset. Networks were each trained on less than 100 strides and accurately predicted knee joint kinematics over various walking speeds. Such a robust system, that is easily trained, could be of substantial use for assist-as-needed exoskeleton devices. Future work conducted by this lab will explore the use of this neural network in the estimation of more complex upper limb joint kinematics, particularly of the hand and wrist.

This methodology could also be used in the post-acute injury rehabilitation setting, to assess functional recovery of patients with range of mobility impairment and better assess the efficacy of rehabilitation techniques being implemented.

## INTRODUCTION

Osteoarthritis (OA) development after ACL reconstruction (ACLR) is well documented[1]. OA is commonly seen within the medial tibiofemoral compartment of the knee; however, recent evidence suggests that patellofemoral OA may be equally prevalent[2]. Medial compartment underloading within the involved limb 6 months after ACLR is associated with radiographic OA development 5 years after surgery[3]; suggesting a potential link between early knee loading after ACLR and eventual OA development. However, no one has examined loading within all three compartments of the knee (medial, lateral, and patellofemoral compartments) and few have examined loading prior to 6 months after surgery. Additionally, many have restricted their analyses of knee loading to specific points within the movement pattern (e.g., peak medial compartment force) creating the possibility of omitting relevant information about the mechanical variable analyzed. Thus, the purpose of this study was to examine loading within the medial tibiofemoral, lateral tibiofemoral, and patellofemoral compartments of the knee 3 months after ACLR over the entirety of the stance phase of overground walking.

## METHODS

48 individuals (20 female; age: 23 ± 7 years; BMI: 26 ± 4 kg/m$^2$) completed motion analysis during overground walking at a self-selected speed (1.5 ± 0.2 m/s) 3.1 ± 0.5 months after ACLR. Prior to walking, surface electromyography (EMG) electrodes were placed over seven muscles on each leg after shaving and cleaning the area over each muscle belly. These seven muscles included the rectus femoris, vastus medialis, vastus lateralis, medial gastrocnemius, lateral gastrocnemius, semimembranosus, and the long head of the biceps femoris. After electrode placement, each participant performed maximal voluntary isometric contractions (MVICs) which were used to normalize the EMG data collected during walking. All EMG data were collected at 1080 Hz. Following completion of the MVICs, retroreflective markers were placed bilaterally on bony landmarks (1$^{st}$ and 5$^{th}$ metatarsal heads, top and bottom heels, femoral epicondyles, greater trochanters, iliac crests) and rigid multi-marker shells were attached to the pelvis, thighs, and shanks. Motion data were recorded using an 8-camera infrared Vicon system at a sampling rate of 120 Hz. Ground reaction forces during walking were captured using a single embedded force plate at a sampling rate of 1080 Hz.

Three trials per leg were used for data analysis. Kinematic and kinetic variables were calculated via inverse dynamics (Visual3D). A SIMM model was anatomically scaled and used to estimate muscle-tendon lengths and moment arms. Each subject's EMG data were high-pass filtered at 30 Hz using a second-order Butterworth filter, rectified, low-pass filtered at 6 Hz, and then normalized to MVICs to create linear envelopes. Linear envelopes for the semitendinosus and short head of the biceps femoris were set equal to the those of the semimembranosus and long head of the biceps femoris, respectively. The linear envelope of the vastus intermedius was estimated as the average of the vastus medialis and vastus lateralis. These EMG signals were used in a validated, subject-specific neuromusculoskeletal model to calculate muscle forces[4]. Briefly, EMG signals were transformed into neural activations using a previously described discretized second-order differential equation to model muscle activation dynamics[4]. These neural activations were subsequently transformed into muscle activations after accounting for the non-linear relationship between muscle stimulation frequency and muscle force. Finally, these muscle activations were used in a Hill-type model of a muscle fiber in series with a tendon to calculate muscle force. The muscle force model was then tuned so that the net extensor moment from the forward dynamics model matched the net extensor moment from the inverse dynamics model. This was done by adjusting the parameters and coefficients involved in the prediction of muscle forces rather than directly altering the muscle forces themselves. These muscle forces, in combination with frontal plane moment arms, were utilized in frontal plane moment

balances to determine medial and lateral compartment forces (MCF and LCF, respectively)[5]. Both MCF and LCF were normalized by bodyweight (BW).

After calculation of muscle forces, a separate two-dimensional model, similar to those of Yamaguchi and Zajac[6] and Shelburne and Pandy[7], was utilized to determine patellofemoral contact force (PCF). Briefly, the 2D model was scaled to each subject's anthropometrics. Using Equation (1)[6,7] the PCF by quadriceps muscle force ratio from 0° to 90° of knee flexion was calculated at 5° intervals.

$$\frac{PCF}{QuadiForce} = i\frac{-\sin i(\theta_q+\beta)}{\cos i(\beta-\alpha)}i \quad (1)$$

Where $\theta_q$ is the angle of the quadriceps tendon with respect to the femur, β is the angle of the patellar ligament with respect to the y-axis of the femur, and α = the patellar flexion angle; all of which are functions of knee flexion angle. A fourth-order polynomial was fit to these data to provide a subject-specific equation for the PCF by quadriceps muscle force ratio as a function of knee flexion angle. Each subject's knee flexion angle throughout stance was then utilized in this equation to determine the PCF by quadriceps muscle force throughout stance. The forces from the vastus medialis, vastus lateralis, vastus intermedius, and rectus femoris were summed to determine the net quadriceps muscle force. Finally, the net quadriceps muscle force throughout stance was multiplied by the PCF by quadriceps muscle force throughout stance to determine PCF. PCFs were normalized by BW.

Statistical analyses were performed in MATLAB with statistical significance defined as α = 0.05. Statistical parametric mapping (SPM) was utilized to perform a two-tailed paired t-test (comparing the involved limb to the uninvolved limb) over the entirety of stance phase. A Bonferroni correction was utilized to account for multiple comparisons.

## RESULTS

Significant underloading of the medial tibiofemoral compartment was present in the involved limb (vs. uninvolved) during the loading response phase of stance (p = 0.016 from 11-21% of stance; max difference = 0.5 BW; **Figure 1A**). Peak MCF was 2.4 BW and 2.9 BW in the involved and uninvolved limbs, respectively. The patellofemoral compartment of the involved limb was underloaded (vs. uninvolved) during initial contact and into loading response (p < 0.001 from 4-38% of stance; max difference = 0.5 BW), and during terminal stance (p = 0.016 from 90-98% of stance; max difference = 0.2 BW) and was overloaded during midstance (p < 0.001 from 53-71% of stance; max difference = 0.1 BW; **Figure 1B**). Peak PCF was 1.1 BW and 1.6 BW in the involved and uninvolved limbs, respectively. LCF in the involved limb was underloaded (vs. uninvolved) during terminal stance (p = 0.044 from 91-94%; max difference = 0.2 BW; not shown); however, this was likely not meaningful given the small range over which it occurred. Peak LCF was 1.6 BW and 1.8 BW in the involved and uninvolved limbs, respectively.

## DISCUSSION

Asymmetries in loading were present in both the medial and patellofemoral compartments of the knee 3 months after ACLR, but not in the lateral compartment. The asymmetries in MCF early after ACLR seen here align well with previous work from our lab which saw asymmetries in MCF pre-surgery and 6 months after ACLR[3]. The PCFs seen here align well with reports of patellofemoral underloading following ACLR during running tasks after return-to-sport time points[8].

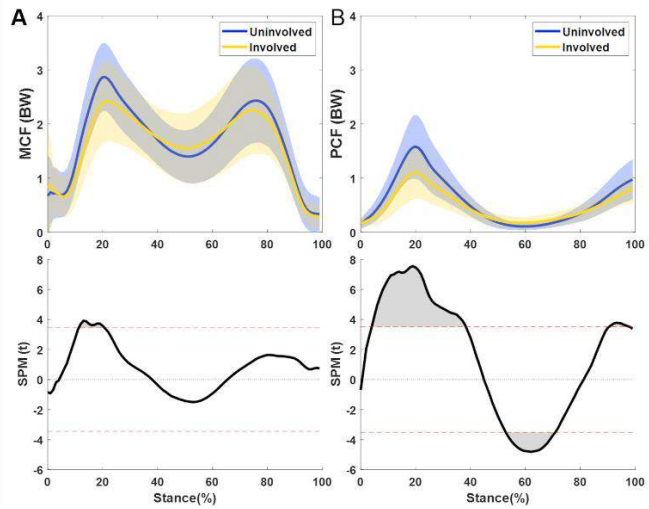

**Figure 1: Top: Average of loading variable in the involved (gold) and uninvolved (blue) limbs ± 1 SD during stance. Bottom: Two-tailed paired t-test test statistic over the entirety of stance. Dashed lines are the critical p-value (α = 0.05); shaded regions are areas of significant differences. (A) MCF (B) PCF.**

Both the medial compartment and patellofemoral compartment displayed reduced involved limb loading (vs. uninvolved) during the loading response phase of stance as the limb accepted load after contacting the ground. This is not surprising as many tend to adopt a stiffened knee gait strategy, typically consisting of reduced vertical ground reaction forces, quadriceps avoidance, and less knee flexion, within the involved limb early after ACLR[9]. These strategies can likely be attributed to reports of patients experiencing pain and Kinesiophobia[10]. Interestingly, the patellofemoral compartment experienced involved limb overloading (vs. uninvolved) during midstance. This, coupled with underloading during the loading response phase of stance, implies that the patellofemoral compartment experiences a much narrower range of forces in the involved limb during walking 3 months after ACLR (i.e., the difference between the peak during loading response and the peak during midstance is less in the involved limb [0.9 BW] vs. uninvolved limb [1.5 BW]). As cartilage is a highly mechanosensitive tissue[11], it may be that this reduction in range of forces applied to the medial and patellofemoral compartments may result in disruption of the biochemical environment of the knee and thus may be a mechanism for eventual OA development. Future work needs to investigate the long-term implications of these early loading asymmetries.

## INTRODUCTION

Glaucoma is the leading cause of irreversible blindness worldwide, and elevation of intraocular pressure (IOP) is the most prominent risk factor for this disease. Clinical treatment of glaucoma seeks to slow or stop vision loss by decreasing IOP using medications, medical devices, and/or surgical procedures. The Multi-Pressure Dial system (MPD; Equinox Ophthalmic) is a medical device that lowers IOP non-invasively [1]. It consists of a pair of goggles connected to a programmable vacuum pump that delivers a negative periocular pressure (NPP), which results in increased ocular globe volume and concurrent IOP reduction. Despite experimental data [1] and lumped biomechanical analysis [2], there is no information about the effects of NPP on optic nerve head (ONH) and corneal biomechanics. Our objective was to evaluate the biomechanical effects of NPP on the ONH and cornea via finite element (FE) modeling.

## METHODS

*Geometry and FE mesh:* We generated a 3D axisymmetric (wedge) model of the eye (Figure 1) based on existing FE models and dimensions of the human eye [3]–[6]. Two planes containing the axis of symmetry bounded the wedge: the *y*-*z* plane, and an obliquely oriented plane having a 3º dihedral angle relative to the *y*-*z* plane. Key dimensions included: axial length = 24 mm; corneal radius = 7.8 mm; scleral radius = 11 mm; and thicknesses of cornea, sclera, retina and lamina cribrosa (LC) = 0.56 mm, 0.8 mm, 0.2 mm, and c. 0.2 mm, respectively. We modeled the extraocular muscles as a rigid body at the superior aspect of the globe. The geometry was meshed with conforming second-order tetrahedral elements (TET10) in Gmsh, and the model was solved in FEBio. The use of high-order elements was necessary to implement incompressible constitutive relations (see below).

*Constitutive modeling:* We modeled the tissues as incompressible neo-Hookean materials (Table 1), with material properties based on literature values [3], [4], [7], [8]. To account for the microarchitecture of the peripapillary sclera (ppSC), we included circumferential (along the x-axis; Figure 1) collagen fibers in the ppSC.

*Boundary conditions:* Nodes on the axis of symmetry were constrained to move along the z-axis. The nodes in the bounding planes of the wedge were constrained to move in-plane, so their displacement was radial relative to the axis of symmetry (Figure 1). The muscle attachment was constrained in all degrees of freedom except displacement along the y-axis ($u_y$), to allow expansion of the ocular globe (Figure 1).

Loads were applied in two configurations, denoted as "Reference" and "Goggle." The Reference configuration describes a normal eye without goggles and corresponded to the following pressures: IOP = 15.8 mmHg, NPP = 0, retrolaminar pressure (RLTP) = 8 mmHg. The Goggle configuration describes the same normal eye with the MPD goggles applied and corresponded to lowered IOP = 11.5 mmHg (based on

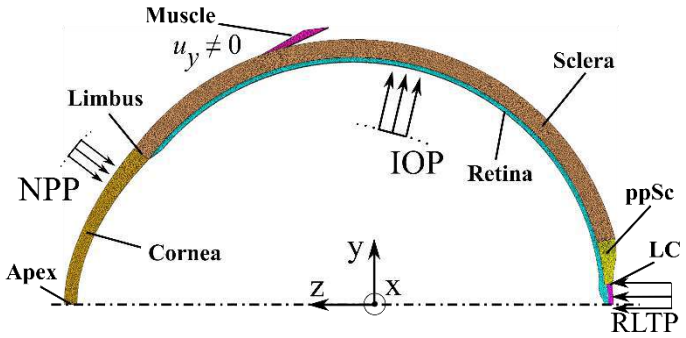

**Figure 1: The axisymmetric finite element model used in this study, showing the different regions of the corneoscleral shell (ppSC=peripapillary sclera; LC=lamina cribrosa), its attachment to extraocular muscle, and the boundary conditions, including intraocular pressure (IOP), negative periocular pressure (NPP), and retrolaminar tissue pressure (RTLP).**

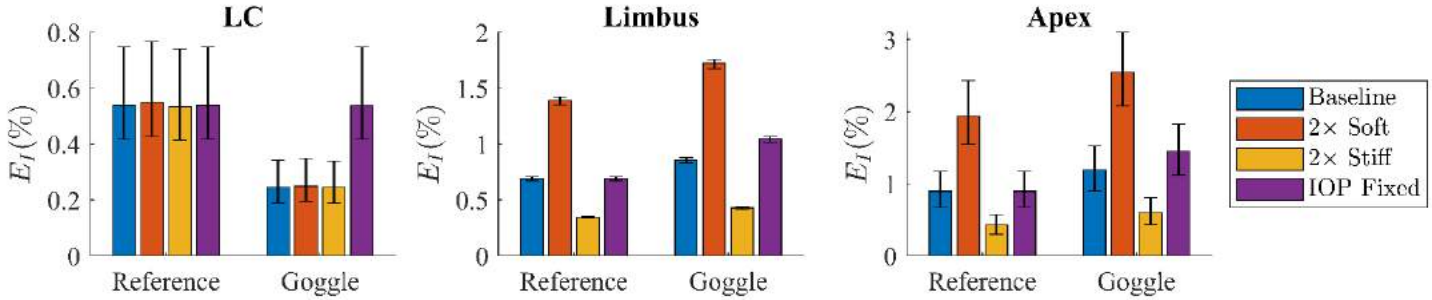

**Figure 2: The results of FE studies showing the volumetric distribution of the first invariant of the Lagrangian strain tensor ($E_1$) in the lamina cribrosa (LC) of the ONH, the limbus, and the apex of the cornea. The data are shown as median and interquartile range (IQR) within the region of interest. Note differing vertical axis scales between graphs**

experimental data [1]), NPP = -7.9 mmHg, and unchanged RLTP. For both configurations, IOP was uniformly applied on the interior surface of the corneoscleral shell, while the NPP was applied uniformly from the corneal apex to ~2.5 mm posterior to the limbus and then decreased linearly to zero near the edge of the ppSC.

*Model validation:* We computed the compliance of the corneoscleral shell as $C$ = d(IOV)/d(IOP) in the Reference configuration, where d(IOV) is the change in intraocular volume, i.e., the volume enclosed within the corneoscleral shell (Figure 1), in response to a change in IOP, d(IOP). The computed value of $C$ was compared to experimental data [9].

*Sensitivity studies and data analysis:* We denote the above FE model as the "Baseline case." We also considered the effects of changing material parameters and loads. Specifically, we evaluated the sensitivity of our results to material parameter values by changing the corneoscleral shell stiffness: we multiplied the sclera, ppSC matrix, and cornea stiffness by a factor of ½ ("2X Soft"), or 2 ("2X Stiff"). Finally, we also investigated the effects of scleral expansion alone by imposing NPP while holding IOP unchanged ("IOP fixed").

Our primary outcome measures were the volumetric median and interquartile range (IQR) of the nodal first principal Lagrangian strain ($E_1$) within the corneal apex (cornea nodes with $y$ = 0), limbus (nodes shared by cornea and sclera), and LC regions (Figure 1).

## RESULTS

*Model validation:* The compliance of the FE model was 3.1 µL/mmHg, which falls within the reported range of values for human eyes of 1.4-3.9 µL/mmHg [9].

*Baseline case*: NPP caused the median $E_1$ in the LC to decrease by 54.5%, from 0.54% [0.42%, 0.75%] (median [IQR]) to 0.25% [0.19%, 0.34%] (Figure 2). Conversely, $E_1$ in the limbus increased by 23.7%, from 0.69% [0.67%, 0.71%] to 0.86% [0.83%, 0.88%], and at the corneal apex by 33.1%, from 0.90% [0.66%, 1.17%] to 1.19% [0.91%, 1.52%].

*2X Soft and 2X Stiff cases:* LC strains were similarly decreased between the Baseline and the 2X Soft/Stiff cases. However, compared to the Baseline case, the strains at the corneal apex and limbus doubled in the 2X Soft case and halved for the 2X Stiff case (Figure 2).

*IOP fixed case:* NPP had a minimal effect on $E_1$ in the LC (-0.1% decrease) but increased limbal (51.2%) and corneal apex (61.5%) strains.

**Table 1: Summary of material parameter values (Baseline). The sclera and ppSC matrix stiffnesses were increased compared to literature values to match experimental ocular compliance.**

## DISCUSSION

This study showed that negative periocular pressure (NPP) decreases strain on the ONH while increasing it on the cornea. The reduction of ONH strain is predicted to be beneficial for glaucoma patients. The predicted corneal straining was small and thus potentially benign (<1% strain; Figure 2).

The observed ONH strain lowering was slightly surprising, since increased globe volume due to NPP could be expected to increase ONH strain. However, this effect was outweighed by the effects of lowered IOP due to NPP. In fact, increased globe volume due to NPP occurred primarily in the anterior eye (data not shown) while the magnitude of scleral stretching in the ppSC region was small, which explains why changes in scleral stiffness did not affect ONH strains. To further understand this effect, it would be of interest to evaluate different boundary conditions to model the effects of the extraocular muscles, as well as different distributions of NPP.

A potential limitation of this study was the assumption that the IOP decrease due to NPP was unaffected by corneoscleral stiffness. In reality, we expect that corneoscleral stiffness will affect the magnitude of the IOP decrease; thus, as a future direction, it would also be worth extending the model to include blood flow and fluid-solid interactions [2].

In conclusion, this study provides novel insights into the biomechanical effects of NPP on the ONH and cornea. We showed that NPP decreases the deformation of key ONH tissues by reducing IOP while slightly straining the cornea and limbus. On balance, this suggests potential benefits of MPD for glaucoma patients.

## INTRODUCTION

Thermoregulation is a process that is essential to the maintenance of life for all warm-blooded mammalian and avian species. It sustains a stable core body temperature in the face of a wide array of environmental thermal conditions and intensity of physical activities that generate internal heat. A primary component of thermoregulatory function is the movement of heat between the body core and the surface via the circulation of blood. The peripheral vasculature acts as a forced convection heat exchanger between blood and local peripheral tissues throughout the body enabling heat to be conveyed to the skin surface where it may be transferred to and from the environment via conduction, convection, radiation, and/or evaporation of water as local conditions dictate. Humans have evolved a particular vascular structure in glabrous (hairless) skin that is especially well suited for heat exchange. These vessels are called arteriovenous anastomoses (AVAs) and can vasodilate to large diameters and accommodate high blood flow rates. We report herein a new technology based on a physiological principle that enables simple and safe access to the thermoregulatory control system to allow manipulation of thermoregulatory function via glabrous skin blood flow (GSBF) to AVAs. The technology operates by applying a small amount of local heating to control tissue on the body surface overlying the cerebral spine that upregulates AVA perfusion. This technology is called Selective Thermal Stimulation (STS). During STS heat exchangers can be applied to glabrous skin, preferably on the palms and soles, to alter the temperature of elevated blood flow prior to its return to the core, resulting in the ability to manipulate the internal body temperature on demand.

## METHODS

An important application of STS involves enhancing the onset and quality of sleep. The human thermoregulatory system operates on a circadian cycle in coordination with sleep. Physiological sleep data show that as late hours in the circadian cycle approach, there is a significant upregulation in GSBF, opening the primary heat exchange portal from the warmer core to the (usually) cooler environment. A subsequent drop in core temperature occurs via enhanced convection of blood to glabrous skin, facilitating the loss of core heat to the environment, with a time constant on the order of 2–3 h, and with sleep onset following thereafter in an additional 0.5 h. Absence of the normal nocturnal decline in core temperature by approximately 1°C can be associated with sleep-onset insomnia.

Another important benefit of AVA vasodilation during sleep is that the diminished terminal vascular resistance to blood flow results in a reduced sleep-time blood pressure that is increasingly recognized as protective against risk of cardiovascular diseases and major organ (kidney, eye, etc.) pathology [1]. An overnight dip in blood pressure has been identified as a significant contributing factor in lowering the occurrence of cardiovascular-derived events by as much as 40% or more, even when daytime blood pressure is elevated (hypertensive).

STS intervention was evaluated on a male subject who typically experiences difficulty falling asleep after going to bed and entering a productive sleep state. Two nights of data were acquired with continuous monitoring of GSBF on the foot sole via a laser Doppler perfusion probe, of core temperature via a sublingual thermocouple, and of mean arterial pressure via a pulse transit time monitor. STS was produced with a heated pillow maintained at 39°C for 30 minutes, after which it was turned off. The male subject was clothed in shorts and a tee shirt.

In another study STS intervention was also measured for being able to delay the onset of AVA vasoconstriction during body cooling by lowering the mean skin temperature with a water circulation suit. Four subjects underwent two trials each, with and without STS applied. The trial protocol consisted of an initial passive baseline period followed by lowering the suit water temperature to the point where there was no further vasoconstriction for the subject on that particular day. Next the suit water temperature was adjusted to 40°C and held for 30 min to

allow subjects to reach their personal maximum level of vasodilation on the trial day. If the experiment included STS, after the initial 15 min of warming a resistance heater was set to hold a temperature of 40°C on the skin surface overlying the cervical region of the spine. The STS heater remained energized for the duration of the experiment. Following 30 total minutes of warming, water bath temperature was decreased at 1°C/min until a state of maximum vasoconstriction was observed for 5 min. Each of our subjects underwent control and STS trials separated by at least 7 days.

## RESULTS

The results of the sleep study are shown in Fig. 1 with STS producing an immediate increase in GSBF (a), drop in core body temperature (b), and dip in MAP (c). Fig. 2 shows that STS enables maintenance of GSBF to substantially lower skin temperatures during body cooling. Heat exchangers may be applied to the palms and soles to add heat to blood circulating back to the core to facilitate the body's ability to defend against the dangerous perioperative hypothermia.

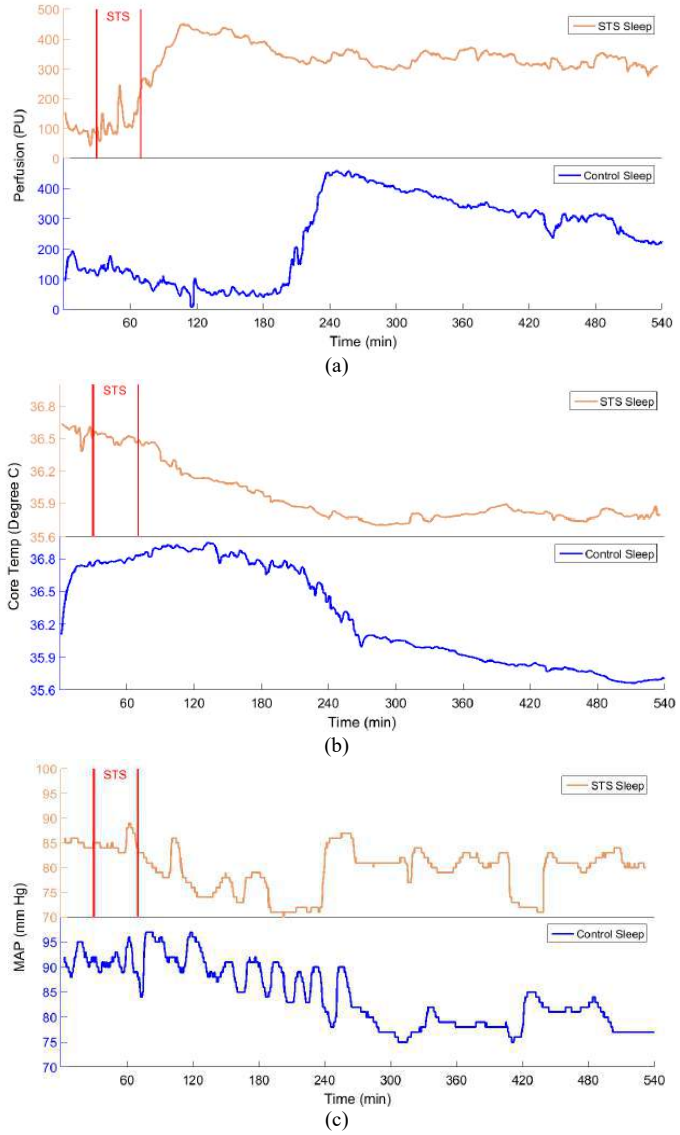

**Figure 1. Overnight physiological data measured on a subject who slept one control night without using (STS) (*lower blue plots*) and one night with STS applied for 30 min at bedtime (*upper orange plots*). (*a*) Blood flow to glabrous skin of the foot measured from an initial 20-min baseline period. (*b*) Core temperature measured with a sublingual probe. (*c*) Mean arterial blood pressure (MAP).**

## DISCUSSION

In Fig. 1, GSBF is induced by STS three hours earlier than in its absence, leading to more effective sleep onset. Simultaneously, the enhanced convective heat loss by greater blood flow to glabrous skin from the core directly produces an immediate decline in core temperature that is required for healthy sleep. Finally, STS induced vasodilation of AVAs reduces the systemic vascular resistance resulting in a healthy overnight dip in MAP and its associated health benefits.

During skin temperature cooling, for all 4 subjects GSBF was maintained with STS to a lower temperature by 2 - 4°C, meaning that STS will enable heat to be transported by blood flow to the core under conditions for which it would otherwise not be possible, thereby defending against the occurrence of perioperative hypothermia.

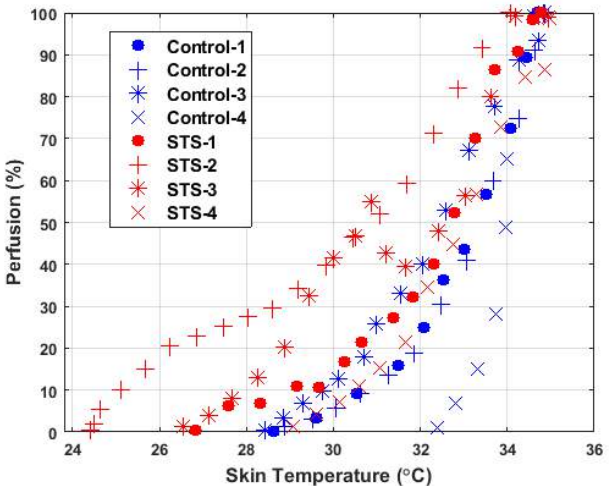

**Fig. 2. GSBF plotted as a function of mean skin temperature during active cooling induced vasoconstriction with and without STS applied. 0% and 100% perfusion represent the range of minimum and maximum perfusion values for individual subjects.**

## INTRODUCTION

Pressure and thermal injuries affect millions of lives every year. Typically, each injury mechanism is studied in isolation due to differences in the primary factors causing the trauma. The confluence of applied tissue deformation, inflammation, and ischemia combine over time to cause mechanically derived injury, whereas high or low-temperatures are independent causative factors for thermal injuries. Modeling and simulation analyses have been used to develop an understanding of both types of injury pathways to predict threshold conditions for the onset of damage and to develop methods of prevention. Although thermal and mechanical injury processes are often viewed separately, prior experiments have demonstrated that these two phenomena may have active cross-coupling. Temperature can act as prophylactic or accelerant to pressure injuries, depending on its magnitude, to radically alter the outcome. Our objective is to develop a finite element model to predict injury as a combined function of applied temperature and pressure, local blood perfusion and time. The model uses constitutive terms derived from experimental data that are relevant to physiological processes that govern injury occurrence.

In the mid-1990's Iaizzo, et al. conducted a well-designed large-scale study on a porcine model to investigate the relationship between temperature, mechanical loading, and time to graded injury causation [1,2]. The study covered six temperatures from 25–50°C, four pressures from 10-150 mm Hg, and three exposure times up to 10 hours at 840 sites in 70 animals. Injury was graded at three levels of severity at four tissue depths: epidermis, dermis, subcutaneous fat, and muscle. It stands as the largest and most comprehensive study of its kind, and (to the authors' knowledge) it has not been replicated since. The results document how temperature can modulate pressure ulcers (PU's) in view of the complex coupled relationship between temperature and pressure in injury causation. The study also showed that lowered temperature is prophylactic against mechanical loading injury. Conversely, elevated temperature may act as an accelerant to mechanical loading in PU formation. An ancillary observation of the study was that elevated local pressure increased the rate by which burns occurred. More recently Gefen and colleagues [3] have conducted an extensive series of experimental and modeling studies into the formation of PU's. This body of work has provided valuable guidance for the current research on pressure/temperature coupling in soft tissue injury etiology.

## METHODS

Even though the Iazzo data set embodied a large matrix of measurements, the actual density of the data was sparse, particularly for assessment of wound severity. Thus, our initial work was to fit a mathematical function to the data set to enable smooth interpolation for each independent variable to create a continuous set of injury outcomes. The model was formulated to include thermal and elastic stress distributions, local blood perfusion, and the kinetics of injury formation. Details of the models are published in a companion paper [4].

The evolution of cell viability (injury) over time was described using temperature and blood perfusion as quantitative predictors, with perfusion coupled directly to tissue mechanical stress. The injury model was fit to the survival data directly using least-squares regression based on Cox's proportional hazard model [5]. The baseline viability was represented as a Weibull distribution. Injury coefficients were determined by optimal fitting to the experimental data using the methodology described in [4].

## RESULTS

The model was applied to simulate the combined action of applied temperature, blood perfusion normalized from 100% at no applied pressure, to 0% for pressure in excess of the mean arterial pressure, and exposure time up to 10 hours. A three-dimensional representation of a simulation of the progressive loss of cell viability in a representative tissue system is shown in Fig. 2.

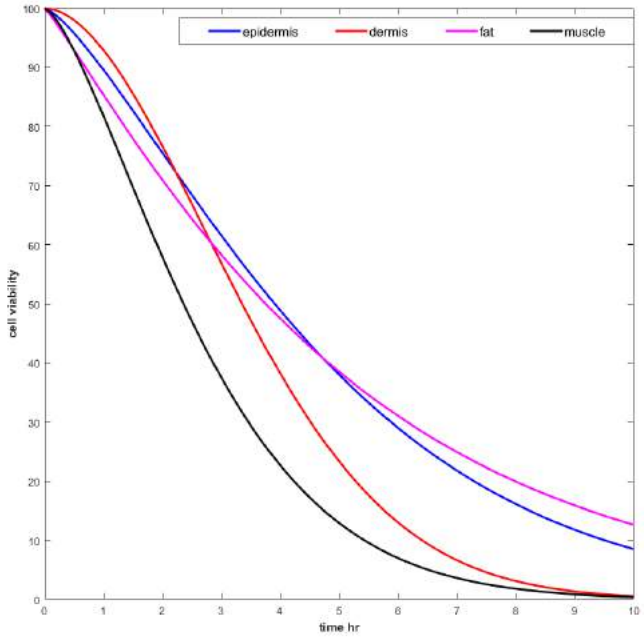

**Fig. 1. Predicted temporal cell viability in epidermis, dermis, fat and muscle for surface exposure to 40°C and 100 mmHg.**

Injury develops most rapidly in the superficial epidermis and dermis under the action of heat diffusion from the surface. Pressure is transmitted much more rapidly than heat diffusion deep into the tissue, but the kinetics of the development of pressure derived injury are slower resulting in a longer time constant to manifestation.

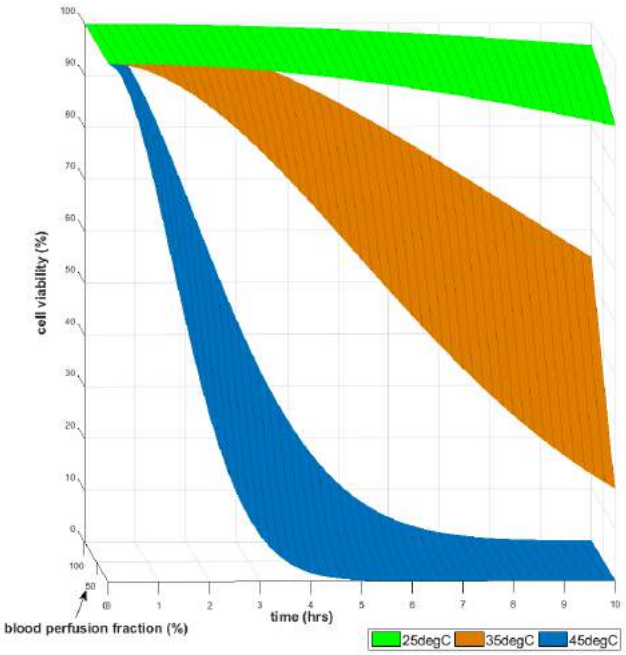

**Fig. 2. Injury model simulation of the combined effects of applied pressure and temperature over time in reducing viability of a representative cell line. Time and pressure effects are continuous plots at three incremental temperatures of 25°C, 35°C, and 45°C.**

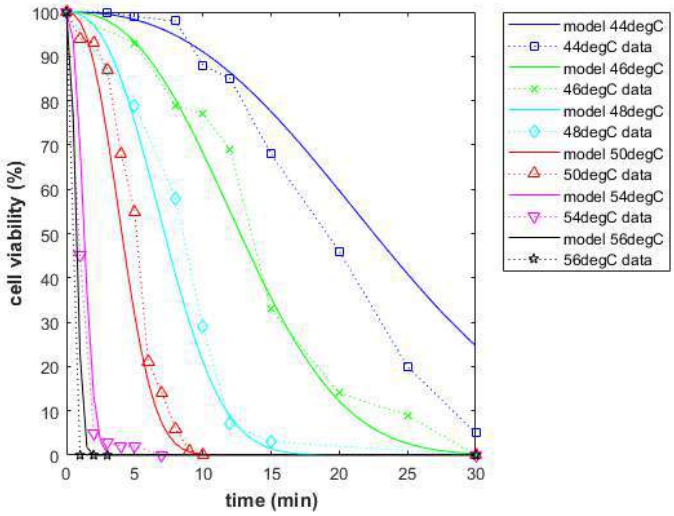

**Fig. 3. Comparison of the present injury model (continuous lines) with experimental data (symbols) for loss of viability during continuous heating of prostate cancer PC3 cells over the temperature range between 44 and 58°C [6]. The regression between the model and the data of $R^2 = 0.95$ demonstrates an effective capability for predicting thermal injury even in the range of low temperatures and long exposure times for which a traditional Arrhenius model has limited accuracy [7]**

## DISCUSSION

The differential influences of temperature and pressure in injury causation are seen in Fig. 1 as noted. Pressure dominates at greater depths, and temperature more superficially. Fig. 2 demonstrates the strong coupling between temperature and pressure in causing injury. Lower temperature is prophylactic against pressure injury. In contrast, higher temperatures accelerate the action of pressure in producing necrosis. Also, at intermediate pressures injury is less dependent on temperature coupling. The results plotted in Fig. 3 show that the current model can be used for pure thermal injury as well as for when pressure effects are also involved. At the lower temperature range close to the threshold for causing a burn, it is likely that the long exposure times allow enough time for expression of heat shock proteins that diminish the extent of injury, leading to over prediction of injury extent by traditional Arrhenius-based models.

## ACKNOWLEDGEMENTS

This research was sponsored in part by the Robert and Prudie Leibrock Professorship in Engineering at the University of Texas at Austin. We thank the current Iaizzo lab at the University of Minnesota for providing archival data from their original experiments that were crucial in the effort to build and validate our injury model.

## INTRODUCTION

Glioblastoma multiforme (GBM) is the most common and aggressive malignant brain tumor in adults. The major obstacle in GBM treatment is the presence of the blood-brain-tumor barrier (BBTB), which displays heterogeneous permeability to circulating drugs [1], and presents as a challenge for drug delivery across this barrier. Over the last decades, approaches for drug delivery to GBM have been investigated, such as convection enhanced delivery, intranasal delivery, intra-arterial delivery, and focused ultrasound with microbubbles. However, they have not yet led to a significant increase in survival for most patients with GBM due to their invasiveness, toxicity, and poor drug delivery efficacy to the brain [2]. Therefore, novel approaches to non-invasively modulate the BBTB for drug delivery are the unmet need in GBM treatment.

Entry of circulating molecules into the brain is strictly limited by the blood-brain barrier (BBB) that includes the endothelial tight-junction (TJ) complex and low rates of transcytosis. To safely and reversibly increase the BBB permeability, we have developed a method that non-invasively modulates the BBB with picosecond laser excitation of TJ-targeted plasmonic gold nanoparticles (AuNPs) [3]. In this approach, AuNPs were conjugated with the antibody BV11 (AuNP-BV11) to target JAM-A, which is a part of the TJ complex. Then the picosecond laser pulse excitation of AuNPs leads to the generation of mechanical wave that perturbs the TJ, and increases the BBB permeability without compromising normal brain function. This method allows the delivery of immunoglobulins, adeno-associated viral vectors, and liposomes to the brain parenchyma.

In this work, we successfully exploited this optical approach to modulate the BBTB (named optoBBTB technique). We demonstrated that optoBBTB can enhance the drug delivery to the tumor, suppress the tumor growth, and increase the survival rate of tumor-bearing mice. Our results also suggested that taxol is a potent anti-cancer drug in GBM treatment, which has not been used in the clinic previously due to its poor penetration ability across the BBB [4]. The optoBBTB paves a new way of drug delivery to treat glioma.

## METHODS

*Glioma model*: 73C glioma cells were used, which were generated in primary astrocyte cultures from neonatal mice and carried conditional mutations for $Pten^{f/f}$, $p53^{f/f}$, and $LSLBraf^{V600E}$. 90 µL of the cell suspension ($2\times10^5$ cells/µL) was transplanted into the left hemisphere of nude mice (Nu/J, stock no.002019, 7 weeks) at 500 µm depth.

*OptoBBTB and drug delivery for glioma treatment*: The molecular targeting nanoparticles AuNP-BV11 were prepared as reported [3]. At 4 days post injection (dpi), the glioma-bearing mice were randomly divided into 4 groups with 5 mice in each group: (1) vehicle control, (2) free taxol control, (3) optoBBTB+vehicle, and (4) optoBBTB+taxol. Specifically, taxol was dissolved in a vehicle of Cremophor EL: absolute ethanol (1:1 v/v) to 6 mg/mL and then diluted to 2 mg/mL with saline. To modulate the BBTB, 37 µg/g of the AuNP-BV11 was administrated by intravenous (i.v.) injection into the tumor-bearing mouse. 1 hour later, the mice were received either vehicle or taxol via i.v. injection. Then the mice received picosecond-laser excitation (40 $mJ/cm^2$, 1 pulse, pulse duration was 28 ps, and beam size was 6 mm) in the tumor area. The treatment was repeated every 4 days during 4-12 dpi. The tumor size was measured by 3T-MRI (T2-Weighted scan) at 3 and 15 dpi. To obtain the survival rate, similar treatment groups were used with 7 mice in each group.

## RESULTS

*Characterization and optimization of optoBBTB:* To modulate the BBTB in 73C glioma model, we i.v. injected AuNP-BV11, followed by applying a transcranial picosecond laser pulse after 1 hour. We then i.v. injected a fluorescent dye (Evans blue) to visualize the increase in BBTB permeability (Figure 1a). AuNP-BV11 was exploited in this study because it preferentially targeted the tumor area, as it showed doubled accumulation in the tumor than in the normal brain tissue as analyzed by ICP-MS (Figure 1b). By using laser fluence of 40 mJ/cm$^2$, the BBTB permeability can be successfully increased after single pulse laser excitation, indicated by the Evans blue extravasation from blood vessel to the brain parenchyma (Figure 1c).

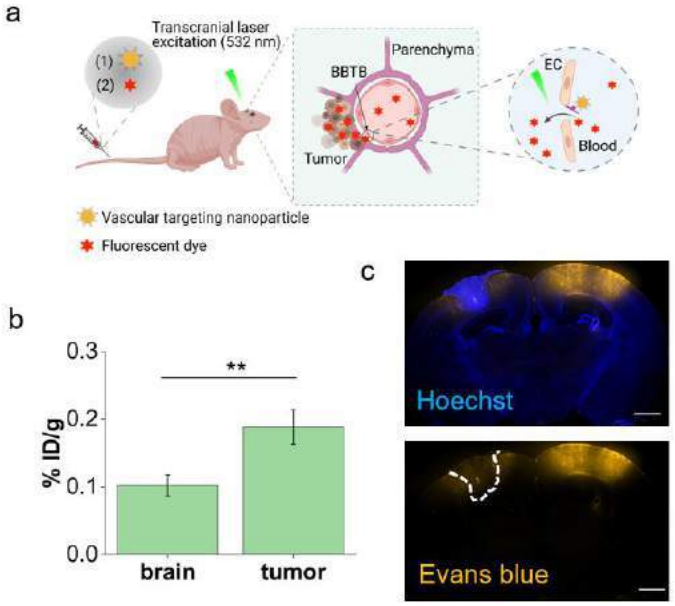

**Figure 1: Characterization and optimization of optoBBTB in 73c glioma model. (**a) Schematic illustration of optoBBTB. (b) The analysis of AuNP-BV11 accumulation in 73C tumor bearing mice. Student's t-test, n=3 mice, ** p<0.01. (c) Optimization of optoBBTB. Scale bar represents 1 mm.

We next investigated the feasibility of using optoBBTB to deliver anti-cancer drug taxol for 73C glioma treatment. We showed that optoBBTB enhanced the delivery of fluorescent taxol into the tumor core and margin, while it could not cross the intact BBTB at the early tumor stage (Figure 2a). The combination of optoBBTB and taxol showed great potential in 73C glioma treatment, and the tumor growth was suppressed significantly after 3 treatments (Figure 2b). The result was further supported by the significantly decreased tumor volume (i.e., 100 mm$^3$ in the control groups and 40 mm$^3$ in the optoBBTB+taxol group) measured by MRI (Figure 2c). More importantly, we also observed that optoBBTB and taxol increased the survival rate of the tumor-bearing mice, and the median survival time was increased from 16 to 24 days (Figure 2d).

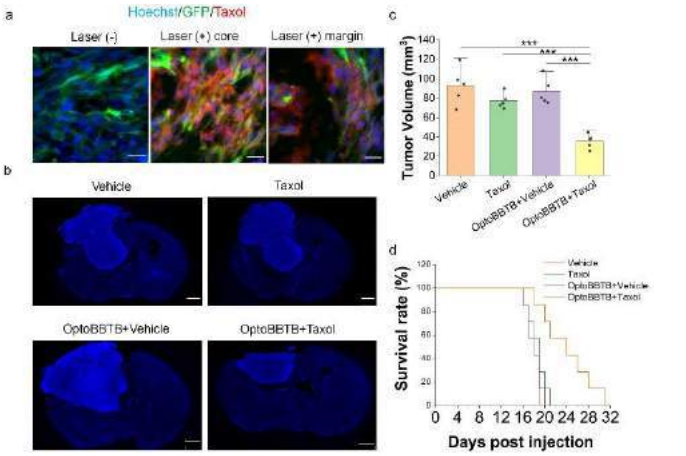

**Figure 2: Evaluation of optoBBTB for 73C brain tumor treatment.** (a) OptoBBTB facilitated the delivery of fluorescent taxol to the tumor. Scale bar represents 20 μm. (b) Tumor size indicated by fluorescent imaging at 15 dpi using Hoechst staining. Scale bar represents 1mm. (c) The analysis of tumor volume at 15 dpi. One way Anova, ***p<0.001, n=5 mice in each group. (d) Kaplan-Meier survival analysis, n=7 mice in each group.

## DISCUSSION

The standard of care for GBM is maximal safe resection followed by radiation and chemotherapy. However, since gliomas infiltrate into surrounding healthy brain tissue, unresected tumor margin is the primary cause of recurrence. Moreover, since the BBTB remains intact at the tumor margin, the chemotherapy drug concentration is much lower within the tumor margin than at the tumor core [5]. Therefore, GBM always results in poor patient prognosis, and there is an imperative need for the development of novel, targeted, and effective therapies for GBM.

This study shows that the BBTB permeability can be non-invasively enhanced using picosecond laser excitation of TJ-targeted AuNPs, which enjoys high spatial resolution. We demonstrated that, taxol, which has not been used in clinical due to its incapability of crossing the BBTB, could be delivered to tumor core and margin using optoBBTB technique, and it is actually a potent anti-cancer drug for glioma treatment. By using the combination of optoBBTB and taxol, the growth of 73C glioma can be significantly suppressed, and the median survival rate of the tumor bearing mice was increased by 50%. Therefore, optoBBTB is a novel, non-invasive and effective approach to increase local drug concentration for glioma treatment.

Future work will be focused on optimizing the optoBBTB modulation efficacy by using tumor specific targets, and test the optoBBTB in other infiltrative brain tumor models.

## INTRODUCTION

Loop-mediated isothermal amplification (LAMP) has emerged as an alternative to polymerase chain reaction and allow point-of-care testing without the need for thermal cycling.[1] Although simple, LAMP is susceptible to non-template amplification and its simple readout (e.g., based on pH change) cannot distinguish template versus non-templated amplification, resulting in false-positive results. Methods that mitigate this issue rely on the utilities of molecular beacons, strand displacement probes, and clustered regularly interspaced short palindromic repeats diagnostic methods. They provide additional sequence identification for improved specificity, however, extensive expertise in molecule design (i.e., primers and probes) is required to identify LAMP amplicons. Motivated by this challenge, we have developed an approach, termed as plasmonic LAMP, that utilizes oligonucleotide-labeled gold and silver (Au-Ag) nanoshells as plasmonic sensors and presents color change upon detecting amended amplicons via DNA hybridization (**Figure 1**).[2] Importantly, the detection specificity and sensitivity of plasmonic LAMP is significantly improved over commercially available LAMP kit and allows virus diagnosis at its early representation.

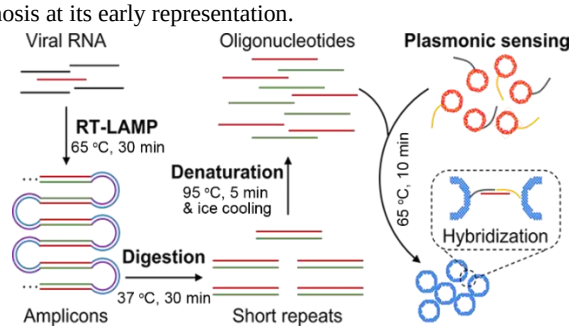

**Figure 1: Schematic illustration of the major steps for the proposed plasmonic LAMP single-molecule RNA detection.**

## METHODS

*Preparation of plasmonic nanoparticles.* In brief, ~50 nm gold-silver (Au-Ag) nanoshells were prepared via galvanic replacement reaction, where Ag templates were mixed with sodium citrate in deionized water and preheated at 95 °C, followed by the injection of $HAuCl_4$ solution using a syringe pump. The products were washed and collected by centrifuge and finally re-dispersed in water.

*RNA detection by plasmonic LAMP.* In brief, RNA sample was mixed with RT-LAMP master mix containing Warm Start RT-LAMP mix and primers for RT-LAMP reaction. The products were then subjected to restriction endonuclease digestion by HincII and EaeI and heat denaturation to form single-strand DNA for the plasmonic sensing using a set of Au-Ag shells-based probes.

## RESULTS

Due to the presence of sodium citrate in the reaction, the as-prepared Au-Ag nanoshells show thick and solid walls on the surface and a hollow interior (**Figure 2A**). In contrast, the absence of sodium citrate led to the formation of thin and porous Au-Ag nanocages. The energy-dispersive X-ray (EDX) mapping of an individual Au-Ag shell shows that the Au and Ag elements are distributed across the entire particle (**Figure 2B**) and thus confirms the alloyed structure, which is expected to improve the corrosion resistance of Au-Ag nanoshells. More importantly, the extinction peak of Au-Ag shells shows restricted shift from 392 nm to 530 nm (**Figure 2C**), while that of cages shifts to longer near-infrared wavelength (**Figure 2D**). To understand the optical change for the Au-Ag shells, we performed the simulation using boundary element method (BEM). The simulation result reveals that the formation of thick and solid walls during the shell growth is the key for the limited peak shift (**Figure 2E**). In addition, we found that the Au-Ag shells show a similar peak position at visible wavelengths and 4-times higher peak extinction over 50 nm Au counterparts at the same particle concentration.

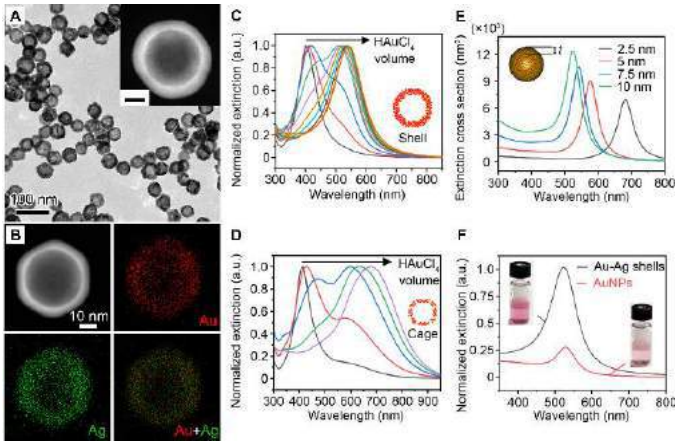

**Figure 2. Structural characterization and optical properties of Au-Ag nanoshells.** (A, B) Morphological and elemental analyses of Au-Ag shells. Scale bars in insets are 10 nm. (C, D) Spectral monitoring during the growth of Au-Ag shells and cages. (E) BEM simulation of Au-Ag shells. (D) Comparison of optical property between Au-Ag shell and AuNPs.

For the plasmonic LAMP, we first carried out the RT-LAMP (65 ºC, 30 min) for the amplicon production. The agarose gel image confirms the successful LAMP amplification in the presence of target SARS-CoV-2 RNA (red box of **Figure 3A**). The amplicon was then subjected to restriction endonuclease digestion by HincII and EaeI (37 ºC, 30 min), which recognize and cleave the conserved regions GTY/RAC and Y/GGCCR sites, respectively. As a result, the gel image (blue box of **Figure 3A**) reveals clean bands located below 200 base-pair (BP) length, confirming the effective and uniform digestion. Next, the reaction product was denatured into single-strand DNA (ssDNA) by heating to 95°C for 5 min and cooling on ice (2 min), followed by mixing with a set of shells-based probes and incubated at 65 ºC for 10 min or room temperature for 30 min. **Figure 3B** shows corresponding LSPR extinction spectra normalized at 537 nm. A linear relationship ($R^2$=0.99) was observed covering 3 logs from 1 to 1,000 copies/μL (**Figure 3C**). The limit of detection (LOD) was determined to be 1.3 copy/μL or 10 copies per reaction equivalent.

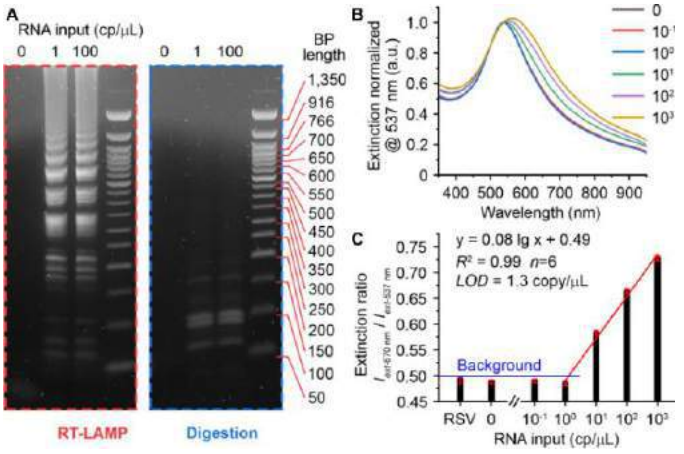

**Figure 3. Plasmonic LAMP for SARS-CoV-2 RNA detection.** (A) Gel images showing the LAMP amplicons before and after enzyme digestion at different RNA inputs. (B) SARS-CoV-2 RNA detection results recorded by spectral measurements. (C) Spectral analysis of the detection results by plasmonic LAMP.

## DISCUSSION

The plasmonic LAMP has two key features. First, it represents a significant step forward in sensor innovation with materials advances. Previous efforts in developing colorimetric plasmonic sensors mainly focused on Au and Ag nanoparticles (NPs), whereas AuNP has a weak plasmonic response and AgNP is not stable. Promising advances have been made on Au-Ag nanocages, but its near-infrared absorption is not suitable for naked-eye detection. We overcome this challenge by developing Au-Ag nanoshells with plasmonic peaks in the visible wavelengths (500-600 nm) and 4-times higher extinction intensity over AuNPs. Importantly, Au-Ag-shells-based sensors allow ~20 times improvement in the analytical sensitivity for the oligonucleotide detection compared with same-sized AuNPs (data not shown). As a result, the Au-Ag shells have the potential to be a class of highly sensitive plasmonic sensors.

Second, the plasmonic LAMP allows highly sensitive detection of nucleic acids with improved specificity. With restriction enzyme digestion and heat denaturation, the LAMP amplicons can be converted from concatemers into short repeats that are amendable for subsequent hybridization with plasmonic sensors (**Figure 1**). The dual sequence identification of plasmonic LAMP, enabled by the primers and plasmonic sensors, eliminates the contamination from non-template amplification and thus improves the detection specificity and sensitivity. Using SARS-CoV-2 RNA as an example, we demonstrate that the plasmonic LAMP approach detects a single RNA molecule per microliter with colorimetric readouts. Compared with the commercially available colorimetric RT-LAMP kit, the plasmonic LAMP has enhanced detection sensitivity and reduced false results (**Figure 4**).

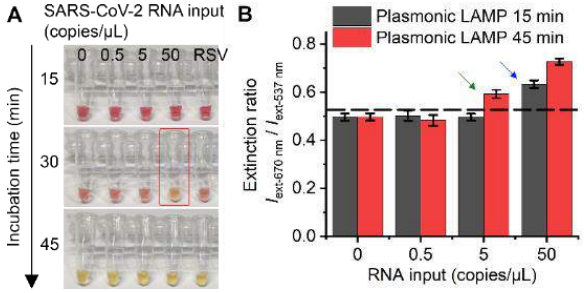

**Figure 4. Comparison of plasmonic LAMP and a commercially available colorimetric LAMP kit for SARS-CoV-2 RNA detection.** (A) Colorimetric LAMP kit. (B) Plasmonic LAMP.

Despite the superior detection performance, plasmonic LAMP suffers from the multistep operation and multiple temperature controls. We aim to optimize the protocol for further improving the detection sensitivity and simplifying the workflow. For example, we may adopt a longer LAMP reaction time to generate more amplicons and thereby detect lower analyte copies. Also, integrating a portable cartridge with pre-stored reagents and a heating dock (similar to the Accula™ SARS-CoV-2 Test, available at https://www.mesabiotech.com/) is a potential way to enable the plasmonic LAMP with a sample-to-answer workflow and a minimal hands-on time.

## INTRODUCTION

Ageing is used to describe a broad set of conditions that lead to impaired biologic function and vulnerability to death [1]. It includes changes at cell, tissue and organ levels. Vascular ageing, where changes in vascular cells and structure lead to impaired organ function, is an important aspect of ageing. Vascular ageing is a complex biological process and has multiple aspects to it including cell dysfunction, impaired signaling, stiffening of the blood vessels etc. [1]. With recent advances in mechanobiology, role of mechanics in ageing is being increasingly appreciated. Tissue mechanics influences local cell signaling as well as organ function. Alterations in tissue mechanics can be a cause as well as a consequence of ageing, but understanding this intricate biological process can be a challenge. Murine ageing models can provide more control over data collection and have proved very useful in studying changes to vascular mechanics with ageing. Prior efforts on quantifying vascular mechanics in ageing murine models have focused on systemic arteries [2,3]. Pulmonary artery mechanics remains relatively unexplored. Here, we quantify biaxial mechanics in the pulmonary arteries of three different mouse models of ageing and ascertain common underlying themes to vascular ageing from a mechanics perspective.

## METHODS

We report mechanics for four different groups of male mice – 12-week C57Bl/6J (C57-12wk; n=5) mice serve as controls while Fibulin5 knockout mice (Fib5 KO; n=6, ~ 20 weeks old), deficient in elastin associate glycoprotein fibulin5, serve as an accelerated model of ageing. Progeria mice (HGPS-168d; n=7, ~168days old), homozygous to $Lmna^{G609G/G609G}$, serve as a mouse model of the Hutchinson Gilford Progeria Syndrome (HGPS) – a devastating condition that accelerates many characteristics of aging in humans. Finally, 120-week old C57Bl6/J (n=5; C57-120wk) mice serve as a natural ageing group.

All animal protocols were approved by the Institutional Animal Care and Use Committee of Yale University. Tissue dissection, cleaning, and preparation for biaxial testing is similar to our previous work [4]. Briefly, pulmonary arteries were bluntly dissected out of euthanized and exsanguinated mice. Perivascular tissue and fat were gently cleaned and branch vessels were ligated. The right pulmonary artery, from the main pulmonary bifurcation up to the first branch into the parenchyma, was ligated on custom glass pipettes and mechanically tested using a custom computer-controlled biaxial testing device [5]. Biaxial protocols consisted of three pressure-distension tests at fixed stretches (5% above, 5% below and at *in vivo* stretch) and four axial force-extension tests at fixed pressures (fixed pressures of 5, 15, 25 and 40 mmHg). Pressure and force were measured using standard transducers, diameter was measured using a videoscope and length was controlled using a submicron resolution stepper motor.

Similar to prior work [4], biaxial data was modeled using a pseudo elastic constitutive formulation where vessel mechanical behavior is modeled using four 'Fung-like' exponential families of fibers along axial, circumferential, and two symmetric diagonal directions, and a neo-Hookean term to model elastin contributions. Constitutive parameters were determined from best-fits to experimental data using MATLAB's *lsqnonlin* function. Mechanical metrics of interest (e.g., stress, stiffness and stored energy) were computed at physiologically relevant conditions. A one-way ANOVA a one-way ANOVA with Tukey's post-hoc analysis was used to probe potential statistical differences between groups. A $p$ value less than 0.05 was the threshold for statistical significance.

## RESULTS

We report mechanical metrics of interest at a physiologically relevant, subject-specific axial stretch and a pressure of 25 mmHg. Axial stretch (Figure 1a) was significantly lower in the aged groups compared to control group suggesting a higher collagen to elastin ratio in the wall.

Consistent with this, stored energy (Figure 1b), a measure of energy available in the wall to augment diastolic flow, was significantly lower in the aged groups, with the HGPS-168d having the lowest stored energy. Similarly, circumferential and axial stress (Figure 1c and d) were significantly lower in the aged groups compared to the control. Fib5-KO group had significantly higher stresses (both circumferential and axial) and stored energy than the HGPS-168d groups. Notably, circumferential stiffness was comparable and not significantly different across groups (Figure 1e). Axial stiffness was significantly lower in C57-120wk and HGPS-168d groups (Figure 1f) compared to the control group. There were also significant differences in axial stiffness between Fib5 KO and C57-120wk, and Fib5 KO and HGPS-168d.

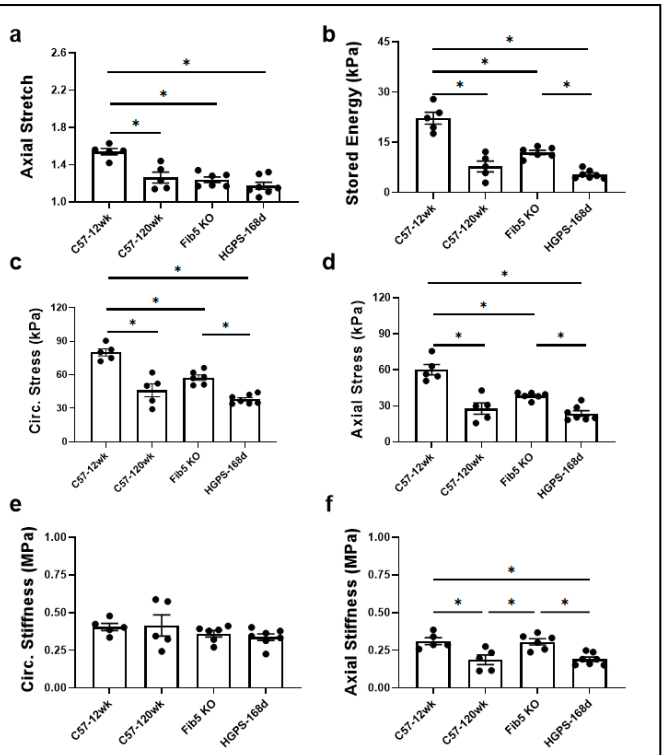

Figure 1 – Axial Stretch (a), Stored Energy (b), Circ. Stress (c) and Stiffness (e), Axial Stress (d) and Stiffness (f) in C57Bl/6J 12 weeks (C57-12wk; control), 120-week (C57-120wk), Fibulin-5 Knock out (Fib5 KO), Hutchinson Gilford Progeria Syndrome 168 days (HGPS-168d) groups. $p<0.05$ is significant (*). Results are reported at specimen-specific *in vivo* stretch and

## DISCUSSION

Murine models cannot phenocopy a human completely. But consistent findings across multiple murine models can yield insights into human health and disease. Here we show that all ageing models are associated with a reduced in vivo axial stretch, axial and circumferential stress and stored energy. Importantly, circumferential stiffness was preserved across multiple ageing models. Indeed, these findings are consistent with prior studies that have looked at ageing in the systemic arteries [2] with the exception of circumferential stiffness, which was significantly lower in the aged aorta of a Fib5-KO. These differences in mechanical metrics may be of relevance to ageing in human pulmonary arteries.

Lower axial in vivo stretch and a reduced stored energy suggest a higher collagen to elastin ratio in the wall. These findings will be confirmed using histology. Future efforts will also be directed towards quantification of lung function using pulmonary function test and cardiac function using echo [6]. This will enable understanding change in vascular mechanics within the context of remodeling in adjacent organs.

Major limitation of this study is only male mice were used. Challenges associated with breeding and maintaining mice up to 120 weeks for C57Bl/6J and 168 days for HGPS mice prevented us from achieving enough number of female mice for statistical tests. We will address this limitation in the future.

## ACKNOWLEDGEMENTS

Authors would like to acknowledge Dr. Sae-il Murtada's help in maintaining the mouse colonies.

## INTRODUCTION

Computational methods have gained significant traction in the risk assessment for thoracic aorta aneurysm (TAA)[1]. However, the computational demand of such simulations is high, and there is a relative lack of large datasets to be used for training and testing. Thus, there is considerable interest in reduced-dimension representation of the aorta. Statistical shape models (SSMs) describe the geometry of semantically similar objects to recover morphological features. SSMs have been used previously to model geometric variations in TAA[2], but those SSMs considered only the parent vessel of the thoracic aorta and removed the branching head vessels of the aortic arch[2,3]. Branching flows introduce recirculation regions that could affect the observed wall shear stress and flow profile[4]. Therefore, we introduced and evaluated an SSM method that incorporates the head branches.

## METHODS

The general method follows a standard SSM framework with additional modelling of the head vessels included in the shape descriptor. First, 3D geometries of the ascending aorta were extracted from 33 patient scans, scaled, and aligned based on generalized Procrustes analysis. These geometries were then parameterized onto a cylindrical coordinate system, as described by the vessel radius (r), polar angle ($\theta \in [0,2\pi)$), normalized centerline length ($s \in [0,1]$), and centerline coordinates ($C$), such that any surface quantifiable values (e.g., $r$) can be described in a shared parametric space of (θ,s).

The presence of holes marking the location of branches would violate the cylinder homeomorphicity constraint. Instead, branching holes were defined by an implicit closed curve in (θ,s) space as:

$$f(\theta,s) = 2/\left(1+e^{-\frac{4G_{signed}(\theta,s)}{k}}\right) - 1 = L \qquad (1)$$

where $f$ is a logistic function of a signed geodesic distance function ($G_{signed}$) that classifies whether a point on the surface is found within a branch hole. This function is normalized by $k = |min(G_{signed})|$, and $L$ is a level set segmentation value, iteratively determined by an auto thresholding algorithm[5].

These parameterized variables were concatenated into a shape descriptor matrix ($M$), for each subject ($n$), up to N number of subjects. $M$ could be reconstructed by principal component analysis (PCA) as the summation of weights ($w$) for $N_{PC}$ number of basis vectors ($\overrightarrow{PC}$):

$$M = \begin{bmatrix} C^{(n)} & f^{(n)} \\ \vdots & i \\ C^{(N)} & f^{(N)} \end{bmatrix} \approx \begin{bmatrix} w_{n_{PC}}^{(n)} \cdots w_{N_{PC}}^{(n)} \\ \vdots \\ w_{n_{PC}}^{(N)} \cdots w_{N_{PC}}^{(N)} \end{bmatrix} \begin{bmatrix} \overrightarrow{PC}_{n_{PC}} \\ \vdots \\ \overrightarrow{PC}_{N_{PC}} \end{bmatrix} i \qquad (2)$$

Once the SSM had been generated, the ability of the model to represent the original branched geometry was assessed. Aside from a geometrical comparison by distance and curvature, CFD was also performed, using Simvascular[6], on all reconstructed geometries at $N_{PC} = 20$ and 3 cases at $N_{PC} = 5,10,15,20,25,30$. Each geometry was meshed with ~1 million tetrahedral elements, following a mesh convergence study. Boundary conditions were set to be subject-specific flow rate from PC-MRI at the inlet and three-element windkessels at the outlets, calibrated to match clinically measured flow split and pressure via differential evolution. Blood was modelled as Newtonian with viscosity 4cP and density 1.06g/cm$^3$, yielding similar results to its non-Newtonian counterpart[7]. CFD were run to the fifth cardiac cycle using 500 timesteps of ~0.002s per cycle.

## RESULTS

The first few $\overrightarrow{PC}$s have mainly vessel radius information, so radius errors decreased quickly at low $N_{PC}$ (Fig. 1a), with -3dB cutoff of the variance explained at $N_{PC} = 1$ (Fig. 1b). A spider plot of the first 3 $\overrightarrow{PC}$s illustrates their major effect on vessel geometry: $w_1$ affects primarily overall radius-to-centerline-length ratio, $w_2$ affects radial dilation near the aortic root, and $w_3$ affects constriction in the mid-aorta (Fig. 1c).

SB³C2022-312

The distribution of $f$ at low $\overrightarrow{PC}$ reflects the common location of the branches along the centerline. At low $N_{PC}$, many of the head branches were joined, but they were well separated at high enough $N_{PC}$ (Figure 1d) as high $\overrightarrow{PC}$ generated large gradients to distinguish the outlet holes. This effect explained the large $N_{PC}$ for geodesic distance to reach -3dB cutoff, at $N_{PC} = 9$ (Figure 1a). $\overrightarrow{PC}$ carried the least amount of centerline information, as the centerline hardly varied across the cases. Thus, the Euclidean distance error of the centerline starts small and decreases modestly with $N_{PC}$ (Figure 1b), with the -3dB cutoff being at $N_{PC} = 14$ (Figure 1a).

The time- and wall-surface-averaged pressure across $N_{PC}$ did not vary significantly from the original geometry ($p > 0.3$ by a paired, two-tailed t-test). The average pressure error was typically less than 4% and largely independent of $N_{PC}$ (**Figure 2**a) as flow impedances were mainly determined by the windkessel outflow parameters. At the same time, vessel resistance (as a function of radius and vessel length) was already well represented in the lower $N_{PC}$. Furthermore, while the lower $N_{PC}$ cases often had merged branches of the head vessels, if the windkessel parameters were also parallelly merged, the aberrant branching pattern hardly affected the surface averaged pressures.

Similar to pressure, the surface- and time-averaged wall shear stress (SA-TAWSS) did not differ significantly from the original geometry ($p > 0.3$, **Figure 2**a). In contrast, the distribution of WSS error was sensitive to local vessel geometry. While the surface-averaged value was similar, the wall shear stress pattern differed with $N_{PC}$. Further breakdown of distribution of WSS error along the surface at $N_{PC} = 20$ are shown in **Figure 2**b. The location of the highest wall shear stress error in the geometry was found where the vessel branched, as caused by a recirculation region found near the branches.

## DISCUSSION

In general, the branching pattern did not affect global measures, such as SAWSS and surface averaged pressure. Even when the branches were merged, if their lumped parameter models are properly combined, the resulting pressures were similar to the fully branched model. Aortic shape variations may indicate adaptation to abnormal changes in pressure[8], but they do not drive these changes. The diameter is, however, still an important metric that relates how these pressures translates into stress experienced by the wall via the law of Laplace.

Meanwhile, WSS is known to be sensitive to variation in geometry, however, the variations were highly localized, with the location of the highest WSS found near the branches, similar to other studies[9]. The locations of highest WSS error were also near the branches, which required high $N_{PC}$ for accurate representation. Despite high local errors, surface-averaged WSS was well captured with low $N_{PC}$. In a study correlating WSS obtained from 4D MRI and aorta's shape, the diameter and velocity were strongly associated with WSS value[10], such that the radius-dominant low $N_{PC}$ could be sufficient to represent the SAWSS. Other locations of WSS errors appear to be weakly correlated with the surface curvature error. The curvature of the aorta introduced secondary flow patterns that depend on aortic curvature (**Figure 2**c)[11], primarily because the curvature affects the angle of inflow boundary condition and therefore downstream flow profile. Therefore, low $N_{PC}$ may be sufficient to describe the average WSS, but a high $N_{PC}$ is required to obtain more accurate surface distribution.

## INTRODUCTION

Soft biological tissues respond to unprecedented stimuli (e.g., diseases) by adapting, repairing, and growth and remodeling (G&R). In most cases, these stimuli are sensed by certain receptors, and the related signals transduce chemically and mechanically, leading to alterations in cell behavior. These cellular changes often lead to changes in organ-scale geometry and function. These observations can be explained across the scales from cellular to tissue-scale levels [1].

Numerous studies highlight the role of continuum mechanics modeling in understanding the responses to these stimuli at the tissue-scale level [2]. For example, disease and aging-driven quantification of G&R improve our understanding of the interaction between tissue growth and mechanical forces [2,3]. Subsequently, knowing the underlying biochemistry of cell signaling pathways, a mathematical description could be developed to model a system of differential equations to represent the cellular level. These models, which are in two different scales are dependent on each other and studying them individually will give us imperfect information [4].

Coupling cell-scale biology and tissue-scale G&R models is challenging. Herein, we developed simple cases to illustrate different approaches to achieving this task. Particularly, one vs. two-way coupling between mechanics and biology, ordinary vs. partial differential equation approach for modeling the biology, and coupling to transient mechanics (elastodynamics) is investigated.

## METHODS

A cube and a cylinder (idealized aneurysm) were assumed as our test-case geometries. Systems of ordinary differential equations (ODEs) representing reactions between biochemicals (cell-scale level) were coupled (1-way and 2-way) with kinematic G&R (tissue-scale level). Also, for the cylinder, a system of partial differential equations (PDEs) model was implemented to smoothly model the spatial pattern of cell reactions.

**Cube (1-way coupling of ODEs with kinematic growth):** The geometry was discretized into 10000 quadratic tetrahedral elements. An idealized system of ODEs representing cell signaling of three species was implemented. These ODEs include three equations representing the reactions of three species A, B, and C:

$$if_i \rightarrow A \quad A + B \rightarrow C \quad where \quad = each \; node \tag{1a}$$

$$\frac{dy_j}{dt} = F(y_j) \quad where \quad y_j = A, B, C \tag{1b}$$

$f_i$ represents an arbitrary function for each computational node $i$ described as $f_i(x,y) = \frac{|x_i+y_i|}{2}$ and was used for the first species [A] as a source term driving its concentration. The initial conditions for species concentration [A] and [B] were set to one and for [C] was set to zero. Kinematic growth was used for the growth model at the tissue scale:

$$F_t = F_e F_g \quad \text{where} \quad F_g = I + \nu ik \otimes k \tag{2}$$

The growth rate ($\nu$) in each node was assumed as a function of the normalized output of the third species [C] in each timestep ($\nu = 0.01\frac{C}{C_0}$). The growth direction was in the z-direction. The cube was fixed at the bottom surface and was not pressurized.

**Cube (2-way coupling of ODEs with kinematic growth):** In this part, the source term for species A was modified to include the mechanical stress ($f_i(x,y,\sigma)\, i = \frac{|x_i+y_i|}{2} + \frac{|\mathrm{tr}(\sigma_i)|}{\sigma_0}$), where at t=0, $\sigma$ was assumed to be zero. The system of ODEs was solved,

and the growth rate was updated in each timestep. Next, by updating the stress from the G&R simulation, the source term for [A] was updated.

**Cylinder (1-way coupling of ODEs with kinematic growth):** A cylinder was modeled to represent an idealized artery. The geometry was meshed into 51000 quadratic tetrahedral elements. The aim was to study an idealized aneurysm growth (a common test case in the G&R literature). Cell signaling with a system of ODEs with five species was used from a previous study [5]. TGF-β, MAPK, Smad, MMP, and TIMP were the species featured in this model. A Gaussian distribution of the coordinates of the mesh was used as an input (source term) for the first species (TGF-β) and zero initial conditions were used. The growth rate $(\boldsymbol{v})\dot{\boldsymbol{\iota}}$was implemented as a function of MMP and was set in the radial direction. A pressure waveform was applied to the aneurysm wall during the G&R simulations.

**Cylinder (2-way coupling of ODEs with kinematic growth):** In this case, the TGF-β source term was defined as a function of stress and the aforementioned Gaussian distribution. Similar to the last 2-way coupling case, the stress value used in the systems biology model was updated based on the G&R simulations.

**Cylinder (1-way coupling of PDEs with kinematic growth):** In this case, the previous 1-way coupled model was extended to include diffusion terms, which were added to each equation of the system of ODEs to generate a system of unsteady reaction-diffusion PDEs.

## RESULTS

The displacement results for 1-way coupling and 2-way coupling of the ODE model with kinematic growth for the cube are shown in Figure 1. In the 1-way coupling case, more localized growth was observed at the tip of the cube, whereas in the 2-way coupling case the growth at the top surface was more homogeneous. Additionally, the stress induced by growth showed heterogeneous patterns with higher stress within the middle of the cube (results not shown).

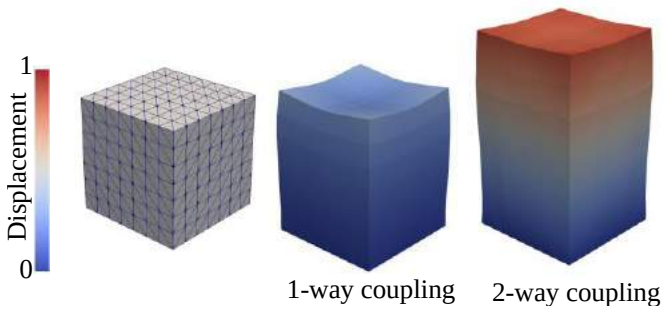

**Figure 1. Displacement results for 1-way coupling and 2-way coupling of the box.**

The displacement results for the cylinder case are shown in figure 2. The growth of the aneurysm in the 1-way coupling ODE model is consistent with the input of TGF-β. However, in the 2-way coupling cases, because of pressurizing the artery, the stress alters the growth to expand the artery more in the longitudinal direction. Finally, the results for 1-way coupling of the system of PDEs with kinematic growth indicate that the aneurysm length and diameter are altered slightly compared to the 1-way coupling of the system of ODEs.

## DISCUSSION

We modeled two different test case geometries representing an idealized tissue block and aneurysm to compare the results of 1-way and 2-way coupling strategies in modeling kinematic G&R coupled with systems biology. We observed the different growth patterns in both geometries between 1-way and 2-way coupling approaches. Additionally, we implemented a system of PDEs approach for modeling the systems biology and compared the results to the ODE approach. Our models were implemented in the open-source finite-element software FEniCS. The future release of our code will enable the implementation of flexible coupling strategies between systems biology and continuum mechanics models of G&R. In future work, we will implement the 2-way coupling of the system of PDEs. Additionally, we are currently implementing our framework to study calcific aortic valve disease growth based on our prior systems biology [6] and continuum [3] calcification models where we will study large deformation elastodynamics.

# ON-FIELD EVALUATION OF MOUTHPIECE- AND HELMET-MOUNTED SENSOR DATA FROM HEAD KINEMATICS IN FOOTBALL

**Ty D. Holcomb (1, 2), Madison E. Marks (1, 2), N. Stewart Pritchard (1, 2), Logan E. Miller (1, 2), Jillian E. Urban (1, 2), Joel D. Stitzel (1, 2)**

## INTRODUCTION

Concussive and sub-concussive head impacts in contact and collision sports are of increasing concern as changes in cognition and neuroimaging associated with repeated head impact exposure (HIE) in football have been observed following a single season of play.[1,2] Helmet-mounted sensors have allowed researchers to measure the frequency and magnitude of head impacts experienced by athletes on-field; however, coupling of sensors has been questioned.[3,4] Advances in sensor technology have allowed for the development of mouthpiece-based sensors with improved kinematic measurement, in some load cases, with improved coupling;[5] however, evaluation of field variance between sensor systems in an on-field environment has been limited. Therefore, the objective of this study was to compare HIE measured from athletes dually instrumented with the Head Impact Telemetry (HIT) System and a mouthpiece-based sensor system.

## METHODS

A total of five high school football athletes (ages 15-18) were enrolled in this study, approved by the Wake Forest School of Medicine Institutional Review Board. Each player was fitted with either a Riddell Speed or Speed Flex football helmet containing a HIT System MxEncoder and simultaneously instrumented with a custom-fit mouth guard containing the mouthpiece (MP)-based sensor system[5]. The athletes were instrumented with the aforementioned sensors during a single spring football season. The HIT System was set to record at the default 10g threshold while the MP-based sensors were set to record when 5g was exceeded on any axis for at least 3 milliseconds. Trained researchers monitored the HIT System and MP-based sensors at all contact practices and games. Two cameras were used to capture time-synchronized film at each session with a camera placed at the end zone and on the sideline. Events from each sensor system were time-aligned and verified with video. The frequency and peak magnitude of video-verified head acceleration events (i.e., events) were compared across sensor systems. Peak resultant linear and angular acceleration was calculated for each recorded event and compared across sensor systems. Head acceleration events were paired between devices using the measured event recording time and the synchronized video time. Peak resultant linear and angular acceleration recorded on each sensor system was then compared for paired events by subtracting the HITS measurement from the MP-based sensor measurement and outliers were identified by evaluating the distribution of differences in peak magnitude between paired events.

## RESULTS

A total of 7189 events were collected with the MP-based sensor system and a total of 1523 events were collected with the HIT System throughout the season. Using video-verification, 6006 false-positive events (83.5%) were excluded from the MP-based sensors data and 817 (53.6%) false-positive events were excluded from the HIT System data. A false event was typically due to handing of the sensor off the field (e.g., removing helmet or mouthpiece). In total, 1183 true-positive head acceleration events (16.5%) were identified from the MP-based sensor data and 706 true-positive head acceleration events (46.3%) were observed from the HIT system sensor data. These events were then paired based on the time of the recorded event coincident with observed contact. 537 events were captured by both sensor systems. The analysis that follows refers to these paired events.

Figure 1 demonstrates the peak resultant linear acceleration recorded by each device for each paired event. The origin regression line represents the same linear regression calculation forced through the origin. Greater variation in the linear acceleration was observed as the linear acceleration measured by the sensor systems increased. A histogram of the difference in peak resultant linear acceleration between the sensor systems is provided in Figure 2. Approximately 78.8% of the paired events fell between ±20 g difference in peak resultant linear acceleration. Angular acceleration measured by each device is shown in

Figure 3 and angular acceleration difference in peak resultant is shown in Figure 4. Summary statistics for the peak resultant kinematics recorded by each sensor system are provided in Tables 1 and 2.

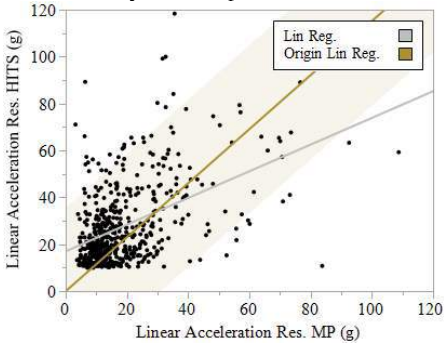

**Figure 1: Linear Acceleration MP vs. HITS**

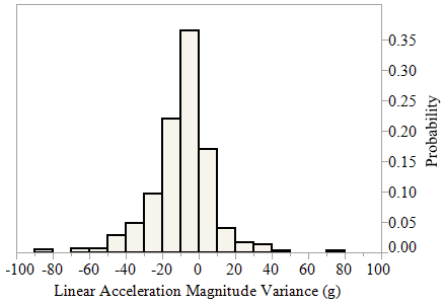

**Figure 2: Linear Accel Magnitude Variance (MP-HITS)**

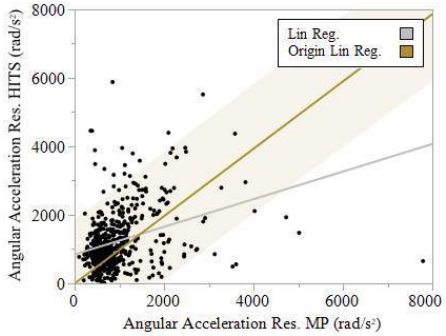

**Figure 3: Angular Acceleration MP vs. HITS**

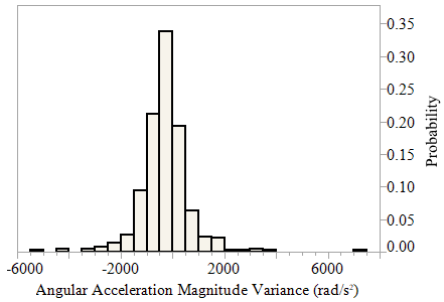

**Figure 4: Angular Accel Magnitude Variance (MP-HITS)**

**Table 1: Linear Acceleration Comparison MP vs. HITS**

| Lin Accel (g) | Mean | SD | Median | 95% | Max |
|---|---|---|---|---|---|
| MP | **19.0** | **13.9** | **14.5** | **46.4** | **108.8** |
| HIT System | **27.8** | **17.0** | **22.6** | **63.1** | **118.4** |
| Difference | **-8.6** | **16.2** | **-7.1** | **12.5** | **73.0** |

**Table 2: Angular Acceleration Comparison MP vs. HITS**

| Ang Accel (rad/s²) | Mean | SD | Median | 95% | Max |
|---|---|---|---|---|---|
| MP | **959** | **696** | **774** | **2132** | **7789** |
| HIT System | **1236** | **857** | **1008** | **2841** | **5884** |
| Difference | **-277** | **910** | **-275** | **1025** | **7135** |

Paired events were classified as outliers by evaluating the respective cumulative distribution function. 90% of paired events varied by less than 30g for linear acceleration or less than 1500 rad/s$^2$ for angular acceleration; therefore, >30g and >1500 rad/s$^2$ difference was used to categorize linear angular acceleration outliers respectively for a total of 88 events. These outliers were re-evaluated using the video-verification review process. The description of each impact was further evaluated. In 72 instances (82%), the MP-based sensor measurement appeared to be a more realistic and lower measurement compared to the HIT System, but this was subjectively determined from video.

## DISCUSSION `

The objective of this study was to compare HIE measured from athletes dually instrumented with the HIT System and a MP-based sensor system with improved skull coupling. The MP-based sensors recorded lower linear and angular acceleration magnitudes, on average, with an average difference in magnitude of 8.6g for peak resultant linear acceleration and an average difference in magnitude of 277 rad/s$^2$ for peak resultant angular acceleration. This could potentially be attributed to sensor coupling with the head of the athlete. Helmet fit plays a role in how well the HIT System is coupled to the head of an athlete, as the HIT System assumes the helmet and the skull move as a single rigid body [4,6]. The MP-based sensors are custom-fit and coupled to the roof of the mouth. The results of this study differ from those produced by Shah et al in that the MP collected more video-verified events than the HIT system most likely due to the difference in device impact threshold [7]. Approximately 10% of events had greater than 30g difference in peak resultant linear acceleration and 1500 rad/s$^2$ and were deemed outliers.

The limitations of this study include a small sample of size of 5 athletes, multiple film reviewers which has the potential to introduce human bias, the different trigger thresholds of 5g for the MP-based sensors and 10g for the HIT System, and that the data was collected from a single football team.

The results of this study demonstrate a difference in the HIT System and MP-based sensors. While the difference in peak resultant kinematics was, on average, -8.6g and -277 rad/s$^2$, greater differences in peak resultant magnitude were observed at higher magnitude events. The HIT System generally recorded higher acceleration measurements for outlier events than the MP-based sensors. The results of this study help to improve our understanding of the sensors utilized in the collection of head acceleration data and may inform interpretation of head acceleration data collected from different sensors.

## INTRODUCTION

Each year ~1.4 million patients require arterial grafts in the US. Synthetic vascular grafts are required in ~10-20% of patients when autografts are unavailable; however, synthetic vascular grafts in small diameter applications (ID < 6 mm) have high failure rates. Synthetic grafts are associated with a 40-50% reduction in patency after 2 years and a 40% failure rate at 5 years [1]. This loss of patency due to intimal hyperplasia has been attributed, in part, to poor compliance-matching with native arterial tissue [2]. Data demonstrate that the high compliance of native vessels (e.g., coronary artery, 10-15 %/mmHg*$10^{-2}$) permits expansion and contraction during the cardiac cycle, whereas commercially available synthetic grafts have limited deformation at these pressure loads (e.g., ePTFE, 1-2 %/mmHg*$10^{-2}$). Notwithstanding the role of altered hemodynamics at the graft-tissue interface leading to neointimal hyperplasia, improved compliance matching between the graft and arterial tissue has been identified as a key determinant of long-term patency and graft success.

Advances in material chemistry and microfabrication strategies have allowed the manufacturing of polyurethane-based small diameter vascular graft with improved compliance matching [3]. Indeed, these grafts have been shown to reduce cellular markers for intimal hyperplasia, however, the increased compliance resulted in grafts that were prone to kinking. To improve kink-resistance, a polymeric coil was added, but the addition negatively impacted compliance [4]. The ideal graft (i.e., high compliance and high kink-resistance) requires a balance between multiple biomechanical properties that are in opposition (e.g., methods to increase graft kink-resistance reduce its compliance). Between geometric and material property tunability, the number of design parameter combinations for coil-reinforced graft manufacturing via a trial-and error approach is nearly limitless and prohibitively time-consuming. Herein, we develop and apply a novel computational biomechanics approach to inform graft design and identify mechanically-optimized tissue engineered candidate designs.

## METHODS

**Computational Geometry and Modeling:** The graft was modeled as an axisymmetric cylinder ($l = 40$ mm, $d_i = 4.74$ mm, $d_o = 4.94$ mm) with a reinforced coil wrapped helically around the outer surface (Fig. 1A). The graft and spiral coil were discretized with hexahedral and tetrahedral elements, respectively. Both the graft and coil were described as a nearly incompressible neo-Hookean solid with material properties derived from mechanical testing performed in our laboratory. Two computational simulations were performed for each coil-reinforced graft to quantify compliance and kink resistance (Fig. 1B-C). To quantify compliance ($C$, Eq. 1), the graft was inflated to a lumen pressure of 80 mmHg and 120 mmHg. Predicted inner diameters at these pressures were extracted and compliance was calculated as,

$$C = \frac{d_{i,120\ mmHg} - d_{i,80\ mmHg}}{d_{i,80\ mmHg} * 40\ mmHg} \quad (1)$$

To quantify kink-resistance, a 1° bend (i.e., imperfection) was applied to the central axis of the graft to facilitate buckling, as previously established [5]. The lumen was pressurized to 100 mmHg, and the graft was compressed axially by application of a displacement to initiate kinking. Kink-resistance was quantified as the axial displacement (mm) at which a kink forms in the graft (i.e., discontinuity in the geometry). For all models, symmetry boundary conditions were enforced on the graft to restrict rigid body motions in the circumferential and axial directions. A tied-elastic contact formulation was implemented between the outer graft surface and the spiral coil. Finite element analysis was performed using FEBio [6].

**Batch-Processing Scheme:** To advise and accelerate the graft design process, an optimization scheme was utilized to sweep the multi-dimensional design space to identify optimal parameter combinations for grafts with target compliance and kink-resistance. As an extension to the computational models, a batch processing scheme was implemented using GIBBON (open-source MATLAB toolbox) and

FEBio. [6,7] First, a parameter sweep analysis was used by selecting parameter sets from uniform distributions over the defined parameter ranges (Fig. 1D). Coil diameter ($d_{coil}$) ranged from 0.1 to 0.5 mm, and coil spacing (i.e., pitch; $P_{coil}$) ranged from 2 to 10 mm. The coil modulus ($G_{coil}$) was defined as either 8.13 MPa (Bionate® PCU 55D) or 2.93 MPa (Bionate® PCU 80A). Lastly, the graft modulus ($G_{graft}$ = 1.315 MPa) was chosen to match the compliance of native arterial tissue at physiologic pressure. The batch-processing algorithm automatically generated and solved 2 FEBio models (compliance and kink-resistance) for each of the 72 unique parameter combinations (144 models in total).

**Graft Optimization:** To balance the contribution of competing mechanical responses (i.e., compliance versus kink-resistance), an optimization function (φ) was defined and sought to be minimized across the parameter search space. For each combination of design parameters, the value φ was calculated as,

$$\varphi(d_{coil}, P_{coil}, G_{coil}, G_{graft}) = \alpha\left[\frac{C_{graft} - C_{artery}}{C_{artery}}\right]^2 + (1-\alpha)\left[\frac{K_{graft} - K_{ePTFE}}{K_{ePTFE}}\right]^2 \quad (2)$$

where $C_{graft}$ and $C_{artery}$ are the compliance values for the examined graft and artery tissue, respectively, $K_{graft}$ and $K_{ePTFE}$ are the kink-resistance values of the graft and ePTFE, respectively, and $\alpha$ is a weighting coefficient, which was defined as 0.5 (i.e., equal weight between compliance and kink-resistance). Note that a minimized $\varphi$ value indicated the modeled graft had a graft compliance and kink-resistance comparable to native arterial tissue and ePTFE grafts, respectively.

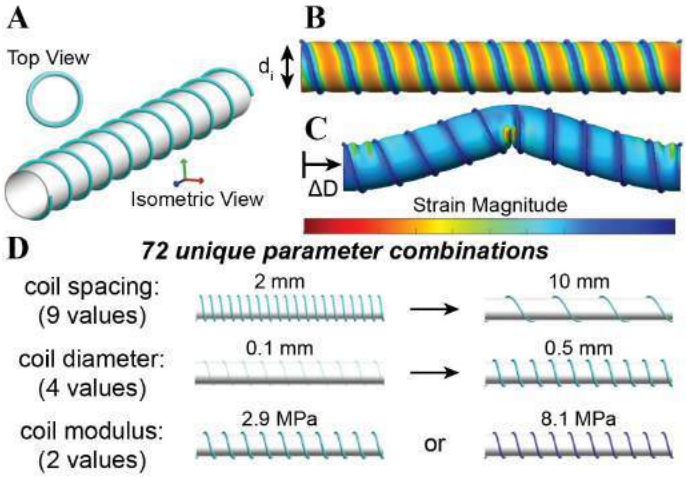

**Figure 1: A) Representative geometry of coil-reinforced graft at reference configuration. B) Compliance quantified via changes in inner diameter ($d_i$). C) Kink-resistance quantified via axial displacement distance (Δ$D$). D) Batch-generated coil-reinforced graft geometries via Gibbon.**

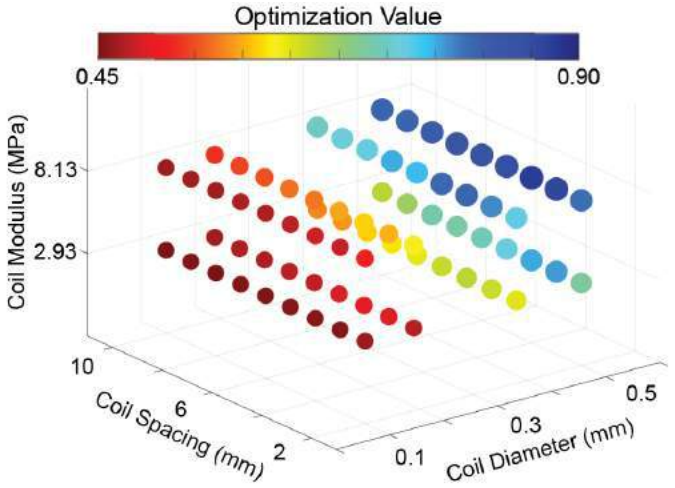
## RESULTS

Across the 72 parameter combinations (~9 days of computational time on 12-core, 4.4 GHz processor), graft compliance displayed a wide range of values. For example, the compliance values varied from 0.39 to 7.17 %/mmHg*$10^{-2}$ across the parameter space, and values were dependent on both coil diameter and coil spacing. Surprisingly, however, there were minimal changes to kink-resistance (i.e., prescribed axial displacement when kinking initiates) across the parameter space, except at coil spacings of 2 mm. More specifically, for coil spacings >2 mm the axial displacement that initiated kinking was 2.07 ± 0.12 mm, but values 3.58 ± 1.32 mm were observed for coil spacings of 2 mm (higher kink-resistance). Predicted compliance and kink-resistance values led to diverse values for the optimization function (Fig. 2). The minimum value of φ = 0.44 resulted from the combination of a coil diameter = 0.1 mm, coil spacing = 10 mm, and coil modulus = 2.93 MPa (Bionate® PCU 80A). For this parameter combination, the compliance and axial displacement were 7.10 %/mmHg*$10^{-2}$ and 2.08 mm, respectively. The maximum optimization value of φ = 0.88 had the combination of a coil diameter = 0.5 mm, coil spacing = 4 mm, and coil modulus = 8.13 MPa (Bionate® PCU 55D).



## DISCUSSION

Our investigation demonstrates the success in implementing an FE-batch processing framework to accelerate model-directed tissue engineered vascular graft design. Results suggests that smaller coil spacing improves kink-resistance of the graft but reduces compliance; whereas, compliance and kink-resistance are independent of coil moduli. Furthermore, the data suggests that coil spacings <2 mm should be explored to improve optimization values, but fabrication limitations may constrain this parameter space. Importantly, the optimization scheme successfully identified a graft with improved kink-resistance without sacrificing compliance. It should be emphasized that experimental fabrication and testing of 72 grafts would take 6-9 months. We anticipate that this model-directed design approach is expected to provide a kink-resistant graft with high compliance for small diameter vascular graft applications. Ultimately, these unique grafts have potential to improve clinical outcomes by addressing failures of current synthetic grafts.

## INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a genetic disease of the sarcomere that results in overgrowth of the left ventricular septum. This overgrowth often causes mitral valve regurgitation and additional stress on the heart. A fibrotic collagenous microenvironment is associated with HCM due to this altered stress condition [1]. Hypertrophy of the cells and the fibrotic environment contribute to the abnormal biomechanical properties of the septal tissues. Additionally, previous literature has shown that the circumferential myocardial shortening of ventricular muscle during contraction often occurs and is directly involved in the preservation of left ventricular systolic performance in HCM [2]. Reduced left ventricular strain, due to the thickening of the wall, has also associated with poor cardiac outcomes, which consequently result in heart failure and mortality [3]. In this study, we performed thorough microstructural and biomechanical characterizations on human septal tissues in both healthy condition and hypertrophic condition.

## METHODS

Hypertrophic septal samples were obtained from the surgical waste of clinical myectomy of the HCM patients (UTSW: IRB STU 082017-072). Patients include both male and female and range in age from 19 years to 71 years. Healthy human septal tissues were obtained from a tissue bank under the same IRB protocol. Septal tissues were then dissected for histology and uniaxial tensile testing. Samples prepared for uniaxial testing were aligned with the longitudinal direction of the septum. Tissue samples were then mounted onto the TestResources Universal Testing Machine (Shakopee, MN) and tested in 1X Phosphate Buffered Saline (PBS). After preconditioning, the sample were loaded until failure (tissue breakage). For histology, all samples were fixed in 10% neutral buffered formalin for 24 hours and were processed through a standard histological preparation protocol, including alcohol-dehydration and paraffin-embedment. 5 μm sections were cut and a standard Masson's trichrome staining protocol was performed. The Masson's trichrome protocol stained heart muscle red and collagen blue. Histological images were taken under bright light field using a Nikon Eclipse Ti Series Microscope (Nikon).

## RESULTS

The averaged uniaxial stress-strain curve of the healthy septal tissues showed a very typical nonlinear concave upward stress-strain relation (**Figure 1**). The HCM tissues, however, showed a stress-strain trend that was much less nonlinear. The HCM septal tissues had an initial modulus that was higher than healthy septal tissues, most likely due to the abundant fibrotic collagen associated with HCM. Very interestingly, we found that the healthy septal tissues had much higher mechanical strength than the HCM septal tissues, demonstrated by the failure stress (healthy: 2,561 ± 919 kPa vs HCM: 494 ± 206 kPa). In the high strain region, the healthy septal tissues were also stiffer than the HCM septal tissues, as shown by the maximum tensile modulus of the tissues. Overall, HCM septal tissues were stiffer at the initial phase of tissue loading, less nonlinear, less stiff in the linear region, and much weaker in mechanical strength. This is a very novel biomechanical finding of this disorganized,

hypertrophic, and fibrotic septal muscle tissue. Masson's trichrome staining revealed that the HCM septal tissue had hypertrophic cardiomyocytes that were significant larger and disarrayed when compared with the healthy cardiomyocytes (**Figure 2**).

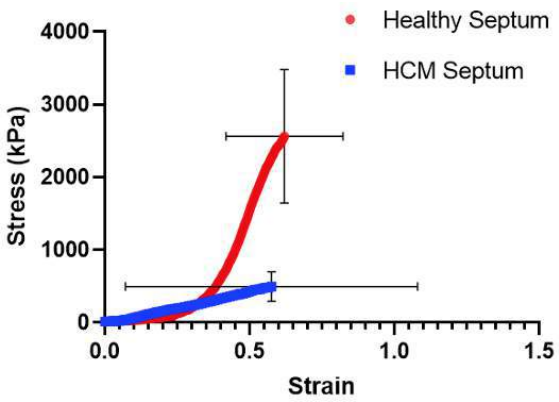

**Figure 1: Average stress-strain behavior of healthy (red) and HCM (blue) human septal tissues.**

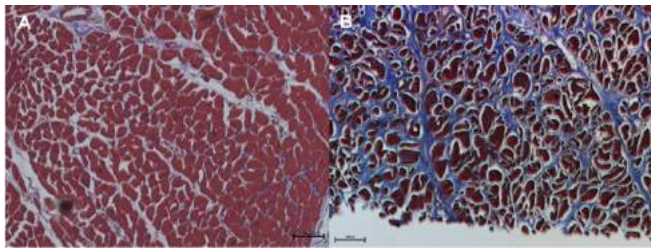

**Figure 2: Masson's trichrome images of healthy (A) and HCM (B) human septal tissues.**

## DISCUSSION

Uniaxial tensile stress-strain curves up to failure revealed that healthy human septal tissues were less stiff in the initial loading region, but was much stiffer in the linear region and had a much higher mechanical strength than the HCM human septal tissues. The healthy septal tissues took an optimal soft tissue biomechanical behavior, and the HCM septal tissues exhibited deteriorated mechanical behavior due to pathological structural alterations of HCM. Our biomechanical and microstructural data provide a strong foundation to understand tissue behavior of HCM septal tissues in relation to healthy septal tissues.

# ASSESSING LOCAL DELIVERY CAPABILITY OF A NOVEL SEPTAL ABLATION SYSTEM VIA AN *EX VIVO* PIG HEART MODEL

## INTRODUCTION

For inoperable hypertrophic cardiomyopathy (HCM), surgeons often inject pure alcohol into the septum via a septal perforator to destroy part of the septal muscle by triggering necrosis. This alcohol septal ablation (ASA) procedure is common but has risky complications (a periprocedural mortality rate of ~2%), including atrioventricular block, ventricular septal defect, ventricular fibrillation/tachycardia, and need for pacemaker, all due to the diffusive nature of alcohol (uncontrollable necrosis). To overcome ASA limitations, we have designed a novel collagenase-coated, doxorubicin-loaded nanoparticle (NP) ablation system to achieve a controllable, localized septal tissue shrinkage and hence a safe ablation [1]. To determine the localization patterns of our novel NP ablation system, we performed an *ex vivo* study using a pig heart model to measure the mean diffusion area of the injected ablation solution in the cardiac septum. With this *ex vivo* pig heart model, we were able to determine the localization capability of our NP ablation system.

## METHODS

Cy5 NPs were prepared by a standard double emulsion process. Briefly, 100 mg of PLGA (90% PLGA 50:50, 10% PLGA-NHS) was dissolved in 3 mL DCM. Cy5 was dissolved in dimethyl sulfoxide (DMSO) and was added dropwise to the PLGA solution on a stir plate at room temperature. After overnight stirring, the NPs were washed with deionized water and were collected by centrifugation and lyophilization. To conjugate collagenase (COL) to the surface of the Cy5 particles, 20 μg (per 10 mg of NPs) of COL were added to a NP solution in PBS (1 mg/mL). 1 mL of each COL-PLGA-Cy5 and PLGA-Cy5 solutions were injected *ex vivo* into the septum of fresh porcine hearts via the uppermost septal perforator of the left anterior descending coronary artery using a 21-gauge needle. Note that 1 mL of Cy5-Alcohol was used as a control. After injection, images were taken of the hearts using a custom-built fluorescent microscope. After the initial image, each heart was washed with PBS and reimaged to capture how the NPs could migrate under fluid flow. Quantitatively, we used the area of Cy5 signal on images of each group to assess whether the solution was diffusing from the injection site or staying close the injection site (localized delivery).

## RESULTS

As reported in literature, alcohol is not specifically localized to the septal tissue which results in alcohol diffusing and expanding into other regions. Our results confirmed that, when delivered via a septal perforator, alcohol signal covered a large anterior septal surface area (390±10 $cm^2$). PLGA-Cy5, on the other hand, covered 94 $cm^2$, while COL-PLGA-Cy5 covered the least amount of area (61±8.5 $cm^2$) (Fig. 1B,C). In short, PLGA-Cy5 and COL-PLGA-Cy5 appeared to localize close to the injection site, while alcohol dispersed downwards and outwards. In this study, the use of *ex vivo* healthy porcine heart model was a limitation; however, as a proof-of-concept study the reported results demonstrated a localized spatial distribution of NPs and formed a strong foundation for future validation using diseased tissues and *in vivo* model.

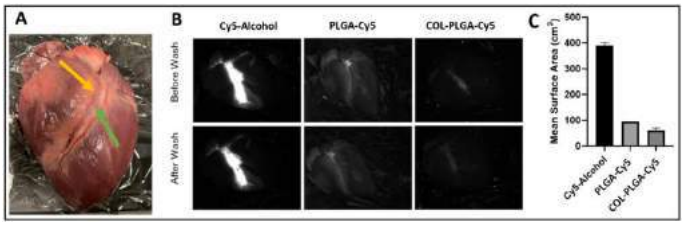

**Figure 1: (A) Injection site on a fresh porcine heart (orange arrow) and visible septal perforator (green arrow). (B) Anterior view following treatments with Cy5-Alcohol, PLGA-Cy5, and COL-PLGA-Cy5. (C) Mean surface area coverage after Cy5-alcohol, PLGA-Cy5, and COL-PLGA-Cy5 injections.**

## DISCUSSION

Using an *ex vivo* porcine heart model, we demonstrated that our targeted COL-PLGA NP ablation system had better localization capability than the treatment of alcohol, covering the least amount of septal area after the uppermost septal perforator injection.

# COMPARISON OF DISC DESIGNS AND OUTCOMES IN CERVICAL DISC ARTHROPLASTY USING MULTISCALE MODELING

**Yuvaraj Purushothaman, Jamie Baisden, Hoon Choi, Narayan Yoganandan**

Department of Neurosurgery
Medical College of Wisconsin
Milwaukee, WI

## INTRODUCTION

Cervical disc arthroplasty (CDA) is designed as a motion preserving technique to overcome the problems associated with anterior cervical discectomy and fusion (ACDF) used to treat cervical radiculopathy and myeloradiculopathy [1]. The CDA's have survived the noninferiority tests in comparison to ACDF but the ideal CDA has yet been determined. Clinical problems associated with ACDF are potential decrease in the range of motion and increase in adjacent segment degeneration, potentially requiring additional surgery. There have been multiple arthroplasty devices designed but only seven FDA has approved for commercial use [FDA.gov]. The inherent design features and biomaterials used affect cervical kinetics (loads and motions). Multiple models are needed to compare the responses of different devices, and a head-to-head evaluation using laboratory and clinical models is often the optimum choice. In this study a three-tiered multi-scale modeling approach was used to study the CDA's: longitudinal caprine model, human patient outcome analysis, and computational finite element modeling of different CDAs and ACDF.

## METHODS

**Animal Study: T**he study was approved by the institutional review boards (IRB), Institutional Animal Care and Use Committee at the VA, and sponsor. Eleven Alpine caprine (weight ranging from 36.4 to 72.2 kg) underwent anterior cervical discectomy fusion and plating in four animals, Mobi-C in four animals, and Prestige in three animals. All surgeries were done at the C3-C4 spinal level. The rationale for selecting the caprine is provided in the discussion. Pre- and immediate post-operative radiographs were taken to ensure the implant. Continuous monitoring of the animal was done in the Veterinary Medical Unit of the VA Medical Center. It included obtaining longitudinal x-rays until the six-months, after which time the animal was euthanized, and images were obtained after excision. Two neurosurgeons performed the procedure on every animal.

**Human Study:** A literature review was conducted with human data using the PubMed database. It covered 30 years for the five commonly used FDA approved CDA's: Prestige LP by Medtronics; Secure-C by Globus; Prodisc-C by Centinel Spine; Mobi-C by Biomet; and Bryan disc by Medtronic. Patient outcomes from our institution were examined after obtaining approvals from the local IRB and sponsor. Complications and outcomes were reviewed for each artificial disc.

**Finite element modeling study:** A previously validated three-dimensional osteoligamentous finite element model of the cervical column (C2-T1) was used [2]. The model simulated the vertebra of the body, posterior elements, intervertebral disc, and ligaments. Each vertebral body of the body consisted of a thin cortical shell, a softer cancellous bone, endplate, and a posterior bony structure. The cortical bone was modeled as a linear isotropic material of 0.5 mm thick shell surrounding the cancellous bone, and a 0.2 mm thick endplate was placed on the superior and inferior surfaces of the disc. The intervertebral disc was modeled composed of the nucleus pulposus, annulus ground substance, and annulus fibrosus. All major ligaments were included. Material properties from literature were used. Using standard surgical procedures, the intact spine was modified at the C5-C6 vertebral level to simulate the biomechanics of ACDF and two types of CDAs. One was a metal-on-metal (MOM) and the other one was a metal-on-polymer (MOP) type device. The anterior longitudinal ligament was removed at the surgical level in all cases. In the case of ADR, a cavity was created at the implanted level for the placement of the disc prosthesis. In the case of ACDF, the disc properties were altered at the surgical level to simulate the trabecular bone, and this simulated complete fusion. The plate was placed along the anterior surfaces from C5-C6 level, and four titanium screws were simulated. Figure 1 shows the coronal views of the finite element model for each case.

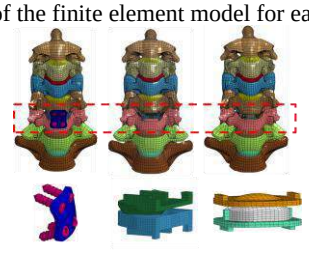

**Figure 1**: **Top row shows the coronal views of the spinal column and bottom rows show the ACDF, and MOM and MOP CDAs.**

All finite element models were fixed at the first thoracic vertebra in all degrees-of-freedom, and the load was applied at the superior endplate of the C2 vertebra. A follower load of 75 N and a bending moment of 2 Nm under flexion and extension and lateral bending were applied to the three groups, ACDF, MOM and MOP CDAs. The range of motion was measured at each level and across the C3-C7 levels. The variable moment loading protocol, also known as hybrid loading, was then applied [4]. The bending moment was varied until the ACDF, metal-on-metal and metal-on-polymer models responded with the same total C3-C7 range of motion. The range of motion and facet force were obtained at the index and adjacent segments under each loading mode.

## RESULTS

**Animal Study:** All four metal-on-polymer implants experienced anterior extrusion from the disc space and no additional animals were used to implant this device. Metal-on-metal implants experienced one anterior migration in six animals.

**Human study:** The kinematic responses were similar for all CDAs, i.e., improved range of motion and similar clinical risks/complications. The outcomes were mixed, however, with respect to the reported reduction in adjacent segment disease and need for additional surgeries.

**Finite element modeling study:** The metal-on-metal device had lower range of motion, lower facet forces at the index level and both adjacent levels compared to the metal-on-polymer device. The ACDF resulted in an increase in the range of motion at each spinal level except at the index level, and this was higher than the intact spine and both types of CDA's.

With respect to the intact spine, in flexion, the ACDF at C4-C5 and C6-C7 levels showed 27% and 16% increase in the range of motion. The metal-on-metal CDA had a decrease in the range of motion of 8% at the cephalad and 5% at the caudal level. The metal-on-polymer CDA responded with decreases of 5% and 14% at these levels, respectively.

In extension, for the ACDF, the increase in the range of motion at the cephalad and caudal levels were 34% and 21%, respectively. For the metal-on-metal CDA, the decrease in the range of motion was 7% at the cephalad level and 4% at the caudal level. For the metal-on-polymer CDA, the decrease was 12% and 13%, respectively.

In lateral bending, compared to the intact spine, for the ACDF, the increase in the range of motion at the cephalad and caudal levels were 19% and 10%, respectively. For the metal-on-metal CDA, the decrease in the range of motion was 8% at the cephalad level and 15% at the caudal level. For the metal-on-polymer CDA, the decrease was 5% and 15%, respectively.

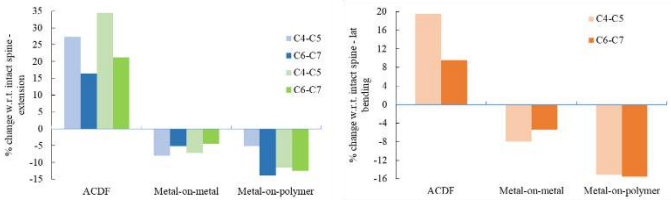

**Figure 2: Change in the range of motion at adjacent segments. Left chart shows the flexion (blue bars) and extension (green bars), and right chart shows the data for lateral bending.**

With respect to the intact spine, in the metal-on-metal CDA, facet forces decreased by 17% each at the cephalad and caudal levels. The increase in the facet force was 11% at the cephalad level and 12% at the caudal level in lateral bending. The metal-on-polymer CDA responded with a 34% decrease at the cephalad level and 27 % decrease at the caudal level in extension, and 18% decrease at the cephalad level and 7% decrease at the caudal level, in lateral bending.

At the index level, facet forces increased in both CDA's: 56% in extension and 20% in lateral bending for the metal-on-metal CDA and 174% in extension and 43% in lateral bending for the metal-on-polymer, while the ACDF responded with decreases of 85 and 90%, respectively.

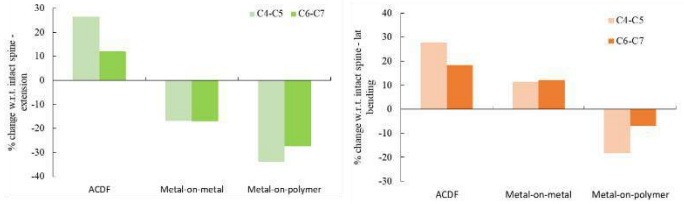

**Figure 3: Change in the fact force at adjacent segments. Left and right charts correspond to extension and lateral bending modes.**

## DISCUSSION

Differences in the range of motion and facet forces were noted within the CDA implants. This is attributed to the inherent design of the implant, i.e., material type and material properties of the CDA implant. The metal-on-metal implant exhibited less range of motion and less facet forces at the index/operative level compared to the metal-on-polymer implants that demonstrated greater motion and facet forces at the operative level and lower values at the adjacent segment levels. The differences in motion and facet forces between the metal-on-polymer CDA's infers that the intended design feature, i.e., the translational potential, and fixation of the implant to the adjacent endplates is responsible for these differences. This type of kinematic and load response would be theoretically predicted based on the proposed advantages of CDA over the ACDF but not necessarily observed in the clinical data as the determination of in vivo segmental loads are not possible. The potential advantage of CDA over the ACDF with respect to decreasing adjacent segment disease in humans has not been clinically confirmed and will require further studies. While the caprine model may be somewhat hypermobile, it was selected due to its striking similarities in the axial loading compared to the human, comparable size of the cervical vertebrae, and ability to accommodate the same FDA commercially available CDA implants used in patients, and the capacity tolerate the implantation surgery with a relatively quick recovery time. The hypermobility in the caprine with the most mobile CDA- metal-on-polymer correlated with anterior migration of the implant in all four animals. This is supported by the high facet force response elicited from the computational modeling study. Complications of human CDA's are somewhat difficult to quantify as anterior migrations may also be categorized as revision surgery non-specified in the human clinical literature.

## CONCLUSION

Distinct differences in the kinetics between metal-on-polymer and metal-on-metal CDAs were found in our multi-scale modeling that consisted of longitudinal patient outcomes, longitudinal animal surgical outcomes, and finite element modeling with a generic spinal column. Patient-specific models that accurately mimics patient anatomy, pain pattern, cervical pathology and occupation/ lifestyle risks should be used to select the optimal CDA to minimize patient risks, minimize the potential need for additional surgeries, and maximize patient outcomes. Such studies may have implications to military and civilian patients.

## INTRODUCTION

Cardiac disease is the leading cause of death in the United States. Approximately 800,000 people suffer a heart attack each year, and the resulted myocardial infarction (MI) places a heavy burden on the healthcare. Hydrogels have emerged as a promising option for the treatment of MI. Injectable hydrogels can be delivered to the injured heart with minimally invasive procedures, such us catheter placement, which makes it an attractive approach as a new cardiac therapy. Several studies of adult cardiac ECM hydrogel have demonstrated benefits in the treatment of MI [1]. However, there has been no study that harnesses the regeneration potential of porcine neonatal heart extracellular matrix (ECM) and makes it a novel hydrogel platform. In this study, we aim to bridge this gap by developing a porcine neonatal heart ECM hydrogel (nhECM) that leverages the regenerative capacity of ECM microenvironment at the neonatal stage.

## METHODS

Neonatal porcine hearts were obtained from 0-day old piglets from a local farm (**Fig. 1A**). Each ventricle was visually inspected and followed by decellularization. A 1% SDS solution was used for decellularization, and the tissue was rinsed with DI water after full decellularization. The acellular nhECM was frozen overnight and then lyophilized. The obtained lyophilized nhECM was digested in 1 mg/ml HCL/pepsin solution. The mixture was then neutralized with NaOH and brought to pH at 7.4 PBS was added to achieve a final concentration of 10 mg/ml. The digested solution was then placed in a mold and incubated at 37 $^{o}$C for 30 minutes for gel formation. H&E staining was performed to verify decellularization. The nhECM hydrogel was characterized by SEM to assess microstructural morphology. Rheological properties were measured with a rheometer to obtain storage modulus, loss modulus, and gel dynamic behavior. Cell biocompatibility was assessed using MTS assay and Live/Dead staining.

## RESULTS

Thorough decellularization was achieved and confirmed by H&E staining. A white and opaque hydrogel could be obtained at 10 mg/ml concentration and 37$^{o}$C (**Fig. 1B**). SEM images of the nhECM hydrogel exhibited a typical porous structure of gel (**Fig. 1C**), which would allow cell growth and migration within. The MTS and Live/Dead results showed that the nhECM hydrogel had good cell compatibility with HL-1 cardiomyocytes, and allowed for HL-1 cell growth (**Fig. 1D**). The rheological measurement presents a storage modulus of approximately ~10 Pa in the linear viscoelastic region, and the nhECM hydrogel has the behavior of a gel-like structure.

## DISCUSSION

In this study, we have successfully developed an effective protocol to reliably fabricate porcine neonatal heart ECM hydrogel. The porcine nhECM hydrogel demonstrated excellent structural and mechanical integrity, a gel-like rheological behavior, and good cell compatibility. In short, our study proved the feasibility of porcine nhECM hydrogel as a potential cardiac injectable biomaterial. Further characterizations of the nhECM hydrogel system are ongoing, with an ultimate goal of developing new MI therapies.

## INTRODUCTION

For patients born with univentricular hearts, the Fontan surgery, the final of three staged palliative surgical procedures, places the pulmonary and systemic circulations in series. Though it extends the life expectancy of patients significantly, survivors of the Fontan procedure tend to develop a state of circulatory inefficiency due to the lack of a subpulmonary ventricle. This inefficiency leads to an elevation in central venous pressure while simultaneously reducing pulmonary artery pressure and pulsatility in a condition known as the Fontan paradox [1]. Over time, the Fontan paradox may contribute to various morbidities, including early demise, arrythmias, and reduced exercise tolerance [2]. Years of research aimed at preventing or reversing the Fontan paradox have unfortunately produced limited clinical benefit. Replacement of the missing subpulmonary pump source has been proposed as a means to overcome the Fontan paradox. Mechanical circulatory pumps have received considerable attention, and remain promising, but are hindered by limitations of external battery supply and artificial materials. Thus, our group is exploring 3D bioprinted conduits as a possible replacement for traditional conduits which lack growth potential. Connecting the inferior vena cava (IVC) to the pulmonary arteries, bioprinted conduits could theoretically contract to provide a pulsatile energy source to the lungs.

Bioprinting of large-scale contractile materials is currently an expensive and complex procedure. Computational modeling provides a means to accelerate conduit design by allowing for efficient exploration of the design space and an assessment of how the hemodynamics of a Fontan patient changes in response to conduit design choices. In this study, we construct both a reduced order model and a 3D model of the pulsatile conduit to evaluate design parameters of interest. Using a closed-loop lumped parameter network (LPN), we show how valve placement, conduit geometry, and contractile properties change patients' hemodynamics, thus evaluating the functionality of the conduit. Using a 3D model, we evaluate mechanisms of contraction, combining electrophysiology and active contraction models. These models can provide a comprehensive means to evaluate bioprinted conduit designs and narrow the design space prior to printing in the lab.

## METHODS

We have developed a closed-loop LPN computational model of a Fontan patient based on work by Kung et al [3] (Fig. 1a). LPN parameters were tuned for a 6-month post-Fontan patient studied by Schwarz et al [4]. The proposed pulsatile Fontan conduit was designed in the Skylar-Scott laboratory at Stanford University. Briefly, the conduit will be 3D bioprinted using a combination of two printing techniques: freeform reversible embedding of suspended hydrogels [5] and sacrificial writing of functional tissues [6]. The myocardial walls will be manufactured using a cardiac organoid-laden bioink, while the valves will be printed with a collagen ink. The vasculature will be created by bioprinting a sacrificial gelatin ink into the myocardial walls and later evacuating the ink to yield perfusable channels (Fig. 1b). The conduit is designed to achieve a 5 mN/mm$^2$ active stress generation and is assumed to have a passive stiffness of 3 mN/mm$^2$.

We began by creating a 0D model of the pulsatile conduit. Having similar function as a ventricle, the 0D conduit model is simplified to be a time-varying elastance component of our LPN model of the Fontan circulation. The pressure of the conduit is governed by its volume and capacitance (Equation 1). The parameters of the conduit were tuned to achieve 30% volume amplitude, comparable to initial estimates of pulsatile conduit performance. We coupled the 0D valve model and simulated the situations with zero valve, one valve, and two valves.

$$P_{con} = i\frac{V_{con}-V_0}{C_{con}} + c_{con}(\exp(d(V_{con}-V_0)) - 1) \quad (1)$$

We further investigated how significantly these the initial radius, initial thickness, and activation function impacted the conduit design by creating a 1D model of the pulsatile conduit. The 1D model is a simplified cylinder with passive and active stress responses. Assuming contraction is purely circumferential and material is incompressible, we

derived the stress expression (Equation 2) and weak form of mechanical equilibrium (Equation 3) [7-8]. The inlet and outlet boundary conditions were prescribed with pressure waveforms at the inlet of 12-14mmHg and distal pressure of 7.5 mmHg. To find the conduit design providing maximum pressure and volume pulses, we performed parameter sweeps of the maximum active stress, thickness and radius. The maximum active stress ranged from 0 to $4 \cdot 10^4$ N/m$^2$, thickness from $1 \cdot 10^{-3}$ to $4 \cdot 10^{-3}$ m, and radius from 0.005 to 0.2 m.

$$\sum_y = 2(1 - C_{\sigma\sigma}^{-2})\left(\frac{dW}{J_1} + \frac{dW}{J_2}\right) + 2\frac{dW}{J_4} + i\sigma_{1D} + \eta(\dot{C} + C^{-4}) \quad (2)$$

$$\rho d_0 \ddot{y} + \frac{d_0}{R_0}\left(1 + \frac{y}{R_0}\right)\sum_y = C_{\sigma\sigma}^{1/2} P_{con} \quad (3)$$

Last, a full 3D finite element model was implemented combining the passive and active stresses from the myocardium fiber, and Purkinje fiber propagation of the cardiac action potentials. We used the Guccione model for myocardium fiber's material property, and tenTusscher-Panfilov model for the electrophysiology. These two models were one-way coupled and simulated in the svFSI finite element solver provide with the open-source software SimVascular [9]. The output action potential of Purkinje fibers from the electrophysiology simulation triggered the active contraction of the myocardium fiber. Boundary conditions were prescribed by hemodynamic pressure acted on the inner wall, and the outer wall was traction-free. Dirichlet boundary conditions were applied to top and bottom faces. Similar inlet and outlet pressure waveforms in the 1D simulation were used for this 3D conduit.

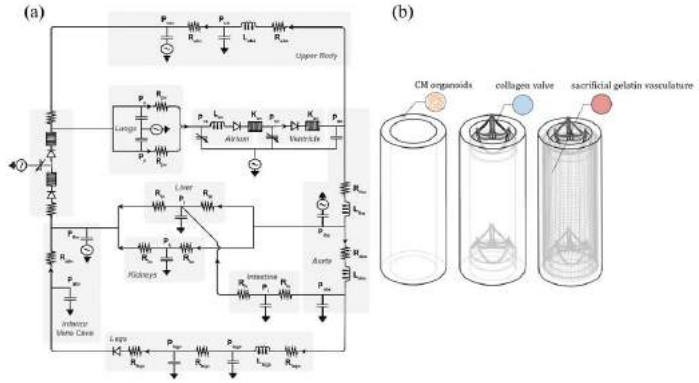

**Figure 1: (a) Layout of the post-Fontan LPN. (b) Conduit prototype and valve placement**

## RESULTS

We used the LPM model to compare conduit designs with zero, one or two valves and varying capacitances and frequencies. There was no significant change in pulmonary pressure or flow rate with or without valves. The one valve and zero valve cases were similar because there is relatively low backflow into the IVC due to the elevated IVC pressure. The implementation of two valves decreased the liver pressure from 16.38 to 15.23 mmHg, while the pressure of the conduit decreases from 11.17 to 9.87 mmHg. The capacitance of the system reduced the effects of the transient pressure reductions in the conduit. Higher elastance increased the volume amplitude from 29.4% to 48.77%. Increasing frequency of conduit induced a 15.0% reduction in liver pressure despite having roughly the same volume amplitude around 32.3%. Further, it better transfers pulsatility to the pulmonary junction.

Performing the parameter sweeps of the 1D model with two valves, we demonstrated that maximum stress and thickness were positively correlated with the volume and pressure pulses. At constant maximum active stress, thickness, and length, there is a radius that achieves the highest pressure pulse. Our results indicate that within certain constraints like conduit volume, the conduit design can be optimized to maximize performance metrics such as volume and pressure pulse.

The assumption of circumferential and simultaneous contraction is no longer applicable in 3D simulation which more accurately recapitulates the behavior of bioprinted tissue. Coupled with electronic propagation of Purkinje fiber, starting at the top end, the conduit is gradually activated over the first 4.85% of the cardiac cycle. Here, the maximum difference in active time is 38.8 ms and the isovolumetric contraction is assumed to last 100 ms. The volume pulse is 56.89% with an average ejection fraction during contraction of 38.98%. In contrast the case of simultaneous contraction over the conduit length produces a volume amplitude of 36.12%. We further investigated the role of fiber direction. We assign the fibers helically around the conduit with varying angles between fibers and the horizontal plane. The circularly oriented fiber gave a maximum volume pulse of 46.4%. With longitudinal orientation, the change in volume decreases to 20.82%. A conduit with mixed fiber directions resists volume changes and reduces the volume pulse to 15.38%. Multiple layers with different fiber directions in each layer generate 9.0% volume change.

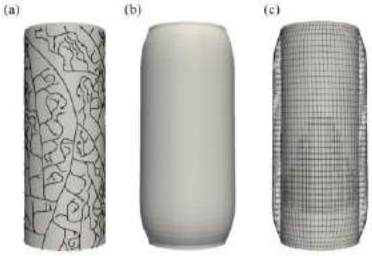

**Figure 2: (a) Illustration of Purkinje fibers. (b) Inflated conduit after prestress. (c) Maximum volume amplitude is 36.12% for the circumferential contraction.**

## DISCUSSION

We have developed 0D and 1D LPN models to explore how different pulsatile conduit designs can impact the hemodynamics and physiology of Fontan patients and possibly reverse the Fontan paradox. In our 0D LPN study, we showed that two valves are needed to optimally reverse the Fontan paradox. Increasing elastance is a way to increase volume amplitude and decrease central venous pressure, but increasing frequency can better increase the pulsatility of flow into the lung as well as reduce IVC pressure. The relation of geometry parameters and conduit performance was studied in our 1D model. The existence of a non-monotonic relationship between radius and conduit performance demonstrates the ability to use parameter-sweeping simulations to provide optimal design guidance prior to printing in the lab. 3D results demonstrate the importance of spatially varying activation and fiber direction. However, the clamping boundary conditions at the top and base faces may overcome the effects of longitudinal force. Future work should modify our approach to apply moving boundary conditions. We also plan to couple the full 3D model with the LPN framework to evaluate patients' hemodynamics and the effectiveness of the conduit in preventing or reversing the Fontan paradox.

## INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC), a lethal and one of the most aggressive malignancies, has a five-year mean survival rate of around 10%[1]. Current treatment methods including surgery and different ablation techniques such as radiofrequency ablation and photodynamic therapy are lacking in improving the survival rate that could be attributed to advanced age, late-stage diagnosis, poor specificity, and adverse side effects[2]. Hence, innovative, selective therapeutic approaches for targeting and controlling the ablation volume are desperately needed. Plasmonic photothermal therapy (PPTT) utilizes different gold nanoparticles, i.e., gold nanorods (GNRs) to target tumor region followed by exposure to near-infrared light (NIR) to induce hyperthermia and tissue damage[3]. The advantage of using GNRs includes size and shape tunability, that would allow to utilize a specific light wavelength for achieving the surface plasmon resonance (peak absorption of photon by the GNRs)[4]. Literature review showed that biological tissue demonstrates lower light absorbance rate at ~800 nm wavelength that could be utilized for selectively heating of the GNRs[4]. In current study, a fiberoptic microneedle device (FMD, earlier developed by our group) was utilized for codelivering the GNRs and light to the targeted tissue volume through a silica-based light guiding capillary[5]. We hypothesized that local delivery of custom GNRs and ~800 nm range light via FMD into the targeted tissue volume would selectively heat the GNRs with minimum thermal damage to the healthy surrounding tissue. The aim of this study is to characterize the photothermal heating of *ex vivo* porcine pancreas tissue at two clinically important light wavelengths, 808 and 1064 nm. Light delivery was explored with both a collimated beam and through the FMD, both with and without the presence of GNRs. The effect of laser exposure time and GNRs concentrations were also investigated and reported.

## METHODS

Porcine pancreas tissue samples were collected from a USDA-approved abattoir and transported to the lab immediately (~30 min). Upon arrival, the samples were washed in phosphate-buffered saline (PBS) solution and sliced in a 3 × 3 $cm^2$ cross-section area using a scalpel. Samples used in different experiments had a thickness of approximately 1 ± 0.05 cm. GNRs were synthesized by a seed-mediated growth protocol described in the literature[6]. The optical absorbance of the nanorods was confirmed via UV-Vis spectroscopy (400–1100 nm) and their geometry (length, width, aspect ratio) was measured via SEM (scanning electron microscopy) imaging and analyzed in ImageJ. As-synthesized GNRs were utilized in this experiment where GNRs were suspended in CTAB solution (Cetyltrimethylammonium bromide).

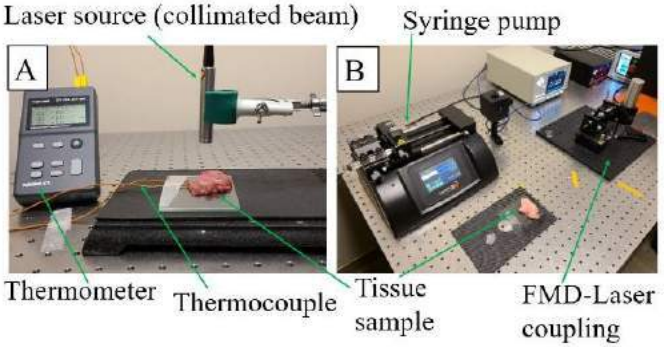

**Figure 1: Experimental setup for *ex vivo* porcine pancreas tissue photothermal heating via (A) collimated beam, (B) FMD.**

Two different continuous wave laser sources were utilized with collimated beam outputs at 808 nm and 1064 nm wavelengths. The tissue specimen was placed on a glass slide 4 cm beneath the laser

attached to an adjustable holder (Figure 1A). Two K-type thermocouples were inserted into the tissue at 5 mm below the tissue surface to measure the temperature at 5 Hz frequency. Laser exposure continued until the tissue temperature reached a steady state. In next set of experiments, FMD tips (365 µm diameter) were inserted horizontally (2–3 mm) into the tissue top surface for light delivery with/without GNRs (0.1-1 nM concentrations) (Figure 1B). Laser exposure continued for 60s followed by free convective cooling. Tissue temperatures were measured via a thermal camera (2 Hz). In both experiments, laser irradiations were set within 20-50 mW·mm$^{-2}$. The range was selected through preliminary tests to avoid tissue burning. All experiments started when tissue sample reached the room temperature (22°C). The tissue samples were discarded after each test. A single test was repeated five times (n = 5) for each laser irradiation and GNR concentration.

## RESULTS

SEM images of the GNRs were utilized to measure the average dimension of nanorods: length = 95.2 ± 4.7 nm and width = 24.8 ± 1.5 nm (Figure 2A). A spectrometric analysis showed the resonance wavelength (peak photon absorbance) of the GNRs to be 813 nm (Figure 2B). At 1064 nm, the GNRs' optical absorbance reduced to less than half of the peak absorbance.

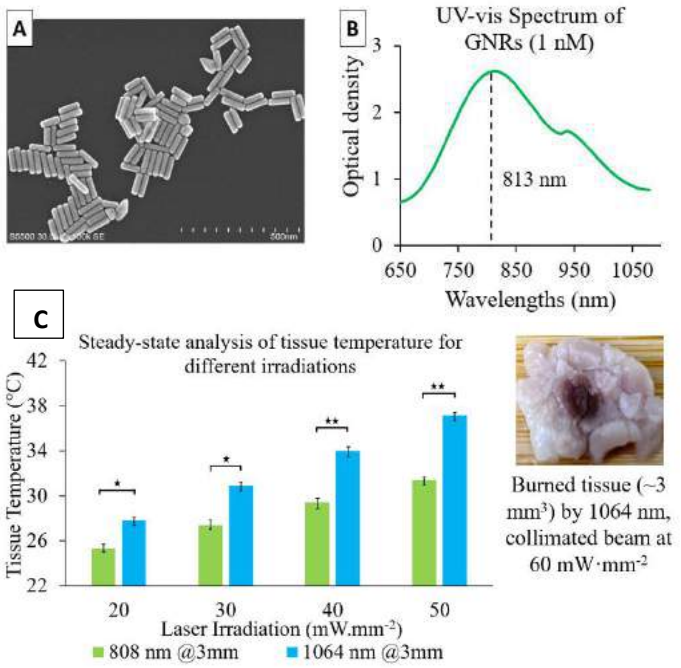

**Figure 2: (A) SEM image of GNRs, (B) UV-vis spectrum of GNRs, (C) Tissue temperature vs. Laser irradiation graph**

Preliminary tests demonstrated the threshold light intensity (≥ 60 mW·mm$^{-2}$ for 1064 nm and ≥ 80 mW·mm$^{-2}$ for 808 nm) that would induce tissue carbonization, an unwanted outcome to avoid during tissue photothermal heating. Analysis of the results (Figure 2C) showed that, at 808 nm, both tissue temperature increase (ΔT) and rate of temperature rise (ΔT/time) were 51.4 ± 5.5% and 87.7 ± 6.1% higher for 1064 nm, respectively. It implies that 808 nm will be less harmful than 1064 nm during plasmonic heating of pancreas tissue when paired with appropriate GNRs (peak resonance at ~800 nm).

Results from tissue photothermal heating by FMD+GNR (Figure 3) showed that the plasmonic heating of GNRs at 808 nm resulted in a sharp increase of porcine pancreas tissue temperature (~200% temperature rise than FMD only exposure, Figure 3A vs. 3C). GNRs absorbed maximum photon energy at 808 nm and dissipated heat, resulting in significant tissue temperature rise within a short time (60s). In contrast, 1064 nm laser increased the overall tissue temperature due to the higher photon absorption, which is not desired during selective tissue heating.

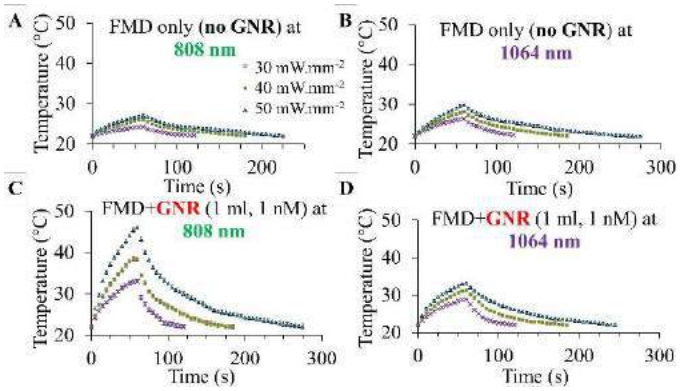

**Figure 3: *Ex vivo* porcine pancreas tissue plasmonic photothermal heating without GNRs at (A) 808 nm, (B) 1064 nm; and with locally infused GNRs (1 nM, 1 ml) at (C) 808 nm, and (D) 1064 nm.**

## DISCUSSION

808 nm demonstrated selective plasmonic heating capability of GNRs while being less lethal to the healthy pancreas tissue. However, laser intensity, exposure time, and GNR concentrations have direct impact on tissue plasmonic heating. Selective photothermal heating procedure can be controlled by manipulation of these parameters to achieve less tissue photothermal damage while ensuring high light to heat conversion of GNRs. A major limitation of this *ex vivo* study could be the tissue physiological condition as pancreas tissue degrades quickly over time which might affect the optical properties. This error was minimized by emphasizing on using fresh tissue samples in majority of the experiments. Custom GNRs utilized in this study can be functionalized through PEG (polyethylene glycol) coating to target the tumor tissue for future clinical application. Further investigation with human pancreas tumor tissue would bolster the hypothesis proven in this study.

## INTRODUCTION

Aortic stenosis is the most common cardiovascular disorder, that may be treated with medication, valve repair, or valve replacement depending on the severity [1]. Aortic valve replacement is the replacement of the native aortic valve with a bioprosthetic valve either surgically or through transcatheter approaches. Transcatheter aortic valve replacement is a minimally invasive method that has been growing in recent years [2]. Bioprosthetic valves exhibit limited durability of 12-20 years due to structural valve deterioration. Therefore, younger patients undergoing aortic valve replacement with a bioprosthetic valve would need multiple interventions over the span of their lifetime [3]. Valve-in-valve transcatheter aortic valve replacement (ViV TAVR) is one possible solution for treating patients with failed prosthetic aortic valves who are too frail to undergo redo surgery [4, 5]. Coronary obstruction is one of the main problems related to the ViV TAVR procedure due to the proximity of the coronary ostium to the bioprosthetic leaflet and the supra-annular positioning of surgical bioprostheses [3]. Patient specific finite element simulations enable optimization of device selection and placement to reduce obstruction risk. The goal of this study is to demonstrate the role of computational modeling to reduce coronary obstruction risk in procedural planning of TAVR in a patient with one failed surgical valve, and two failed transcatheter heart valves in place.

## METHODS

A 78-year-old male with three bioprosthetic valves in place (a CoreValve 23, a Sapien 23, and an Edwards 3000 bovine pericardial valve) showing restricted motion of leaflets and mild calcification, was analyzed. Cardiac computed tomography (CT) images were imported to Materialise MIS (Leuven, Belgium). The aortic root and a portion of left ventricle were segmented using Mimics 24.0. CAD models of the

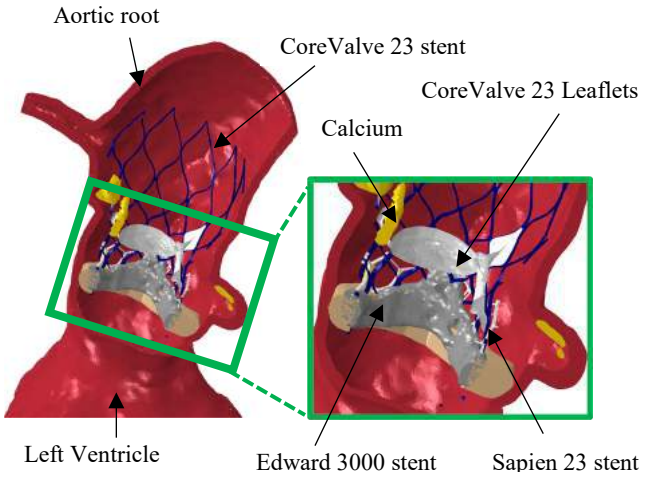

**Figure 1:** Patient segmentation including the aortic root and calcium and valve registration of the Edwards 3000 bovine pericardial valve, Sapien 23, and CoreValve 23**.**

CoreValve, Sapien, and the surgical valves were generated in Solidworks (Waltham, MA, USA) based on a microCT performed on the actual valves. To avoid significant blooming present in the CT images, the 3D models of the valves were registered and reconstructed using an in-house code (**Figure 1**). The bioprosthetic valve stents, aortic root, calcium, and leaflets were meshed in 3-Matic 15.0. ViV TAVR deployment for the CoreValve 23 and Sapien 23 were simulated using finite element method in Abaqus Explicit (Johnston, RI, USA). Sapien

23 was deployed by inflating a 23mm balloon using a fluid-cavity approach. CoreValve 23 was deployed by leveraging the shape-memory properties of the nitinol material model by crimping the stent then allowing it to expand [6]. The material properties for all components was derived from literature [7-10].

Coronary obstruction risk was evaluated by measuring the ratio of the distance from the bioprosthetic leaflet to the coronary ostium (DLC) by the diameter of the coronary (d) with a DLC/d of <0.7 considered to be representative of high risk of coronary obstruction [11].

## RESULTS

The patient had a prior coronary artery bypass graft surgery for the right coronary, and hence the right coronary is located much farther from the valve leaflets. As a result, the ratio of the distance from the coronary from bioprosthetic leaflet to the coronary ostium by the diameter of the coronary will be larger than 0.7. Thus, there is no concern of right coronary obstruction. The diameter of the left coronary in the widest region is 6.75 mm, and the distance of Sapien 23 leaflets from the coronary ostium is about 4.85 mm (see Figure 2 (a)), DLC/d = 0.71. The distance of CoreValve 23 leaflets from the coronary ostium is 9.79 mm, DLC/d = 1.45 (See **Figure 2** (b)). Therefore, the risk of coronary obstruction is lower for CoreValve 23. The results of the deployment simulation for both Sapien 23 and CoreValve 23 were presented to physicians and the CoreValve 23 was selected to be implanted in this specific case. The post-TAVR fluoroscopy image and the simulation results are illustrated in **Figure 3**. The comparison of the predicted final location of the valve and the post-TAVR fluoroscopy image, confirmed the predictive capabilities of the simulation (**Figure 3**).

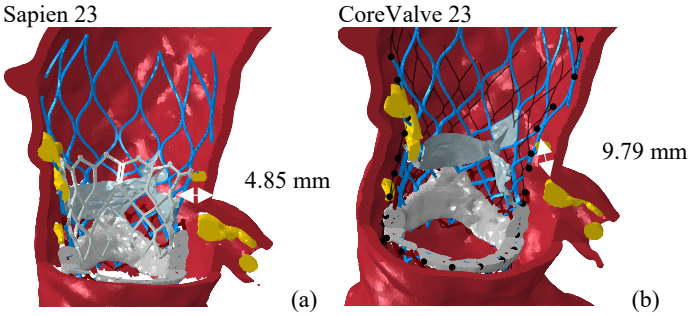

**Figure 2.** The distance from the bioprosthetic leaflet to the coronary ostium ($D_1$), (a) Sapien 23, (b) CoreValve 23.

## DISCUSSION

This study shows one application of computational modeling for pre-planning of ViV TAVR procedures in assisting physicians to predict and prevent possible complications. Due to the patient's condition, the post-TAVR CT imaging was a challenging task. Therefore, it was difficult to achieve enough data to validate the simulations results with CT images. Further studies are required, including performing computational fluid dynamics to quantify Post-TAVR pressure gradient, washout time, and resident time.

# EFFECTS OF COMPROMISED SYNOVIAL FLUID ON ARTICULAR CARTILAGE TRIBOLOGICAL REHYDRATION AND LUBRICATION

**Shamimur R. Akanda (1), David L. Burris (1), Christopher Price (1,2)**

(1) Mechanical Engineering, University of Delaware, Newark, DE, USA
(2) Biomedical Engineering, University of Delaware, Newark, DE, USA

## INTRODUCTION

Articular cartilage is the shock absorbing and lubricating tissue that allows near frictionless ($\mu$ ~0.002*)* joint articulation. Cartilage's phenomenal tribomechanical functions have predominately been ascribed to two mechanisms, interstitial and boundary lubrication.[1] Pressurization of cartilage's interstitial fluid allows it to carry nearly all applied stresses upon initial loading. This high fluid load support (FLS) shields the matrix from deformation and promotes exceptional lubricity.[1] However, under quasistatic contact stresses (which range from 0.2-2MPa *in vivo)*[2] time-dependent interstitial fluid exudation occurs, leading to elevated tissue strains and equilibrium friction coefficients (*~0.3*). Thus, mechanisms to minimize interfacial shear/friction forces appear necessary to mitigate the negative effects of fluid exudation on lubrication.

Synovial fluid (SF) is the native bathing solution of joints and contains constituents (hyaluronic acid (HA) & lubricin) thought to act as classical friction-reducing boundary lubricants. However, under very low (*i.e.*, zero) FLS and slow sliding speeds (≤1mm/s), rather unremarkable $\mu$ values (~0.2) have been observed for SF-lubricated cartilage; vs. ~0.3 for PBS.[3] To what degree such conditions replicate the *in vivo* sliding environment is also unclear. This fact is highlighted by our findings, using the convergent stationary contact area (cSCA) testing configuration, that cartilage can effectively combat load-induced interstitial fluid loss via articulation. Under sliding conditions consistent with average *in vivo* contact pressures (~0.25MPa) and sliding speeds (<30mm/s), interfacial sliding drives potent interstitial fluid recovery.[4-6] This 'tribological rehydration' robustly rescues tissue compression, FLS, and interstitial lubrication ($\mu$ ~0.02*)*—in the absence of SF.

Furthermore, when high-speed cSCA studies were performed in SF (and HA), an unanticipated lubrication synergy between sliding-driven fluid recovery and bath composition was observed. Tribological rehydration within SF-lubricated cartilage produced equilibrium friction coefficients ~10-fold lower than through tribological rehydration within PBS alone (0.002 for SF vs. 0.02 for PBS) with no concomitant benefit to hydration recovery.[7]

While the mechanisms underpinning this lubrication synergy are uncertain, a key question of clinical significance arises: *how might alterations in SF composition, including those seen in osteoarthritic disease, alter FLS recovery and lubricity in the presence of tribological rehydration promoting conditions?* On the one hand, the HA content of SF decreases with disease severity, resulting in decreased SF viscosity and 'boundary mode' lubricating capacity.[8] On the other hand, 'diseased' SF is more dilute than naïve SF (270mOsm vs. 450mOsm),[9] potentially altering tissue swelling responses. Either change could impact tribological rehydration and subsequent lubrication behaviors, and the study of their effects on cartilage could yield key insights into the natural tribomechanics of both healthy and diseased joints.

In the present study we investigated the tribological rehydration and lubrication behaviors of bovine cSCA explants, under both high- and low-speed sliding, in the presence of healthy SF vs. SF treated to model 'diseased state' compositions (*i.e.*, dilution by 25% or digestion with hyaluronidase). We hypothesized that if 'diseased' SF is a poor lubricant, then dilution and/or degradation of SF would generate significantly higher friction coefficients and a less lubricious sliding environment during both high and low cSCA sliding speeds. OwHo

## METHODS

19mm ϕ osteochondral cores were extracted from skeletally mature bovine femoral condyles using a coring bit, washed, and stored in 400mOsm phosphate buffered saline (sucrose was added to increase the osmolarity of 1x PBS). Pairwise tribological characterization of individual cSCA explants were performed on a reciprocating *in situ* tribometer in a compression matched manner for the following bathing solution combinations: i) 400 then 300mOsm PBS, ii) 100% bovine SF then 75% SF (diluted with di$H_2O$), or iii) naïve (100%) SF then SF digested for 2 hrs with 25ug/ml of hyaluronidase (Hyal). The tribological testing protocol comprised 20 min of compression at 5N

followed by 10 min of compression + sliding at 80 mm/s or 10 mm/s while bathed in the first solution (test 1; Fig. 1). Explants were then washed with 400mOsm PBS and allowed to free swell for ≥2 hrs in their second (test 2) bathing solution. Explants then underwent tribological testing in the second bathing solution; here, explants were statically loaded to the compression value reached during test 1 followed by 10 minutes of sliding. Separate explants were tested at each sliding speed.

Start- and end-of-sliding compression ($\delta$) and kinetic friction coefficients ($\mu$) were recorded via LABVIEW and analyzed in MATLAB. The effects of 'diseased' bathing solution were compared using paired *t*-tests (*, naive vs. diluted/digested), and the effects of sliding speed via *t*-tests (#) for each individual bathing solution; $p<0.05$.

## RESULTS

As seen previously in cSCA explants,[10] stereotypical sliding-speed-dependent compression (*i.e.*, tribological rehydration) and friction recovery behaviors (Fig. 1) were observed for all bathing solutions (Fig. 2). As reported previously, a potent lubrication synergy between tribological rehydration and synovial fluid presence at high sliding speeds[6] was observed (Fig. 2C). Contrary to our hypothesis that diluted and/or degraded SF is a 'poor' lubricant, we observed little to no effect of SF-dilution or enzymatic digestion on the lubrication responses of cSCA explants. There were no statistically significant pairwise differences in the friction behaviors of cSCA explants bathed in normal SF vs. either 25% diluted or Hyal-digested SF. Furthermore, dilution had no meaningful effect on compression recovery, while Hyal digestion produced a modest, statistically significant increase in high-speed compression recovery (Fig. 3).

Tribomechanical tests in 400 vs. 300mOsm PBS were conducted as controls to highlight the specific contributions of both SF presence and bath osmolarity changes on tribological rehydration and lubricity

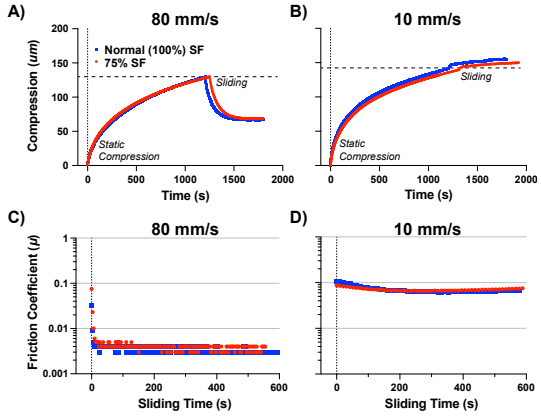

**Fig. 1 Representative compression and friction traces from two bovine cSCA explants slid at 80mm/s (A&C; sample 1) and 10mm/s (B&C, sample 2), respectively, in the presence of normal (100%; blue) vs. diluted (75%, red) synovial fluid (SF).**

## DISCUSSION

The present study highlights the unique additive lubrication benefit that interstitial fluid recovery, interstitial lubrication, and SF presence combined provide under high sliding speeds.[6] As expected, high-speed cSCA sliding led to compression recovery/tribological rehydration and friction suppression irrespective of bathing solution. In contrast, slow sliding resulted in continued interstitial fluid exudation and reduced lubricity under all bathing solutions.[3-6] Critically, SF promoted vanishingly low equilibrium friction coefficients at high speed (among the lowest values observed in benchtop studies; $\mu$ ~0.005 compared to ~0.02 in PBS), while disease-associated changes to SF composition (simulated through dilution/digestion) had no meaningful impact on

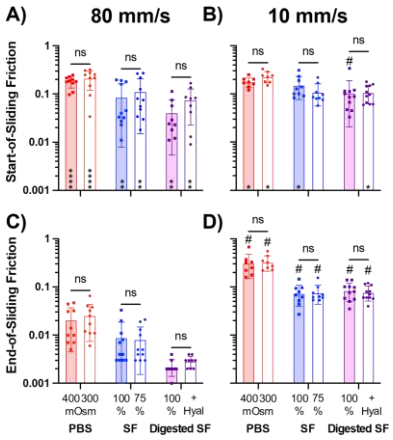

**Fig. 2 Start- (A, B) and end-of-sliding friction (C, D) outcomes for pairwise cSCA tests in the presence of 400 vs. 300mOsm PBS, 100% vs. 75% SF, or naïve vs Hyal digested SF at either 80 or 10mm/s.**

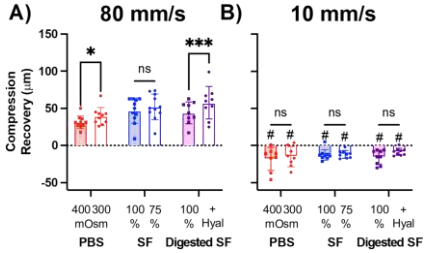

**Fig. 3 Compression recovery of cSCA explants slid in the presence of 400 vs. 300mOsm PBS, 100% vs. 75% SF, or naïve vs Hyal digested SF at either A) 80 or B) 10mm/s. Negative compression recovery indicates exudation.**

high- or slow-speed sliding frictional outcomes. Despite unaltered lubrication responses, SF degradation and dilution modestly enhanced high sliding speed-mediated compression recovery (*i.e.*, tribological rehydration) compared to naïve SF. These findings hint at a role for subtle changes in bathing solution osmolarity (such as those seen in the 400 vs. 300mOsm 1xPBS tests) on tribological rehydration magnitudes (and thus tissues strain), but not upon the lubrication synergy between SF and tribological rehydration.

Overall, these findings call into question the conventional wisdom that SF from osteoarthritic joints represents an inferior lubricating solution. Instead, when mechanisms that enable the active recovery and maintanence of tissue hydration, FLS, and interstitial lubrication are explicitly preserved during sliding tests, mimicking what we belief to be the predominate sliding environment experienced *in vivo*, both compromised and naïve SF appear equally effective in generating vanishingly low equilibrium interfacial frictions. Ongoing work seeks to characterize the mechanisms underlying these unanticipated lubrication synergies, as well as how they might influence and inform cartilage physiology/health. Such investigations will be critical to unlocking the true nature of the natural tribomechanics of both healthy and diseased joints.

# Comparative Study of Chemical and Nanomechanical Properties of Cat and Rat Vibrissae

**Davin Sim (1), Donna M. Ebenstein (1)**

(1) Biomedical Engineering, Bucknell University, Lewisburg, PA, USA

## INTRODUCTION

Known for their immense sensitivity to touch, vibrissae, or animal whiskers, can serve as a biomimetic model to enhance the functionality of the current mechanosensory mechanisms in robots [1]. Improved sensing mechanisms would enhance robot performance in many different applications – from pipeline inspection to non-invasive surgery [2]. Researchers have long been studying tactile sensing in rats for robotics applications [1]. However, these studies have primarily focused on the neural pathways involved in the sensing mechanisms, not on the whisker structure (internal or external) or considering rat whiskers in comparison to other species. Therefore, further understanding of the structure-property relationships of animal whiskers such as rats and cats may provide clues about how autonomous robots could improve their sensory capabilities by leading to enhanced design of the whiskers themselves.

Being predators, cats can protract and retract groups of whiskers to aid in hunting, while rats, as scavengers and prey, use active whisking to navigate in tight, dark spaces. Rat whiskers are more flexible than cat whiskers and differ from cat whiskers in both their external (e.g., length, diameter, tapering) and internal structure. For example, the center (medulla) of the cat whisker is filled compared to the rat medulla which is hollow (Fig. 1). To understand how the differences in structure and composition of different animal whiskers affect their function, the goal of this study was to characterize the chemical and mechanical properties of cat and rat whiskers using μRaman spectroscopy and nanoindentation. The results will help improve our understanding of structure-property relationship in animal whiskers, and hence better inform the design of bioinspired whiskers for robots.

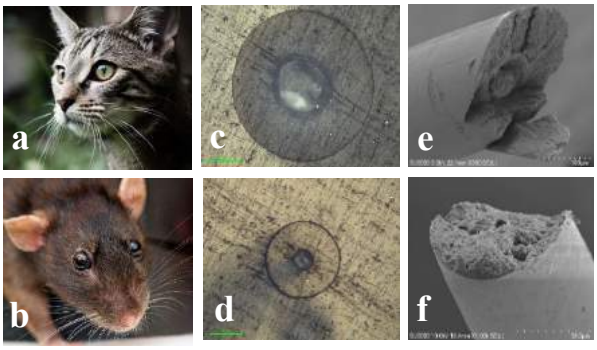

**Figure 1: Images of (a) cat and (b) rat whiskers. Optical microscope images of transverse sections of embedded and polished (c) cat and (d) rat whiskers. SEM images of cryofractured (e) cat and (f) rat whiskers.**

## METHODS

To prepare whiskers for chemical and mechanical analysis, whiskers from cats and rats were embedded in an epoxy resin and polished to reveal transverse or longitudinal sections.

Animal whiskers, like human hair, are made up of a protein called keratin, which can be chemically identified μRaman spectroscopy. Raman spectra were collected from each embedded whisker using a Horiba Xplora Plus spectrometer equipped with a 785-nm laser. Collected whisker spectra were compared to Raman spectra of pure keratin.

For mechanical analysis, nanoindentation was performed on each sample. Indents were performed to a depth of 1 micron using a TI-950 Triboindenter equipped with a Berkovich (3-sided pyramidal) tip (Fig. 2a). Unloading curves were analyzed to calculate a modulus ($E_r$) for each indent site [3]. Anisotropy ratios were calculated for cat and rat whiskers using Eq. (1),

$$A = 1 - \frac{E_{long}}{E_{trans}} \quad (1)$$

where $E_{long}$ and $E_{trans}$ are the mean reduced moduli for indents in the longitudinal and transverse sections, respectively.

## RESULTS

Spectral peaks found in cat and rat whiskers (Fig. 2a) are similar to peaks found in pure keratin, including disulfide Cys (S-S), symmetric ring breathing of Phe, and C-H stretching. The spectral peak area associated with disulfide bonds were more prominent in cat than rat whiskers (Fig. 2b).

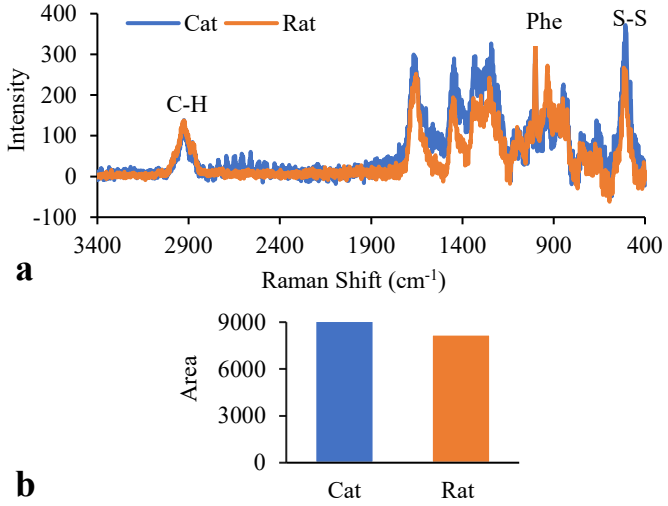

**Figure 2: (a) μRaman spectra of cat and rat whiskers were normalized to the C-H peak (~2900 cm$^{-1}$) and processed with baseline correction using LabSpec6 software. (b) Comparison of disulfide (S-S) bond peak areas from cat and rat spectra (cat area = 9074, rat area = 8204).**

Results from nanoindentation (Fig. 3) revealed that the mean modulus of cat whisker keratin in transverse sections (5.9±0.3 GPa) was significantly higher than the mean modulus in rats (5.0±0.3 GPa). Similarly, the mean modulus of cat whisker keratin in longitudinal sections (3.3±0.3 GPa) was significantly higher than in rats (2.6±0.1 GPa).

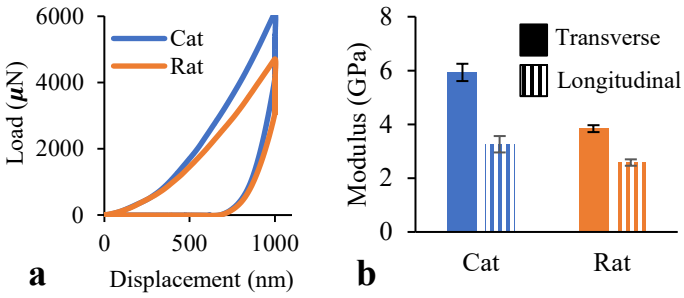

**Figure 3: (a) Representative load-displacement curves for indents in transverse sections of cat and rat whiskers and (b) a comparison of mean $E_r$ of cat and rat whiskers in transverse and longitudinal sections illustrate that cat whiskers are stiffer than rat whiskers. Error bars indicate one standard deviation.**

As the whisker keratin is stiffer in transverse than in longitudinal sections (Fig. 3b), whiskers were also found to be anisotropic. The anisotropy ratios of cat and rat whiskers were both approximately 4.0.

## DISCUSSION

Other studies have shown that an increase in disulfide bonding (Fig. 4a) is associated with increased keratin stiffness [4]. In this study, disulfide bond content is higher in cat than in rat whiskers. Therefore, cat whisker keratin is expected to be stiffer than rat whisker keratin. The results from nanoindentation support this conclusion from chemical analysis as cat whiskers had higher moduli than rat whiskers in both transverse and longitudinal sections. Hence, the increased flexibility of rat whiskers is due not only to having thinner, more tapered whiskers than cats (Fig. 4bc) but also due to differences in their chemical composition, and hence mechanical properties.

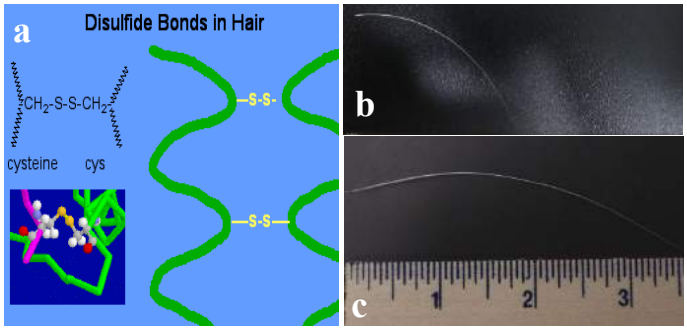

**Figure 4: (a) Cysteine S-S bonds in hair leads to crosslinking, folding, and stiffening of keratin [4]. Photographs of (b) a rat whisker and (c) a cat whisker showing that the cat whisker is longer, thicker, and less tapered than the rat whisker.**

The results of this study also demonstrated that cat and rat whiskers are both anisotropic, with anisotropy ratios (4.0) similar to results reported for spider silk fibers and bone [5]. This degree of anisotropy is consistent with the whisker microstructure, which shows keratin fibrils aligned along the long axis of the whisker (Fig. 1ef).

In the future, results from mechanical and structural analysis will be used as inputs for computational models to investigate how whisker microstructure and mechanical properties affect macroscale whisking mechanisms, and thus help further the development of bioinspired tactile sensors for robots.

## ACKNOWLEDGEMENTS

The authors would like to acknowledge Bucknell University's Program for Undergraduate Research and the Emmitt Memorial Chair in Biomedical Engineering for funding of this project.

# MULTISCALE ANALYSIS OF THE STRUCTURE-MECHANICS RELATIONSHIP OF MYCELIUM-BASED COMPOSITES

**Z. Qin (1), L. Yang (1)**

(1) Department Of Civil & Environmental Engineering, Syracuse University, Syracuse, NY, USA

## INTRODUCTION

Mycelium-based bio-composites materials have been invented and widely applied to different areas, including construction, manufacturing, agriculture, and biomedical [1]. As the vegetative part of a fungus, mycelium has the unique capability to utilize agricultural crop waste (e.g., sugarcane bagasse, rice husks, cotton stalks, straw, and stover) as substrates for the growth of its network, which integrates the wastes from pieces to continuous composites without energy input nor generating extra waste. Their low-cost and environmentally friendly features attract interest in its research and commercialization. For example, mycelium-based foam and sandwich composites have been actively developed for construction structures. It can be used as synthetic planar materials (e.g., plastic films and sheets), larger low-density objects (e.g., synthetic foams and plastics), and semi-structural materials (e.g., paneling, flooring, furniture, decking). Literature studies have shown that the material function of these composites can be further tuned by controlling the species of fungus, the growing conditions, and the post-growth processing method to meet a specific mechanical requirement in applications. Moreover, mycelium can be used to produce chitin and chitosan, which has the potential for biomedical applications. Given the strong potential and multiple advantages of such a material, we are working toward combining multiscale computational modeling with experimental synthesis and characterization in studying the composite mechanics.

## METHODS

### Preparation of Experimental Samples

**Figure 1** shows the 10-ton hydraulic press machine for performing the heat press test, which allows us to set different temperatures and pressure during sample preparation. In our experiment, we set three different temperatures including 80, 90, and 100°C. We also set the different applied press forces which are 1, 2, and 3 metric tons. Since the pressure gauge only shows the pressure, we convert the applied force to the pressure on the pressure gauge of the machine, as summarized in the different conditions in Fig. 2.

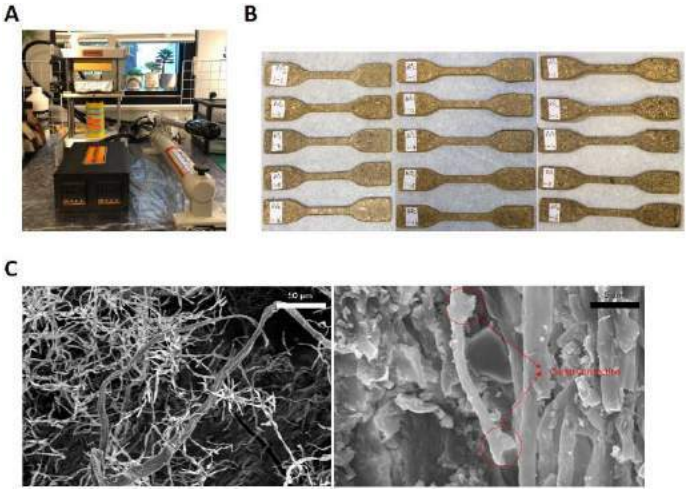

**Figure 1.** A. 10-ton hydraulic cylinder heat press machine with dual 3×5 inches heated plates. B. The dog bone shape samples (prepared under 80°C temperature and 6.75 MPa pressure baked for different times: 1, 2, 4, 8, 16 hours.) C. The SEM image of mycelium-based bio composite material at room temperature dried one month (left) and after the hot processing method (right).

For each of the different temperature-pressure combinations (9), we set the 5 different baking times including 1, 2, 4, 8, and 16 hours. Moreover, we take a piece from the sample that we processed hot press treatment to do the SEM image to compare with mycelium-based bio composites without hot processing (Fig. 1C).

### Tensile Test

The tensile tests were carried out at room temperature with a standard tensile testing machine (Instron 5966, USA). In each of the tensile tests, the dog bone sample was clamped to a pair of grips with the upper end

moved at a constant rate of 0.5 mm/min displacement. The sample was held by a force transducer and the reaction force was measured. The crosshead displacement was measured using a linear voltage displacement transducer mounted inside the actuator.

**Molecular Simulation of Cellulose-Chitin Interface**

Multiscale modeling starts with massively parallelized molecular dynamics (MD)[2] is used to characterize the structure-mechanics relationship of the cellulose-chitin interface at the nanoscopic scale. Large-scale MD models are a precise tool to investigate biological materials' mechanics and interfacial interaction by simulating their mechanical responses in different mechanical and environmental conditions. It reveals their nanomechanics and relates this characteristic to macroscopic material deformation, failure, and disease state[2–6]. Here, we investigate cellulose-chitin adhesion with varying orientations of crystal by using the CHARMM36 force field[7] with NAMD[2,8].

## RESULTS

We perform the tensile test with Instron for each sample to measure how the mycelium and environmental factors can affect the mechanical properties of the composite materials.

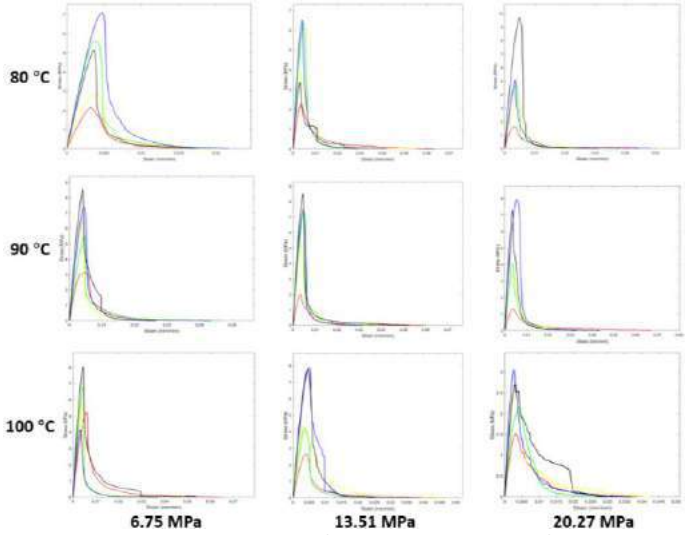

**Figure 2.** The stress-strain curve for dog bone samples of the mycelium composite as the mixture of hardwood with mycelium after heat press treatment under different temperatures, pressure, and baking time (1 hour-red, 2 hours-yellow, 4 hours-green, 8 hours-blue, 16 hours-black.)

It is shown that the existence of mycelium makes the composite slightly stiffer and stronger. Moreover, the higher temperature and pressure generally leads to materials of a higher density as well as a higher stiffness and strength. However, the toughness of the composite is not significantly affected by increasing the processing temperature and pressure.

To understand the effect of the mycelium on composite, we compare the naturally dried mycelium-based composite material at room temperature with the baked ones under 90 °C for an hour in SEM (**Fig. 1C**). We can see that under the condition of slowly losing water, all the mycelium become long flat strips and many of them are found to entangle with the wood fibers. The structure of mycelium after heat treatment is very different as the fibers break into smaller pieces and maintained a thicker rounded shape.

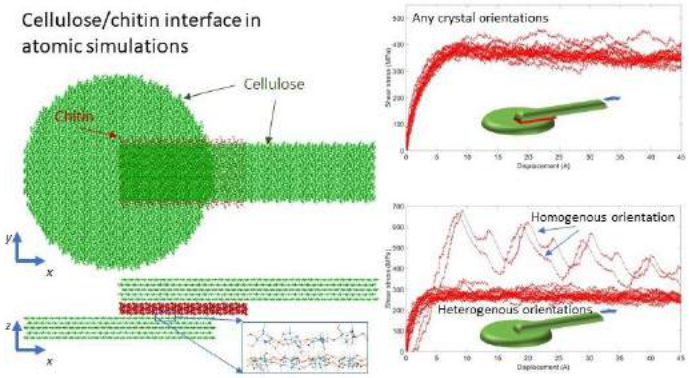

**Fig. 3** Chitin as a glue to enhance the interaction between cellulose: atomic simulations.

Using MD simulation, we investigate the cellulose-chitin adhesion with varying orientations of crystal (Fig. 3). We find that the chitin layer forms more hydrogen bonds (two times)[9] to a cellulose crystal than the pure cellulose-cellulose interface. Because of different lattice sizes, a chitin chain at the interface can form hydrogen bonds with 2~3 cellulose chains even they are overall parallel. Pure cellulose-cellulose interface with chains of same orientation yields a highest strength (~450 MPa) during the shear test. The interface of heterogeneous orientations is much weaker (~250 MPa). In contrast, the strength of the chitin-cellulose interface is much more consistent, with the consistent mechanical strength of ~375 MPa obtained for any crystal orientations.

## DISCUSSION

Our results suggest that the mycelium can enhance the stiffness and strength of the wood composite material. The elastic-plastic behavior of the chitin-cellulose interface at the nanoscale is very similar to the cellulose-cellulose interface[10], and the mechanism for energy dissipation is the stick-slip between polymers at the interface conjugate with breaking and reforming of hydrogen bonds. Further quantitatively studies include optimizing the processing conditions for composite with highest mechanical properties based on the experimental trials and coarse-grained models based on the atomic models to investigate the reinforcement mechanism of mycelium fibers at larger scales.

# PREDICTION OF DIABETES MELLITUS PROGRESSION USING SUPERVISED MACHINE LEARNING

**Apoorva S. Chauhan (1), Mathew S. Varre (2), Kenneth Izuora (3), Mohamed B. Trabia (1), Janet S. Dufek (2)**

(1) Department of Mechanical Engineering, University of Nevada Las Vegas, Las Vegas, NV, USA

(3) Department of Internal Medicine, University of Nevada Las Vegas, Las Vegas, NV, USA

## INTRODUCTION

Diabetes Mellitus (DM) is a medical condition in which individuals are unable to produce enough or no insulin at all, or the body cannot use insulin correctly [1]. This condition can cause many complications, such as vision loss, heart disease, stroke, kidney failure, or the amputation of lower extremities. Neuropathy is a common complication that damages the nervous system, resulting in the degradation of nerves of extremities. This degradation, which leads to loss of sensation, can cause persons affected by it to apply elevated pressure on the affected plantar tissues, leading to plantar ulceration, which if left untreated can lead to limb amputation [2].

The most accessible methods to diagnose diabetic neuropathy include sensory testing with a 10-gram monofilament and a tuning fork. However, these tests are crude and highly subjective, which can lead to missing the early signs of neuropathy [3]-[5]. More reliable diagnostic tools, such as nerve conduction studies, are expensive and time consuming [5], [6]. A more cost-effective, reliable, and available method of diagnosing neuropathy has the potential to improve the accuracy and timeliness of detection, which can prevent further complications [5].

Studies have shown that static plantar pressure data of patients with DM were different from healthy participants [8]. Plantar pressure measurements taken during walking can show the tissue response to stress that correlates with ulceration. Supervised machine learning algorithms and dynamic plantar pressure parameters have been used to successfully classify individuals with diabetic neuropathy and DM from healthy individuals [9]. However, this study was unable to differentiate pre-diabetic patients from DM patients when compared to healthy individuals.

The aim of this research was to develop a diagnostic tool that can classify persons who have pre-diabetes, diabetes, or diabetes with neuropathy using supervised machine learning. Several plantar pressure features taken during walking, as well as patient-specific features would be used. The success of the proposed approach would be assess based on its classification efficacy to ensure that it is suitable for clinical use.

## METHODS

Data was collected from 110 participants, 19 with pre-diabetes, 62 with diabetes, and 29 with diabetes with neuropathy. Participants were fitted with Medilogic® pressure measuring insoles (60 Hz) and walked at their normal walking speed. Each participant performed three to five trials, with three to five steps occurring in the calibrated walking space, for a total of 1621 steps (observations). To allow granularization of the data, each foot was divided into three regions: rearfoot, midfoot, and forefoot, RF, MF, FF, respectively. The pressure data collected was used to calculate the peak plantar pressure (PPP), peak pressure gradient (PPG), and pressure time integral (PTI) for the fore-, mid-, and rearfoot during the support phase. Instead of including left and right feet, only left was considered along with the Asymmetry index (AI), which was calculated for each pressure feature in each region,

$$AI = \frac{|Right\ Foot - Left\ Foot|}{Left\ Foot} \quad (1)$$

In addition to these eighteen pressure features, the participants' age, mass, height, and HbA1c were also used as features for a total of twenty-one. Excluding HbA1c, features were tested in seven cases to assess the effect of combining features differently. Each combination was tested twice, with and without HbA1c for a total of fourteen cases. A variable sensitivity analysis was conducted to determine the five features with the greatest impact on classification. It was found out these features: age, mass, height, rearfoot PTI, and HbA1c. These five features were assessed in Case 15 while the first four were used in Case 16.

The K-Nearest Neighbors (KNN) classification algorithm was used, which classifies data points based on the classification of the K nearest data points to the point in question [10]. Each case was cross-validated using the holdout method where 20% of the data was randomly selected to be the test data and the remaining 80% was used

to train the model for twenty iterations. The average of these 20 trials was used to determine the overall efficacy of the algorithm's performance in each case. The average false negative rate for misclassifying participants was also recorded. To understand how accurately the algorithm is classifying DN participants only the average false negative rate for DN participants is reported.

## RESULTS

Table 1 lists the features in each tested case while Table 2 lists the cross-validated machine learning results. Case 15 was the best performing case had an accuracy of 99±0.59% and a false negative rate of 0.41% in diagnosing diabetic neuropathy. Including Case 15, cases 5, 6, and 13 produced accuracies greater than to 95%, with no false negative rates exceeding 0.5%.

## DISCUSSION

The results show that including many features does not necessarily produce good results. The four cases with the best performance included PTI of the rear foot, which suggests this feature may play a greater role in determining an individual's diagnosis than peak pressure gradient. When HbA1c was removed, cases only dropped approximately 1% in accuracy. However, when removing HbA1c from Case 15, there was a 26% drop in accuracy and significant rise in DN false negatives, which may indicate that a significant reduction in the number of pressure features may make the model unstable. The results suggest that PPG does not contribute to the prediction of diabetes for this sample of participants,

The presented research suggests that the KNN algorithm can be used to classify the progression of diabetes based on a combination of plantar pressure variables at different foot regions, along with patient-specific features. These findings indicate that this approach may be suitable for use in a clinical setting to inexpensively, quickly, and objectively classify individuals with diabetic neuropathy.

**Table 1: Features of Each Case in Addition to Age, Mass, and Height**

| Case | Features |
|---|---|
| 1 | $PPP_{LFF}$, $PPP_{LMF}$, $PPP_{LRF}$, $PPPAI_{FF}$, $PPPAI_{MF}$, $PPPAI_{RF}$, $PPG_{LFF}$, $PPG_{LMF}$, $PPG_{LRF}$, $PPGAI_{FF}$, $PPGAI_{MF}$, $PPGAI_{RF}$, $PTI_{LFF}$, $PTI_{LMF}$, $PTI_{LRF}$, $PTIAI_{FF}$, $PTIAI_{MF}$, $PTIAI_{RF}$, HbA1c |
| 2 | Same as Case 1 without HbA1c |
| 3 | $PPP_{LFF}$, $PPP_{LMF}$, $PPP_{LRF}$, $PPPAI_{FF}$, $PPPAI_{MF}$, $PPPAI_{RF}$, $PPG_{LFF}$, $PPG_{LMF}$, $PPG_{LRF}$, $PPGAI_{FF}$, $PPGAI_{MF}$, $PPGAI_{RF}$, HbA1c |

## INTRODUCTION

It is known mechanical properties of brain tissues are important to understand its disease and development [1]. Many studies have used magnetic resonance elastography (MRE) to measure the biomechanical properties of brain in vivo [2]. Diffusion weighted imaging (DWI) provides important information of tissue structures in terms of water diffusion [3]. Studies have shown a strong correlation between diffusivity and elastic properties in liver [4]. However, the potential relationship between structural and biomechanical properties of brain is yet to be explored.

In this study, we used DWI and MRE to characterize the potential correlation between structural and biomechanical properties of brain. Apparent diffusion coefficient (ADC) and shifted ADC (sADC) values were estimated. The correlations between sADC and shear stiffness were analyzed for each of the specific brain region at 3 different actuation frequencies. A phenomenological model based on sADC and the shear stiffness was proposed.

## METHODS

A total of 43 healthy volunteers were recruited in this study. Among all the subjects, data from the 32 subjects were used for modeling and the rest 11 subject data were used for validation. MRE imaging was performed using a custom-built electromagnetic vibration actuator [5] (Figure 1). The measured was carried out using 4 actuation frequencies: 20, 40, 60 Hz for correlation analysis and 30 Hz for generalization validation of the model. Wave images of the brain were acquired using an echo planar imaging (EPI) based MRE sequence with three motion encoding directions. Shear modulus maps were calculated by using a three-dimensional local frequency estimation (LFE) method. For DWI, images were acquired with diffusion encoding along three axis. Among the 16 key b-values between 0 and 2500 s/mm2 acquired, we selected 2 optimized key b-values to calculate sADC, so that Gaussian and non-Gaussian diffusion effect was included. Both MRE and DWI scanning were performed on a 3T MR imager (uMR 790, United Imaging Healthcare, Shanghai, China).

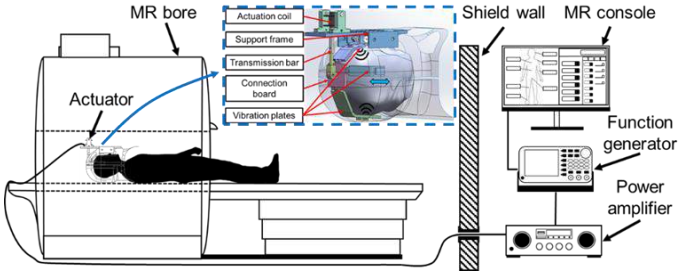

**Figure 1. A diagram of the custom-built electromagnetic MRE system. The vibration signal was generated by the function generator and amplified by the power amplifier before transmitted to the actuator. The MR console would synchronize the actuator vibration and MRE sequence scanning.**

All MRE and DWI images were registered to a common reference (MNI152 T1-weighted 2 mm brain atlas) by using Advanced Normalization Tools (ANTS) for later segmentation and correlation analysis. The whole brain was then segmented into frontal, occipital, parietal, and temporal lobe using the MNI template mask within the FMRIB Software Library (FSL).

Correlation between DWI and MRE registered results were calculated by using MATLAB with Pearson correlation coefficient. The linear correlation coefficient was quantified voxel by voxel at each frequency. All p values were corrected by the false discovery rate (FDR) method. Then the linear regression analysis between the mean values were performed. Finally, An appearance model were proposed based on the correlation results and was validated by the validation dataset.

## RESULTS

Based on the highest correlation between the shear stiffness and sADC at each frequency, we determined the 2 key b-vlaues as 200 s/mm2 and 2000 s/mm2. T1-weighted images, average shear stiffness, and average sADC values over the 32 subjects are shown in Figure 2. We observed the anatomical features of the brain structures such as white matter and ventricle regions could be identified base on the stiffness and sADC maps.

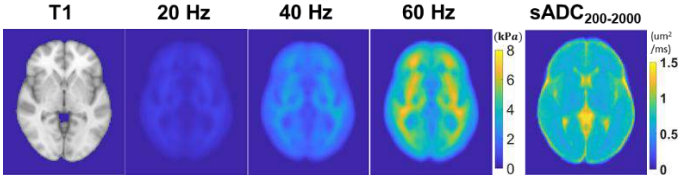

**Figure 2. Column 1 is the T1-weighted brain structure template. Column 2-4 are the mean values of shear stiffness from 32 volunteers at 20. 40, and 60 Hz, respectively. Column 5 is the mean sADC value from corresponding DWI results.**

Voxel correlation results along 3 equal spacing actuation frequencies are shown in Figure 3. The voxel with significant correlation had been indicated in color and large correlation regions for all 3 MRE frequencies were only observed in parietal lobe.

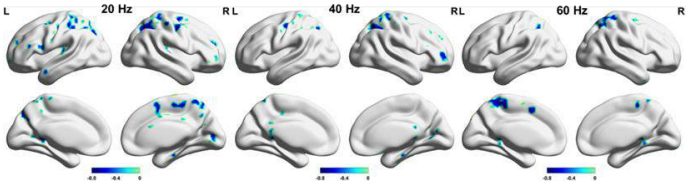

**Figure 3. The correlation results displayed on the cerebral cortex for all 3 experimental frequencies. Only the voxels with significant correlation relationship have been shown in color.**

The results from linear regression study confirmed the specificity of parietal lobe found in voxel correlation maps in Figure 3. The linear correlation was significant for all 3 frequencies in parietal lobe, while frontal lobe and occipital lobe only had significant result for 20 and 40 Hz, respectively. As for template lobe, there were no correlation existing at any frequency.

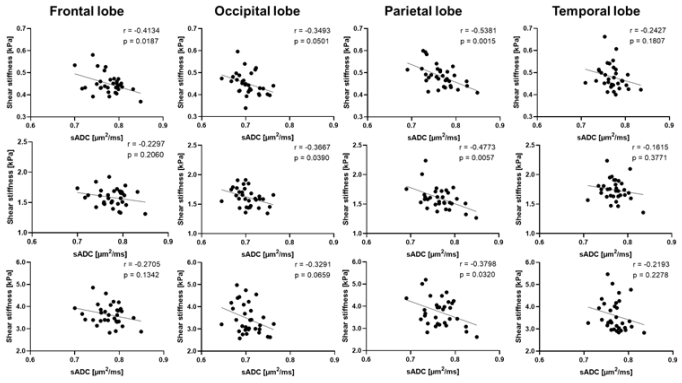

**Figure 4. The linear regression results of the 3 frequencies in the frontal, occipital, parietal, and temporal lobe. Only parietal lobe appeared linear relationship along all frequencies.**

Summarizing the correlation results in parietal lobe and we assumed that the shear stiffness, $\mu_f$, at each vibration frequency, $f$, could be estimated from the sADC as:

$$\mu_f = (\alpha_1 f^{\beta_1} + \gamma_1) \cdot sADC + (\alpha_2 f^{\beta_2} + \gamma_2) \quad (1)$$

where $\alpha_i$, $\beta_i$, and $\gamma_i$ are the model parameter and can be determined by data fitting.

The mean values of the 11 validation subjects using the proposed model and a traditional spring-spot model, standard linear solid (SLS), are shown in Figure 5(a). Comparing with measured data, the proposed results performed well similarity even at 30 Hz. Although the new model had similarity absolute error at 20 and 30 Hz comparing with the two traditional competitors (Figure 5(b)), around 50% prediction error decrease has been achieved for 40 Hz and 60 Hz.

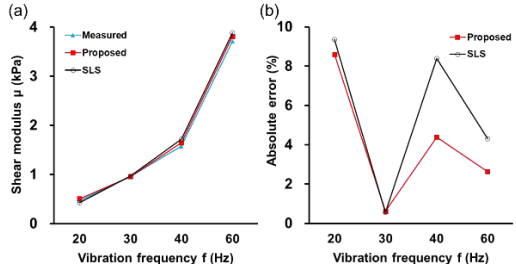

**Figure 5. (a) The comparison results between the measured mean values from measured validation dataset, the predicted values from the proposed model, and the SLS model, respectively. An validation frequency 30 Hz was added for generalization comparison. (b) The absolute error of proposed method and SLS model comparing with the measured results. Proposed model achieved better similarity, especially at 40 Hz and 60 Hz.**

## DISCUSSION

The previous simulation and experiment results have indicated that the biomechanical properties of human brains were related with their structures [6]. However, many traditional frequency response models lacked of structure information. Bihan, DL et al has observed the strong correlation between shear modulus and sADCs on human lives [7], but few similar studies have been applied on brains yet.

In this study, we proposed a phenomenological model for parietal lobe to describe the shear stiffness by sADC at multiple frequencies. The validation results highlighted the utility of the empirical model when comparing with traditional models such as the Maxwell. These results also demonstrated a strong correlation between mechanical properties and structural properties in parietal lobe.

# EXPERIMENT-LED CONTINUUM MODELLING OF MICROSCALE BLOOD FLOW

**Simon Tupin (1), Stavroula Balabani (2), Joseph van Batenburg-Sherwood (1)**

## INTRODUCTION

Modelling blood flow is of great importance for both research and clinical applications. Blood in large vessels can be reasonably modelled using Newtonian or simple non-Newtonian models. For the smallest blood vessels (<30μm) the dynamics of individual red blood cells (RBCs) can be captured using methods such as Immersed Boundary and Dissipative Particle Dynamics (see e.g. reviews [1,2]). For arterioles and venules, the large microvessels (diameter 30-100μm), there are too many RBCs to model individually, but simple non-Newtonian methods are insufficiently detailed to capture the complex local blood rheology.

The rheology of blood is highly dependent on both shear rate and local concentration of RBCs (haematocrit), both of which vary considerably throughout the microvasculature, both between *and within* vessels. Continuum models for blood flow consider blood as a continuum fluid with shear- and haematocrit-dependent viscosity, with RBC motion modelled using a transport equation [3-5] (Figure 1).

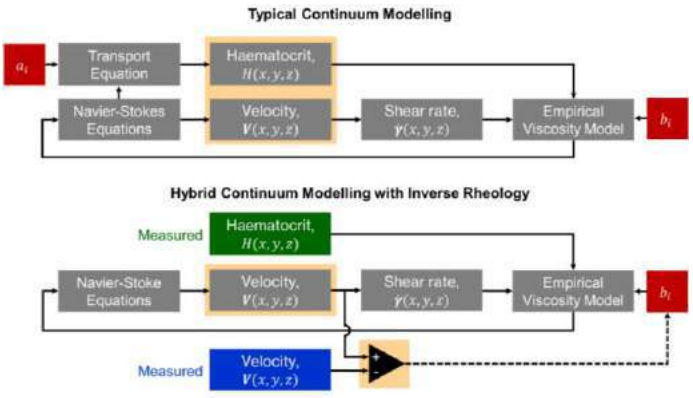

**Figure 1: Typical and proposed approaches to continuum modelling of microvascular blood flow [6].**

This approach is significantly more efficient than modelling individual cells, however, difficulties arise in

i. selecting appropriate transport equations terms and corresponding empirical parameters, $a_i$, to account for migration and margination of RBCs
ii. selecting an empirical viscosity model and corresponding parameters $b_i$, (typically derived in constant shear rheometers) to account for non-linear shear and haematocrit dependence
iii. validating that the modelled results actually represent the behaviour of blood

Irrespective of the modelling technique chosen, the reliance on typically 5-10 parameters and a range of available phenomenological models make the problem ill-defined, and proper validation requires high quality experimental data, which is scarce.

Here, we propose an approach to bypass these difficulties using a hybrid experiment-led approach (Figure 1). Firstly, we eliminate parameters $a_i$ using optical measurements of spatial distributions of haematocrit. Then, we use an iterative parameter optimisation process that we term 'inverse rheology' [7] to find the viscosity model parameters $b_i$ that minimise the error between modelled and measured velocity profiles.

In the present study, we demonstrate the methodology using experimental data of human blood flowing in a sequentially bifurcating microchannel to evaluate the model efficacy and the relative importance of RBC distribution and local shear rate.

## METHODS

### Experimental Methods

Experimental data was used from a previous study [8], comprising human blood samples at a feed haematocrit of 25% perfused through a sequentially bifurcating microchannel with a square cross section and side length 50μm. 38 experimental cases were captured with varying flow rates and flow splits between branches. RBC concentration distributions were calculated based on the light transmitted through the sample when averaged over time [8]. Velocity was measured using ensemble average micro-particle image velocimetry in each of the 5 branches in the region of interest of the channel [8] (see Figure 2 for channel layout). Three-dimensional distributions were estimated on the assumption of 4-fold symmetry in the inlet branch of the channel following a long, straight section.

### Viscosity Model

The Quemada viscosity model was used, with an additional empirical parameter Γ added for the inverse rheology process:

$$\mu = \mu_0/(1-0.5kH)^2$$
$$k = \left(k_0 + k_\infty/\Gamma\sqrt{|\dot{\gamma}|/\dot{\gamma}_c}\right)/\left(1+1/\Gamma\sqrt{|\dot{\gamma}|/\dot{\gamma}_c}\right) \quad (1)$$

where $\mu_0$ is viscosity of the suspending medium, $H$ is the haematocrit and $\dot{\gamma}$ is the shear rate. The parameters $k_0, k_\infty$ and $\dot{\gamma}_c$ were determined as functions of $H$ and $\dot{\gamma}$ from previously published data [9].

### Numerical Methods

Computational fluid dynamics was carried out using ANSYS CFX. For each of the 38 cases, boundary conditions were defined according to measured flow rates at 3 of the four branches with 0 pressure at the outlet. Experimental haematocrit data was mapped onto the mesh of ~2.4M elements and used to calculate the local viscosity using Equation 1 with $\dot{\gamma}$ calculated intrinsically. Velocity profiles at each of the 5 branches were extracted and normalised by the average velocity. The

Velocity Residuals, $e$, were calculated as the difference between the normalised experimental and numerical velocity. The relative error $E^*$ for each branch and case was determined as the root mean square of $e$, divided by the value calculated compaing the experimental data to a Newtonian fluid. $E^*$ thus defined varied between 0 (perfect match to experimental data) and 1 (equivalent to assuming a Newtonian fluid).

**Inverse Rheology Process**

To optimise the numerical model, we considered two parameters. Firstly, we varied the parameter Γ in Equation 1 between 1 and 5. This parameter increases the sensitivity if the local viscosity to shear rate and haematocrit. Secondly, we investigated different widths (0.3 to 2.7 µm) of the exclusion layer, the region of reduced time-averaged haematocrit that has a reduced haematocrit due to the finite size of the RBCs. 8 of the cases were selected to cover a range of flow rates and flow splits. 25 combinations of Γ and the exclusion layer width were simulated and the average $E^*$ for the 8 sample cases was calculated to find the combination that yielded the minimum error.

**Forward Modelling**

All 5 branches for all 38 cases (N=190) were considered for a number of different models. To evaluate the efficacy of the modelling approach, simulations were carried out for all cases using the baseline model, with no exclusion layer and $\Gamma = 1$. To investigate the advantages proffered by the inverse rheology process, simulations were carried with the optimised model. Finally, to evaluate the relative importance of haematocrit and shear dependence, additional simulations were carried out with either the shear rate or haematocrit was held constant.

## RESULTS

The baseline model yielded a mean $E^*$ of 0.38 [0.37,0.39] (mean [95%CI]), indicating a 60% reduction in error relative to a Newtonain model. From the inverse rheology process, $\Gamma = 3$ and an exclusion layer thickness of 1.5µm were found to minimise the averaged relative error. When the optimised model was applied to all data sets, the mean $E^*$ was further reduced by a third to 0.25 [0.24,0.26].

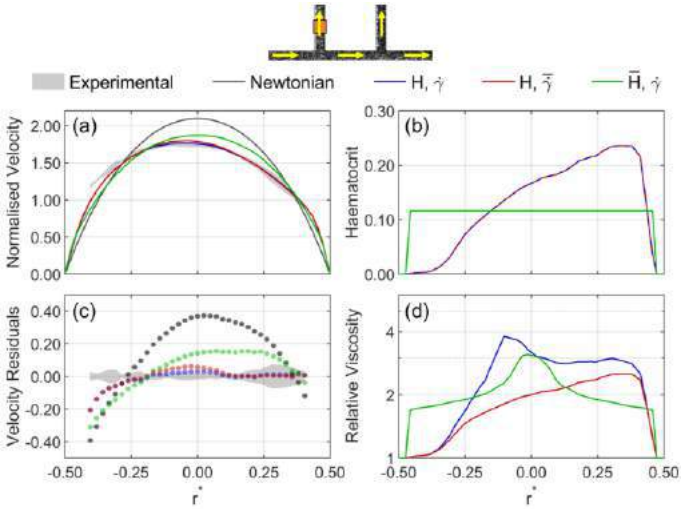

**Figure 2: Image shows channel, with yellow arrows indicating flow direction. (a) Sample velocity profiles, normalised by average velocity. Lines compare different models to experimental data in grey. (b) Haematocrit profiles. (c) Velocity residuals show model values minus experimental values. (d) Simulated relative viscosity.**

Figure 2 compares the results of the optimised ($H, \dot{\gamma}$, blue), constant shear ($H, \bar{\dot{\gamma}}$, red) and constant haematocrit ($\bar{H}, \dot{\gamma}$, green) models for a sample case in the first side branch (orange region in channel image). The normalised velocity profiles and residuals (Fig 2a,c) show that the model does a good job of recapitulating the experimental data when the haematocrit distribution is accounted for ($H, \dot{\gamma}$ and $H, \bar{\dot{\gamma}}$), but not when only the shear distribution is considered ($\bar{H}, \dot{\gamma}$).

The asymmetry in the velocity profile arises from the asymmetric haematocrit distribution, a common feature in branching channels on the scale of arterioles [8]. The different viscosity profiles (Fig 2d) demonstrate that the uniform haematocrit model fails to reproduce the asymmetry in the profile, while the constant shear model does not reproduce the peak in viscosity at the location of maximum velocity. Considering all cases, the uniform shear model had an average 0.47 [0.46,0.48], almost double that for the uniform shear model with 0.26 [0.25,0.27].

## DISCUSSION

The present study provided proof of principle that a continuum model is able to accurately model microscale blood flow when the local distribution of RBC is taken into account. This approach is considerably more efficient than modelling individual RBCs (minutes on a desktop computer, rather than weeks on a supercomputer) and is thus scalable.

The considerable asymmetry in the profiles of haematocrit, velocity and hence viscosity demonstrate the critical importance of evaluating and optimising such models in branching geometries, guided by experimental data. The results also demonstrated that local shear rate is considerably less important than local haematocrit in viscosity models, such that a simpler version of the viscosity model using $k = (k_0 + k_\infty\theta)/(1+\theta)$ may be sufficient.

Improvements to the experimental data include using round channels with different branching features and length scale, improved near-wall resolution and blood sample specific bulk viscosity data.

The next key step in the development of this approach is to incorporate transport modelling into the framework. This could be done using a similar data assimilation process in which the simulated velocity distributions from the inverse rheology are input into a transport model, and the results compared to the experimentally measured RBC distributions. Using such an approach, the model could be tuned for a specific blood sample in one geometry and then investigated in another geometry under different flow conditions.

Once validated, it will be possible to investigate how the model parameters and efficacy are affected by changes in the blood sample that occur in microvascular diseases, such as enhanced RBC aggregation or decreased RBC deformability. Although there is much to do to develop the model into a practical tool, the approach described in this study will provide a framework for this development and makes a step towards better incorporation of experimental and computational data in the study of microhaemodynamics.

# BIOLOGICAL RESPONSE OF RABBIT ANTERIOR CRUCIATE LIGAMENTS TO MECHANICAL LOADING IS SEX-SPECIFIC

**L. Paschall (1), A. Dhawan (2), S. Szczesny (1,2)**

(1) Department of Biomedical Engineering, Pennsylvania State University, University Park, PA, USA
(2) Department of Orthopaedics and Rehabilitation, Pennsylvania State University, Hershey, PA, USA

## INTRODUCTION

Anterior cruciate ligament (ACL) tears are one of the most common knee injuries and affect approximately 100,000 people a year in the USA[1,2]. Recent studies suggest that repetitive subfailure loading creates microtrauma and structural tissue damage, thereby predisposing the ACL to injury[3,4]. Similar fatigue-induced injury is observed in tendons, where structural damage from overloading initiates a degenerative (i.e., catabolic and inflammatory) cell response, which in turn, weakens the tendon[5]. Given the similarity between tendons and ligaments, it is possible that fatigue-induced degeneration also occurs in the ACL and contributes to ACL rupture. However, the biological response of the ACL to cyclic loading is unknown. Furthermore, it is unknown if there is a sex-specific response to loading, which may explain why ACL ruptures occur 2-8 times more often in female athletes than male athletes[6,7] To address these knowledge gaps, we developed a live tissue explant model that can cyclically load rabbit ACLs to a prescribed stress level and maintain cell viability[8]. The objective of this study was to use our explant model to compare the dose-dependent effect of cyclic loading on gene expression within ACL explants from male and female rabbits. We **hypothesized** that the female samples will exhibit an increased catabolic response to mechanical loading compared to male samples, which would be consistent with increased ACL rupture rates in women.

## METHODS

Following IACUC approval, ACLs were harvested from both knees of male and female New Zealand white rabbits and placed in a tensile bioreactor with culture media kept at 37°C and 5% $CO_2$. After 10 h of accumulating the ACLs to explant culture, the bioreactor cyclically loaded the samples to 2 MPa or 4 MPa at 0.5 Hz for 8 h. These stress levels are based on estimates of ACL loading in situ[9], and 8 h of loading was chosen based on previous explant studies of tendon[10]. Control samples were placed in the bioreactor under the same duration but under a minimal (0.1 MPa) static load. ACLs were immediately removed after loading, rinsed with ice cold RNase-free water and flash frozen in liquid nitrogen. Total RNA was extracted with RNeasy minicolumns, cDNA was synthesized from 10 ng of the total RNA, and real time-PCR was performed using Taqman probes to measure expression of anabolic (*COL1A1, COL1A2, LOX, COL3A1, TGFβ1 ACTA2*), catabolic (*MMP1. MMP2, MMP10, MMP13, TIMP1, TIMP3*), and inflammatory (*IL-1β, PTSG2*) genes with *ACTB* as a reference. Quantification of gene expression was performed via the delta-delta Ct method (after correcting for primer efficiencies) relative to the sex-specific statically loaded condition. For the 0.1 MPa data, the female group was compared relative to the male group. Single sample Wilcoxon tests were used to determine differential expression. Data are represented as box and whisker plots with whiskers representing the 10th and 90th percentile of data, and significance for all tests was set at $p < 0.05$.

## RESULTS

For the statically loaded samples, female ACLs (n = 6) exhibited an increased expression of anabolic (*COL1A2, COL3A1*), catabolic (MMP1, MMP2), and inflammatory genes (*IL-1β*, PTSG2) compared to the male samples ($p < 0.05$) (Fig. 1). For the cyclically loaded samples, female ACLs loaded to 2 MPa (n = 6) exhibited a decreased expression of *COL1A1, COL3A1,* and *MMP2* with an increased expression of *LOX* ($p < 0.05$) (Fig. 2). In contrast, there was no change in gene expression for female ACLs loaded to 4 MPa (n = 5); however, there was a trend toward differential expression of catabolic genes with potential downregulation of *MMP2* and *TIMP1* and upregulation of *MMP10* ($p = 0.063$) (Fig. 2). Male samples cyclically loaded to 2 MPa (n = 4-7) exhibited increased expression of anabolic genes *COL1A2* and *TGFβ1* ($p < 0.05$) (Fig. 3), whereas male samples cyclically loaded to 4 MPa (n = 6) exhibited increased expression of anabolic (*COL1A1, COL3A1,*

*LOX, TGFβ1)*, catabolic (*MMP2, TIMP1, TIMP3*), and inflammatory genes (*IL-1β*). ($p < 0.05$) (Fig. 3).

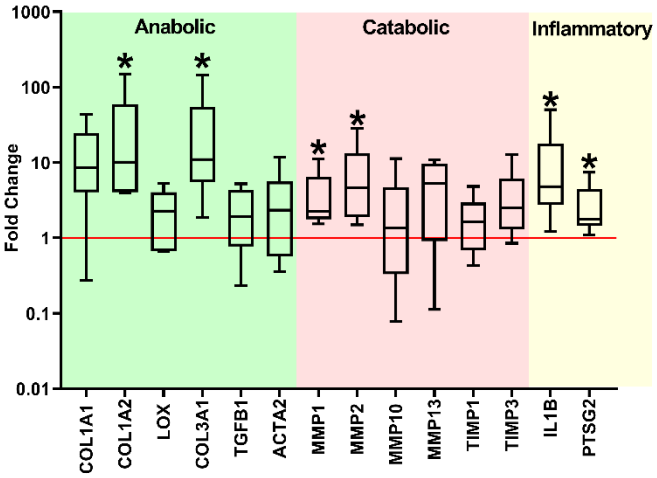

**Fig 1. Change in gene expression of female static control samples relative to males. ( * $p < 0.05$).**

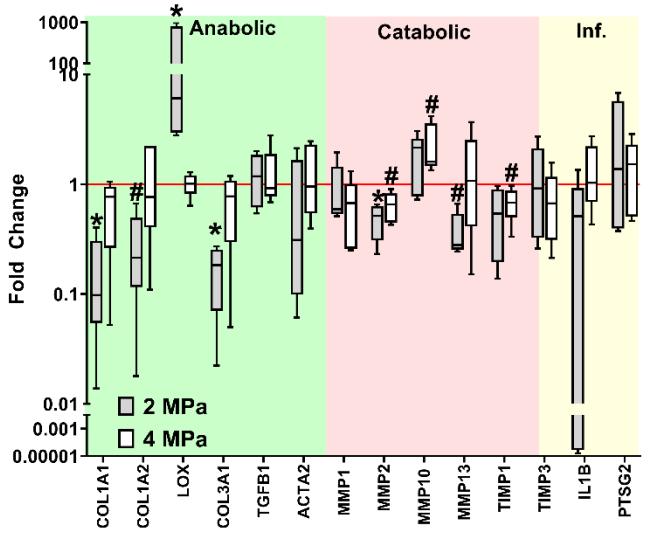

**Fig 2. Change in gene expression of female samples cyclically loaded to 2 or 4 MPa relative to a static control. ( * $p < 0.05$, # $p = 0.063$).**

## DISCUSSION

This study investigated how male and female rabbit ACLs respond to mechanical loading in a tissue explant model. We found that the biological response to mechanical loading was indeed sex dependent. Specifically, in the statically loaded samples, female ACLs exhibited an upregulation of anabolic, catabolic, and inflammatory markers compared to male samples. Upregulation of all gene categories suggests that, at baseline, female ACLs exhibit an increased level of tissue remodeling compared to males. Surprisingly, there was a mild downregulation in expression of anabolic and catabolic genes within female ACLs in response to loading. Note that while there was no statistically significant change with 4 MPa, this is likely due to an insufficient sample size ($p=0.063$). Furthermore, the 4 MPa data exhibited similar trends in gene expression as the 2 MPa data. In contrast, the male ACLs exhibited minimal changes in gene expression at 2 MPa but upregulated multiple anabolic, catabolic, and

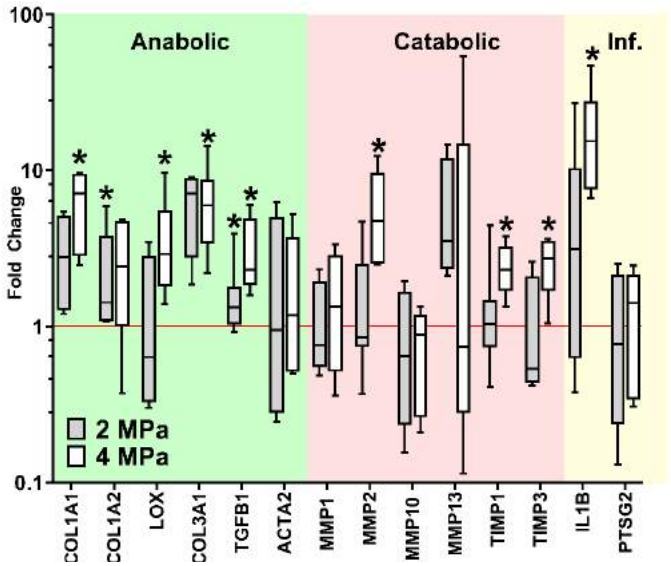

**Fig 3. Change in gene expression of male samples cyclically loaded to 2 or 4 MPa relative to a static control. ( * $p < 0.05$)**

inflammatory genes at 4 MPa, demonstrating that male rabbit ACLs are strongly mechanosensitive to increased loading. Together, these data suggest that male ACLs initiate active tissue remodeling with increased fatigue loading while female ACLs reduce tissue remodeling with loading. This lack of tissue remodeling with cyclic loading may inhibit the ability of female ACLs to repair fatigue damage, which offers insight into the increased rate of ACL injuries observed in women. A limitation to this study is that 8 h of loading is not sufficient to induce fatigue damage or changes in tissue structure/mechanics due to tissue remodeling. Future studies will investigate whether female ACLs have a reduced ability to repair fatigue damage by loading for a longer duration and measuring the change in mechanical properties.

## INTRODUCTION

Current commercially available transcatheter aortic valves (TAV) are either self- or balloon expandable. During the last two decades, tremendous improvements in TAV designs and materials took place to optimize valve performance and maximize its benefits[1]. Metals were replaced (stainless steel vs. cobalt chromium) to ensure stronger and more efficient anchoring, skirts were added and later modified to limit regurgitation, and valve profiles were altered to allow minimal interference with the downstream flow. Despite these improvements, the interaction of each TAV with the flow in the aortic root is associated with non-physiological flow properties compared to flow in a native annuli.

Clinical, in-vitro and in-silico studies have shown that TAV performance varies with valve type (self-expanding vs. balloon-expandable)[2,3], the unique design of each valve within the same type group[4,5], the deployment (axial and commissural)[6], and the surrounding patient-specific anatomy[7]. It is important to evaluate the flow downstream of the aortic valve, as it instructs directly on the performance parameters and ultimately durability (after sufficient follow-up). The turbulence of the flow downstream of the TAV informs on the pressure drop across the valve and explains some of the reasons behind differences in pressure recovery among different valves, as identified by different measurement modalities such as echocardiography and catheterization[2]. The turbulence of the flow downstream of the TAV also informs on the forces that the platelets and red blood cells undergo, in the context of general blood damage such as platelet activation, thrombus formation and hemolysis[8].

In this study, we aim to characterize the differences in the resulting flow dynamics and pressure recovery downstream of multiple self-expanding and balloon expandable TAVs.

## METHODS

The hemodynamic assessment of a 26mm Evolut, a 23mm SAPIEN 3, a small Acurate Neo and a 23mm Allegra transcatheter heart valves (THV) was performed in a left heart simulator under pulsatile physiological conditions. These sizes are equivalent in that they treat similar-sized annuli (20 – 23 mm). For the study, the TAVs were implanted into a rigid idealized test chamber. The aortic pressures ranged from 80 to 120 mmHg, the peak aortic pressure was set at 24 L/min, and the heart rate at 60 beats per minute. The fluid used in the experiments was a mixture of water-glycerin (60/40 by volume) with properties similar to those of blood (density of 1060Kg/m$^3$ and a kinematic viscosity of 3.5cSt). Flow data were acquired using ultrasonic flow probes (HXL, Transonic Inc., Ithaca, NY, USA), and pressures at all the measurement locations were measured with a Millar catheter (ADInstruments Inc., 2205 Executive Circle, Colorado Springs CO) along the centerline of the aortic valve chamber. Recordings of the pressure at every axial location along the ascending aorta with intervals of 5mm downstream of the valves and 1 mm inside the valves. Position 0 mm corresponds to the most upstream measurement (ventricular), and position 120 mm corresponds to the last measurement point in the measurement region of the chamber. Fifty consecutive cardiac cycles of aortic pressure, ventricular pressure, and flow rate data were recorded at a sampling rate of 100 Hz at every measurement location. The mean transvalvular pressure gradient (PG) is defined as the average of positive pressure difference between the ventricular and aortic pressure curves during forward flow.

Particle image velocimetry (PIV) experiments were performed to assess the flow downstream of each TAV. Time series recordings were acquired at a temporal resolution of 500Hz. Phase-locked recordings were acquired to calculate the resulting flow statistical parameters (Reynolds Shear Stress) over 250 images. The Reynolds Shear Stress (RSS), an established metric to evaluate turbulence and any associated blood damage potential, is a statistical quantity that is used to describe a turbulent flow field. The principal RSS and instantaneous viscous shear stress (VSS) were computed, and probability density functions (PDF) were calculated and plotted. The results are presented as mean standard deviations. Statistical analysis was performed using JMP Pro

version 15.2.0 (SAS Institute Inc, Cary, NC). All the data were distributed normally, and therefore, t-test for paired comparison between the vena contracta and recovery zone for each valve was performed along with Tukey test for unpaired comparison for vena contracta and recovery zone gradients of all valves.

## RESULTS

The maximal velocity at peak systole obtained with the Evolut R, SAPIEN 3, Acurate Neo and Allegra was found to be 2.12±0.19, 2.41±0.06, 2.99±0.10 and 2.45±0.08 m/s, respectively ($p<0.001$). Figure 1 shows the principal Reynolds Shear Stresses (RSS) at different phases in the cardiac cycle. The maximum RSS occurs during peak systole where the flow is maximal. The Acurate Neo and the Evolut R present the largest distributions of RSS in all 3 phases (acceleration, peak systole, and deceleration). The Allegra shows the minimal range of RSS magnitudes (up to 320 Pa), followed by the Evolut (up to 600 Pa) and then the Acurate Neo and SAPIEN 3 (up to 650 Pa). All the instantaneous VSS magnitudes obtained were lower than 10 Pa, a threshold associated with potential blood damage. The Evolut was shown to have the smallest magnitude range (up to 3.5 Pa), followed by the Allegra (up to 4.8 Pa), followed by the Acurate Neo (up to 5.5 Pa) and then the SAPIEN 3 (up to 6.2 Pa).

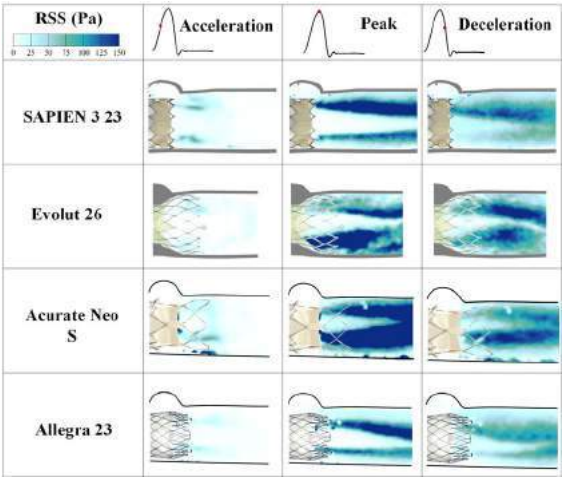

**Figure 1: Principal Reynolds shear stresses (RSS) at different phases in the cardiac cycle. The dark blue patches indicate an elevated RSS magnitude, and the more prevalent elevated RSS magnitudes are, the more turbulent the flow is considered to be.**

The importance of accounting for pressure recovery is that it permits identification of the true pressure gradient across the TAV and accordingly a more accurate assessment of performance. Figure 2 shows the variations of pressure gradients along selected locations in the aortic root with the 4 different valves. The largest pressure drop at the VC occurs with the S Acurate Neo TAV where the minimal pressure reaches 13.96±1.35 mmHg. The PG with the SAPIEN 3, Evolut and Allegra reach 10.54±0.51 mmHg, 10.64±0.38 mmHg, and 11.89±0.61 mmHg, respectively. The 23mm SAPIEN 3 showed the smallest pressure gradient at the VC. At 12 mm, in the recovery zone, the smallest pressure gradient was obtained with the Allegra (3.32±0.94 mmHg), followed by SAPIEN 3 (3.68±0.76 mmHg), then the Evolut R (4.77±0.87 mmHg) and the largest PG was obtained with the Acurate Neo (5±1.21 mmHg). Leaflet flutter was observed mostly with the Acurate Neo and the Evolut.

## DISCUSSION

In this study, we evaluated the hemodynamics downstream of 4 transcatheter aortic valves with variable leaflet position, 3 of which are self-expanding valves (26mm Evolut R, S Acurate Neo and 23mm Allegra) and 1 balloon expandable valve (23mm SAPIEN 3). We report findings on flow turbulence and its relationship to potential for thrombogenicity due to flow turbulence, and on pressure recovery along with its relationship to the assessment of overall valve performance. In literature, it was reported that a limit of 100 Pa to evaluate potential blood damage could be considered appropriate19. Any value that exceeds 100 Pa is considered elevated enough to be associated with blood damage potential. The Allegra TAV showed the smallest range of RSS indicating lowest turbulence levels compared with the other valves. This result was also accompanied by a small leaflet flutter frequency, that helped with the flow stabilization and with the reduction of RSS. The elevated leaflet flutter could be attributed to the supra-annular design of the leaflets and the location of the tip of the leaflet in the Evolut R and the Acurate Neo, in addition to the porcine pericardium material of the leaflets.

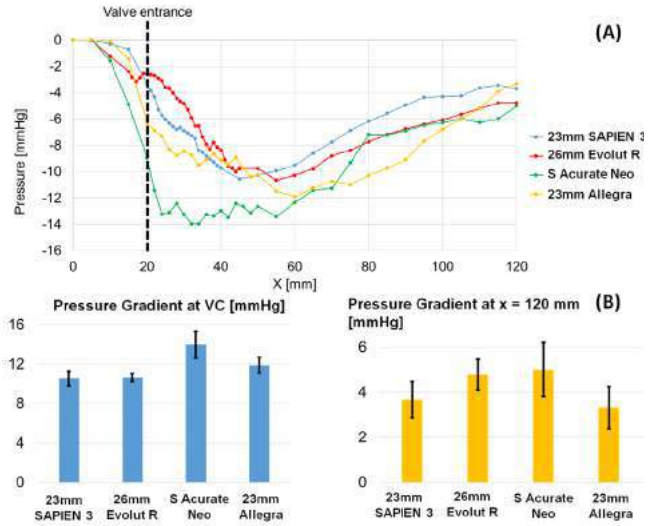

**Figure 2: (A) Variations of pressure gradients (PG) as a function of axial distance at selected location points during peak systole with the 23mm SAPIEN 3, 26mm Evolut R, S Acurate Neo, and 23mm Allegra TAVs. (B) Bar plot showing the pressure gradients at the VC and the recovery zone at x = 120 mm. The dark lines on the bar plots indicate the standard deviations.**

Pressure recovery is an important phenomenon that instructs on the performance of the implanted valve. As the jet expands downstream, its velocity starts decreasing and pressure is recovered depending on several factors such as turbulence, velocity of blood at the VC and the geometry of the aorta. Several clinical studies presented detailed comparative works between echo-based gradients (at the vena contracta) and catheterization-based gradients (in the recovery zone). Some of these studies highlighted that balloon-expandable valves are characterized by higher gradients at the VC and more elevated pressure recovery. Some of these studies were inconclusive. This study shows that pressure recovery is valve dependent, although it is hard to generalize the dependence on the self-expanding versus the balloon expandable type. With various valve types and designs, more experiments and more clinical outcomes are needed to assess the optimally performing valve type.

## INTRODUCTION

Heart failure and death due to sepsis is a growing concern in the medical community. Septic hospitalization rates have steadily increased, reaching a peak of almost 1,700,000 cases in the United States.[1,2] Sepsis is the result of an inappropriate immune response to an infection, where inflammatory cytokines are not kept in healthy concentrations. These inflammatory responses are thought to cause loss of contractility within the heart resulting in septic patients presenting with low blood pressure.[3] The weakened heart muscle tissue cannot overcome the increased end-diastolic volume thereby lowering the output pressure. Previous research has acknowledged that tumor necrosis factor α (TNF-α) and Interleukin (IL)-1β also are increased in individuals with sepsis and lead to reduction in cardiomyocyte lengths.[4] However, a number of other inflammatory factors (IL-6, -8, and -10) have demonstrated upregulation in septic serum and the collective septic inflammatory effects on heart muscle tissues remains to be understood. Therefore, we generated cardiac μtissues on soft lithography derived PDMS μ-pillar arrays to study the inflammatory and contractile responses of cardiac muscle tissue *in vitro*. Cardiac μtissues were dosed with individual inflammatory cytokines and assessed for their inflammatory response and tissue contractility properties. By understanding the effects of Sepsis on Cardiac muscle *in vitro*, we will help to inform future *in vivo* platforms of analysis and therapy.

## METHODS

Silicon wafers were designed and fabricated in a clean room environment and used as master molds for soft lithography polydimethhysiloxane (PDMS, Sylgard 184 DOW Corning) cantilever molding. Induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs), the primary cells that make up cardiac muscle tissues, and bone-marrow derived mesenchymal stem cells (MSCs) are encapsulated in collagen type I and cultured at 37.5 °C, 5% CO2. iPSC-CMs and MSCs self-assemble into spontaneously contractile cardiac μtissues within 48 hours. At 48 hours, μtissues are dosed with a vehicle (control), 2000 pg/mL, or 6000 pg/mL of TNF-α. An inverted microscope was used to record cantilever deflection every 3 hours for 24 hours. After 72 total hours, spent media is collected and μtissues are fixed and stained for DAPI, sarcomeric α-actinin, and connexin-43. An ELISA is used to analyze change in TNF-α levels after the 24-hour dosing.

## RESULTS

Cardiac μtissues present a positive feedback loop in response to dosages of inflammatory cytokines. TNF-α accumulation in spent media showed a significant increase in cardiac muscle release in response to a 2000 pg/mL dosage of TNF-α. ELISA results showed a 3-fold increase in TNF-α concentration after only 24 hours of culture for the 2000 pg/mL group (the 6000 pg/mL group had off-the-chart concentration readings at the time of study and thus have been left out of this data), as seen in **Figure 1A**.

Fluorescence staining of cardiac μtissues revealed continuous rearrangement of the cellular structure, including sarcomeres. In both 2-D and 3-D cultures with increasing amounts of TNF-α, iPSC-CMs stained for α-actinin and DAPI (and connexin-43 for the μtissues) had increasing amounts of misalignment (**Figure 2**) and cell death (**Figure 3**). Contractility studies are still ongoing.

These results confirm the danger of sepsis to the heart; when left untreated, cytokines will continuously self-upregulate in the blood. Unattended exponential growth of cytokines will lead to heart failure and other Sepsis related maladies.

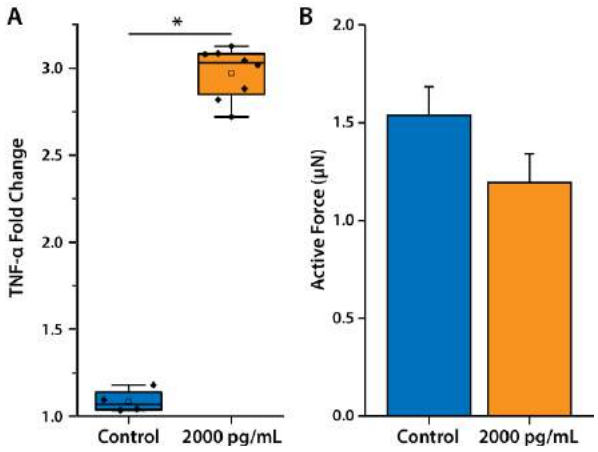

**Figure 1: TNF-α is upregulated in CMTs. In CMTs dosed with 2000 pg/mL of TNF-α, the cytokine is consistently produced to yield a higher concentration after 24 hours. Apparent trend of decreased contractility at 24 hours after TNF-α dosage.**

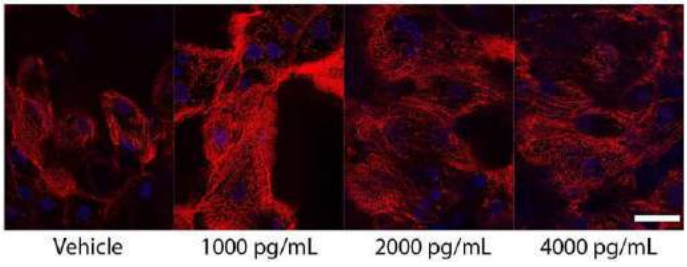

**Figure 2: Dosing iPSC-CMs with TNF-α in 2D monolayer. Representative images showing the degradation of sarcomere alignment (DAPI, Blue; α-Actinin, Red; scale bar is 200 μm).**

## DISCUSSION

The results of these experiments have demonstrated a positive feedback loop of TNF-α production in 3-D cardiac μtissues, consistent with the septic disease state. Additionally, the data show a dose-dependent response between sarcomere alignment and concentration of TNF-α. Lastly, the data show broad cell death over the course of 24 hours with increasing amount of TNF-α. Between sarcomere rearrangement and cell death, the contractility is likely decreasing over time, but further studies will be performed to confirm this hypothesis.

The mechanistic effects of sepsis on the heart are relatively unknown: researchers have theorized the molecular pathways and have performed post-mortem analysis on heart tissue. TNF-α has shown to regulate inducible nitric oxide production[5] and heat shock protein 72[6], two common cellular stress proteins. A critical piece missing is how sepsis affects heart mechanics and contractile properties. We have begun to show how individual septic cytokines can influence the inflammatory response in *in vitro* cardiac tissue. Our hope is to expand this research to include a range of cytokines, including IL-1β, -6, -8, and -10, and determine the contractile responses of septic serum dosing. Collectively, these data will help to drive future research into the relationship between heart muscle condition and sepsis

## INTRODUCTION

Acute or chronic cardiac injuries, such as myocardial infarction or prolonged cardiac overload, cause irreversible damage to the heart[1]. Following myocardial infarction, tissue ischemia and resulting cardiomyocyte (CM) death initiate an inflammatory response and extracellular matrix (ECM) remodeling wrought by activated cardiac fibroblast (CF). This wound healing program results in permanent alterations to myocardial tissue composition, disruption of mechanical and electrical properties, and impaired function[2]. The field of cardiac tissue engineering aims to develop technologies to biomanufacture engineered tissues that could replace injured or diseased native myocardium and restore normal cardiac function for the patient.

Two features critical to healthy myocardial function are the ECM's high degree of structural anisotropy and the organization of resident cell populations (Fig. 1A). The key cell types that structurally compose the myocardium include cardiomyocytes and cardiac fibroblasts[3]. While incorporating these cell types in 3D structures has been well established[4], integrating distinct cell types with tissue-relevant organization and functionally maturing the resulting tissues both remain major challenges for the field. In particular, there is a critical need for new biomanufacturing technologies that can organize ECM and multiple, distinct cell types with microscale precision within tissue grafts of translationally relevant scale. Here, we propose a new method of microfabricating individual anisotropic myofiber bundle-like tissues that can be assembled into larger tissue grafts.

## METHODS

Microchannel devices ranging in channel height and width were designed in Solidworks and 3D printed using a Formlabs Form 3 SLA printer with Grey v4 resin. Sylgard 184 polydimethylsiloxane (PDMS) microchannels were cast from 3D printed molds and treated with 0.3% Pluronic-F127 for 1 hour, then placed channel side down on a 0.3% Pluronic-F127 treated PDMS coated glass coverslip. Channels were perfused with fibrin (20mg/mL fibrinogen with 1U/mL thrombin) containing up to 20M/mL GFP-expressing 3T3 fibroblasts and 2 vol% dextran-vinyl sulfone (DVS) electrospun fibers fabricated via previously described methods[6,7]. Tissues were gelled at 37°C for 30 minutes. Following gelation, PDMS molds were removed, and tissues were cultured in DMEM with 10% FBS and 1% pen/strep (Fig. 1B). Flow-induced alignment of DVS fibers was analyzed using the FibrilTool FIJI plugin to quantify the anisotropic index[8].

## RESULTS

To drive cell alignment, DVS fibers were added to the fibrin precursor solution as a synthetic ECM component and flow-aligned within microfabricated channels. Perfusion of fibrin containing DVS fibers and/or cells resulted in pronounced fiber alignment within formed tissues. Due to the geometry and boundaries of the microchannels, flow-induced alignment of DVS nanofibers within fibrin can be observed consistently across all five channel sizes (Fig. 1C). However, anisotropy of fiber alignment decreased with increasing channel size (Fig. 1D). The decrease in fiber alignment in larger channels is likely due to diminished mechanical boundary effects provided by channel walls. Additionally, fiber alignment varied more by depth within tissue constructs as width of the microchannel increased. While all sides of the gel interact with Pluronic treated PDMS, the surface roughness of 3D printed molds decreases flow-induced alignment. Thus, the top region of formed gels, which are in contact with a rough PDMS surface, were less anisotropic than bottom layers (Fig. 1E).

The inclusion of high-density cell suspensions in gel precursor solutions may influence flow rates and patterns due to changes in viscosity, in turn influencing the final alignment of incorporated fibers. To test whether tissue-relevant cell densities impaired fiber alignment, two cell densities, 10 and 20 M cells/mL, were compared to acellular gel precursor solutions (Fig 2A). Fibers were aligned in all microchannel sizes regardless of cell density (Fig. 2B). Therefore,

including high density cell suspensions in the tissues does not hinder the resulting anisotropy of the myofiber bundle-like tissues.

Upon PDMS mold removal, sustained culture of formed tissues is possible and tissues decreased in diameter due to cell-mediated contraction and proteolysis (Fig. 2C). Overall, these results display the feasibility of our method for producing anisotropic, myofiber-like tissue structures that can be combined to form larger, scalable tissue grafts.

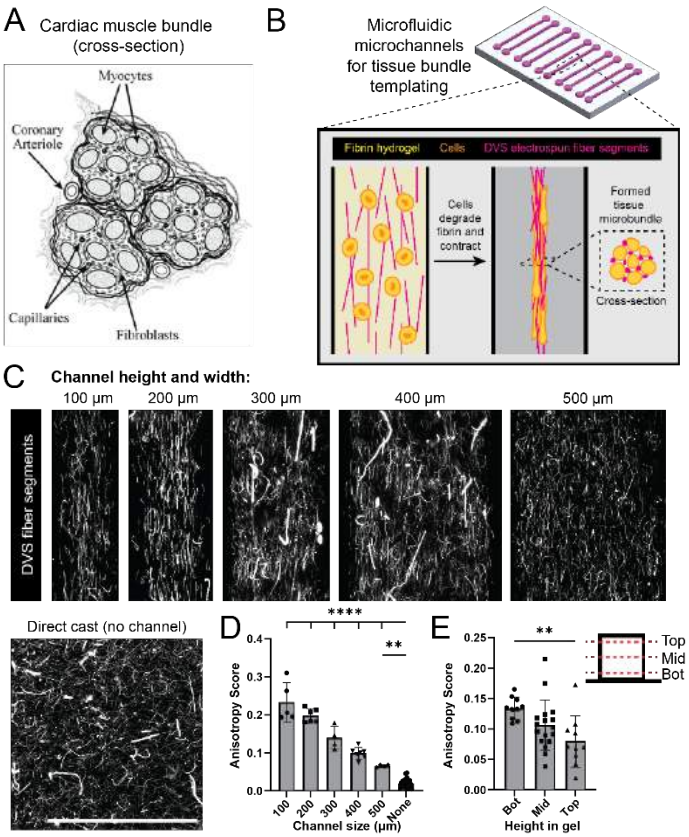

**Figure 1: (A) Diagram depicting a cross-section of myocyte bundles including containing myocytes, capillaries, and fibroblasts[5]. (B) Schematic of microfabricated channels for forming myofiber-like bundles. (C) Immunofluorescent images (scale bar: 500 µm) and (D) quantification of DVS fiber flow alignment via channels of varying sizes. (E) Anisotropy quantification of the bottom, middle, and top planes of formed tissues within all sizes of microchannels. **** p < 0.0001, ** p < 0.005.**

## DISCUSSION

In this study, we developed a microfabrication approach to produce anisotropic myofiber-like bundles using composites of naturally derived ECM and synthetic polymeric fibers that can be flow-aligned within microfabricated microchannels. We show that microchannel geometry controls the anisotropy of ECM-like matrix fibers and the resulting size of tissue bundles. This critical information along with our microfabrication approach allows us to fabricate unit cell tissue bundles of desired size and alignment that can be combined into a larger tissue construct for therapeutic applications. Although these studies were conducted using only fibroblasts, future studies will incorporate a co-mixture of iPSC-derived cardiomyocytes and cardiac fibroblasts. The inclusion of fibroblasts is critical for degrading the fibrin gel and contracting tissue bundles, and we anticipate a careful balance between cardiomyocyte and fibroblast constituents will be required to form cardiac tissue bundles with sufficient electrical and mechanical function characteristic of native cardiac tissues. These metrics will be measured by immunofluorescent imaging of cell-cell junction proteins, such as desmoplakin and connexin-43, and calcium imaging, respectively.

# SPATIAL GRADIENT IN FRONTAL LOBE STIFFNESS DURING BRAIN MATURATION

**Kyra E. Twohy (1), Grace McIlvain (2), Curtis L. Johnson (2)**

(1) Department of Mechanical Engineering, University of Delaware, Newark, DE, USA

## INTRODUCTION

While the human brain develops dynamically from in utero to childhood, maturation is occurring through adolescence into adulthood [1]. Understanding how this development and maturation occurs and the driving mechanisms behind it has been a focus of brain research. One important factor is internal stresses that are critical in brain development and help drive processes such as cortical folding [1]. Measures of these mechanical factors *in vivo* are limited due to the invasive nature of many techniques [1]. A more accessible technique is magnetic resonance elastography (MRE), which leverage phase-contrast MRI to quantify the mechanical properties of brain tissue [2]. Analysis of these properties during late childhood and adolescent development is central to understanding the role internal stresses might play during maturation.

Quantitative values calculated from MRE, including shear stiffness, have been shown to be sensitive to the microstructure of brain tissue [2]. Use of MRE has shown significant changes in brain mechanical properties during aging [3]; however, the application of this technique during maturation is limited [4]. Microstructural changes occurring during maturating include myelination of neural pathways, reorganization and pruning of synaptic connections, and changes in white and gray matter densities [5], all of which are expected to affect brain mechanical properties [6]. MRE can be used to probe brain maturation and examining the distribution of properties spatially throughout the brain could improve understanding of factors supporting maturation. A particular area of interest is the frontal lobe, given its later and prolonged development compared to other areas of the brain [5]. This study aims to compare the spatial variation of shear stiffness in the frontal lobe from childhood to adulthood to understand how development affects the material properties of the brain.

## METHODS

13 children (age range: 5-7 years old, 8M/5F), 14 adolescents (12-14 years old, 8M/6F), and 14 young adults participated in this study (18-32 years old, 5M/9F). All participants completed an MRI protocol on a Siemens Prisma 3T MRI scanner. The MRE portion of the protocol used a custom 3D multiband, multishot spiral sequence with OSCILLATE acceleration to reduce scan time (TE: 76 ms, TR: 140 ms, field-of-view: 240x240 mm$^2$, gradient strength: 70 mT/m) [7]. Vibrations were applied at 50 Hz to the back of the head as shown in Figure 1 and the total MRE portion took 4.5 minutes. A T1-weighted MPRAGE (resolution: 0.9 x 0.9 x 0.9 mm$^3$) was also completed for anatomical segmentation.

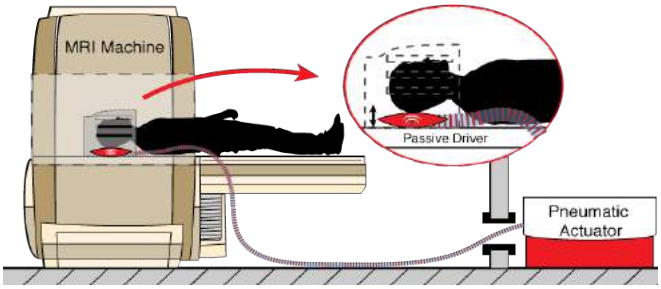

**Figure 1: MRE acquisition set up showing the passive pillow driver in red that applies the vibration.**

Displacement data was converted to shear stiffness using a nonlinear inversion algorithm (NLI) [8]. This defines complex shear modulus (G) by the storage (G') and loss (G") moduli as shown in Equation 1.

$$G = G' + iG'' \quad (1)$$

From complex shear modulus, shear stiffness (μ) can be calculated using Equation 2.

$$\mu = 2|G|^2/(G' + |G|) \quad (2)$$

For each subject, shear stiffness maps were converted into standard space for comparison between groups. The boundaries of the frontal lobe were defined using the WFU-Pick Atlas and the average frontal

lobe stiffness was calculated. To determine gradients in stiffness from the interior to the exterior of the frontal lobe, the stiffness values at each of the boundary points was identified and the gradients were calculated as

$$\frac{(\mu_e - \mu_i)}{d_{avg}}, \quad (3)$$

where $\mu_e$ is the average exterior boundary shear stiffness, $\mu_i$ is the average interior boundary stiffness, and $d_{avg}$ is the average distance between these two boundaries to account for subject specific geometry. This was completed for a middle slice of the frontal lobe. Statistical differences between groups in both frontal lobe stiffness and stiffness gradient were assessed using ANOVA in MATLAB. Additionally, stiffness gradients were correlated with age across all subjects.

## RESULTS

Shear stiffness over the entire frontal lobe was found to be 2.83 ± 0.14 kPa (child group), 2.92 ± 0.18 kPa (adolescent group), and 2.74 ± 0.10 kPa (adult group). Stiffness significantly differed between groups ($p = 0.010$), with significant *post hoc* group differences between the adolescent and adult groups ($p = 0.007$). The calculated average gradient for a middle slice is shown in Figure 2, below, ranging from a mean of -17.16 Pa/mm in the children to -11.42 Pa/mm in the adults. The stiffness gradient significantly differed between groups ($p = 0.035$), with significant *post hoc* group differences between the child and adult groups ($p = 0.031$). The largest magnitude stiffness gradient was found in the child group with the exterior of the brain being softer than the interior. Representative stiffness maps are included for each age group in Figure 2. These visually show that larger differences are found in the child group, but overall stiffness was higher in adolescents. When assessing the influence of age on the stiffness gradient, the gradient magnitude decreased with age ($p = 0.010$), shown in Figure 3.

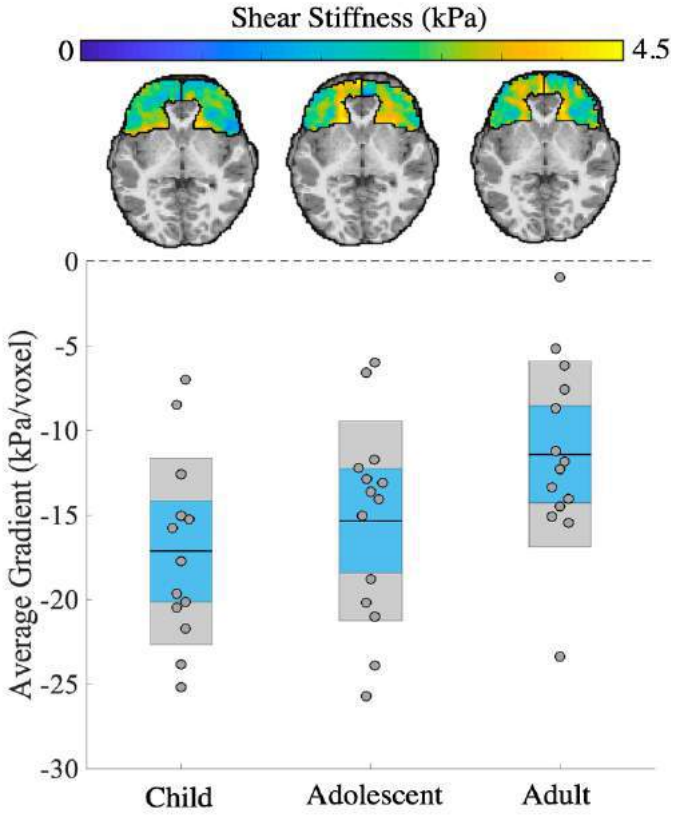

**Figure 2: Average gradient for each age group for a middle slice of the frontal lobe with representative shear stiffness maps shown above. Means are shown by the center line in the blue box, standard deviation by the entire blue box, and the 95% confidence interval identified in the light gray box.**

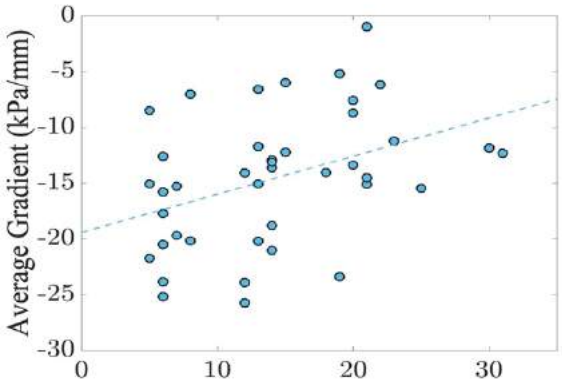

**Figure 3: Stiffness gradient as a function of age.**

## DISCUSSION

This study examined the spatial variation of shear stiffness during development using average stiffness gradients. Significant differences were found when comparing the stiffness gradient from the interior to the exterior of the frontal lobe, specifically between the child and adult groups. The exterior of the frontal lobe is softer than the interior, and across all groups the magnitude of the average gradient decreased with age, i.e., the exterior and interior stiffness became more similar. The sensitivity of this measure to age is likely due to the gradient reflecting maturational changes in the frontal lobe, likely due to microstructural changes in the cortex including myelination and synaptic pruning [5], both of which would impact material properties.

Although previous research comparing adolescent and adult average shear stiffness in the frontal lobe found no significant difference [4], this study found that adolescents had a significantly higher stiffness than adults. There were no statistical differences in average frontal lobe stiffness between the child and adult groups, even though significant structural changes likely occurred between those time points, as reflected in the stiffness gradient measure. Future work will include longitudinally assessing these gradients both in the frontal lobe and other areas of the brain.

# EFFECT OF RESIDUAL STRESSES ON RING-TEST MECHANICAL ANALYSIS

**Manoj Ghosh (1), Marissa Grobbel (1), Lik Chuan Lee (1), and Sara Roccabianca (1)**

## INTRODUCTION

The existence of residual stress distributions is a peculiar characteristic of soft biological tissues, especially in the cardiovascular system [1]. The opening angle method is popularly implemented to estimate the residual stresses in left ventricle (LV) [1-2]. Furthermore, uniaxial tensile test on ring-shaped samples has been often used to estimate the mechanical properties of both arteries and the LV [3]. However, it is unclear how the existence and magnitude of a circumferential, auto-equilibrated, residual stress distribution may affect the estimation of mechanical properties via ring test. Using the data from experimentally quantified opening angles [4] paired with finite element analysis (FEA) we aim to understand the effect that residual stresses have on the stress distribution in the LV, associated with uniaxial mechanical testing.

## METHODS

Our approach can be outlined in two primary steps. First, we used the experimentally quantified opening angle from one representative sample as input for a continuum model to calculate the residual stress distribution, as outlined in [4]. The outputs of the model include the dimensions for the equilibrated closed configuration. Second, we used this geometric information as input for a FEA which includes the finite deformation associated with both the residual stress as well as the ring test [5].

The experimental protocol for the opening angle test as well as the description of the continuum model has been previously described in [4]. For this study, we have selected one representative sample form the isolated collagen experimental group from a healthy male rat (Sprague Dawley). Specifically, the experimental geometrical parameters for the open (after-cut) configuration are: inner and outer radius 4.08 mm 7.75 mm, respectively; and opening angle 96 [deg]. In the continuum model, we described the collagen fibers mechanical behavior employing the following strain energy function.

$$W = c(\exp k(I_1(\boldsymbol{C}) - 3) - 1). \quad (1)$$

Here $I_1(\boldsymbol{C})$ is the first invariant of right Cauchy-Green tensor $\boldsymbol{C} = \boldsymbol{F}^T\boldsymbol{F}$; and the material parameters are $c = 0.47i$Kpa and $k = 31.09$. The deformation gradient for the cut, stress free configuration $(R,\Theta,Z)$ to uncut traction free configuration $(\rho,\theta,z)$ is given by,

$$\boldsymbol{F} = diag\left(\frac{\partial\rho}{\partial R}; i\frac{\rho}{R}; i\frac{2\pi}{2\pi - \Phi}; i\Lambda_z\right). \quad (2)$$

Using this material description, the inner and outer radius for an equilibrated closed configuration was calculated. To understand the effect of the opening angle magnitude on the stress distribution during the opening angle test, we also considered an opening angle of 120 [deg] for the same sample.

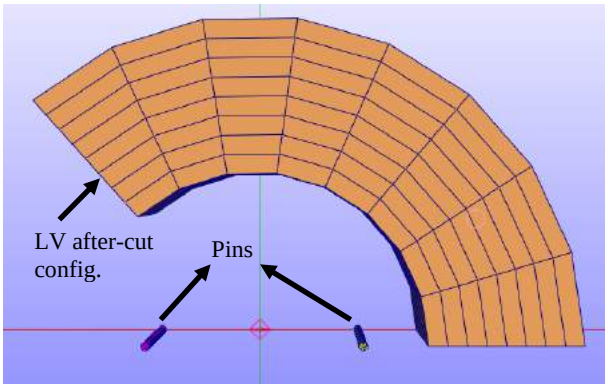

**Figure 1: Stress free ring model used for simulations. The tissue is shown in orange and pins are purple and yellow.**

The FEA was then carried out in two steps: closing the opening angle, first, and simulating the ring test by applying a displacement to the pins, second. A FE model of the after-cut, stress-free configuration of the representative LV was created (**Fig. 1**). For the FEA we used FEBio 3.0, as previously described in [5]. Briefly, the model was created using a solid arc tool, and the two pins used to pull the closed ring during the mechanical test were described as rigid bodies. A sliding node-on-facet contact was implemented between the pin surface and the inner surface of the sample. Both the sample and the pins were meshed using hex8 elements. The strain energy density was given by equation (1) and the material parameters used were the same as in the continuum model (i.e., $c = .47i$KPa and $k = 31.09$). The value of bulk modulus was 1000KPa to approximate the condition of incompressibility employed in the continuum model. For the first step (i.e., the residual stress calculation) the pins were fixed, and the deformation applied to close the model was the one calculated in the continuum model (to ensure an equilibrated condition). For the second step, a displacement of 2 mm was applied to one of the pins and the other one was fixed. We performed the simulation for an opening angle of 96 [deg] (as measured experimentally) and 120 [deg].

## RESULTS

**Fig. 2** represents the x-stress distribution calculated for an opening angle 96 [deg]. **Fig. 2a** shows the x-stress corresponding to the residual stress distribution, in the closed configuration. We can see that the stress distribution corresponds to a finite bending distribution (i.e., inner surface is in compression and the outer surface is in tension). The stress varies from -18.1 KPa to 13.9 KPa. In **Fig.2b**, we show the stress distribution after the ring test simulation, specifically after a 2 mm axial deformation is applied. The stress reaches a maximum tensile value of 28.4 KPa. **Fig. 3a** and **b** show the same set of results for a larger opening angle, namely 120 [deg]. Here, the stress varies from -38 KPa to 31.7 KPa after opening angle closer, and it reaches a maximum tensile value of 56 KPa during ring-test simulation.

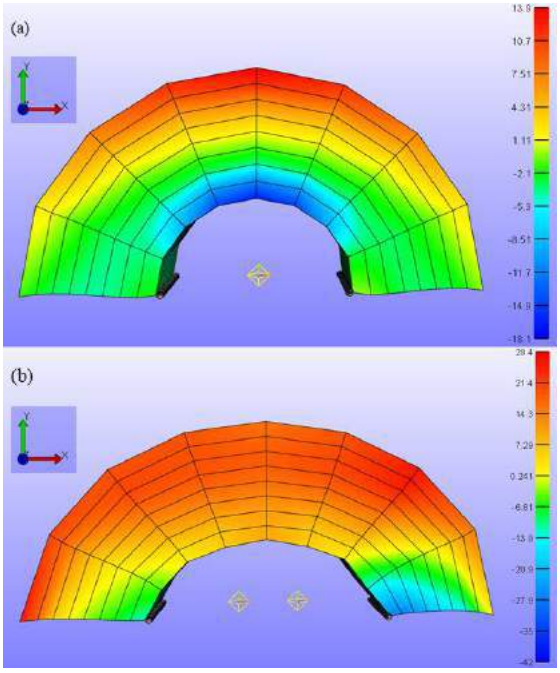

**Figure 2: Stress distribution along the ring after step 1(a) and 2mm pull after step 2(b) for opening angle $96^{\circ}$.**

Comparing the results from **Fig. 2** and **Fig. 3** it suggests that a larger opening angle will generate a larger value of tensile stress, for equal deformation, during the ring test simulation. Furthermore, after an identical axial displacement the change in pick values of the stress in the x direction is larger when the opening angle is larger. Specifically, it goes from 14.5 KPa to 24.3KPa, when increasing the opening angle from 96 [deg] to 120 [deg].

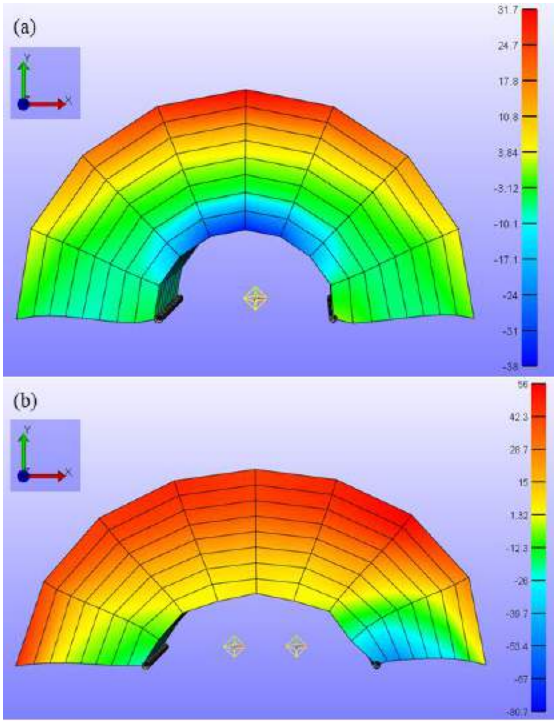

**Figure 3. Stress distribution along the ring after step 1(a) and 2mm pull after step 2(b) for opening angle $120^{\circ}$.**

## DISCUSSION

We performed a FEA to understand the effect of the opening angle magnitude on the maximum value of stress reached in a soft tissue during the ring-test. Our numerical simulations suggest that the opening angle plays a significant role in stress distribution in LV. From the results, we can see that the residual stress increases with a higher opening angle. In future, we will perform a parametric study to investigate the relationship between opening angle and stress distribution. The aim of this study is to understand if residual stresses should be included when estimating material parameters from the uniaxial ring test.

# A NOVEL FIBROUS FINITE ELEMENT MODEL OF SOFT TISSUES

**Mohammad R. Islam (1), Fengting Ji (1,2), Manik Bansal (1), Yi Hua (1), Ian A. Sigal (1,2)**

## INTRODUCTION

Soft connective tissues are characterized by a complex assembly of collagen fibers. Collagen forms three-dimensional (3D) fibrous structures where individual fiber exhibits strong geometric nonlinearities including tortuosity, entanglement, and preferential orientation. The tissue-specific fiber organization together with fiber-scale geometric complexities plays a central role in tissue's biomechanics. However, the fiber mechanics in soft tissues especially the effects of tissue-specific fibrous architecture remain poorly understood. Biomechanical models of soft tissues have been largely developed based on a continuum description which are limited in predicting fiber-scale deformation, and the contributions of fiber-fiber interactions and tissue-specific fiber architecture [1]. Although a few fiber-scale models have been developed recently, they are based on idealized architectures and do not represent tissue-specific fiber organization [1]. Therefore, the mechanistic links between tissue's fibrous structures and their emergent biomechanics cannot be fully understood from the existing models.

The objective of current work was to develop a fibrous finite element (FFE) model of soft tissues with tissue-specific fiber organization and fiber-level resolution, capable of establishing the direct association between tissue's fiber structure and mechanics. Specifically, we developed a FFE model of the peripapillary sclera (Fig. 1a) as a model system and investigated its mechanical behavior under elevated intraocular pressure (IOP). Using the high-fidelity FFE model (Fig. 1e), we examined the fiber-scale strain heterogeneity in the sclera and elucidated the geometric basis of its nonlinear mechanics.

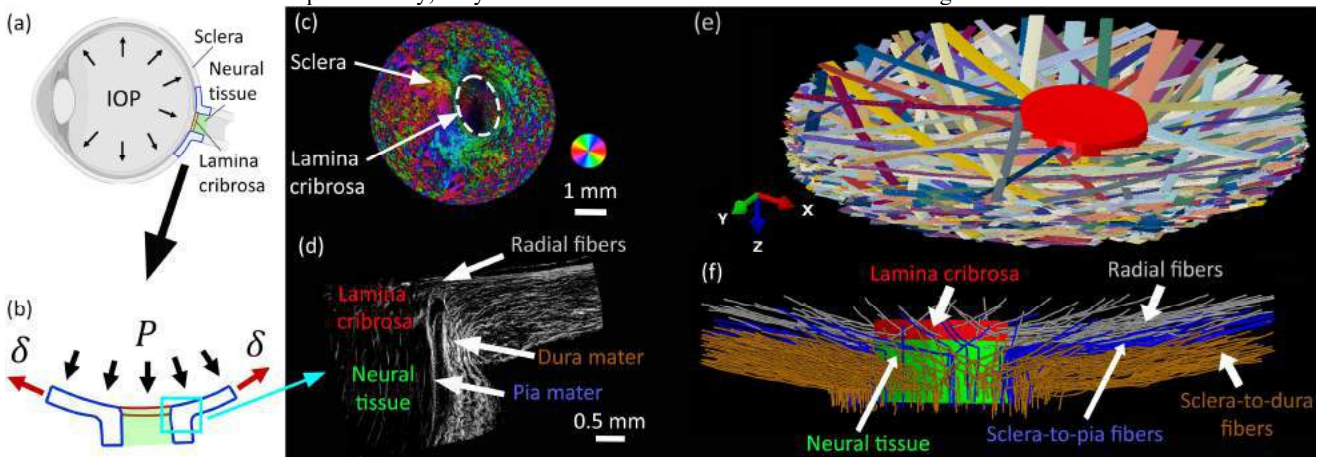

**Figure 1. (a) Schematic of eye cross-section with ONH region highlighted and (b) enlarged view of the region with boundary conditions. PLM images of (c) a coronal section with in-plane fiber orientation in color, and (d) a sagittal section corresponding to the region marked in (b). (e) 3D and (f) sagittal model views. (e) shows full bundle widths. (f) shows only bundle axes of selected fiber families colored according to (d).**

## METHODS

***Model geometry:*** An FFE model of sclera was developed based on highly detailed imaging data of a porcine eye from polarized light microscopy (PLM) [2]. In a coronal PLM image (Fig. 1c), sclera appears as a network of circumferential, isotropic, and radial fiber bundles [2]. The sagittal section (Fig. 1d) shows that a set of fibers merges into the lamina cribrosa (LC) and two other sets of fibers turn outward from sclera to pia mater and dura maters, respectively. To mimic this tissue-specific fiber organization, traces of fiber bundles with PLM-matched local orientation were generated for a stack of coronal images (Fig. 1c) and transformed into a curved assembly using in-house algorithms [3-4]. The circumferential fibers were not included, and collagen was modeled as homogenized fiber bundles.

***Constitutive properties:*** Fiber bundles were discretized with Timoshenko beams of ellipsoidal cross-section and linear elastic material properties ($E_b$). The bundle widths were sampled from the PLM images and a constant thickness of 20 μm was used. The LC and neural tissue (NT) were incorporated as boundary conditions for the sclera. Since the focus of the work is to understand the role of fibrous sclera, both LC and NT regions were modeled as linear elastic continuum solids ($E_{\mathrm{LC}} = 0.1i$MPa$i$, $E_{\mathrm{NT}} = 0.01i$MPa). A 3D illustration of the FE model is shown in Fig. 1e, whereas the sagittal fiber organization with LC and NT regions are depicted in Fig. 1f.

***Boundary conditions:*** The model was subjected to a pressure load ($P$ = 6.35 kPa) equivalent to IOP = 47.53 mmHg. A stretch ($\delta$=0.3 mm) was applied on the boundary to represent radial tension of the sclera due to IOP (Fig. 1b). The fiber-fiber interactions were incorporated using a surface-based contact algorithm and kinematic coupling was employed between the boundary of the solid regions and nearby sclera fibers. The solution was obtained using the FE solver Abaqus/Explicit.

***Parametric study:*** We studied the fiber-scale deformation processes of the sclera as a function of bundle stiffness ($E_b$). The model response was compared with an inflation experiment by calculating average surface strain ($\epsilon$) based on the displacement data of the surface fibers in the model mimicking the experiment [6].

## RESULTS

Fig. 2 compares the pressure-strain responses of the model for a soft ($E_b$= 30 MPa) and a stiff sclera ($E_b$= 100 MPa) with the experiment. The FFE model effectively captured the highly nonlinear response of porcine sclera observed experimentally. The stiff sclera model provided a better approximation compared to the soft sclera model. The nonlinear response predicted is a purely geometric effect since all the material parameters were linear elastic.

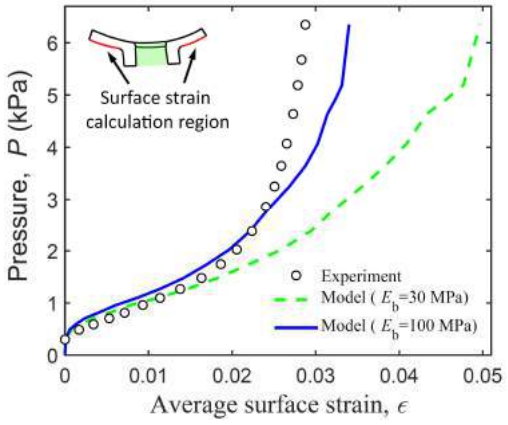

**Figure 2. Pressure-strain responses of the fibrous sclera model compared with the inflation test of a porcine eye [6]. The inset indicates the region used to calculate the average surface strain.**

Fig. 3a shows the heterogeneous strain distribution in the sclera ($E_b = i100i$MPa) at $P$ = 6.35 kPa. The principal strain varied from -2% to 5% where a majority of bundles showed tensile strains and some sclera-to-dura bundles showed compressive strains. Fig. 3b shows the large-scale uncrimping mechanism of a representative bundle with pressure. The extent of uncrimping was dominant for $P \leq 1.5$ kPa and the bundle was entirely uncrimped at P ~ 3.5 kPa.

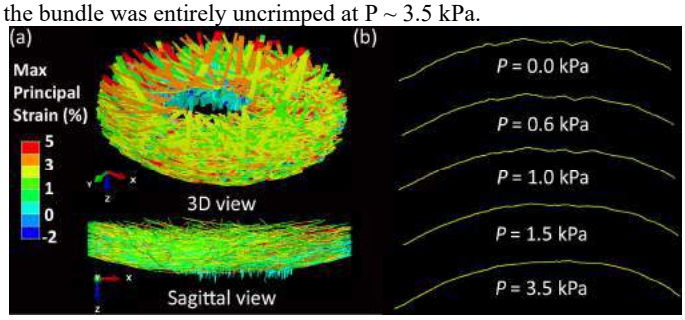

**Figure 3. (a) Strain contour plots of the stiff sclera model. (b) Example fiber bundle uncrimping with pressure ($P$).**

Out-of-plane model displacements are shown in Fig 4. Both soft and stiff sclera exhibited highly nonuniform displacement distribution with a broad range from -50 μm$i$ to 150 μm. The direction of the LC and NT displacements were sclera-dependent. They displaced posteriorly ($U_z > 0$) for the soft sclera and anteriorly for the stiff sclera ($U_z < 0$).

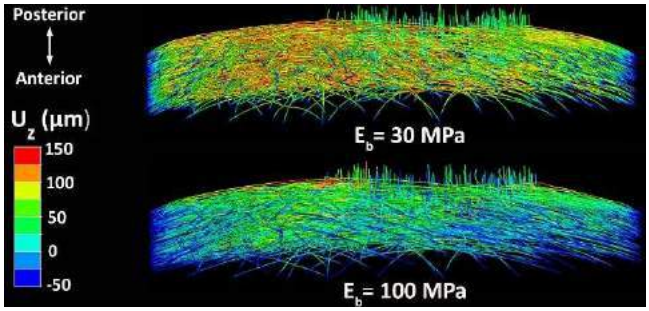

**Figure 4. Deformed configurations of a soft (top) and a stiff sclera (bottom) with z-displacement ($U_z$) contours at $P$ = 6.35 kPa.**

## DISCUSSION

We presented a novel FFE model of soft tissues and demonstrated its ability to reproduce the nonlinear tissue response geometrically from tissue-specific fiber organization and a single stiffness parameter ($E_b$). The FFE model allows for direct analysis of fiber-scale stress/strain distributions and uncrimping processes, which is critical to understand tissue remodeling and cell mechanobiology. Future work will investigate the role of other components in sclera, such as circumferential fibers, elastin and the extracellular matrix, fiber crosslinks and cells.

## INTRODUCTION

The synovial membrane envelopes the diarthodial joint and features two well-defined areas: (i) the lining layer (intima) composed of fibroblast-like synoviocytes (FLS) and macrophage-like synoviocytes (MLS) and (ii) a sublining layer (subintima) of vascularized loose connective tissue [1]. In healthy joints, the synovial cavity maintains a sterile environment and the interplay between FLS and MLS in the intimal lining contributes to synovial homeostasis. In the context of joint injury and/or osteoarthritis (OA), however, the synovial membrane undergoes marked structural and compositional changes, characterized by the infiltration of leukocytes, production of inflammatory cytokines, and fibrotic remodeling of the synovial extracellular matrix [2]. While soluble factors such as chemokines and cytokines are known to regulate the behavior of FLS and MLS during OA pathogenesis, less is known regarding how biophysical cues regulate the individual response and paracrine interactions between these two cell types during disease progression. Recent studies show that macrophages are mechanosensitive and tune their inflammatory phenotypes in response to altered microenvironmental mechanics [3,4]. The purpose of this study was therefore to test the hypothesis that stiffening of the synovial membrane during disease progression impacts the inflammatory secretome of synovial macrophages, which in turn modulates the behavior of FLS.

## METHODS

Assessment of Macrophage Polarization in Synovial Tissues: Following established protocols, paraffin sections of human synovial tissue [(n=4 healthy organ donors), (n=5 total knee arthroplasty (TKA) patients)] were stained for H&E or with DAPI, CCR7, CD68, PRG4, and p65. Synovial scoring of H&E sections was performed as in [2]. The mean intensity of each marker was quantified using ImageJ and CellProfiler as in [5].

Macrophage Secretome Analysis: Polyacrylamide (PA) gels of 5 and 55kPa were fabricated and functionalized with fibronectin as in [5] to create substrates of varying stiffness. THP-1 monocytes were differentiated for 48 hours with 20 nM PMA before being seeded onto PA substrates at a density of 300,000 cells/gel. Cells were cultured in RPMI with or without the addition of 50ng/mL TNF- α for 24 hours. RNA was isolated to measure inflammatory (M1) and pro-healing (M2) macrophage markers using qPCR.

Paracrine Co-culture Studies: Conditioned media from THP-1 macrophages cultured on 5 and 55 kPa substrates with and without TNF stimulation were collected and applied for 24 hours to human mesenchymal stem cells (hMSCs) cultured on tissue culture plastic (TCP). Here, hMSCs were used as a surrogate mesenchymal cell type to represent the FLS cells. RNA was isolated from hMSCs for qPCR analysis.

Statistical Analyses: Statistical significance for gene expression of M1/M2 markers was determined by two-tailed Student's t-test. One-way ANOVA with a Tukey post-hoc was used to evaluate qPCR results from the co-culture study.

## RESULTS

Marked structural differences were observed between synovial tissue derived from healthy organ donors (OD) and total knee arthroplasty (TKA) patients. Namely, TKA synovia

were highly fibrotic and enlarged with hyperplasia of the lining layer in comparison to OD synovia (**Fig 1A, B, C**). Interestingly, synovial histology scores for inflammation were predicted by the fibrosis scores, with a significant correlation coefficient ($r$ =0.65, $P$<0.03). This led us to assess the polarization of macrophages in OD and TKA synovia by staining for CCR7, a surface marker of M1 macrophages (**Fig 1D, E)**. TKA synovia exhibited higher fluorescence intensity for CCR7 than in TKA tissue, indicating greater activation and infiltration of M1 macrophages (**Fig 1F**).

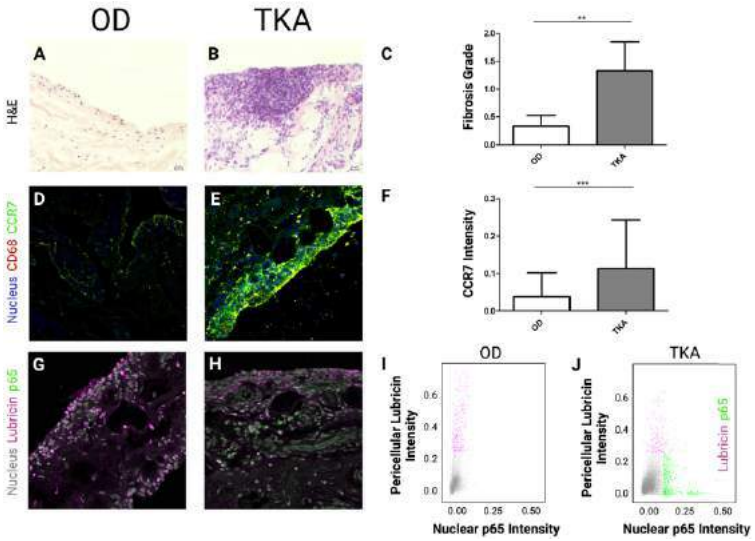

**Fig 1. Representative H&E histology of human synovium from an (A) OD and (B) TKA patient and their (C) fibrosis scores. (D) OD and (E) TKA synovium stained for CD68, DAPI, and CCR7. (F) Quantification of CCR7 fluorescent intensity. (G) OD and (H) TKA synoviums stained for DAPI, PRG4 and p65. Single-cell analysis of lubricin vs. nuclear p65 intensity in (I) OD and (J) TKA synovium. **P<0.01 and ***P<0.001**

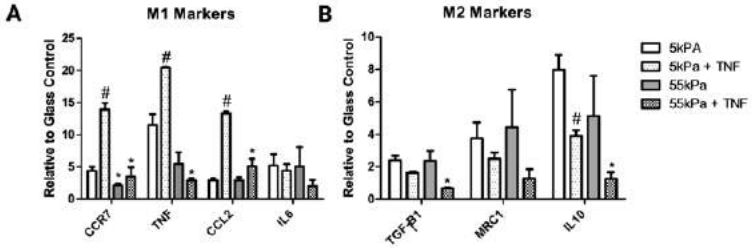

**Fig 2. Expression of (A) M1 and (B) M2 markers in THP-1 macrophages seeded on 5 or 55kPa polyacrylamide gels in the absence or presence of TNF-α. *P<0.05 when comparing substrates with the same soluble condition and #P<0.05 when comparing TNF-α to no TNF-α with the same substrate condition.**

Next, we probed the functional consequences of inflammatory signaling on FLS cells by staining for PRG4 (lubricin) and NF-$\kappa$B/p65 (**Fig 1G, H**). Single-cell analysis revealed that, in OD synovia, FLS cells stained positive for lubricin but not for p65 (**Fig 1I**). Conversely, in TKA synovia, nuclear translocation of p65 was apparent along with a marked decrease in lubricin expression (**Fig 1J**). Due to the fibrosis observed in TKA synovia, we next queried whether microenvironmental stiffness impacts the polarization of synovial macrophages. Here, THP-1 macrophages were used as analogues of synovial macrophages and were seeded on 5 or 55kPa PA gels in the presence/absence of TNF-α to simulate the stiffening and inflammatory signaling of the synovium in joint disease. Expression of M1 markers increased substantially for THP-1 macrophages on soft substrates in the presence of TNF-α (**Fig 2A**), demonstrating that macrophages integrate both chemical and biophysical cues to tune their inflammatory status. For M2 markers, IL-10 expression was significantly reduced on 55kPa compared to 5kPa in the presence of TNF-α (**Fig 2B**) indicating that these cells are generally more responsive to biochemical cues in soft environments. To investigate how macrophages communicate with surrounding cells, we collected conditioned media from THP-1 cells and applied this to hMSCs. Conditioned media from THP-1 cultured on 5kPa with TNF-α induced the greatest inflammatory activation of hMSCs (**Fig3A, B**), increasing the expression of the catabolic enzymes MMP13 and MMP3.

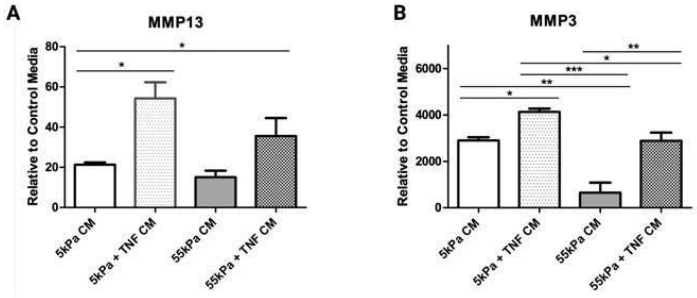

**Fig 3. Expression of (A) MMP13 and (B) MMP3 in hMSCs cultured in THP-1 conditioned media on 5 and 55 kPa with and without TNF stimulation. *P<0.05, **P<0.01 and ***P<0.001**

## DISCUSSION

Our data demonstrate that microenvironmental stiffness and biochemical signals integrate to modulate macrophage polarization, which in turn affects the way macrophages communicate with surrounding cells (i.e., MSCs and/or FLS). Here, we found that adhesion to soft hydrogels increases the inflammatory response of macrophages compared to to stiff substrates. Moreover, the secretome of macrophage cultured on soft substrates increased the catabolic and inflammatory activation of hMSCs. This finding sheds light on a possible feed-forward cascade of disease, where the changing biophysical environment promotes aberrant phenotypic changes.

# THOUGH I WALK THROUGH THE SHADOW OF THE VALLEY OF DEATH… HARD LESSONS LEARNED THROUGH DEVELOPMENT OF THE DREEM MACHINES

**Alan W. Eberhardt**

Department of Biomedical Engineering
University of Alabama at Birmingham
Birmingham, Alabama, USA

## INTRODUCTION

The so-called "Valley of Death" in medical and rehab product development refers to the funding gap often seen at the translational and early clinical development stages. Figure 1 illustrates the phenomenon, where products may be discontinued due to cost overruns before they make sufficient revenues to sustain a viable business. The present abstract describes the author's experiences in the context of a new rehabilitation device, developed through a series of student projects at the author's institution.

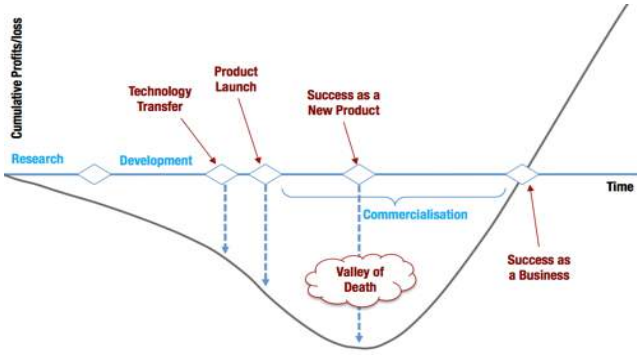

**Figure 1. The "Valley of Death" for new product development.**

For adults with post-stroke hemiparesis, physical activity may be extremely challenging. The resulting sedentary behavior often leads to secondary metabolic conditions that increase morbidity/mortality and reduce quality of life. Upright/mobile exercise is recommended to counter these conditions; however, those with hemiparesis are at high risk for musculoskeletal injury. Exercise machines, such as ellipticals, are rarely adjustable to allow users with musculoskeletal irregularities to enjoy full range exercise.

Our solution, the Differential Resistance Elliptical Exercise Machine (DREEM, Fig. 2a) is an adjustable, motorized elliptical machine that can safely vary resistive leg forces independently and thereby control the mechanical loading of a user's limbs. The DREEM takes advantage of adjustable lever arm mechanics to deliver differential workloads so that the paretic leg is compelled to work harder than the nonparetic leg. By providing variable resistance at variable speeds, user can approach appropriate aerobic workload levels. The value proposition is improved patient rehabilitation that is affordable, convenient, safe and effective for home use.

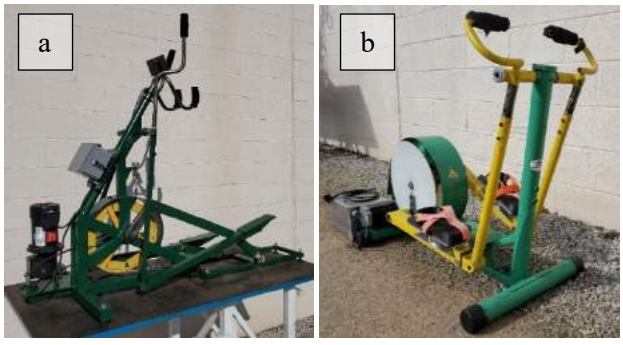

**Figure 2. The DREEM machines for a) adults and b) children**

## METHODS

The author led a student team to design, construct and test the original DREEM for a child with Level IV CP (Fig. 2b). A stepper motor joined to the main wheel of a commercial elliptical trainer provided motorized assistance, where pedals moved continuously or in a prescribed stepping pattern via an Arduino micro-controller. Foot pedal inserts with Velcro secured the user to the device. Safety was

verified by testing according to ASTM and IEC standards. Pilot user testing was completed at Lakeshore Foundation and United Ability (Birmingham, AL) on nine children with various mobility impairments following institutional review board approval (IRB-300003233). A commercial gait trainer (Rifton, NY) was found to be effective for body weight support and fall catch ability. Results from surveys on perceptions of user-friendliness, safety, functionality suggested the DREEM showed promise as an affordable device for home use.

Conversations with physical therapists revealed the need for the user to be able to drive the motion without motor assistance, and encounter resistance for aerobic and strength training. A "free-wheeling" gear system was added that permits the user to take control by pedaling faster than the motor drive. An adjustable band passed around the flywheel generates resistance, while differential resistance between legs is achieved by moving the pedal arm connection along the elliptical axis. These features (Fig. 3) were found to be directly applicable to persons post stroke and the adult DREEM machine was developed to include these features, along with multiple improvements.

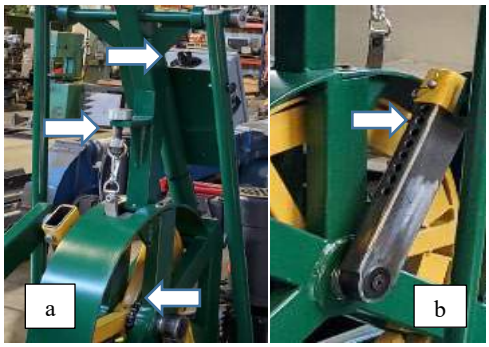

**Figure 3. a) Arrows indicate the speed controller, adjustable resistance belt, and freewheeling gear; b) Each crank arm connection (arrow) can be varied to change the resistance.**

Necessary steps for further product development and to achieve our ultimate goal of commercialization involve user testing to demonstrate that the device is safe and effective. In pursuit of funding for these activities, the author applied to the following programs and sponsors:

1. NSF Disability and Rehabilitation Engineering (DARE) - supports fundamental engineering research that will improve the quality of life of persons with disabilities through development of new technologies, devices, or software [1].
2. NIH Small Business Technology Transfer (STTR) - intended to stimulate technological innovation and increase private sector commercialization of innovations derived from federal research and development [2].
3. NSF Partnership for Innovation (PFI) - funds technology translation and development based on prior NSF-funded research projects from all science and engineering disciplines supported by NSF [3].

## RESULTS

None of the submitted proposals were funded. In the case of NSF DARE, there were concerns about a lack of advancement of scientific knowledge due to the lack of quantifiable kinematic metrics that were being assessed. There were concerns that the graduate student's focus on device construction would not help them develop into an independent researcher. The third aim was a business plan, which they stated would be more appropriate for an SBIR/STTR program.

Following the suggestion of the NSF reviewers, we submitted the NIH STTR, where reviewers identified weaknesses regarding a lack of expertise in rehabilitation devices, unclear milestones of success, questionable affordability, issues with sample size and inclusion criteria, a lack of the patient safety metrics and no discussion on biological variables.

Our most recent attempt was the NSF-PFI. In this case, the proposed applied research tasks were seen as incremental since the project focused only on testing and most of the development work had been done in previous projects. Innovation was deemed incremental and the expected revenue stream was not convincing.

## DISCUSSION

Our long-term goal is to commercialize the DREEM machines to provide a safe and affordable exercise option for home use that overcomes barriers that prevent people with disabilities from exercising. Users will make progress towards walking independently, thereby improving their quality of life. Parents and caregivers will reap the benefit of not having to travel to physical therapy sessions as frequently. Linking the device with telehealth exercise interventions may further increase the impact of exercise in populations where there is a significant need.

The challenges associated with crossing the Valley of Death and commercializing the DREEM machines are extensive. The technology is relatively simple, which was intentional in order to keep costs low and render the device affordable for home use. Competing devices that contain more sophisticated control systems (e.g., Innowalk Pro®, iCARE®) have price tags ranging from $15,000-$30,000. Unfortunately, our low tech, low cost solution was not seen as sufficiently innovative and did not excite reviewers at NSF. Our failure to provide a rigorous clinical evaluation strategy that included biological variables of gender and age as well estimations of appropriate sample sizes, led to poor reviews from the NIH.

Our most recent efforts have been to approach industry to gauge their interest in licensing the technology. Responses have been luke warm, noting the lack of demonstration of clinical efficacy and the need for application of design for manufacturing and assembly principles to develop the next level prototype. As funding is essential for the continuation of any project in academia, the likelihood of the DREEM machines passing out of the Valley of Death seems more and more unlikely.

## ACKNOWLEDGEMENTS

The authors gratefully acknowledge funding and intellectual input from Drs. David Brown (University of Texas Medical Branch, Galveston, TX) and James Rimmer (DHHS 90RE5009-02-00, UAB/Lakeshore Research Collaborative, Birmingham, AL). Special thanks go to Mr. Steven Thompson and the Design and Fabrication Center in the UAB School of Engineering for construction and testing. Dr. Drew Davis (Lakeshore Foundation), and Ms. Marlese Delgado (United Ability) provided the opportunity to perform user testing. Additional financial support was obtained through the University of Alabama Health Services Foundation, P.C., General Endowment Fund, Award #202043, the UAB Department of Orthopedic Surgery, and the UAB School of Engineering.

# A HYDRAULIC RESISTANCE MODEL FOR INTERSTITIAL FLUID FLOW IN THE BRAIN

**Helena E. Schreder (1), Jia Liu (1), Douglas H. Kelley (1), John H. Thomas (1), and Kimberly A. S. Boster (1)**

(1) Department of Mechanical Engineering, University of Rochester, Rochester, NY USA

## INTRODUCTION

Metabolic wastes may be cleared from brain tissue by the flow of water-like fluid through the interstitial spaces between cells, as proposed in the glymphatic model. However, measuring that *in vivo* flow directly is difficult, so models are essential. Here we use an analytic solution for Darcy flow in a porous medium to model the flow and calculate the hydraulic resistance (as a function of tissue permeability and fluid viscosity) for various arrangements of penetrating arterioles and ascending venules, since fluid is believed to flow from periarterial to perivenous spaces. We consider arrangements measured experimentally as well as idealized arrangements with simple geometry. We explore how the number of vessels, vessel density, arteriole-to-venule ratio, and vessel distributions affect hydraulic resistance. Our findings could enable future brain-wide models of glymphatic flow.

## METHODS

We modeled the flow of interstitial fluid as a two-dimensional viscous flow between line sources (representing periarterial spaces) and line sinks (representing perivenous spaces). We solved Darcy's equation and the continuity equation analytically, using superposition, to determine pressure and (superficial) velocity fields. To quantify the viscous opposition to flow, among many sources and sinks, we calculated the average two-dimensional hydraulic resistance

$$R = \frac{\bar{p}_{art} - \bar{p}_{ven}}{q},$$

where $\bar{p}_{art}$ and $\bar{p}_{art}$ are the average pressures in periarterial and perivenous spaces, respectively, and $q$ is the total volume flow rate per unit length. $R$ is an extensive measure of hydraulic resistance, in that it depends on the domain size, or equivalently, the number of periarterial spaces, $n_a$. $R$ also depends on the fluid viscosity μ and the permeability κ of the porous tissue between periarterial and perivenous spaces. Thus, we define an intensive quantity that depends on vessel arrangement but not μ, κ, or $n_a$:

$$\mathcal{R}_{art} = R n_a \kappa / \mu,$$

which we call the dimensionless resistance.

We required that the pressure be zero at infinity. The pressure diverges at a source or sink, so in the results below, we took each periarterial pressure to be the pressure 5.5 μm from the source itself, and we took each perivenous pressure to be the pressure 4.5 μm from the sink itself. $\mathcal{R}_{art}$ is independent of $q$, which cancels out when $\mathcal{R}_{art}$ is expressed as a superposition of line sources and line sinks (each driving a flow known analytically).

## RESULTS

Figure 1 shows the arrangement of periarterial and perivenous spaces in a region of one mouse's cortex, and the corresponding pressure and flow predicted on one slice through the cortex at constant depth $z$. As expected, streamlines connect periarterial spaces to perivenous spaces, and pressure decreases smoothly along streamlines. For this arrangement, $\mathcal{R}_{art} = 0.961$. Examining arrangements at many different cortical depths and in four different mice, we find that the median dimensionless resistance is $\mathcal{R}_{art} = 0.9563$.

Since venules outnumber arterioles by a roughly 3:1 ratio in murine cortex, we also studied an idealized, regular arrangement with an exact 3:1 ratio (Figure 2). By tiling the arrangement to create domains of varying size, we found that $\mathcal{R}_{art}$ converges to a constant value for large domains. In separate calculations (not shown), we observed convergence in *ex vivo* (not idealized) arrangements as well. Convergence is helpful for engineering models: when a large section of cortex is to be simulated, the exact positions of every vessel need not be considered, because $\mathcal{R}_{art}$ can be used instead, being insensitive to domain size and varying relatively little from one animal to the next.

We also considered variation of $\mathcal{R}_{art}$ with vessel density ρ, keeping the domain aspect ratio and the vessel ratio the same. We found that $\mathcal{R}_{art}$ decreases with density and is well-fit by

$$\mathcal{R}_{art} \approx a\, ln\left(1 - \frac{b}{\rho^{1/2}}\right),$$

where, for the idealized mouse arrangement, $a = 0.2204$ and $b = -1.402 \times 10^4$. Future models could use this fit with good accuracy.

To account for natural variation among animals, we went on to study how $\mathcal{R}_{art}$ varies when the idealized arrangement is perturbed, by changing some arterioles to venules and vice-versa, and/or by displacing vessels slightly. Variation (not shown) was relatively small, though more uniform arrangements had lower resistance. We also considered vessel arrangements measured *ex vivo* in primate cortex and corresponding idealized arrangements (not shown).

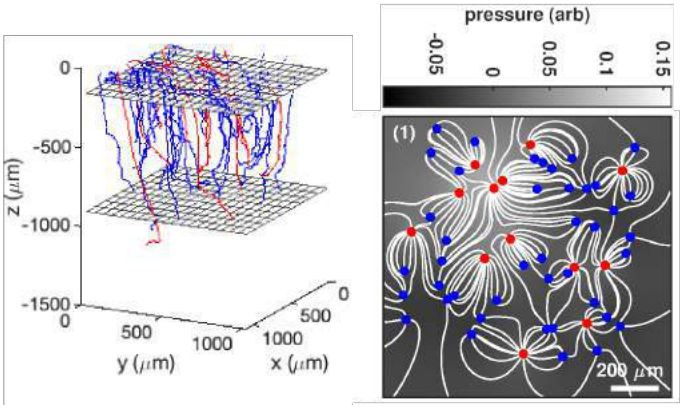

**Figure 1: Predicted interstitial flow among perivascular spaces in mouse cortex. *Left:* Paths of imaged penetrating arterioles (red) and ascending venules (blue) in a mouse cortex. Each vessel is surrounded by a perivascular space, and their paths are nearly parallel. From [1]. *Right:* By approximating each periarterial space as a line source and each perivenous space as a line sink, we calculate the interstitial fluid flow. White curves are streamlines.**

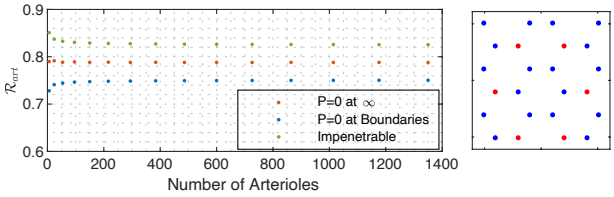

**Figure 2: The dimensionless resistance is an intensive quantity that converges to a constant value as the domain size (or arteriole count) increases, allowing accurate modeling for large domains. *Right:* An idealized arrangement of arterioles (red) and venules (blue). *Left:* Repeating that arrangement to create larger domains produces convergence, regardless of boundary condition (green: impenetrable boundary; red: zero pressure at infinity; blue: zero pressure at domain boundary).**

## DISCUSSION

Our findings could inform future numerical models of interstitial fluid flow in the brain. The convergence of $\mathcal{R}_{art}$ with size demonstrates the importance of calculating the resistance of an array of vessels, rather than isolated vessels. Dimensionless resistance decreases with density and depends non-monotonically on the ratio of arterioles to venules, consistent with another recent study [2]. Less-ordered vessel arrangements typically have higher resistance, all else being equal. However, the dimensionless resistance $\mathcal{R}_{art}$ does not account for flow changes due to variations in the permeability κ, which is highly uncertain; the accuracy of future models can be increased most by determining κ more precisely. More accurate models may be able to predict the relative importance of advection (driven by bulk flow flow) and diffusion for mass transport in brain tissue. That knowledge might facilitate drug delivery and interventions intended to assuage pathologies like stroke. More accurate models may also be able to estimate the pressure gradient necessary to drive physiological flow of interstitial fluid. Our findings were recently published [3].

## INTRODUCTION

Type A Aortic Dissection (TAAD), initiated by an intimal tear in the ascending aorta propagating through the aortic media, is a highly lethal event with a mortality rate of 1-2% per hour for the first 48 hours [1]. Current clinical guidelines for prophylactic surgical replacement of the ascending aorta to mitigate aortic dissection risk are based solely on dimensional characteristics and in rare cases for genetically triggered indices (e.g., Marfan syndrome) [2]. However, large retrospective series and data from the International Registry of Acute Aortic Dissection demonstrate that over 60% of patients with TAAD have aortic calibers less than the 5.5 cm diameter threshold [3] and yet most patients with aortic diameters less than 5.5 cm never dissect [4]. These data indicate that current risk adjudication metrics and clinical indices to intervene prophylactically are inadequate, thus, better dissection risk prediction metrics are needed to direct appropriate prophylactic aortic resection and reduce the risk of TAAD.

Prior work in our lab revealed overlap between intimal tear location and high longitudinal tensile stress in baseline CT angiography (CTA) scans from type A aortic dissection patients. In this work, we sought to create models to predict probability of dissection based on imaging-derived aortic stiffness as well as clinically measured parameters such as age, BMI, blood pressure, etc. with scrutiny of their specificity, sensitivity, and simplicity—*i.e.,* identify the lowest number of parameters that still yield a high predictability.

## METHODS

This study was performed with approval of the University of Pittsburgh Institutional Review Board and informed patient consent. Aortic dissection patients (dissected cohort) were chosen as the study group n=18. An aneurysmal control set of patients (non-dissected cohort) without aortic dissection but with statistically similar aortic diameter (46.17 ± 5.86 mm vs 47.19 ± 2.88 mm, p=0.31) was chosen for comparison (n=22). Patients in both the cohorts were of tricuspid aortic valve (TAV) phenotype. CTA and transthoracic echocardiograms (TTE) obtained **prior to** an aortic dissection event were evaluated.

Systolic (AoS) and diastolic (AoD) aortic diameters for each patient was assessed using the parasternal long axis window of two-dimensional TTE, measured 3 cm above the aortic valve. AoD was obtained at the peak of the R wave in the simultaneously recorded electrocardiogram, while AoS was measured at the initiation of the T wave. Patient specific aortic stiffness was estimated from these diameter measurements and knowledge of corresponding systolic (SBP) and diastolic (DBP) blood pressure [5]:

$$\text{Stiffness Index} = \frac{ln(SBP/DBP)}{AoS-AoD} AoD \quad (1)$$

Where *ln(SBP/DBP)* refers to the natural logarithm of the relative pressure. Blood pressure was measured at the time of echocardiography using a cuff sphygmomanometer. Phase 1 and Phase 5 Korotkoff sounds were used for SBP and DBP, respectively. All measurements were made by a single observer with 3 to 5 measurements per patient, all before the calculation of stiffness indices.

We used Prism (GraphPad, San Diego, CA) to develop single and multiple parameter logistic regression models and evaluate their predictability using the area under the receiver-operator curve (AUC). Receiver-operator curves are constructed to evaluate the true positive rate (Sensitivity) against the false positive rate (1-Specificity). Where the true positive rate is the ratio of the number of times a test result correctly indicates the condition, in this case dissection, to the number of real dissection cases from our database. Correspondingly, false positive rate is the ratio of the number of times a test result correctly indicates the absence of dissection to the number of non-dissection cases from our database. Finally, to increase the generality of our result we calculated AUC using leave-one-out cross validation implemented in RStudio (Boston, MA).

## RESULTS

Patients experiencing dissection at a time after the studied scans exhibited elevated baseline aortic stiffness (7.7 ± 2.3) relative to patients with similarly dilated aortas that did not go on to dissect (4.5 ± 1.56, $p<0.0001$) as shown in Figure 1 (a). A simple threshold model of Stiffness Index > 5 provided a sensitivity of 91% and specificity of 78%. Using aortic stiffness index in a single logistic regression model we calculated AUC of 0.90, ROC shown in Figure 1 (b), and associated odds ratio of 2.40 (95% CI: 1.73-3.63). Finally, we created a multiple parameter logistic regression model with age, gender, BMI, stiffness index, pulse pressure (PP=SBP-DBP), and aortic diameter. Each parameters' odds ratio is reported in Table 1 through a 95% confidence interval (CI) also reported in Table 1 is the corresponding AUC value.

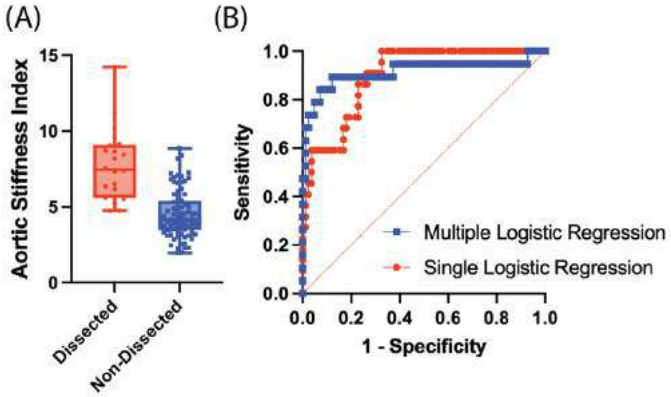

**Figure 1: A box and whisker plot of aortic stiffness index in the non-dissected and dissected cohort with raw data points (A). ROC for a single and multiple parameter logistic regression model with leave-one-out cross validation (B).**

**Table 1. Multiple Logistic Regression Results**

| Included Parameters | Odds Ratio (95% CI) | AUC |
|---|---|---|
| Age (years) | **(0.86-1.10)** | **0.92** |
| Gender | **(0.28-35.22)** | |
| BMI (kg/m$^2$) | **(0.87-1.02)** | |
| Stiffness Index | **(2.19-8.25)** | |
| PP (mmHg) | **(0.88-1.03)** | |
| Diameter (mm) | **(0.51-0.95)** | |

## DISCUSSION

We found that non-invasive TTE measurements were useful in predicting aortic dissection events. Starting at the simplest level we found a significant difference in stiffness among the dissected compared to the non-dissected cohorts (from TTEs done prior to a dissection event). A simple threshold should detect dissection, and indeed we found a high model accuracy with a threshold stiffness index of 5. To increase the accuracy, we went to the next level of complexity using logistic regression with a single parameter. Even with a single parameter, stiffness index demonstrated very strong predictability with the model (AUC of 0.90).

Introducing five additional parameters in the multiple logistic regression model led to a nominal increase in the AUC from 0.90 to 0.92. Review of the 95% confidence intervals of the multiple parameter logistic regression model demonstrate that most parameters do not have a significant impact over and above stiffness (95% CI contains the value of 1). Strikingly, for the parameter of diameter (the only parameter currently used clinically), the odds ratio interval does not contain one, and the interval is close enough to one such that its predictive value is distinctly inadequate.

Limitations of the work include its sample size, while our AUC was high, typical models used in clinical tools should be trained on very large datasets to increase robustness. Despite this limitation, the marked accuracy of the model generates enthusiasm to study the parameter of aortic stiffness more rigorously as measured by simple, serial noninvasive TTE testing as a biomechanically relevant metric for adjudicating the relative potential for aortic dissection in a patient-specific manner.

# ACTOMYOSIN CONTRACTILITY CONTROLS ORGAN-SCALE BUCKLING IN THE DEVELOPING SMALL INTESTINE

**John F. Durel, Hyunjee Lim, Nandan L. Nerurkar**

Department of Biomedical Engineering
Columbia University
New York, NY, USA

## INTRODUCTION

Stress-strain, or constitutive, nonlinearity has been widely characterized in adult soft tissues, with particular focus on the compositional and microstructural basis of this material behavior. However, the emergence of constitutive nonlinearity during embryonic development has received less attention, primarily limited to connective tissues. Moreover, the potential morphogenetic consequences of nonlinearity have been largely unexplored during embryogenesis. The present study frames the question of constitutive nonlinearity in the context of looping morphogenesis of the small intestine.

Looping is the process by which the initially straight intestinal tube is deformed into its seemingly convoluted adult form. In fact, the intestine is precisely and stereotypically organized (Fig. 1) for a given species [1]. Errors in looping give rise to several devastating gastrointestinal birth defects [2], yet the molecular and cellular basis of this important morphogenetic process is poorly understood. From the mechanical standpoint, it is known that looping arises from an elastic instability established by differential growth as the intestinal tube elongates against the constraint of an attached tissue, the dorsal mesentery. The mesentery is stretched and in turn compresses the tube until it buckles into loops [1]. The mesentery has a pronounced constitutive nonlinearity, readily stretching to 100% strain before transitioning to the stiff linear response. This ability to accommodate stretch before stiffening is a key behavior in the looping process, as a shorter toe-region would result in excessive restriction of the elongating tube, leading to excessive buckling. On the other hand, a larger toe-region would reduce buckling, all else being equal. The present study aims to understand the potential cellular and molecular antecedents of constitutive nonlinearity in the mesentery, and the implications of this nonlinearity for intestinal buckling morphogenesis.

***Fig. 1*** *Looping of the chick small intestine. The small intestine begins as an approximately linear tube at embryonic day (E) 5, left, which forms several loops by E16, when the process is complete. At right, E16 intestines from three embryos demonstrate the precise stereotypy of looping across individuals of a given species [1].*

## METHODS

Fertilized chicken eggs were incubated to embryonic day (E) 16. Intestines were harvested and mesentery segments with gut tube attached at either end were isolated. Segments were treated with 0.1% DMSO (control), 25 μM Cytochalasin D (CD), or 30 nM Calyculin A (CA) for 2 hr at 37 ºC, followed by uniaxial tensile testing in a custom micromechanical tester [3]. Briefly, a fine tungsten cantilever (of known bending stiffness) was used as the force transducer, and displacement was applied to this cantilever at a rate of 0.5%/s. The free end of the cantilever was attached to the sample, and progressive deflection of the cantilever was used to calculate force. Fluorescent markers on the sample were tracked to calculate strain. The linear region modulus (E) and the transition strain ($\varepsilon_t$) from toe-region to linear-region were calculated from resulting stress-strain data using custom MATLAB scripts. For Second Harmonic Generation (SHG) imaging, fresh whole mesenteries were flattened under coverslips and exposed to 850 nm excitation from a 2-photon laser. Emission was detected around 425 nm using a 40X lens, and z-stacks were collected with 1 μm slices. Images were analyzed as maximum intensity projections.

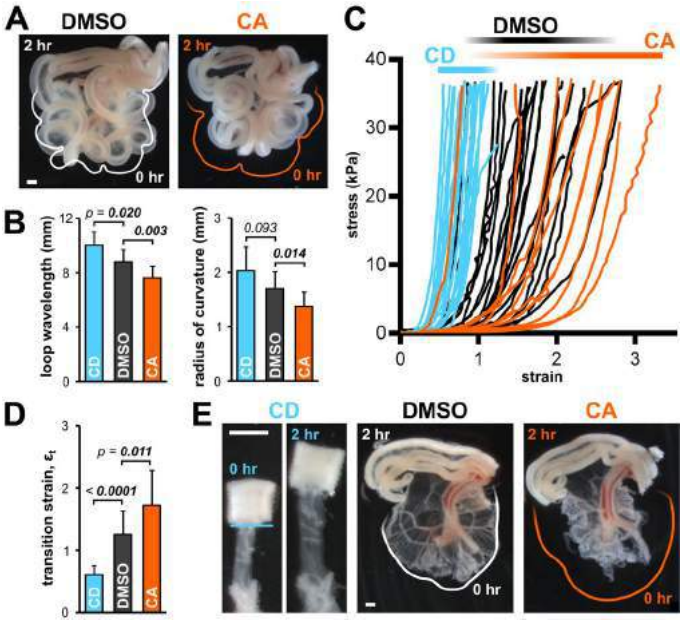

***Fig. 2*** *Cell contributions to mesentery mechanics. A) Treatment of E16 small intestines with 30 nM Calyculin A (CA) increased looping. B) Treatment with 25 μM Cytochalasin D (CD) (n=5) significantly reduced, and CA (n=10) significant increased, loop wavelength and radius of curvature vs. DMSO (n=13) C) Stress-strain curves from tensile tests of treated E16 mesentery. D) Treatment with CD (n=18) significantly reduced, and CA (n=10) significantly increased, the transition strain $\varepsilon_t$ vs. DMSO (n=20). E) Mesentery relaxes upon CD treatment and contracts upon CA treatment, indicative of an active pre-stress in the tissue. Colored lines show size prior to treatment. Scale bars represent 1 mm. p-values are from two-tailed unpaired t-tests.*

## RESULTS

To broadly test for an active cellular contribution to loop morphology, we treated whole small intestines with CD to disrupt the actin cytoskeleton (and by extension acto-myosin contractility) and with the myosin phosphatase inhibitor CA to induce contraction. Short term treatment resulted in significantly increased looping with increasing cell contractility (Fig. 2A, B), indicating that cell forces are sufficiently large to influence organ scale buckling of the intestine. To dissect the mechanics of this process, we subjected treated mesentery segments to tensile testing (Fig. 2C). Surprisingly, we noted that CD treatment to remove active cell contributions resulted in a significant reduction in the toe-region, while increasing cell contractility resulted in a significant increase in the toe region (Fig. 2D). This suggested, somewhat paradoxically, that removing cell contributions actually results in effective tissue stiffening. Measurement of sample length before and after CD (CA) treatment revealed that when cell contractility is inhibited (induced), the mesentery elongates (shortens), providing some explanation for the changes in transition strain (Fig. 2E).

We hypothesized that contracting cells may be modulating the extent of the soft toe-region by dynamically wrinkling extracellular matrix (ECM) fibers that must be decompressed by applied forces before these stiffer structural elements can be loaded (Fig. 3A). SHG imaging of fresh treated mesentery shows qualitatively increased fiber straightness with CD treatment (Fig. 3B). Preliminary quantification of fiber straightness indicates that relaxation of cellular forces significantly increases the straightness of mesentery ECM (Fig. 3C), in agreement with our proposed model.

## DISCUSSION

These results suggest that, unlike many well-studied adult tissues, constitutive nonlinearity of the embryonic mesentery is determined by active cell contraction, even in a mature tissue late in development. Interestingly, modulating contractility did not have a notable effect on the linear-region modulus. This suggests that the stiff linear-region behavior is dictated by ECM, but that the strain at which this stiff response begins is under cellular control. Based on these studies, we propose that cells of the mesentery act as a mechanical 'clutch,' providing compressive pre-stress on surrounding ECM. Consequently, as the mesentery is passively stretched by the elongating intestinal tube, contractile forces in the mesentery set its transition strain and, by extension, the compressive stresses that buckle the tube into loops.

Buckling has emerged as a core morphogenetic mechanism, laying the basic pattern of various organs during development, from intestinal villi [4] to airway branching [5] and folding of cortical sulci [6]. Despite the apparent ubiquity of buckling in morphogenesis, the underlying cell behaviors that control tissue mechanics to drive buckling have not been well characterized in most contexts. Here we show that cell contractility is central to setting the constitutive nonlinearity that drives buckling morphogenesis of the small intestine. Work is ongoing in the lab to identify the regulatory signals that tune mesentery cell contractility to ensure stereotyped morphogenesis of the small intestine.

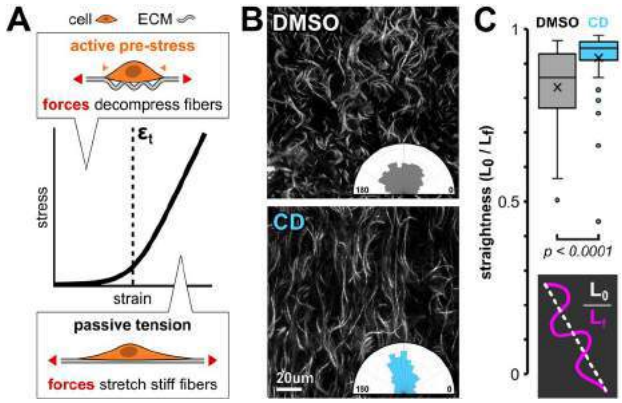

***Fig. 3*** *Cell contraction reorganizes mesentery ECM. A) Proposed model for cell control of nonlinearity: contraction pre-stresses ECM and fibers decompress as stretch is applied, leading to a stiff linear response as fibers are loaded. B) SHG images of DMSO and CD treated E16 mesentery; insets: fiber orientation distributions from 2D Fourier transform. C) Fiber straightness from SHG images. Straightness quantified as end-to-end length $L_0$ divided by contour length $L_f$; n=50-60 fibers, 2 embryos each. p-values are from two-tailed unpaired t-tests.*

# EXAMINING THE EFFECTS OF LOCALIZED ACL DAMAGE ON THE NEIGHBORING LIGAMENTS OF THE KNEE VIA FINITE ELEMENT ANALYSIS

**Alexander M. Knapp (1), Lakiesha N. Williams (1)**

(1) Biomedical Engineering, University of Florida, Gainesville, Florida, USA

## INTRODUCTION

The anterior cruciate ligament (ACL) is a major structural component of the knee, thought to be primarily responsible for inhibiting anterior translation. Due to its role in maintaining stability within the foot it is particularly vulnerable to injury, which is a highly common occurrence in athletes, with approximately 200,000 injuries per year [1]. Once torn, be it partial or full, players are often removed from play, with minimal options for rehabilitation beyond surgical intervention as a result of poor vascularization in the knee joint. Damage, partial or full, is known to lead to joint instabilities, osteoarthritis, and increased risk of tear in the neighboring medial collateral, posterior cruciate, and lateral collateral ligaments (MCL, PCL, and LCL respectively).

While the consequences of a fully torn ACL on the neighboring ligaments are understood to some extent, the complications that may arise from a partially torn or partially compromised ACL are not. Therefore, the present work seeks to investigate the effects of localized damage to the ACL on the mechanics of the neighboring ligaments. This will be done using a novel continuum-damage approach for modeling the constitutive behavior of the ACL through the use of a finite element model of the knee. After inducing localized damage, the changes in stress contour and average stress within the neighboring ligaments will be characterized to gain new insights into the effects of localized ACL damage on the function of the knee joint.

## METHODS

To examine the effects of localized ACL damage on the neighboring ligaments, a continuum-damage constitutive model of the ACL was developed using the stress strain data obtained by Ristaneimi et al. [2]. To implement damage into the constitutive model, an incompressible modified Holzapfel strain energy density approach was developed as shown in Figure 1 [3].

$$\mathrm{W} = \mathrm{G}\left( (\mathrm{C}_1(I_1 - 3) + \frac{k_1}{k_2}\left( e^{k_2\left(k(I_1-3)+(1-3k)(I_4-1)\right)^2} - 1 \right) \right) \quad (1)$$

Here, $C_1$, $K_1$, and $K_2$ represent material parameters, $k$ is the fiber distribution parameter, assumed to be zero, $I_1$ and $I_4$ are the first and fourth invariants of the right Cauchy-Green deformation tensor, while G represents a damage function in the form first coined by Natali et al. that is a function of the maximum fiber stretch ($\lambda_{max}$) achieved such that

$$G(\lambda_{\max}) = \frac{1 - e^{\beta^2(\lambda_{max}^4 - \lambda_c^4)}}{1 - e^{\beta^2(\lambda_0^4 - \lambda_c^4)}} \quad (2)$$

Where $\beta$ represents a damage rate parameter and $\lambda_c$ and $\lambda_0$ represent fiber stretches at which damage completes and initiates, respectively [4]. Table 1 summarizes the final material parameters determined for the ACL. The damage model was implemented into the finite element software ABAQUS using the user defined field subroutine. The remaining ligaments were assigned the same properties as the ACL sans damage properties.

**Table 1. Summary of Material Parameters for ACL**

| C1 (MPa) | Q | $K_1$ (MPa) | $K_2$ | $k$ | $\lambda_0$ | $\lambda_c$ | $\beta$ |
|---|---|---|---|---|---|---|---|
| 5.0 | 1E -9 | 20.6 | 0.20 | 0 | 1.183 | 1.35 | 0.00019 |

To create the requisite finite element model, images obtained courtesy of the National Institutes of Health's Visible human Project were used [5]. These images were edited using thresholding techniques and stacked to develop the 3-D CAD geometry for the tibia, fibula, femur, ACL, MCL, PCL, and LCL, with the meniscus left out as early investigations indicated it played a minimal role in the loading cases

examined in this work. With the geometry developed, the models were imported to ABAQUS and meshed to an appropriate level using convergence studies to guide the meshing process.

To induce damage, a quadriceps force of 2000 N was applied to the tibia and removed (Figure 1A), similarly to DeMorat et al. [6].

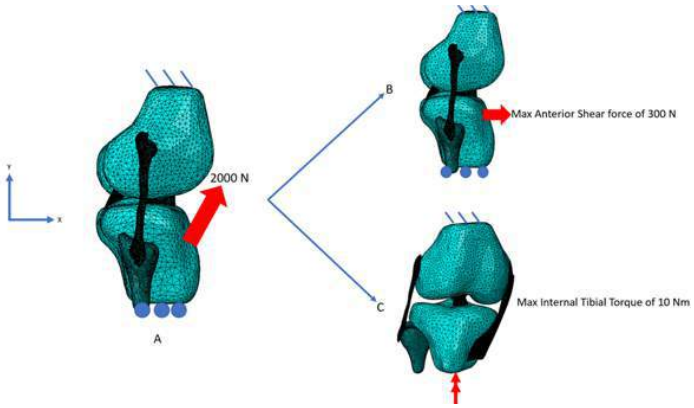

**Figure 1. Illustration of loading and boundary conditions. A) Illustration of loading to induce damage via quadriceps force loading. The simulation was then examined for loading cases of B) anterior shear forces or C) internal tibial torques**

Then, the effects of localized damage were studied under two loading cases, anterior shear loading of a maximum magnitude of 300 N and an internal tibial torque of up to 20 Nm, as shown in Figure 1B and 1C. The femur and tips of the ligaments were held fixed in all directions and the ligaments were attached to the tibia using tie constraints. In addition, to inhibit rotations in about the x axis the tibia was fixed in the y direction. Once the simulation was performed, the von Mises stress contours as well as the average mid-substance von Mises stresses were examined in the mid substance of the MCL, PCL, and LCL ligaments.

## RESULTS

Running the simulation for the prescribed loading cases yielded the following results. For each ligament, the von Mises contour plot changed significantly by altering the plots non-homogenously. One such example is shown in Figure 2, depicting the results for the MCL for the case of anterior shear forces (2A) and internal tibial torque (2B) post damage initiation.

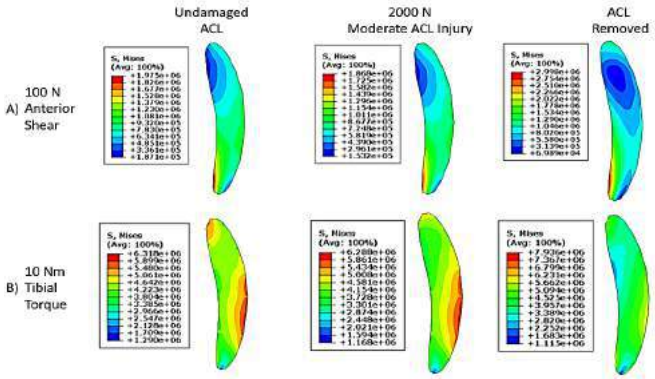

**Figure 2. Von Mises stress contour plots for the mid-substance of the MCL. A) Contour plot evolving under *anterior shear loading* between cases of no ACL damage, moderate ACL damage caused by quadriceps force loading, and for a fully torn ACL case. B) Presents the same trend for *tibial torque loadings* for the three damage cases.**

For both loading cases, the maxima and minima of the contour plot can be seen to shift following ACL damage, both partial and full. Similar trends were observed in the PCL and LCL (images omitted for brevity).

Similar shifts were observed in the average von Mises stress in the mid-substance of each ligament (images omitted for brevity). Under localized ACL damage and complete damage, it was found that the average stress generally increased in each ligament, with the dominant ligament changing as damage was induced.

## Discussion

The results of this study carry two major implications for the effects of localized ACL damage on the knee joint. First, the non-homogenous shifting of the von Mises indicates that under the effects of localized damage, non-homogenous morphological changes may occur in the neighboring ligaments. Over time, these changes may yield both degradations and increased stiffness in the ligaments, ultimately altering the load distribution in the joint, leading to instabilities. This finding is consistent with the minimal literature examining contour changes post damage [7]. With the alterations in load distribution, joint instabilities may be more likely to occur. The second major implication is that moderate localized ACL damage is also capable of inducing substantial shifts in the stress carrying capacity of each of the neighboring ligaments. As with the changing contours, this implies that with time shifts in the morphology of the ligaments will occur, with the dominant ligament (which itself can change based on the amount of damage) carrying more loading, leading to stress shielding effects in the other ligaments. Based on these results, it is therefore evident that moderate localized ACL damage may be sufficient to cause joint instabilities, giving evidence as to the need for early clinical diagnosis and intervention to circumvent these problems before they yield further injury and complications.

## INTRODUCTION

Blood vessel growth is a vital part of development; however, dysregulation of vascular structures is involved in various disease states such as arterial stiffening, ischemia, and cancer [1-3]. This process of new vessel growth from preexisting vasculature is known as angiogenesis, which is a key factor in tumor progression [4]. When small, a tumor can rely solely on diffusion to receive nutrients and oxygen, but in order to grow, a vascular network is required to deliver the increased nutrient supply [3, 5]. Tumors induce an angiogenic signaling cascade which causes nearby vessels to grow towards the mass [6]. Two major promoters of this process are vascular endothelial growth factor (VEGF) and VEGF receptor-2 (VEGFR-2). Cancer treatments targeting these factors have been employed clinically with the hope that inhibiting proangiogenic pathways will stop tumor growth [7, 8]. However, notwithstanding the critical role of VEGF and VEGFR-2 in angiogenesis, these therapies are often unable to stop tumor development [9].

One reason why anti-angiogenic therapies have proven ineffective may be because of VEGFR-2 mechanoactivation, which remains understudied in cardiovascular and cancer research [10]. Many cellular pathways can be activated by physical forces such as matrix stiffness, flow or shear stress, and compression, and several groups have shown VEGFR-2 activity to be affected by these forces, with various known mechanotransducers occurring downstream of this receptor [11-13]. Different VEGFR-2 tyrosine residues have shown varied phosphorylation patterns depending on mechanical cues, with non-soluble ligand stimulation causing prolonged Y1214 phosphorylation [14]. Furthermore, the tumor microenvironment (TME) often expresses altered mechanics such as stiffer matrices, increased interstitial fluid pressure, and irregular flow conditions [5, 15, 16]. Understanding how the mechanical environment surrounding a cell affects VEGFR-2 activation and angiogenesis is an important step in developing anti-angiogenic therapies that can effectively inhibit tumor growth. We hypothesize that endothelial cells exposed to biomechanical stimulation will express increased VEGFR-2 phosphorylation at the Y1214 residue and enhanced angiogenic activity. Results from these studies will be useful in addressing the knowledge gap related to mechanically-driven blood vessel regulation and possibly provide novel targets for anti-angiogenic therapeutic strategies.

## METHODS

To study expression and activity patterns of VEGFR-2, human umbilical vein endothelial cells (HUVECs) were seeded in EGM-2 (Lonza) media without VEGF for 24hr. Cells were then exposed to 150ng/ml VEGF for 0, 5, or 15 minutes, before lysing with RIPA buffer plus HALT solution for Western Blot analysis. The membrane was stained for phosphorylation of Y1054/Y1059 and Y1214 on VEGFR-2. HUVECs were also grown for four days in EGM-2 with 3μM SU5416, a VEGFR-2 inhibitor, or DMSO as a vehicle control. Blots were co-stained for YAP. Densitometry was performed using FIJI, and all expression levels were normalized to β-actin.

A custom-built, multi-microtissue microfluidic platform was utilized to determine the effect that mechanical stimulation has on angiogenesis [17]. The system has three separate chambers that can be loaded with matrix and cells, each with its own fluidic lines to permit control over interstitial flow. Tissue chambers were filled with 10mg/ml fibrin gels with the middle chamber filled with 1:1 HUVECs and normal human lung fibroblasts (NHLFs). The side chambers were filled with either thrombin-coated magnetic beads or cell-free fibrin gels. The magnetic beads permit mechanical stimulation of the microtissues without requiring stromal cells. Half of the devices were placed above a magnet on a rotating orbital shaker inside the incubator, while the other half were kept in a control incubator. Devices were fed with EGM-2 for 7 days, then were fixed and stained for VE-Cadherin, a blood vessel marker. Devices were then imaged and processed with AngioTool to quantify blood vessel growth in each of the chambers.

SB³C2022-342

## RESULTS

HUVECs exposed to soluble VEGF showed prolonged phosphorylation at Y1054/Y1059 at 15min, and phosphorylation at Y1214 dropped after 5min (Figure 1A). HUVECs that were exposed to the VEGFR-2 inhibitor SU5416 showed a ~69% decrease in pY1054/Y1059, while the inhibitor only caused a ~27% decrease in pY1214 (Figure 1B). Overall VEGFR-2 expression increased, likely due to decreased receptor activation. Furthermore, expression of YAP, a known mechanotransducer, decreased with VEGFR-2 inhibition.

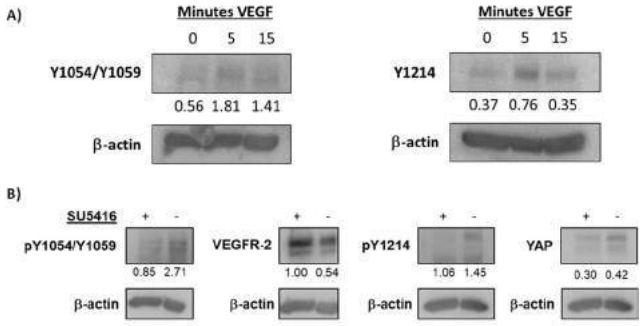

**Figure 1: Phosphorylation of VEGFR-2 in HUVECs. (A) HUVECs treated with soluble VEGF for 0, 5, or 15 minutes. Representative images of Western Blots quantifying VEGFR-2 pY1054/Y1059 and pY1214. (B) HUVECs grown in the presence of 3μM SU5416. Western Blot performed quantifying VEGFR-2 pY1054/Y1059, pY1214, and overall VEGFR-2 and YAP. All inset numbers are normalized to β-actin.**

Microfluidic devices were used to determine how angiogenesis is affected by mechanical strain. HUVECs and NHLFs in the center chamber effectively created a self-assembled, stable vascular network, with the left chamber gel containing magnetic beads (Figure 2A). Fluorescent images were successfully taken, showing sprouting vessels penetrating the side chambers, particularly in the devices exposed to the rotating magnet (Figure 2C,D). When total vessel length in each of the chambers was quantified and normalized to total vessel length in the center chamber, devices that experienced mechanical strain induced by the magnetic stimulation and magnetic beads showed increased angiogenesis in both side chambers compared to devices without the magnet (Figure 2B).

## DISCUSSION

Based on our studies, we have shown differential phosphorylation of tyrosine residues on VEGFR-2 when HUVECs are exposed to stimulation by the VEGF ligand or when treated with an inhibitor. VEGF displayed less prolonged phosphorylation at Y1214 compared to Y1054/Y1059. However, a VEGFR-2 inhibitor caused a larger drop in Y1054/Y1059 phosphorylation compared to Y1214. These results suggest that Y1054/Y1059 is more sensitive to soluble VEGF stimulation than Y1214, which is more resistant to SU5416. VEGF-independent mechanoactivation of VEGFR-2 could cause differential phosphorylation of Y1214. Total VEGFR-2 levels increased with SU5416 treatment, possibly due to the decrease in receptor activation which normally triggers VEGFR-2 endocytosis and degradation [13]. Further study of the effects of mechanical strain on Y1214 phosphorylation would provide deeper understanding of how the physical environment affects activity patterns of this residue and VEGFR-2 as a whole.

In a pilot study to test if magnetic mechanical stimulation could drive angiogenesis in a 3D microtissue model, we showed that there was a small increase in angiogenesis in chambers containing magnetic beads and cultured above a magnetic force. While some growth is seen in chambers without beads, further studies will focus on increasing mechanical strain and refining parameters used to quantify blood vessel development. Overall, this work suggests that mechanically-active environments result in increased angiogenesis, in line with previous results from our lab [17]. The TME can produce similar mechanical forces, which may be one reason why anti-angiogenic therapies have often proven ineffective in stopping blood vessel development in tumors. Understanding how the TME mechanically regulates angiogenesis is a critical area that requires further investigation in order to develop effective anti-angiogenic therapies.

# ULTRASONIC ANALYSIS REVEALS LAYER-DEPENDENT SHEAR WAVE PROPAGATION IN THE PATELLAR TENDON AND SUPERFICIAL TISSUES

**Stephanie G. Cone (1), Lauren K.M. Welte (1), Darryl G. Thelen (1,2)**

## INTRODUCTION

Shear wave speed measurements have been employed to assess mechanical properties and dynamic loading in musculoskeletal tissues for many applications [1]. Traditional shear wave elastography employs an acoustic push and uses ultra-high frame rate ultrasound to track shear wave propagation within a region of interest [2]. In contrast, shear wave tensiometry [3] uses a mechanical tap and skin-mounted accelerometers to measure a single value for bulk shear wave speed in a superficial tendon. Each of these techniques have unique strengths and weaknesses. Ultrasonic measurements leverage a series of images to ascertain wave speeds within different tissues but are not suitable for high wave speeds or dynamic tasks. Tensiometry enables collections of time-varying wave speeds during dynamic tasks. However, further studies are needed to ascertain how wave propagation through the subcutaneous tissue and skin may differ from that in the underlying tendon.

To better understand the multi-layer implications of wave propagation, we implemented a high frame rate ultrasonic approach for measuring shear wave propagation induced via mechanical excitation. We then investigated the relationship between shear wave speeds near the skin over the patellar tendon and directly in the patellar tendon. This relationship was explored over a range of passive stretch and active loading about the knee. We anticipated finding an increase in shear wave speed both in the tendon and near the skin interface with active loading in knee extension, and little change due to passive stretch loading in the tendon.

## METHODS

For this study, 6 healthy young adults (2F/4M, ages (years): 27.8 ± 4.9, heights (meters): 1.79 ± 0.1, weights (kilograms): 80.0 ± 13.6) were recruited in an IRB approved study (University of Wisconsin IRB: 2018-0487-CP019). Shear waves were excited and measured in the left patellar tendon in static holds of the following conditions: relaxed or loaded with a voluntary knee extension moment, with the knee in 0° and 90° of flexion. Isometric flexion moments were measured via a handheld dynamometer (Mark 10) placed against the proximal tibia.

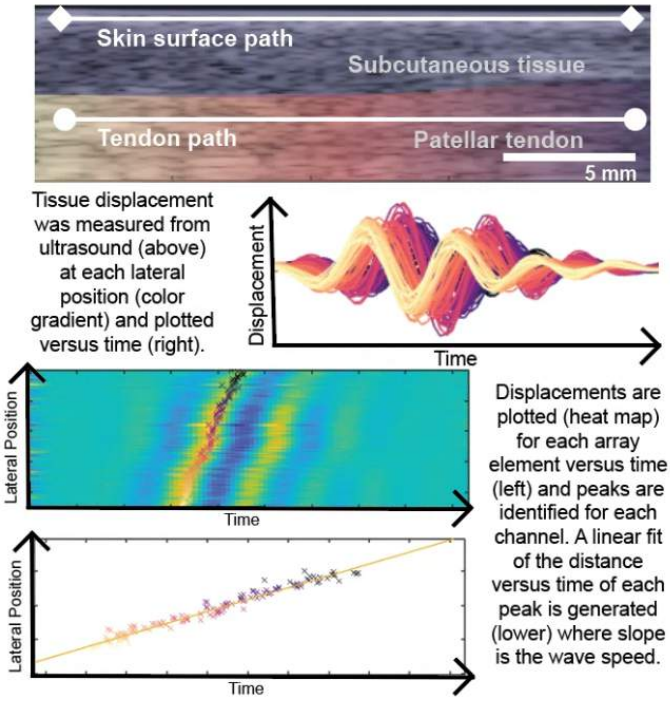

**Figure 1: Shear wave speeds are calculated within the patellar tendon in response to an external mechanical tap.**

Shear waves were excited via an electrodynamic mechanical tapping device described previously [3] placed at the proximal end of the superficial patellar tendon. High frame rate (20kHz) ultrasonic

images were captured of the central region of the patellar tendon using a commercially available programmable ultrasound system (Vantage 64LE, Verasonics) and a linear array transducer (Phillips CL 15-7). These images were exported into a custom MATLAB code for reconstruction and shear wave speed calculation (Figure 1). Briefly, the displacement of the tissue was measured for each pixel (0.18mm x 0.17mm) using a 2D autocorrelation algorithm [4]. The slope of a linear fit of time to peak displacement and the position along the line of interest measured shear wave speed. For the purposes of this study, a single measurement of the shear wave speed was taken over ~20 mm in the patellar tendon, with an example of the typical image shown in Figure 1. For each condition, the shear wave speed and the corresponding correlation coefficient ($R^2$ value) was recorded. Statistical analyses were performed in commercial software (JMP Pro 15) and consisted of one-way ANOVA tests for comparisons of loading conditions, postures, and tissue regions as independent factors ($p<0.05$) and individual subjects as a repeated measure.

## RESULTS

Shear wave speeds within the patellar tendon increased significantly (~4X, $p<0.005$) with active quadriceps loading (Table 1). Wave speeds near the skin tended to increase with loading ($p=0.07$), but to a lesser degree than increases seen in the tendon. Knee flexion did not consistently increase shear wave speeds in the unloaded tendon ($p=0.94$) or at the surface ($p=0.66$), suggesting that the loading due to passive muscle-tendon stretch were much less than the responses to active loading.

**Table 1: Extension torque about the knee, shear wave speeds (SWS) measured in the patellar tendon and at the skin surface, and correlation coefficients ($R^2$) for measurements in flexed (90°) and extended (0°) postures (mean ± standard deviation).**

| Knee Angle | Torque (Nm) | Tendon SWS (m/s) | Tendon $R^2$ | Surface SWS (m/s) | Surface $R^2$ |
|---|---|---|---|---|---|
| 90° | 13.3±4.8 | 40.3±28.5 | 0.67±1.2 | 20.5±16.6 | 0.67±0.2 |
| 90° | -- | 11.8±1.8 | 0.78±0.1 | 18.8±9.2 | 0.59±0.2 |
| 0° | 9.4±3.7 | 34.5±22.6 | 0.64±0.1 | 32.5±19.3 | 0.65±0.2 |
| 0° | -- | 9.8±4.1 | 0.60±0.2 | 12±7.5 | 0.50±0.2 |

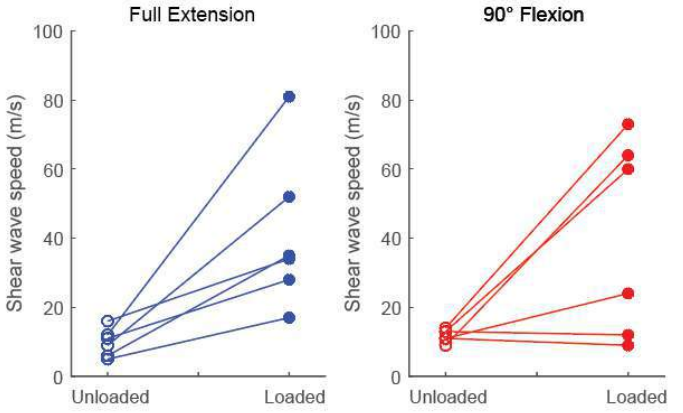

**Figure 2: Increased loading resulted in increased patellar tendon wave speeds across most subjects (individual data paired by lines).**

Within measurements taken in the patellar tendon tissue, a significant increase was seen in shear wave speed with the application of voluntary knee extension torque. These increases were seen in both the extended and flexed postures, with more consistent increases in the extended knee position (Figure 2). Comparisons of extension torque and shear wave speed revealed no significant relationship in either knee posture (0°: $p=0.12$, 90°: $p=0.84$).

Shear wave speed measurements differed between the skin and patellar tendon when participants actively loaded their knee joints (Figure 3). Interestingly, tendon measurements revealed greater magnitude increases with loading, improved correlation coefficients for wave speed calculations, and significant trends with loading compared to skin measurements.

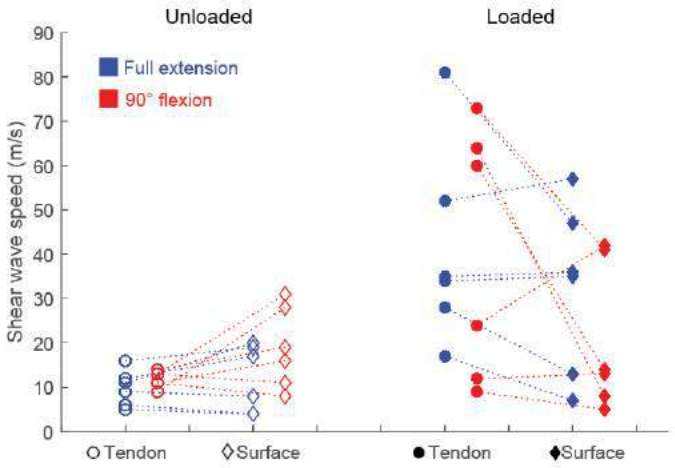

**Figure 3: Shear wave speed measurements are consistent across tendon and surface-based measurements in the unloaded knee, but are highly variable in the loaded state (tendon and surface data paired within individual images via dashed lines).**

## DISCUSSION

Tendon shear wave speeds increased with active muscle-tendon loading, and were higher than the wave speeds detected in layers of subcutaneous tissue near the skin surface. These wave speed increases were significant across subjects in this initial study only when measured directly in the tendon region, suggesting that this method varies in sensitivity across tissue layers in response to passive and active loading. Interestingly, the magnitude of patellar tendon responses to loading were subject-specific, suggesting potential differences in either the efficacy of mechanical taps or specific tissue loading between subjects following this protocol. Prior work in shear wave tensiometry has shown that bulk patellar tendon wave speeds modulate in proportion to the tendon load as ascertained from inverse dynamics [5]. This prior success in measuring patellar tendon wave speeds via shear wave tensiometry suggests that other experimental factors can amplify the load-dependent effects of wave speed measurements. While this study suggests potential challenges in measuring patellar tendon mechanics via skin-mounted sensors, experimental considerations such as interference pegs (allowing for deeper tissue measurement) and further modeling to understand the multi-layer effect may improve ongoing innovation in wearable sensors capable of tracking dynamic loading.

# INDEPENDENT AND SYNERGISTIC EFFECTS OF INTERSITIAL HYDRATION AND SYNOVIAL FLUID PRESENCE ON CARTILAGE LUBRICATION

**Emily P. Lambeth (1), Meghan E. Kupratis (1), David L. Burris (2), Christopher Price (1)**

(1) Biomedical Engineering, University of Delaware, Newark, DE, USA
(2) Mechanical Engineering, University of Delaware, Newark, DE, USA

## INTRODUCTION

Articular cartilage is the lubricious connective tissue that facilitates remarkably low friction during joint motion ($\mu$~0.002).[1] Several lubrication theories have been proposed for articular cartilage, including boundary and interstitial lubrication. In boundary lubrication, synovial fluid (SF) facilitates low friction through surface chemistry interactions.[2,3] In contrast, interstitial lubrication occurs through the pressurization of cartilage's interstitial fluid, allowing it to support >90% of the applied loads. Under high fluid load support (FLS), little stress is carried by the solid matrix, promoting low friction sliding.[4] Although these (and other) lubrication modes can be isolated and tested in *ex vivo* studies, no singular lubrication mode can recapitulate cartilage's true *in vivo* friction behavior on the benchtop (**Table 1**).

**Table 1: Minimum equilibrium friction coefficients ($\mu_{Eq}$) *in vivo* and under boundary (SF) & interstitial (PBS) lubrication regimes.**

| | ***in vivo*** | **boundary** | **interstitial** |
|---|---|---|---|
| $\mu_{Eq}$ | ~0.002[1] | ~0.02[5] | ~0.02[6] |

Recently, *ex vivo* studies using the convergent stationary contact area (cSCA) testing configuration have enabled the identification of a potent sliding-driven cartilage lubrication mechanism, termed tribological rehydration,[7] that finally permits facile replication of cartilage's truly remarkable *in vivo* lubricity on the benchtop. In the cSCA, and in the presence of PBS alone, sliding promotes speed-dependent, hydrodynamically-mediated recovery and maintenance of high FLS and low friction values ($\mu$~0.03).[7] When SF was introduced into high-speed cSCA sliding studies, vanishingly-small, *in vivo*-like equilibrium frictions ($\mu$~0.003) were recorded—a first for benchtop studies.[8] Presently, the mechanism(s) underlying (and the limits to) this un-anticipated lubrication synergy remain a mystery. Here, we explored friction mitigating interactions between interstitial lubrication (titrated through sliding speed-dependent tribological rehydration) and SF presence by comparing the tribomechanical response of PBS- and SF-lubricated cSCA cartilage contacts. Stribeck analysis was then used to inform the independent and synergistic effects of both interstitial lubrication and SF presence on the friction behaviors of cSCA explants.

## METHODS

19mm ϕ osteochondral explants (n=6) were extracted from the femoral condyles of skeletally mature bovine stifles. Explants were rinsed and stored in 1xPBS to which sucrose was added to match the osmolarity of synovial fluid (400mOsm; hereon referred to as PBS).[9]

A reciprocating tribometer[7] was used to statically compress each cSCA explant against glass at 7N (~0.25MPa) for 6 hours, to fully depressurize the contact, followed by sliding, in order, at 80, 60, 40, 30, 20, 10, 5, 1, & 0.5mm/s (**Fig. 1**). During this speed sweep, sliding speeds were changed when deformation rates <1µm/min and changes in friction coefficients <0.01/min (for $\mu$ >0.1) or <0.001/min (for $\mu$ <0.1) were achieved. Following initial characterization in PBS, explants free swelled in SF for >2hr, and were then tested in SF. Equilibrium compression ($\delta$) and kinetic friction coefficients ($\mu$) at each sliding speed were recorded in LABVIEW and analyzed in MATLAB.

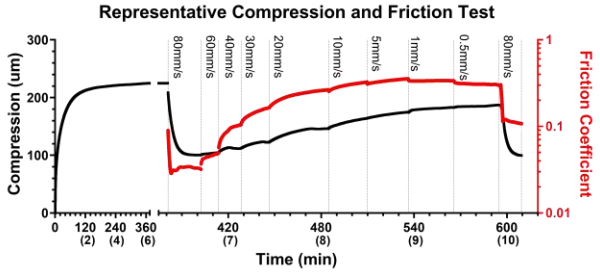

**Fig. 1: Representative tribomechanical test. This PBS-lubricated sample was statically compressed (7N) for 6 hrs followed by a speed iterative sweep (80-0.5mm/s, + 80mm/s run-out; under 7N).**

For Stribeck curve analysis,[3] Hersey's number ($\mathcal{H}$) was calculated as:

$$\mathcal{H} = i\frac{sv}{F_N} \quad (1)$$

where $s$ is sliding speed, $v$ is dynamic viscosity, and $F_N$ is normal force. For each sliding speed, shear-rate dependent SF viscosities ($v_{SF}$) were extrapolated from published data for various interfacial gap heights (0.8, 8, 80, & 800nm), corresponding to maximal shear rates of 100, 10, 1, & $0.1x10^6$ $s^{-1}$ respectively, at 80mm/s.[8,10] Repeated measure one-way ANOVAs or paired ratio $t$-tests were used to detect groupwise differences; significance was set at a multiplicity-adjusted $p < 0.05$.

## RESULTS

In a manner uniquely observable in the cSCA, the lowest equilibrium friction ($\mu_{Eq}$) values occurred at sliding speeds ≥30mm/s irrespective of bathing solution (**Fig. 2A**). SF significantly reduced $\mu_{Eq}$ at all speeds (**Fig. 2A**); however, the largest effects of SF on friction reduction (compared to paired PBS values) occurred at speeds ≤1mm/s & ≥30mm/s. Reduction in friction, calculated as the ratio of friction in PBS versus SF, was 11.8±3.2-fold at 0.5mm/s, only 1.7±0.6-fold at 10mm/s, yet 9.6±4.9-fold above 30mm/s (**Fig. 2B**).

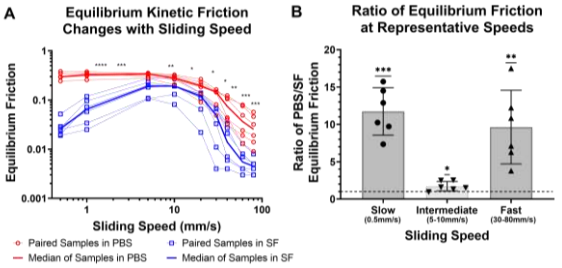

**Fig. 2: (A) Sliding speed-dependent $\mu_{Eq}$ for PBS-lubricated (red) and SF-lubricated (blue) explants. Thick lines indicate median responses for each lubricant. (B) Ratio of $\mu_{Eq}$ in PBS vs. SF at slow (0.5mm/s), intermediate (10mm/s), and fast (≥30 mm/s) sliding speeds. (* p<0.05, ** p<0.01, *** p<0.001, **** p<0.0001).**

Stribeck analysis identified noticeably different shaped PBS and SF cSCA curves (**Fig. 3A**; $v_{SF}$ estimated for a 80nm gap height, $v_{PBS}$ was fixed at 0.88mPa·s.). At intermediate Hersey numbers, PBS and SF-lubricated contacts exhibited similar overall friction behaviors (monotonically decreases with increasing $\mathcal{H}$. However, major differences between PBS and SF were observed at: (i) low and (ii) high Hersey numbers. At low Hersey numbers, PBS and SF generated distinctly different $\mu_{Eq}$ values (0.3 vs 0.03, respectively). At high Hersey numbers, both PBS and SF lubricated contacts exhibited remarkably low $\mu_{Eq}$ (<0.05), however, in SF, $\mu_{Eq}$ was an order of magnitude lower than in PBS (0.005±0.002).

Notably, the position of the SF Stribeck curve relative to PBS depended upon the gap height, and thus the shear-dependent SF viscosities, used to calculate $\mathcal{H}$ (**Fig. 3B**). When gap heights of 80 and 800nm (corresponding to $\nu_{min}$ 2.29 and 4.44mPa·s, respectively) were utilized, the resultant SF Stribeck curves fell to the right of the PBS curve. For a gap height of 8nm ($\nu_{min}$ 1.18mPa·s), the two curves largely overlapped at intermediate Hersey numbers, while for a 0.8nm gap ($\nu_{min}$ 0.61mPa·s), the SF curve fell entirely to the left of the PBS curve.

## DISCUSSION

The cSCA configuration, with its ability to titrate tissue hydration through sliding-speed dependent control of tribological rehydration, is uniquely suited to interrogate cartilage's frictional behaviors under both high and low FLS conditions. The rapid and robust recovery of tissue compression and lubricity by high-speed sliding after the complete (6hr) depressurization of cartilage highlights the robust ability of tribological

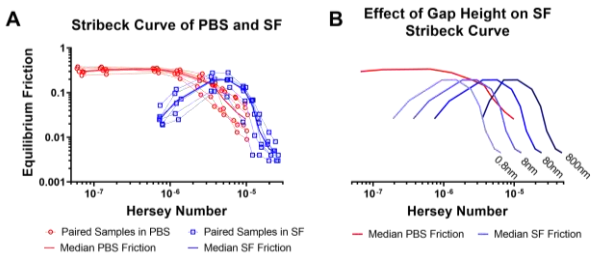

**Fig. 3: (A) Stribeck analysis of $\mu_{Eq}$ vs. Hersey number for paired samples in PBS (red) & SF (blue); SF viscosities predicted for an 80nm gap utilized. (B) Stribeck curves for PBS (red) & SF (blue), for SF viscosities predicted for gaps of 0.8, 8, 80, and 800nm.**

rehydration to drive interstitial fluid recovery. Our findings of maximal lubricity always accompanying the highest applied sliding speeds (and compression recoveries), irrespective of bathing solution, further confirms the importance of interstitial hydration (and its recovery) as a master regulator of cartilage lubrication.

However, SF presence did influence lubricity, and in ways that might not have been anticipated. The greatest relative changes in lubricity—but not the lowest absolute friction magnitudes—occurred at very low sliding speeds and low Hersey numbers. While these results confirmed the boundary lubricating function of SF at very slow speeds (<1mm/s) in fully-depressurized cartilage,[2-4] sliding speeds within joints are on the order of ~100mm/s during most activities[11] and it is unlikely that cartilage ever experiences near total fluid exudation/fluid loss *in vivo*.[12,13] Instead, our cSCA tests indicate that at modest sliding speeds (≥30mm/s), exceptional cartilage lubricity is promoted by the synergistic action of tribological rehydration and SF presence, supporting equilibrium friction coefficient values previously only observed in intact joints (~0.005).[1] Thus, while SF may act as a classical boundary lubricant under rather specific benchtop conditions, the lubrication of intact joints appears more likely to result from synergy between the active maintenance of interstitial hydration and FLS (fostered by tribological rehydration, bath exposure, and/or contact migration) and SF presence within rapidly articulated/slid contacts. Ongoing studies characterizing our samples after 'reducing' them to classical SCA sized contacts (~6mm ϕ), thereby explicitly eliminating their ability to sustain tribological rehydration, will serve to confirm the synergistic nature of FLS and SF supported lubrication.

Lastly, our parametric assessment of Stribeck curve behavior demonstrated that our SF and PBS curves only collapsed onto a single overlapping lubrication curve when shear-rate-dependent SF viscosities for a predicted interfacial gap height of ~8nm was utilized, corresponding to peak interfacial shear rates of $\sim 10x10^6$ $s^{-1}$ and a minimum $v_{SF}$ of ~1.2mPa·s (approximately that of water) at high sliding speed. This behavior again indicates that both interfacial $v_{SF}$ and gap heights are likely far smaller than previously anticipated.[8,10]

Overall, the present study highlights key additive effects of interstitial hydration and synovial fluid presence on cartilage lubrication. These insights further advance our objective of identifying the independent and combinatorial mechanisms governing the unmatched natural tribomechanics of articular cartilage *in vivo*.

## INTRODUCTION

Simulating the transport and fluid-structure interaction (FSI) of flexible and geometrically realistic blood clots in the circulation is critical to accurately modeling the performance of embolic protection devices like inferior vena cava (IVC) blood clot filters. IVC filters are cardiovascular devices that are implanted in the IVC, a large vein in the abdomen through which blood flow from the lower extremities returns to the heart. IVC filters capture clots before they can migrate to the lungs and cause a pulmonary embolism that is potentially fatal. Traditionally, non-clinical IVC filter clot trapping performance is evaluated through in vitro bench testing. Computational modeling has the potential to be used to complement or in lieu of experimental testing, however, if the simulations are rigorously verified and validated. To date, though, simulating the transport and trapping of realistic deformable blood clots in the circulation has been extremely challenging.

In this work, we use our recently developed sharp interface FSI framework [1,2] to simulate the migration and trapping of blood clots in the IVC, which is especially challenging due to the relatively large size of the clots that affects the local fluid dynamics, the large deformations that are generated, and the occurrence of contact between the clots, the vein wall, and the implanted device. The performance of the IVC filter in capturing realistic, flexible clots is investigated numerically and the results are compared with experimental data. It is important to note that in the literature, modeling realistic blood clots anywhere in the circulatory system (e.g., in the cerebral vasculature for predicting ischemic stroke), is currently restricted to either modeling rigid spherical clots or a small number of deformable clots, partly due to the computational expense of fully coupled FSI. Our sharp interface algorithm with features such as parallelized adaptive mesh refinement and multi-rate time-stepping is a significant improvement over alternative approaches, providing the capability to model large structural deformations of a number of deformable clots within complex patient-specific geometries.

## METHODS

Our numerical algorithm uses a partitioned approach to FSI with a sharp-interface immersed coupling strategy that resolves flow features up to the fluid-structure interface. It extends our recently developed rigid body immersed Lagrangian Eulerian (ILE) method for FSI [1] to models involving immersed flexible structures. The method combines a partitioned approach to FSI with an immersed coupling strategy. Like other partitioned formulations, the ILE approach uses distinct momentum equations for the fluid and solid regions. Unlike body-fitted arbitrary Lagrangian-Eulerian methods, our approach uses a non-conforming discretization of the dynamic fluid-structure interface that is "immersed" in the surrounding fluid and does not require any grid regeneration or mesh morphing to treat large structural deformations. We use a penalty approach to relax the kinematic constraint as well as a nearly incompressible solid mechanics formulation to relax the incompressibility constraint of the solid structure. Specifically, the penalty formulation uses two representations of the fluid-structure interface, including a thin surface mesh and a bulk volumetric mesh, that are connected by forces that impose kinematic and dynamic interface conditions. The dynamics of the volumetric mesh are driven by the accurate exterior fluid traction obtained from the sharp interface approach.

In our simulations, blood is modeled as a Newtonian fluid with a density of $\rho_f = 1.0\ \ \mathrm{g \cdot cm^{-3}}$ and dynamic viscosity of $\mu = 0.03\,\mathrm{g \cdot (cm \cdot s)^{-1}}$. The IVC filter used in this study is a new generic conical-type filter, referred to as the GENI (GEneric NItinol) filter, designed for research purposes by U.S. Food and Drug Administration (FDA) scientists and collaborators [3]. It resembles the support structure of an umbrella consisting of a central hub with 16 evenly spaced radial struts (Fig. 1). We first simulate the dynamics of clot transport and capture with the filter deployed in a rigid circular tube that is representative of the IVC vein. A realistic cylindrical blood clot with the length $L_{\mathrm{clot}} =$

2.0 cm and diameter $D_{\text{clot}} = 2.5$ mm is considered. The blood clot is modeled as a nearly incompressible hyperelastic material with Poisson ratio $\nu = 0.499$ and shear modulus $G_s = 2000$ dyn $\cdot$ cm$^{-2}$ and density $\rho_s = 1.2\rho_f$. In these initial simulations, we ignore the influence of gravity. The clot and the filter are deployed in a circular tube of length $L_{\text{tube}} = 6.4$ cm and diameter $D_{\text{tube}} = 2.8$ cm. A fully developed parabolic velocity profile with the maximum velocity of $U_{\max} = 15.0$ cm $\cdot$ s$^{-1}$ is imposed at the inlet of the tube at the bottom boundary ($y = -3.2$ cm), corresponding to the normal physiological flow conditions. Zero normal traction and tangential velocity conditions are imposed at the outlet of the tube at the top boundary. The boundary conditions along all the other parts of the Cartesian domain boundary are set to no-slip wall (zero velocity). Both the IVC filter and the circular tube are assumed to be rigid, stationary structures modeled by linear spring forces that tether the material coordinates of structural points to their initial positions. The surface of these structures is covered by two-dimensional bilinear quadrilateral surface elements. The mesh of the blood clot is discretized with trilinear hexahedral elements.

**Figure 1: Anatomical IVC model (left), generic IVC filter (middle), and cylindrical bovine blood clots (right). Adapted from [3].**

## RESULTS

A simulation of the transport and capture of a blood clot by the filter is demonstrated in Fig. 2. As time proceeds, the clot becomes more ensnared in the filter while undergoing deformations caused by the clot interacting with the local flow and because of contact with the filter and the tube wall. The overall dynamics of the clot's motion appear to be qualitatively similar to those observed in recent in vitro experiments using the same device [3].

## DISCUSSION

This study will advance the use of verification and validation (V&V) methods in computer modeling and simulation. We have previously performed simulations of flow in a realistic anatomical IVC model using our sharp interface algorithm and compared the simulated flow patterns with particle image velocimetry (PIV) measurements (Fig. 3). Our ongoing work is focused on further experimental validation of the simulated clot trapping physics with the IVC filter implanted in this anatomical IVC model. In each case, we are conducting a rigorous mesh convergence study to estimate the numerical uncertainty associated with the predictions. Our goal is to predict the statistical clot trapping performance of the GENI IVC filter for different clot sizes and vessel orientations and to validate the results by comparing with recent experimental data [3].

# THE RISK OF RECURRENT DISC HERNIATION FOLLOWING DECOMPRESSION SURGERY WITH SURGICAL DETACHMENT OF THE POSTERIOR EXTENSOR MUSCLES

**S. Rossman (1), E. Meyer (2), J. Isaza (3), S. Rundell (1)**

## INTRODUCTION

Disc bulging and herniation are two of the most frequently diagnosed low-back (lumbar) pathologies [1]. Herniations can compress the nerve roots and result in pain. If conservative treatment fails, surgery may be required. The most common low-back surgery performed in the United States is lumbar discectomy, which often includes facetectomy and laminotomy [2,3]. Recurrent disc herniations following surgical decompression has been reported in patients at rates between 5% and 21% and often require additional operations [4,5].

The facet joints and lumbar posterior extensor muscles (PEMs) help maintain proper spinal biomechanics, and decrease the risk for recurrent herniation [6,7]. Specifically, increased activation of the PEMs results in increased facet joint engagement and decreased disc pressure and posterior stresses [8]. Essentially, the facet joints assist the disc in carrying axial loads applied to the spine [9,10]. Engagement of the facet joints has the ability to reduce the loads carried by the discs, and thus, reduce the risk of herniation.

Lumbar discectomy can be performed through various techniques using open, microtubular, or endoscopic approaches to visualize the disc herniation. These techniques vary in invasiveness through the approach taken to access the herniation. Invasive surgical approaches, such as the posterior midline approach results in damage to the PEMs while minimally invasive approaches minimize muscular damage [11,12]. Surgical detachment of the PEMs during decompression surgery may limit the spine's ability to fully engage the facet joints and result in an increased risk of recurrent herniation.

Therefore, the objective of the current study was to evaluate the risk of herniation following bony decompression surgery with varying amounts of PEM detachment. We hypothesized that the removal of the facet joint (i.e., facetectomy) or detachment of the PEMs would result in a disc loading environment consistent with an increased herniation risk.

## METHODS

We previously developed and validated a finite element (FE) model of a lumbar motion segment that was then utilized for the current study [13]. Specifically, the model has been demonstrated to accurately predict disc herniation risk. Under the guidance of a spine surgeon, the FE model was surgically altered by either unilateral hemilaminotomy or unilateral facetectomy. PEM muscle detachment was simulated by reducing the muscle force. All other boundary conditions remained constant for each of the simulations. The following scenarios were simulated: unaltered; hemilaminotomy with no PEM detachment, partial unilateral PEM detachment, and complete unilateral PEM detachment; facetectomy with limited unilateral PEM detachment and complete unilateral PEM detachment.

Axial compression representative of body weight above the L4-5 motion segment for a 50$^{th}$ percentile male was applied anterior of the center of the L4 superior bony endplate to simulate forward bending. The location of the torso center of gravity was determined by an analysis utilizing a 3-Dimensional Static Strength Prediction Program. The inferior bony endplate of L5 was fixed rigidly in space. A surface-to-surface contact was established between the L4 and L5 posterior elements. The PEMs were modeled as two cable discrete beams attached between the spinous processes on bi-lateral sides of the model and four cable beams attached within each facet joint. Abdominal pressure force was represented by a force applied to a node constrained to the L4 superior bony endplate and located 8.4 cm anterior of the center of rotation of the vertebrae (Figure 1). The facet joint reaction forces, nuclear extrusion force, disc pressures, disc 1$^{st}$ principal stresses, and disc max shear stresses were recorded.

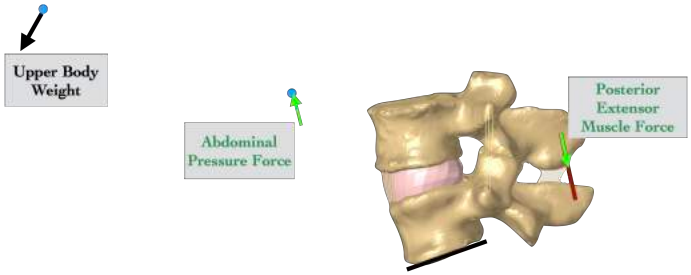

**Figure 1: Lateral view of the L4-5 motion segment FEM depicting the boundary conditions utilized to simulate forward bending.**

## RESULTS

The results for left and right hemilaminotomy and left and right facetectomy indicated similar trends. Therefore, only the results after right hemilaminotomy will be discussed. The interface contact force between the posterolateral circumference of the nucleus and inner annulus (i.e., NP extrusion force) ranged between 310 and 319 N for all scenarios with intact PEMs. The posterolateral NP extrusion force increased as the amount of PEM force was decreased (Figure 2).

There was an inverse relationship between facet joint contact force and disc pressure/stresses as the PEM force decreased. Specifically, after right hemilaminotomy, the peak disc pressures increased from 1.47 MPa to 2.12 MPa, and the facet joint contact force decreased from 746 N to 361 N as the amount of PEM force decreased from 2,376 N to 1,188 N (Figure 3). When the PEM was left intact, there were insignificant differences between the unaltered model and the surgically altered model. Similar trends were seen for peak disc 1st principal stress, peak disc max shear stress, and posterolateral NP extrusion force. Specifically, the peak disc 1st principal stress increased from 1.01 MPa to 2.65 MPa, the peak disc max shear stress increased from 1.12 MPa to 1.73 MPa, and the posterolateral NP extrusion force increased from 319 N to 355 N as the amount of PEM force decreased from 2,376 N to 1,188 N.

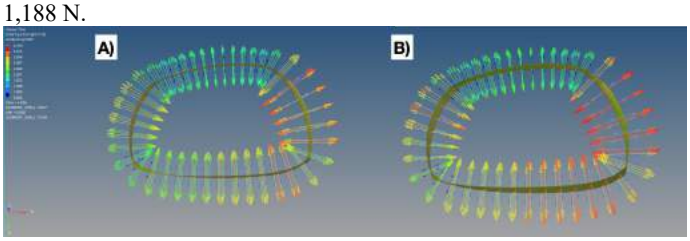

**Figure 2: NP extrusion force of the A) unaltered model compared to B) complete PEM detachment after right hemilaminotomy.**

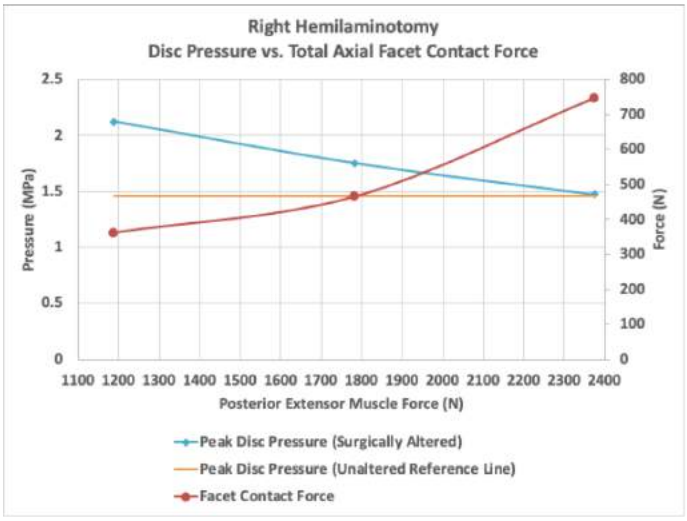

**Figure 3: Line graph showing the correlations between facet joint contact force, PEM force, and peak disc pressures following right hemilaminotomy.**

## DISCUSSION

Results of the current study partly confirmed the hypothesis that detachment of the PEM would reduce facet joint contact force and increase disc stresses. However, the hypothesis that removal of the facet joint would increase disc stress was not confirmed. Rather, the greatest risk for recurrent herniation occurred because of PEM detachment and not bone removal. Specifically, there was no significant change in the risk of recurrent herniation after hemilaminotomy or facetectomy when the muscles where left intact or when there was only limited muscle detachment. The highest magnitude of posterolateral NP extrusion force occurred on the right posterolateral aspect of the disc. These results are consistent with the literature which indicates that disc herniations are most common on the posterior or posterolateral aspect of the disc [14].

Previous studies have reported between 46% and 47% of subsequent operations were performed within 6 months of the original surgery regardless of whether endoscopic or open discectomies were performed [15,16]. These results suggest that the disc is most vulnerable immediately after surgery. This is consistent with decreased PEM activation either due to damage during surgery, atrophy, or poor bending and lifting techniques following surgery. These same studies show that the rate of recurrent surgery in the first 90 days after initial surgery following laminectomy was two times higher than for open or endoscopic discectomy alone. Since laminectomy may require full or partial detachment of the PEM, these clinical findings are consistent with the results from the current study. Regardless of the surgical technique utilized to treat the disc herniation, clinical data and the results of the current study suggest that PEM damage leaves the disc most vulnerable to recurrent herniation.

Results of the current study have clinical applications to surgeons who utilize techniques that require bone removal to gain access to the disc herniation during decompression surgery. Specifically, if removal of the laminae or facet joint is necessary, care should be taken to avoid detachment of the PEM from the vertebrae. However, if muscle detachment is unavoidable, post-surgical rehabilitation and care should be taken to minimize risk to the disc. Specifically, exercises that strengthen the remaining torso muscles and bending and lifting techniques that accentuate bending with a taught back should be emphasized. Additionally, establishing pre- and post-op methods for quantifying muscle strength may assist in determining an optimal recovery strategy.

# VAGINAL BIOMECHANICAL FUNCTION AND COMPOSITION IN PREMENOPAUSAL WOMEN WITH AND WITHOUT PELVIC ORGAN PROLAPSE

**Qinhan Zhou (1), Benard Ogola (2), Jasmine Kiley (1), Shelby White (1), Lyndsey R. Buckner (3), Laurephile Desrosiers (4), Leise R. Knoepp (4), Sarah H. Lindsey (2), Kristin S. Miller (1)**

## INTRODUCTION

Pelvic organ prolapse (POP) is the descent of the female pelvic organs, such as the uterus, bladder, and rectum, into the vagina. While the etiology of POP is not fully understood, loss of mechanical integrity of the vagina, uterosacral ligaments, and other muscular and connective tissues may contribute to POP development and progression [1]. While the incidence of POP is higher in postmenopausal women, 2.4‰ of premenopausal women require surgical intervention to restore normal anatomy and relieve symptoms such as voiding dysfunctions [2]. Previous biomechanical studies investigated the mechanical properties of premenopausal vaginal tissue by uniaxial tensile testing and suggested that the prolapsed vagina is stiffer than normal tissue; however, these protocols did not consider multiaxial loading or link mechanical changes to risk indexes [3,4]. The structural and compositional changes that dictate the loss of mechanical integrity are not fully understood, and research on vaginal tissue, especially in premenopausal women, is limited. The relationship between most mechanical properties, biochemical composition, and demographics in premenopausal vaginal tissue remains unknown.

Therefore, the objective of this study was to quantify biaxial mechanical behavior and biochemical content in vaginal tissue from premenopausal women with and without prolapse. Potential correlations between mechanical properties, protein content, and demographics were evaluated.

## METHODS

Samples were obtained from Ochsner Biobank following routine gynecological procedures as approved by the Ochsner Clinical School Institutional Review Board (2017.016A). De-identified demographic information including menopausal status, BMI, and age at surgery, etc. was collected from clinical records, and the POP stage and compartment during POP-Q examination was recorded. The inclusion criteria were female, older than 18 years old, and no prior pelvic floor reconstructive surgeries. The tissue was collected from either the apex or anterior wall of the vagina (Fig 1A) from women undergoing hysterectomy with no symptoms of POP (n=8) or symptomatic POP at stage 2 (n=5) or 3 (n=5). Samples were immediately snap-frozen and then stored at -80°C until the time of mechanical assessment.

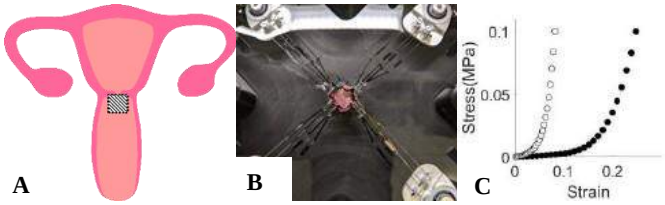

**Fig 1: (A) Tissue collected from apex or anterior wall (shadow). (B) Biaxial testing. (C) Directional difference in stress-strain behavior, circumferential (not filled) and axial (dark).**

For mechanical testing, samples were thawed at room temperature for one hour, and then planar biaxial testing was performed (Fig 1B) as described previously [5]. The specimen was preloaded to 0.1 N, followed by preconditioning from the preload to target stress of 0.1 MPa for at least ten tensile cycles. After a 10-minute re-equilibration period, samples were subjected to 5 displacement-controlled equibiaxial tensile tests, and the last loading cycle was used for data analysis. Data was analyzed using GOM correlate (GOM GmbH, Braunschweig, Germany) and the first image at the beginning of loading cycle was selected as reference configuration. Four points were optically tracked throughout the experiment and a custom MATLAB script was used to calculate the deformation gradient, the first Piola–Kirchhoff stress, and Green strain tensors from the displacements of reference points and real-time force (Fig 1C). The *lsqcurvefit()* function was used to fit the experimental data to a bilinear curve, and the linear modulus and peak strain were calculated as representative metrics of material stiffness and extensibility. Lilliefors test and Levene's test were implemented to evaluate the normality and homogeneity of variance of data error. A 2-way ANOVA or nonparametric alternative, Scheirer-Ray-Hare (SRH)

test, (direction, clinical group) followed by post-hoc Dunn & Sidák's approach assessed potential effects of direction and POP. Western blotting was performed to measure the content of collagen-I, collagen-III, fibulin-3, fibulin-5, and elastin in the tested specimens as described previously [6]. Protein content was calculated by dividing band intensity of each protein of interest by the band intensity of the selected control. A 1-way ANOVA or nonparametric alternative, Kruskal-Wallis (KW) test, followed by post-hoc Dunn & Sidák's approach evaluated the differences in protein content percentage among clinical groups. Pearson's correlation evaluated potential relationships between material stiffness, protein content, and demographics.

**RESULTS**

No significant correlations were identified with respect to age, BMI, parity, and gravidity between clinical groups. Vaginal material stiffness was normally distributed with equal variance; however, the peak strain was not normally distributed. Therefore, the 2-way ANOVA and SRH tests were used to evaluate vaginal stiffness and peak strain, respectively. The results showed that vaginal tissue was stiffer ($p=0.01$) and less extensible ($p=0.048$) in the axial than circumferential direction (Fig 2), however, no significant differences in material stiffness ($p=0.13$) or extensibility ($p=0.15$) were identified with POP. Moderate negative Pearson's correlations were identified between circumferential stiffness and gravidity ($R=-0.51$, $p=0.021$) and parity ($R=-0.54$, $p=0.029$). No other comparisons were statistically significant.

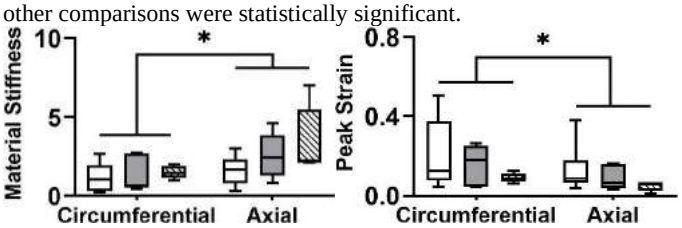

**Fig 2: (A) Vaginal stiffness and (B) extensibility between the control (n=8, not filled), POP-II (n=5, grey), and POP-III (n=5, shadow).**

Collagen-I and fibulin-5 content were normally distributed with the equal variance, and therefore were evaluated using a 1-way ANOVA. However, KW tests were used to evaluate collagen-III, fibulin-3, and elastin, and demonstrated that clinical group was significant factor for collagen-III content ($p=0.002$) (Fig 3). No significant difference was identified in collagen-I, fibulin-3, fibulin-5, or elastin content (Fig 3). Post hoc tests showed that the patients at POP stage 3 had a higher vaginal collagen-III content compared to non-POP control ($p=0.02$). A mild positive correlation was identified between axial stiffness and fibulin-3 content ($R=0.62$, $p=0.01$). Positive correlations were identified between elastin content and patient parity ($R=0.72$ and $p=0.002$) and gravidity ($R=0.63$ and $p=0.001$). No other comparisons were significant.

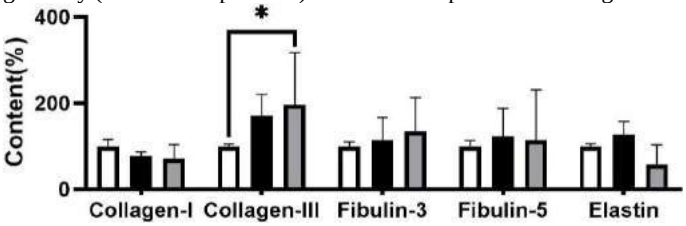

**Fig 3: Biochemical composition in control (n=8, not filled), POP-II (n=5, dark), and POP-III (n=5, grey).**

**DISCUSSION**

While no significant mechanical changes were observed with POP in premenopausal women, collagen-III content was higher in the POP-III group compared with controls, which is consistent with prior study [7]. Collagen-III plays a critical role in wound healing, and an increased production of collagen-III may occur during the tissue repair process after overstretching of the vaginal tissue [7], which occurs with POP. The increased vaginal stiffness with POP noted in previous studies was not identified herein. This may be due to the wide range of patient age (33 to 53 years old), limited sample size (n=5 in POP-II and POP-III), and the mixture of prolapse compartment or type (all cases diagnosed at least two of cystocele, rectocele, or uterovaginal prolapse). Cosson et al. showed that vaginal tissue exhibits high variability in function between patients [4], and age is both the main risk factor for POP and strongly influences mechanical properties of connective tissue [8].

We hypothesized that premenopausal vaginal tissue would be stiffer and less extensible in the circumferential compared to the axial direction, motivated by prior observations in women with POP and mice [5,6]. This may be due, in part, to collagen fiber orientation, however vaginal collagen fiber orientations with and without POP are not known. As for the correlations between direction stiffness and demographics, first, the circumferential stiffness mildly decreased as patients' parity and gravidity increased. An epidemiology study indicated the correlations between POP risk and patients' parity and gravidity [9], however, previous uniaxial studies on human vagina did not identify significant correlations between these indicators and tissue stiffness [3,4]. Therefore, it is possible that parity and gravidity predominantly influence circumferential vaginal stiffness, as prior work largely quantified uniaxial properties in the axial direction. Secondly, the mild correlation between axial vaginal stiffness and fibulin-3 content may offer insight into vaginal prolapse development and progression as mice deficient in fibulin-3 develop prolapse [10], however, more studies are needed to understand the functional contributions of fibulin-3. Further, the elastin content increased with patients' parity similar to prior work [11]. Both increased parity and gravidity may result in the vaginal distension during pregnancy to accommodate the growing fetus and in preparation for delivery, which may correlate to changes in elastin content.

While this study investigated the preliminary biomechanical and biochemical properties of the vagina, this study is not without limitations. One limitation is the wide range of patient ages, the mixture of POP compartments, and the limited sample size. In the future, optimized patient recruitment is needed for variability control. It is necessary to eliminate individual differences by recruiting more patients in each group and controlling for patient age and POP compartment, as variations in POP compartment likely lead to local variations in mechanical load and subsequent tissue remodeling. Consequently, a more comparable result will benefit the assessment of POP progression in vaginal tissue. Although sample variability hindered the identification of mechanical differences between tissues at different stages of POP, valuable information was obtained about mechanical and biochemical properties of the human premenopausal vagina. The directional mechanical properties and their correlations with fiber content identified in this study highlight the need for future investigations into the microstructure of vaginal tissue in the circumferential and axial directions. This will provide insight into the mechanical response of vaginal tissue during the development of POP.

## INTRODUCTION

The Incapacitation Prediction for Readiness in Expeditionary Domains: An Integrated Computational Tool (I-PREDICT) program is designed to address the limitations of current human body models (HBMs) and provide the military with an advanced, state-of-the-art model that may be used to assess injury risk in various mission environments (Figure 1). For the last decade, the model has been developed in LS-DYNA and has primarily been used for high-rate loading events, such as pilot ejections and behind armor blunt trauma. Recently, other aviation and maritime risks have been considered, such as long-duration flight and spinal injuries occurring therein. To accommodate these new programmatic goals, a parallel I-PREDICT HBM has been developed in FEBio to leverage the unique tissue damage capabilities, active musculature, and other relevant functionalities that facilitate high-fidelity modeling. The following methods, results, and discussion provide an update on model development and recent implementations.

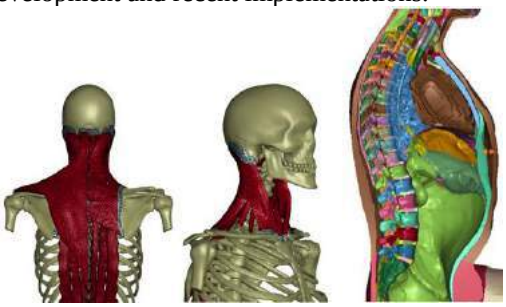

**Figure 1. Three perspectives of the I-PREDICT HBM torso, head, and neck to reveal model detail.**

## METHODS

### Overall Modeling Approach

The I-PREDICT HBM is a probabilistic model that accounts for uncertainty and variability in material properties, threats, model boundary conditions, etc. Moreover, the probabilistic approach guides model development. This is accomplished by distinguishing between epistemic and aleotric sources of uncertainty using probabilistic software (NESSUS, Southwest Research Institute). In situations where the output of interest is highly influenced by a variable with large epistemic variability (uncertainty arising from too few data points), experimental efforts are directed towards addressing this exposed variable. This underlying probabilistic approach taken with the I-PREDICT HBM allows for both a more accurate assessment of injury risk and a more efficient use of resources to improve model shortcomings.

### Anatomy

The I-PREDICT HBM anatomy was developed from Zygote 5.0 geometry of the 50$^{th}$ percentile male.

### Material Properties

Material properties are primarily derived from literature with in-house experimental testing saved for special tissues of interest and tissues identified as contributing high uncertainty to relevant outputs. One such tissue given special attention in the FEBio implementation of the model is the intervertebral disc. Since lumbar pain is a focal concern of this program, intervertebral disc degeneration may be a contributing factor. As such, porcine

annulus specimens have bene rigorously tested with non-damaging step-and-hold tensile loading in the circumferential direction, non-damaging cyclic tension in the circumferential direction, and damaging cyclic tension testing. Using FEBio and an external optimizer (DAKOTA, Sandia National Labs), inverse finite element analyses have been used to fit annulus properties to the experimental data. The annulus is modeled as a solid mixture of a ground matrix (Holmes-Mow) with two crossing fiber families (fiber-pow-linear). The fibers are modeled with reactive viscoelasticity and reactive damage mechanics. First, matrix properties have been taken from literature [1]. Next, using the non-damaging tensile loading, fiber properties are fit (both elastic parameters and reactive viscoelastic parameters). Next, these properties are held fixed and reactive damage mechanics parameters are fit to match the experimental damaging cyclic loading testing. Thus far, the elastic and reactive viscoelastic properties have been fit.

Active Musculature

Another tissue of special interest in this program is musculature. Muscles are modeled as 3D continuum and controlled with active contraction using the trans-iso-Mooney-Rivlin material. As a preliminary demonstration of the role of active musculature in spinal mechanics during a long-duration flight, an analysis was performed to compare a pilot slouching during flight and a pilot with an erect posture accomplished via contraction of the erector spinae muscles. A torque was placed on the C1 vertebra to slump the pilot forward with vibrational loading on the pelvis to simulate the flight boundary conditions. In the active contraction model, the torque was resisted via contraction of the muscles controlled by a PID controller with a target C1 vertebra rotation of zero.

Hierarchical Modeling

Solving a full, long-duration flight (greater than 4 hours) with a full human body model can take weeks, or even months. With a probabilistic modeling approach, hundreds of simulations are run per analysis, and the time constraint per simulation becomes mountainous. To address this limitation, we have developed a hierarchical modeling approach that uses OpenSim to generate relevant muscle forces over a full flight duration, the full HBM to generate boundary conditions in the spinal tissues, and then spinal component models that run for extended periods of time. After a set period of time, the component model is sent back to the full HBM, and a new muscle force is sampled from the OpenSim model. The process is then repeated.

## RESULTS

With annulus testing and inverse finite element analyses, fiber modulus was found to be 3.5±1 MPa. The toe exponent was 6.5±2, and the exponential decay time constant for reactive viscoelasticity was 30±22 s.

In the active muscle demonstration, the slouched posture resulted in high peak stresses occurring in the lumbar discs. With active contraction, peak stresses were reduced by ~40% and occurred in the thoracic and cervical discs. Average stresses were higher in the active contraction model.

The pipeline for hierarchical modeling has been developed and has been successfully demonstrated using a smaller, simple model. Results were similar between the hierarchical model and the full model ran for the full duration. A single python script controls the entire modeling loop.

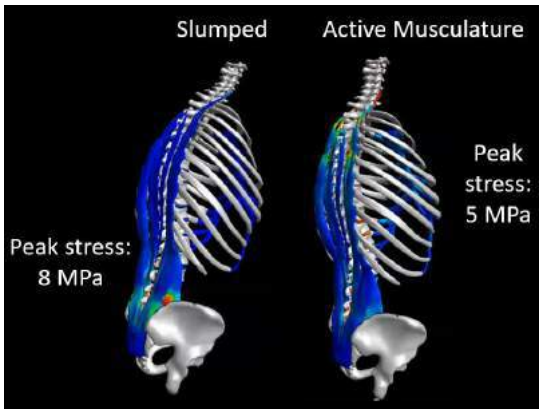

**Figure 2. Comparison between a slumped posture and an erect posture during long-duration flight.**

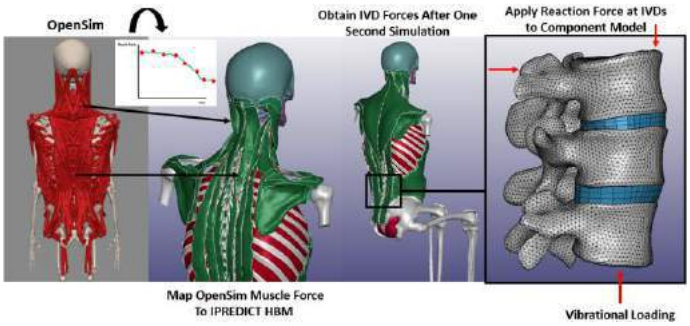

**Figure 3. I-PREDICT HBM Hierarchical modeling approach.**

## DISCUSSION

To the authors' knowledge, the I-PREDICT HBM is the first full-body finite element model implemented in FEBio. FEBio's unique constitutive modeling options tailored to biomechanics have provided the means for a novel approach to modeling the annulus fibrosis. Moreover, enabling 3D solid-element active musculature within the code provides physiologically consistent boundary conditions and response to load – an important consideration in injury risk. Lastly, we have developed the pipeline for a unique hierarchical modeling approach to speed the analysis of large computational models.

# MECHANICAL ANISOTROPY OF THE EQUATORIAL SCLERA DOES NOT CONCUR WITH THE PRIMARY COLLAGEN FIBER ORIENTATIONS

**Yi Hua (1), Samuel Salinas (3), Marissa Quinn (1), Fengting Ji (1,2), Rouzbeh Amini (3,4), Ian A. Sigal (1,2)**

(4) Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, USA

## INTRODUCTION

Collagen fibers provide the sclera with the mechanical strength to be the principal load-bearing component of the eye (**Figure 1**) [1]. Compared to the tissues at the front or back of the eye, such as the cornea, limbus, and peripapillary sclera, little is known about the biomechanics of equatorial sclera [2].

We set out to measure the equatorial sclera mechanical behavior and collagen fiber architecture, focusing on the anisotropies in stiffness and fiber orientation. The degree to which the tissues exhibit either anisotropy was unclear from the literature, and we did not have a defined expectation. Conversely, it has become standard in soft tissue biomechanics to assume that mechanical and structural anisotropies concur, and thus this was our expectation.

Specifically, we used biaxial tensile testing to characterize the stiffness in the circumferential and meridional directions and polarized light microscopy to quantify collagen fiber orientations.

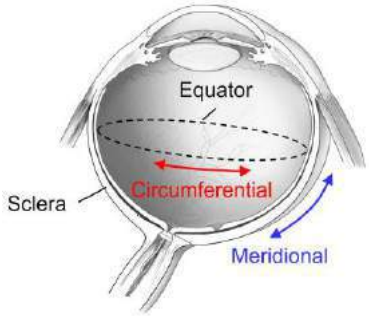

**Figure 1: Schematic cross-section through a human eye. The black dashed line indicates the equator of the eye. The red and blue arrows indicate the circumferential and meridional directions, respectively (consistent throughout the paper).**

## METHODS

*Biaxial tensile testing*. Five porcine eyes were obtained from a slaughterhouse within 24 h postmortem. Equatorial sclera samples (11 mm × 11 mm) were excised from each of four anatomical quadrants: nasal (N), superior (S), temporal (T), and inferior (I) (**Figure 2**). Each sample was mounted on a custom-built biaxial mechanical testing system [3], with the loading axes aligned with the circumferential and meridional directions of the sample. Four submillimeter glass markers were attached to the surface of the sample for optical tracking of tissue deformation (strain). The sample was then loaded under equal-biaxial stress control, with a maximum stress of 120 kPa. Each test consisted of ten loading/unloading cycles, and only data from the tenth cycle was used in the analysis. During the test, the sample was immersed in PBS. After testing, the samples were fixed overnight in 10% formalin [2].

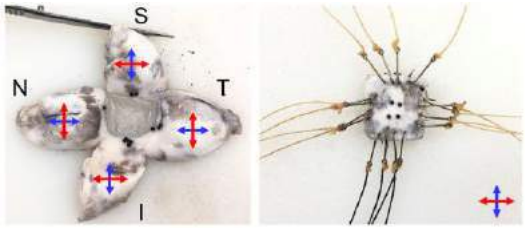

**Figure 2: (Left) Example of a dissected eye with cornea in the center and the four quadrants labeled. (Right) Example of a sample with hooks attached for biaxial testing.**

*Polarized light microscopy*. Four samples from three eyes were cryosectioned into 30-µm-thick sections. Sections were imaged using polarized light microscopy and collagen fiber orientations determined using a previously reported technique (**Figure 3**) [2]. Orientation maps were stacked, registered and analyzed to determine the fiber orientation distributions and the preferred orientation of each sample.

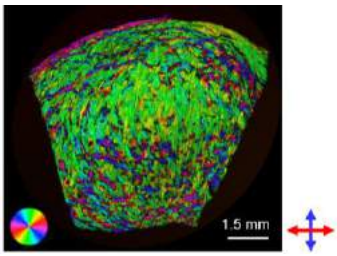

**Figure 3: Example orientation map of a section from the temporal quadrant obtained by polarized light microscopy. Colors indicate the orientations of fibers as shown in the color wheel.**

## RESULTS

Biaxial tensile testing showed that the superior and inferior quadrants had the highest anisotropy (**Figure 4, Left column**), with much higher stiffness along the circumferential direction (red) than along the meridional direction (blue). Microstructural analysis showed that all four quadrants were highly anisotropic (**Figure 4, Right column**), with clearly preferred fiber orientations in the meridional direction (or nearly meridional in the inferior quadrant).

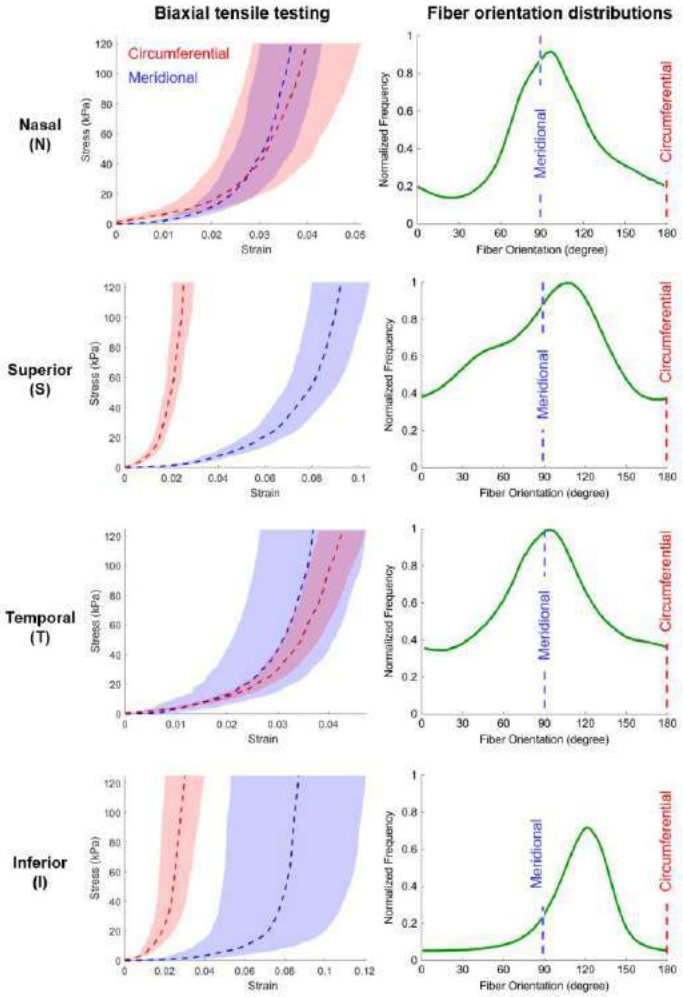

**Figure 4: (Left) Average stress-strain responses (N = 5) along circumferential and meridional directions as measured by the biaxial tensile testing. Shaded regions are standard error of the mean. (Right) Fiber orientation distributions obtained using polarized light microscopy of four samples.**

## DISCUSSION

The equatorial sclera is central to overall globe mechanics. Our goal was to quantify its mechanical and microstructural anisotropy. The superior and inferior quadrants of equatorial sclera were consistently mechanically anisotropic: stiffer in the circumferential direction. All four quadrants of equatorial sclera were microstructurally anisotropic: collagen fibers primarily oriented in the meridional direction. Altogether, the results show that equatorial sclera anisotropy did not concur with the primary collagen fiber orientations. Below we discuss the findings.

A sclera that is softer in the meridional direction may steer the eye to respond to loads by elongating longitudinally (or anteriorly-posteriorly), without increasing the equatorial diameter. This is consistent with previous MRI observations that the equatorial diameter of sheep eyes did not change as intraocular pressure increased from 0 to 40 mmHg [4]. This finding may relate to the mechanisms underlying myopia, in which the sclera undergoes a large degree of permanent stretching along the longitudinal axis [5].

The nasal, superior, and temporal quadrants had fibers clearly oriented in the meridional direction. In the inferior quadrant, the primary orientation was shifted about 30º, but it was still closer in orientation to meridional than circumferential. The inferior quadrant had the highest anisotropy. Despite variability section by section, overall orientation distributions were smooth and unimodal.

It was unexpected to find that the equatorial sclera mechanical anisotropy did not concur with the primary collagen fiber orientations. The contrast was most evident in the superior and inferior quadrants, but in all quadrants, there were clear differences. The origin for the observed discrepancy remains unknown. It may be that not all collagen fibers are equally stiff. For instance, it is possible that the collagen fibers in the meridional direction are more compliant than those in the circumferential direction. This could be if they are more crimped, and thus recruiting only at higher levels of stretch. The meridional fibers may also be more compliant if they are thinner or sparser, yet have a similar birefringence. Further analysis of the biaxial tests and of the orientation maps, including higher resolution imaging to measure fiber crimp, is necessary to identify the origin of the differences.

It is important to consider that we have only analyzed four of the tested quadrant samples so far, and it is unknown how common the discrepancy is. Nevertheless, we posit that a discrepancy between mechanical and microstructural anisotropy is potentially crucial even if it only occurs sporadically.

In summary, we quantified the mechanical and microstructural anisotropies of equatorial sclera. Quantitative anisotropy data is essential to understand the eye and to build accurate models. Further work to understand the origin of the apparent discrepancy between mechanics and microstructure is thus of great importance.

# REGIONAL MAXIMUM PRINCIPAL STRAIN RESPONSE OF AN ANATOMICALLY ACCURATE FINITE ELEMENT HUMAN BRAIN MODEL

**Tyler F. Rooks, Jamie L. Baisden, Narayan Yoganandan**

Department of Neurosurgery
Medical College of Wisconsin
8701 Watertown Plank Road
Milwaukee, WI 53226

## INTRODUCTION

Brain sensitivity to loading direction has been shown in animal [1–3] and finite element (FE) modeling [4–6] studies with increased susceptibility to injury (animals) and higher global strain responses (FE) for lateral than frontal impact. Additionally, computational models have shown that brain strains are dependent on the impact direction due to the involvement of the falx cerebri [7]. As the falx splits the brain laterally, it is not expected to influence anterior/posterior motion of the brain as much as lateral motion. This study was based on the hypothesis that strains increase, albeit nonuniformly, in all regions in lateral impact compared to frontal impact. The objective of the study was to determine the regional strains under both impact conditions to test the hypothesis.

## METHODS

The Medical College of Wisconsin-USAARL Head Impact Model (MUHIM) is a newly developed, anatomically accurate FE human brain model. The SIMon model was used as the baseline. Its solid elements were split into 8 equally sized elements and all shell elements were split into 4 equally sized elements, while maintaining the remaining element definitions. The refined mesh was overlaid with anatomical reference shells extracted from the *fsaverage* template [8]. Elements within the refined mesh corresponding to the reference anatomy were manually selected to create components defining the brain regions in the new model. In addition to the *fsaverage* template, the anatomical region location, volume, and shape were reviewed with a neurosurgeon. Upon review, the model was further refined to define the hypothalamus and midbrain structures, not segmented in the original *fsaverage* template. Anatomic regions of interest included the cerebrum grey matter, cerebrum white matter, corpus callosum, basal ganglia, pallidum, thalamus, midbrain, hypothalamus, hippocampus, amygdala, brain stem, and cerebellum. Additional structures included were the falx, tentorium, foramen magnum, meninges, cerebral spinal fluid, bridging veins, a rigid skull, and the 3rd, 4th, and lateral ventricles. Material properties were obtained from literature [9]. A summary is included in Table 1.

**Table 1: Summary of MUHIM material properties.**

| | Density (kg/m^3) | Bulk (GPa) | $G_0$ (GPa) | $G_\infty$ (GPa) | beta |
|---|---|---|---|---|---|
| **Corpus callosum / white matter** | 1060 | 0.2 | 3.75E-6 | 7.5e-7 | 0.2 |
| **Basal Ganglia / pallidum / hypothalamus / thalamus / cerebellum** | 1060 | 0.2 | 3e-6 | 6e-7 | 0.2 |
| **Grey matter / hippocampus / amygdala** | 1060 | 0.2 | 6e-6 | 6e-7 | 0.2 |
| **Brain stem / midbrain** | 1060 | 0.2 | 6e-6 | 1.2E-6 | 0.2 |
| **Ventricles / CSF** | 1040 | 0.2 | 5e-7 | 1e-7 | 0.2 |

The MUHIM model was driven using data from our laboratory experiments. Tests were performed with a rigid arm pendulum striking a helmeted head-neck system. The headform used for all tests was the Facial and Ocular CountermeasUres for Safety (FOCUS) headform [10]. The headform is an anthropomorphic test device (ATD) based on the anthropometry representative of male military aviators. The FOCUS headform was mounted to a H-III neck and fitted with an Advanced

Combat Helmet (ACH) for all tests. The Frankfurt plane of the head was maintained in a horizontal position for all tests. Impacts from tests conducted at two sites around the helmet, front, and left side, at a velocity of 6 m/s was used in the present modeling study.

The model was run using LS-DYNA (Livermore Software Technology Corporation, Livermore, CA). The 95th percentile of the Maximum Principal Strain (MPS) for each brain region was calculated for both exposure directions. Percent differences were calculated between the frontal and lateral loading directions.

## RESULTS

Regional MPS (rMPS) ranged from 0.14 to 0.36 for frontal and from 0.20 to 0.51 for lateral impacts (Figure 1). Percent difference in rMPS (Figure 2) between frontal and lateral impacts ranged from 0.4% (for the right Thalamus) to 59% (for the left cerebellum). Several brain regions responded with decreased rMPS for lateral impacts versus frontal (hippocampus: 8% and 46% reduction in the left and right hemispheres; grey Matter: 20% and 4% reduction in the left and right hemispheres; and amygdala: 4% reduction in the right hemisphere). The percent difference between the left and right hemisphere regions for frontal test was between -3% and 3%, while the percent difference between the left and right hemisphere regions for the lateral test was between -23% and 28%.

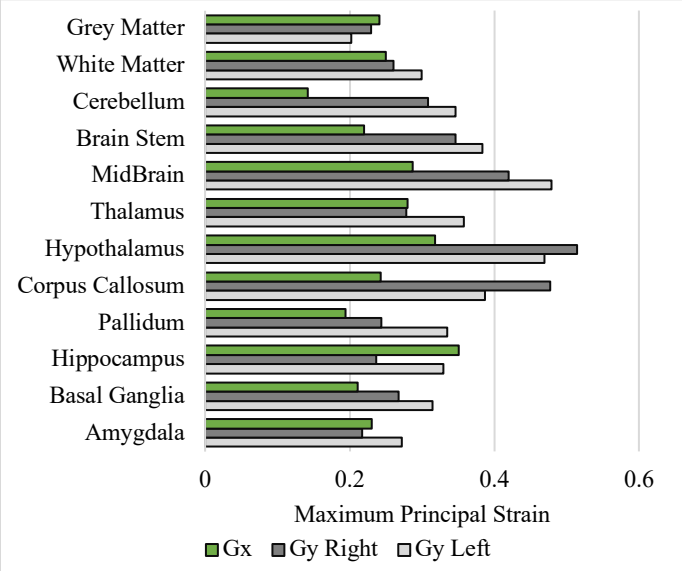

**Figure 1: Regional Maximum Principal Strain Response for the Frontal (Gx) test compared with the Lateral (Gy) test. Frontal (Gx) results are shown as the average of the left and right hemispheres.**

## DISCUSSION

These results showed a sensitivity of the human brain to loading direction. Further, not all regions showed increased MPS for the lateral versus frontal impact conditions. These results highlight the variability in the sensitivity for each brain region to impact direction. The reduction in MPS and the variability between the two hemispheres was unexpected and is under further investigation with additional impact severities and directions. Similar results with the MUHIM model have been seen previously in the regional CSDM response [11].

It is well known that neural functions are related to anatomical structures (e.g., hippocampus for memory, corpus callosum for interhemispheric communication, and basal ganglia and cerebellum for motor control). Understanding the regional response of the brain is important for an improved understanding of brain injury as well as informing clinicians of expected symptoms based on the damaged region. It may also assist in the development of advanced injury criteria for impact-induced brain injuries and applicable to sports and military environments.

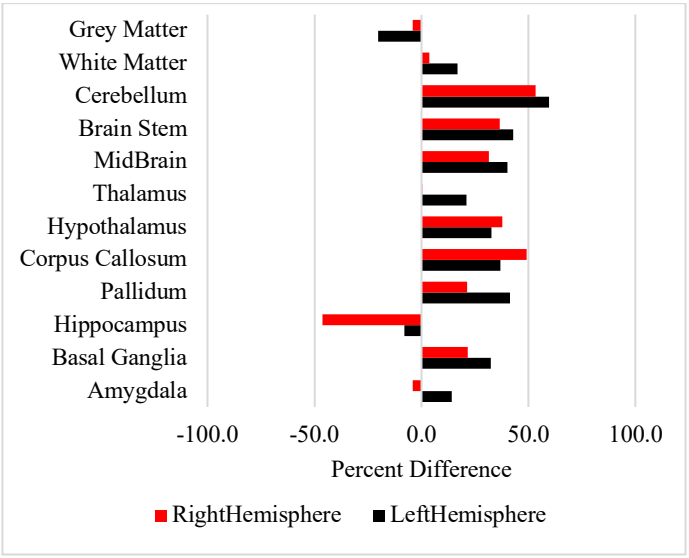

**Figure 2: Percent difference in regional Maximum Principal Strain Response between the lateral (Gy) and frontal (Gx) tests for the left (black) and right (red) hemispheres.**

# COMMUNITY BASED CAPSTONE DESIGN PROJECTS AT THE UNIVERSITY OF SOUTH FLORIA (USF)

**Stephanie L. Carey (1,2), Stephen Sundarrao (1), Rajiv Dubey (1)**

(1) Department of Mechanical Engineering, University of South Florida, Tampa, FL USA
(2) Department of Medical Engineering, University of South Florida, Tampa, FL USA

## INTRODUCTION

The Accreditation Board for Engineering and Technology (ABET) adopted a new definition for engineering design that went into effect with the 2019-2020 evaluation cycle[1]. The required student outcomes include an ability to 1) apply engineering design to produce solutions, 2) communicate effectively, and 3) recognize ethical and professional responsibilities in engineering situations. Recent articles suggest implementing industry engagement and real-world projects to meet the ABET requirements for engineering design[1]. The Capstone Design course in the Department of Mechanical Engineering at the University of South Florida (USF) meets these ABET student outcomes. The course has used real-world assistive design projects informally for over 15 years,[2-3] but has recently implemented a formal community-based engagement to motivate engineering students and increase soft skills such as communication, organization, collaboration, and critical thinking.

## METHODS

The community at USF includes local companies, government agencies such as the VA and NASA, nonprofit organizations that help the elderly and wounded warriors, and a vibrant interdisciplinary, innovative team on the academic campus. The Capstone Course at USF has two primary instructors and a liaison to assist with community engagement. Before the start of the semester, the liaison reaches out to the community to recruit real world-based projects. Potential community partners fill out a form that includes a project description, problem/need, design considerations, desired student skills, acceptable solutions or deliverables, and technical contact. This form also helps to set expectations and deliverables. At the beginning of the course, student teams are given options for real-world projects or create their topic within their group. Student teams communicate with their community contact to discuss and negotiate design considerations, budgets, expectations, and acceptable deliverables within the academic time frame. Before graduation, it gives students direct contact with possible users, manufacturers, or designers.

The real-world design projects give students a chance to recognize ethical and professional responsibilities in engineering situations. Student teams write a report and present the final design, a Solidworks and 3D printed model, a prototype, or a working product that is often delivered to the community partner representative. The community partners are invited to attend the presentations in person or via online streaming and ask questions and give comments.

## RESULTS

Students are engaged with various types of partners and motivated by the real-world application of designs and working with experts in multiple fields, as explained in the following example projects.

### Industry Partners

There are companies within the community that need well-skilled engineers. These companies may hire interns, which helps with hiring and recruitment. The Capstone Design course is another opportunity for companies to inform engineering students about their company and share the skills required to be a successful engineer. At USF, the community liaison for this course solicits projects from companies by tapping into the USF engineering alumni pool and engaging with the members of the Advisory Board. Companies such as General Electric, Top End, Jormac Aerospace, Tampa Electric, Sun Hydraulics, JTD Enterprises, and Jabil have sponsored student design projects at USF. Nearby tourist locations such as Busch Gardens, the Lowry Park Zoo, and the Victory Ship have also proposed design projects. Students seem motivated by completing these projects that are used around the community. A student design team worked with a local company, JTD Enterprises, to improve the efficiency of filling ballast bags used for sonobuoys often used by the U.S. Navy. The engineering students designed and fabricated a vibratory table

that helps with the dispersion of the ballast bag filler material and assists in the zip tying of the bags. The students delivered the product to the company CEO. This project also exposed students to the manufacturing chain in this case: the filler material company to the ballast bag filling company to the sonobuoy company to the U.S. Navy

### Government Agencies and Nonprofit Organizations

Government agencies such as the National Science Foundation (NSF) and NASA often deploy student design competitions that may be relevant and appropriate for a Capstone Design project. These contests come with design criteria, expectations, and acceptable deliverables already in place. These contests are often motivating to the students for their real-world nature and their competitiveness. Top teams may be rewarded with a trip to a NASA center, a visit with an astronaut, or a chance to travel to a conference to disseminate the results of their design project. Figure 1 shows a USF team awarded top honors at a NASA competition. The Tampa Bay area also has a large military and Veteran population. The recently formed Institute of Applied Engineering (IAE) at USF has agreements with SOFWERX, a venue operated under an agreement between the United States Special Operations Command (USSOCOM) and DefenseWERX. With these new collaborations in place, the Capstone Design students will soon have military-type design projects to tackle. The James A. Haley Tampa VA hospital is located across the USF's main Tampa campus. The collaboration with the Tampa VA generates design projects in the assistive technology and rehabilitation engineering realm.

**Figure 1: USF engineering students design a rock sampling device for NASA's competition**

Nonprofit organizations may also have design projects appropriate for Capstone Design students. Although these organizations may not have the funds to financially sponsor a project directly, they may have donors willing to provide financial assistance if required for the project budget. The Shriners Hospital for Children in Tampa has provided projects for teams such as a prosthetic knee for pediatric patients learning to walk and a prosthetic hand to play the violin.

### Campus Partners and Alumni

The rehabilitation engineers at the Center for Assistive, Rehabilitation & Robotics Technologies (CARRT) at USF often identify specific assistive device needs in the community to improve the lives of local persons with disabilities[2,3]. The Capstone Design course also receives projects from other departments and investigators on campus. Examples include a dance chair and an omnidirectional platform for the USF School of Theatre and Dance. Engineering students have designed a temperature sensor and a prosthetic kayak hand in collaboration with the USF School of Physical Therapy.

Recent graduates are appointed as Teaching Assistants (TA)s for the course as they pursue graduate studies at USF. Their recent experience in the Capstone Design course and having some entry level engineering experience allows the TAs to provide the students unique perspectives on managing projects and overcoming pitfalls. More experienced alumni provide projects, serve as mentors, and guest speak at lectures leading to informative discussions about career pathways and important qualities for a successful job search.

### Individuals

The students or faculty may also come across individuals in the community that have specific, personal, and unique design needs. For example, a team designed a specialized tray attached to a wheelchair for a student's brother with cerebral palsy. Another student designed an all-terrain wheelchair, so his father could visit the beach. A backpack retriever was designed for a student on campus that uses a wheelchair. Figure 2 shows the student design team's handcycle case design for an Army Veteran to transport his handcycle more effectively and safely.

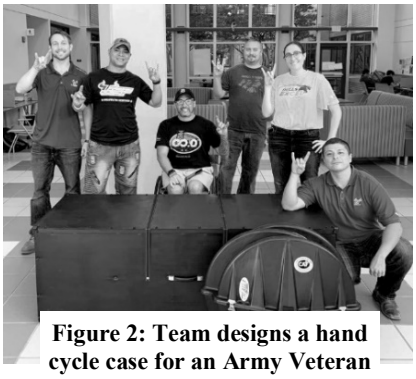

**Figure 2: Team designs a hand cycle case for an Army Veteran**

A recent student design team worked on a wrist hand orthosis that is currently being further developed. A USF employee has requested designs for assistive devices to help her granddaughter with cerebral palsy.

## DISCUSSION

These real-world projects from the community of industry partners, government agencies, nonprofit organizations, alumni and needs on campus inspire students and provide the necessary skills to become successful engineers. Direct collaborations between engineering students and these community partners will be mutually beneficial during the recruitment and hiring process. Anecdotal evidence has shown that student groups are more motivated by community-based projects. It has been seen by the time and care put into the projects and the outcomes.

Although the USF Capstone Design Course team has been informally engaging the community to help with real-world project ideas, a new formal approach will better track and assess the benefits to the students and the community. The project suggestion form is on the various USF websites. Still, there are plans to solicit more community engagement through more in-person meetings such as lab tours and increase the online and social media presence of the student project successes and community needs. The USF College of Engineering also is planning an interdisciplinary approach to these design projects by forming student teams from multiple engineering departments. The student outcomes such as motivation, communication skills, and critical thinking will be tracked and assessed.

# DEVELOPMENT OF AN IN VITRO EXPERIMENTAL MODEL TO STUDY ENDOTHELIAL DYSFUNCTION FROM COARCTATION OF THE AORTA

**Dylan J. Schock (1), Hilda Martinez Ramirez (1), Joy Lincoln (2,3), Abdel A. Alli (4) and John F. LaDisa Jr. (1,2,3)**

(4) Department of Physiology and Functional Genomics, University of Florida, Gainesville, FL, USA

## INTRODUCTION

Coarctation of the aorta (CoA) is one of the most commonly occurring congenital heart defects (5,000 to 8,000 births annually) and is characterized as the constriction of the descending thoracic aorta[1]. This constriction results in elevated mechanical forces such as blood pressure (BP), wall stress, and strain on the aortic tissue proximal to the coarctation (**Fig 1**). Early surgical intervention is the preferred treatment option due to positive short-term outcomes in restoring normal blood pressure and flow. However, long-term studies of post-operative patients report higher risks of cardiovascular (CV) complications, among the most prevalent being systemic hypertension (HTN)[2].

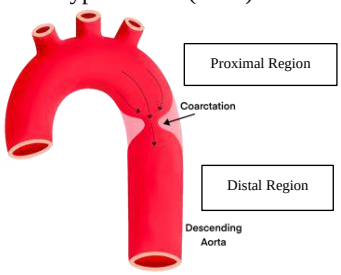

**Figure 1. Coarctation of the aorta (CoA) is characterized by a constriction of the descending thoracic aorta, often near the left subclavian artery. CoA results in altered mechanical stimuli in the region proximal to the coarctation.**

The mechanistic development of HTN associated with CoA is not yet completely understood. Identifying specific mechanisms in humans is difficult due to confounding variables such as age of repair, severity of coarctation, genetic variability, and the presence of other congenital CV defects. Studies done with clinically representative rabbit models of CoA (20 mmHg BP gradient) and treatment have shown that altered endothelial function is associated with pathologic strain and deformation and persists after treatment[3]. Moreover, RNA sequencing of aortic tissue collected from humans with CoA has shown downregulation of natriuretic peptide receptor C (NPR-C; aka NPR3) in the proximal sections exposed to elevated BP[4]. Complimentary microarray analysis of proximal aortic tissue from the in vivo rabbit model showed a similar downregulation of NPR-C in the proximal section[4]. The functional ramifications of altered NPR-C activity have been associated with decreased intracellular calcium concentration ($[Ca^{2+}]_i$) activity in response to application of C-type natriuretic peptide (CNP) in the intact artery sections from the proximal section of the rabbit model. Use of this model to further probe the mechanisms of hypertension from coarctation induced stiffening and endothelial function is not tractable due to the experimental duration and limitations on the long-term usefulness of the tissue ex vivo. The objective of the current work was to develop an in vitro experimental CoA model to study the endothelial dysfunction seen with the previously developed in vivo model by inducing cyclic strain on cultured cells using a mechanically active bioreactor.

## METHODS

Primary human aortic endothelial cells (HAECs) from Cell Biologics were cultured with the manufacture recommended human endothelial cell medium supplemented with 5% fetal bovine serum, 10mL/L of L-Glutamine and Antibiotic-Antimycotic, and 1mL/L of VEGF, HEPARIN, EGF, and FGF. The cultures were maintained in a humidified incubator at 37°C and atmosphere of 5% $CO_2$-95% air. Cells were received frozen at passage 3 and initially seeded onto a T25 cell culture flask where they were passaged in a 1:3 ratio every 5-6 days. All culture flasks were coated with the manufacture recommended Gelatin-Based Coating Solution (Cell Biologics) prior to seeding. At passage 7, the cells were split at a 1:2 ratio onto a T75 culture flask. Once >80% confluent, the cells were either frozen for later experiments or then transferred from a single T75 flask onto a six-well Bioflex plate coated with Collagen I (FlexCell International Corporation). All experiments were conducted at passage 8.

Once >90% confluent, the cultured HAECs in the Bioflex plate were transferred to the FX-6000T Tension System (FlexCell International), which is a pneumatic bioreactor that induces equibiaxial

tension on cultured cells in monoculture. Tension was set to be applied cyclically for twelve hours using a triangular waveform pattern, with a duty cycle of 33% to replicate the physiologic pattern of strain experienced by the aortic wall over a cardiac cycle. Maximum strain conditions were derived from measurements of the CoA rabbit model, with a 12% elongation being the physiologic Control condition and 17% elongation designated as the pathologic CoA condition.

Average HAEC calcium transients ($[Ca^{2+}]_i$) were recorded (n=5 cells/well) during experimentation using an upright Olympus Fluoview FV1000 microscope equipped with Ti:sapphire lasers set to a wavelength of 810nm and imaged with a 25X water-immersion objective lens (XLPL25XWMP, Olympus). Prior to imaging, cells were loaded with Fluo-4AM (3.8uM, Invitrogen) using 0.02% Pluronic acid (Pluronic F-127, Invitrogen) in serum-free media for one-hour. Afterwards, the flexible silicone Bioflex membranes containing the cells were carefully sectioned from the Bioflex plate and pinned down in a silicone-coated 35mm imaging dish containing a $Ca^{2+}$ buffer solution (2mM). Continuous image acquisition settings were set to capture every 1.644s for a maximum duration of 200 frames (328.5s). Upon starting experiments, 30 frames were allowed to pass to establish a baseline intensity. At frame 30, 1.5e-6M of CNP was diluted into the imaging dish. This dose was chosen to balance the response to the agent with cellular toxicity[4].

The HAEC response to CNP application was also quantified after preloading a Control group with 10µM of NPR3-specific inhibitor, M372049 (AstraZeneca)[5], in serum-free media for 45 minutes. The treated media was then replaced with fresh media and loaded into the bioreactor. Tension was induced and the cells were imaged as previously described.

Image stacks were quantified using the Loci tool plugin in Fiji (National Institute of Health). Regions of interest (ROIs) were identified over five different cells and the Measurement option within the Analyze tool was employed to record the mean intensity, among other features to describe intensity distribution and cellular morphology across all frames. The resulting intensities were then normalized to the background and to their respective baselines.

## RESULTS

Preliminary two-photon imaging of the Control HAECs (n=3 six-well plates) after undergoing physiologic in vivo strain conditions reveals a rapid decrease in cytosolic $[Ca^{2+}]_i$ in response to CNP **(Fig 2)**. In comparison, the CoA HAECs (n=3 six-well plates) exposed to pathologic strain conditions show a decreased response to CNP when applied under the same conditions.

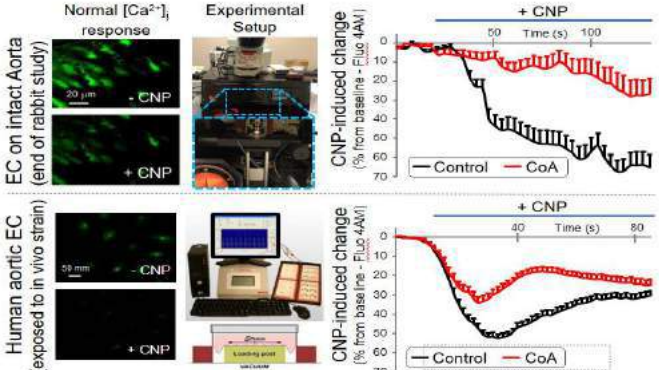

**Figure 2. Preliminary two-photon imaging results of HAECs after undergoing Control and CoA strain conditions and their associated experimental setups. The $[Ca^{2+}]_{in}$ results from the intact artery (in vivo) model are shown for comparison.**

Initial interrogation of Control HAECs (n=3 wells) that have been pretreated with an NPR3 inhibitor reveals that the response to CNP diminishes as compared to the group without the inhibitor (**Fig 3**).

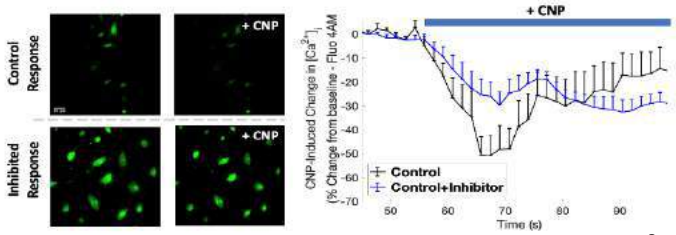

**Figure 3. Comparison of the CNP-induced change in $[Ca^{2+}]_i$ between a Control group and HAECs pretreated with NPR3 inhibitor, M372049 (AstraZeneca)**

## DISCUSSION

The objective of this study was to develop an in vitro experimental model using cultured cells and a mechanically active bioreactor to recapitulate the altered endothelial function that has been shown to develop in a previously established in vivo rabbit model of CoA. Preliminary data shows that when HAECs undergo pathologic levels of cyclical tension their cytosolic $[Ca^{2+}]$ response to CNP diminishes as compared to cells that undergo normotensive strain conditions. This general CNP response between the two strain conditions correlates with the results of the in vivo CoA study (**Fig 2**), suggesting this model's usefulness in recreating the environment and dysfunction of the intact CoA endothelium, however further study is needed to establish the robustness and reproducibility of the model. Current limitations of this study include the small data set, however additional experiments are planned to validate the Control and CoA CNP response as well as more testing with the NPR-C inhibitor to further compliment and validate against the available data from the in vivo model[4]. Furthermore, variable-selection techniques (*i.e.*, machine learning) will be applied to study and correlate specific cellular features that best predict functionally relevant responses to CNP application.

## INTRODUCTION

Lower urinary track symptoms (LUTS) generally progress with age. Existing methods to evaluate the lower urinary tract are invasive and provide limited information. Importantly, these tests do not offer dynamic anatomical evaluation of the lower urinary tract (LUT)[1]– [3] and specifically the bladder. Previous studies have demonstrated that MRI can provide both static and dynamic high fidelity 3D images of the bladder, prostate, and urethra[4]. Therefore, the aim of this study is to implement an MRI urodynamics protocol for the comprehensive assessment of the bladder biomechanics during voiding.

## METHODS

In this HIPAA compliant, IRB-approved study, 5 healthy males and 1 BPH patient were recruited equipped with a condom catheter and instructed to void in the MRI scanner. All scans were completed on a clinical 3T scanner (Premier, GE Healthcare, Waukesha, WI), using a high-density flexible surface coil array (AIR Coil, GE Healthcare). A dynamic acquisition was performed using 3D Differential Subsampling with Cartesian Ordering (DISCO) with a temporal resolution of 3.7 seconds, generating a total of 40 time steps. 15 minutes prior to the MRI scans, 1/3 of a single weight-based dose (0.1 mmol/kg) of gadolinium-based contrast was hand injected intravenously into each subject to enhance the visualization of bladder deformation, volumetric displacement over time, bladder wall thickness, bladder neck funneling, post void residual (PVR) and total voided volume (TVV). Images were imported into MIMICS (Materialise, Leuven, Belgium), where bladder wall and lumen were segmented to obtain 3D renderings of the bladder lumen and bladder wall (Figure 1 and 2). Two critical points during the voiding event were determined from the 3D segmentations, pre-void phase and maximum flow rate phase.

Bladder lumen volumes are then used to calculate volumetric flow rate throughout the voiding event by calculating the volume change over time. Median Bladder wall thickness was calculated by importing the bladder wall segmentation into 3-Matic (Materialise, Leuven, Belgium) and using the "Create Wall Thickness Analysis" tool.

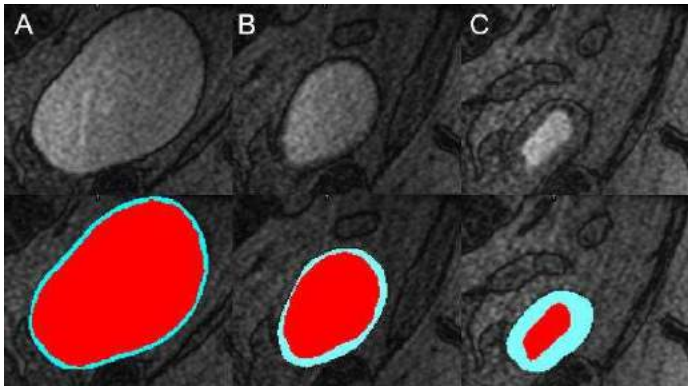

**Figure 1: Sagittal cut of 3D renderings of the wall and lumen of the bladder at the critical points a) pre-void, b) maximum flow rate, c) post-void.**

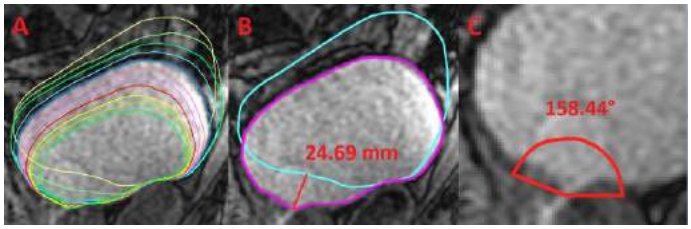

**Figure 2: a) Contour lines of bladder lumen segmentations though the voiding event. b) Bladder emptying prolapse distance and c) EBNA at maximum flow rate for P1.**

Bladder neck funneling was measured with the change of the external bladder neck angle (EBNA). EBNA was taken at all critical points of each voiding event as observed in figure 1c). This angle is measured at the internal urethral sphincter.

Alongside the angle measurements, maximum emptying prolapse was measured as the distance between the lowest internal sphincter to the other internal sphincter locations at the critical points.

## RESULTS

A methodology to evaluate and characterize biomechanics of the bladder during voiding in human subjects was successfully implemented. Figure 3 shows the flow rate and bladder wall thickening for obtained for all 6 subjects.

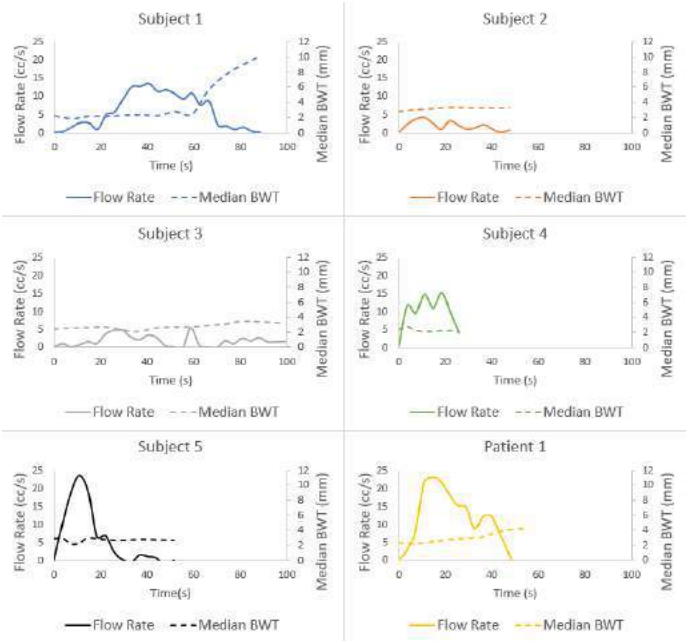

**Figure 3: Flow rates and BWT over the voiding events**

A wide range of voiding rates (Q), voiding times, TVVs, and PVRs were found as shown in Table 1.

| *Subject* | *TVV (ml)* | *PVR (ml)* | $Q_{max}$ *(ml/s)* | $Q_{avg}$ *(ml/s)* |
|---|---|---|---|---|
| ***S1*** | 521.78 | 9.63 | 13.53 | 5.9 |
| ***S2*** | 91.23 | 598.77 | 4.13 | 1.92 |
| ***S3*** | 186.83 | 277.65 | 5.33 | 1.88 |
| ***S4*** | 379.49 | 361.33 | 15.21 | 14.76 |
| ***S5*** | 315.74 | 263.33 | 23.59 | 6.16 |
| ***P1*** | 596.94 | 104.79 | 22.91 | 11.05 |

**Table 1: Calculated bladder micturition metrics**

During the pre-void (resting) phase, all healthy subjects displayed EBNA between 130° and 170°, while P1 had EBNA of 209.98° indicating prostate protrusion. At maximum flow rate, P1 had an EBNA decrease of at least double of any other healthy subject at 51.54°. Subject 2, which voided less than 150 cc and had the lowest flow rate, showed an increase in EBNA between these critical points. Subjects with the highest flow rates show the highest variations in EBNA between pre-void and maximum flow phases. Also observed between pre void and maximum flow was the bladder prolapsing between 3 mm and 25 mm for all 6 subjects.

## DISCUSSION

To our knowledge, biomechanics of the bladder has not been possible to evaluate during a voiding event non-invasively, and current diagnostic methods fail to completely characterize voiding mechanics. This non-invasive, novel MRI–based technique, allows for the quantitative assessment of the bladder during a voiding event. Correspondingly, measurements of volumetric flow rate, BWT, TVV, PVR and EBNA were able to be obtained during these voids. BWT, EBNA and bladder emptying prolapse displayed similar characteristics between subjects. BWT increased significantly only in patients that voided more than 500 cc. EBNA decreased in every patient that voided over 150 cc. EBNA measurements are also affected by prostatic protrusion into the bladder. For bladder emptying prolapse, as flow rate increases, the bladder neck descends towards the lower pelvis to potentially assist the funneling of the bladder neck, favoring the urine flow until it reaches a maximum flow rate. When the flow rate starts to decrease the bladder retracts to its resting position as the void comes to an end. These bladder's emptying prolapse measurements allow us to understand the motion of the bladder as the bladder neck funnels and how adjacent structures like the rectal cavity, lower pelvic muscles and plexi around the bladder behave at critical points during the voiding event.

In our results, flow rates, TVV and PVR varied largely between all 6 subjects. This shows the ability of this novel methodology to characterize diverse bladder biomechanics during any voiding event. For example, subject 2's voided volume wouldn't have qualified for urodynamic studies as it voided less than 150 cc. Nevertheless, our methodology allows us to analyze low volume voids. Appropriately, EBNA shows an increase between pre-void and maximum flow phase, during which the bladder only prolapsed 3 mm. These are characteristics opposite to ones displayed by the other 5 subjects. This proves the necessity for patient specific methodologies to analyze bladder biomechanics.

In summary, MRI is an invaluable imaging modality that can be used to characterize anatomical and functional information of the LUT throughout the voiding cycle in a safe, accurate, and reproducible way. Future advancements in this study will be aimed at using the data acquired to further deepen the comprehension of the bladder voiding events and how they get affected by different diseases.

# THE STRAIN RESPONSE OF THE HUMAN LAMINA CRIBROSA FROM INTRAOCULAR PRESSURE DECREASE

## INTRODUCTION

The lamina cribrosa (LC) is a connective tissue that forms part of the eyewall covering the optic nerve head (ONH). It is composed of a stack of perforated plates that appears as a network of beams and pores when viewed in the transverse plane. The LC acts as the primary structural support for the axons of the retinal ganglion cells (RGC) exiting the eye, astrocytes, and other glial cells that provides physiological support to the axons [1,2]. Glaucoma is a progressive neurodegenerative disease marked by dysfunction and injury of the RGC axons at the level of the LC. Glaucoma damage is associated with intraocular pressure (IOP), thus it is important to understand the deformation response of the LC to IOP.

Recent advances in ophthalmic imaging using optical coherence tomography (OCT) have allowed researchers to track the motion of structural features *in vivo* in response to changes in IOP [3.4]. However, the motion of structural features, such as change in the anterior LC depth (ALD), may not predict the strain response of the LC. We previously measured the change in ALD to an IOP decrease from trabeculectomy and found that the anterior LC surface could move either into the eye (anterior) or outward (posterior) [3].

More recently, our group developed a method using digital volume correlation (DVC) to accurately calculate the strain field in OCT images [5]. We acquired 24 radial OCT scans of patients immediately before and 20 minutes after laser suturelysis surgery after trabeculectomy, and applied DVC to correlate the natural speckle patterns of the two image pairs to calculate the three-dimensional strain field in visible LC volume [5]. We estimated the baseline and displacement correlation errors and found that on average, the baseline and correlation errors for the displacement components were less than 0.25 pixels and the average error for all the strain components was less than 0.37%. In this study, we applied the method to measure the strain response and ALD change response in the LC from IOP decrease after suturelysis surgery. We analyzed for possible correlations between the ALD and the strain components. We also evaluated whether the degree of glaucoma damage was related to the change in ALD or strain responses.

## METHODS

Twenty-nine suturelysis procedures were performed on 27 eyes from 26 patients. The average age was 67.7 +/-8.5 years old with an average IOP decrease of 11.9+/- 8.9 mmHg and mean deviation (MD) range of -0.17 to -29.2 dB.

Twenty-four radial scans by spectral domain, optical coherence tomography (SD-OCT) of the optic nerve were captured using Heidelberg Spectralis (Heidelberg, Germany, Heidelberg Engineering) immediately before and 20 minutes after suturelysis laser surgery [5]. IOP was measured using the iCare rebound tonometer right before each set of imaging. The contrast of the images was enhanced using contrast limited adaptive histogram equational (CLAHE) and Gamma correction was used to reduce noise in areas with low signal (Fig. 1). The anterior lamina surface and Bruch's membrane opening were marked manually on each radial scan, and a parallel curve was drawn 250 μm posterior to the anterior lamina surface to segment the anterior portion of the LC.

DVC was applied to correlate the natural speckle patterns of the OCT images taken before and after suturelysis to calculate

the strains caused by the decrease in the intraocular pressure (Fig. 1). Linear regression was used to analyze for relationships between the tissue-averaged ALD and the strain components; between the strains/ALD and the IOP, between strains/ALD and functional measurements of glaucoma severity, i.e. MD and visual field index (VFI), and structural measurements of glaucoma severity, i.e., retinal nerve fiber layer (RNFL) thickness. The strain components, ALD, and RNFL thickness were also averaged in the 4 quadrants (nasal, temporal, inferior, superior) of the LC to analyze for regional variations in the relationship between strain and ALD.

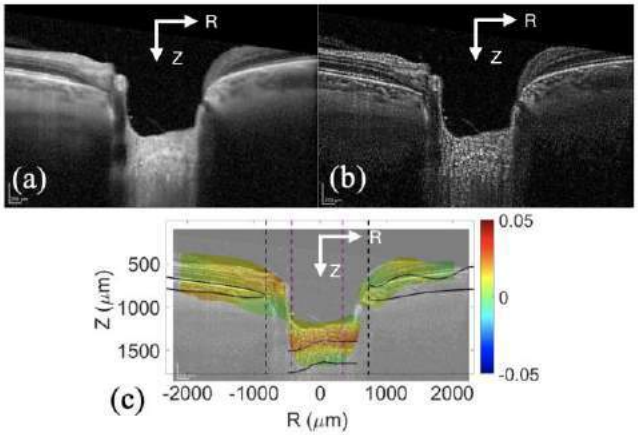

**Figure 1: Slice 1 of a) the original OCT image, b) contrast enhancement, and c) the $E_{max}$ outcome.**

## RESULTS

A larger IOP decrease produced larger tensile strain in the anterior-posterior direction ($E_{zz}$), maximum principal strain ($E_{max}$), and maximum shear strain ($\Gamma_{max}$) ($p<0.01$). The tissue-averaged ALD change ranged from -20 μm to 15 μm and was not statistically significantly different than zero. However, ALD was significantly associated with the torsional shear strain $E_{\theta z}$ ($p=1e\text{-}6$) and $\Gamma_{max}$ ($p=0.01$). A more anterior ALD change produced a larger, more positive $E_{\theta z}$ (clockwise twist) and a larger $\Gamma_{max}$. However, the tissue-averaged ALD was not associated with the normal strain components nor with $E_{max}$. Analyzing the quadrant averages showed a more nuanced relationship between strain and ALD. A more posterior ALD change produced greater $E_{zz}$ and $E_{rr}$ in the clock hours of the nasal quadrant ($p<0.05$). In contrast more anterior ALD change produced greater $E_{max}$ and $\Gamma_{max}$ in the inferior and temporal quadrants, and greater $E_{rr}$ in the inferior quadrant ($p<0.05$).

Compliance of the strain or ALD response was defined as the strain or ALD, respectively, divided by the IOP change. Eyes with a thinner RNFL had a more compliant tissue-averaged $E_{max}$, $\Gamma_{max}$, and $E_{\theta z}$ response to IOP change ($p<0.04$) (Fig. 2a). A more complaint $E_{max}$, $E_{\theta z}$, $E_{rz}$ response was found with worse (more negative) MD ($p<0.05$) (Fig. 2b). Likewise, a more compliant $E_{\theta z}$, and $E_{rz}$ response was associated with worse VFI ($p<0.05$). We also found borderline significant results showing a more compliant $\Gamma_{max}$ response for worse MD ($p=0.08$) and a more compliant $E_{max}$ response for worse VFI ($p=0.08$). A thinner RNFL had a more complaint $E_{max}$ response in the nasal quadrant and a more compliant $\Gamma_{max}$ response in the nasal and inferior quadrants ($p<0.05$).

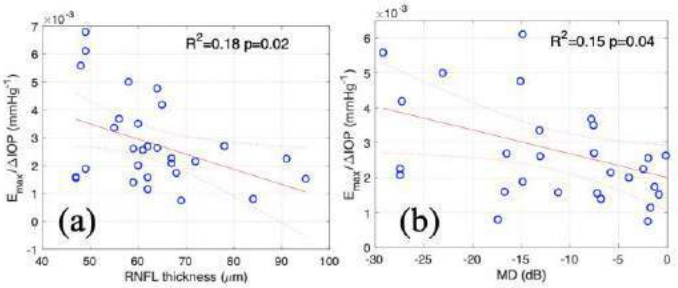

**Figure 2: The relationship between compliance, RNFL, and MD using linear regression. A more compliant $E_{max}$ response was found with a) a thinner RNFL, and b) worse MD.**

## DISCUSSION

IOP decrease produced on average tensile $E_{zz}=0.9\% \pm 1.2\%$ ($p=.0002$), compressive $E_{rr}=-0.2\% \pm 0.3\%$ ($p=.004$), and clockwise twist $E_{\theta z}=0.2\% \pm 0.5\%$ ($p=0.07$). Surprisingly the maximum shear strain $\Gamma_{max}$=5.0% ± 3.4% was larger than the maximum tensile strains $E_{max}$=2.8% ± 2.0%. IOP did not produce a significant average ALD change = $1.33\ \mu m \pm 6\ \mu m$ ($p=0.26$). While the tissue-averaged $E_{zz}$, $E_{max}$ and $\Gamma_{max}$ increased with IOP ($p\leq0.002$), ALD change did not vary significantly with IOP. The average ALD change was predictive of shear strains $E_{\theta z}$ and $\Gamma_{max}$, but not normal strains. However, analyzing quadrant averages, we found significant correlations between the ALD change and normal strains, but the correlations could be positive or negative depending on the quadrant. These results showed the complex relationship between ALD change and the strains.

The LC of eyes with more severe glaucoma damage (thinner RNFL, worse MD, and lower VFI), had a more compliant strain response overall and in the inferior and nasal quadrants. These findings may result from progressive LC remodeling with glaucoma damage into a more curved structure or may represent baseline LC biomechanics prone to damage.

# DESIGN AND MECHANICAL TESTING OF A SHOULDER-ASSISTIVE EXOSUIT

**Kaleb Burch (1), Cara McKenna (2), Michael McIntire (2), Jill Higginson (1,2)**

(1) Mechanical Engineering, University of Delaware, Newark, DE, USA
(2) Biomedical Engineering, University of Delaware, Newark, DE, USA

## INTRODUCTION

Nearly 800,000 Americans suffer a stroke each year [1], and 66% of these people will consequently experience upper extremity impairments [2]. These impairments often pose consequences such as reduced independence and compromised ability to perform activities of daily living [3].

Prior work has suggested that mechanical assistance can improve post-stroke arm function by increasing reachable workspace and reducing required muscle activity [4,5]. Early assistive devices [4] were stationary and could not assist patients during daily life, but recently wearable assistive devices, or exosuits, have been developed to meet this need while at home and not just in rehabilitation clinics [5-7].

We developed an exosuit that uses a cable to assist shoulder motion. In order to benchmark and optimize device performance, we conducted quasi-static mechanical testing to quantify the cable forces required to lift the arm over a range of flexion angles. Furthermore, theoretical cable forces were estimated by modeling the arm as a pendulum subject to gravity in order to evaluate experimental results.

## METHODS

The exosuit used in this study (Figure 1A&B) was developed using a shoulder brace (ZENKEYZ) with custom 3D-printed cable attachment points sewn in as well as a custom elbow wrap. A cable (braided nylon twine) was affixed to the elbow wrap and routed through the attachment points on the shoulder brace.

In order to evaluate the exosuit, it was placed on a mannequin. We conducted a quasi-static test to quantify cable forces required to lift the arm. Starting with the mannequin arm resting at the side (approximately 0˚ flexion), the cable was slowly pulled to lift the arm to approximately 90˚ flexion, and then slowly released to lower the arm back to 0˚ flexion. During this motion, data was recorded at 2,000 Hz using a load cell (ATO-LC-TC01, 50kg capacity, ATO, Diamond Bar, CA, USA) affixed to the end of the cable (Figure 1A). Retroreflective markers were placed on the mannequin (Figure 1A&B) and on cable attachment points on the exosuit. Motion capture (Oqus, Qualysis AB, Gothenburg, Sweden) was then used to track arm movement and positions of the cable attachment points at a rate of 100 Hz.

Marker positions and load cell forces were lowpass filtered using zero phase shift 4th order Butterworth filters with 6 Hz and 1 Hz cutoff frequencies, respectively.

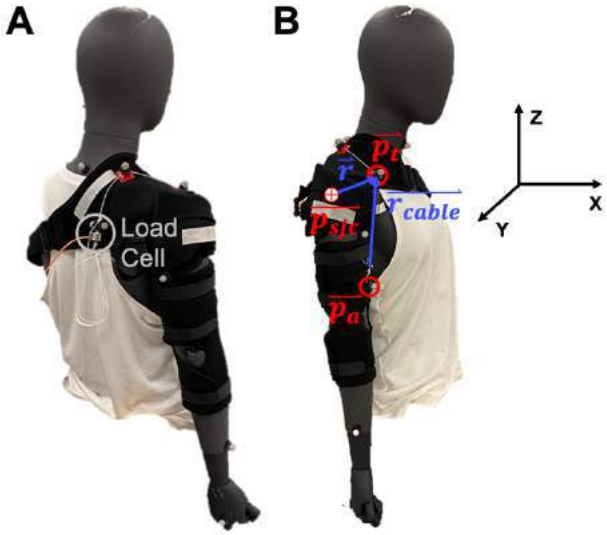

**Figure 1: Back (A) and front (B) view of the experimental test setup of the exosuit placed on the mannequin with markers and load cell attached. Variables used in the model are overlaid, with the positions of attachment points and shoulder joint center in red and vectors between positions shown in blue.**

Inverse kinematics was used to compute shoulder elevation angle based on a model of the arm developed in Visual3D software. Markers on cable attachment points enabled definition of cable position and orientation.

These data were input into a custom MATLAB script which computed theoretical cable forces at each arm position. First, gravitational moment, $M_g$, about the shoulder was computed for each arm position according to equation 1.

$$M_g = mgl_{com}\sin(\theta) \quad (1)$$

In the above equation, $m$ represents arm mass, $g$ represents acceleration due to gravity, $l_{com}$ represents arm center of mass position, and $\theta$ represents flexion angle.

Instantaneous attachment point positions were estimated based on their positions at the beginning of the trial and then simulating their movement assuming they are rigidly fixed to the corresponding bodies. Consequently, $\vec{p}_t$, the position of the attachment point on the torso in Figure 1B, remains fixed in place, while $\vec{p}_a$, the position of the attachment point on the arm in Figure 1B, rotates with the arm. This motion can be computed using $\theta$ to define a rotation, $R_y(\theta)$, about the shoulder joint center $\vec{p}_{sjc}$ according to equation 2:

$$\vec{p}_a = R_y(\theta)\left(\vec{p}_{a,initial} - \vec{p}_{sjc}\right) + \vec{p}_{sjc} \quad (2)$$

Then, the cable moment arm about the shoulder, $\vec{r}_{ma}$, was computed based on positions $\vec{p}_{sjc}$, $\vec{p}_t$, and $\vec{p}_a$, according to equations 3-6.

$$\vec{r}_{cable} = \vec{p}_t - \vec{p}_a \quad (3)$$
$$\vec{r}_{loa} = \vec{r}_{cable}/\|\vec{r}_{cable}\| \quad (4)$$
$$\vec{r} = \vec{p}_t - \vec{p}_{sjc} \quad (5)$$
$$\vec{r}_{ma} = proj_{XZ}(\vec{r}) \times proj_{XZ}(\vec{r}_{loa}) \quad (6)$$

In the above equations, $\vec{r}_{cable}$ represents the orientation of the cable between attachment points (Figure 1B), $\vec{r}_{loa}$ represents the unit vector describing the cable's line of action, $\vec{r}$ represents the vector from the shoulder joint center to the torso attachment point ($\vec{p}_{sjc}$ to $\vec{p}_t$, Figure 1B), and the notation $proj_{XZ}$ indicates a projection onto the XZ plane within which shoulder flexion occurs. Finally, theoretical cable force was computed using equation 7 to solve for the force required to balance the gravitational moment given the magnitude of the cable moment arm, $\|\vec{r}_{ma}\|$.

$$F_c = M_g/\|\vec{r}_{ma}\| \quad (7)$$

## RESULTS

The mechanical testing demonstrated that cable forces up to 91.6 N are required to balance the arm against gravity. This maximum experimental cable force was 2.2 times greater than the theoretical maximum cable force (41.7 N). Flexion angle at maximum force was comparable between theoretical results (96.4˚) and experimental results (90.6˚).

In general, experimental forces were higher than theoretical forces during the elevation phase of the motion (Figure 2). The largest instantaneous cable force error in this phase was 52.8 N. During the descent phase, experimental forces were generally lower than theoretical forces. Furthermore, experimental forces matched theoretical forces more closely during the descent phase at arm angles below 90˚. Experimental forces were within 17.4 N of the tracked theoretical force during this phase of the motion.

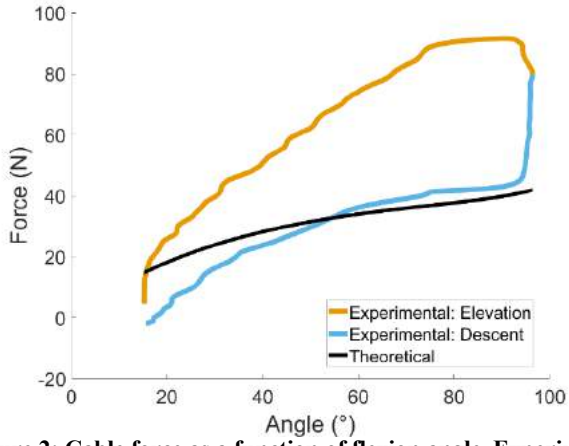

**Figure 2: Cable force as a function of flexion angle. Experimental forces during the elevation phases (before maximum angle has been reached) are shown in orange; experimental forces during the descent phase are shown in blue. Theoretical cable forces are shown in black.**

## DISCUSSION

This study benchmarked cable forces required for a shoulder-assistive exosuit. Required cable forces were larger than predicted to counteract gravitational moments alone, and therefore this basic model requires further development. These discrepancies can be reduced by accounting for friction forces or attachment point movement in the model. Alternatively, these factors can be mitigated by improving the design of the device.

The results of this study were comparable to prior studies. Kesner et al., 2011 developed a cable-driven shoulder-assistive exosuit that required cable forces of approximately 80 N at arm angles near 80˚ to lift a robotic arm with the same mass as the mannequin's arm in this study (1.6kg). The exosuit in this study also exhibited significant hysteresis, similar to prior cable-driven shoulder exosuits [6,7]. This hysteresis is likely due to friction at the cable attachment points.

The choice to conduct mechanical testing on a mannequin posed both benefits and limitations. Benefits of this approach include a repeatable test setup and the ability to restrict arm movement to a single degree of freedom. Limitations of the mannequin include evaluation of only a single body size and shape, not representing the mechanical effect of body tissues interfacing with the exosuit, and not representing the mass of the body.

This study demonstrated that this exosuit exhibits comparable mechanical behavior to prior exosuits. The mechanical performance data measured in this study also provided a reference to guide future design iterations and establish requirements for actuation.

# MITRAL VALVE PARAMETERIZATION

**Shelley C. Gooden (1), Mani A. Vannan (2), Konstantinos D. Boudoulas (3), Vinod H. Thourani (2), Pradeep K. Yadav (2), Lakshmi P. Dasi (1)**

## INTRODUCTION

The mitral valve is an essential component of the left heart and is composed of an annulus, the anterior and posterior mitral leaflets (AML and PML), chordae tendinea, and two papillary muscles. The PML most commonly shows all three scallops, where the P2 scallop is in the center scallop and the P1 and P3 scallops surround P2. However, anatomical features of the mitral valve vary from patient to patient.

In assessing mitral valve therapies, there is a need to parameterize the mitral valve during diastole for a geometry resembling the human mitral valve that is not patient specific.

Although others have parameterized the mitral valve as a representative model, these models are highly idealized and do not faithfully capture human mitral leaflet morphology [1, 2, 3]. For example, in 2017, Shen et. al. [4] developed a parameterized mitral valve. While key dimensions characterizing the mitral valve model fell within known ranges, the final geometry did not resemble a human mitral valve; the annulus was fully planar, the leaflets were perpendicular to the annulus, and the leaflets were over-simplified as a semi-ellipse lying perpendicular to the annular plane.

The objective of this study is to develop a framework for parameterizing the human mitral valve with a goal of simplifying without over-simplifying.

## METHODS

The mitral valve was segmented using Materialize Mimics in diastole from four patient CT scans with no known mitral lesion, and points were extracted to form the annulus, AML free-edge, and PML free-edge.

Of these, key points for parameterization were selected to define the annulus and leaflets. For the annulus, these points included the two commissures, the center of the anterior annulus, and the center of the posterior annulus.

For the AML, key points included the connection between the AML and PML, the corner of the AML, and the central tip of the AML. For the PML, key points included the connection between the AML and PML, the P1/P3 length, the connection between P1/P3 to P2, the corner of P2, and the P2 length.

Figure 1 shows an example of the mitral valve geometry with overlayed points (red) and key points for measurement (black).

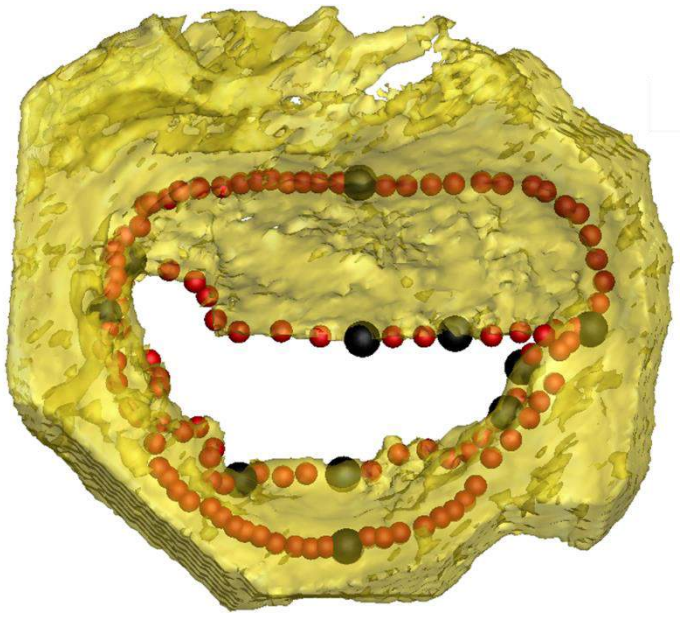

**Figure 1: Mitral Valve Geometry (yellow) with Overlayed Points (red) and Key Points (black)**

To parameterize the valve, the annular commissural and septolateral dimensions as well as the angle between the anterior and posterior annulus segments were calculated, assuming a symmetric valve, and each segment was defined as a partial ellipse. The leaflet free-edge curvature was defined using the Modified Amika interpolation.

## RESULTS

The raw points and parameterized mitral valve points are shown for one patient in Figure 2.

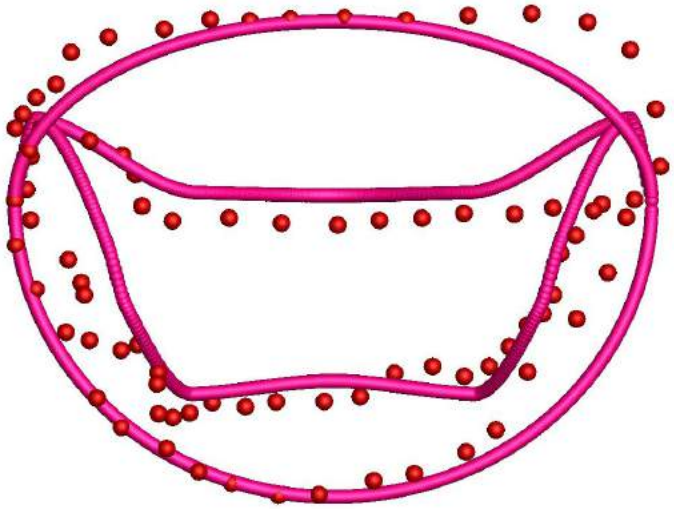

**Figure 2: Raw and Parameterized Mitral Annulus, Anterior Leaflet, and Posterior Leaflet**

To assess the fit of the parameterized model, root mean square error (RMSE) was calculated as in Eq 1, where $p_i - \hat{p}_i$ is the distance between the raw point $p_i$ and the closest parameterized point $\hat{p}_i$.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(p_i - \hat{p}_i)^2}{N}}i \quad (1)$$

RMSE values for each patient are noted in Table 1 for the annulus, AML, and PML.

**Table 1: Root Mean Square Error for Each Patient**

| Patient | Annulus [mm] | Anterior Leaflet [mm] | Posterior Leaflet [mm] |
|---|---|---|---|
| 1 | 1.45 | 2.93 | 1.94 |
| 2 | 1.25 | 4.28 | 4.20 |
| 3 | 1.88 | 4.39 | 6.98 |
| 4 | 2.40 | 4.39 | 2.98 |

RMSE for the annulus was 1.45 mm, 1.25 mm, 1.88 mm, and 2.40 mm for patients 1, 2, 3, and 4, respectively. RMSE for the AML was 2.93 mm, 4.28 mm, 4.39 mm, and 4.39 mm for patients 1, 2, 3, and 4, respectively. RMSE for the PML was 1.94 mm, 4.2 mm, 6.98 mm, and 2.98 mm for patients 1, 2, 3, and 4, respectively.

## DISCUSSION

Looking at the RMSE values, parameterization for the annulus had the best match for each patient compared to the leaflets. The AML and PML had more variability between the patient anatomy and the smoothed geometry, reaching up to 6.98 mm for patient 3's PML. This is likely because the valve was assumed to be symmetric, and the annulus has a simpler, more symmetric geometry while the AML and PML have more asymmetry and variability.

However, deviation of the parameterized geometry and patient geometry is expected because the goal is to parameterize without adding too many points, which would instead lead to recreation of the patients' individual anatomy.

Results from this study expand the current parametric modeling of mitral valves to better incorporate the leaflet free-edge curvature and allow for simplification of the mitral annulus and leaflets while being representative of the patients' anatomy.

Limitations to address in continuing work on this model include that the assumption that the mitral valve is symmetric. The annulus was defined using only four points, and the shape can better match patient geometry if more points were used. Only seven points were used to define the leaflet free-edge curvature, which should be expanded to better capture leaflet features, perhaps with an alternative interpolation function. Lastly, this model focused on the mitral valve and leaflet free-edge and does not yet include curvature of the leaflet belly.

Improvement of this model along with normalization can provide a representative mitral valve geometry for which mitral therapies can be assess, whether by computation simulations or *in vitro* testing.

# EFFECT OF SMOOTH MUSCLE TONE AND AGE ON BIAXIAL MECHANICS OF THE MURINE VAGINA

**Shelby White (1), Qinhan Zhou (1), Kristin Miller, Ph.D. (1)**

(1) Biomedical Engineering, Tulane University, New Orleans, Louisiana, USA

## INTRODUCTION

Increased age is associated with higher risk of vaginal tearing during childbirth [1]. While the etiology of the increased risk is not known, remodeling of the vaginal extracellular matrix (ECM) may contribute. The ECM is comprised of collagen and elastic fibers, which provides tensile strength and recoil, respectively. In addition to vaginal contractions, smooth muscle cells (SMCs) provide structural and functional integrity to the vaginal wall. Biaxial extension-inflation protocols are useful tools to evaluate SMC responses, including the baseline contractile potential in the absence of external stimuli (basal tone) as well as the behavior of the vagina without tone wherein the collagen and elastic fibers are the main contributors of the mechanical properties. Towards this end, our prior work showed that vaginal stiffness increases with age [2] and that the 4–6-month murine vagina demonstrates increased stiffness in the absence of SMC tone [3]. However, it is unknown if SMC basal tone contribution changes with reproductive aging, which may be important to delineate potential structural processes that may contribute to increased vaginal tear risk [4]. Therefore, the objective of this study was to quantify the biaxial mechanical properties of the vagina with increasing age and smooth muscle tone. We hypothesized that the vagina materially stiffens in the absence of SMC tone, and with increased reproductive age. Additionally, we hypothesized that the vagina is materially stiffer in the circumferential direction.

## METHODS

A total of n=32 CD-1 mice aged 2-3 months (n=8), 4-6 months (n=8), 7-9 months (n=8), and 10-14 months (n=8) were utilized within this study (Tulane IACUC approved) (Figure 1A) [5]. Mice at estrus were weighed using a digital scale and euthanized via guillotine without anesthesia. Vaginal tissue was dissected from the cervovaginal complex and cannulated onto an extension-inflation device (Danish MyoTechnololgy, Denmark) [3]. The extension-inflation device was filled with active Krebs Ringer Buffer (KRBs), which allowed for smooth muscle cells to maintain contractile function (tone). A water bath heated the KRBs testing media at 37 degrees Celsius throughout the test and aerated the media with 95% oxygen and 5% carbon dioxide to maintain pH near 7.4. The unloaded configuration was identified as previously described, followed by determining the physiologic length wherein the transducer-measured axial force remained constant over an increasing range of pressure [6] (Figure 1B). After a 10-minute equilibration period, the vagina was subjected to cyclic pressure diameter protocols over a range of physiologic pressures (0-15 mmHg) at the physiologic length and about -2% and +2% of the length. Smooth muscle tone was removed by adding 2 mM of a calcium-chelating agent, egtazic acid (EGTA), to the organ bath. The organ was then incubated for 30 minutes. The KRBs solution was replaced with passive KRBs, which does not contain calcium and therefore limited the contractile function of smooth muscle cells. After smooth muscle tone was removed, pressure-diameter testing was then conducted as described above (Figure 1C). The material stiffness in both the circumferential and axial direction were calculated by using the MATLAB polyfit linear function to define the region from the lower physiologic bound (LPB) and upper physiologic pressure boundary (UPB), which corresponded to +/- 1 standard deviation of the physiologic pressure (Figure 1D, Figure 1E). Statistics were performed using R software (version 3.6.2). To ensure normality, Shapiro-Wilks tests were completed for each data set. Separate 3-way ANOVAs (age, direction, tone) evaluated potential differences in the material stiffness and physiologic stress of the vagina in both the circumferential and axial directions. Data reported as mean +/- standard error of mean herein.

## RESULTS

**Material stiffness:** A 3-way ANOVA (age, direction, tone) observed significant differences in material stiffness with respect to age ($p<0.001$) and direction ($p<0.001$). The interaction between age and direction was also statistically significant ($p<0.001$).

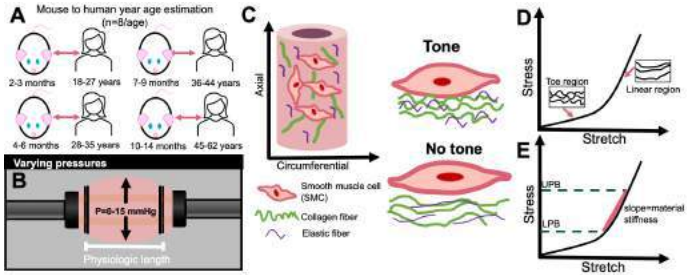

**Figure 1: A total of 32 female CD-1 mice at estrus were used (A; human year age correlations) [5]. Extension-inflation protocols were employed to characterize the vagina with smooth muscle tone (B; basal conditions) and without tone (passive). Further, it was hypothesized that the two conditions will be statistically different due to potential SMC contractile function (C). When SMCs relax (no tone), it was hypothesized that the load during mechanical testing transferred to collagen and elastic fibers and results in subsequent uncrimping or straightening of the fibers. This change in fiber geometry may contribute to material stiffening of the vagina with no tone, which was assessed using stress-stretch curves (D). The material stiffness was determined as the slope between the physiologic pressure range (UPB, LPB), which corresponded to +/- 1 standard deviation of the physiologic pressure (E).**

Post-hoc tests were not performed due to the significant interaction between age and direction. In both the circumferential and axial direction, the material stiffness increased with increased reproductive age (Figure 2A, 2C). Further, the material stiffness was greater in the circumferential direction (Figure 2A) than that of the axial direction (Figure 2C). Smooth muscle tone demonstrated a statistical trend although was not statistically significant (p=0.1). **Physiologic stress**: A 3-way ANOVA (age, direction, tone) identified statistical differences in the physiologic stress with respect to age (p<0.001), tone (p=0.004), and direction (p<0.001). Further, the interaction between age and direction was statistically significant (p<0.001). Post-hoc tests were not performed due to the significant interaction. In both the circumferential and axial direction, the physiologic stress increased with the removal of smooth muscle tone (Figure 2B, 2D). Furthermore, the stress values increased with increased reproductive age.

## DISCUSSION

The contribution of smooth muscle tone to the physiologic stress was statistically significant. Without SMC contraction, the initial load is likely born by collagen fibers, which may result in a decrease of collagen undulation, thus increasing the resistance to loading and subsequent calculated tissue stress in the passive state or the conditions without smooth muscle tone [4]. Further, similar findings were reported in the arterial wall and thought to be the result of smooth muscle cells transferring the load to the fibrous components of the extracellular matrix [4]. Herein, the smooth muscle tone contribution to vaginal material stiffness was identified as a statistical trend. However, a power analysis suggested a sample size of 14 mice would be needed to provide statistical significance for the role of basal tone.

Reproductive age as well as an interaction between age and direction were observed to be statistically significant in the material stiffness and physiologic stress of the vagina. Similarly, our prior work reported that material stiffness in the passive conditions increased with reproductive age [2]. In both conditions, the increased material stiffness may result from changes in the microstructural composition or organization of the vagina with aging. Similar findings were denoted in human cadaveric pelvic floor samples due to accumulation of collagen and advanced glycation end products [7]. To date, changes in the vaginal ECM content and organization that occurs during reproductive aging remain unknown.

Further, direction was observed to be a statistically significant factor for vaginal material stiffness and physiologic stress. This anisotropic behavior may be due to the fibrous ECM components and SMCs organization as well as the direction specific innervations of the vagina [8]. Clark et al detailed that in the C57BL/6 mouse, the elastic fiber area fraction was greater in the axial plane as compared to the circumferential and that collagen fibers were highly aligned towards the circumferential plane [3]. Thus, the vaginal composition likely contributes to the anisotropic characterization, though further work is needed to confirm the vaginal organization in the circumferential and axial planes in the CD-1 mouse.

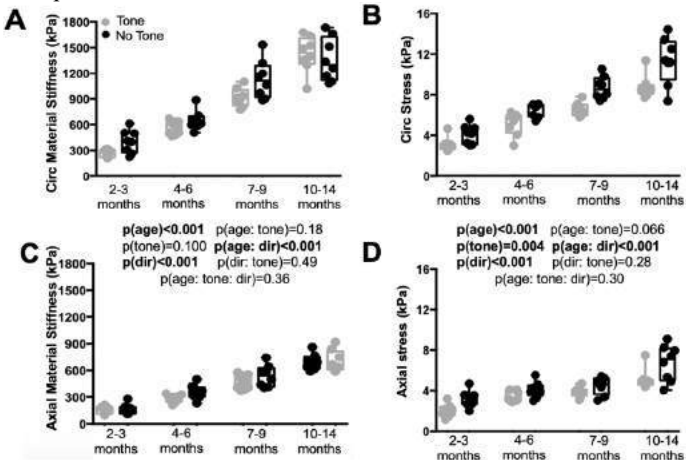

**Figure 2: The material stiffness in the circumferential (A) and axial (C) direction under smooth muscle tone (grey) and no tone (black) conditions for each age group. The 3-way ANOVA (age, direction, tone) observed statistical differences among age (p<0.001), direction (p<0.001), but not tone (p=0.10). Post-hoc analysis was not performed due to significant interactions among age and direction (p<0.001). Additionally, the physiologic stress of the vagina was assessed with tone and without tone in the circumferential (B) and axial direction (D). A 3-way ANOVA (age, direction, tone) observed that age (p<0.001), direction (p<0.001), and tone (p=0.004) were all statistically significant. Post-hoc tests were not performed due to significant interactions (p<0.001) among age and direction.**

**Conclusion**: Characterizing the direction-dependent mechanical properties of the vagina as a function of increasing reproductive age and tone may provide insight to how structural changes alter the functional integrity of the vagina. Future experiments for this study include investigation of how the vagina remodels with age during postpartum healing as well as immunostaining of the vagina to better elucidate the biochemical underpinnings of the biomechanical findings. Such studies are crucial towards developing therapeutics to better aid older mothers during childbirth or other age-related reproductive pathologies.

# ROLE OF MICROTUBULES IN RIGHT VENTRICLE ANISOTROPIC VISCOELASTICITY WITH PULMONARY HYPERTENSION DEVELOPMENT

**Kristen E. LeBar (1), Wenqiang Liu (2), Kellan Roth (1), Matt Ahern (1,2), Erith Evans (1,2), Jassia Pang (4), Jessica Ayers (4), Adam Chicco (2,3), Zhijie Wang (1,2)**

## INTRODUCTION

Heart failure (HF) is the leading cause of death in both the US and worldwide. The nonlinear, anisotropic elasticity of the ventricular wall directly impacts the diastolic function [1]. But the ventricle is viscoelastic, which means that two types of resistant forces exist during diastole: elastic and viscous resistance [2]. Viscous resistance originates from the sliding of molecular bonds and works as a 'damper' to cause a delay between the force and deformation, which leads to strain- and time-dependent behavior. However, current studies of ventricular biomechanics mainly focus on the elastic property and the viscous behavior is less known. Moreover, the anisotropic viscoelasticity of right ventricle (RV) has not been studied despite an increasing awareness of the importance of this organ. Therefore, our overall goal was to investigate the viscoelastic behavior of the RV tissue in healthy and diseased states.

Microtubules in the cardiomyocytes (CM) are key elements contributing to myofiber viscoelasticity, and destabilizing microtubules reduces CM viscoelasticity [3,4]. Microtubules are increased in HF progression including the RV failure. However, prior studies investigated CM or myofiber viscoelasticity in 1D, at the cellular level. How exactly the microtubules affect entire tissue's anisotropic viscoelasticity is unclear. The aim of this study was to investigate the role of microtubules in RV anisotropic, viscoelastic behavior in healthy and failing RVs induced by pulmonary hypertension (PH). We hypothesize that the PH leads to increased viscoelasticity of the RV only in the longitudinal direction, and the microtubules contribute significantly in RV tissue elasticity but not viscosity.

## METHODS

All procedures were approved by Colorado State University IACUC. Adult male Sprague-Dawley rats were treated with single monocrotaline (MCT) (60 mg/kg) injection and then housed in normal condition for 3 weeks to induce PH, and intact healthy rats served as control (CTL). RV function was quantified by echocardiography and in vivo pressure-volume (PV) measurements as described previously [5]. After euthanasia, RV free wall, was placed and dissected in cardioplegic solution (CPS) and then placed in a 30mM 2,3-butanedione monoxime (BDM) bath at body temperature (37C) for 30 minutes to remove the active contraction of the myocardium. The RV underwent equibiaxial stress relaxation testing to obtain passive, biaxial viscoelastic behavior of the tissue. The tissue was stretched at 20% of strain and with physiological stretch rates (ramp speeds) of 5 and 8Hz to mimic resting and exercised heart rates, using an in-house biaxial tester. Preconditioning and tissue relaxation were included before and after data collection. The tissue was then treated by colchicine (0.3mM) for 30 minutes and the same mechanical tests were performed. Relaxation modulus and normalized stress at 0.01 s after reaching peak stress were derived to quantify RV elasticity and viscosity, respectively. These methods were established previously [6]. Student t test was performed.

## RESULTS

***RV Failure Establishment in MCT rats***

In vivo RV function measurements showed the development of PH and RV failure in the MCT rats (**Table 1**). Marked RV dilation and decreased fractional shortening confirmed the development of RV failure (n=8/group). PV loop measurements with fewer samples (n=3/group) also implied declines in cardiac output, load-independent contractility (Ees) and ventricular-vascular coupling (Ees/Ea).

***PH led to increased viscoelasticity in longitudinal direction only***

In the intact RVs (at baseline), PH development led to a trend of increased relaxation modulus (**Fig. 1A**) and significantly increased normalized stress (**Fig. 2A**) in the longitudinal direction. There was no change of viscoelasticity in the circumferential direction, though (**Figs. 1B&2B**).

***Colchicine affects RV anisotropic viscoelasticity differently in healthy and failing RVs***

We firstly examined the effect of colchicine on RV elasticity (**Fig. 1**). We observed a significant decrease in elasticity after colchicine treatment in healthy RVs in the longitudinal direction, but not the circumferential direction. In the failing RVs, though, there were significant decreases in elasticity after colchicine treatment in both directions. The percent reduction in elasticity after colchicine treatment was similar between groups and between directions, indicating a similar contribution of microtubules to RV anisotropic elasticity.

Next, we examined the effect of colchicine on RV viscosity (**Fig. 2**). Unexpectedly, we did not observe significant changes in viscosity after colchicine treatment in either group or in either direction, although there was a trend of increasing viscosity in the circumferential direction in the MCT RVs (p=0.07). As a result, the MCT RVs exhibited significantly higher viscosity than CTL RVs after colchicine treatment (**Fig. 2B**). Alternative to the elasticity, the percent changes in viscosity between groups or between directions were marginal and the trends were inconsistent. This suggests an insignificant contribution of microtubules to RV viscosity in both healthy and diseased states.

**Table 1: Function Measurements in Healthy and MCT RVs.**

| **RV Function (Echocardiography)** | **CTL** | **MCT** |
|---|---|---|
| End-Diastolic Diameter (cm) | 0.18 ± 0.03 | 0.30 ± 0.06 * |
| End-Systolic Diameter (cm) | 0.11 ± 0.01 | 0.21 ± 0.05 * |

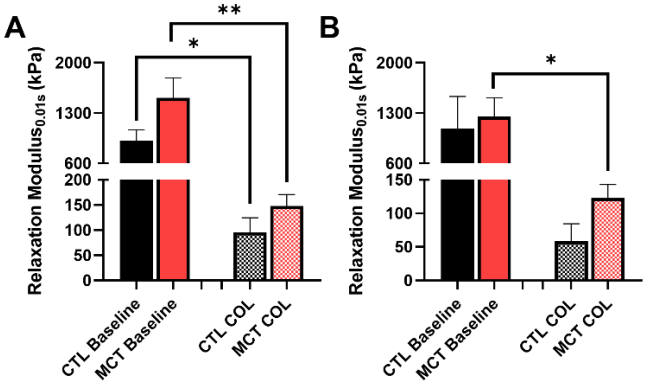

**Fig 1:** Relaxation modulus of CTL and MCT RVs before (baseline) and after colchicine (COL) treatment in the (A) longitudinal direction and (B) circumferential direction. N=4-5 per group. *<0.05, **<0.01.

## DISCUSSION

To our knowledge, this study is the first to quantify passive, anisotropic viscoelasticity of RV tissue by biaxial stress relaxation tests. A critical setting that we applied in the tests is to match the ramp speed to represent the diastolic stretch-rate in the rat species. This protocol will enable us to observe more physiologically relevant viscoelastic behavior of the RV. The equibiaxial mechanical test allows us to obtain anisotropic viscoelastic behavior of the RV, which is impossible for the 1D myocyte or myofiber force-length tension curve measurement.

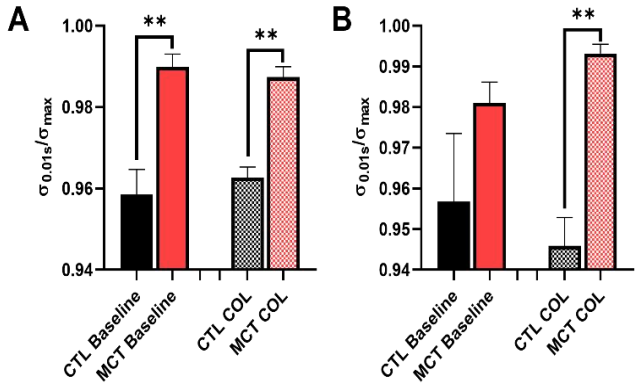

**Fig 2:** Normalized stress of CTL and MCT RVs before (baseline) and after colchicine (COL) treatment in the (A) longitudinal direction, and (B) circumferential direction. N=4-5 per group. *<0.05, **<0.01.

Firstly, we observed that the PH development did not result in equal changes in the viscoelasticity in both directions. Instead, the increases in elasticity and viscosity in the MCT group were more pronounced in the longitudinal direction than the circumferential direction. Like in the discussions on cardiomyocyte hypertrophy, it is yet unclear if the mechanical changes of ventricles are an adaptation or maladaptation of the RV. The implications of anisotropic viscosity in RV function awaits further investigation.

Second, our results from colchicine treatment demonstrated a significant impact of microtubules on RV elasticity but only marginal effect on RV viscosity. In isolated CM studies, it is found that colchicine treatment reduced viscosity and elasticity significantly [3,5], suggesting a role of microtubules in CM viscoelasticity. But the contribution at cell level seems to not translate to the tissue level. Microtubule depolymerization caused no change in healthy RV viscosity but a trend of increased viscosity in the circumferential direction in the failing RV. This suggests that microtubules do not play a major role in RV viscosity at the tissue level. Other components are contributing more greatly to tissue viscosity than cardiomyocytes, especially in diseased RV.

Additionally, our findings suggest that microtubules are contributing significantly to RV tissue elasticity. The marked drop (~90%) in elasticity after colchicine treatment suggests that microtubules (or cardiomyocytes) rather than other components (e.g., titin, collagen) play a major role in RV elasticity. This finding is consistent with prior studies on hyperelastic behavior of myocardium that shows the myofibers are dominant factors in determining tissue stiffness than collagen fibers. Further study with a larger sample size is needed to confirm these findings.

In summary, in this work we measured the anisotropic viscoelastic property of RV in healthy and diseased states. The role of microtubules in these RVs was examined and distinct impacts on elasticity and viscosity were observed. These findings will deepen the understanding of biomechanical mechanism of RV failure.

# OVERSTRETCH-INDUCED SOFTENING IS INDEPENDENT OF STRAIN RATE IN CEREBRAL ARTERIES

**Noah R. Pearson (1), Gregory M. Boiczyk (2), Kenneth L. Monson (1,2)**

(1) Mechanical Engineering, University of Utah, Salt Lake City, UT, USA
(2) Biomedical Engineering, University of Utah, Salt Lake City, UT, USA

## INTRODUCTION

Mechanical damage is common in arteries following both trauma and surgical intervention. This damage is considered to primarily affect the collagen fibers [1], consistent with various histologic examinations demonstrating structural damage in the collagen [2]. We previously characterized mechanical softening following quasi-static (QS) overstretch of cerebral arteries [3] and used a collagen-hybridizing peptide (CHP) [4] to identify denatured tropocollagen following such overstretch [5]. We then predicted the amount of tropocollagen denaturation from mechanical softening data in a continuum damage model [6]. Further, we showed that high strain rate vessel rupture significantly reduces the amount of tropocollagen denaturation relative to QS failures [7].

Similar rate-dependent shifts in tropocollagen damage patterns have been previously observed in tendon (e.g. [8-10]). Furthermore, rate-induced changes in the ratio of fibril to tissue strain have been identified in tendon [11, 12]. These rate-changes in microstructure mechanics have been attributed, in part, to the interfibrillar proteoglycans [12, 13].

Given the apparent rate-dependent shift in collagen damage mechanisms, and the importance of collagen fibers in the mechanical response of arteries, we speculate that the rate of subfailure overstretch may affect the subsequent mechanical response, including softening, of tissue. Additionally, with the theory of interfibrillar proteoglycan damage, we hypothesize that high strain rate overstretch affects the subsequent high-rate response of a vessel more severely than its QS response, and conversely, that QS overstretch softens the subsequent QS response of the tissue more than its high-rate response. In the present work, we characterize the baseline rate-stiffening response of cerebral arteries, overstretch them to various magnitudes over a range of strain rates, and then recharacterize their rate-stiffening baseline response.

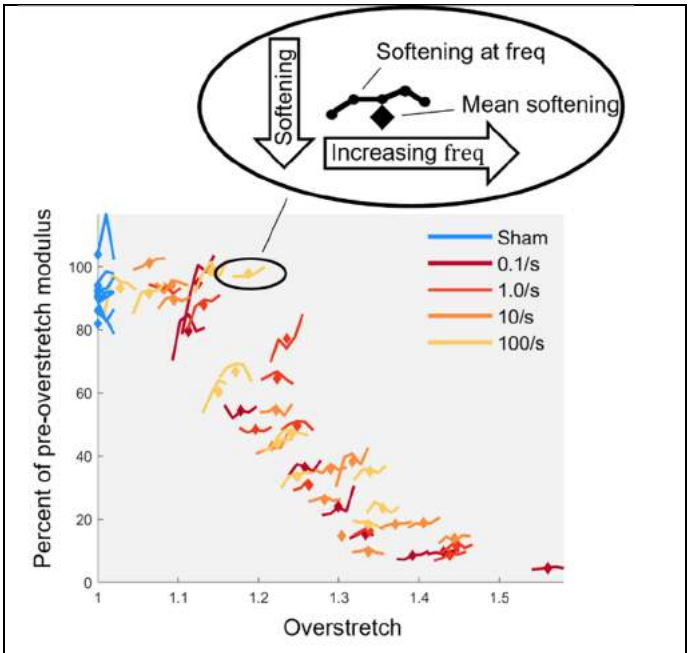

**Figure 1 Softening (characterized as reduction of dynamic modulus) at each characterization frequency as a function of overstretch (x-axis) and overstretch rate (color). For interpretation, each set of data corresponds to one sample. As the accompanying schematic illustrates, if each dataset is likened to a bird, the bird's body represents the mean extent of softening (over all characterization frequencies), while its wings, from left to right, correspond to softening values at increasing characterization frequencies.**

## METHODS

Göttingen minipigs (24-26 weeks old) were euthanized by Beuthanasia under the approval of the University of Utah Animal Care and Use Committee. The brains were removed from the skull, and the middle cerebral arteries (MCAs) were resected from the brain. Side branches were ligated, and rings were cut from either side of the sample and imaged to provide a reference cross-sectional area. Samples were then mounted onto cannulas on the testing apparatus. Vessels were preconditioned by oscillating luminal pressure between 50 and 150 mmHg five times at incrementally increasing axial stretch levels up to the *in vivo* length, defined as the axial stretch where changes in luminal pressure did not change axial force. A final preconditioning cycle was applied at 1.05 times the *in vivo* length.

The baseline rate-stiffening response of the vessels was evaluated using axial stretch cycles conducted at five different frequencies (giving maximum strain rates of 0.1, 0.31, 1.0, 3.1, and 10 $s^{-1}$) around three mean stretch values ($\lambda_{IV}$ = 0.95, 1.00, 1.05). Samples were then overstretched, with a single ramp, at strain rates ranging from 0.1 to 100 $s^{-1}$ to a maximum stretch value ranging from 1.1 to 1.4 times the *in vivo* stretch. Sham vessels were not overstretched. Following overstretch, the rate-stiffening baseline response was recharacterized.

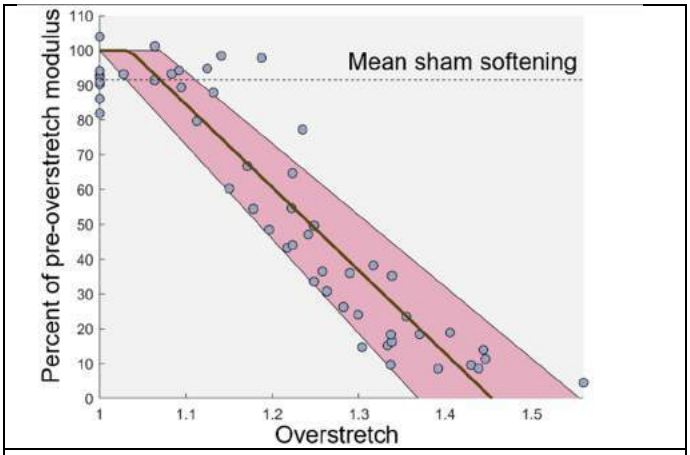

**Figure 2 Mean softening data as a function of overstretch magnitude. A regression line with 95% confidence intervals is plotted over the softening data.**

First Piola-Kirchoff stress was used to define stress, and stretch was calculated as the suture-to-suture stretch ratio. Dynamic modulus at each characterization frequency, calculated as the peak-to-valley stress divided by peak-to-valley strain, was used to define rate-stiffening response. Post-overstretch dynamic moduli were divided by pre-overstretch moduli at corresponding frequencies to quantify softening as a function of overstretch rate, overstretch magnitude, and characterization frequency.

Final overstretch magnitudes did not fall neatly into the targeted bins, preventing the use of discrete statistical techniques such as ANOVA. We thus used linear regression to evaluate the effect of the independent variables on the observed softening in the samples. A p-value assessing the difference between each variable's scaling coefficient and zero was calculated to determine statistical significance.

## RESULTS

As in our previous work, Figure 1 shows a clear pattern of increased softening with overstretch, but we did not find any effect of overstretch rate or characterization frequency on softening. This is presented visually in Figure 1, where softening values are plotted as a function of overstretch, overstretch rate, and characterization frequency. These visual observations are reinforced by the linear regression model, where only the scaling parameters on overstretch and the intercept were significantly different than zero.

Based on these initial observations that overstretch rate and characterization frequency did not affect softening, we performed another linear regression wherein the mean (all frequencies) softening values were predicted entirely by overstretch (Figure 2). In this case, we find good agreement between the overstretch and the amount of softening. We thus conclude that softening is independent of both the rate of overstretch and the rate of characterization.

As noted in Figure 2, sham vessels softened (between the baseline characterization and the recharacterization) to an average of 91.5%, indicating that a certain level of inelasticity was induced by the characterization process.

## DISCUSSION

The objective of this study was to examine the influence of overstretch rate and characterization frequency on extent of cerebral artery softening. Results show that while overstretch influences vessel softening, neither overstretch rate nor characterization frequency does.

These findings run counter to our hypothesis and seem to be inconsistent with the previously identified rate-induced reduction in molecular-level collagen damage [7]. While the implications of this are not yet fully understood, there are several points worthy of discussion. The first is that the present results appear to challenge the effect of tropocollagen denaturation on mechanical softening implied by our previous work with Marino *et al.* [6]. Tropocollagen denaturation may not directly cause softening, though it is clearly correlated with it following QS overstretches. While there is a paucity of research on fibril-to-tissue stretch ratio in arteries, this ratio has been shown to be on the order of 3.75% of the total tissue strain [14]. The collagen fibrils themselves thus do not actually account for much of the global tissue stretch in arteries. The non-collagenous interfibrillar matrix can be expected to contribute substantially to the mechanics of the tissue, perhaps reinforcing our present findings.

The present results also suggest that strain rate may be used as a design parameter to target damage in different parts of the ECM while maintaining the desired softening of the tissue. This could prove to be useful in angioplasty, wherein softening of the vessel is desirable, yet post-intervention inflammation is unwanted.

## INTRODUCTION

Age related fractures are an increasing challenge in terms of healthcare costs and quality of life. In this study, a method is described for evaluating fracture mechanics in bone using in-situ three-point bend testing in a 3D X-ray microscope. The microstructure of bone is composed of layers of mineralized collagen fibrils with elongated tubular voids that result in a condition where crack growth deviates from an idealized planar crack. Studies on fracture of human and animal bones have used optical imaging and scanning electron microscopy (SEM) imaging to determine crack length during loading, yet this limits crack measurements to the surface [1]. Bone fractures have also been investigated with synchrotron imaging, yet this requires access to a central beamline which can prove challenging for use with fresh human bone tissue [2]. We investigated an alternative experimental approach that permits in-situ analysis of fracture mechanics by combining loading and imaging. We employed a mechanical loading state (CT5000 Deben) within a 3D X-ray microscope (XRADIA Zeiss). To date, evaluations of post-loading 3D crack geometry with this instrumentation have occurred following loading, but the combination of in-situ loading and imaging applied to cortical human bone has not been previously documented.

## METHODS

Sample Preparation. Human femur bones were obtained from unembalmed cadavers through the Indiana University School of Medicine body donation program. Femurs were kept frozen at -20 ºC until processing. The femurs were cut into 35 mm sections from the diaphysis and then processed into 4 x 4 x 33 mm beams using a low-speed saw under irrigation with Phosphate Buffered Saline (PBS) (Buehler Isomet, Sigma Aldrich). Frozen beams were transported wrapped in PBS-soaked gauze on dry ice for scanning. Beams were stored at -20 ºC; Prior to an experiment, bone tissue was thawed at 4 ºC overnight. Samples were notched by hand using a 0.02 mm thick saw. A pre-crack was created at the root of the notch using a repeated motion with a razor blade. All notching was done under irrigation of 0.2 µm diamond slurry (Buehler).

Loading and Imaging. Beams were kept in PBS-soaked gauze until immediately before testing. A Deben CT5000 displacement-controlled load rig fitted with a three-point bending fixture (Deben UK Ltd) was assembled in a Zeiss XRADIA Versa 510. Bone beams are loaded into the Deben fixture with the notch centered under the middle rod. The system was brought to a 5 N touch load to set all X-ray parameters. Loading was conducted at a displacement rate of 0.1 mm/min with a data sample rate of 100 ms. During loading, 2D through thickness X-ray images were taken in succession at 80 kV, 7 W, with a pixel size of 5 µm, and 1 s exposure time. After crack instability but retaining the applied displacement of the load rig, a 3D X-ray scan of the beam under load was performed with 80 kV, 7 W, with a pixel size of 5 µm, 5 s exposure time, and 2401 projections.

Post-Processing. Images were reconstructed using the XRM Data Explorer, and then exported as tiff files. Fiji was used to analyze all X-ray images [3]. Window leveling techniques with a greyscale threshold intensity, $I$, were used to determine crack tip location. Crack lengths were correlated with load, $F$, and stress intensity factors, $K(a)$, were calculated following ASTM methods [4]. Using the crack extension, $\Delta a = a - a_0$, and stress intensity factor, $K$, crack growth resistance curves, $K(\Delta a)$, are determined. From these plots, the blunting onset, $K_b$, the slope of the blunting line $T_b$, the crack initiation toughness $K_{ini}$, and tearing modulus $T_t$ can be obtained. During blunting, irreversible deformation processes in the tissue cause deformation of the initial (sharp) crack. Tearing occurs when continuous tissue is separated by the crack propagation. 3D image segmentation was conducted in Dragonfly (Object Research Systems); region of interest (ROI) tools were used to segment the crack and analyze geometry. In this abstract, one representative experiment is described; work on a larger number of samples is ongoing.

SB³C2022-360

## RESULTS

Changes in the X-ray attenuation properties of virgin and damaged bone tissue enable visualization of the processes (blunting and material separation) at the crack tip by using changes in the pixel intensity. Figures 1 and 2 contain 2D through thickness X-ray images obtained during the in-situ experiment. 2D X-ray images (Figure 1A-C) taken at several instances during loading visualize an effective, through thickness, crack advance. Differences in X-ray attenuation properties, as void-spaces are formed by fracture propagation, are thereby translated into changes in pixel intensity (Figure 2). This in turn enables the measurement of the crack propagation path within the beam. The resulting crack growth resistance curves (Figure 3) distinctly depict the blunting onset, blunting, crack initiation and tearing: $K_b$=4.9 MPa√m, $T_b$=201 x $10^3$ MPa/√m, $K_{ini}$ = 13.90 MPa√m, and $T_t$=40.2 x $10^3$ MPa/√m. Full details of the crack geometry are obtained from full 3D scans of the specimen while under load. Figure 4 depicts sections of a complete 3D reconstruction of the sample after crack instability but still under load. Image segmentation is used to highlight the crack path. The effective crack path obtained from the 2D x-ray (Figure 2B) is comparable to that of the specimen interior (Figure 4B). Images of the surface (Figures 4A,C) provide only limited information of the effective crack advance.

## DISCUSSION

We demonstrate the use of a 3D X-ray microscope with an in-situ load rig for the evaluation of bone fracture behavior of human cortical bone. We thereby, can measure both an effective crack advance (by use of 2D through thickness x-rays) as well as the full 3D-shape of the crack under load. In particular, using the 2D-xray images we are able to provide distinct measurements of the blunting and tearing resistance of a cortical bone tissue. We show that imaging in an X-ray microscope used in combination with in-situ loading allows for visualization of the complex fracture geometry within bone tissue.

# MEASURING THE ANISOTROPIC MECHANICAL PROPERTIES OF SINGLE NEONATAL MOUSE CARDIAC MYOCYTES

## INTRODUCTION

Congenital heart defects and subsequent surgical interventions alter the loading conditions on the heart muscle.[1] Biomechanical models of congenital heart defects are useful for understanding disease progression and aiding clinicians in planning treatment. In order to formulate the most predictive tissue and organ level biomechanical models, the mechanical properties of the individual components must also be elucidated. In order to fully understand the mechanical properties of the heart, the mechanical properties of cardiac myocytes, the force generating cells in the heart muscle, must also be characterized. Cardiac myocytes play an important role in remodeling of the heart muscle and are sensitive to mechanical stimuli.[2-3] As cardiac myocytes exist in a dynamic mechanical environment and have a highly organized cytoskeletal architecture, there is a need to understand how complex mechanical loading conditions influence the cell's anisotropic mechanical properties. Here, we measure the stress-strain behavior of cardiac myocytes in response to biaxial loads.

## METHODS

**Substrate Fabrication and Cell Culture.** Neonatal mouse ventricular myocytes (NMVMs) were isolated from one-day-old mouse pups using standard methods.[4] As previously described,[5] NMVMs were micropatterned in an elongated architecture (aspect ratio 7:1 and an area of ~2250 μm$^2$) on a fluorescent-bead-doped polyacrylamide (PA) gel with a Young's modulus of 13.5 kPa bonded to an elastomer membrane (Fig. 1A).

**Cellular Micro-Biaxial Stretching (CμBS).** CμBS experiments were performed using a custom-built microscope-mounted device to perform traction force microscopy experiments on cells exposed to biaxial stretching (Fig. 1B). Four straining protocols were applied to the micropatterned NMVMs: axial tension, axial compression, transverse tension, and transverse compression, where the axial direction is parallel to the long axis of the cell and the transverse direction is parallel to the short axis of the cell (Fig. 1C). Strains were evaluated in 5% increments to a maximum of 15% for all protocols. NMVMs were paced at 1 Hz using an Ionoptix MyoPacer to induce contraction (Fig. 2A). High temporal resolution (100 Hz) images of the fluorescent bead layer were acquired to capture the full contraction of the cell and used to calculate traction forces of the cardiac myocytes at each applied strain. Traction forces at each stretch were calculated using standard methods.[5] First Piola-Kirchhoff (PK1) stresses, represented by $P_x = f_x/(2A_x)$ and $P_y = f_y/(2A_y)$, where $f$ is the total traction force and $A$ is the undeformed cross-sectional area of the cell, were calculated at the mid-plane of the cell (Fig. 1D). The cross-sectional areas of micropatterned NMVMs were estimated to be $A_x = 19$ μm$^2$ and $A_y = 131$ μm$^2$.[6] Sarcomere spacing during stretching was measured using a fast Fourier transform (FFT) on bright field images of the contracting NMVMs in which the sarcomere structures are visible.

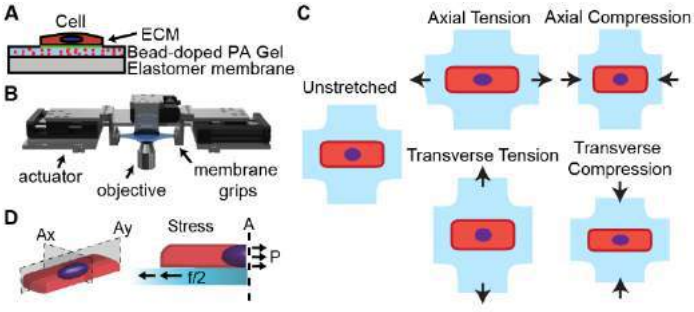

**Figure 1: CμBS device and methods for measuring cell stress. (A) Schematic of cell patterned on PA gel.[5] (B) CμBS device.[5] (C) Schematic of a cell under axial tensile, axial compressive, transverse tensile, and transverse compressive strains. (D) Relationship between the cell's cross-sectional area, traction force, and PK1 stress.**

## RESULTS

Traction forces of the NMVMs during contraction were measured and were greatest along the long axis of the cell (Fig. 2B-C), which is consistent with the underlying sarcomeric architecture. Using FFT, the sarcomere spacing prior to stretch was measured to be ~1.97 μm, which is consistent with measurements from fluorescently stained cells (Fig. 2D) and literature values.[7] When the NMVMs were exposed to axial tensile strains, the spacing between sarcomere subunits increased with stretch (Fig. 2E).

(C) Trace of the traction forces in a micropatterned NMVM. (D) Micropatterned NMVM stained for nuclei, F-actin and α-actinin. (E) Sarcomere spacing of NMVM stretched to 25% applied axial strain.**

NMVMs were extended or compressed using CμBS and PK1 stresses were calculated in the direction of the long axis (axial stress, $P_X$) and the short axis (transverse stress, $P_Y$) for each deformation. To determine the effect of biaxial stretch on the functional contractility of the NMVMs, passive and active cell stresses were calculated, where the passive stress was defined as the stress in the cell when the cell is not contracting and the active stress is defined as the difference in cell stress between the fully contracted and non-contracted states. During axial stretching (Fig. 3A), the active $P_X$ (Fig. 3B) of the contracting myocytes decreased as the cell was compressed and initially increases as the cell is extended before decreasing at the larger strains. This is consistent with previous understanding of the length-tension relationship in striated muscle.[8] The passive stress and the stress in the short axis of the cell, $P_Y$ (Fig. 3C), remained relatively unchanged under both axial tension and compression compared to the active stress in the long axis. Under transverse stretching (Fig. 3D), the active $P_X$ stress decreased with increasing stretch (Fig 3E) and the active $P_Y$ stress increased with increasing stretch (Fig 3F). This could also be due to inhibiting the interactions of the acto-myosin lattice by altering the lattice spacing in the micropatterned cells similar to what is described by the length-tension curve.[9] Passive stresses remained relatively unchanged. These data suggest that biaxial loads affect NMVM functional contractility.

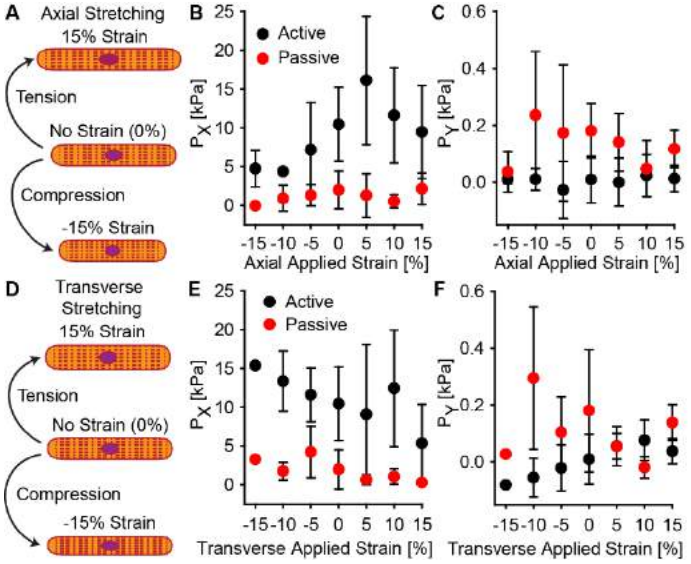

**Figure 3: Stress-strain measurements for NMVMs. Axial Stretching (A-C). (A) Schematic of a cell exposed to axial tensile and compressive strains, (B) axial direction PK1 stress, and (C) transverse direction PK1 stress. (For strains from -15% to 15%, n = 5, 3, 9, 25, 13, 13, 21). Transverse Stretching (D-F). (D) Schematic of a cell exposed to transverse tensile and compressive strains, (E) axial direction PK1 stress, and (F) transverse direction PK1 stress. (n = 1, 2, 4, 25, 4, 4, 3).**

## DISCUSSION

To develop the best tissue and organ level biomechanical models of the heart, the mechanical properties of the cardiac myocytes must be understood. The length-tension relationship is fundamental in understanding striated muscle contraction and has been characterized in cardiac muscle.[8] However, it is not well-understood on the single-cell level in cardiac myocytes. Thus, there is a need to fully characterize the anisotropic mechanical properties of cardiac myocytes. In this study, we used CμBS to measure the stress-strain behavior of NMVMs under biaxial loads. We found that in the axial direction, the stress-strain behavior is similar to what is described by the length-tension relationship of striated muscle in which changing the sarcomere spacing from an ideal distance decreases the force the cell is able to generate.[8] Additionally, we found that strains applied in the transverse direction altered cell stress as the active stress appeared to decrease with applied tensile strain. This could be due to inhibiting the interactions of the acto-myosin lattice in the micropatterned cells similar to the axial stretching. Future work includes expanding the stretching protocols to include equi-biaxial tension and characterizing the measured cell stresses with a strain energy density function. Overall, our results suggest that complex loads affect the functional contractility of NMVMs.

# VASCULAR SMOOTH MUSCLE CELLS UPREGULATE GLYCOLYTIC AND CONTRACTILE PHENOTYPE GENES IN THE PRESENCE OF GLUTAMINE

**Pattie S. Mathieu (1), Alisa M. Clyne (1)**

(1) Fischell Department of Bioengineering, University of Maryland College Park, Maryland, USA

## INTRODUCTION

Vascular disease is the leading cause of death in the western world. Many vascular diseases are caused by vascular smooth muscle cell (VSMC) proliferation that narrows the vascular lumen. VSMC proliferation occurs during a shift in phenotype from a contractile to a synthetic phenotype. Contractile VSMC express proteins such as α-smooth muscle actin (αSMA), calponin, SM22α, and smooth muscle myosin heavy chain (SM-MHC), while synthetic VSMC proliferate and secrete extracellular matrix proteins.

VSMC phenotype may also be linked with metabolism. *In vitro*, increased VSMC proliferation has been linked with increased glycolytic flux and mitochondrial oxygen consumption.[1] When VSMC change from a contractile to a synthetic phenotype, they also become more glycolytic.[2,3] One study showed that increasing glutamine concentration increases VSMC proliferation and decreases contractile protein expression.[4] Glutamine metabolism is linked to glucose metabolism through the tricarboxylic acid (TCA) cycle since glutamine can be converted to α-ketoglutarate (αKG). However, no work has been done to understand how glutamine affects VSMC glycolysis.

To further understand the effects of glutamine on VSMC, we performed RNA sequencing on VSMC grown with or without glutamine, then confirmed the phenotypic changes through proliferation and protein expression. We hypothesized that the absence of glutamine would increase VSMC gene expression of glycolytic enzymes as well as gene transcription and protein expression of contractile markers.

## METHODS

*Cell Culture* Human coronary artery smooth muscle cells were cultured in smooth muscle growth medium (Lonza) with 10% FBS, 1% penicillin/streptomycin, and 2mM L-glutamine. For experiments, cells were switched to glutamine-free DMEM with 10% FBS and 1% penicillin/streptomycin, with increasing L-glutamine added to the media. In some experiments, medium was supplemented with 7 mM dimethyl-α-ketoglutarate (αKG), the cell soluble form of the molecule.

*RNA Sequencing* Total RNA for RNA sequencing was isolated using RNeasy Mini kit (Qiagen). RNA was sequenced by Novogene using the NovaSeq 6000 with 150-bp paired end reads. Data were cleaned and assessed in Galaxy and visualized in Advaita iPathway.

*Western Blot* Cells were lysed in cold RIPA buffer. Protein was quantified by BCA assay and equal concentrations of protein were run on NuPage 4-12% Bis-Tris gels and then transferred to a nitrocellulose membrane. Proteins were probed using 1:1000 primary antibody in 1% BSA in PBS-T overnight at 4°C. Membranes were incubated in HRP-conjugated secondary antibodies (1:2000 in 1% BSA in PBS-T) for 2 hours at room temperature. Membranes were treated with Western Lightning Chemiluminescence Substrate and then imaged on an Alpha Innotech Fluorochem Q gel imager. Western blot intensity was normalized to the average intensity of the samples cultured in media with glutamine.

*Immunostaining* Cells were fixed in 4% PFA for 20 minutes and blocked and permeabilized with 5% BSA and 0.2% Triton X-100 in PBS for 40 minutes. Antibody solutions were made in 0.5% BSA and 0.2% Triton X-100 in PBS. Primary antibody was diluted 1:200, and cells were incubated for one hour at room temperature. Secondary antibody was diluted 1:1000 with 1:1000 DAPI and cells were incubated for one hour at room temperature. Cells were imaged using Nikon Eclipse Ti2-E at 10x, taking five random images of three wells each. Total nuclei and Ki67+ nuclei were counted in Image J.

*Statistics* Differential expression of sequenced RNA was assessed using the EdgeR function in Galaxy with a Benjamini-Hochberg p-value correction. Genes with an adjusted p-value of less than 0.05 and a log fold change of at least 0.5 were identified as being significant. Western blots and proliferation results were analyzed using a one- or two-way ANOVA both in GraphPad Prism.

## RESULTS

VSMC cultured with or without 2mM glutamine for 24 hours showed differential expression of 4144 genes, with 2022 upregulated

and 2122 downregulated in the presence of glutamine (Figure 1A). Of note, 15 genes involved in glycolysis were upregulated, while three were downregulated in VSMC cultured with glutamine. (Figure 1B).

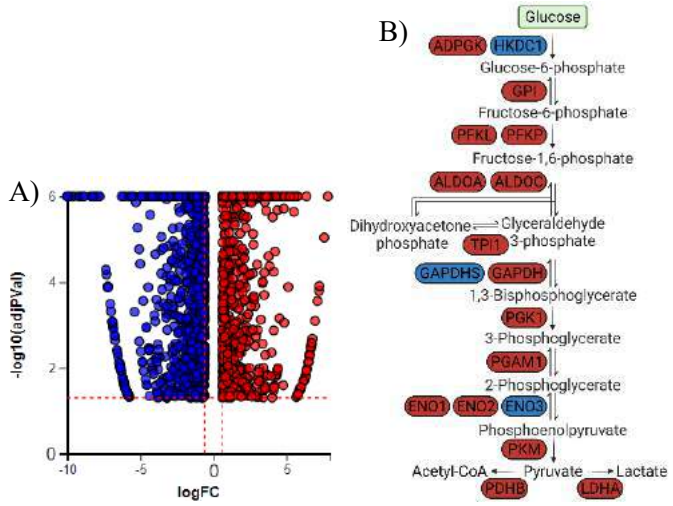

**Figure 1: A) Volcano plot showing genes that were significantly differentially expressed in response to 2mM glutamine. B) Glycolytic genes that were differentially regulated. Red = upregulated with glutamine; blue = downregulated with glutamine.**

VSMC differentially expressed genes involved in the VSMC contractile phenotype, with genes for αSMA(ACTA2), Calponin (CNN1, CNN2), and SM22α (TAGLN) all showing greater expression in the presence of glutamine. (Table 1)

| Gene | LogFC | p-value |
|---|---|---|
| ACTA2 | 3.170 | 1.000e-6 |
| CNN1 | 3.322 | 1.000e-6 |
| CNN2 | 2.044 | 1.000e-6 |
| TAGLN | 2.441 | 1.000e-6 |

**Table 1: Genes indicating contractile phenotype were significantly upregulated in the presence of 2mM glutamine.**

Culturing VSMC without glutamine decreased glycolytic enzymes phosphofructokinase-1 (PFK) and pyruvate kinase isozyme M2 (PKM) and contractile proteins αSMA, and calponin. Replacement with αKG restored PFK partially, PKM fully and contractile proteins partially at 4 days, and completely by 10 days. After 4 days, VSMC showed increasing cell proliferation as glutamine increased (Figure 3).

## DISCUSSION

Prior work suggested that glutamine promotes a synthetic VSMC phenotype. However, our RNA sequencing data shows that the presence of glutamine results in the upregulation of both glycolytic genes and contractile genes and proteins. While a previous paper showed a decrease in contractile VSMC markers in the presence of glutamine in pulmonary artery VSMC,[4] our experiments using coronary artery VSMC showed upregulation of contractile genes and proteins in the presence of glutamine. Conversely, increased glycolysis is associated with a synthetic phenotype in VSMC.[2,3] Therefore, the role of glutamine may be more complex than making VSMC more "contractile" or more "synthetic" as it promotes markers of both phenotypes.

A signaling pathway that might explain the glycolytic gene changes is the HIF-1 pathway. The gene HIF1A is shown to be upregulated with a log fold change of 1.111 in cells with glutamine compared to cells without glutamine. In cancer cells, the presence of glutamine increases HIF1α protein expression,[5] which in turn increases glycolytic enzymes.[6] However, HIF1α has also decreases contractile proteins in VSMC,[7] so glutamine likely affects other pathways involved in contractile protein expression that will need to be further investigated.

This study highlights the importance of glutamine for VSMC and indicates the further need for study on glutamine's effects on VSMC phenotype and glycolysis. Furthermore, it will need to be confirmed that the changes in glycolytic gene transcription and protein expression ultimately change VSMC glucose metabolism.

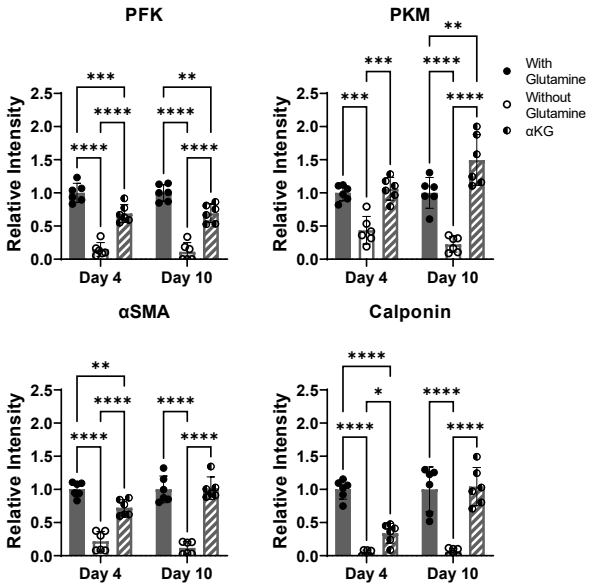

**Figure 2: VSMC treated without glutamine for 4 or 10 days show decreased PFK, PKM, αSMA, calponin, expression. αKG enabled partial or total recovery of these proteins. n=6 *p<0.05, **p<0.01, *** p<0.001, **** p<0.0001**

## INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has become a viable alternative for patients with severe aortic stenosis who are unable to undergo traditional surgical treatments. Within the TAVR pre-procedural planning pipeline, there is a need for accurate assessment of potential complications that may arise post-TAVR., such as coronary obstruction, paravalvular leakage, and leaflet thrombosis [1]. Computational modeling has become a critical tool that can be used to visualize the deployment behavior of transcatheter heart valves (THV) in patient-specific TAVR procedures, and help predict the likelihood of post-TAVR complications [2]. In the context of TAVR deployment analysis, the finite element (FE) method is the most commonly used computational modeling technique, where the THV stent frame and leaflets, as well as the patient-specific aortic root, native leaflets, and calcium deposits are all incorporated into the model. Due to the intrinsic geometrical and mechanical complexities of these components, the modeling process quickly becomes computationally expensive.

A common approach to introduce significant computational advantages is the customization of the FE basis functions from a *data-driven paradigm*, within the general idea of "Model Order Reduction" [3]. The reduced order model (ROM) here can be divided into two primary stages, the *offline* and *online* stages. In the offline stage, all computationally expensive full order model (FOM) simulations are performed for a specific set of parameters to create a library of solutions or *snapshots*. This is followed by a prompt recycling of the snapshots in the online stage for a rapid reduced order solution. Although ROMs have been employed in various biomedical engineering applications previously, the application of ROMs in TAVR modeling has not yet been studied.

The primary objective of this study is to develop a ROM framework based on the Proper Orthogonal Decomposition (POD) approach for the structural deformation of the 29 mm Medtronic CoreValve. Specifically, the focus here is on the use of POD for significantly reducing the computational costs of simulating the deformation of the CoreValve in response to defined sets of applied loads that mimic *crimping* and *expansion* of the THV stent frame. The framework serves as the first step towards real-time simulations of the entire TAVR deployment procedure which will allow for rapid identification of potential post-operative complications.

## METHODS

As an initial step towards creating the ROM framework, a linear elastic constitutive law is assumed where the problem considered reads as: find *u(x)* such that

$$\nabla \cdot \sigma = \mathrm{F}, \quad x \in \Omega \tag{1}$$

$$\sigma = \lambda(\nabla \cdot u)\mathrm{I} + 2\mu\varepsilon \tag{2}$$

$$\varepsilon = \frac{1}{2}(\nabla u + \nabla u^T) \tag{3}$$

where σ is the Cauchy stress tensor, $\varepsilon$ is the strain tensor, $I$ denotes the identity tensor, $F$ is an external volume force, and $\lambda$ and $\mu$ are the Lame' constants. The prescribed boundary conditions (BC) over the domain $\partial\Omega$ is split into three parts. First, the displacement was set as $u = 0$ at the lower and upper edges of the stent frame. Second, it was assumed that the normal stress was given at a set of 15 points, i.e. $\sigma \cdot n(P_i) = d_i$ for $i = 1, 2, \dots, 15$, where $n$ is the outward normal vector. All possible pairs among the 15 points were selected and $d_i$ was defined as a vector that was oriented along the line connecting the two end points of each pair. These "force pair" BCs idealize the loads applied from the native aortic wall and leaflets onto the CoreValve stent frame, as well as mimic crimping and expansion of the stent frame. For the remaining BCs, homogenous Neumann BCs were applied, i.e., $\sigma \cdot n = 0$.

In the offline stage of the ROM framework, a series of FE simulations of (1) with the parameterized force pair BCs are performed. The 3D geometry utilized was a model of the 29 mm Medtronic CoreValve stent frame without the leaflets included, allowing us to solely focus on the stent deformation. The CoreValve stent frame was

modeled with linear elastic material properties with a Young's modulus of 50 GPa and Poisson's ratio of 0.33. With the 15 nodes used to parametrize the BCs, a total of 105 offline stage simulations were run. Crimping and expansion of the stent frame was simulated at three planes P1, P2, and P3 via force pairs (Fig. 1) to form a *snapshot* library.

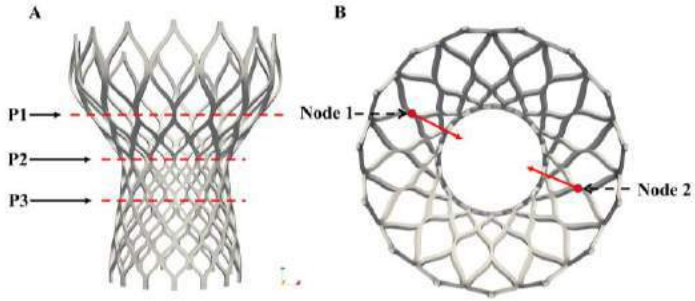

**Figure 1. Model of the CoreValve stent frame.**

To filter out the redundancy from the snapshot library, the *Singular Value Decomposition* (SVD) is employed, from which the singular values were analyzed. A rapid decay in the singular values indicates high redundancy in the snapshot library, and that the key features of the matrix can be captured by a linear combination of those left eigenvectors associated with the largest singular values. These eigenvectors form the reduced basis functions, such that the ROM solution reads as follows, where $W$ is the reduced order matrix, and the coefficients $c$ are found by solving the reduced problem.

$$u_{ROM} = \sum_{i=1}^{n_{ROM}} c_i W_i = Wc \qquad (4)$$

After discretization of the problem, the FOM from (1) leads to the solution of a linear system in the following form, where $u$ is the vector of displacements, $A$ is the stiffness matrix, and $b$ is the forcing terms.

$$Au = b \qquad (5)$$

Using the POD approach, an approximate form of (4) is created and after plugging in (5), the following reduced order system is obtained.

$$W^T AWc = W^T b \qquad (6)$$

In (6), $W^T AW$ is a matrix featuring a size in the range of tens or hundreds of rows. Using (6) with the vector $b$ incorporating new BCs in the online stage, the vector $c$ can be found from (4), from which the final reduced order solution can be solved for. The savings in computational costs becomes evident when comparing the size of $A$ (thousands or millions of rows) to the reduced order matrix $W^T AW$.

All offline stage simulations were performed using an in-house solver built in *FEniCS*, an open-source FE library, followed by a manual model reduction using the above approach in *MATLAB* [4]. The entire framework presented above was then also implemented into the *FEniCS*-based library *RBniCS*, an open-source model reduction library, which allowed us to combine the offline stage simulations, model reduction, online reduced order solutions, and speed-up analysis all into a single solver [3]. Results were visualized and analyzed in *ParaView*.

## RESULTS

Crimping and expansion of the CoreValve stent frame simultaneously at planes P1, P2, and P3 is shown in Fig. 2. Maximum deformation in the ROM and FOM simulations was 3.985 mm for crimping (Fig. 2A), and 3.981 mm for expansion (Fig. 2B). The degrees of freedom required for the FOM was 227,511, which was reduced to 15 when performing the model reduction. This led to the FOM requiring an average of 122.28 seconds to simulate, while the online phase of the ROM taking only an average of 2.14 seconds, a 98.25% reduction in computational time.

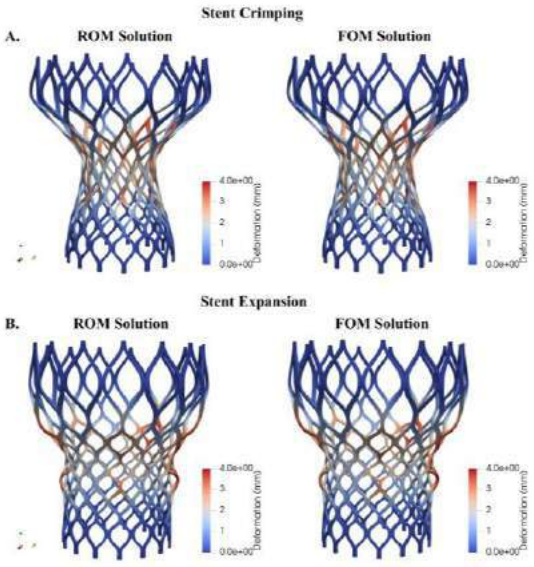

**Figure 2. Comparison of ROM and FOM solutions for stent crimping (A) and expansion simulations (B).**

The computational details for the ROM and FOM simulations are summarized in Table 1 below.

**Table 1. Summary of computational details.**

| Mesh Size | Number of Snapshots Computed | FE Degrees of Freedom | Number of Reduced Basis | Avg. Computational Time (s) | | |
|---|---|---|---|---|---|---|
| | | | | FE Simulation | ROM Offline | ROM Online |
| 257671 | 105 | 227511 | 12, 13, and 15 (depending on crimping/expansion plane) | 122.28 | 2654.39 | 2.14 |

## DISCUSSION

In this study, we introduce a ROM framework applied towards rapidly simulating the structural deformation of the Medtronic CoreValve. Utilizing the POD approach in the online phase of the ROM resulted in a reduced order solution that was identical to the FOM simulations with similarly applied BCs. The ROM solutions also required significantly less computational time, which suggests that the POD-based ROM results in an accurate and computationally efficient solution. Enhanced computational efficiency using this framework suggests a significant role of the ROM in segregated algorithms for solid-solid interaction simulations in TAVR. One limitation of this study is that the stent was modeled as a linear elastic material, while the self-expandable nitinol frame would be more accurately modeled as a superelastic alloy. A constitutive model for hyperelasticity (Generalized Neo-Hookean) is proposed as an initial step to capture the nonlinear properties of the stent. The basic POD approach also requires linear differential operators, and thus the Empirical Interpolation Method will be applied to perform model reduction for nonlinear problems.

In conclusion, the POD based ROM framework significantly reduces the computation time required to simulate crimping and expansion of the CoreValve stent frame, while retaining the accuracy from FOM models. Further refinements are underway to incorporate the nonlinear nature of the stent frame, as well as to rapidly and accurately simulate the entirety of the TAVR deployment process.

# COMPUTATIONAL MODELING OF IPSC-DERIVED ENGINEERED CARDIAC MICROTISSUES

## INTRODUCTION

Heart disease is one of the leading causes of mortality within the US, causing about 1 in every 4 deaths [1]. One of the reasons for this high prevalence is the lack of regenerative capabilities of the myocardium [2]. One option to tackle this problem is through engineered heart tissues (EHT) constructed using induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs). These EHTs can be used to better understand the mechanisms for heart regeneration on a cellular level and can be used to engineer tissues for transplantation. Creating EHTs that are similar in function and structure to adult heart tissues remains a challenge, in part due to our incomplete understanding of the mechanobiology of iPSC-CMs. Modifications to the mechanical environment of EHTs have been shown to influence cardiomyocyte organization and structure [3]. However, how factors like extracellular matrix stiffness and alignment (see Fig. 1) influence the local micromechanical environment remains poorly understood. Further, while the function of EHTs is usually measured globally (e.g. total force generation), the local mechanical environment for cardiomyocytes is usually unknown. In this work, we implemented a computational model that integrates the global data of an experimental setup to quantify and study how the local mechanics determine iPSC-CMs maturation and organization.

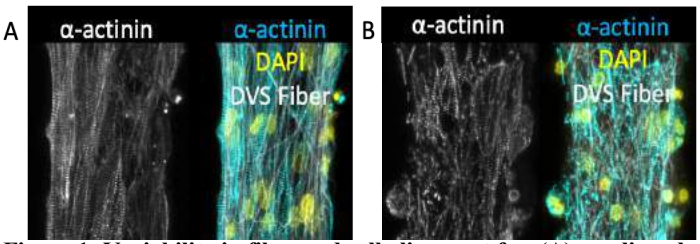

**Figure 1: Variability in fiber and cell alignment for (A) an aligned fiber matrix and (B) a random fiber matrix.**

## METHODS

We considered EHTs made of dextran vinyl sulfone (DVS) fibers suspended between PDMS posts and seeded with iPSC-CMs. The EHT fiber scaffolds investigated were either aligned or non-aligned between the posts (Fig. 1) and varied in stiffness via photoinitiator concentration (0.1, 1.0, and 5.0 mg/mL) of lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP) [3].

**Geometric Model Development:** To characterize the ETs, tissue-specific continuum models were developed for each sample using 20x magnified tissue images (Fig. 2A). The images were then segmented using localized adaptive thresholding in MATLAB to produce a fiber mask. The mask was used to calculate a continuum field representing the fiber density and alignment for use within a finite element model (Fig. 2B). The tissue-specific mesh consisted of 2D quadratic quadrilateral elements.

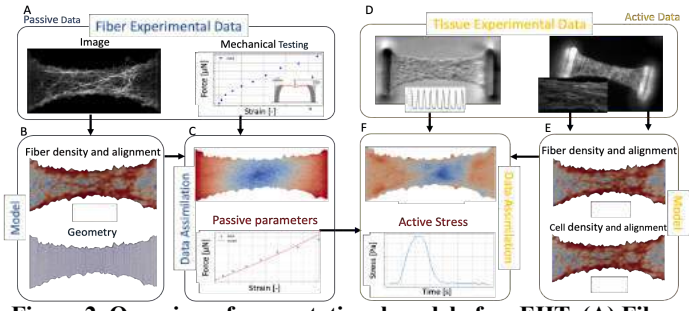

**Figure 2. Overview of computational model of an EHT. (A) Fiber structure and indentation test data. (B) Homogenized field of fiber density and alignment obtained from (A). (C) Passive stiffness parameterization from indentation test (D) EHT with iPSC-CMs and force quantification from post deflection. (E) Homogenized cell density and alignment for active data assimilation. (F) Active stress parameterization from force measurements**

**Passive Data Characterization:** The EHTs fibers were modeled by a modified neofiber material law where the strain energy function is given by

$$\Psi = \frac{\gamma C_1}{4}\left(I_{C_f} - 1\right)^2 + \frac{\gamma C_2}{2}(I_{\hat{C}} - 3) \quad (1)$$

where $I_{C_f} = C{:}\, f_0 \otimes f_0$ is the first invariant of the right Cauchy-Green tensor $C$ in the reference fiber direction $f_0$ and $I_{\hat{C}} = J^{-1}C{:}\, I$ is the first invariant of the isochoric component of $C$ and $J$ its determinant. $C_1$ and $C_2$ are material parameters representing the fiber and isotropic stiffness respectively [5] and $k_b$ regulates the compressibility penalty. The ratio of $C_1$ and $C_2$ was optimized based on explicit fiber meshes, enabling the homogenized models to be parameterized by a single scaling constant, $\gamma$. To find this value, we follow a similar approach to the one presented in [4], where Lagrange multipliers constrain a mechanics problem to meet the known boundary conditions and solve for the unknown displacement field and parameters. Experimentally, indentation tests were conducted to measure the passive stiffness of the different fiber conditions where iPSC-CMs were seeded on (Fig. 2C). From this experiment, the force $F(t)$ and displacement $d(t)$ at the post were obtained for the different permutations, and the passive forward problem and parameterization can be written as: Given the tissue domain $\Omega$ with the post boundary denoted by $\Gamma_b$, find $u, \lambda, \gamma \in X$ such that,

$$\int_\Omega \sigma(u,\gamma){:}\,\nabla\omega\, d\Omega + \int_{\Gamma_b} \lambda \cdot w d\Gamma + \int_{\Gamma_b} \left(u - d(t)\right) \cdot v d\Gamma + \int_{\Gamma_b} \lambda \cdot e_x q\, d\Gamma - \frac{F(t)}{t_t} \cdot e_x q = 0 \quad (2)$$

for all $w, v, q \in X$ where $X$ denotes the appropriate finite element spaces, $\sigma$ is the Cauchy stress and $e_x$ is a unitary vector perpendicular to the boundary and $t_t$ is the tissue thickness.

**Active Data Assimilation:** The fibers samples are then seeded with contractile iPSC-CMs and allowed to culture for 7 days to mature. From the videos, displacement of the tissue at the boundary of the EHT at varying time points were obtained (Fig 2D). We consider the active stress of the fibers as shown in Equation 3.

$$\sigma_a = \alpha f_c \otimes f_c \quad (3)$$

where $\alpha$ is a parameter that represents the active stress that the cells exert to contract and $f_c$, the deformed cell alignment direction (Fig. 2E). Using the $\gamma$ value solved in the passive data problem and the boundary displacement $d_a(t)$ obtained from the videos, we can find $\alpha(t)$ and the tissue displacements by solving: find $u(t), \lambda(t), \alpha(t) \in X$ such that,

$$\int_\Omega \sigma(u,\gamma){:}\,\nabla\omega\, d\Omega + \int_{\Gamma_b} \lambda \cdot w d\Gamma + \int_{\Gamma_b} \left(u - d_a(t)\right) \cdot v d\Gamma + \int_{\Gamma_b} \lambda \cdot e_x q\, d\Gamma - \frac{k d_a(t)}{t_t} \cdot e_x q = 0 \quad (4)$$

for all $w, v, q \in X$, with $k$ post stiffness.

## RESULTS

Both passive and active data assimilation tests were conducted on CHeart [6]. The proposed pipeline to characterize the tissue data is robust and allowed us to characterize myocyte function under the varying permutations of the tissue microenvironment (changes in fiber-matrix stiffness, post stiffness, matrix alignment). For each EHT model, we obtained the material parameters that characterize the experimental observations and the internal displacement fields (Fig. 3A). The method allows us to study the impact that the different stiffness and alignment conditions produce on material parameters (Fig. 3C). Using the material parameters found, the active data assimilation allows us to look at the deformed configuration (Fig. 3B) due to the contraction of the cells and quantify estimated active stresses that the cells are generating internally. For example, we note that aligned fiber matrices generate higher cellular stress (Fig. 3D). Importantly, this approach allows us to estimate the internal activity of the EHTs under varying micromechanical conditions, providing estimates of iPSC-CM function throughout the EHT.

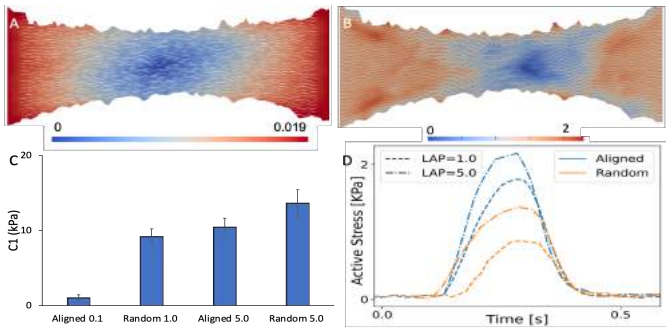

**Figure 3: Resulting displacement field for (A) indentation test and (B) contracting EHTs. (C) C1 value and (D) active stress for different fiber alignment and LAP concentration**

## DISCUSSION

In this work, we present a data-driven tissue-specific modeling pipeline to study how the mechanical environment of cardiac EHTs influence the function of iPSC-CMs throughout the tissue. This approach represents an advance with respect to the general measurements usually used in the tissue engineering field to assess EHT biomechanics, allowing us to differentiate between tissue-scale and cell stresses across varied microenvironments. For example, it is possible to study the effects of anisotropy and fiber stiffness on the contractility of the cells and tissue organization. We can also develop higher throughput data *in silico* by adding variation to fiber alignment and stiffness to suggest promising permutations that can then be tested experimentally. This work shows how combining experimental and computational approaches can shed light on the mechanical cues that determine the assembly and function of EHTs. This work serves as an important step towards the goal of generating better and more mature engineered cardiac tissues that can be used in clinical applications.

# EFFECT OF RENAL DENERVATION ON THE BIOMECHANICAL PROPERTIES OF COMMON CAROTID ARTERIES IN RATS

**Anastasia Gkousioudi (1), Margherita Razzoli (2), Jesse D. Moreira (3), Gianluca Harbert (2), Richard D. Wainford (3), Katherine Y. Zhang (1,2,4)**

## INTRODUCTION

Hypertension (HT) affects approximately 1 billion people worldwide and its prevalence increases with age [1, 2]. Resistant HT manifests when the conventional antihypertensive therapy fails to control blood pressure. Uncontrolled HT carries a mortality risk to resistant hypertensive patients who are more likely to develop irreversible damage in end-organs such as the kidneys and brain [3]. Several studies have reported the role of the renal sympathetic nervous system, comprised of both afferent and efferent nerves, as a regulatory mechanism for blood pressure through modulation of electrolyte balance, renin production and renal blood flow [4]. Renal denervation (RDN) has emerged as a potential therapeutic approach to resistant HT by selectively removing the renal nerves and therefore attenuating or even inhibiting the activity of the renal sympathetic nervous system [5]. However, the effect of RDN on the microstructure and biomechanical response of elastic arteries is not understood.

This study focuses on investigating the alterations in mechanical properties and microstructure of rat common carotid arteries (CCAs) following RDN. Biaxial extension-inflation tests were performed on CCAs from the 3-month-old (3mo), 8mo, and 8mo denervated groups. Structural changes of the underlying extracellular matrix (ECM) were investigated through multi-photon microscopy.

## METHODS

Renal denervation: All animal experimental procedures were approved by the Institutional Animal Care and Use Committee (IACUC) of Boston University. Sprague Dawley (SD) male rats were used in the study. Spontaneous HT is developed in the 8mo group with mean arterial pressure (MAP) of 136 ± 3 mmHg, when compared to the 3mo group with MAP of 123 ± 3 mmHg. RDN attenuated HT in 8mo rats (MAP 126 ± 3 mmHg). The kidneys from SD rats were exposed by flank incisions and complete RDN was performed by stripping of all visible renal nerve bundles and painting the renal vein and artery with 10% phenol in ethanol [5] prior to closing of the incision. Rats were left to recover for 2 weeks before tissue harvesting.

Biomechanical testing: CCAs were excised from the 3mo, 8mo, and 8mo denervated groups (n=9) and carefully cleaned from surrounding connective tissue and fat. Segments of approximately 5 mm were cannulated and secured to a pressure myograph (110P DMT, Denmark) while being immersed in a PBS bath at room temperature throughout the mechanical testing. After preconditioning, the *in vivo* stretch ratio of each artery was estimated [6]. Arteries were then subjected to biaxial inflation-extension tests, at the *in vivo* axial stretch ratio, from 0 to 140 mmHg with 10 mmHg increments and a loading rate of 5 mmHg/sec. The axial force, outer diameter and pressure were recorded. After the testing, the unloaded arterial dimensions were measured by imaging arterial rings of ~0.5 mm in length. The images were then imported into FIJI (http:/Fiji.sc/Fiji, Ashburn, VA). The outer and inner circumference were manually traced, and the corresponding diameters were calculated. Under thin wall assumption, Cauchy stresses in circumferential and longitudinal direction can be calculated as [7]:

$$\sigma_\theta = \frac{Pr_i}{h} \quad \text{and} \quad \sigma_z = \frac{f + P\pi r_i^2}{\pi h(2r_i + h)} \tag{1}$$

where $P$ is the transmural pressure, $f$ is the axial force, $r_i$ is the deformed inner radius and $h$ is the deformed thickness.

Multi-photon imaging: CCA segments were mounted into a custom-built tissue stretching-inflation chamber which can subject the artery to physiological loading while being imaged using a Carl Zeiss LSM 710 NLO microscope system equipped with a tunable femtosecond IR pulse laser (Coherent Chameleon Vision-S) [8]. Samples were stretched to *in vivo* stretch ratio and imaged under a set of pressure values (0, 30, 60, 90 and 120 mmHg). An excitation wavelength of 810 nm was used to generate two-photon fluorescence (500/550 nm) from elastin and second harmonic generation (395/415 nm) from collagen. Arterial samples were imaged to a depth of ~100 μm with a 1 μm spacing and a field of view of 425 × 425 μm using a

water immersion objective (20×, NA 1.0, W Plan-Apochromat, Zeiss). Z-stack images of elastin and collagen were acquired at every pressure level.

## RESULTS

Figures 1A and 1B show the response of CCAs under pressurization for the three experimental groups. The axial force needed to maintain the CCAs at their *in vivo* stretch increased for the 8mo group (Figure 1A). After RDN, the axial force decreased to the values of the 3mo arteries. On the other hand, the outer diameter (Figure 1B) showed a rightward shift at 8 months which remained about the same after RDN.

Cauchy stresses were calculated under an intraluminal pressure of 100 mmHg and are presented in Figures 1C and D. Arteries responded with an increased wall stress from 109.91 ± 15.71 kPa to 146.99 ± 16.16 kPa in longitudinal direction (Figure 1C) and from 49.84 ± 5.06 kPa to 78.73 ± 5.9 kPa ($p < 0.05$) in circumferential direction (Figure 1D) due to maturation from 3mo to 8mo. RDN restored stresses to values similar to the 3mo arteries, with a significant decrease to 98.58 ± 5.5 kPa and 61.92 ± 4.4 kPa in longitudinal and circumferential direction, respectively ($p < 0.05$).

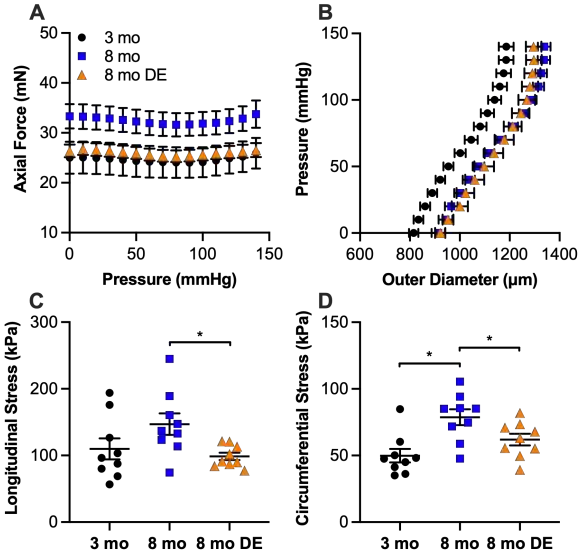

**Figure 1: Biomechanical response of rat carotid arteries under pressurization. Average (mean ± SEM) axial force – pressure (A) and pressure – outer diameter (B) response, Cauchy stress at 100 mmHg in longitudinal (C) and circumferential (D) direction as a function of age and renal denervation.**

Representative multi-photon images of collagen and elastic fibers are shown in Figure 2. The CCA from 3mo appeared to have a denser external elastic lamella at the adventitia-media interface (Figure 2A). On the other hand, the 8mo and 8mo denervated CCAs seem to be sparse with more straightened and disorganized elastic fibers (Figures 2C, E). Collagen fibers in the adventitia of the 3mo CCAs appear to be undulated (Figure 2B). Straightening of the collagen fibers at 8mo with the presence of thicker collagen bundles was observed, while after RDN a mixture of undulated and straight collagen fibers present in the adventitia (Figures 2D, F).

## DISCUSSION

Here we studied the structure and biomechanical response of CCAs after RDN using a rat model. Our results suggest that sustained elevated blood pressure resulted in arterial remodeling which was manifested as a significant increase in stresses after 8 months. In addition, RDN had a favorable impact on CCAs with a reverse of stresses in values similar to the 3-month-old ones. Multi-photon images indicated structural alterations of the main ECM components which possibly affecting arterial biomechanical response.

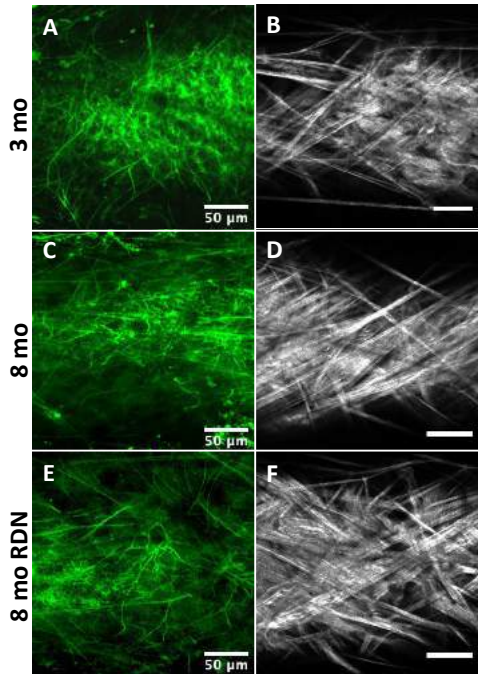

**Figure 2: Representative multi-photon images of elastic (A, C, E) and collagen (B, D, F) fibers of CCAs at 90 mmHg pressure.**

Vascular remodeling is known to be associated with HT [1]. Using a rat model of spontaneous HT, our results show an enlargement of the deformed outer diameter at 8 months which remained after RDN (Figure 1B). In addition, the sparse elastic fiber network in conjunction with the straight collagen fiber bundles (Figures 2C, D) indicated that there is a shift of the load bearing to the stiffer collagen fibers, which could explain the increase in stresses of the 8mo CCAs [2]. Even though deformed diameter remained about the same for the 8mo denervated, multi-photon images revealed a remodeling of ECM components with similarly disrupted elastic fiber network as the 8mo, as well as the presence of undulated collagen fibers (Figure 2E, F). Given that arterial wall stresses decreased, this finding indicates that RDN result in changes in ECM components, and possibly cells, which in turn effectively reversed the biomechanical behavior of CCA.

Effect of RDN on large elastic arteries and HT remain to be understood. Future studies to quantify the ECM structural changes and include RDN in older rat groups could provide more insight on understanding the effectiveness of RDN in the aged group.

## INTRODUCTION

Tendons undergo complex region-dependent mechanics when loaded physiologically [1][2]. Currently, researchers rely on inverse finite element modeling to infer regional stress from measured strain patterns. However, it remains challenging to ascertain the veracity of model-based stress estimates because there is a paucity of techniques for direct measurements of regional stress. Researchers would benefit from a technique to directly measure regional soft tissue stress to enhance analyses of physiological soft tissue behavior.

Shear wave tensiometry is a measurement technique to gauge loading in tendons [3] and ligaments [4] directly based on the shear wave speed in the loaded tissue, where the shear wave speed squared is proportional to the axial stress. Tensiometry measurements are usually used to infer bulk tissue stress. However, computational studies [5] suggest that the shear wave speed varies regionally with the axial tissue stress when there is a load gradient across the tissue cross-section. If correct, then measurements of regional shear wave speeds could be used to evaluate regional variations in axial tissue stress.

This study empirically investigated relationships between regional shear wave speed and axial stress using multipoint laser Doppler vibrometry to track variations in shear wave profiles across a tendon surface. The objective of this study was to determine how well regionally measured shear wave speeds predict regional axial stress. Our hypothesis was that regional shear wave speeds would track regional stress according to the tensioned beam model underlying shear wave tensiometry.

## METHODS

***Mechanical testing procedure:*** Three porcine digital flexor tendons were loaded into a uniaxial testing system (Acumen 3, MTS, Eden Prairie, MN) with the tendon oriented longitudinally (y-direction, Fig. 1). Specimens were first preconditioned for 100 cycles from 0 to 5% strain in a uniformly loaded reference configuration (0°) [6]. We loaded the specimens using a ramp to 5% grip-to-grip strain at a strain rate of 0.5/s. This loading ramp was performed both in the reference configuration and with the proximal end of the tendon rotated 10° (determined using a digital protractor) within the grip of the MTS to generate a nonuniform strain gradient across the tendon width. The tendons were kept moist with 0.9% saline during the testing procedure.

***Shear wave speed measurement:*** Shear waves were excited over the entire width of the tissue cross-section using a piezoelectric tapper (20 micron ramp over 0.62 ms, PK4JQP1, Thorlabs Inc, Newton, NJ) on the back of the tendon. The tissue's transverse surface motion (x-direction, Fig. 1) was recorded at 15 locations (5 locations each on left, middle, and right sections of the front of the tendon, Fig. 1) using a multi-point laser Doppler vibrometer system (MPV-800, Polytec Inc., Irvine, CA). The surface of the tendon at the measurement locations was

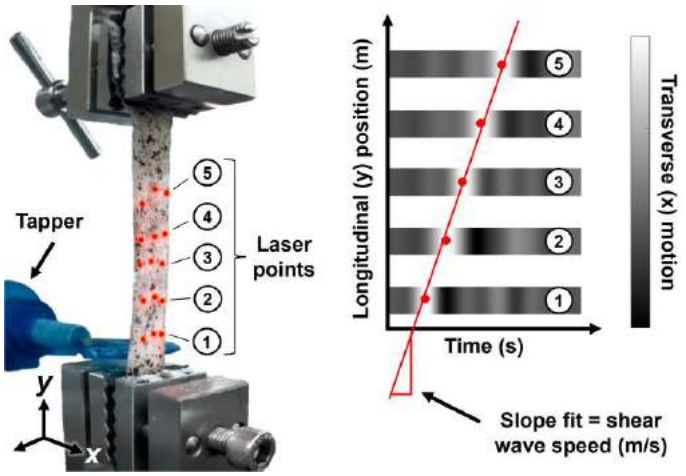

**Figure 1: Tendons were loaded longitudinally, and the shear wave speed was computed as the slope between the laser location and the wave arrival times at each laser location.**

lightly coated with titanium dioxide to enhance surface reflectivity. The distance between laser locations was determined using ImageJ (NIH, Bethesda, MD). Shear wave speed (in m/s) was computed as the linear fit of the wave arrival time vs laser location for the five laser locations within a section (Fig. 1). Outlier exclusion of the shear wave speeds was performed using a Hampel filter [7].

***Digital image correlation (DIC):*** Specimens were speckled with black India ink prior to mechanical testing. During the loading ramp for the 0° and 10° configurations, the deformation of the speckle pattern on the tissue surface was recorded with two cameras (Raspberry Pi 4 with HQ camera, 25 fps). The longitudinal 2D strain in each measurement region was computed using an open-source DIC toolbox [8].

***Analysis and statistical methods:*** Regional axial stress was estimated for the 10° rotated condition using the regional strain from the 10° rotated condition loading ramp and the bulk axial stress-strain relationship from the 0° reference configuration loading ramp for a particular region on the tissue (Fig. 2). We performed a linear regression between the estimated axial stress (dependent variable) and squared shear wave speed (independent variable) to calibrate the slope and intercept (i.e., density and shear modulus, Fig. 2, Eq. 1) for each tendon in the 0° configuration. We then used that slope and intercept to predict the regional stress from regional wave speed in the 10° configuration.

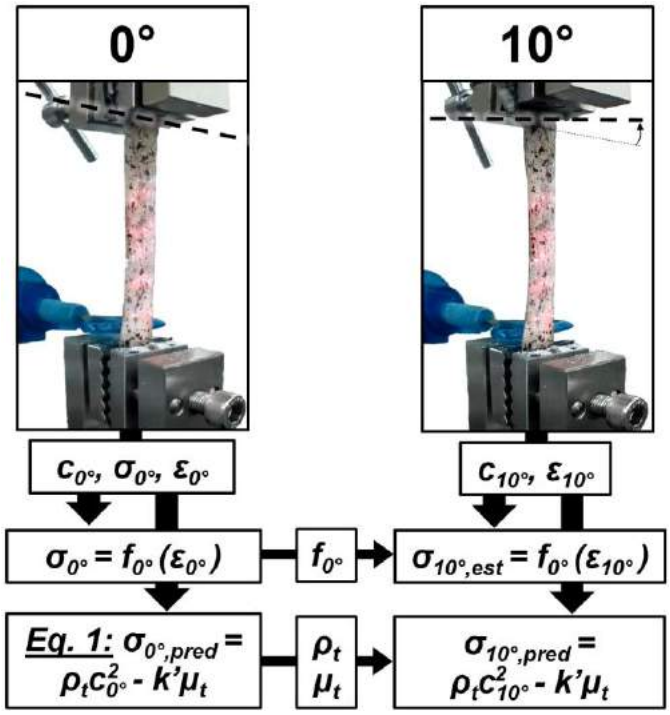

**Figure 2: The stress-strain relationship from the 0° loading ramp ($f_{0°}$), the tendon density ($\rho_t$), and the tendon shear modulus ($k'\mu_t$) were used to estimate regional stress ($\sigma_{est}$) in the 10° configuration from the regional strain ($\varepsilon$) and predict regional stress ($\sigma_{pred}$) using the shear wave speed ($c$) measured in each region.**

## RESULTS

Measured shear wave speeds increased with increasing regional strain, and the tissue strain increased monotonically with axial loading. The squared shear wave speed and estimated regional axial stress during the loading ramp demonstrated strong linear relationships for each specimen in both the 0° reference configuration (average $r^2 = 0.93 \pm 0.07$) and the 10° configuration (average $r^2 = 0.81 \pm 0.19$) for all measurement regions. On average, we could predict axial stress from shear wave speed within 0.17-1.01 MPa for the 0° configuration, and within 0.22-1.59 MPa for the 10° configuration when using tendon-specific analytical model fits (Fig 2).

**Table 1: Errors in predicting regional stress (in MPa) for the left, middle, and right sections of each tendon using shear wave speed (predicted value) and regional strain (estimated true value).**

| Tendon | Config. | Left | Middle | Right |
|---|---|---|---|---|
| 1 | 0° | [b]-1.01 ± 0.44 | [a]0.27 ± 0.65 | [b]0.72 ± 0.99 |

[a]0-10% of max observed stress, [b]10-20% of max observed stress

## DISCUSSION

The objective of this study was to determine whether regionally measured shear wave speeds could predict regional axial stress. We found that relationships between regional shear wave speeds and estimated regional stress are highly linear. We also found that, in select trials, regional stress predicted using shear wave speed corresponded to regional stress estimated using regional strain.

Shear wave speeds measured regionally using the slope fit of five vibrometer points were in range of bulk shear wave speeds measured previously in flexor tendons using a normalized cross-correlation between two vibrometer points [9]. Regional strains measured using DIC were less than the global grip-to-grip strain, which is in accordance with previous DIC studies [10]. We found that shear wave speeds are proportional to estimated axial stress at every location across the tendon width. However, there was variability in the slope and intercept (i.e., density and shear modulus, Fig. 2, Eq. 1) of the linear fit between shear wave speed squared and estimated axial stress across measurement locations and loading configurations (0 and 10°) across tendons. This variability contributed to errors in predicting axial stress using shear wave speed. These regional variations in slope and intercept should be accounted for to make more accurate regional stress predictions.

This study has limitations to consider when interpreting the results. First, we used the bulk stress-strain relationship in the tendon to estimate regional axial stress. An inverse FE model could better account for variations in tendon geometry and material properties and is a focus on our ongoing work. Second, regional strains were determined using 2D DIC. In the future, we plan to perform 3D DIC to capture out of plane strain and thus a more representative measure of the tendons' deformation state during loading.

The findings of this study suggest that increases in regional shear wave speed are proportional to increases in estimated regional stress in porcine digital flexor tendons. These observations suggest that it may be viable to predict regional stress from spatial shear wave speed measurements. Variability between specimens remains a challenge and may be best considered by using inverse finite element models to better account for both material and morphological factors.

## INTRODUCTION

The Fontan operation is the culmination of a staged surgical procedure for children with congenital single ventricle defects such as hypoplastic left heart syndrome. During the operation, venous return from the inferior vena cava (IVC) is rerouted to the pulmonary arteries (PA) using a surgical graft, resulting in the formation of the total cavopulmonary connection (TCPC). The TCPC prevents mixing of oxygenated and deoxygenated blood in the malfunctioning ventricle, which in general results in favorable short-term outcomes for patients. However, long-term complications are still prevalent, such as pulmonary atriovenous malformations (PAVMs) and limited exercise capability of the heart. Previous studies have shown the importance of optimizing pulmonary flow and TCPC hemodynamics to significantly reduce the likelihood of these long-term complications.

Surgical planning via computational modeling has allowed for pre-operative examination of a wide range of potential patient-specific morphologies for the TCPC, typically by varying the placement of the IVC with respect to the superior vena cava (SVC) and the left and right PAs. This represents a shape optimization problem, where differences in the anatomical connection between the IVC, SVC, and PAs result in unique hemodynamics and flow distributions. Hemodynamic factors such as hepatic flow distribution (HFD) and power loss (PL) can be numerically quantified, and thus aid clinicians in choosing the optimal morphology. HFD has been an apparent target for optimization, as the absence of hepatic flow from the IVC has been previously linked to the development of PAVMs in patients [1]. PL due to the collision of colliding fluid fronts in the TCPC may also cause turbulent flow dynamics, leading to potential blood damage and viscous shear losses.

However, due to the intrinsic numerical complexities required to discretize and linearize the time-dependent Navier-Stokes equations (NSE) that govern flow dynamics, the computational costs of modeling these surgical planning cases become extremely high, especially for repetitive testing of various patient-specific TCPC geometries in a trial-and-error fashion [2-3]. Therefore, there is a need for rapid and accurate predictive models that can optimize patient-specific TCPC geometries, and thus allow for real-time Fontan surgical planning.

Reduced order models (ROMs) are a common *data-driven paradigm* used to simplify full order models (FOMs) to their dominant components, thus significantly reducing the required computational resources. ROMs can be divided into two stages: the *offline* stage, where computationally expensive simulations are offloaded, and the *online* stage, where these simulations are promptly recycled for a rapid reduced order solution [4]. Although ROMs have been employed in previous fluid dynamic studies, the application of ROMs towards real-time shape optimization of the TCPC has not yet been studied.

In this preliminary study, we introduce a ROM framework using the Proper Orthogonal Decomposition (POD) Galerkin approach for rapidly assessing hemodynamics through idealized models of the TCPC. Specifically, the proposed POD approach allows for a significant reduction in the computational costs of simulating blood flow dynamics in 2D TCPC geometries. This framework serves as a first step towards real-time shape optimization simulations of the TCPC, which will allow for rapid identification of the optimal TCPC morphology.

## METHODS

We began by developing a reference geometry of an idealized 2D TCPC geometry where specific nodes of the TCPC were parameterized, as indicated by $\mu_0 \dots u_5$ (Fig. 1). Each of the variables $\mu_0 \dots u_5$ were parameterized within a certain range as shown in Fig. 1. This geometrical parameterization resulted in the formation of different TCPC morphologies, each with varying offsets between the IVC and SVC, as well as varying inlet diameters for both the IVC and SVC. In each case, parabolic velocity boundary conditions were enforced at the SVC and IVC ($v_{max} = 100 icm/s$ at the SVC, and $v_{max} = 50 icm/s$ at the IVC). At the right pulmonary artery (RPA) and left pulmonary artery (LPA), pressure boundary conditions were enforced ($P_{RPA} = 200 iPa$, $P_{LPA} = 1000 iPa$).

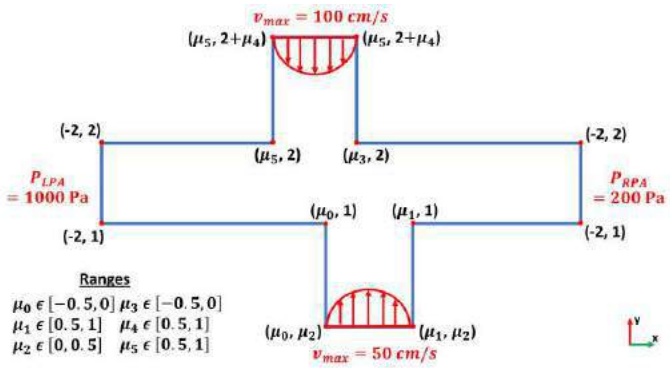

**Figure 1: Reference geometry for idealized 2D TCPC.**

A total of 100 computational fluid dynamics (CFD) simulations were performed with the parametrized TCPC geometries in the offline stage of the ROM framework, from which a *snapshot* library was created. Specifically, these simulations were performed with the steady NSE after discretization with the finite element (FE) method.

The online stage of the ROM framework began with filtering out redundancy from the snapshot matrix via the *Singular Value Decomposition* (SVD), and the resultant singular values were analyzed. A rapid decay in the singular values indicates that the snapshot library can be well approximated by utilizing a select few of those eigenvectors associated with the largest singular values. Using these eigenvectors, the POD-Galerkin approach was implemented to create the reduced basis functions. This was done by first representing the FOM as a linear system obtained after FE discretization, as shown below.

$$Au = b \tag{1}$$

Here, $A$ is the *stiffness matrix* extracted from the FE simulations featuring a size in the range of thousands or millions of rows, $u$ is the resultant solution, and $b$ is a matrix containing the applied boundary conditions. Using the POD-Galerkin approach, the solution $u$ to the differential problem can be rewritten as

$$u_{ROM} = W\underline{c}. \tag{2}$$

Here, $\underline{c}$ is a vector of unknown coefficients, and $W$ is a matrix formed from the eigenvectors obtained from the SVD analysis. Plugging in Eq. (2) into Eq. (1) and multiplying both sides by $W^T$ results in the final reduced order problem, which reads as

$$W^T AW\underline{c} = W^T b. \tag{3}$$

From Eq. (3), $W^T AW$ is a matrix that features a size in the range of tens or hundreds of rows. When compared to the size of the stiffness matrix $A$, the savings in computational costs become evident.

The ROM framework described above was implemented in an open-source model reduction library known as *RBniCS*, which allows for all offline stage simulations, model reduction, and online phase calculations to be combined into a single solver [4]. In the online phase, new geometrical parameters different from those used to generate snapshot library were applied, and the resulting reduced order solution was simulated. Visualization of all results was done in *ParaView*.

## RESULTS

Velocity streamlines and pressure contours for the ROM and FOM solutions are shown in Fig. 2. The ROM solutions were in strong agreement with the FOM CFD simulations with regards to resultant pressure drops and contours, velocity streamlines, and flow dynamics. Peak velocities in the ROM and FOM solutions were identical (99.91 cm/s), while peak pressures were 5408.32 and 5407.14 Pa in the ROM and FOM solutions, respectively. The ROM was also able to accurately capture unique regions of flow separation (corner between the SVC and LPA) that occur due to an adverse pressure gradient from the nonlinear term of the NSE. In terms of computational costs, the FOM required an average of 153.46 seconds to simulate, while the ROM reduced this to 27.48 seconds, an 82.09% decrease in computational time.

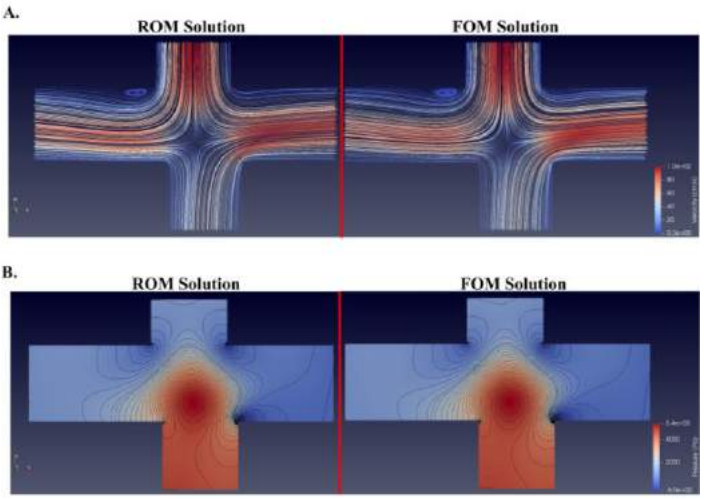

**Figure 2: Comparison between resultant velocity streamlines (A) and pressure contours (B) from ROM and FOM solutions.**

## DISCUSSION

In this study, we introduce a POD-based ROM framework applied towards real-time fluid dynamic simulations in idealized 2D TCPC geometries. The ROM framework resulted in a significant decrease in the computation time required to simulate blood flow dynamics through the TCPC morphology, all while providing identical hemodynamic results as compared to the FOM simulations. Although this framework shows promise in rapidly simulating TCPC flow dynamics, further refinements are underway to fully incorporate the shape optimization problem and thus allow for real-time assessment of the optimal TCPC geometry in 2D scenarios. The optimization criteria will rely on the previously mentioned HFD and PL. Using these quantities, a possible function can be formed to use in the optimization problem, which reads

$$J_{TCPC} = \frac{\alpha_1}{2} PL^2 + \frac{\alpha_2}{2} (HFD_{RPA} - 0.5)^2, \tag{4}$$

where $\alpha_1$ and $\alpha_2$ are user-defined parameters that minimize the PL ($\alpha_1$) and maximize the HFD to the LPA ($\alpha_2$). If $b$ are the geometrical parameters that define the TCPC, then the shape optimization can be formalized as follows: find a value $b$ that minimizes $J_{TCPC}$ under the constraints of the NSE. This optimization problem will be implemented into the in-house solver using the Karush-Kuhn-Tucker (KKT) conditions. A significant limitation of this preliminary investigation is the use of idealized 2D geometries to model the TCPC. Moving forward, the ROM framework will be adapted to parametrize 3D models of the TCPC. This will require the use of advanced techniques such as radial basis functions (RBFs) that allow for adaptive mesh morphing.

In conclusion, the POD-based ROM framework presented here significantly reduces the computational costs of simulating flow dynamics through 2D TCPC geometries. Further refinements of the ROM framework are underway to incorporate the shape optimization problem, as well as to transition towards 3D TCPC morphologies.

# DEVELOPMENT OF A 3D MICROFLUIDIC LIVER CONSTRUCT MODEL FOR ASSESSING THE EFFECT OF PUFA DIETS

**N. Hauser (1), L. Madison Kirk (1), E. Rahbar (1)**

(1) Department of Biomedical Engineering, Wake Forest School of Medicine, Winston-Salem, NC, United States

## INTRODUCTION

Three dimensional (3D) cell culture for *in-vitro* studies has existed since the 1980's. In the decades since, 3D cultures have gained increasing popularity and have demonstrated increased physiological relevancy when compared to 2D cultures due to the ability for cells to spatially arrange, extracellular matrix (ECM) interactions, and a closer material approximation to native tissue. However, 3D cell cultures still lack critical factors found to have a noticeable impact on cell phenotype such as shear stress or other mechanical conditions (1).

Cell culture within a microfluidic chip offers an opportunity to create more relevant microphysiologic systems. Through the addition of fluid flow, mechanical forces simulating physiologic factors such as flow or shear and strain can be introduced (2). Additionally, the introduction of highly controlled fluid movement allows for the ability to connect varying cultured organ systems in an organized manner which enables precise control of nutrient and metabolite flow within the cultured systems. Specifically, for this study we are looking to examine the downstream effects of omega-3 (n-3) and omega-6 (n-6) dietary polyunsaturated fatty acids (PUFAs). These dietary fatty acids are metabolized by the liver into long chain PUFAs, which are precursors to bioactive lipid mediators including prostaglandins, leukotrienes, thromboxanes, and specialized pro-resolving mediators (SPMs). Omega-3 PUFAs have been shown to play a role in resolving various acute and chronic inflammatory diseases within animal models, but translation of these findings into humans has been difficult. We postulate that genetic variability in humans and their PUFA metabolism may be contributing to this challenge and there is a need for further examination into the mechanisms of human PUFA metabolism within the liver (3).

In this abstract, we leverage microfluidics and 3D cell culture to create a highly controllable and physiologically relevant liver model for use in assessing the effects of dietary PUFAs. We aim to create liver-like constructs that recapitulate structures and cell populations within the liver and to allow for a simulated nutrient exchange like those in the hepatic portals. This is accomplished by incorporating three distinct cell types found within the liver into each construct: hepatocytes, stellate cells, and liver sinusoidal endothelial cells. Through the inclusion of these cells in a layered organization (Figure 1) we aim to closely simulate the process through which dietary PUFA's are processed within the body. This design also allows for the selective removal of different cell types to determine their importance in PUFA metabolism.

Another, a key feature of this microfluidic chip is the two distinct flow channels only bridged by the hepatic constructs. By introducing nutrients of interest to the endothelial side we can determine that any change in the lumen channel from baseline is due to metabolic processing through the hepatic-like structure. Once the model is tested, we aim to be able to use these liver chips as a plug-and-play system to work with similar microfluidic chips modeling other organ systems both upstream (intestinal models) and downstream (lung, heart, brain) with the goal of viewing the effects of PUFA metabolism in a more complete system than just hepatic constructs alone.

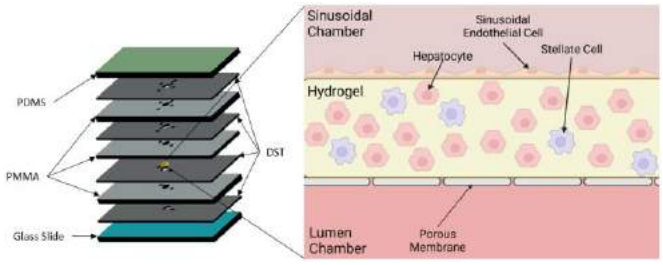

**Figure 1: Illustration of microfluidic chip architecture (exploded view) and hepatic culture cross section**. (This figure was partially created with BioRender.com).

## METHODS

The microfluidic chips used in this study were constructed from stacked layers of double sided adhesive tape (DST) and poly-methyl-methacrylate (PMMA). A laser cutter was used to cut channels and fluid wells into the materials and then they were sandwiched together as shown in Figure 1 to create a microfluidic chip with two separate fluid chambers and a liver construct suspended between them. A PDMS cap was placed as the last layer to fully enclose the chip.

The constructs within the microfluidic chips were made using commercially available methacrylated gelatin (GelMa) hydrogel (Advanced Biomatrix #5272). HepG2 and Lx-2 cells were suspended in a 5% GelMa and lithium phenyl-2,4,6-trimethylbenzoylphosphinate (LAP), a photocrosslinker, prepared according to the manufacturer's specifications. The cells were suspended at a concentration of 20 million cells/mL and with a 3:1 ratio of HepG2 to Lx-2 cells. Linear RGD peptide was then added to create a 1mM solution. 12.5 µL of hydrogel is then pipetted onto the membranes suspended within each microfluidic channel. The constructs were then crosslinked using 365nm UV light for 7 seconds to photo-polymerize the hydrogel. 200,000 EA.hy926 cells were then seeded onto the apical surface to create the endothelial monolayer.

Hepatic constructs were maintained for 24 hours in static conditions before being attached to microfluidic flow. The flow rate used to maintain the constructs was 9.5 µL/min. Cultures were then maintained with regular media changes for up to 14 days.

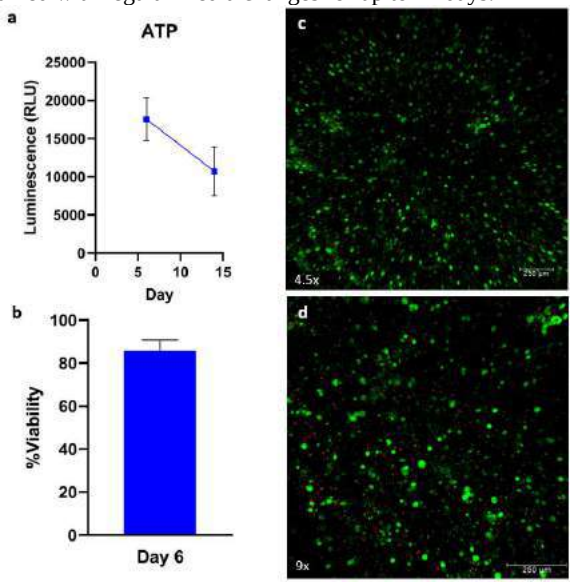

**Figure 2: (a) ATP measures of hepatic cultures over time. (b) ImageJ cell count of living vs dead cells. (c, d) LIVE/DEAD macroconfocal images of HepG2+Lx2 constructs after 6 days in culture, scale bars are 250µm**

## RESULTS

Currently, we have determined that the constructs remain fairly viable out to one week with a moderate reduction (~30%) in metabolism at the two week margin (Figure 2) based on ATP output. Confocal imaging using LIVE/DEAD staining reinforces these findings. Notably, the constructs here demonstrate a uniform viability throughout the entire structure indicating that there is no necrotic core formation, a common problem in larger static construct cultures.

Based on confocal imaging (Figure 3) it was determined that the stellate and hepatocyte cells within the constructs were evenly distributed. Examination of the Lx2 stellate cells (Figure 3a) shows a more rounded morphology compared to 2D cultures of these cells which is associated with a non-fibrotic state. Figure 3d demonstrates the capability to seed an endothelium onto these constructs.

## DISCUSSION

The overall goal of this chip is the creation of a microfluidic construct system for use in multi-organ PUFA dietary studies. The first step to establishing that system is ensuring that the cell populations required to simulate physiological liver activity are both viable and functional within the constructs. Here, we have shown the potential to create liver constructs stable out to at least two weeks using commonly available liver cell lines. This time period is long enough to examine the acute effects within the liver and body of varying PUFA diets. Specifically, this timeframe would be useful for examining the use of PUFA's for treating acute inflammatory conditions after traumatic injuries including concussions, TBI, and ALI/ARDS.

The next step will be examining the metabolic function of these constructs over time by looking at CYP expression, FADS expression and urea and albumin production. Following that would be the inclusion and use of primary human hepatocytes to further increase this model's physiological relevance. Finally, the primary evaluation for this model will be PUFA feeding studies where various blends of n-3 and n-6 PUFAs are introduced via the sinusoidal channel and gene expression, as well as downstream metabolic outputs will be measured from the lumen channel. We expect that the presence of flow in conjunction with a modeled endothelium will increase the metabolic activity of these constructs compared to static models.

# VERIFICATION OF BIPHASIC MATERIAL PARAMETER IDENTIFIABILITY BY FULLY AUTOMATED SENSITIVITY ANALYSIS AND ERROR CHECKING

**John M. Peloquin (1), Harrah R. Newman (1), Dawn M. Elliott (1)**

(1) Biomedical Engineering, University of Delaware, Newark, DE, USA

## INTRODUCTION

Recent work in biomechanics increasingly relies on structural material models because they provide clear physical interpretations and, potentially, predictive validity. They naturally complement the widely-held structure-function hypothesis that tissue organization and composition reflects its health and physiologic role [1]. Despite the expectation that tissue organization is linked with mechanical function, experiments often find structure or composition to be uncorrelated with material parameters [2]. Accordingly, there is growing interest in scrutinizing the methods used to quantify material parameters.

A range of potential inadequacies in material parameter quantification have been described, including specimen preparation, test protocols, and parameter estimation via model fitting [3–5], but these findings unfortunately had limited impact on common practice. Estimating material parameters from data is a multi-stage process (Fig 1). Consequences from a flaw in the test protocol design are often hidden until after data collection when parameter estimation is attempted; then, the root cause is obscured in the muddle of all prior choices. Here, we focus on evaluating the capacity of a test protocol to constrain a material parameter estimate; i.e., whether all parameters in a chosen material model will be *identifiable* from a test protocol's data.

The objectives of this work were: (1) develop software to assess parameter identifiability for any chosen protocol that is suitable for use across research groups, and (2) evaluate a practically significant protocol, confined compression of the intervertebral disc (IVD) cartilaginous endplate (CEP). Endplate permeation is an important transport pathway for the IVD and accurate CEP properties are needed for continued development of IVD FEA models with predictive validity.

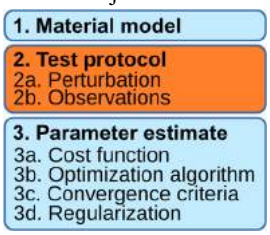

**Figure 1: Decisions in fitting material parameters to data**

## METHODS

Global sensitivity analysis was used because it can evaluate a test protocol prior to data collection, without knowledge of which parameter values are correct. FEBio was used for the simulations due to its flexibility and widespread adoption. A template FEA model was created to represent a CEP specimen (Fig 2). The material model was a biphasic mixture of a Holmes–Mow elastic solid, Holmes–Mow strain-dependent permeability, and Donnan equilibrium swelling (10 parameters total). Each material parameter was varied using full factorial sampling with 3 equally spaced levels spanning best estimates of the 95% confidence intervals for human CEP [6–8], generating 59,049 cases. The need for 3 levels was confirmed by comparison to a 2-level analysis (1,024 cases).

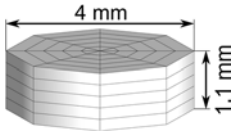

**Figure 2: Simulated confined compression specimen geometry**

Confined compression for each case was simulated consistent with a confined compression test protocol with prior and ongoing use [6,9], consisting of isometric swelling followed by three 10% strain incremental stress relaxation periods in a 0.15 M PBS bath (Fig 3a). The bottom surface was free-draining. In a physical experiment, the CEP is already swollen with unknown strain at t = 0 s, and this preswelling strain was parameterized as $f_s$. Axial compression force, $Fz$, was tabulated for all cases as the test protocol's output variable (Fig 3a).

Parameter effects at each time point were quantified by Pearson correlation coefficient (r) between the parameter and $Fz$. Similarity (redundancy) in the parameter effects was quantified by hierarchical cluster analysis, similar to its use in genetic analysis. A new Python package, "spamneggs", was written to automatically create and run cases, check output for errors, and tabulate and plot results. All computation took < 48 h on a standard office PC.

## RESULTS

$Fz$ was affected most strongly by intrinsic permeability ($k0$), fixed

charge density (FCD), and preswelling strain fraction ($f_s$) (Fig 3b, magnitude of correlation coefficients, r). $E$, $\phi$, $M$, and α had moderate to weak effects on $Fz$. However, decomposition of total variance via Sobol analysis (not shown) revealed that M and α, which govern permeability's strain-dependence, had strong effects due to parameter interactions or nonlinear effects not captured by Pearson correlation.

The distinctiveness of each parameter's effects on $Fz$ ranged from unique to redundant (Fig 3b, correlation patterns and clusters). $\phi$, $k0$, and β had unique correlation patterns with $Fz$. However, $E$ and ν were fully redundant with each other, as were FCD and Φ. Redundancy in a pair of parameters implies that at least one is non-identifiable. $f_s$ was similar to FCD and Φ but, fortunately, not entirely identical.

Parameters can have mutually redundant effects in combinations of 3 or more, not only pairwise. Therefore, the identifiability provided by the entire protocol was quantified using the eigenvalues of the matrix of all correlation coefficients (i.e., normalized covariance). Two eigenvalues were ≈ 0, reflecting the two fully redundant pairs noted above, and six eigenvalues were ≥ 1% of the total normalized variance (Fig 4). Thus, data from this protocol provides enough information to constrain ~ 6 of this material model's 10 parameters.

Unexpectedly, the automated error checks provided important information. 20% of cases had one or more output errors (Fig 5a). Only 1/3 of errors were reported by FEBio; the rest were detected by custom error checks, the most important of which were for protocol errors (boundary conditions not enforced) and pore collapse (pore volume ≤ 0, a violation of biphasic theory's assumptions) (Fig 5b). Cases with errors were excluded from quantification of each parameter's effects above;

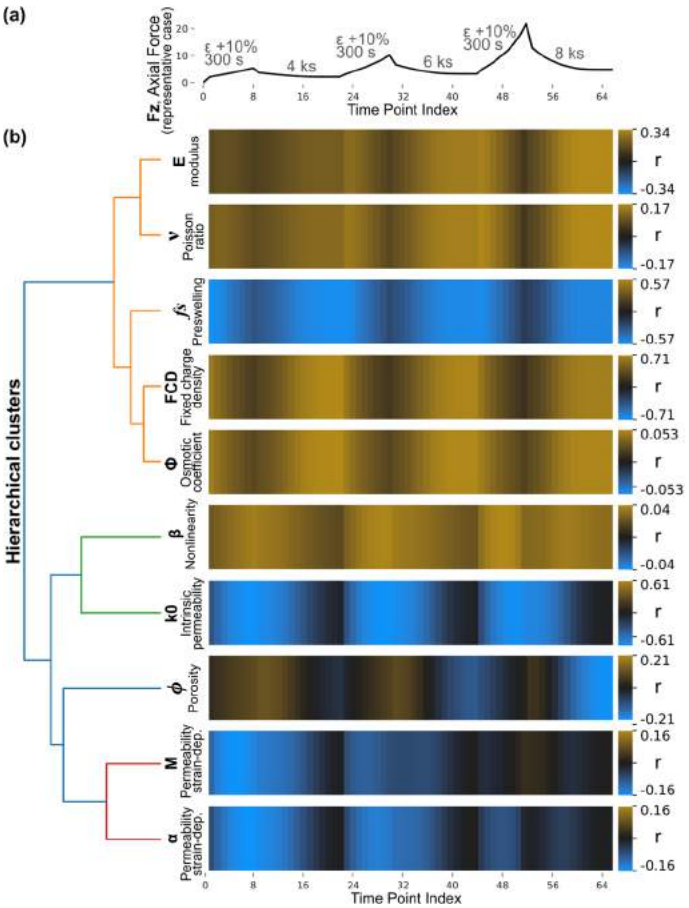

**Figure 3: (a) Test protocol; (b) Parameter effects (correlation coefficients, r, between the parameter and Fz across time).**

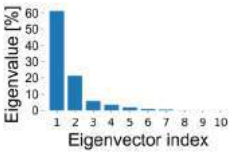

**Figure 4: Eigenvalues of the parameter correlation matrix**

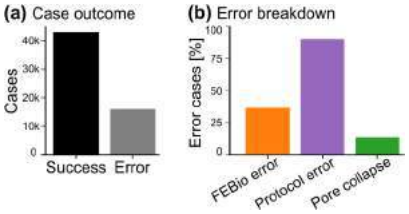

**Figure 5: Error counts and proportions**

without these checks, parameter effects were severely distorted.

## DISCUSSION

Automated global sensitivity analysis was successfully performed for an IVD CEP confined compression test protocol and nonlinear biphasic material model that is also applicable to cartilage and other soft tissues. Due to redundant parameter effects, only ~ 6 parameters are identifiable by model fitting, *if* the remainder can be constrained by other methods.

Selection of constraints should be based on the parameter effects (Fig 3). Only one parameter in each of the redundant pairs can be fit. Φ is already assumed [6,8], and ν = 0 could be assumed (treating $E$ like an aggregate modulus). FCD can be measured by DMMB assay [6], and usually is; $\phi$ can be measured [7]; and $f_s$ can be calculated from $E$, ν, β, and FCD at equilibrium [6]. To consistently achieve equilibrium, the protocol duration must be extended. Because assay errors are uncorrelated with the major axes of a model fit's solution domain, small direct measurement errors tend to cause an outsized reduction in model accuracy [10]. We recommend using direct measurements only to regularize (softly constrain) FCD, $\phi$, and $f_s$. These 2 hard constraints and 3 soft constraints should provide parameter identifiability when fitting the model. Alternatively, confined compression could be exchanged for indentation, as was done for fitting linear elastic constant-permeability biphasic models [3], to hopefully provide better data for model fitting.

Simulation errors were frequent but were successfully managed by an additional layer of automated error checking. These checks were critical to obtain valid results and would also be necessary when fitting a model to experimental data, as optimization algorithms will not function correctly when 10–20% of the model evaluations are incorrect. These results reveal that parameter estimation for a biphasic model involves identifying both the feasible region as well as the parameters themselves. This dual task is under-studied; many optimization algorithms accept parameter bounds but these must be chosen up front.

Importantly, the software we developed for this study is general-purpose. It can operate on any FEBio model, and tables and figures are produced automatically, adapting to the chosen material parameters and output variables. Given a template FEBio model, and assuming the automated error checks remain adequate, the corresponding sensitivity analysis takes < 1 h of human time. The software is published at https://github.com/jpeloquin/spamneggs. We therefore expect that these methods will provide practical assistance during experimental protocol design, making material parameter estimation easier and more reliable.

## INTRODUCTION

Developing musculoskeletal tissues consist of a dynamically changing extracellular matrix (ECM) that can directly and indirectly regulate cell behavior. Tissue mechanical properties and composition activate and control key cellular processes through reciprocal cell-matrix interactions. Researchers have been unable to capitalize on these instructive cues for tissue engineering scaffold design due to limited knowledge of the cell microenvironment during musculoskeletal ontogeny [1]. Furthermore, while research efforts are usually concentrated on tissue-specific development, how these vastly different structures and functions become integrated remains unclear.

Skeletal muscle transmits forces to the skeleton through the enthesis, a strong interface between tendon and bone. This interface effectively attaches mechanically dissimilar tissues by providing stress and strain reduction via splayed collagen microfibrils [2]. Because these fibrous tissues do not regenerate, the only time that a strong, functional attachment forms is during initial tissue assembly [3]. The migration and stabilization of enthesis progenitors relies on postnatal muscle loading, resulting in a mineralized and mechanically strong tissue gradient [4]. The dynamics of the developing enthesis in prenatal development, however, has been underexplored.

The objective of this study is to define how mechanical properties and proteome of the assembling enthesis change as a function of development and motility. Specifically, we investigate the Achilles enthesis at the pre-osteogenic calcaneus in murine embryonic and postnatal timepoints. Furthermore, we investigate the impact of muscle forces on enthesis development using the *muscular dysgenesis* (*mdg*) murine model in which skeletal muscles lack excitation-contraction coupling due to a mutation in the calcium channel subunit Cacna1s [5].

## METHODS

To investigate the influence of muscle contractions on enthesis development, mice heterozygous for Cacna1s$^{mdg}$ were paired to generate wildtype controls (+/+), normal-appearing littermates (+/mdg), and homozygous (*mdg*/*mdg*) paralyzed mutants for testing. Homozygous mice do not survive postnatally, so these studies were conducted at embryonic day (E) 18.5. To investigate the influence of development on enthesis formation, adolescent wild-type mice (C57B6/J) were obtained postnatal day (P) 21. Cacna1s$^{+/mdg}$ mice were combined with mice expressing Scleraxis-GFP (Scx-GFP) to visualize tendon progenitors and identify the enthesis *ex vivo*. Cacna1s$^{+/mdg}$ and Scx-GFP mice were provided by R. Schweitzer at OHSU.

Tissue specimens were collected and analyzed the same day via atomic force microscopy (AFM) while still viable, confirmed with EthD-1 staining. AFM tests were conducted while tendon/entheses tissues were undeformed. A Keysight 5500 AFM system facilitated mapping of micromechanical properties of the ECM in tendon, enthesis, and cartilage tissues. Tissues were characterized with a cantilever equipped with a 5µm borosilicate glass sphere (NovaScan), pre-calibrated to be 0.07 N/m. The tissue was identified optically and then indented at 1.2µm/s until the setpoint force of ~12nN was reached, and the probe was retracted. AFM was performed over the approximate area of the cell microenvironment 15x15µm, with 16 or 64 independent indentations as technical replicates. The indentation curves were fit to a two-parameter model developed by Fung to extract an initial stiffness modulus and a strain-stiffening, nonlinear parameter [7]. Two-way ANOVA was used to calculate significant interactions between ECM stiffness, genotype, and developmental timepoint, and Tukey or simple effects post-hoc tests were conducted for independent comparisons.

To identify ECM composition in developing cartilage, tendon, and enthesis tissues, liquid chromatography-tandem mass spectrometry (LC-MS/MS) was utilized. At E18.5 and P21, tissues from the Achilles enthesis (tendon, calcaneus, and interface) were isolated and tissues were mechanically homogenized with 8M urea, 100mM ammonium bicarbonate, and 10mM DTT following [8]. Protein concentrates were sent to the Mass Spectrometry facility at CU Boulder for analysis.

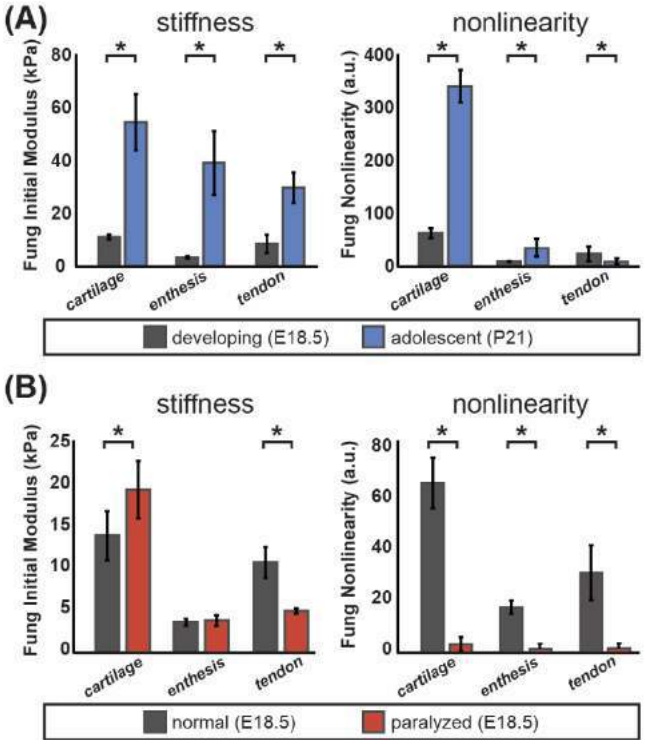

**Figure 1: Stiffness and nonlinearity significantly change with postnatal development (A) and embryo motility (B).**

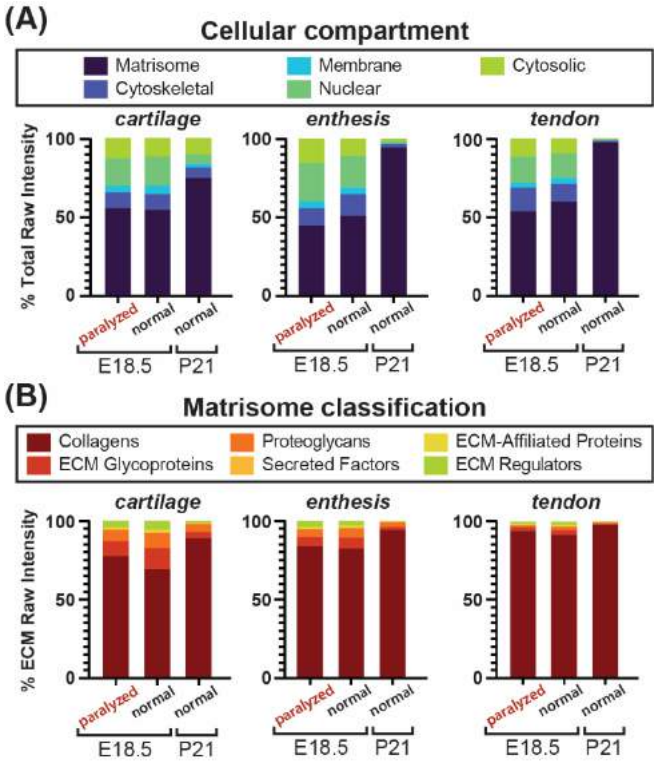

**Figure 2: Distribution of proteins identified by LC-MS/MS. Raw intensities of tissue compartment (A) and matrisome classification (B) were plotted as a percent of total raw intensity.**

Proteins were annotated as cytosolic, nuclear, membrane, cytoskeletal, or matrisome based on a list of cellular compartments derived from The Matrisome Project [6].

## RESULTS

Two-factorial ANOVA identified a significant interaction between the effect of embryo motility on tissue stiffness ($p<0.05$). A follow-up test for simple effects detected significant differences between each tissue type both as a function of motility ($p<0.05$) and developmental timepoint ($p<0.05$). While we did not identify a significant interaction between stiffness and developmental timepoints ($p=0.12$), Tukey post-hoc tests were significant between tissue types within each developmental stage ($p<0.05$). Significant differences of nonlinearity were detected between developing and adolescent timepoints ($p<0.05$), and as a function of embryo motility.

Comparison of the proteome of developing tissues (normal vs. paralyzed) and adolescent tissues (wildtype only) showed that the effect of ECM category was significant between tissues ($p<0.0001$). The proteomic makeup divided into cellular compartments showed little change as a function of embryo movement; however, relative abundance of collagens decreased in paralyzed embryos, particularly in developing cartilage. The relative abundance of ECM regulators increased at the onset of movement during development, then decreased in adolescence.

## DISCUSSION

We measured mechanical properties of the ECM cell microenvironment and characterized the ECM proteome in the enthesis as a function of development and embryo movement. The initial stiffness of each region in embryonic tissue did not demonstrate a linear gradient, but rather a bimodal characteristic where the enthesis is the least stiff between tissues. Interestingly, by the time the hindlimb is routinely loaded at P21, a stiffness gradient was observed. These results support the hypothesis that the mechanical gradient of the enthesis is established during postnatal loading/walking. Postnatal activity may be responsible for the nonlinearity of cartilage and functional grading of the tendon interface. Preliminary data of the proteome in the developing enthesis suggests that embryonic motility potentially stimulates ECM production and diversity in matrisome composition, particularly levels of collagens and ECM regulators. Possibly, collagens contribute to the linear stiffness parameter providing tissues with structural integrity. On the other hand, collagen-based biopolymers exhibit a nonlinear strain stiffening response to applied shear stress, providing inherent stability to connective tissues under tenson [9].

This is the first study to measure the mechanical properties of the enthesis during embryogenesis and compare the tissue composition of enthesis and neighboring tissues as a function of embryonic movement and developmental timepoint. The study is currently limited to correlational comparisons. However, not only does this work define mechanical and proteomic changes in enthesis development, but it can also form a basis for design of synthetic ECM networks for tissue engineering. Future work will investigate enthesis matrix organization and validation of unique protein identifications, and reductionist experimentation will be applied to identify ECM networks responsible for linear vs. nonlinear mechanical properties.

## INTRODUCTION

Knee osteoarthritis affects around 16% of the global population[1] and meniscal tears are among the most common knee injuries[2]. The menisci are C-shaped fibrocartilaginous tissues that distribute 60% of the load from the upper body[3] and are critical to healthy knee function. The meniscus, however, is avascular and struggles to heal when damaged. Repair approaches have limited success[4] and tissue graft demand exceeds supply. Thus, tissue-engineered alternatives are desired to replace damaged menisci.

Tissue engineered meniscal scaffolds are often fabricated though molding techniques, bioprinting, or electrospinning. These fabrication techniques, however, have limited design options and struggle to fully restore load distribution. Designing a meniscal replacement is further complicated by trying to balance the need for load support with a pore size that supports cellular infiltration.

Our group has designed a tissue-engineered system that uses additive manufacturing. To improve mechanical properties while enabling tissue regeneration, we propose fabricating stiff structures using a commercially available liquid deposition printer (Stratasys® Polyjet™), and then infilling these structures with a degradable hydrogel cell scaffold. This composite approach may enable scaffolds that distribute physiological loads while providing a suitable volume fraction for a cell-laden hydrogel infill.

The objective of this study was to establish a structural design, evaluated via computational modeling, that bears physiologically relevant loads, maximizes structural efficiency, and maintains a total volume fraction under 0.4 to allow for a cell-laden hydrogel infill. We hypothesize that scaffold designs that help to transmit load radially and circumferentially will outperform the more basic lattice structure.

## METHODS

**Structure Designs and Outcome Measures:** All scaffolds were designed to fit an idealized circular shape with wedge-shaped cross-sections (Figure 1). All designs had a diameter of 10 mm, inner diameter of 3 mm, and a radius of curvature of 7 mm which is comparable to native rabbit menisci[5]. Structures were limited to volume fractions ($V_f$) less than 0.4 to allow future infilling of a cell-laden hydrogel. Three designs were evaluated with finite element (FE) modeling (Figure 1B-C): a classic square lattice ($V_f$ = 0.35), a truss frame ($V_f$ = 0.30) meant to direct loads radially, and a circumferentially reinforced truss frame ($V_f$ = 0.37) which provides additional circumferential support. A solid-material design ($V_f$ =1) was also modeled for comparison (Figure 1A).

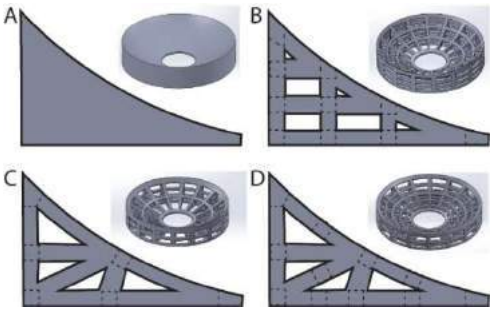

**Figure 1: Cross section and overview of scaffold designs (dashed lines in cross section represent circumferential components). A) solid B) classic square lattice C) truss frame and D) circumferentially reinforced truss frame**

Outcome measures included local strain in the articular cartilage at physiological load (20 N), structural efficiency (Table 1), and von Mises stress distributions at 10% local strain (Figures 2 and 3). We defined local strain as the indentation depth of the femoral condyle divided by articular cartilage thickness. Physiological load (20 N) was determined from gait analysis of skeletally mature (4-5kg) New Zealand White rabbits, suggesting the mean intersegmental axial knee force is 40%

body weight[6]. Structural efficiency was calculated as load divided by displacement divided by material volume; high structural efficiency indicates that a design optimizes load bearing capability while retaining a low enough volume fraction to infill with a cell-laden hydrogel.

**Simplified Femoral Condyle-Meniscus-Articular Cartilage 3D FE Model:** We used FE analysis in Abaqus to model the femoral condyle (rigid sphere) indenting to a depth of 10% of the thickness of the tibial plateau articular cartilage (simplified as a flat substrate). The outcome measure "Strain at 20 N load" was interpolated from the results. Each model was simplified to a 1/16 sector of their full designs using cyclic symmetry (Figure 3A). Both the structure and articular cartilage were modeled as linear elastic materials with $\nu = 0.45$. Elastic modulus for the structure ($E$ = 50 MPa) was estimated from shore hardness provided by Stratasys for material FLX9130-DM. The elastic modulus for cartilage ($E$ = 10 MPa) assumed near-instantaneous loading[7]. All parts interacted with frictionless sliding contact. Analyses were static and considered nonlinear geometric effects.

The mesh for the articular cartilage substrate used 1,375 quadratic hybrid hexahedral elements (C3D20H) and 389 quadratic hybrid tetrahedral elements (C3D10H). Meshes for the meniscal structures used between 2.5–15k linear hybrid incompatible mode hexahedral elements (C3D8IH). Mesh refinements verified that results converged with decreasing mesh size. Final meshes featured at least four elements across the smallest features of the frame.

We verified our implementation of cyclic symmetry and spherical indentation by comparing a sub-model to Hertz' analytical solution for spherical indentation of a half-space. Our sub-model of pure indentation used a 100 mm thick substrate and was within 3% of the Hertz solution.

**3D Printing:** A "truss frame" prototype structure was fabricated using Stratasys Polyjet printer and Agilus30Clear material.

## RESULTS

Regardless of design, peak stress was observed in the inner third of the meniscal construct (Figure 2). Circumferential beams in all designs were loaded in tension and had higher stress than radial and vertical features (Figure 3A). Of the three structure designs, the circumferentially reinforced truss frame resulted in the least local articular cartilage strain (5.25%) while having the highest structural efficiency at 6.66 N/mm/mm$^3$ (Table 1). However, the circumferentially reinforced truss frame design also had the highest $V_f$ at 0.37. The less dense truss frame ($V_f$ = 0.30) allowed more strain than the square lattice design but improved upon structural efficiency (Table 1).

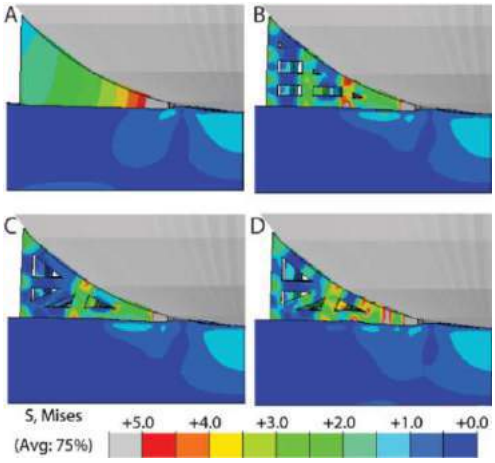

**Figure 2: Von Mises stress at 10% local strain for each design: A) Solid B) classic square lattice C) truss frame and D) circumferentially reinforced truss frame.**

**Table 1: Measured Outcomes.**

| | Solid | Square lattice | Truss frame | Circum. reinforced |
|---|---|---|---|---|
| **Volume fraction, $V_f$** | 1.00 | 0.35 | 0.30 | 0.37 |
| **Strain at 20 N load** | 2.6% | 5.97% | 6.74% | 5.25% |
| **Structural Efficiency** | 4.99 $\frac{\text{N/mm}}{\text{mm}^3}$ | 6.18 $\frac{\text{N/mm}}{\text{mm}^3}$ | 6.36 $\frac{\text{N/mm}}{\text{mm}^3}$ | 6.66 $\frac{\text{N/mm}}{\text{mm}^3}$ |

We printed a proof-of-concept "truss frame" to scale (10 mm dia.) with Agilus30Clear material (Figure 3B). Degradable support material enabled all truss features, including horizontal overhangs, to be printed.

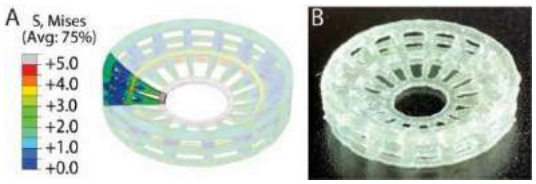

**Figure 3: A) Stress field of truss frame visualized from cyclic symmetry of 1/16 sector; B) 3D printed truss frame design**

## DISCUSSION

Additive manufacturing has enabled the design of complex load-bearing structures for tissue scaffolds. However, existing meniscus designs are limited to overlayed bio-ink lattices or a classic square lattice design (Figure 1B)[8]. This study showed that a more complex truss design (Fig. 1C) could reduce material volume by almost 15% while increasing structural efficiency by 3%. Our models revealed how circumferential features in these structures experience the greatest stress. Acting on this insight, we improved upon structural efficiency in our circumferentially reinforced design (Fig. 1D) at the cost of an increased volume fraction. When infilling a scaffold with a hydrogel, it is critical that enough space remains for complete infill, cell infiltration, and new extracellular matrix production. For this reason, we concluded that the truss frame was preferred because it balanced a lower $V_f$ with high structural efficiency. We then demonstrated the design was feasible to 3D print (Figure 3B). However, future prints should use a stiffer material like FLX9130-DM to better match our models.

It is not surprising that the circumferential features experienced the highest stresses. In the native tissue, circumferential collagen fibers help to resist lateral expansion and convert axial loads to circumferential hoop stresses. Future designs may be optimized by reducing the volume of radial features while reinforcing circumferential features.

This study highlights how scaffold design can impact structural efficiency and how 3D printing enables more complex designs. While our current study idealized the shape of the meniscus to reduce computational complexity, this same approach can be implemented into more accurate meniscal shapes obtained from medical imaging. Overall, our findings here may inform future implant designs that effectively recapture the meniscus' native mechanical function.

## Background

Repair after tissue injury involves a dynamic interplay among not just tissue resident cells (e.g., fibroblasts)[1], but also cells recruited from the circulation. Myeloid cells, such as monocytes and macrophages, are derived from hematopoietic precursors and migrate to sites of injury where they play a role in modulating all stages of wound healing and scar formation[2]. There is mounting evidence that mechanical stimuli are also able to modulate monocyte and macrophage response during tissue healing, but the exact mechanisms behind this "mechano-immunomodulation" remain incompletely understood[3].

## Methods

We attached a mechanical strain device to the mouse dorsum to initiate a uniform and consistent strain profile across an incisional wound to create hypertrophic scar (HTS) formation in mice[4]. These devices are steel palatal expanders with rod extender arms that are attached to the backs of the mice using skin adhesive and staples to allow for a uniform strain profile. We waited 4 days after the incision to mount the device, allowing the wound to close. Next, we extended the device every other day for a 14-day time period.

To analyze the scar tissue, we took photos of the scars before we explanted. Then, once we explanted the scar tissue, we stained it using picrosirius red, a type of staining that magnifies collagen formation and structure. With the stained tissue, we were able to use CurveAlign and CT-Fire collagen architecture algorithms[5]. CurveAlign quantifies all fiber angles within the given image, while CT-Fire analyzes individual fiber measurements.

To investigate mechano-responsive immune cells, we performed parabiosis of wildtype (WT) and GFP+ mice, allowed the mice to develop a shared blood circulation, initiated HTS formation in the WT mouse, and analyzed the cells using single cell RNA sequencing (scRNA-seq), fluorescent-activated cell sorting (FACS), and immunofluorescent staining.

We then specifically bred mice to knockout focal adhesion kinase (FAK, encoded by *Ptk2*) signaling in either fibroblasts (*Col1a2 Cre, Ptk2-flox*) (n=3) or myeloid cells (*Lyz2-Cre, Ptk2-flox*) (n=3), We used the HTS model on both breeds of mice, along with WT mice. Of a total of 18 WT mice, (n=2) received an incision but no device (control); (n=10) received an incision with mechanical strain (HTS); (n=6) were treated with FAK inhibitor (FAKI) hydrogels in conjunction with mechanical strain (S+FAKI)[6].

## Results

Utilizing these devices created scars in wildtype mice with increased levels of fibrotic tissue and highly aligned collagen as compared to the control wildtype mice without extension. Mechanical modulation significantly upregulated the presence of inflammatory subtypes within the healing tissue, characterized by an increase in infiltrating GFP+ immune cells from 5.4% to 12.2%. In the GFP+ circulating immune cells, mechanical strain directly increased the proportion of fibrotic myeloid cells, primarily defined by the monocyte marker *Ly6c2* as well as the TGFB responsive and macrophage activating gene *Thbs1* (which codes for the protein Thrombospondin 1). Mechanical strain also increased the proportion of inflammatory myeloid cell populations, defined by *Ccl* and *Il6* chemoattractants, and *Cd74*+ migratory myeloid cells.

SB³C2022-372

With gross photography, we took measurements of both the length and width of the scars to compare the fibroblast and myeloid FAK KO scars with wildtype HTS scars. We observed that both knockout strains generated visually less scarring than in wildtype mice. Furthermore, FAKI treated wounds also improved healing and reduced fibrosis compared to HTS groups.

Using picrosirius red staining, we observed that the HTS collagen fibers were also significantly longer and more highly aligned than FAKI treated and FAK KO scars, as well as unwounded skin.

Using scRNA-seq, we found that FAK inhibition inhibition reduced the proportion of *Thbs1+/Ly6c2+* fibrotic cells and *Ccl+/Il6+* inflammatory myeloid cells within the healing murine wound and instead promoted a unique subset of regenerative myeloid cells. Regenerative myeloid cells primarily upregulated anti-inflammatory myeloid markers *Mrc1*, *Cd163,* and *Selenop*, as well as *Egr1* (encoding early growth response protein 1). We have previously demonstrated that *Egr1* signaling in fibroblasts is promoted by FAK inhibition, mediated by Akt signaling, and associated specifically with regenerative phenotypes that suppress fibrosis[1].

Using immunofluorescent staining, we confirmed that the scars in the HTS mice had significantly elevated levels of a pro-fibrotic extracellular matrix marker Thrombospondin1 compared to FAKI treated and KO scars. We also confirmed an upregulation of Selenoprotein P (encoded by *Selenop*) with FAK modulation.

## Conclusions

Tissue injury activates a cascade of signaling pathways to recruit and orchestrate various cell types during healing. Our study indicates that modulating mechanical stress directly affects myeloid cell phenotypes and interactions with other cell types in the complicated, multicellular milieu of wound healing. This principle has been previously unexplored in the context of fibrosis and regeneration, with most previous studies focused on fibroblast heterogeneity and transcriptional profiles. To our knowledge, this is the first study to directly investigate the effects of modulating mechanotransduction on immune cell response at the single cell level utilizing parabiosis and wound healing. Collectively, we demonstrate that mechano-immunomodulation of the “early responders” of healing can trigger a cascade of downstream regenerative healing.

## INTRODUCTION

Left ventricular outflow tract (LVOT) obstruction is a prevalent and potentially fatal complication of transcatheter mitral valve replacement (TMVR) caused by displacement of the anterior leaflet towards the ventricular septum. Laceration of the Anterior Mitral leaflet to Prevent Outflow Obstruction (LAMPOON) is a catheter-based technique designed to alleviate the risk of obstruction by mimicking surgical anterior leaflet resection [1]. The optimal result of the LAMPOON procedure is a complete midline laceration of the anterior leaflet which, following TMVR, exposes open cells of the transcatheter valve. These exposed cells are thought to permit additional blood flow through the LVOT and decrease the risk of obstruction.

Despite the growing clinical experience with this technique, a controlled clinical trial comparing the outcomes of patients undergoing TMVR with versus without LAMPOON has never been designed nor conducted. It would be *impossible* to conduct such a trial in which the control intervention (i.e., TMVR without LAMPOON) would be anticipated to cause immediate LVOT obstruction following valve implantation. Thus, while the LAMPOON technique has been shown to be safe and feasible, its impact on left ventricular outflow tract hemodynamics has never been investigated.

Therefore, the *goal* of this computational (*in silico*) controlled study was to compare the hemodynamics of TMVR with LAMPOON versus TMVR without LAMPOON. We *hypothesized* that LAMPOON improves flow dynamics through the LVOT in patients with a small residual LVOT (neo-LVOT).

## METHODS

LAMPOON Trial Dataset: De-identified subject data from the LAMPOON investigational device exemption trial (NCT03015194) were retrospectively evaluated under an Institutional Review Board approved protocol [1]. All subjects in that trial (N=30) were considered at prohibitive risk for TMVR-related LVOT obstruction based on a predicted end-systolic neo-LVOT area of <200 $mm^2$. Subjects underwent a valve-in-ring or valve-in-mitral annular calcification procedure with the SAPIEN 3 valve (Edwards Lifesciences, Irvine, CA) with retrograde LAMPOON prior to valve implantation.

Selection of Study Cohort: Inclusion criteria for this study were: (1) the availability of a post-procedure, multi-phase CT scan with contrast-enhancement, and (2) a splayed anterior leaflet that was visible on post-procedure CT and exposed cells of the implanted transcatheter valve. Of the thirty subjects in the LAMPOON investigational device exemption trial, eight subjects were selected for the present study.

3D Models Created for Each Subject: Contrast-enhanced, multi-phase CT scans were acquired after the procedure, either pre-discharge or within 30-days of follow-up. CT images were reconstructed in 10% intervals over the cardiac cycle within <1.0-mm slice thickness. Mimics 20.0 (Materialise, Leuven, Belgium) image post-processing software was used to generate 3-D models of the left ventricle and aorta using conventional segmentation techniques.

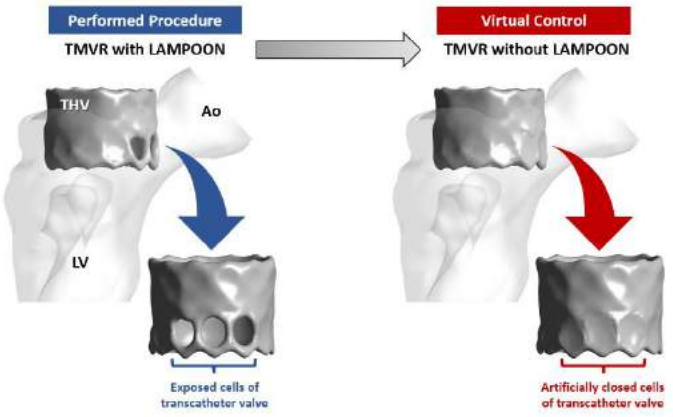

**Figure 1: 3D anatomical models created for each subject**

Two different 3D models were created for each subject. The first model represented 'TMVR with LAMPOON'. In this model, the *actual* implanted transcatheter valve and splayed anterior leaflet were reconstructed in 3D from the post-procedure CT (**Figure 1**, left). The second model represented 'TMVR without LAMPOON'. In this model, the exposed cells of the transcatheter valve were *artificially closed*, mimicking a completely intact anterior leaflet geometry (**Figure 1**, right). Since the model of 'TMVR with LAMPOON' mimicked the performed interventional procedure, the model of 'TMVR without LAMPOON' was considered to mimic a 'virtual control'.

Computational Fluid Dynamics (CFD) Simulations: We utilized a validated workflow for generating patient-specific CFD simulations of left ventricular outflow which has been previously reported in detail [2]. Patient-specific CFD simulations were performed for both modeled conditions (TMVR with and without LAMPOON) for each subject. For each 3D model, an inlet was placed at the left ventricular apex, and an outlet was placed at the sino-tubular junction. The time-varying left ventricular volume curve (obtained from the post-procedure CT dataset) was used to calculate a peak systolic flow rate, which was then prescribed as the inlet boundary condition. The CT phase which most closely coincided with the peak systolic flow rate was selected for creating a volumetric mesh using ANSYS Fluent Meshing (Ansys, Inc. Canonsburg, Pennsylvania). This mesh included polyhedral elements with an edge length of 0.5 mm, and a prismatic boundary layer mesh which was applied on the left ventricular wall. The outlet boundary condition was set to a zero-reference pressure. Transition-to-turbulence characteristics in the flow field were accounted for using the scale-adaptive simulation turbulence model. All structures were assumed to be rigid and non-permeable, and a no-slip condition was applied at the walls. Blood was modeled as a single-phase Newtonian fluid with a density of 1060 kg/m$^3$ and dynamic viscosity of 0.0034 poise. The 3D Navier-Stokes equations were solved in ANSYS Fluent 19.0.

Obtaining Simulated Hemodynamics: Hemodynamic metrics were extracted from each CFD simulation, including the peak outflow velocity ($V_{peak}$), peak LVOT pressure gradient ($\Delta P_{peak}$), and peak LVOT effective orifice area ($EOA_{peak}$). To calculate $\Delta P_{peak}$, the ventricular pressure was derived from an average pressure across the model inlet (LV apical plane), and the aortic pressure was derived from an average pressure across the model outlet (sino-tubular junction plane). $EOA_{peak}$ was calculated as the ratio of the peak volumetric flow rate ($Q_{peak}$) to the peak outflow velocity ($V_{peak}$).

Data Analysis: All data analyses were performed with the MedCalc statistical software package (MedCalc, Ostend, Belgium). Simulated hemodynamics for each subject were compared between the two modeled conditions using the paired samples t-test or Wilcoxon test for parametric and non-parametric data, respectively. Statistical significance was defined as $p<0.05$.

## RESULTS

Across all subjects, simulated hemodynamics were improved for TMVR with LAMPOON compared to TMVR without LAMPOON (**Figure 2**). As compared to TMVR without LAMPOON, TMVR with LAMPOON resulted in lower $V_{peak}$, lower $\Delta P_{peak}$, and higher $EOA_{peak}$ by 14±7% (p=0.006), 31±17% (p=0.01), and 17±9% (p=0.002), respectively. Following LAMPOON, $V_{peak}$ decreased from 2.6±1.1 m/sec to 2.2±0.9 m/sec, $\Delta P_{peak}$ decreased from 17.5±19.6 mmHg to 10.0±8.8 mmHg, and $EOA_{peak}$ increased from 1.6±0.6 cm$^2$ to 1.8±0.7 cm$^2$ ($p<0.05$ for all comparisons).

LAMPOON was most effective in improving hemodynamics in subjects who had a small post-procedure neo-LVOT area (**Figure 3**). The largest hemodynamic improvement with LAMPOON was observed in the subject who had the smallest post-procedure neo-LVOT area across all subjects (49 mm$^2$). This subject experienced a 32 mmHg reduction in the simulated LVOT gradient following LAMPOON. As the post-procedure neo-LVOT area increased beyond 250 mm$^2$, LAMPOON began to demonstrate a smaller hemodynamic effect.

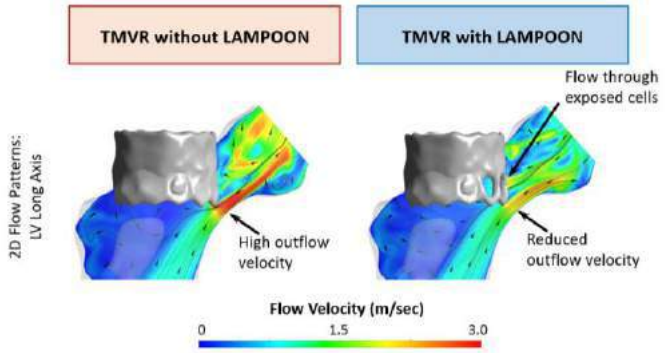

**Figure 2: Effect of LAMPOON on left ventricular flow patterns in a representative subject.**

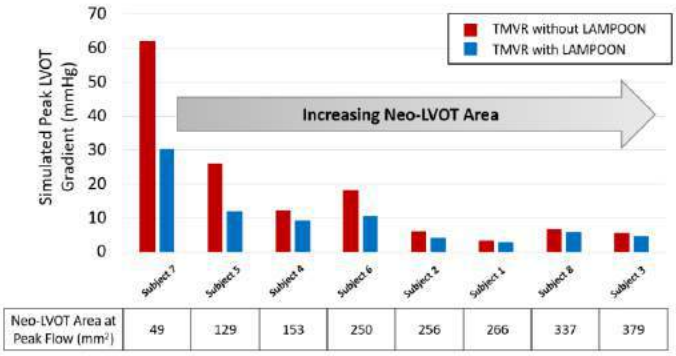

**Figure 3: Relationship between residual LVOT (neo-LVOT) area and the hemodynamic impact of LAMPOON**

## DISCUSSION

A controlled *in silico* study was performed to investigate the hemodynamic impact of LAMPOON in TMVR. LAMPOON achieved a critical increment in outflow area which resulted in a consistent improvement in hemodynamic outcomes and flow patterns following TMVR. Patients with a smaller post-procedure neo-LVOT area experienced a greater hemodynamic improvement with LAMPOON. Importantly, in this study, the TMVR without LAMPOON condition could not be conducted *in vivo* due to prohibitive patient risk. Furthermore, only an *in silico* study could be used to examine the hemodynamic effects of LAMPOON. This study highlights the growing potential for *in silico* studies to evaluate procedures virtually which may improve cost-effectiveness and patient safety as compared to a conventional clinical trial.

# SHEAR PROPERTIES OF COLLAGEN CROSSLINKED PROCINE CORNEA

## INTRODUCTION

The cornea is the outer transparent part of the eye which provides structural integrity and contributes vastly to refract light. The tissue acts as a protective layer for internal contents of the eyeball and its structural properties are important for proper vision. The optical properties of the cornea include transmission and refraction of the light. The cornea is subjected to intraocular pressure from the inside and could be subjected to external forces caused by eye rubbing, for example. The mechanical properties of the cornea are altered in several diseases such as keratoconus, which is an eye disease changing the corneal microstructure. Keratoconus affects about one in 2000 individuals and causes the cornea thins and gradually becomes a cone-like bulge. Any change in the shape of the cornea interferes with its optical properties and causes the vision to become blurry and distorted. At initial stages of the disease, eyeglasses or lenses can be used to correct for vision abnormalities. However, keratoconus is a progressive disease making the cornea to bulge more. Thus, the vision of individuals significantly decreases if no medical intervention is done.

The corneal collagen cross-linking procedure has been shown to be effective in halting or at least slowing the progression of keratoconus. In this procedure, the corneas are soaked in riboflavin solution and crosslinks are created in the corneal stroma by shining ultraviolet (UV) light. It has been shown that corneal structural properties improve because of this procedure, the progression of the disease stops, and individuals may not need corneal transplants. The strengthening effects of the collagen crosslinking treatment procedure have been commonly investigated by performing uniaxial tensile experiments [1-2]. For example, we have shown that corneal collagen cross-linking resulted in a significant increase of tensile stress–strain response which is dependent on the hydration of the samples [3]. The primary objective of the present work was to conduct shear experiments in order to determine how corneal collagen crosslinking procedure influences shear properties of corneal samples in vitro. For this purpose, we used porcine corneas and used the Dresden crosslinking protocol to create crosslinks in vitro. We then performed oscillatory shear experiments to characterize the dynamic modulus of treated and untreated samples.

## METHODS

Fresh porcine eyes were collected from an abattoir and brought to the laboratory. Corneal samples with a scleral rim were prepared after removing epithelial and endothelial layers from the samples. We divided the samples into two groups. The samples in the first group were crosslinked using photosensitizer riboflavin solution. In order to prevent excessive swelling of the specimens, we used 20% dextran in the riboflavin solution. All samples were initially soaked in the riboflavin dextran solution for 30 minutes in order to ensure proper penetration of riboflavin inside the specimens. Then, the samples were irradiated with UV light (370 nm, 3 mw/cm$^2$) for 30 minutes. During this period, we continued instilling drops of riboflavin dextran solution every 5 minutes on the samples. Following crosslinking the samples, we used a biopsy punch to obtain corneal disks from the center of the samples.

A rheometer (DHR-2, TA instruments, Delaware) was used to perform the shear mechanical experiments. These tests were done using

the protocol that we have used before [4]. Briefly, the samples were mounted in the rheometer and the chamber was filled with PBS solution, Figure 1. In order to avoid samples to slip during the experiments, sand papers were glued to the machine. The upper geometry was then brought down and both shear frequency and strain sweep experiments were performed. The strain sweeps were performed using oscillating strains ranging from 0.01% to 10% at the frequency of 1 Hz. Furthermore, frequency sweep experiments were performed at constant oscillating strain of 0.02% and with frequencies between 0.01 HZ and 2 Hz. The storage modulus ($G'$) and loss modulus ($G''$) were calculated using the experimental measurements. The one-way ANOVA was used to compare the behavior of treated and untreated groups. The significance level of 0.05 was used in the statistical analysis.

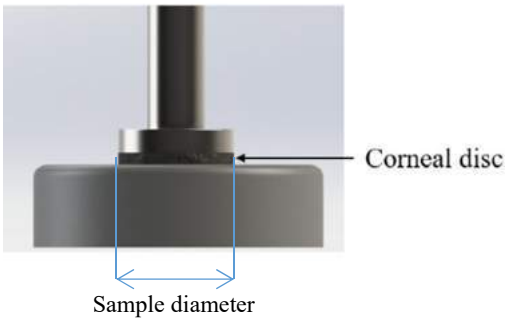

**Figure 1. A schematic plot of the dynamic torsional experimental setup. The samples were placed between the top and bottom platens and sand papers were used to avoid slippage. Furthermore, all experiments were done inside the PBS solution.**

## RESULTS

The storage and loss moduli of the samples in the collagen crosslinked group and the untreated group are shown in Figure 2 as function of the applied shear strain. It is seen that the shear modulus of crosslinked samples is significantly larger than the storage modulus of untreated samples. This figure also shows the range of linear viscoelasticity is almost the same in both groups, i.e. crosslinking of the samples does not have any effect on the overall shear viscoelastic response of the cornea.

## DISCUSSION

The main goal of this study was to characterize the effects of corneal collagen crosslinking on shear properties of porcine corneas. The experimental measurements clearly showed that the corneal collagen crosslinking significantly increased the shear modulus of the samples. We did not see any significant difference in the characteristic curves between both groups, i.e., the linear viscoelastic region for both crosslinked and untreated groups was found to be the same. The range of linear viscoelasticity and the shear modulus of untreated samples were consistent with previous findings [4]. The possible reason for the improvement in the shear properties of the crosslinked cornea could be the crosslinks that are formed in the collagen proteoglycan matrix. This is an important finding because although collagen fibers are important in tensile properties of the samples, shear properties of the samples are determined from the interaction of collagen fibers with the proteoglycan matrix.

# MITRAL VALVE LEAFLET COAPTATION IN THE POST-MYOCARDIAL INFARCTION HEART

## INTRODUCTION

Mitral regurgitation (MR) is the most common valvular disease in the United States with a prevalence of over 2% of the entire population, and is a major prognostic factor of mortality [1, 2]. Ischemic mitral regurgitation (IMR) is a subtype of MR characterized by the insufficiency of an otherwise healthy MV, occurring secondary to myocardial infarction (MI) as the left ventricle (LV) dilates in response to the impaired contractility of an infarcted region [3]. IMR is particularly deadly: five-year mortality after MI with IMR is 62% [4].

Undersized ring annuloplasty (URA) is currently the preferred treatment and reduces the annular orifice area to better approximate the leaflets based on Carpentier's principle that increased coaptation results in a more durable repair [5, 6]. However, long-term patient outcomes remain unpredictable, suboptimal, and poorly understood; six months after URA repair, up to 30% of patients experience recurrent MR [7]. Thus, there is an urgent need to deepen understanding of MR to develop durable IMR treatments to improve long-term patient outcomes.

Given that poor coaptation is the mechanistic driver of IMR, restoring normal coaptation is an important objective in MV repair. However, the full coaptation zone is difficult to visualize using real-time 3D echocardiography (rt-3DE) due to signal loss near the free edge of the leaflets in the systolic position. Consequently, coaptation is generally quantified indirectly or as a one-dimensional length index using 2D echocardiography [8]. Using our state-of-the-art, extensively validated noninvasive image-based modeling approach, we are able to directly quantify the full coaptation area and also resolve this zone into its subregions, providing a more nuanced understanding of the closing behavior of the regurgitant MV.

## METHODS

Rt-3DE images of the MV from 14 IMR patients were obtained from an extant database from a previous study on MV leaflet strain pre- and post-URA repair [9]. 7 showed no recurrence of MR six months after repair, while 7 had recurrence. These images were segmented and processed to produce 3D medial surface representations of each valve in the fully open and fully closed states, before and after repair.

In order to build direct material point correspondence between the open and closed state and to recover the full coaptation zone, we morphed the open state MV mesh to its corresponding closed shape using a hyperelastic shape morphing technique in a finite element (FE) framework [10]. The simulation was conducted in the commercial FE software Abaqus by applying an annular displacement boundary condition, a physiological ventricular pressurization, and a downward chordal-mimicking force. After the leaflets have initially coapted, a local corrective pressure field was applied to penalize any mismatch between the simulated geometry and the true closed-state rt-3DE reconstruction. Using this technique, we can achieve a close match between the simulated geometry and the imaged closed state (Fig. 1).

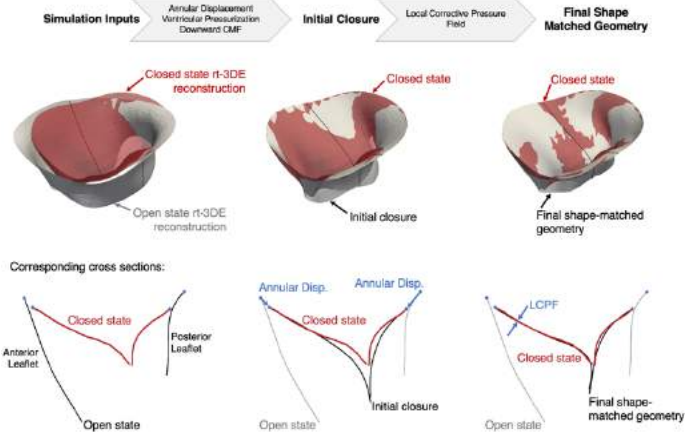

**Figure 1: The progression of the FE-based closure simulation from the open state to the final, shape-matched closed state.**

The coaptation zone of the MV was subdivided into the contact region, the region where the two leaflets are in direct contact, and the redundant region, the portion of the leaflet which hangs below the free edge of the opposing leaflet (Figure 2). Contacting elements are defined as those with centroids within 0.8 mm (the voxel resolution) of each other and with nearly antiparallel outward normals, such that

$$\boldsymbol{t}_a \cdot \boldsymbol{t}_b \leq -0.98, \quad (1)$$

where $\boldsymbol{t}_a$ and $\boldsymbol{t}_b$ are the respective outward normals for any two elements *a* and *b*. Redundant region elements were selected manually in ParaView (Kitware Inc.) by visualizing the valve from the positive and negative y axes and extracting all elements that were visible below the free edge of the other leaflet. Any elements which were identified as both contact and redundant were assigned to the contact set. To determine which elements corresponded to the anterior and posterior leaflets, the outward normal of each element was dotted with the unit y-normal vector; a positive dot product corresponds with the anterior leaflet, and a negative dot product with the posterior leaflet. Finally, the areas of the elements in each set were calculated and summed to compute the total area of that region.

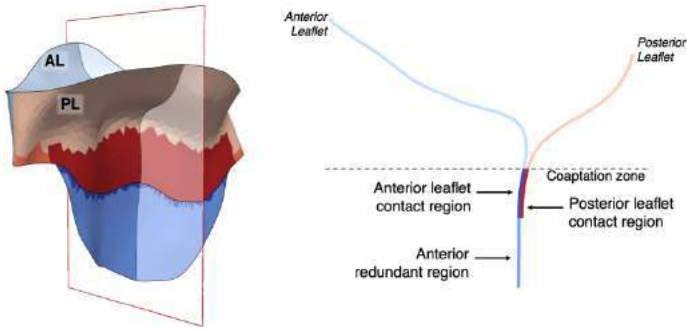

**Figure 2: A cross section of a representative recurrent MV illustrating the coaptation zone and sub-regions on each leaflet.**

## RESULTS

First, the shape-matching technique recovered the full coaptation zone, which is ordinarily not visible in part or in full on rt-3DE. This area was recovered in the final simulated geometry as the open state reconstruction is morphed to shape of the closed state (Figure 3).

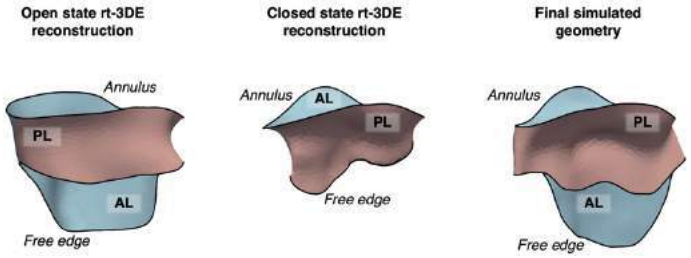

**Figure 3: The open and closed geometries, as well as the simulation output, for a representative recurrent MV.**

Furthermore, this method was able to resolve the coaptation zone into its subdivisions, a distinction which is otherwise impossible to achieve using modern echocardiographic imaging data alone (Figure 2). This more precise insight into the closing behavior of the MV in both the diseased state and after URA repair will deepen our understanding on the impact of the ring on the MV and may help contextualize the divergent clinical outcomes among patient groups. Total systolic leaflet surface area decreased following surgical repair in both the nonrecurrent and recurrent valves ($p < 0.05$). Contact area increased more post-surgically in the recurrent group (Fig. 4A; $p = 0.0203$, $p > 0.05$ for nonrecurrent), a trend which held even when normalized to total systolic leaflet area to account for generally larger recurrent valves (Fig. 4B; $p = 0.0080$, recurrent; $p = 0.0401$, nonrecurrent). The redundant region also increased post-surgically in recurrent valves ($p = 0.0050$, recurrent; $p > 0.05$, nonrecurrent), and again when normalized ($p = 0.0022$, recurrent; $p > 0.05$, nonrecurrent). A general increase in contact area is expected in the context of URA repair; however, it is important to note that MVs with recurrence of MR at six months showed *greater* normalized contact immediately after repair.

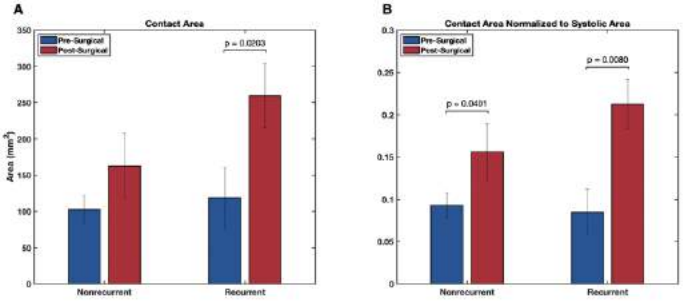

**Figure 4: A: Contact region area in nonrecurrent and recurrent valves before and after URA repair. B: Contact region area normalized to total systolic leaflet area.**

## DISCUSSION

We found that in patients who develop recurrent MR six months after URA repair, the contact area immediately after repair was greater than that of patients who did not have recurrent MR at the same time point. Moreover, the contact area normalized to total systolic leaflet area increased more for recurrent MVs compared to nonrecurrent MVs. This trend could be explained by the fact that recurrent valves tend to have more dilated pre-surgical annuli than nonrecurrent valves, and therefore experience a greater percent change in annulus reduction post-repair [9]. As a result, more leaflet tissue is shunted into the coaptation zone, increasing both contact and redundant region area for the recurrent subset. Importantly, this finding suggests that greater coaptation area alone may not necessarily indicate a more durable repair in the long-term, especially in patients whose LV dilatation is more pronounced. Therefore, improved contact alone may not be a reliable metric for determining durability of the repair. In this study, we have also demonstrated the capability of our shape-matching technique in recovering the full coaptation zone, which can be underestimated in rt-3DE. Moreover, we were able to further resolve this zone into its subregions, which will allow us to refine our understanding of MV coaptation behavior in MR as well as the functional consequences of available repair techniques.

## INTRODUCTION

Tissue-engineered vascular grafts (TEVGs) offer hope for improved long-term functionality in congenital heart surgeries due to their abilities to grow with native vessels and limit long-term complications from the permanent presence of synthetic material [1]. The ability of cells infiltrating the TEVG to alter their gene expression and matrix production or degradation kinetics in accordance with variations in mechanical stimuli allows for adaptation in maturation or changing hemodynamic loading. However, early TEVG remodeling is also dictated by the foreign body response to the polymeric scaffold. Variations in the material properties or microstructure of the scaffold can mediate changes in the phenotypes of the immune cells responsible for removing the scaffold and replacing it with new extracellular matrix [2]. Furthermore, timing of acidic products generated by the hydrolytic degradation of commonly used ester-containing polymers lead to different inflammatory responses [3]. As such, there is a complex interplay between the mechanobiological and immunobiological aspects of remodeling that determines the success or failure of implants.

Our group previously examined the link between the formation of early stenosis in TEVGs and the immune response, which demonstrated that narrowing could reverse with resolution of inflammation and the inhibition of new matrix deposition by mechanobiological cues [4, 5]. Scaffolds used in these studies consisted of a knitted polyglycolic acid (PGA) mesh enclosed in a porous sealant of caprolactone and lactic acid co-polymers (PCLA). Earlier work on TEVG design had replaced the PGA knit with a poly-L-lactide (PLLA) knit for a subgroup of a clinical trial that showed no long-term differences in outcome between the two different knitted polymers [6]. However, the differences in initial remodeling were not well characterized between PGA and PLLA knitted TEVGs.

In this work, we sought to predict potential differences in TEVG evolution for scaffolds made with these different materials. To that end, we utilized a computational model of TEVG growth and remodeling (G&R) that has been shown to capture geometric and mechanical changes of the remodeling time course [7]. We developed novel constitutive relations that relate the scaffold degradation time course to inflammatory kinetics and simulated perturbations to the degradation behavior of the PGA knitted grafts to understand potential changes to the severity and persistence of stenosis. These simulations suggested that delaying degradation beyond the initial foreign body response could reduce stenosis severity.

## METHODS

A constrained mixture theory G&R framework was used to simulate the evolving composition and geometry of the TEVG through one year of implantation in an ovine model of the Fontan procedure [4]. Briefly, each of the structurally significant constituents was prescribed constitutive relations for material behavior, production kinetics and degradation behavior. The neotissue was assumed to consist of collagen and smooth muscle cells produced according to both mechanobiological and immunological stimuli, where different behavior was used for constituents produced due to each stimulus. Polymeric constituents were present initially and degraded over time with a sigmoidal behavior

$$\varepsilon^p(s) = \frac{1+\exp(-k^p\zeta^p)}{1+\exp\left(k^p(s-\zeta^p)\right)}\varepsilon_0^p \qquad (1)$$

where $\varepsilon^p(s)$ is the surviving volume fraction of polymeric constituent $p$ with original volume fraction $\varepsilon_0^p$, $k^p$ is the degradation rate parameter, and $\zeta^p$ is the offset to rapid degradation. Effects of changing $k^p$ and $\zeta^p$ are shown below (**Fig. 1A and B**). Neotissue production $m^i(s)$ for inflammatory constituents $i$ was prescribed as a sum of two stimulus functions tailored by a decaying windowing function $w^i(s)$, written as

$$m^i(s) = m_h^i\left(K_\rho^i\Upsilon_\rho^i + K_{\rho'}^i\Upsilon_{\rho'}^i\right)w^i(s) \qquad (2)$$

with basal production rate $m_h^i$. The first stimulus function depends on the presence of the foreign body response-inducing scaffold

$$\Upsilon_\rho^i = \sum \varepsilon^p(s)/\sum \varepsilon_0^p \qquad (3)$$

which decreases monotonically as the polymer degrades. The second stimulus is a function of the rate of change of polymer mass

$$\Upsilon^i_{\rho\prime} = \sum \varepsilon^{p\prime}(s)/(\sum \varepsilon^{p\prime}(\zeta^p) \sum \varepsilon^p_0) \quad (4)$$

where $\varepsilon^{p\prime}(s) = d\varepsilon^p/ds$ and the stimulus increases during periods of rapid scaffold degradation.

In vitro degradation experiments informed the degradation parameters $k^p$ and $\zeta^p$ for each of the polymers used in this study [5]. Geometry and thickness data from implants using scaffolds with PGA knitted fibers were captured to provide parameters for neotissue production and removal [4]. The parameters $k^p$ and $\zeta^p$ were then varied parametrically to examine the potential differences in TEVG evolution for knitted fibers that had different degradation profiles.

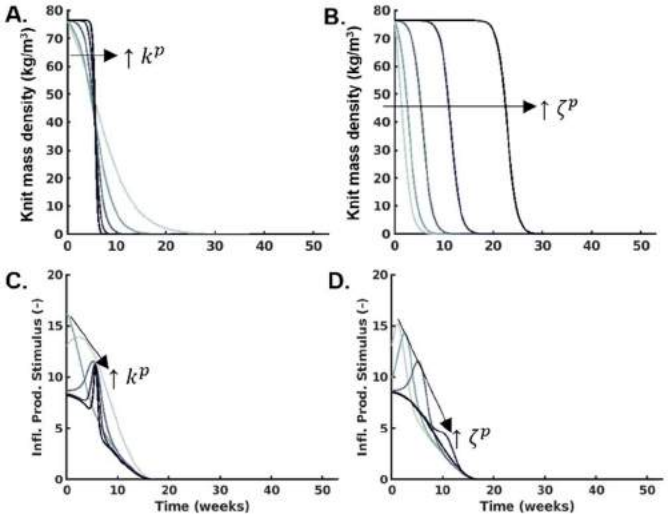

**Figure 1. Parametric studies of knitted scaffold degradation rate $k^p$ (A) and degradation offset $\zeta^p$ (B) and their corresponding effects on the inflammatory production stimulus for neotissue deposition (C, D), respectively. Darker lines and arrows indicate results for increasing parameter values.**

## RESULTS

For increasing values of $k^p$, the rate of mass loss during rapid degradation increased (**Fig. 1A**), while increasing $\zeta^p$ shifted the period of rapid degradation rightward to occur later in the time course (**Fig. 1B**). The inflammatory production stimulus for increasing $k^p$ showed a sharper peak at higher values of $k^p$ for shorter durations, but total inflammatory matrix production first increased and then decreased (**Fig. 1C**). For increasing $\zeta^p$, the time to peak inflammatory matrix production shifted rightward and decreased in magnitude as the decaying window function reduced immune activity (**Fig. 1D**).

We then examined changes in the inner radius (**Fig. 2A and B**) and thickness (**Fig. 2C and D**) for corresponding changes in the scaffold degradation parameters to determine how the potential for stenosis is affected by the resulting inflammatory stimuli. Total inflammatory matrix produced determined the degree of narrowing and thickening as increased areas under the inflammatory production stimuli curves (**Fig. 1C and D**) resulted in lower values of radius and higher values of thickness (**Fig. 2**). However, peak narrowing and thickening did not necessarily occur at the time of peak inflammatory matrix production, as, for example, the simulation with the lowest value of $k^p$ had its highest production value within the first simulated week but did not reach peak narrowing until 9 weeks (**Fig. 1C and Fig. 2A**). Changes in inflammatory stimuli with both degradation parameters produced non-monotonic changes in radius and thickness. Substituting the degradation parameters for those of a scaffold with PLLA knitted fibers that degrade slower and with a lower degradation rate than PGA suggested that scaffolds made with PLLA would tend to exhibit less stenosis than those made with PGA knitted fibers.

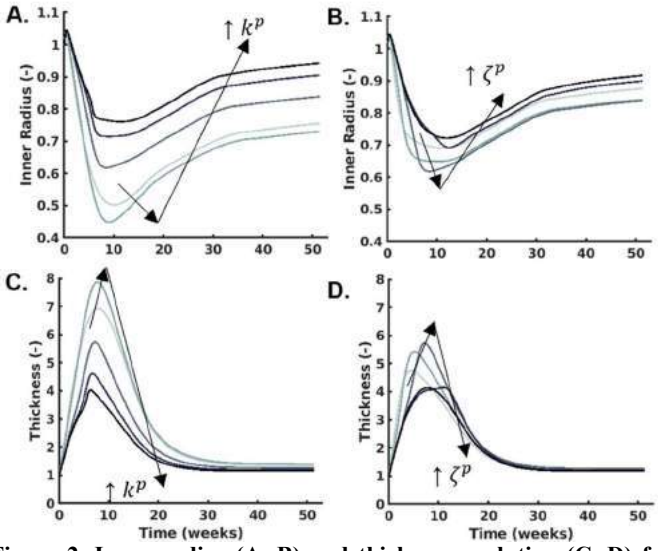

**Figure 2. Inner radius (A, B) and thickness evolution (C, D) for corresponding variations in $k^p$ (A, C) and $\zeta^p$ (B, D) from Figure 1. Quantities are normalized by their implantation values. Darker lines and arrows indicate results for increasing parameter values.**

## DISCUSSION

Computational models of scaffold evolution have been used to guide the design of subsequent design iterations [8, 9]. Here, we take this approach to understand potential changes in TEVG outcomes by changing the degradation properties of the scaffold components. As scaffolds with PLLA knitted fibers had been fabricated with a similar microstructure and mechanical behavior as those with PGA knitted fibers used in preclinical studies [1, 4], G&R simulations offered the chance to predict differences in evolution between designs based purely on the difference in degradation behavior. Therefore, we adapted our G&R framework to account for differences in inflammation caused by the presence of a foreign body and the accumulation of acidic degradation products. Parametric variation of the degradation rate and onset of rapid degradation demonstrated benefits to delaying the onset of rapid degradation beyond the initial foreign body response to the scaffold. Non-monotonic changes to the degree of narrowing and thickening with variations in degradation behavior highlight the utility of computational simulations to determine parameter ranges with improved outcomes. Though the novel constitutive relations require additional validation with implantation of PLLA scaffolds, these simulations suggest that delayed degradation of the knitted fibers can reduce stenosis and will be compared against future experimental data.

# RELATIONSHIPS BETWEEN ATHLETIC PERFORMANCE MEASURES AND HEAD KINEMATICS IN YOUTH ICE HOCKEY

## INTRODUCTION

Nearly 1 million athletes under the age of 20 participate in ice hockey each year.[1] The sport is characterized by frequent player-to-player contact and has a high rate of concussion;[2-3] however, most impacts hockey athletes experience are subconcussive (i.e., not acutely symptomatic). Subconcussive head impact exposure (HIE) poses a risk to brain health, as evidence from other contact and collision sports suggest subconcussive HIE may lead to neurologic sequelae observed even after a single season of youth sport participation.[4-5] Therefore, it is critical to understand factors influencing HIE to inform evidence-based strategies to reduce head impacts in youth hockey. While several studies have characterized hockey HIE,[6-8] none have investigated the relationship between sport-specific skills (broadly referred to as athletic performance) and HIE. Well-developed, hockey-specific skills may allow athletes to better avoid collisions with opponents. Interventions aimed at improving skills may be one avenue to reduce injury, as evidence from other sports suggests refining sport-specific skills reduces HIE.[9] Thus, this study assessed relationships between HIE and hockey-specific athletic performance assessments.

## METHODS

Youth ice hockey players (n=42 boys; ages 9-16) from a single organization participated in a preseason athletic performance combine event to assess sport-specific skills. Athletic performance in hockey was evaluated using a series of on- and off-ice tasks to assess speed, agility, power, and stick-handling.[10-11] On-ice tasks separately measured included stick-handling, cornering S-turn, acceleration & sprint skating, and modified Reed repeat sprint skating (Fig 1). Off-ice ("dry land") tasks included vertical jump, 30 meter sprint, and 5-10-5 yard agility shuttle. Two trials were completed for each task. Each athlete's mean times across trials were recorded for sprinting and skating tasks; mean number of times the athlete crossed the puck over a line on the ice was recorded for stick-handling; mean maximum jump heights were recorded for vertical jump.

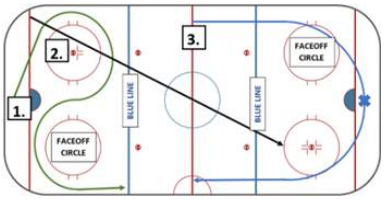

**Figure 1. The on-ice assessment components. 1) S-turn, 2) Accel. & sprint skating, 3) Reed repeat skating (not pictured: stick-handling).**

A subset of these participants (n=12, ages 12-14) consented to wear a custom-fit instrumented mouthpiece in the ensuing hockey season; mouthpiece data were excluded from analyses for goaltenders or if an athlete did not participate in the combine (n=4). The mouthpiece used a 5 g threshold to measure frequency and magnitude of head acceleration events (i.e., events).[12] Raw data were processed as described previously.[12-13] Mouthpiece events were then paired to time-synchronized video collected from 24 games during the ongoing season to characterize on-ice events by contact characteristics (e.g., head contact) using a custom MATLAB graphical interface (MathWorks, Natick, MA).

Preliminary statistical analyses examining relationships between preseason performance measures and head kinematic metrics were completed in SAS using generalized linear regressions (Cary, NC). For all regressions, Cook's distance was calculated and outliers were removed using a threshold of 4/n.

## RESULTS

Summary statistics for on- and off-ice combine assessment components are provided in Tables 1 and 2. A total of 304 visually-verified contact scenarios were collected from 12 youth athletes during 24 games. Following exclusion of the goaltenders and those that did not participate in the combine (n=4 athletes), 236 visually-verified contact scenarios recorded by the mouthpiece from 8 athletes were analyzed.

Number of contact scenarios per athlete ranged from 12 to 56; proportion of head impacts (i.e., number of contact scenarios with head contact / total number of contact scenarios) ranged from 0.21 to 0.55. Median (95th percentile) peak linear acceleration (PLA), rotational velocity (PRV), and rotational acceleration (PRA) for all verified contact scenarios were 8.09 (26.44) g, 6.63 (16.4) rad/s, and 549.4 (1565) rad/s$^2$, respectively.

**Table 1. Pooled mean [standard deviation; SD] preseason scores for on-ice tasks.**

| | S-turn | Accel & Sprint Skate | | Reed Skate | Stick-handling |
|---|---|---|---|---|---|
| | Time (s) | Accel time (s) | Total time (s) | Time (s) | # Crosses |
| Instrumented athletes (n=8) | 10.53 [1.60] | 2.16 [0.22] | 7.42 [0.85] | 11.23 [1.85] | 58.8 [10.60] |
| All athletes (n=42) | 10.68 [1.54] | 2.09 [0.31] | 7.41 [0.85] | 11.24 [1.47] | 57.00 [11.45] |

**Table 2. Pooled mean [SD] preseason scores for off-ice tasks.**

| | Vertical Jump | | 30 m Sprint | Agility Shuttle |
|---|---|---|---|---|
| | Standing Height (in) | Jump Height (in) | Time (s) | Time (s) |
| Instrumented athletes (n=8) | 83.35 [4.72] | 97.95 [5.73] | 5.21 [0.33] | 5.60 [0.36] |
| All athletes (n=42) | 81.05 [6.72] | 94.86 [9.14] | 5.51 [0.55] | 5.89 [0.53] |

Several notable relationships between preseason performance and head kinematic metrics were observed. Namely, athletes with faster mean completion times on skating tasks had significantly lower median PLA [S-turn (p=.02, $r^2$=.65), acceleration skate (p<.01, $r^2$=.76), sprint skate (p<.01, $r^2$=.71), Fig 2A, B)].

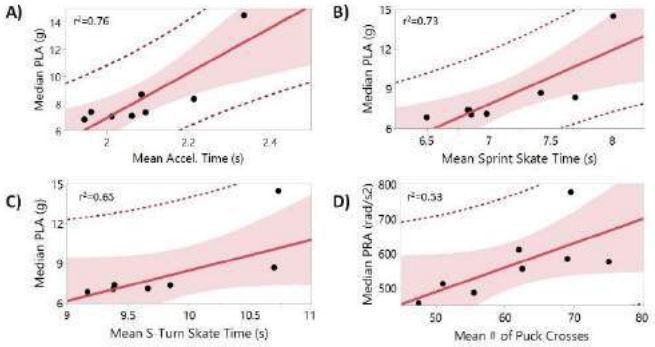

**Figure 2. Significant relationships between median PLA & A) mean accel. skate time, B) mean sprint skate time, C) S-turn skate time; D) median PRA and # of puck crosses during stick-handling.**

Additionally, faster mean completion time for the Reed skating task and S-turn skating task were associated with lower proportion of head impacts [S-turn (p=.03, $r^2$=.55) Reed skating (p=.03, $r^2$=.63)]. Greater stick-handling skill (i.e., greater number of puck crosses) was associated with higher median PRA (p=.04, $r^2$=.53). There were no significant associations between off-ice tasks and head kinematic metrics or between 95th percentile kinematics and performance on any task. In general, better performance scores correlated with decreases in head kinematic metrics, particularly for on-ice tasks.

## DISCUSSION

This study sought to examine preliminary relationships between measures of ice hockey athletic performance both on- and off-ice and head kinematic metrics using accepted measures of performance adopted from literature.[11-12,14] Previous literature from other collision sports such as football has indicated higher levels of physical performance correlate with greater HIE metrics;[14] however, this study hypothesized the opposite trend would be observed in hockey athletes, as increased hockey-specific skills such as skating and stick-handling would better allow athletes to avoid opponents and unnecessary body collisions on ice.

Findings from this study indicate that greater performance measures are associated with lower median PLA, particularly for skating tasks measuring speed and agility. Interestingly, we did not observe the same relationship between off-ice measures of speed and agility (5-10-5 yd. agility shuttle, 30 m sprint) and median PLA. This may be because there are differences between on- and off-ice forward motion[10] and that head accelerations in ice hockey may be more influenced by sport-specific characteristics than raw measures of speed or agility alone.

We additionally found greater stick-handling skill was associated with higher median PRA. It is possible that the stick-handling task as designed is not sensitive enough to accurately measure stick-handling ability. Athletes during this task may have directed their attention downwards to the puck, while in real gameplay would be focused on their surroundings rather than keeping their head down. This supports a possible methodological change to consider for future studies whereby this task should be completed with the athlete looking forward instead of down during task completion. This revised method has translational significance as previous literature has demonstrated that poor body positioning and collision anticipation (i.e., athlete keeps their head down) result in more severe head impacts than good body positioning and anticipation.[7] Refining this task may better elucidate relationships between stick-handling ability and HIE.

This study was limited in several areas. Firstly, the sample of athletes with both combine data and biomechanics data was small. As such, the statistical analyses may not be sufficiently powered. Expanding our sample size will reduce this limitation, as will continued biomechanics data collection as the current season continues. This study also only investigated preseason performance and does not reflect performance or skill degradations, or improvements that may occur during the season or measured post-season. The latent period between regular hockey season end (early spring) and the preseason combine (late summer) may also reduce discernable differences in performance between athletes due to lack of practice. We aim to host a post-season combine to innovatively understand the influence of performance level changes on HIE across the span of the season.

This preliminary study investigated relationships between athletic performance metrics and exposure to head acceleration events in boys' hockey athletes. While there have been studies characterizing HIE in youth ice hockey, and studies of ice hockey performance measures, this is the first study to assess how performance influences measured head kinematics. Our findings support the notion that ice hockey HIE is influenced by hockey-specific performance measures, with better performance corresponding to decreased exposure. This is an important addition to the literature, as it may support evidence-based skill-development strategies to reduce HIE and head acceleration events among youth hockey athletes, improving sport safety.

# IMPLEMENTATION OF A LOW-COST OFF-AXIS LOADING FIXTURE (OALF) TO ADD SPINE BENDING TO A UNIAXIAL COMPRESSION DEVICE

**Axel C. Moore (1), Harrah R. Newman (1), Raith Nowak (1), Sean Magee (1), Gabriela Carlisle (1), Imani Carter (1), Justin Bouyer (1), Edward J. Vresilovic (1), Dawn M. Elliott (1)**

## INTRODUCTION

The primary function of the spine is to support and distribute large loads in all six degrees of freedom (DOF). Clinical disorders, such as degeneration or scoliosis, alter the structure and mechanical properties of spine tissues, subsequently changing the six DOF spine mechanical behavior. However, effectively isolating tissue-level changes in a coupled system such as the spine requires several careful considerations. First, multi-axial loading is needed to simulate all the degrees of mechanical function. Second, axial compression needs to be added to rotational loadings, such as lateral bending or flexion, to mirror physiological conditions (e.g., musculature and mass of the upper body). Therefore, mechanical evaluation of the spine should be capable of controlled multi-axial loading. Third, any applied loading introduces off-axis forces and moments that need to be accounted for and ideally minimized [1].

Single- and dual-axis testing platforms are widely used to measure compression and compression-torsion spine segment mechanics [2]. These systems are widely available in many biomechanics labs, but unfortunately are not readily adapted for flexion or bending conditions that are important for assessing spine function. Multi-axis testing platforms that integrate multiple linear and rotary motors, hexapod platforms, and serial arm robots have been used to quantify all six DOF spine segment mechanics [1], [3], [4]. While these are highly effective solutions, they involve significant equipment costs ($200k+) and are therefore not as accessible for spine researchers.

The objective of this study was to design an off-axis loading fixture (OALF) that is comparatively low-cost (~$10k) and can apply off-axis lateral bending or flexion-extension in combination with axial compression, on an existing uniaxial test frame. Here we use a TA Electroforce 3510, but similar test frames can be found in many materials research facilities. The OALF can be easily installed and

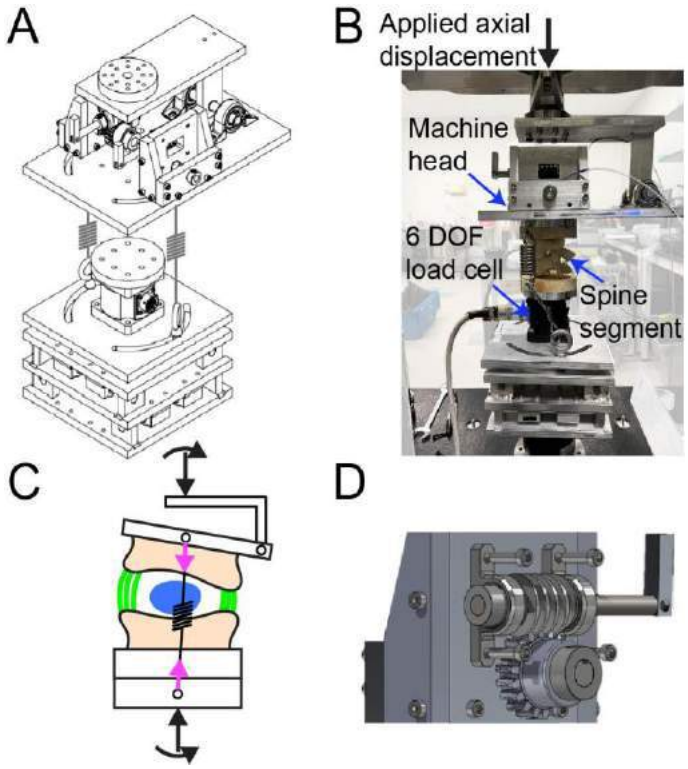

**Figure 1: (A) OALF design schematic showing the upper and lower assemblies. (B) OALF is bolted to a uniaxial test frame with a simulated spine segment. (C) Free body diagram. (D) Machine head assembly.**

removed in a single testing period. Preliminary data is presented demonstrating proof-of-concept.

## METHODS

The OALF was constructed to interface with an existing TA Electroforce 3510 uniaxial test frame (**Fig 1A**). The OALF enabled the axial displacements imposed by the Electroforce test frame to be transformed into angular displacements through a lever arm attached to the spinal motion segment (**Fig 1B**). The design allows for axial compression and one axis of rotation (lateral bending or flexion-extension) **(Fig 1C**) while minimizing shear forces.

Axial compression was applied through a guitar inspired machine head assembly (**Fig 1C(pink spring),D**). The machine head was used to apply tension to two wire stays which axially compressed the spine segment. Inline tension springs were installed to enable fine tuning of the resulting compressive force. A 6 DOF load cell (AMTI MC3A-500) was placed below the OALF fixture (**Fig 1A,B**). The total cost of design is approximately $10,000 which includes $2,000 for materials and machining and $8,000 for the load cell.

A single functional spinal unit (bone-disc-bone) from a Yucatan minipig was used in this proof-of-concept study. The facets were removed and the superior and inferior vertebrae were fixed in PMMA (polymethyl methacrylate) bone cement and bolted into the OALF. The disc was wrapped in phosphate buffered saline (PBS)-soaked gauze throughout testing to prevent tissue dehydration.

Three cycles of lateral bending (±4 degrees [1]) were applied to the spine segment [5]. To achieve this target rotation a ±11.18 mm axial displacement was imposed at 0.05 Hz via the Electroforce linear actuator. To demonstrate the addition of physiological compression, the test was repeated with a 100 N axial compression load. Forces and moments in six DOF were measured throughout the test, and the neutral zone and linear region stiffness were calculated.

## RESULTS

Applying a displacement to the OALF resulted in the expected lateral bending moments (**Fig 2**), with a neutral zone of ±2 degrees and a stiffness of 0.25 Nm/degree. The addition of a 100 N axial load led to a larger neutral zone of ±3 degrees and larger lateral bending stiffness of 0.50 Nm/degree (**Fig 2**). The axial force variation induced by the OALF converting axial displacement to bending was less than 15 N (**Fig 3C,D**). The off-axis coupled shear forces were negligible **(Fig 3C,D**) and the coupled flexion moments were small (**Fig 3A,B**). However, a large coupled torsional moment of similar magnitude to the lateral bending occurred during unloaded testing, but was mitigated with the addition of axial compression (**Fig 3A,B**). This limitation will be addressed in future work, as described below.

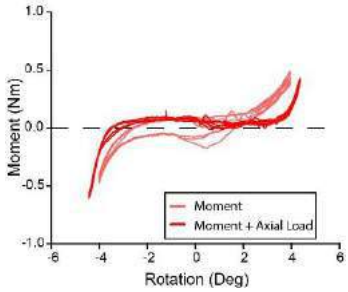

**Figure 2: The moment produced during lateral bending with and without a 100 N axial load.**

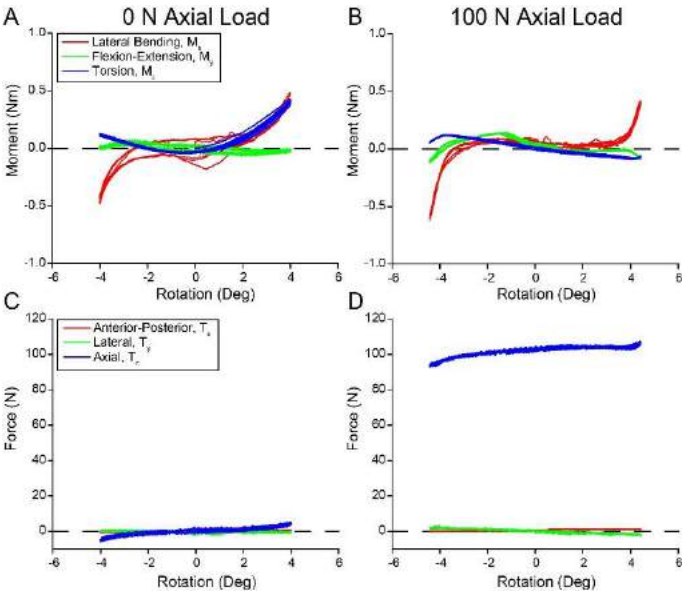

**Figure 3: Measured (A,B) moments ($M_{x,y,z}$) and (C,D) forces ($T_{x,y,z}$) for lateral bending. The axial compressive load was set at (A,C) 0 and (B,D) 100 N.**

## DISCUSSION

We have developed an off-axis loading fixture, OALF, which enables combined lateral bending (or flexion-extension, not shown) with axial compression and measures all six DOF (force and moments). The device is low-cost when compared to existing multi-axis testing platforms such as hexapods and serial arm robots.

Developing this low-cost solution led to several design constraints. The first design limitation is the fluctuation in axial force (**Fig 3**), as axial force drives the bending moment of the system. This variation is minimized as the line of action for the tension springs approximate the center of rotation for the spine segment. With the addition of physiological compression loads, this fluctuation is ~15% of the applied compression. While we successfully minimized off-axis shear forces, the second limitation was the substantial torsional coupling, which was not anticipated (**Fig 3A**). A thrust bearing will be added to address this limitation. In conclusion, we have implemented a low-cost system to apply off-axis loads to spine segments; ongoing work will quantify system capabilities and apply OALF to quantify multi-axial spine biomechanics in human and animal spine studies.

# INJURY CRITERIA: DEFINING MECHANICAL THRESHOLDS FOR COLLAGEN IN SOFT TISSUES

**Callan M. Luetkemeyer (1), Kaitlin P. McCreery (1,2), Kathryn R. Jacobson (3), Corey P. Neu (1,2), Sarah Calve (1,2,3)**

## INTRODUCTION

Injuries to soft tissues like ligaments, intervertebral discs, and cartilage are debilitating, costly, and common [1]. Because injuries are the result of excessive mechanical deformation, computational methods like finite element analysis are an ideal means by which to study injury risk and prevention in a systematic and deterministic way. However, predictive computational models require accurate, experimentally-derived models of tissue mechanical behavior. To this end, progress has been made to model the stress-deformation relationship for soft tissues [2]. Yet, methods for characterizing the deformation thresholds for injury are lacking. Such models are critical for informing computational studies on injury risk, as well as for directly assessing how material differences – i.e., extracellular matrix composition (ECM) and organization – affect injury susceptibility.

We propose a method for defining injury criteria (multimodal mechanical thresholds) for soft tissues [2]. In this work, we focus on molecular-level collagen damage, which can be spatially mapped using collagen hybridizing peptide (CHP) [3]. The objectives of this study were (1) to develop a method to identify molecular-level collagen injury criteria for soft tissues that accounts for multimodal and spatially heterogeneous deformation and (2) to examine the effect of fibrosis and disorganized ECM on injury risk by comparing injury criteria for medial collateral ligaments (MCLs) from *Fbn1*$^{Tsk}$ (Tsk) heterozygous mice [4] – a fibrillin-1 (Fbn1) knock-in mutation that results in hyperplasia of connective tissues – and wild-type (WT) controls. Results demonstrate that mechanically-induced collagen denaturation can be driven by multiple modes of tissue-level deformation. Moreover, the Tsk mutation appears to increase the influence of shear strain on thresholds for collagen denaturation.

## METHODS

Hindlimbs from 10-14 week old WT and Tsk mice (obtained and euthanized in accordance with CU Boulder IACUC regulations) were isolated, and the skin, tendons, muscles, and fascia around the knee joint were removed. Specimens were stained with Ghost Dye (Tonbo Biosciences), which binds to amine groups, and NucBlue (ThermoFisher Scientific), which stains cell nuclei, for 3 hours at 4 ºC in 1× PBS to provide trackable image texture for deformation mapping from confocal images.

All remaining soft tissues were then removed except for the MCL. Both bones were potted in custom grips with heat-set polystyrene, and the grips were secured to a custom loading chamber in a 1× PBS bath mounted under an upright confocal microscope (Leica STELLARIS). A 0.1 N pre-load was used to define the reference state.

The PBS in the bath was exchanged for a 5 µM solution of CHP for 15 minutes. Following CHP staining, samples were imaged at 10× magnification (2.14 µm resolution) to provide a sample-specific baseline from which to map mechanical deformation and collagen damage. Samples were imaged in 3 deformed configurations, defined by actuator displacements of 250–1000 µm in the longitudinal/fiber direction. After each deformation, samples were returned to the reference state, stained again with CHP for 15 minutes, and reimaged.

Surface voxels were used to create 2D projections of each specimen. 2D displacement fields were estimated using composite Ghost Dye and NucBlue reference and deformed images with Matlab's *imregdemons* function, from which Lagrange strain fields were estimated. Pixels were considered to have significant collagen denaturation if its CHP image intensity was above the following threshold:

$$\gamma_i = \mu_i + 3\sigma_1 \quad (1)$$

Where $\gamma_i$ is the CHP image intensity threshold for the $i^{\text{th}}$ reference image, $\mu_i$ is the mean CHP intensity of the $i^{\text{th}}$ reference image, and $\sigma_1$ is the standard deviation in CHP intensity of the original reference image. From the strain fields and binary damage maps, injury criteria were developed using logistic regression (Matlab) to determine the strain thresholds for collagen denaturation.

## RESULTS

The proposed damage mapping method demonstrated an ability to distinguish between increased image intensity resulting from additional stain time versus collagen damage. With additional stain time on a static specimen, CHP image intensity histograms shift, but there is little effect on the standard deviation or the number of pixels above the threshold (Eq. 1). However, following deformations and additional staining, distributions widen and the proposed method identifies a greater number of pixels above the damage threshold.

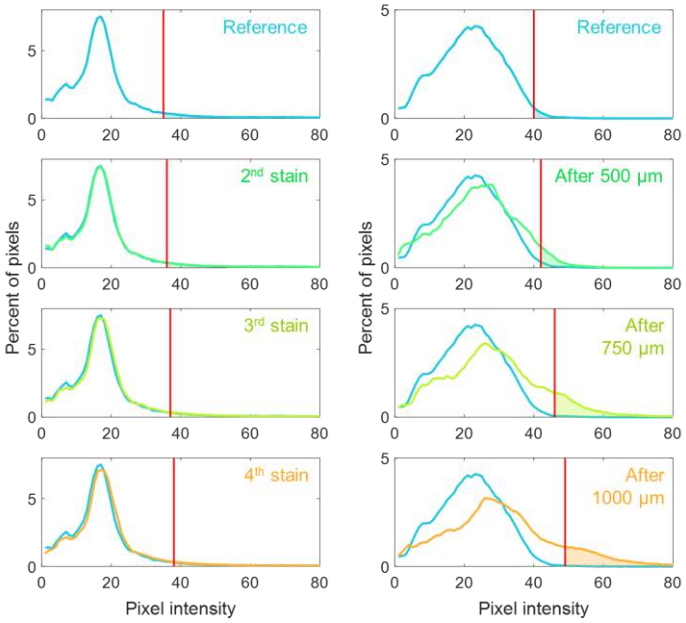

**Figure 1: CHP image intensity histograms shift with stain time in a static specimen (left), but the number of pixels above the damage threshold (red line, Eq. 1) increase only after deformation (right).**

Deformation fields and damage maps were spatially inhomogeneous (Fig. 2). In general, collagen denaturation most closely correlated with $E_{11}$ (strain in the mean collagen fiber direction), but $E_{22}$ (transverse strain) was also consistently an important predictor of damage (Fig. 3A).

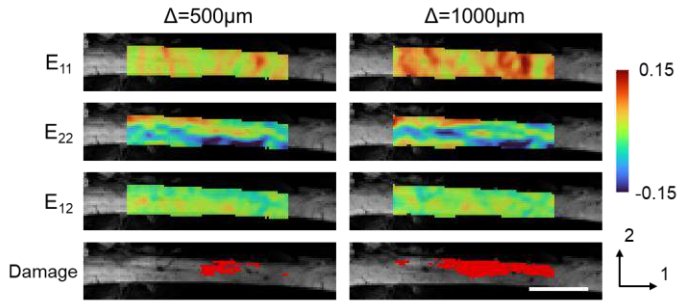

**Figure 2: Lagrange strain fields and damage maps (damage in red) after 500 and 1000 µm applied displacements reveal spatial heterogeneity in deformation and damage (scale bar = 500 µm).**

Comparing MCLs from one male Tsk mouse to a male WT (littermate) control, we saw no significant differences in injury criteria in the $E_{11}$-$E_{22}$ plane (Fig. 3A). However, shear strain ($E_{12}$) was a significant predictor for collagen damage in the Tsk MCL, while shear strain did not affect the injury criterion for the WT MCL (Fig. 3B).

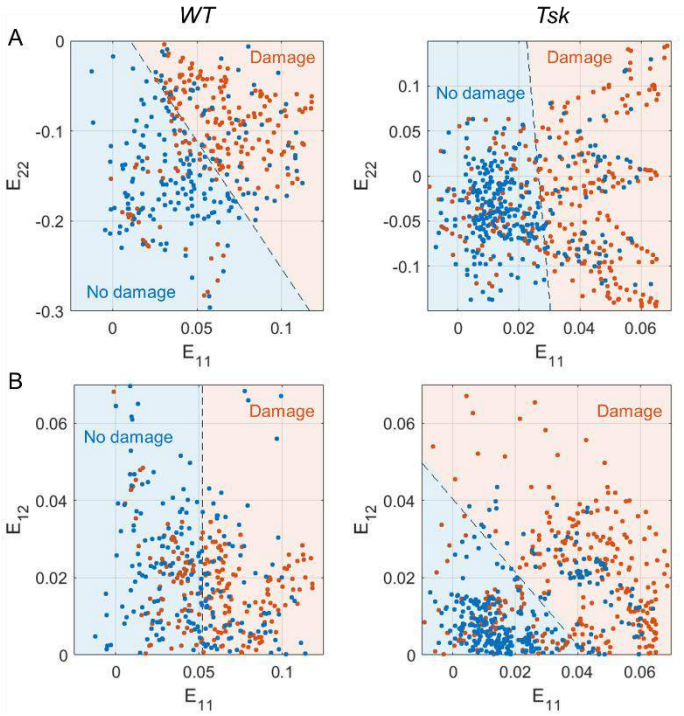

**Figure 3: Collagen injury criteria in the $E_{11}$-$E_{22}$ plane (A) and $E_{11}$-$E_{12}$ plane (B) for MCLs from WT (left) and Tsk (right) mice indicate deformation thresholds are multimodal.**

## DISCUSSION

We developed a method for defining injury criteria for collagen molecules in soft tissues. The method is robust to shifts in CHP image intensity that result from staining a specimen multiple times (Fig. 1) and it accounts for spatial heterogeneity and multimodal strain (Fig. 2). Our findings demonstrate that, in the normal MCL, mechanically-induced collagen denaturation depends on tissue-level tensile strains in the longitudinal and transverse directions (Fig. 3A). Furthermore, preliminary data comparing MCLs from Tsk and WT mice suggest that the Tsk MCL is also susceptible to damage from shear strain (Fig. 3B). This finding suggests that fibrotic ligaments with more disorganized ECM [5] are at higher risk of collagen damage and failure.

This is the first study to model the multimodal, tissue-level mechanical thresholds for collagen denaturation. Limitations include noisy image-based strain field estimates, 2D surface measurements, and linear strain thresholds identified by logistic regression. Still, the utility of the proposed method is readily demonstrated by the difference observed in injury criteria for the Tsk MCL and WT control. Future work will use these findings to inform multi-scale damage models with which to study injury in a computational framework.

# INTRAOCULAR PRESSURE-INDUCED LAMINA CRIBROSA DEFORMATIONS ARE LARGER AND MORE INHOMOGENEOUS BETWEEN QUADRANTS IN AN EXPERIMENTAL GLAUCOMA EYE THAN IN HEALTHY EYE

**Bingrui Wang (1), Fuqiang Zhong (1), Junchao Wei (1), Yi Hua (1), Juan Reynaud (3), Brad Fortune (3), Ian A. Sigal (1,2)**

## INTRODUCTION

Elevated intraocular pressure (IOP) is a primary risk factor for the development and progression of glaucoma [1]. However, the mechanisms by which the elevated IOP leads to neural tissue damage remain unclear [2]. A leading hypothesis is that the mechanical loads of IOP cause deformations and remodeling of the lamina cribrosa (LC), such as stretch, compression, and shear, and that these deformations act as mechanical stimulus to the astrocytes and retinal ganglion cell axons at the LC, triggering or contributing to mechanisms of axon degeneration, and thus loss of vision [3, 4]. Evaluating this hypothesis requires a better understanding of the effects of elevated IOP on the LC deformations.

Our goal was to measure in-vivo the IOP-induced LC deformations in experimental glaucoma and healthy eyes. Specifically, we analyzed the stretch, compression, and shear in four anatomical quadrants of the LC: temporal, superior, nasal, and inferior.

## METHODS

The optic nerve head of a rhesus macaque monkey with unilateral experimental glaucoma was imaged using optical coherence tomography (OCT) (**Figure 1**). [5] For this study we compare images of the right eye, the control eye, obtained at baseline, with images of the left eye, the experimental glaucoma eye, obtained at glaucoma onset. In each session, OCT images were acquired at controlled IOPs of 10, 20, 30, 40, 50, and 60 mmHg. A high-accuracy digital volume correlation method was used to analyze the OCT image sets for displacement field [6]. From the displacement results relative to 10 mmHg, we calculated the maximum principal strain (stretch), the minimum principal strain (compression), and the maximum shear strain (shear) of the LC region.

The LC region was marked manually and divided into four quadrants (**Figure 2**): temporal (T), superior (S), nasal (N), and inferior (I). All the strains in each quadrant were extracted and compared.

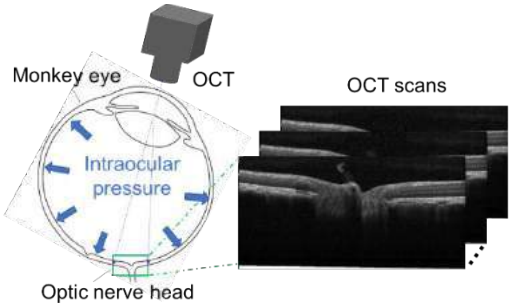

**Figure 1: Optical coherence tomography volumes of the lamina cribrosa were acquired using raster scanning.**

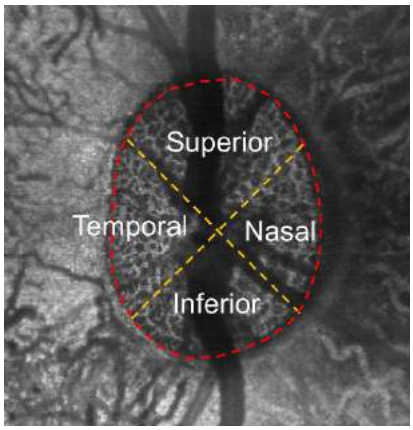

**Figure 2: C-mode view of an LC illustrating the quadrants.**

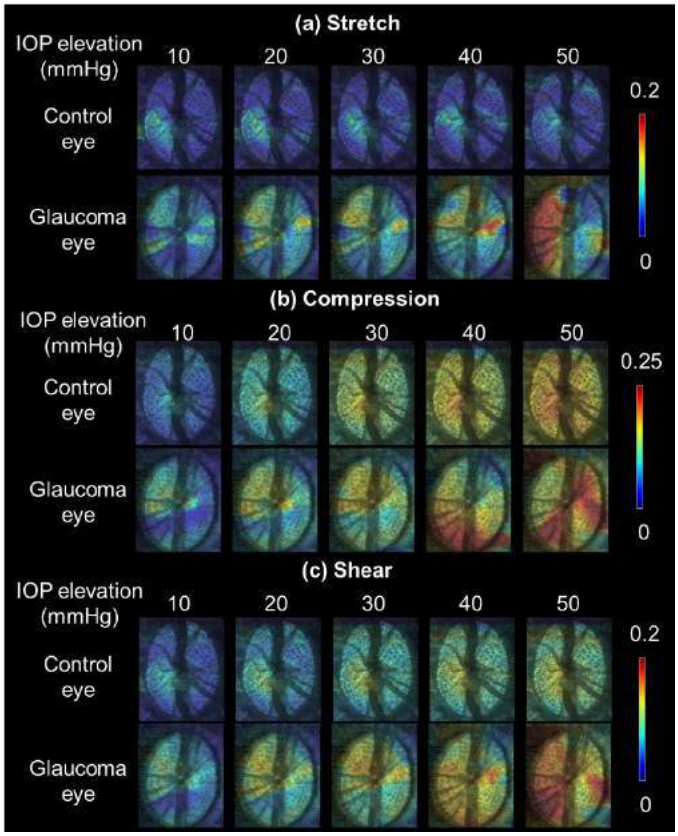

**Figure 3: Both eyes exhibited substantial deformations as IOP increased. Deformations were larger in the glaucoma eye. Shown are deformations from the baseline IOP of 10 mmHg.**

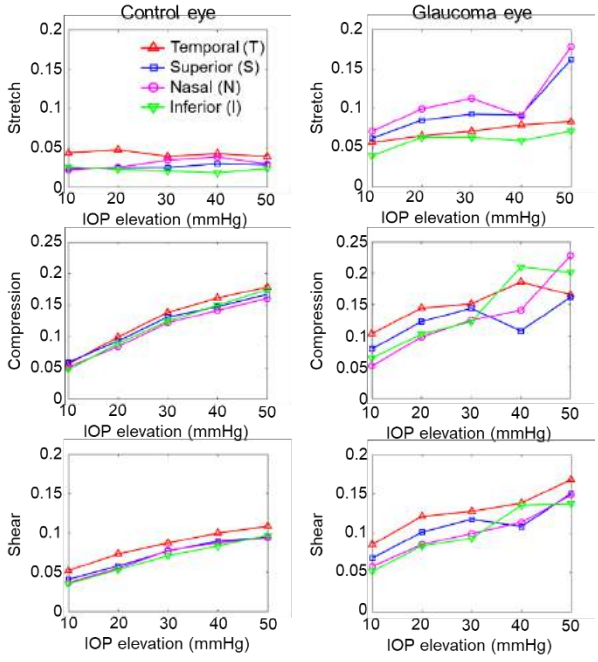

**Figure 4: The median values of stretch (first row), compression (second row), and shear (third row) in four quadrants for both control eye (left column) and glaucoma eye (right column).**

## RESULTS

Strain plots of the LC region at different elevated IOPs were obtained (**Figure 3**). When the IOP increased from 10 mmHg to 20 mmHg, the differences of stretch, compression and shear between both eyes were small. However, with further IOP increases, the glaucoma eye had larger strain compared to that of the healthy eye. For example, when IOP increased from 10 mmHg to 60 mmHg, shear in the glaucoma eye doubled compared to that in the control eye (0.2 vs. 0.1).

The median values of stretch, compression, and shear in four quadrants of both eyes are shown in **Figure 4**. In the control eye, the values of stretch, compression, and shear in all four quadrants were fairly homogeneous in contrast with the inhomogeneous values obtained in the glaucoma eye. In addition, in the control eye, the temporal quadrant had a larger deformation compared to others. In the glaucoma eye, the nasal and superior quadrants had a larger stretch than the other two quadrants. Specifically, when IOP increased from 10 to 60 mmHg, the stretch in nasal and superior quadrants is almost three times larger than those in the temporal and inferior quadrants.

## DISCUSSION

Our goal was to measure in-vivo the IOP-induced LC deformations in healthy and glaucoma eyes. Three main findings arise from this work. First, as IOP increased, the LC deformations of the glaucoma eye were larger than those of the healthy eye. Second, the LC strain distribution in the glaucoma eye was inhomogeneous across the four quadrants, whereas the healthy eye strain distribution was relatively homogeneous. Third, in the glaucoma eye, the stretch in the nasal and superior quadrants was larger than in the temporal and inferior quadrants, especially at very high IOPs. Below we discuss each of the main findings in detail.

We found that the IOP-induced LC deformations of the glaucoma eye were larger than those of the healthy eye. A possible explanation could be that tissues in the glaucoma eye are more compliant at this early stage, resulting in larger deformations as IOP increases. These large deformations may contribute to retinal ganglion cell axon damage in the LC leading to vision loss.

We also found that the LC strain distribution in the glaucoma eye was inhomogeneous throughout the four quadrants, a phenomenon that we did not observe in the healthy eye. It is possible that as glaucoma develops, tissue remodeling in the LC is not uniform, resulting in the non-uniform compliance of tissues in the LC.

We further found that in the glaucoma eye, the stretch in the nasal and superior quadrants were larger than that in the temporal and inferior quadrants, especially at very high IOPs. This may help explain the region-dependent axon damage commonly observed in glaucoma eyes.

In summary, we have measured in-vivo the IOP-induced LC deformations in glaucoma and healthy eyes. Results from this study are essential to understanding the mechanisms of the IOP-induced retinal ganglion cell axon damage in glaucoma. Efforts to expand the measurement of LC deformation to more eyes are currently underway.

## INTRODUCTION

Pediatric pulmonary arterial hypertension (PAH) is a complex disease, characterized by functional and structural changes that can lead to right ventricular (RV) failure. While ventricular-arterial interactions between the RV and pulmonary vasculature are well established [1], interactions between the left ventricle (LV) and RV are less understood [2]. To broaden our understanding of PAH, there is a need to identify metrics of ventricular-arterial and interventricular interactions.

The aims of this work were to: (A) construct high-resolution (3D) arterial and ventricular computational models to study cardiopulmonary mechanics and hemodynamics, using a workflow previously developed by our group [3]; (B) calibrate the models to match prospectively acquired clinical data on two patient cohorts (PAH patients and control subjects); and (C) derive functional and structural metrics from clinical data and computational models to compare these patient cohorts.

## METHODS

**Clinical Data**. Clinical data was prospectively acquired in two pediatric patient cohorts: 12 PAH patients and 14 cardiac transplant patients, who serve as control subjects. Magnetic resonance imaging (MRI) was performed to acquire data on cardiac and vascular anatomy. Phase-contrast MRI was performed to obtain dynamic data of luminal area changes and blood flow velocity. LV and RV volume waveforms were generated by segmenting endocardial surfaces using software packages CVI42 (Circle Cardiovascular Imaging, Calgary, Canada) and MeVisLab (www.mevislab.de). Pressure waveforms were acquired via invasive right heart catheterization.

**Arterial Modeling.** Patient-specific closed-loop 3D fluid structure interaction (FSI) models were constructed from anatomical data using the CRIMSON software [4] (**Fig. 1A**). Clinical data were used to inform arterial wall properties, inflow, and outflow boundary conditions (BC). Dynamic luminal area and pressure waveforms were used to derive spatially-varying arterial wall stiffness [5]. Resistance and compliance of the distal vasculature was described using lumped-parameter three-element Windkessel models (**Fig. 1A**). The heart was described using a lumped-parameter network of models that represent the atria, ventricles, and valves [6].

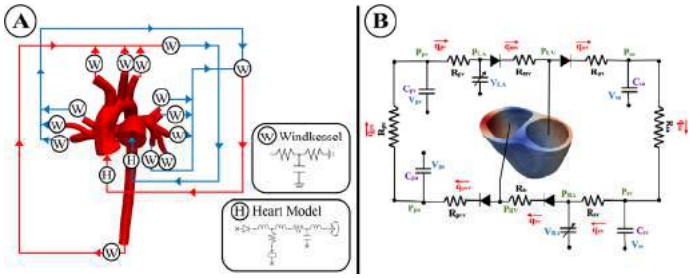

**Figure 1. (A) Arterial model has high-resolution (3D) models of the large arteries, and low-resolution (0D) models of the heart and veins. (B) Ventricular model contains a 3D biventricular model, and 0D models of the vasculature, atria, and valves.**

**Ventricular Modeling.** Finite-element (FE) models of the LV and RV were constructed using the open-source modeling platform FEniCS (www.fenicsproject.org). This biventricular model was coupled to closed-loop lumped parameter circuits of the systemic and pulmonary circulations [7] (**Fig. 1B**). Passive constitutive model [8], active contraction model [9] and lumped-parameter model values were tuned to match clinically-acquired ventricular pressure-volume (PV) loops and arterial pressure waveforms. RV end-systolic pressure volume relationship (ESPVR), a contractility metric, was estimated in a fully-calibrated model by varying preload and calculating the slope between maximum end-systolic elastance values (**Fig. 2**).

## RESULTS

We present results for one representative subject for each group – a PAH patient and a control.

**Arterial Modeling.** Simulated mean flow rates at the MPA and ascending aorta were matched within 3% of clinically-measured data; systolic, diastolic, and mean pressures were matched within 5% (**Fig. 3**).

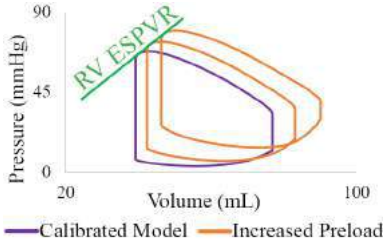

**Figure 2. RV ESPVR estimation**

**Ventricular Modeling.** Closed-loop 3D ventricular models successfully reproduced the clinically-measured PV loops of the LV and RV and pressure waveforms at the MPA and aorta (**Fig. 4**).

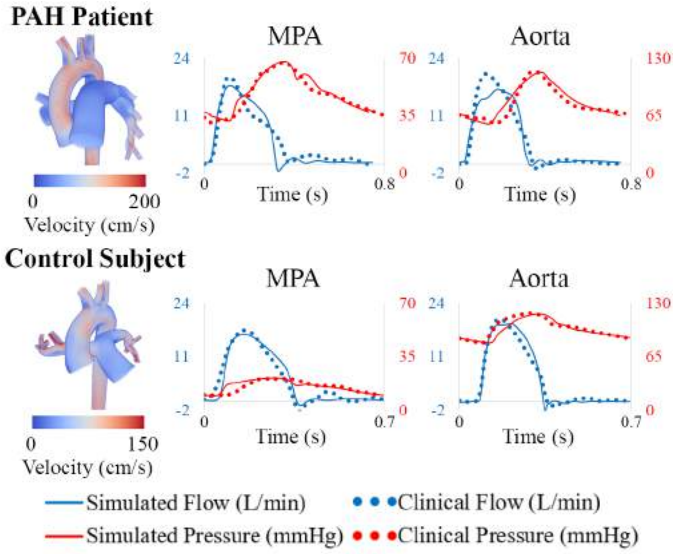

**Figure 3. Left: Peak systolic velocity maps in a PAH and control subject. Right: Comparison between clinically measured (dots) and simulated hemodynamics (solid lines) at the inlets of the main pulmonary artery (MPA) and aorta.**

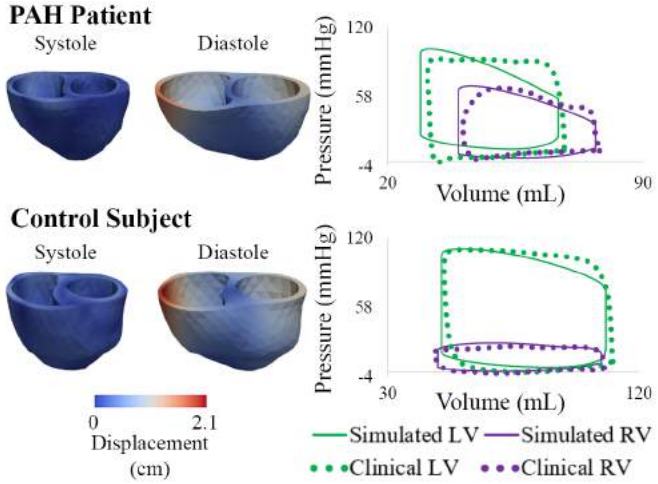

**Figure 4. Anatomical ventricular models with maps of maximum fiber stress (left) and displacement (middle). Right: Comparison of clinically-measured (dots) and simulated (solid lines) PV loops.**

**Metric Comparison.** As expected, all pulmonary pressures (mean, systolic, diastolic, pulse) and MPA stiffness were higher in the PAH patient than in the control subject (**Fig. 5**). However, while systemic pulse arterial pressure was higher in the PAH patient, systemic mean arterial pressure was surprisingly lower. Both subjects had healthy RV ejection fractions (≥ 55%), and similar end-systolic, end-diastolic, and stroke volumes (**Fig. 5**). RV ESPVR was found to be higher in the PAH patient (1.63 mmHg/mL) than in the control subject (0.43 mmHg/mL).

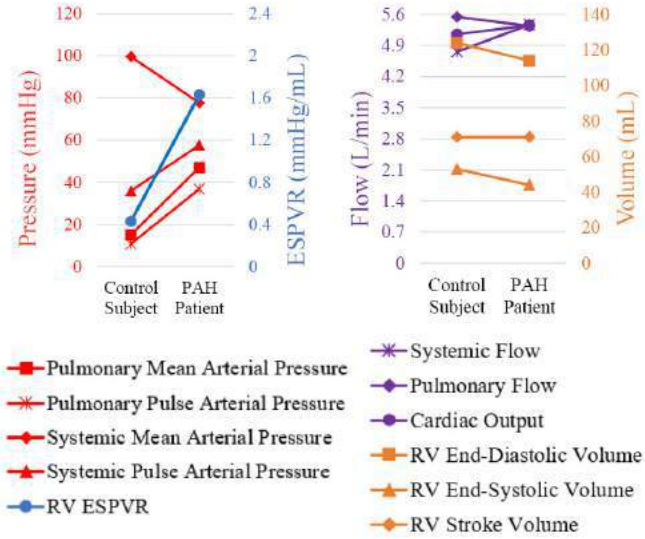

**Figure 5. Comparison of various hemodynamic parameters between PAH patient and control subject models.**

## DISCUSSION

We developed a framework that combines ventricular and arterial computational models to study hemodynamics in PAH and control subjects. We successfully matched clinically-acquired hemodynamic data and used the model to derive functional and structural metrics to compare these subjects. While the cardiac output and ventricular volumes were similar, pressures were drastically different in the cardiopulmonary circulation, cementing the complexity in the presentation of this disease.

Given the choice of active contraction model and the outlined calibration process, we can estimate ESPVR by varying preload. Our modeling results show that the PAH patient has a higher RV ESPVR than the control subject, which suggests that the PAH patient's RV and septum may have undergone remodeling to compensate for the increased pulmonary arterial pressures. This RV and septal remodeling could alter LV function [2] and therefore systemic hemodynamics.

While these results are based on a PAH and a control subject, future work will be focused on constructing models for all subjects in the PAH cardiac transplant control subjects in the study. This will help us provide a better description of functional and structural PAH metrics.

## INTRODUCTION

Stent Retriever Thrombectomy (SRT) for Acute Ischemic Stroke (AIS) aims to physically remove the occlusive clot. The main goal of SRT is the restoration of blood flow in one treatment pass. However, only ~30% of treatments are successful in the first pass [1], while the rest need to undergo more attempts that are associated with added mortality and mobility. Computer simulation of SRT can help understand underlying factors in unsuccessful cases and create a testbed for developing safer, more effective devices.

To date, few SRT computer models have been developed, but none can realistically simulate the complex stent-clot interactions, especially in failed cases. Finite element analysis (FEA) and XFEA based models were tested for patient specific models [2,3], but these models were not able to show the clot fragmentations or embolus dissection from the clot1's mass. Moreover, most previous computer models were developed for ideal geometries which do not consider the effect of the patient's vessel geometry [4].

Recently, we developed a method to accurately model the clot behavior in interaction with stent wires, which was even able to simulate clot fragmentation and embolus creation in failed cases [5]. In order to consider the vessel geometry in our simulation, we are expanding our method for patient specific vasculature and proposing a new workflow to model the SRT. Our new workflow is capable of accurately addressing two major problems faced in previous studies. Firstly, our clot model, which uses a hybrid FEA-SPH technique, realistically simulates the tissue's behavior in failed cases where an embolus could be created or the clot does not get retrieved at all. Secondly, it is implemented in patient specific vasculature geometries to accurately capture the effect of parent vessel geometry and Circle of Willis configuration.

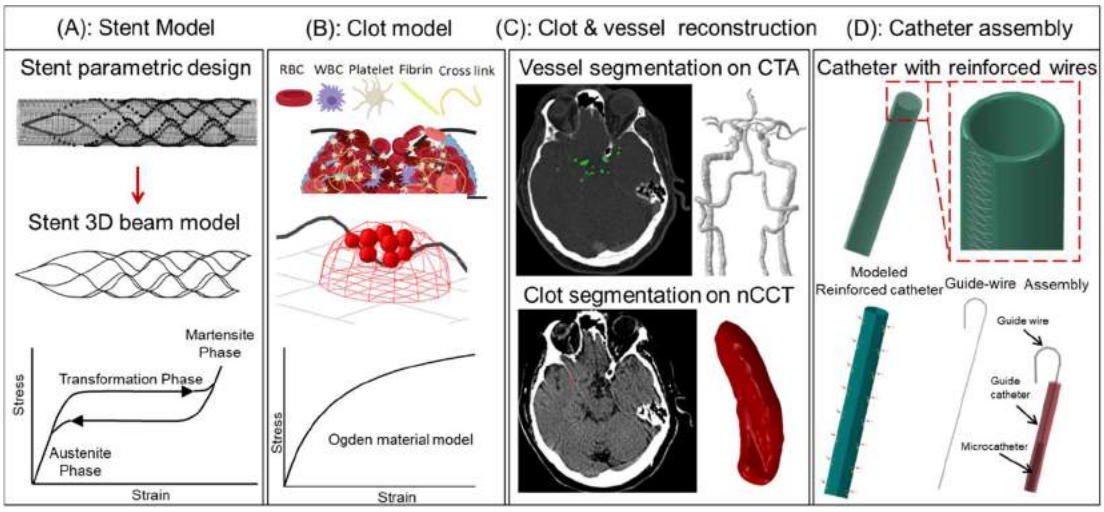

**Figure 1: Modeling Workflow. A).** The stent parametric geometry and nitinol superelastic behavior. **B).** The clot's hybrid FEA-SPH model and hyperelastic material behavior. **C).** Reconstruction of the patient's cerebral vessels and clot geometry from nCCT and CTA. **D).** The catheterization device assembly including microcatheter, guide-wire and guide catheter are also modeled to capture pre-deployment and retrieval steps.

## METHODS

In our method, all the parts involved in a thrombectomy procedure were modeled assuming that the blood flow is arrested. The major modeled components include the stent, clot, vessel, and wire-guided catheter. To model different parts, considerations for each portion of the device are applied individually to assure the accuracy of the simulation. Our workflow is illustrated in Figure 1.

*Stent model:* The stent model follows a parametric design procedure as detailed in [5] in which different parameters are modifiable like cell size and shape, stent length and diameter, overlapping edges distances, working length versus nonworking length ratios. After having stent's geometry, Timoshenko beam elements and superelastic material behavior of nitinol was assigned to the stent's wires.

*Clot model:* The hybrid FEA-SPH model for clot was developed and explained in details in our previous work [5]. In this method, a combination of grid-based FEA and meshless SPH methods was implemented. In the beginning, clot is in FEA mode and as it deforms under the loading, elements which their strain passes a threshold convert to more flexible and separable particles.

*Vessel and clot reconstruction:* The realistic geometry of vessel was reconstructed from CTA images of real patients (UB institutional review board study 00002092). Also, the geometry of the same patient's clot was reconstructed from nCCT.

*Catheter assembly modeling:* Catheterization to deliver the stents to a clot's site include using a guideare, guidecather and microcather in combination. Real Microcather and guidecathers are reinforced with embedded wires, to model them we used shell elements for both catheters with rebar reinforcement. Guide wire was modeled as J-shape with beam elements and modified material properties to consider its multi-structure and maneuverability.

## RESULTS

Figure 2 shows the results for a failed case in which the clot was not retrieved. As seen, in this workflow, all five steps of a real thrombectomy procedure were successfully simulated: (1) placing the stent into a packager, (2) deploying the microcatheter to pass the clot, (3) delivering the stent to the clot site, (4) deploying the stent across the clot so it can engage the tissue (done by holding the push wire and unsheathing the catheter), (5) attempted retrieval of the clot by pulling the stent through the cerebral vessels. As it can be seen, the stent was not able to hold the clot after cavernous curve, and failed to retrieved it.

## DISCUSSION

We developed a workflow that was able to accurately capture the real behavior of clot and stent in a thrombectomy procedure. Since catheter deployment and its positioning against clot is a driving factor in the deployment of a stent into the clot mass, we also modeled the catheter deployment procedure. In the example case, we showed that our model simulates different behaviors of different parts in a thrombectomy procedure accurately including passing a catheter from clot, penetration of stent wires into a clot and engaging with it, fragmentation of clot under the stent's load, and the separation of the clot from stent. The clot's FEA-SPH solver accurately simulated the dynamic clot behavior throughout, as it was deflected and moved by the wire and catheter, began breaking, and then dissociated from the stent.

This workflow represents a significant advance compared to previous models that have been unable to model failed SRT cases (e.g. clot fragmentation during retrieval). In the future, we will implement our method on larger cohorts of patient-specific cases to study how different factors, such as like vessel tortuosity, clot material and mechanical behavior, , catheter deployment and stent retrieval techniques, contribute to successful or unsuccessful SRTs.

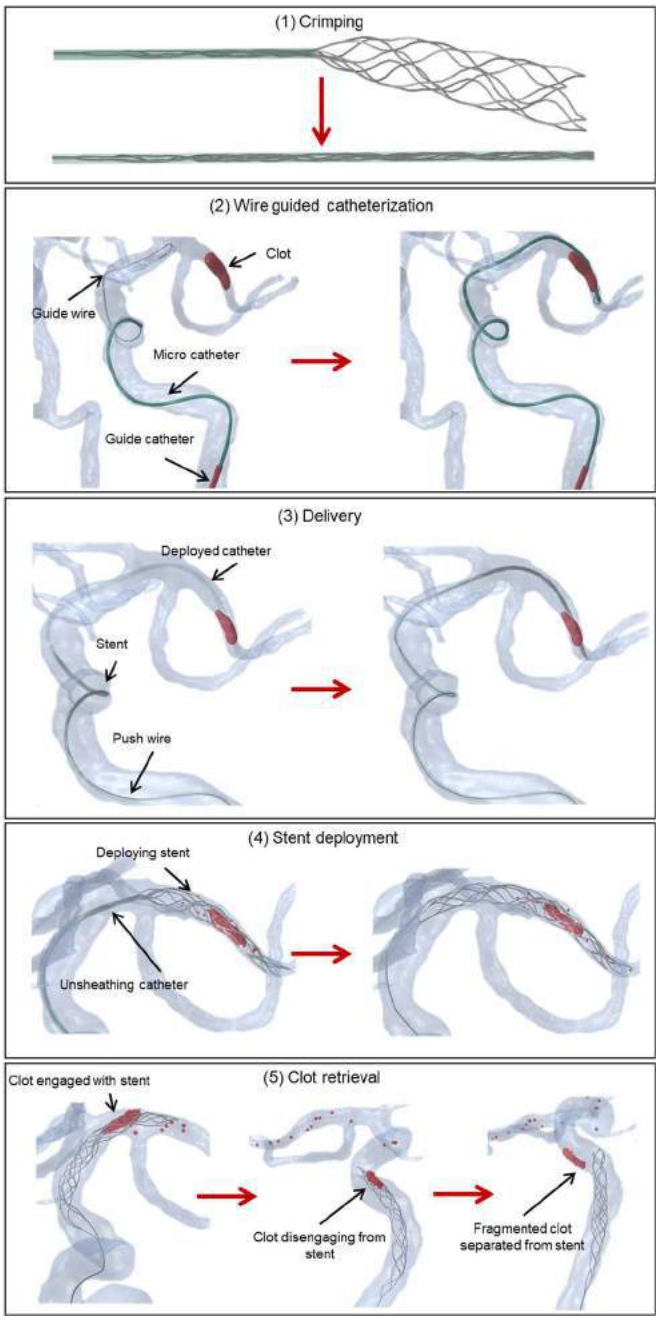

**Figure 2: A Patient-Specific SRT Case.** All components of SRT are modeled, including stent packaging, wire manipulation and microcatheter deployment, clot interaction with the stent, and retrieval. As seen here, SRT was unsuccessful in retrieving the clot past the cavernous ICA region.

# SIMULATIONS OF THE GRAVID HUMAN UTERUS AND CERVIX FOR PATIENTS AT HIGH- AND LOW-RISK FOR PRETERM BIRTH

**Erin Louwagie (1), Mirella Mourad (2), Michael House (3), Ronald Wapner (2), Kristin Myers (1)**

## INTRODUCTION

Preterm birth (PTB), defined as delivery before 37 weeks gestation, occurred in 10.1% of deliveries in the United States in 2020 [1]. Globally, complications arising from PTB are the leading cause of death for children under five years of age, and infants who survive are at an increased risk of short- and long-term health problems [2]. The current gold standard for predicting PTB is the ultrasonic measurement of cervical length, where a cervical length of less than 25 mm is considered at increased risk for PTB [3]. However, this method of PTB risk assessment has only moderate ability to predict PTB, even in populations considered at high risk for PTB (those with a history of PTB) [4,5]. Many patients with short cervices also present with cervical funneling, where the fetal membranes protrude into the cervical canal, which is also thought to increase the risk of PTB [4]. To improve preterm birth prediction, we sought to achieve a better understanding of how the cervix and other reproductive tissue are loaded throughout gestation in order to identify loading patterns that could cause these tissues to fail mechanically. We present patient-specific computational models of patients at high- and low risk for PTB in this work.

Because studying the *in-vivo* gravid environment poses both ethical and practical obstacles, *in-silico* methods have been pursued which rely on medical images for patient geometry. Though MRI and 3D ultrasound provide high-fidelity patient-geometry, these imaging modalities are not frequently used in prenatal care [6,7]. Therefore, parametric patient-specific modeling methods based on 2D ultrasound, standard in prenatal care, have been implemented to study the gravid environment [8,9]. This research aims to generate hypotheses on what causes cervices to funnel and identify patterns of loading that will ultimately lead to PTB. Finite element analysis (FEA) is conducted for patients at high- and low risk for PTB, including patient-specific geometry and cervical tissue stiffness. The pattern and magnitude of strain in the proximal cervix are compared across cohorts.

## METHODS

Two cohorts of patients were recruited at Columbia University Irving Medical Center. The first cohort is patients considered at high-risk for PTB based on a sonographic cervical length of less than 20mm and typically presented with cervical funneling, with no prior history of PTB. This cohort was recruited at and underwent their first research examination at 16-24 weeks gestation. High-risk patients underwent a second research examination at 26-30 weeks gestation. The second cohort is patients considered at low-risk for PTB based on screening to exclude subjects with known risks. These patients were recruited in the first trimester (before 14 weeks gestation) and underwent the first of four research exams at the time of recruitment. The other research exams were conducted at 18-20 weeks, 24-26 weeks, and 34-36 weeks gestation. In both cohorts, the research exam included the collection of ultrasonic measurements characterizing the overall size and shape of the maternal uterus and cervix and the measurement of cervical stiffness. Cervical stiffness was measured using the Pregnolia system (Pregnolia AG, Switzerland), a device that captures *in-vivo* cervical tissue stiffness.

To compare the simulations of the high- and low-risk cohorts, we used measurements taken in the 16-24 week window for the high-risk patients (n = 12) and 18-20 week window for the low-risk cohort (n = 12) to ensure overlapping gestational ages between groups. Using our established parametric modeling workflow, we automatically generated patient-specific geometry from the ultrasonic measurements in Solidworks 2019 (Dassault Systemes, Vélizy-Villacoublay, France) [9]. We used a reference cervical length for the high-risk cohort to simulate the loading on their cervices before cervical funneling. A fetal membrane and supporting abdomen were included in each model, and a quarter model geometry used for computational efficiency. The geometries were imported in Hypermesh 2021 (Altair Engineering Inc., Troy, Michigan), where they were discretized into finite element models. The meshed models were imported into FEBio studio (v1.3.0) for model setup and simulation [10].

SB³C2022-384

The material properties, boundary conditions, and contact conditions were assigned in FEBio. The cervix, uterus, and fetal membranes were given material properties based on existing literature [11-13]. Inverse FEA was used to determine patient-specific fiber stiffness from the cervical stiffness measurements [14]. The abdomen was assigned nearly incompressible neo-Hookean material properties. Physiologically inspired contact conditions were set between tissues, and the model was fixed in the normal direction on the superior, inferior, and anterior surfaces, as well as in the sagittal cut plane. A gestationally determined intrauterine pressure was applied to the inner membrane surface [15]. Levels and patterns of strain in the proximal cervix were compared across cohorts.

## RESULTS

The high-risk cohort has higher magnitudes of 1st principal Lagrange strain at the internal os (opening of the cervical canal into the intrauterine cavity) and the uterocervical than the low-risk cohort (Fig. 1).

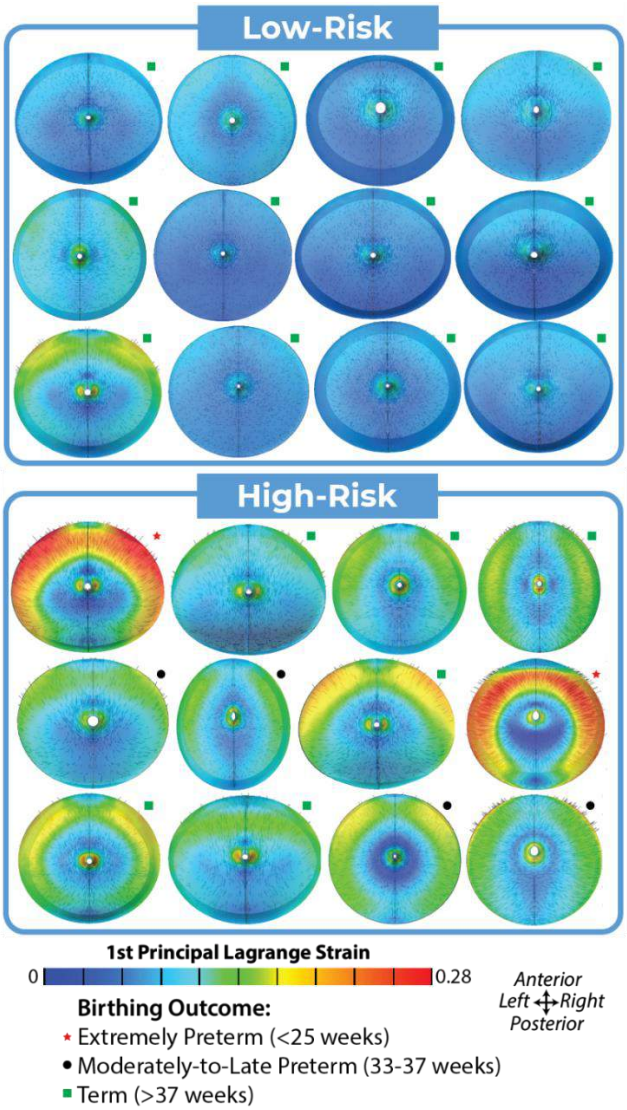

**Figure 1: Heat maps of 1st Principal Lagrange strain in the proximal cervix for subjects at high- and low-risk for preterm birth, with strain direction noted by black lines within the heat map. Birthing outcome is noted on the top-right of each cervix.**

Across cohorts, the direction of the 1st principal Lagrange strain is conserved at the internal os, where it is aligned circumferentially, and at the uterocervical junction, where it is aligned radially (Fig. 1). In the high-risk cohort, two patients delivered extremely preterm (before 28 weeks gestation). These patients have the highest magnitude 1st principal Lagrange strain at the uterocervical junction and the lowest cervical stiffnesses measured by cervical aspiration.

## DISCUSSION

A distinct strain pattern is shown in the FEA results for the high-risk cohort. The high-risk subjects tend to have larger magnitudes of 1st principal Lagrange strain at the internal os and uterocervical junction than the low-risk subjects. Because the high-risk subjects clinically presented with cervical funneling, we believe this strain pattern in the proximal cervix uncovers the possible mechanism by which cervical funneling initiates and propagates, where membranes push into the cervical canal, causing high levels of circumferential strain at the internal os. The uterocervical junction also pulls the cervix open, shown by the high levels of radial strain between the uterus and cervix. We believe these higher tensile strain levels between the uterus and cervix are associated with extremely preterm birth.

A primary limitation of this work is the geometries are built using measurements of the uterus and cervix in a loaded state, excepting the reference cervical length used for high-risk subjects. Thus, the reference configuration in these geometries is not in a stress-free state. Additionally, patient-specific uterine and fetal membrane tissue properties and intrauterine pressure are unknown, and the FEA results have no *in-vivo* loading results to be compared. Thus, the degree to which the FEA results provide a true measure of strain in the cervix is unknown. However, the results thus far are promising and warrant further investigation.

## INTRODUCTION

Diffusion in the tumor extracellular space (ECS) is extremely important for the delivery of intravenous or directly injected therapeutics to tumor cells. Once in the brain, the diffusion is governed by the geometry of ECS and the extracellular matrix. Glioblastoma is the most common and aggressive malignant brain tumors among adults. Although several studies have investigated the molecular diffusion in glioma by real-time iontophoretic method[1] and photobleaching measurements[2], the diffusion properties of glioma are only moderately understood. The challenge is the lack of reliable method and complexity of tumor microenvironment.

In this work, we developed a new optical method based on the fast release from **P**lasmonic n**A**novesi**C**l**E**s (PACE v1.0) to measure the molecular diffusion in the normal brain and tumor ECS. Fluorescent dye calcein could be encapsulated in the plasmonic nanovesicles and released within sub-second under the stimulation of near-infrared laser pulses. The bolus of released calcein worked as a point diffusion source and the diffusion was recorded by a two-photon microscope with tight spatial and temporal resolution. We validated the PACE technique by successfully measuring the calcein diffusion *in vitro* and in different mouse models. Importantly, we found that the diffusion is faster in tumor than that in tumor margin in a 73C glioma model.

## METHODS

*Nanovesicles preparation:* Gold-coated calcein-loaded liposomes (Au-nV-Cal) were prepared by the thin-film rehydration method reported previously.[3]

*Animal and brain slice preparation:* 400 μL of tdTomato-labelled 73C cell suspension ($2\times10^5$ cells/μL) was transplanted into the left hemisphere of the Nu/J mice at 500 μm depth. After 4 weeks, acute brain slice with a thickness of 400 μm was prepared in artificial cerebrospinal fluid continuously bubbled with a mixture of 95% $O_2$ and 5% $CO_2$. Hyaluronan-deficient brain model was established by intraventricular injection of 4 μL of 20 mg/mL hyaluronidase two days before the diffusion measurement. To induce the brain ischemia, 1 mL of 1M KCl was administrated intracardially to cause the immediate cardiac arrest. Finally, 20 nL of Au-nV-Cal were stereotaxically injected to 0.2% agarose gel and above brain samples by a nanoinjector at 1 nL/s.

*Diffusion measurement:* Au-nV-Cal were imaged at 920 nm and stimulated at 720 nm (75 or 100 mW) to trigger calcein release by a multi-photon laser scanning microscope (FVMPE-RS, Olympus).

*Data analysis:* A Point-source paradigm was used to analyze the calcein diffusion. The concentration $C(r,t)$ with respect to location $r$ (distance from the source) and time $t$ is given by Eq. 1. The fluorescence intensity in the two-photon images can be mapped to the shape of Eq. 1 by a two-parameter ($E$ and $\gamma$) Gaussian function (Eq. 2). Images at each time point are fitted to this 2D Gaussian function by non-linear fitting with the Nelder-Mead algorithm (Eq. 2). The acquired $\gamma^2$ increases linearly with time ($t$) (Eq. 3), which is further linearly fitted to estimate the diffusion coefficient.

$$C\ (r,\mathrm{t}) = \frac{Q}{\alpha}\cdot\frac{\lambda^3}{(4D\pi t)^{1.5}}\cdot\exp\left(-\frac{\lambda^2 r^2}{4Dt}\right) \quad (1)$$

$$\Delta F\ (r) = E\ \cdot\ \exp\left(-\frac{r^2}{\gamma^2}\right) \quad (2)$$

$$\gamma^2 = 4\ D\ (t + t_0) \quad (3)$$

where $Q$ is the total molecule number from the source; $\alpha$ is the volume fraction of brain ECS; $D$ is the diffusion coefficient.

## RESULTS

To test the feasibility of the PACE technique, we first demonstrated measuring the diffusion properties of fluorescent dye calcein both *in vitro* and in mouse cortex. Gold-coated nanovesicles packed with calcein dye (Au-nV-Cal) were injected into 0.2% diluted

agarose gel, which can be considered as "free" medium (**Figure 1a**).[4] In the nanovesicles, calcein fluorescence is self-quenched due to the high concentration (75 mM). The photo-stimulation releases the calcein dye and the dilution increases its fluorescence (ΔF) before the fluorescence decreases as the dye diffuses away. Thus, the stimulated nanovesicles can be considered as the point source for calcein diffusion. Representative image sequences after laser stimulation clearly show the hindered diffusion for calcein dye in mouse cortex compared with that in agarose gel (**Figure 1b**). The ΔF in each pixel was fitted by a 2D Gaussian model (Eq. 2), resulting in a time-dependent parameter γ. The diffusion coefficient was acquired by the linear fitting $\gamma^2$ versus $t$ (**Figure 1c**). The effective diffusion coefficient of calcein ($D^*$) is 3.4-fold lower than the free diffusion coefficient ($D$) in the diluted agarose, suggesting the slow diffusion in the brain ECS (**Figure 1d**). The measured values by PACE are close to the results from a traditional method, integrative optical imaging (IOI). We further investigated the $D^*$ in a hyaluronan-deficient brain model (Hyase) and an ischemic brain model. The $D^*$ is 2-fold higher in Hyase group than that of normal cortex. It suggests that the diffusion is faster in hyaluronan-deficient brain because diffusion becomes less hindered when long-chained hyaluronan is reduced in brain ECS. The $D^*$ under brain ischemia decreased to 8% of its normoxic value due to the swelling of brain cells.[4] Taken together, we demonstrate that the PACE is reliable and robust for molecular diffusion measurement at different contexts.

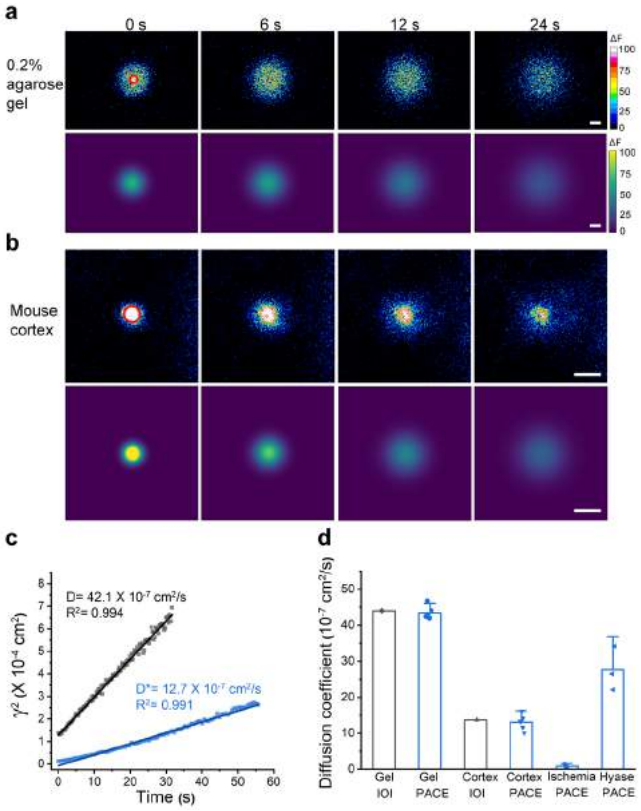

**Figure 1. Calcein diffusion in 0.2% agarose gel and mouse cortex.** (a, b) Two-photon fluorescent images (upper panel) and 2D Gaussian fitted images (lower panel) of calcein diffusion in (a) 0.2% agarose gel and (b) in mouse cortex. 75-μm-diameter and 60-μm-diameter tornado scans (red circle) were performed on Au-nV-Cal for 0.1 s before the diffusion recording in (a) and (b), respectively. Scale bar (a,b): 100 μm. (c) Linear fitting of $\gamma^2$ versus $t$ to get the diffusion coefficient. (d) Measured diffusion coefficients at different conditions compared with the results from integrative optical imaging (IOI) method.

Next, we measured the calcein diffusion in the astrocyte-derived 73C glioma model (*BRAF*$^{V600E}$; *Pten*$^{-/-}$; *p53*$^{-/-}$),[5] which expresses td-Tomato for bioimaging. Since there is negligible binding or uptake of calcein by the cells in the brain, we can image the brain ECS by incubating calcein with glioma slice. **Figure 2a** shows that the interstitial space between brain cells was filled with calcein. In the tumor, glioma cells take up of most of the space and the gaps between the cells are clearly observed, while the density of glioma cells is low, and the gaps are too narrow to be captured in the tumor margin. The PACE was performed at these two areas to measure calcein diffusion. The $D^*$ of calcein in the tumor is 2.3-fold higher than that in the tumor margin (**Figure 2b**), which is consistent with the wider ECS in the tumor. This is probably due to the enlarged ECS resulted from degradation of extracellular matrix and neuronal death in the tumor.[1]

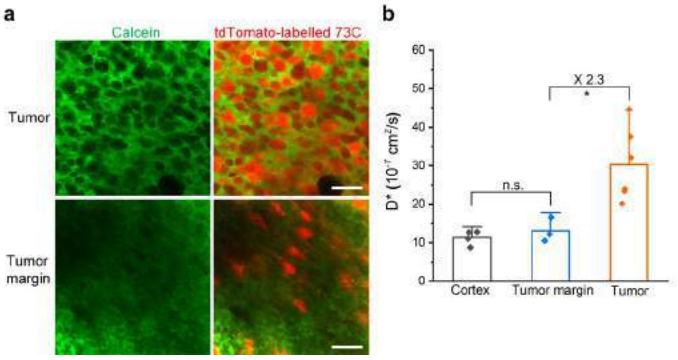

**Figure 2. Calcein diffusion in glioma slice.** (a) Two-photon fluorescent image of calcein and tdTomato-labelled 73C glioma cells at a depth of 50 μm. 50 μM of calcein was incubated with glioma slice for 5 minutes. Scale bar: 20 μm. (b) Comparison of calcein diffusion coefficient ($D^*$) in cortex, tumor margin and tumor. Statistical analysis was performed by Student's t-test in Origin. Single asterisk (*) indicates $p < 0.05$.

## DISCUSSION

The diffusion of anticancer drugs in ECS determines their distribution and therapeutic effects after the entry into brain parenchyma. Taking advantage of the fast release from plasmonic nanovesicles, we successfully developed a PACE technique to measure the molecular diffusion both in normal brain and glioma. Our measurements suggest that the calcein diffusion is faster in tumor than that in the tumor margin, which indicates that tumor margin could be the main obstacle and new target for glioma treatment. Since there are nearly no neuronal structures in the core of 73C glioma, the diffusion measurement is ongoing in a highly invasive glioma model, in which most of the brain parenchyma elements are present. The diffusion measurements in these gliomas will advance our understanding the tumor microenvironment and facilitate the new strategy for cancer treatment.

## INTRODUCTION

Tissue-engineered tumor aggregate models are gaining increasing utility for *in vitro* study of cancer progression and drug discovery. Once grown to volumes of 0.03-0.5 $mm^3$, these relatively simple avascular constructs mimic key aspects of *in vivo* tumors, such as 3D structure and pathophysiological gradients [1], [2]. Critical insight can be gained by characterizing aggregate model behavior during development and in response to drug; however, their requisite size drastically limits the tools that can be used, particularly for non-destructive assessment.

Previously, our lab has used Optical Coherence Tomography (OCT) structural imaging and Imaris image analysis for rapid, non-destructive, and label-free quantitative measurement of 3D tumor model morphology [3], [4]. We also utilized Imaris to count the number of cell-sized objects present in each scan, which, when normalized to the measured aggregate volume, provided a systematic estimation of total cell density within the aggregate [3]. Additionally, this technique accurately measured the number of live cells present within drugged tumor aggregates, thus establishing a non-destructive approach to longitudinally measure cell viability over a full drug timecourse within a 3D tumor aggregate.

Herein, we present an extension of this technique for regional cell density quantification in multicellular aggregates; assessing cellularity within the outer, inner, and core regions of a given aggregate. We also apply this technique to drugged samples, non-destructively tracking regional cell death throughout the depth of these samples over a 5-day timecourse.

## METHODS

In our established method [3, 4], OCT imaging is performed to obtain a 3D volume scan of an aggregate, which is then imported into Imaris software (Bitplane, UK) for image analysis. Following intensity thresholding to isolate the aggregate, the "spots" function within Imaris is used to count the number of cell-sized objects present in each scan, providing an estimation of total cell density within the aggregate.

To extend this technique to measure local cell densities, we use OCT-Imaris to count cells within small defined zones (i.e., regions of interest), at sequential radial depths throughout an aggregate. These zones, or "regional plugs", provide indications of the local cell density, akin to a virtual biopsy at each selected radial depth. To begin this analysis, we identify the aggregate center and radius, then add reference frames within the software to the center point, midpoint (radius ÷ 2), and outer point (radius location - 50 μm) of the sample, along a single axis. The file statistics for that aggregate may then be exported, and the number of objects within 100 μm of each reference frame can be calculated. The resulting value corresponds to the number of cells in that 100-μm diameter regional plug. This value is then divided by the volume of the plug to obtain local cell density, which we assume to serves as a representative measure of the cell density at that depth within the aggregate. For more detailed studies, this analysis can be adapted to include more reference frames (e.g., every 100 μm) to provide a more spatially-refined measure of local density throughout the aggregate.

To establish the fidelity of this technique, we investigated regional cell densities in multiple cell lines, selecting MDA-MB-231 triple negative breast cancer cells and AU565 HER2+ breast cancer cells. Liquid overlay (L.O.), the current gold standard method for aggregate production [5], was used to form aggregates from each cell line. Cells were seeded (2.5 $x10^4$ cells/well) in non-adherent U-shaped 96-well plates and cultured for 4 days until maturity, either with or without the addition of 2.5% Matrigel, to explore aggregates of different morphologies. Matrigel is solubilized basement membrane derived from mouse sarcoma and is well-documented to aid in cell aggregation [6]. OCT imaging was performed on day 4, and the Imaris-based regional assessment described above was performed to quantify cell density at the central core, midpoint, and outer zones of each aggregate.

Next, we wanted to apply this technique to explore potential regional differences in drug response, as well as possible indications of drug penetration. Focusing on HER2+ samples, AU565 L.O. samples prepared with Matrigel were drugged on Day 4 with Trastuzumab (TZM), a clinically-used chemotherapeutic, at a dose concentration of 50 µg/mL. Samples were continuously exposed to the drug for 5 days, and OCT imaging was performed longitudinally; immediately prior to addition of the drug (t = 0), and at 24 hours and 120 hours (5 days) post-addition. Cell density was quantified following drugging within progressively deeper 100−$\mu$m zones using the detailed approach described above. This analysis was performed at each timepoint, ***within each individual aggregate,*** throughout the drug timecourse.

## RESULTS

Qualitatively, AU565 aggregates grown with liquid overlay were quite flat, while those grown with Matrigel became thicker and more disk-like (**Figure 1, lower row insets**). MDA-MB-231 aggregates were disk-like when grown without Matrigel and grew to be spherical when Matrigel was added (**Figure 1, upper row insets**). Despite these morphologic changes, Matrigel addition did not affect the number of cells in the aggregate. For all observed morphologies, we found that cell density was substantially higher in the core of the spheroid than in the middle and outer layers, for both cell types (**Figure 1**). This trend was most prominent in the samples prepared with Matrigel, suggesting that Matrigel does not affect proliferation but does redistribute cell density, promoting core compaction and decreasing cell density in outer layers.

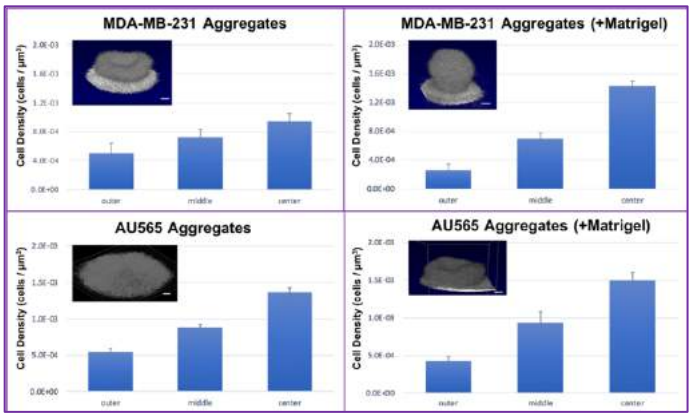

**Figure 1: Matrigel addition redistributes cell density in multiple cancer cell lines, decreasing density in outer zone and increasing compaction in center (n=3). Image scale bars = 100 µm.**

Next, we sought to use this regional approach to non-destructively track cell death in drugged AU565 aggregates. These aggregates were relatively large, with radii of approximately 700 µm on day 4. The diameter of the central plugs was held constant at 100 µm while the outer was allowed to fluctuate in diameter corresponding to changing aggregate size. We observed only minor fluctuations in cell density over time in the inner 500 µm of each aggregate, indicating minimal cell death (**Figure 2**). Indeed, the majority of cell death occurred in the outer 200 µm of each aggregate, particularly in the outer 100 µm, which disappeared by the 120h timepoint for all three aggregates analyzed.

## DISCUSSION

Our goal was to establish a technique to non-destructively assessthe regional cell density within matured multicellular aggregates. We also sought to apply this technique to longitudinally track regional cell viability within drugged aggregates. Our data show that cell density increases towards the aggregate center, regardless of aggregate morphology or cell type (for those tested herein). This result indicates compaction in the model core after 4 days, which agrees well with literature that has well-documented the increased hypoxia in this region as the deeper cells fight for limited oxygen [7]. This trend was exacerbated in samples prepared with Matrigel, an exogenous

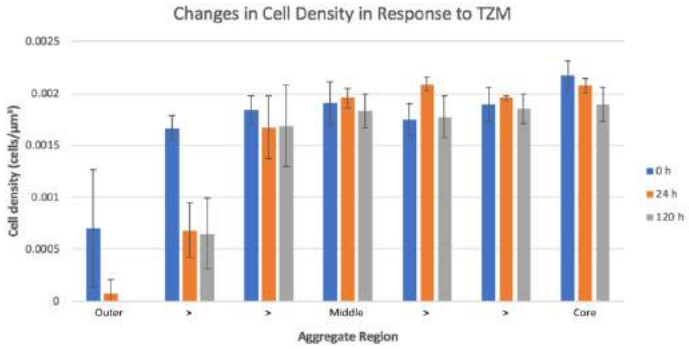

**Figure 2: Cell viability in response to drug (TZM), as a function of aggregate radial depth. The inner core was kept constant at 100 µm diameter, while the outer zone was allowed to fluctuate with changing aggregate size. Cell death was largely constrained to the outer 200 µm, particularly the outermost 100 µm, which disappeared completely after 120 hours of treatment. The inner 500 µm thickness of the aggregates saw little change in cell viability (n=3).**

additive which is poorly characterized, yet known to promote aggregation. This finding provides valuable insight into the physical mechanisms by which Matrigel enables cell aggregation. To our knowledge, this is the first method to non-destructively quantify regional cell density within dense, cellular tissues.

When we applied our technique to drugged samples, we saw different cell behaviors at different depths within the three samples tested. The density within the inner 400 µm of all aggregates remained fairly stable over 5 days. The zone 300 µm deep (3rd cluster of data from left, **Figure 3**) saw larger fluctuations in density over the timecourse than the inner layers. Predictably, much of the cell death observed was constrained to the outer 200 µm of the aggregate, the layers that experienced either direct drug exposure or a relatively short diffusion of the drug inwards (< 200 µm). Given these results, this technique holds great potential as a tool to measure regional cell viability *non-destructively.* This approach also provides an indirect measure of drug penetration without the need for sample fixing and staining, enabling live, continuous drug screening with cell-scale information.

# COMPUTATIONAL FRAMEWORKS TO INVESTIGATE AGING AND DISEASE IN ELASTIC TISSUES AT THE NANOSCALE

**Anna Tarakanova (1)**

(1) Department of Mechanical and Biomedical Engineering, University of Connecticut, Storrs, CT, USA

## INTRODUCTION

Biological aging, as well as many age-related diseases including diabetes mellitus and atherosclerosis, is characterized by compromised elastic tissue function, which significantly impacts human morbidity and mortality. A number of debilitating diseases of genetic origin, e.g. cutis laxa, Williams Syndrome and supravalvular aortic stenosis, present similar properties and modified mechanical function in elastic tissue. In this work we investigate the molecular origins that drive changes in elastic tissue function, by considering the behavior of its nanoscale building blocks, from the bottom up. Elastin is the dominant building block of elastic fibers in the extracellular matrix that impart structural integrity and elasticity to a range of elastic tissues, including the lungs, blood vessels and the skin. The elastin polymer is assembled from its molecular precursor tropoelastin. Historically, elastin's dynamic nature has precluded traditional approaches such as X-ray crystallography to understand its detailed features. In this work we present a series of experimentally-validated computational models to probe elastin's structure, origins of its mechanical function, and changes to its function as a result of modifications associated with disease.

## METHODS

We use atomistic and coarse-grained models based on a particle dynamics approach, as detailed in the references.

## RESULTS

We propose a molecular model to describe elastin's atomistic structure, self-assembly, mechanics and dynamic interactions with other components of elastic fibers and the extracellular environment. We further use the models to probe the functions of key molecular regions, investigate disease etiology — associated with mutations in the elastin gene, as well as with aging-linked physicochemical modifications that alter elastin's structure and function, and explore implications for hierarchical assembly, coupling these to a suite of experimental studies for validation.

## DISCUSSION

This research pioneers novel nanoscale insight into mechanical degeneration of elastic tissue under the presence of genetic mutations and physicochemical stress associated with aging and aging-linked diseases, by establishing a new validated in silico framework, calibrated from experiment, for investigating multifactorial modifications to elastin at multiple length scales, and leverages models to elucidate molecular mechanisms on mechanical function.

## ACKNOWLEDGEMENTS

# COMPARISON OF VELOCITY AND FLOW-BASED METHODS TO CALCULATE WALL SHEAR STRESS FROM 4D FLOW cMRI DATA

**Elliott R. Hurd (1), Elizabeth Iffrig (2,3), John N. Oshinski (3,4), Lucas H. Timmins (1,5)**

## INTRODUCTION

Four-dimensional flow cardiac magnetic resonance imaging (4D flow cMRI) is a non-invasive, non-ionizing radiation-based imaging tool that can interrogate the *in vivo* blood flow environment. This imaging modality has shown promise as a diagnostic and prognostic tool to evaluate and quantify complex flow patterns in the setting of several vascular pathologies. For example, studies have demonstrated the utility of 4D flow cMRI in distinguishing between normal and pathologic flow patterns associated with aortic valve disease and associated secondary aortopathy [1]. In addition, methods have been developed to quantify wall shear stress (WSS) from these image data and highlight its clinical value [2,3]. Importantly, however, the methods used to calculate WSS from 4D flow cMRI data have yet to be validated.

Various methods have been established to calculate WSS directly from 4D flow cMRI data. The most commonly applied approach seeks to quantify the gradient in the 4D flow-derived velocities at the wall and calculate WSS by taking the product between the velocity gradient and the fluid (blood) viscosity (Fig. 1) [4]. However, the limited spatial resolution of MRI, and particularly the inability to capture the gradient within the fluid boundary layer, and image noise can impact determining the near-wall velocity gradient. A more recently developed approach utilizes the 2D phase-contrast MRI-derived volumetric flow waveform constrained by the Womersley solution for pulsatile flow in a cylinder to calculate WSS [5]. Briefly, image data are divided into $i$-sectors, temporal flow waveforms are determined in each sector ($Q_i$), and waveforms are decomposed into harmonics to calculate WSS via the Womersley solution (Fig. 1). As this method only utilizes through-plane velocities (i.e., axial component), it is limited in only calculating the axial component of the WSS vector. This method, too, has yet to be validated for accuracy.

Thus, the goal of this study was to extend the application of the flow-based method to 4D flow cMRI data and examine the accuracy (i.e., validate) of the velocity and flow-based methods to calculate WSS.

## METHODS

**Generation of Synthetic 4D flow cMRI Data.** To compare the 4D flow-derived values of WSS against exact solutions, synthetic MRI data were created from the analytical solutions of the Navier-Stokes equations for steady (Poiseuille) and pulsatile (Womersley) flow in a straight tube (Fig. 2). The fluid was described as Newtonian ($\mu$ = 3.5 cP, blood) with flow rates in the physiologic domain. Data were generated to include variations in tube radius (2.4-4.2 mm), fluid velocity (0.1-100 cm/s), and image signal-to-noise ratio (SNR; 20-80). Two-dimensional flow profiles derived from the analytical solutions were down-sampled to a resolution of 1.2 × 1.2 mm to represent acquired 4D flow cMRI data. To provide a more complex and anatomically representative geometry to examine 4D flow-derived WSS calculation accuracy, WSS values were also derived from a patient-specific fluid-structure interaction (FSI) computational model of the carotid bifurcation. Briefly, the FSI model was taken from the FEBio repository (Fig. 3) [6].

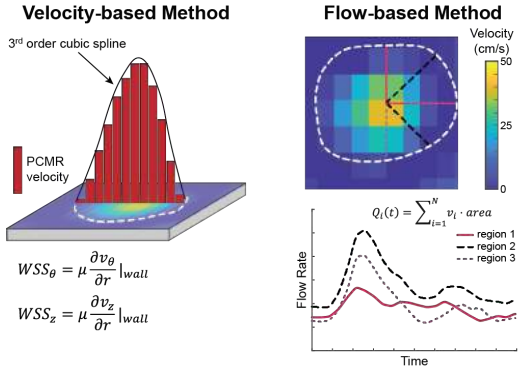

**Figure 1: Illustration of the velocity and flow-based methods to calculate WSS from 4D flow cMRI data.**

The model simulated pulsatile flow of a Newtonian fluid through a two-layered vascular structure, with unique material properties for each layer described by a microstructurally-motived strain energy function. Predicted velocity field data were extracted at the location of the carotid bulb and down-sampled to a resolution of 1.2 × 1.2 mm.

**Methods to Calculate WSS from 4D Flow Data.** Synthetic image data derived from the analytical solutions and FSI model were processed using both the velocity and flow-based methods to calculate WSS. All image data were segmented with the exact known position of the wall boundary. For the velocity-based method, image data were upsampled to an isotopic in-plane resolution of 0.75 mm using weighted nearest-neighbor interpolation. A cubic spline was fit to the 4D flow derived velocity values across the full diameter, and the derivate of the spline was calculated to determine the velocity gradient and WSS value (Fig. 1). Values were determined at 256 points around the circumference, and data were averaged within 12 sectors (central angle of 30°). For the flow-based method, flow waveforms were determined in 80 overlapping 90°-regions around the circumference (Fig. 1). Each flow waveform was reconstructed with 10 Fourier harmonics. WSS values were calculated via the Womersley solution and defined at the central angle for each overlapping region. Values were averaged over 12 sectors.

**Statistical Analysis.** Accuracy in the velocity and flow-based methods were determined by taking the difference between the analytical or model-predicted WSS value and each 4D flow cMRI method. A two-tailed paired Student's *t*-test was used to evaluate statistical significance.

## RESULTS

Across all cases using the exact solutions for calculating WSS, the flow-based method demonstrated greater accuracy than the velocity-based method for determining WSS directly from 4D flow cMRI data. For example, variations in steady fluid velocity showed that on average the flow-based method was ~13% more accurate than the velocity-based method (Fig. 2a). Moreover, the flow-based values were significantly different from the velocity-based values. Similar observations were seen with changes in tube radius and image SNR with the flow-based method being ~13% and ~12% more accurate on average, respectively, than the velocity-based method. Notably, data from the steady flow cases also demonstrated that the flow-based method was less sensitive to changes in the location of wall boundary (i.e., segmentation) than the velocity-based method. For the flow-based methods, changes in the wall boundary of ±20% resulted in WSS deviations <16%, whereas the velocity-based method had changes exceeding 75%. Results from the pulsatile flow cases demonstrated comparable results, whereby the flow-based method showed greater accuracy across all cases examined. Whether examining time-averaged WSS or peak WSS, values derived from the flow-based were closer to the analytical solution across changes in tube radius or inlet velocity (Fig. 2b).

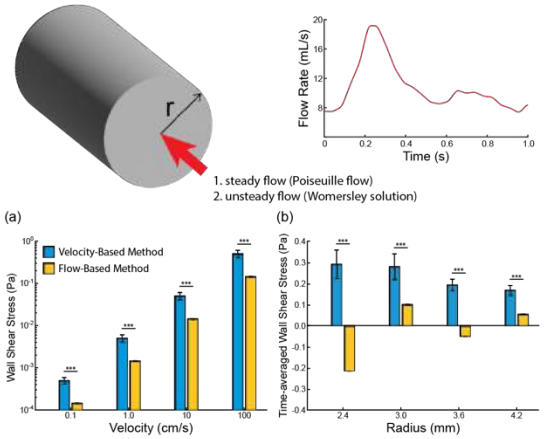

**Figure 2: Analytical solution geometry and flow conditions. Differences between analytical solution and 4D flow-derived values of WSS under (a) steady flow with changes in velocity and (b) pulsatile flow with changes in radius (*r*). *** indicates $p<0.001$.**

Comparing FSI predicted WSS values to those calculated with the velocity and flow-based methods further demonstrated the improved accuracy of the flow-based method. At the carotid bulb, for example, the velocity and flow-based methods exhibited averaged differences in time-averaged WSS (TAWSS) values from the FSI predictions of 0.22 and 0.07 Pa, respectively, across the 12 sectors (Fig. 3). In addition, peak TAWSS occurred in sector 8 in the FSI model and from flow-based calculations, whereas the peak TAWSS value from the velocity-based calculations occurred in sector 6.

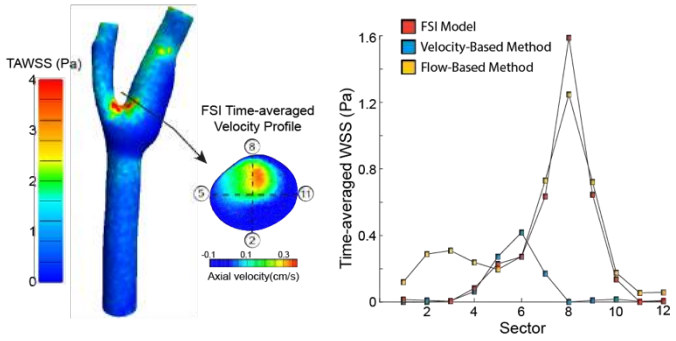

**Figure 3: Time-averaged WSS values derived from velocity and flow-based methods versus FSI predictions in a patient-specific carotid bifurcation at the carotid bulb (dashed line).**

## DISCUSSION

Herein, we present data from a study examining the accuracy of two distinct methods (velocity and flow-based) to calculate WSS from 4D flow cMRI data. Using synthetic MRI data generated from flow profiles calculated from analytical solutions of the governing equations of fluid flow, we observed that the flow-based method showed increased accuracy over the velocity-based method for calculating WSS when compared to analytical values (i.e., ground-truth values). Furthermore, these observations persisted when comparing against predicted WSS values from an FSI simulation of a patient-specific carotid bifurcation. It is important to highlight that while both methods are impacted by the limited spatial resolution of MRI, the flow-based method is more accurate and robust to changes in image quality (SNR). In addition, the flow-based method is more stable to inaccuracies in lumen boundary detection. It is recognized that the full potential of the flow-based method will require application and integration into the clinical setting; however, these data provide confidence in the *in vivo* quantification of an important mechano-biologic metric.

# A STAND-ALONE MODULE TO INTRODUCE MEDICAL IMAGE SEGMENTATION INTO THE BME CURRICULUM

**Donna M. Ebenstein (1), James W. Baish (1), Christine M. Buffinton (2)**

(1) Department of Biomedical Engineering, Bucknell University, Lewisburg, PA USA
(2) Department of Mechanical Engineering, Bucknell University, Lewisburg, PA USA

## INTRODUCTION

Clinical practice has long made use of medical images for diagnosis and treatment planning. With the recent advances in 3D digital imaging technology, the need for biomedical engineering (BME) students to learn the basics of extracting specific anatomical features from the images, a process called segmentation (Fig. 1), has grown significantly. The trend towards patient-specific healthcare provides many examples of the need to segment a region from clinical imaging data and create a model that can be 3D printed or imported into a CAD program for further processing. For example, printed models are especially useful in orthopaedics for understanding the anatomy of bones and joints, manufacturing customized orthotics and implants, surgical planning, teaching, and research [1]. Commercial enterprises have also developed to offer customized hip, shoulder, and cranio-maxillofacial replacements using a combination of clinical imaging data and CAD software (e.g., KLS Martin WORLD, Tuttlingen, Germany; LOGEEKs Medical Systems, Novosibirsk, Russia; Materialise, Leuwen, Belgium). Patient-specific, 3D printed models are also well-suited for diagnosis and treatment planning for congenital heart disease, helping to clarify the complicated anatomy of the heart, great vessels, and coronary arteries before intervention [2]. To highlight these current clinical and industry applications of CAD and 3D printing, a stand-alone class module was developed to teach BME students the principles of medical image segmentation and its interface with CAD post-processing.

## METHODS

The introductory medical image segmentation stand-alone module was developed for a biomechanics course, and further refined for biomedical engineering courses in both imaging and fabrication. It uses ITK-SNAP, a free, open-source application designed to segment structures in 3D medical images [3]. ITK-SNAP provides semi-automatic segmentation using active contour methods, and had the best combination of cost, ease of use, and industry adoption when compared to other available image-processing software packages.

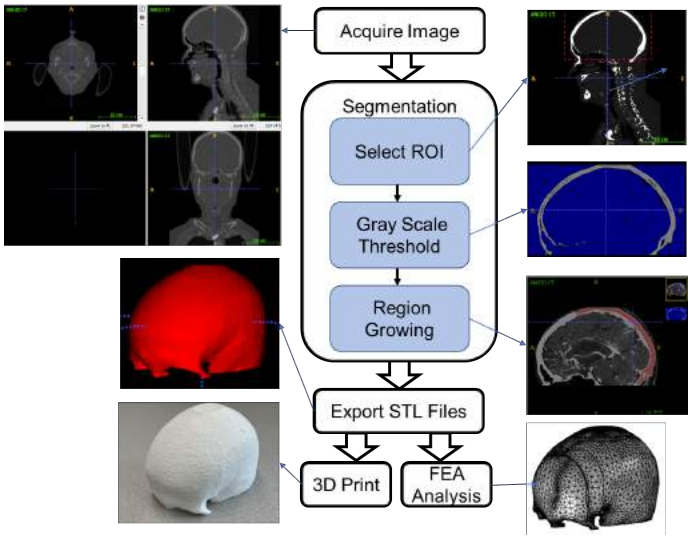

**Figure 1: The process of image segmentation applied to a set of CT images to extract part of the skull using the software ITK-SNAP. The exported STL file was 3D-printed and converted to a finite element modeling (FEM) mesh in COMSOL.**

The module consists of an introduction, a tutorial that guides students through a step-by-step process to extract a skull from a provided set of CT data, and a culminating assignment where students use the same software program to extract a different body part from clinical imaging data.

To introduce the module, the instructor provides basic background on how CT scans work and an explanation of the clinical relevance of image segmentation, often using videos. The instructors have found that showing videos of specific patients who were treated using these techniques can be an effective way to motivate students.

The tutorial document provides students with background information on image segmentation, instructions on how to install ITK-SNAP, and step-by-step instructions on how to extract a portion of the skull from a provided DICOM dataset of the head and neck with 460 CT slices of 512x512 pixels [4]. These step-by-step instructions include screen captures along with written instructions on how to perform each step. Three different methods of segmentation are introduced in the tutorial background section (threshold-based, edge-based, and region-growing), and two of the three are implemented in the tutorial.

While completing the tutorial, students load the image series, adjust the contrast, select a region of interest, and try auto-segmentation with the Snake Tool to extract a portion of the skull from the CT data (Fig. 1). Custom thresholding is applied to refine the selection and the students then explore different combinations of seed point quantity and size. After segmentation, students export files suitable for 3D printing or import into a CAD program.

The culminating assignment varies by instructor and course, but in all classes has included tasking the students with extracting a different body part from clinical imaging data using ITK-SNAP. In addition to this base task, some instructors have included additional components in the culminating assignment, such as having the students 3D print their extracted body part and evaluate the outcome, reflect on the challenges of segmenting different anatomical structures, or place images of the extracted body part into a portfolio to share with potential employers.

## RESULTS

This module has been implemented in approximately two courses per year since it was developed in 2016, impacting more than 150 students. Students complete the tutorial exercise in an 82-min class and then independently segment regions of their own choice from the provided images or another publicly available data. The primary learning objective for this module, "Students will be able to perform segmentation from a set of medical images," can be assessed directly from student completion of the culminating assignment in the module, since all faculty have required students to independently extract a new anatomical feature from clinical imaging data. 100% of students have successfully achieved this learning objective. As shown in Figure 2, students were able to segment a wide variety of mineralized and soft tissues from the provided or publicly available datasets. Most datasets were CT scans, but some body parts were extracted from MRI data.

The students engage well with this assignment and appreciate its clinical relevance. Students showed interest and excitement about segmenting their own choice of images/body parts, and particularly about 3D printing to obtain a physical object of their own creation. In reading student reflections on this activity, a few themes emerge. Students typically found the software to be easy to learn and user-friendly, even when independently applying the software to segment soft tissue. They also found it easy to 3D print a model using the exported segmentation file, although some students noted that "small details do not print accurately". Most of the challenges identified by the students were related to seed placement and propagation during region growing, and issues with file size. Students noted that if you used too many seed points, or seed points that were too large, the software might crash or freeze up. File size was an issue both when seeking other datasets to use for image extraction (many datasets students found on their own were too large for ITK-SNAP), and when slicing the exported file for 3D printing.

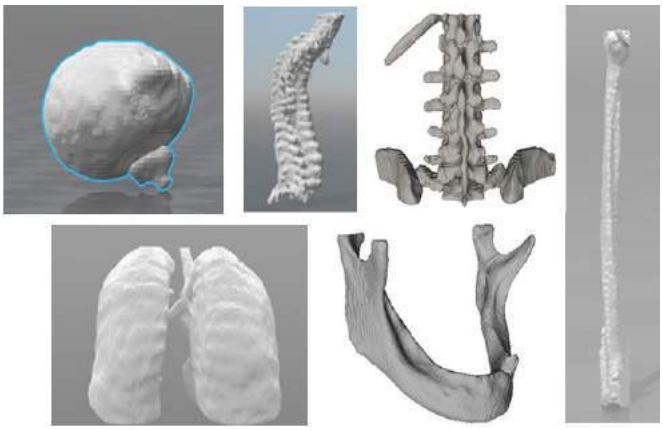

**Figure 2. Examples of extracted body parts from culminating assignments.**

## DISCUSSION

Successful completion of the tutorial and culminating assignment, particularly the ability of students to segment soft tissues on their own after only being trained to segment a mineralized tissue, showed that it is possible for students to sufficiently master the image segmentation technique in ITK-SNAP using the provided tutorial. In addition, instructors have observed that students often apply these skills independently in later courses, such as senior design and independent research projects. Several of our BME students have also landed internships or jobs at companies that create patient-specific implants using image segmentation.

Five different faculty members have utilized this learning module. Instructors previously unfamiliar with the technique were able to learn the package well enough for demonstration to students through completion of the tutorial. In addition to being easy to learn, this module is low-cost to implement. The software is free, and the module introduction and tutorial require less than 2 hours of classroom time to complete (even with troubleshooting of student computer issues). Hence, this module would be easy to incorporate into a variety of lecture and lab classes. So far, the stand-alone module has been successfully implemented in a biomechanics elective, a medical imaging elective, and a biomedical fabrication core course. It has been taught to sophomores, juniors, and seniors, and would also likely also be successful in a first-year course as it requires no pre-requisite material.

In conclusion, this stand-alone module provides a low-cost, flexible way to bring the clinical and industry trends combining medical image segmentation, CAD, and 3D printing into the undergraduate BME curriculum, and provide students with a concrete skill to market when applying for summer internships, jobs, or graduate school.

## ACKNOWLEDGEMENTS

The authors would like to thank Tyler Chlebowski, a Bucknell student ('16) who helped develop the original body part extraction exercise in collaboration with CMB. The authors would also like to acknowledge that initial development of ITK-SNAP was funded by NIH grant R01 EB014346 and was a collaboration between PICSL at U Penn and SCI at the University of Utah, and that PICSL maintains the software.

# NON-MUSCLE MYOSINS ARE CRITICAL REGULATORS OF SKELETAL AND CONNECTIVE TISSUE FORMATION

**Mary K. Evans (1), Tonia K. Tsinman (1), Xi Jiang (1), Ellie J. Ferguson (1), Joel Boerckel (1), Lin Han (2), Eiki Koyama (3), Robert L. Mauck (1), Nathaniel A. Dyment (1)**

## INTRODUCTION

The site where tendons insert into bone is known as the enthesis, which acts to mitigate stress concentrations between stiff bone and compliant tendon and is essential for the efficient transfer of muscle generated forces to bone, enabling skeletal motion. Tendon entheses often insert into bone eminences (i.e, tuberosities) which are protrusions on the ends of long bones that increase the mechanical advantage during ambulation. Tuberosities and the entheses attached to them develop in a biphasic process where cells specify into a distinct progenitor population that co-express Scleraxis (Scx) and Sox9. This is followed by a growth and differentiation phase where these progenitors proliferate to grow the eminence and then differentiate into tuberosity chondrocytes or enthesis fibrochondrocytes [1]. Studies have shown that both biophysical and biochemical cues are critical to enthesis development at each of these stages, as the disruption of key signaling pathways (TGFβ and BMP4) in the limb mesenchyme, ablation of Sox9 in Scx lineage cells, and the absence of muscle contraction all attenuate tuberosity formation [2]. Since cells sense mechanical stimuli and translate them into biochemical signals through their cytoskeleton via actomyosin contractility, studies have looked at the role of this process in directing cell differentiation and matrix production. However, studies thus far have been limited to *in vitro* experiments that fail to recapitulate the complex interaction of tendon and bone at the enthesis. While it is clear that applied (external) loading is critical for enthesis development, the role of cell-mediated (internal) forces generated via actomyosin contractility, is largely unknown. In order to disrupt cell-mediated contractility, we chose to ablate non-muscle myosin II, which interacts with actin filaments to initiate critical cell functions, such as cytoskeletal rearrangement, cell migration, and cell proliferation. NMII is encoded by the Myh9 (NMIIA), Myh10 (NMIIB), and Myh14 (NMIIC) genes; however, Myh14 expression is limited to a small set of differentiated tissues [3]. Therefore, to determine the extent to which actomyosin contractility governs tissue formation at this interface between tendon and bone, we ablated NMIIA and NMIIB in either all limb mesenchyme or targeted to tendinous tissue. We hypothesized that NMII ablation in both mesenchymal cells and tendinous tissues would disrupt enthesis and tuberosity formation and maturation.

## METHODS

All animal work was approved by the UPenn IACUC. Mouse Models: $Myh9^{f/f}$;$Myh10^{f/f}$ mice were crossed with either Prrx1Cre or ScxCre to target all limb mesenchyme or to restrict ablation to dense connective tissues, respectively. Because homozygous double knockouts did not appear with the Prrx1Cre driver at birth, suggesting embryonic lethality, we analyzed Prrx1Cre;$Myh9^{f/wt}$;$Myh10^{f/f}$ (Prrx1Cre $Myh9^{HET}$ $Myh10^{KO}$) and Prrx1Cre;$Myh9^{f/f}$;$Myh10^{f/wt}$ (Prrx1Cre $Myh9^{KO}$ $Myh10^{HET}$) mice. The ability of a single allele of either gene to rescue embryonic lethality reinforced previous findings that Myh9 and Myh10 are mutually compensatory; therefore, we only analyzed ScxCre;$Myh9^{f/f}$;$Myh10^{f/f}$ double knockouts (ScxCre dKO). Micro-CT: Prrx1Cre $Myh9^{HET}$ $Myh10^{KO}$, Prrx1Cre $Myh9^{KO}$ $Myh10^{HET}$, and ScxCre dKO mice were sacrificed at 5 weeks of age along with Cre-negative littermate controls (n=3 per genotype) and tissues were scanned at 10μm resolution. Skeletal Preparations: Prrx1Cre $Myh9^{HET}$ $Myh10^{KO}$ (n=1) and Cre-negative littermate control (n=3) mice were sacrificed at P0, stained with Alcian blue and Alizarin red, and cleared. Histology Sample Preparation: Knees, ankles, and shoulders from ScxCre dKO (n=3) and Cre-negative littermate control mice (n=2) were harvested, fixed in formalin, cryo-embedded, and serially sectioned in the longitudinal plane. Staining: Sections were stained for alkaline phosphatase (AP) activity with ELF97 endogenous phosphatase fluorescent substrate, counterstained with Hoechst-33342 (nuclei), and imaged by brightfield and polarized light microscopy.

## RESULTS

Non-muscle myosin is critical for appendicular skeletal

development. To assess the roles of NMIIA and NMIIB in appendicular skeletal development we conditionally ablated Myh9 and Myh10 with Prrx1Cre. Physical examination of Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ mice at 5 weeks of age revealed a marked shortening of the forelimbs coinciding with impaired mobility. Interestingly, these limb shortening and ambulation defects were less severe in Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ mice, indicating that NMIIB is more dominant than NMIIA in limb formation. Micro-CT reconstruction showed severe abnormalities in the Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ mutants (**Fig. 1**) including, a subluxed patella (P), missing trochlear groove (TG), unfused tibia and fibula (T), and missing third trochanter in the hindlimb (100% penetrance). These abnormalities are also present in the hindlimb of Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ mice; however, these mice display some, albeit incomplete fusion of the tibia and fibula. In the forelimb of Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ mice, the deltoid tuberosity (DT) was missing, the humeral head and scapula were misshapen, and the spine of the scapula (S) was absent. In the Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ mice, the humeral head, scapula, and spine of the scapula appeared normal and the deltoid tuberosity was present; however, it was severely misshapen. This led us to question if the absence of the deltoid tuberosity in the Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ mutants was due to a lack of tuberosity initiation, or a failure of mineralization. P0 skeletal preparations revealed that the deltoid tuberosity absence was due to lack of initiation (**Fig. 2**).

Non-muscle myosin regulates tuberosity development and mineralization. To target non-muscle myosin ablation more in the tendon than the adjacent cartilage anlagen, we created ScxCre dKO mice. These mice display a strikingly similar shoulder phenotype to the Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ mice, with a misshapen tuberosity, despite no other apparent skeletal defects (**Fig. 3**). Further investigation into the mineralization of several tendon entheses demonstrated a severe lack of mineral apposition at the tibial tuberosity enthesis (**Fig. 4**), with disorganized mineralization in the Achilles and supraspinatus tendons.

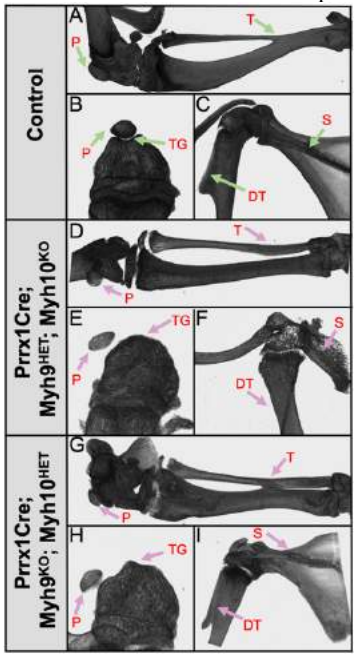

**Figure 1: NMII is critical to long bone and tuberosity formation. 3D µCT renderings of the hindlimb (A), frontal view of the knee (B), and shoulder joint (C) of control samples with arrows denoting important skeletal features that are lacking or abnormal in the Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ (D-F) and Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ (G-I) mutants. P: patella, TG: trochlear groove, T: tibia-fibula fusion, DT: deltoid tuberosity, S: spine of scapula.**

## DISCUSSION

Despite the well-known role of applied (external) loading in the development of the enthesis, the role of cell-mediated (internal) forces in enthesis development is unknown. Here we show that mice retaining a single copy of either Myh9 or Myh10 in limb mesenchyme demonstrate similar, yet less severe, abnormalities to mice lacking skeletal muscle contraction. The differences in skeletal defects observed depending on which gene remains active, highlights the differential roles of Myh9 and Myh10 in tuberosity and bone formation. Additionally, we show that NMII ablation in tendons disrupts deltoid tuberosity formation and yielded markedly reduced mineral apposition in the distal patellar tendon enthesis. Interestingly, ScxCre dKO mice phenocopy the deltoid tuberosity defects found in Prrx1Cre Myh9$^{KO}$ Myh10$^{HET}$ mice but are less severe than Prrx1Cre Myh9$^{HET}$ Myh10$^{KO}$ mice. Therefore, we will investigate allele dosages in Scx Cre mutant mice to determine the cell autonomous roles of NMIIA and NMIIB in enthesis development. These results also raise the question of whether defects in tuberosity development are due to disrupted transduction of applied loads to the cells or rather loss of actomyosin contractility which alters cell patterning during tuberosity initiation and growth. Future studies will investigate these important questions.

# MODELING VENTRICULAR MECHANICS IN PATIENTS WITH OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY (HOCM)

**Lei Shi (1), Hiroo Takayama (2), Vijay Vedula (1)**

(1) Department of Mechanical Engineering, Columbia University, NY, USA

## INTRODUCTION

Hypertrophic obstructive cardiomyopathy (HOCM) is an inherited cardiac disease where the left ventricle (LV) myocardium thickens abnormally around the basal plane, dynamically obstructing the flow into the aorta. Affecting 14-35 million people worldwide [1], HOCM can increase the risk of heart failure which leads to sudden cardiac death. Septal myectomy, an open-heart procedure, is the current gold standard to treat HOCM patients that involves removing excess myocardial tissue. However, the procedure relies heavily on the surgeon's expertise and may lead to repeat interventions [2]. Patient-specific modeling of cardiac mechanics in HOCM patients provides a viable myectomy planning tool by virtually predicting the mechanical response of the myocardium before and after performing the surgery.

Cardiac mechanics is composed of a passive component and an active contraction component. The primary step for simulating cardiac mechanics is to obtain the passive material parameters of the myocardium and the stress-free reference configuration. In this work, we developed an inverse finite element analysis (iFEA) framework to estimate the passive material parameters and the stress-free reference configuration of the ventricular myocardium in a HOCM patient. We plan to further extend the framework by including electrophysiology modeling and active contraction to analyze the myocardial mechanics during the entire cardiac cycle, before and after performing myectomy. Such a modeling framework, coupled with optimization, may find clinical utility in planning myectomy for optimized cardiac performance, thereby leading to improved patient outcomes.

## METHODS

A schematic of the workflow for patient-specific characterization of myocardial material parameters is shown in Figure 1. Briefly, we obtained high-resolution dynamic CT (3D+time) data for three HOCM patients from the database at Columbia University Medical Center (CUMC). We used our previously developed workflow to segment the ventricular myocardium at four phases during diastole ($t_{n,\ n=1\text{-}4}$, typically between 45%R-R and 100%R-R), to create FEA-ready models [3]. Optimization is subsequently applied to not only characterize the myocardial material parameters but also determine the stress-free configuration using the augmented inverse Sellier's method [4], described next (Figure 2).

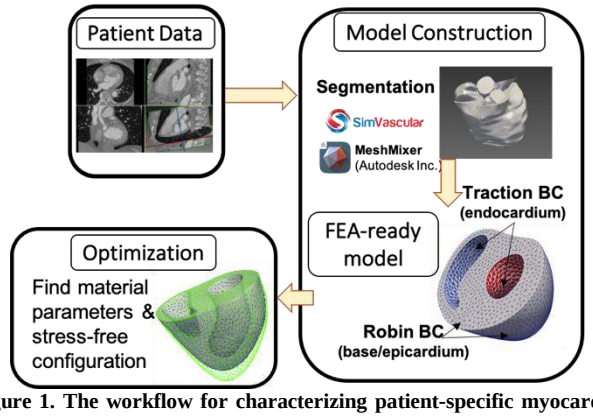

**Figure 1. The workflow for characterizing patient-specific myocardial properties and stress-free configuration in HOCM patients using finite element analysis (FEA) and optimization.**

The basic idea of the algorithm (Figure 2) was to iteratively update the reference configuration based on the result of each forward FEA to reduce the difference between the image-based configuration $\mathbf{X}_{imag}$ and the loaded reference configuration $\boldsymbol{\psi}_{p_1}(\boldsymbol{X})$ predicted by the FEA at pressure $p_1$. Here, $\psi(\boldsymbol{X})$ is the standard mapping between the reference configuraton $(\boldsymbol{X})$ and the deformed configuration $\boldsymbol{x} = \psi(\boldsymbol{X})$ in nonlinear continuum mechanics. During the update, we apply Aitken's relaxation to accelerate convergence [5]. Meanwhile, the material parameters of the constitutive model were optimized by reducing the

difference between the `measured' and the predicted diastolic pressure-volume ($p$-V) profiles at all the acquired phases ($t_{n,\ n=1\text{-}4}$). Since pressure data is not routinely acquired for these patients, we approximate the diastolic $p$-V relation using an exponential profile, characterized by two constants $p_0$ and $k_0$. These constants are determined using a Python-based Levenberg-Marquardt algorithm such that the diastolic pressures are bound within empirically determined clinical data (8-20mmHg).

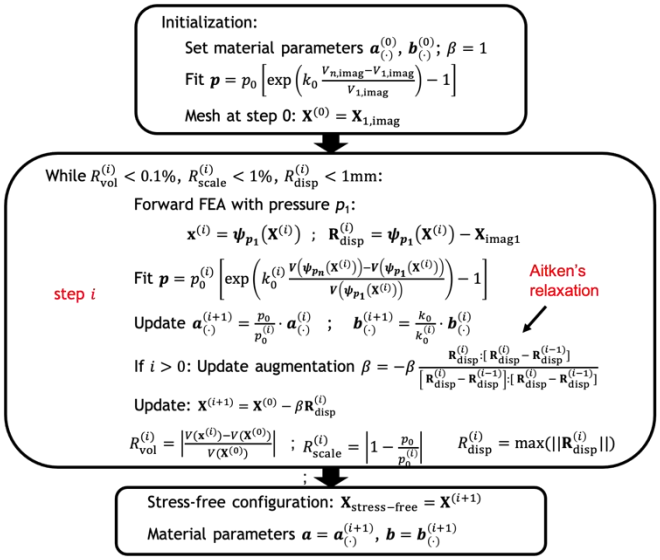

**Figure 2. Algorithm to find the stress-free configuration and parameters of the Holzapfel-Ogden constitutive model for the myocardium.**

We begin our algorithm with the ventricular configuration at the beginning of the diastole (or end-systole ~45%R-R). The forward FEA is then performed by applying pressure boundary conditions on the endocardium such that the pressure on the RV endocardium is about 1/5$^{th}$ of the pressure on the LV endocardium (~8mmHg at beginning of diastole) [6]. We employ the open-source multiphysics finite element solver, svFSI, and the myocardium is modeled using the Holzapfel-Ogden (HO) orthotropic constitutive model with initial values for the parameters extracted from Pfller et al. [7]. The fiber directions of the myocardium were determined using a rule-based method [7]. The top surface was fixed and a Robin boundary condition was applied on the epicardium surface to model the effects of the pericardium [7]. The process is iterated until the errors in myocardial volume ($R_{\text{vol}}$), maximum displacement ($R_{\text{disp}}$), and material parameter scaling ($R_{\text{scale}}$) are within acceptable ranges.

## RESULTS

The parameter estimation process converges in less than 6 steps for all the three patients with $R_{\text{disp}}$=0.7±0.2mm, $R_{\text{vol}}$=0.49±0.43%, and $R_{\text{scale}}$=0.81±0.15%. The optimized reference configuration of a representative patient is shown in Figure 3a, where the green mesh is the image-based configuration at the beginning of the iterative process (beginning of diastole), and the gray surface is the optimized stress-free reference configuration. When loaded with a mid-diastolic pressure (14.15mmHg), that corresponds to 80%R-R, there is a reasonable agreement between the deformed reference configuration (Figure 3b, gray) and the image-based model (Figure 3b, green) with a slight mismatch near the basal plane of the ventricular free-wall. The LV cavity volumes of both the image-based and the predicted models are within 3.3% for all four diastolic pressure loads (Table 1), while the optimized passive material parameters of the HO model for the three HOCM patients are given in Table 2.

**Table 1: Comparison of the image-based and predicted LV cavity volumes (ml) during diastole for the three HOCM patients**

| Phase | | Patient #1 | | Patient #2 | | Patient #3 | |
|---|---|---|---|---|---|---|---|
| (%R-R) | p(mmHg) | $V_{\text{imag}}$ | $V_{\text{pred}}$ (%diff) | $V_{\text{imag}}$ | $V_{\text{pred}}$ (%diff) | $V_{\text{imag}}$ | $V_{\text{pred}}$ (%diff) |
| 45% | 8 | 74.3 | 74.8 (0.7) | 114.3 | 115.2 (0.8) | 71.2 | 71.2 (0.0) |
| 70% | 11.25 | 90.3 | 87.3 (3.3) | 130.9 | 129.6 (1.0) | 91.3 | 88.6 (3.0) |
| 80% | 14.15 | 101.7 | 99.3 (2.4) | 148.9 | 145.6 (2.2) | 100.4 | 98.1 (2.3) |
| 99% | 20 | 118.6 | 118.5 (0.1) | 167.5 | 166.9 (0.4) | 111.4 | 111.7 (0.3) |

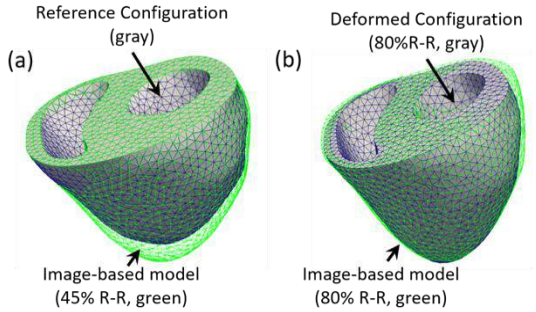

**Figure 3. (a) The optimized stress-free reference configuration (gray) superposed on the image-based model at the beginning of the iteration (45%R-R, green). (b) Comparison of the deformed configuration (gray), obtained by loading the reference configuration with an LV $p$=14.15 mmHg, and the image-based model at 80%R-R (green).**

**Table 2: Material parameters of the Holzapfel-Ogden (HO) constitutive model for the myocardium of the 3 HOCM patients.**

| Parameter | $a$ (Pa) | $b$ | $a_f$ (Pa) | $b_f$ |
|---|---|---|---|---|
| Value | 27±15 | 1.6±0.4 | 8339±4679 | 3.1±0.7 |
| Parameter | $a_s$ (Pa) | $b_s$ | $a_{fs}$ (Pa) | $b_{fs}$ |
| Value | 1120±628 | 2.2±0.5 | 97±55 | 2.2±0.5 |

## DISCUSSION

We developed an inverse FEA-based framework (Figures 1, 2) to determine the passive material parameters and the stress-free reference configuration of a patient-specific HOCM myocardium. The framework has been applied on three patients and shows reasonable agreement between the FEA-based model and image-based ventricular myocardium (Figure 3, Table 1). Next, we will establish the complete cardiac mechanics model of a HOCM patient by including electrophysiology modeling and active contraction in the current framework. We will first apply the integrated model on a preoperative HOCM patient with the myocardial parameters estimated during diastole using inverse FEA. We will then perform virtual myectomy using post-operative CT data as reference and assess the effect of myectomy on the cardiac mechanics. Validation will be performed by comparing CT-based image data and ECG waveforms pre- and post-myectomy. Our long-term goal is to couple the framework with topology optimization leading to a myectomy planning tool for optimal cardiac performance.

## INTRODUCTION

Cardiac tissue is traditionally modeled as a pseudo-elastic anisotropic material using the language of nonlinear solid mechanics. Different models represent this anisotropy in different ways, but all require some manner of translating tissue structure into the mathematical formalism. At their simplest, models such as these may locally identify a preferred fiber direction, and then construct a transversely isotropic strain energy density from that direction using strain invariants and pseudo-invariants. Other more complex models may define fiber, sheet, and normal directions as an orthonormal frame, and then build an orthotropic material model based on this data. One challenge that faces all of these models is the difficulty in connecting model anisotropy to the actual structure of the tissue.

Diffusion Tensor Magnetic Resonance Imaging (DTMRI) is a convenient way to noninvasively locally measure the structure of fibrous biological tissues like axonal tissue and myocardium. Despite this, current models based on DTMRI measurements only incorporate secondary quantities derived from the positive definite diffusion tensor field **D**. For example, **D**'s eigenvectors may be extracted to determine local orientation without regard for the strength of the anisotropy; there is currently no material model that fully incorporates **D**, which contains rich structural information embedded within it. We introduce a material model that directly incorporates **D**, resolves degeneracy conditions and singularities, and is easily modified to suit other fibrous biological materials.

## METHODS

**Structural DTMRI Data.** Ex-vivo DTMRI data was densely mapped on 1 $cm^3$ cubes of passive ovine myocardium (Figure 1). The diffusion tensor **D** is a quantity that relates the gradiant in osmotic pressure ρ to fluid flux J within tissue.

$$J = -\boldsymbol{D}\nabla\rho \qquad (1)$$

The diffusion tensor **D** is a positive definite symmetric tensor, meaning that it possesses a spectral representation.

$$\boldsymbol{D} = \sum_{i=1}^{3} \lambda_i \boldsymbol{n_i} \otimes \boldsymbol{n_i} \qquad (2)$$

There are several natural symmetries of such data, namely that permuting the eigenvalues of **D** is locally indistinguishable from a material rotation. Additionally, whenever two or three of these eigenvalues are equal, the corresponding set of eigenvectors ceases to be uniquely defined.

We demanded that our model respect these symmetries, in that it gives the same physical predictions for materials that only differ by these symmetry transformations. This lets it reduce to the degenerate symmetry cases of transverse isotropy and isotropy whenever the DTMRI data itself adopts these symmetries. Because this does not completely determine the model form, we make further simplifying assumptions to obtain a particular model form. We distinguish between necessary functional forms induced by the inherent symmetries of the diffusion tensor, and the particular functional choices we make in this specific model, demonstrating the generality of this approach, and making clear where modification can be freely made without losing the desirable symmetry features of the model.

**Model Form.** Our model is a pseudo-elastic material model, so we define a strain energy density Ψ depending on the Lagrange strain tensor $\mathbf{E}=(\mathbf{F}^T\mathbf{F}-\mathbf{I})$.

We adopt an exponential polynomial form in accordance with earlier work [1], drop odd order terms to ensure convexity, and enforce major and minor symmetries on $Q_2$ and $Q_4$ because of the symmetric action on **E** and the symmetry of **E**. In terms of the spectral basis $\{\mathbf{n}_i\}$, and utilizing Einstein summation, this energy takes the form

$$\Psi = e^{\left(Q_0 + Q_2^{ABCD} E_{AB} E_{CD} + Q_4^{ABCDEFGH} E_{AB} E_{CD} E_{EF} E_{GH}\right)} \qquad (3)$$

SB³C2022-392

In this basis, we compute the components of $Q_2$ and $Q_4$, and enforce symmetry conditions. The major symmetries of $Q_2$ and $Q_4$ require that pairs of indices can be arbitrarily permuted, while their minor symmetries require that the indices within each pair can be swapped.

**Symmetry Conditions.** Because the permutation of the eigenvalues of **D** is indistinguishable from certain rotations of **D**'s eigenvectors as shown in Figure 1, we want to ensure that our model's dependence on **D** is insensitive to this distinction. To enforce this, we permute the eigenvalues, and then apply the rotation that places the eigenvectors back in their original orientation. This is a nontrivial transformation on the components of the strain energy, which yields a set of functional equations that must be satisfied by the different components of our model's energy.

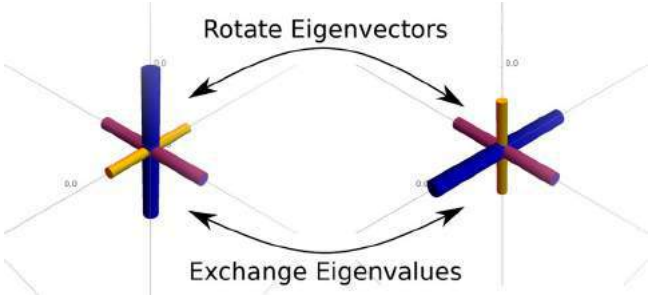

**Figure 1: Cubic rotations of the diffusion tensor's eigenvectors are indistinguishable from permutations of the diffusion tensor's eigenvalues.**

These symmetries reduce $Q_0$ to be a symmetric function of DT's eigenvalues, the components of $Q_2$ to be determined by three underlying functions, and the components of $Q_4$ to be determined by ten underlying functions. Furthermore, because our model must become transversely isotropic or isotropic when **D** does, these functions are not arbitrary, but must satisfy functional equations at particular values of the eigenvalues. If these underlying functions are linear combinations of simple functions, these functional equations become linear, and can be explicitly solved to obtain a set of independent free parameters.

## RESULTS

We nondimensionalize the eigenvalues of **D** so that the sum of their squares is 1. Taking the remaining free components of $Q_0$, $Q_2$, and $Q_4$ to be linear in these projectivized eigenvalues $\{\widetilde{\lambda}_i\}$, we obtain a model with

$$Q_0 = q_0 + q_1\left(\widetilde{\lambda}_1 + \widetilde{\lambda}_2 + \widetilde{\lambda}_3\right), \quad (4)$$

$$Q_2 = Q_2\left[f_{shear}, f_{couple}, f_{normal}\right], \quad (5)$$

with

$$f_{shear}(l,e) = \mu_{00} + \mu_{10}\, l + \mu_{01}\, e, \quad (6)$$

$$f_{couple}(l,e) = \nu_{00} + \nu_{10}\, l + \nu_{01}\, e, \quad (7)$$

$$f_{normal}(l,e) = \nu_{00} + 2\mu_{00} + \left(\nu_{10} + 2\mu_{10}\right)e + \left(2\,\nu_{01} - \nu_{10} + 4\,\mu_{01} - 2\,\mu_{10}\right)l, \quad (8)$$

l and e being different linear combinations of the projectivized eigenvalues, and $Q_4$ similarly depending on 10 underlying functions involving 10 parameters $a_{00}$, $a_{10}$, $a_{01}$, $c_{000}$, $c_{100}$, $c_{010}$, $c_{001}$, $i_{00}$, $i_{10}$, and $i_{01}$, these 18 parameters being the structural sensitivities.

Applying our model to extant data from [2], we obtain an inhomogeneous anisotropic material model with fixed global parameters, the inhomogeneity and anisotropy being induced by the diffusion tensor field itself (Figure 2). We perform inverse modeling in FEniCS to find values for model parameters that best capture the behavior of our samples. The parameters appearing in our model reflect the sensitivity of the material's stiffness in particular deformation modes to its diffusivity in different directions.

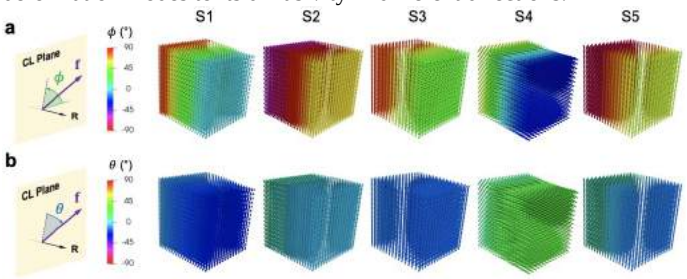

**Figure 2: a) In-plane fiber angle φ of each specimen. b) Out-of-plane fiber angle θ for each sample.**

## DISCUSSION

Using these structural stiffnesses instead of fiber, normal, and sheet moduli eliminates the need to manually identify which DT eigenvector field corresponds to which material direction, since all three eigenvector fields are used along with their respective eigenvalues. This is especially useful in regions where two the diffusion tensor's eigenvalues are close since in these regions small variations in the diffusion tensor's components can lead to rapid changes in eigenvector orientation, which is only exacerbated by noise in data. Because we incorporate the relative strengths of these orientations, rapid changes in orientation due to nearly equal eigenvalues is attenuated by the nearly equal eigenvalues themselves, leading to nearly transversely isotropic behavior. This approach also allows us to describe both healthy and diseased tissue with a single material model when the disease is primarily manifested structurally, since the local DTMRI data captures this structural defect through **D**.

While the overall form of our model is very similar to previous models, being exponential polynomial, the work we have done ensures that the structure of the DTMRI data is preserved by the final model exactly. By incorporating dense diffusion tensor mappings, we capture the subtle effects of material structure. For example, our model captures twisting and shearing due to transmural fiber variation that a homogenous model cannot.

In summary, we have developed a flexible material model for myocardium and any other 3D soft tissue that directly incorporates D in a robust manner. This model is inhomogeneous, yet relies on a set of fixed global parameters, and automatically reduces to the degenerate symmetry cases of transverse isotropy and isotropy whenever the diffusion tensor's eigenvector fields become ill-defined or degenerate. Furthermore, our derivation is easily modified for application to other fibrous biological tissue, and produces sample-specific material models.

# AORTIC COARCTATION ASSESSMENT – IN VITRO 4D FLOW MRI APPROACH

**James P. Rice (1,2), Labib Shahid (1,2), Haben Berhane (3,5), Cynthia K. Rigsby (4), Joshua D. Robinson (4), Lindsay M. Griffin (4), M. Markl (3,5), A. Roldán-Alzate (1,2)**

**INTRODUCTION:**

Coarctation of the aorta is a common congenital heart defect (5-8%), presenting as a narrowing of the proximal descending aorta [1]. COA can be discrete or more complex and associated with severe secondary complications such as diffuse arch hypoplasia and descending aortic aneurysm. The most common therapy is to restore normal aortic blood flow thus, understanding pre- and post-interventional COA hemodynamics is crucial [1-4].

4D flow MRI shows promise in assessing 3D aortic hemodynamics in patients with COA [2-3]. 4D flow MRI data are acquired with velocity encoding sensitivity ($V_{enc}$), set above the expected maximum velocity in the vessel of interest. High $V_{enc}$ is necessary to capture high velocity regions without aliasing, like in the stenosis in COA. However, noise in velocity measurements is directly proportional to $V_{enc}$ and increasing $V_{enc}$ leads to difficulties in distinguishing low velocities from noise, like in an aortic aneurysm (slow vortex flow) [4-5]. This complicates 4D flow MRI measurements in complex flow regimes.

Pulsatile in vitro flow models allow for systemic evaluation of 4D flow MRI performance by providing a way to produce anatomically accurate, patient-specific geometries that can be analyzed with higher resolution flow methods [6-7]. The goal of this study was to develop an accurate and reproducible modeling framework using in vitro models and 4D flow MRI to evaluate the hemodynamics of three different clinical presentations of COA, pre- and post- intervention.

**METHODS:**

In this HIPAA compliant study, three pediatric patients underwent standard-of-care cardiothoracic MRI pre- and post-COA repair following an IRB approved protocol (Table 1). MR imaging included aortic 4D flow MRI and 3D contrast-enhanced (CE)-MR angiography (MRA), which was used to segment aortic geometries and construct two in vitro, patient-specific models per patient using additive manufacturing [8]. The models were connected to a pulsatile flow circuit and scanned on a 3.0T MRI scanner (Signa Premier, GE, Waukesha, WI). 3D flow dynamics were measured using the 4D flow MRI sequence PC-VIPR [9]. Scan parameters were 1.3mm isotropic spatial resolution, TR=6.1ms, flip angle=8°, 320 mm FOV, and 160 cm/s $V_{enc}$. Heart rate was simulated to 60 beat/min and a 35% systolic cardiac waveform was prescribed resulting in mean inlet aortic flow of 2.0 liters/min. ECG gating was achieved via signal output from the pump. A blood mimicking solution of water and glycerol (42:58 by weight) was used in the flow loop.

**RESULTS:**

The Study cohort is outlined in Table 1. The cohort included three patients (mean age 10 ± 4 years) with a median follow-up duration of 5 ± 3 years (2 males). Figures 1-3 depict the 4D flow MRI data obtained at peak systole in the pre- and post-intervention cases for patients 1-3, respectively. For patients 1 and 2, high velocity jets extending into the descending aorta are observed in pre-interventional models in the COA location. For both patients, it is evident that COA-interventions reduced peak velocity at the site of the repair. Similar consistencies are seen in the flow maps depicted for patient 3 in Figure 3, which shows improvement in flow profiles between pre- and post-cases despite prior stenting, suggesting re-intervention improved aortic hemodynamics. For patient 1, full-field flow visualization is achieved in the pre-repair aortic aneurysm, which is not available in the in-vivo dataset (Figure 1). The same is true for the stented region in patient 3, where in-vitro flow information fills the void seen in the in-vivo flow map (Figure 3). Pre- and post-repair peak velocities at the location of the coarctation and results of volumetric flow analysis are summarized in Table 1.

**Table 1:** Demographic and procedure information for patient cohort. 4D Flow MRI obtained peak velocities pre- and post-intervention and results from volume flow analysis for validation of 4D flow MRI data (* indicates patient underwent reintervention for COA).

| Patient | Intervention Strategy | Gender | Case | Age | Peak Velocity [m/s] | Inflow [ml/cycle] | Outflow [ml/cycle] | Error [%] |
|---|---|---|---|---|---|---|---|---|
| 1 | COA repair and pseudoaneurysm resection with placement of 16mm gel weave interposition graft | Female | Pre | 6 | 1.17 | 35.8 | 31.8 | 11.2 |
| | | | Post | 8 | 0.414 | 52.2 | 57.2 | 9.49 |
| 2 | Ebstein anomaly and dysplastic mitral valve. Repair with interposition graft. | Male | Pre | 14 | 0.927 | 33.8 | 30.2 | 10.8 |
| | | | Post | 20 | 0.414 | 37.8 | 35.0 | 7.34 |
| 3* | Reintervention with 16mm gel weave end-to-end interposition graft | Male | Pre | 10 | 0.769 | 38.6 | 34.5 | 10.5 |
| | | | Post | 15 | 0.743 | 39.2 | 40.9 | 4.41 |

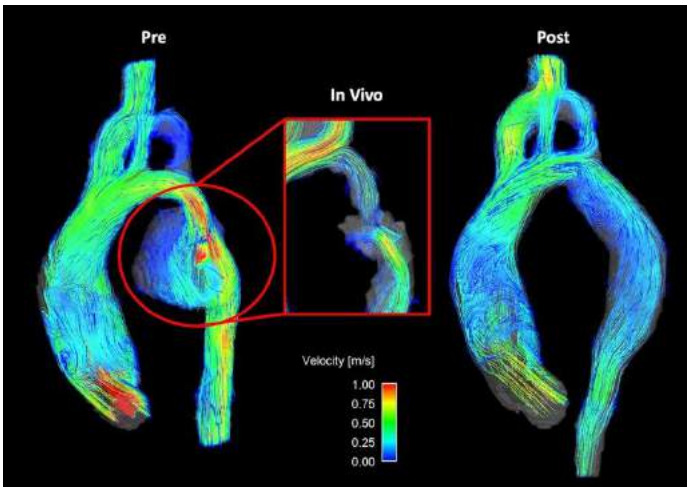

**Figure 1:** Comparison of pre- (left) and post-repair (right) in vitro model flow fields derived from 4D flow MRI for patient 1. Highlighted is a comparison of the in vitro and in vivo flow profiles in the aneurysm region of the descending aorta. In vitro modeling enhances slow, recirculating flow that is lost in the in vivo acquisition.

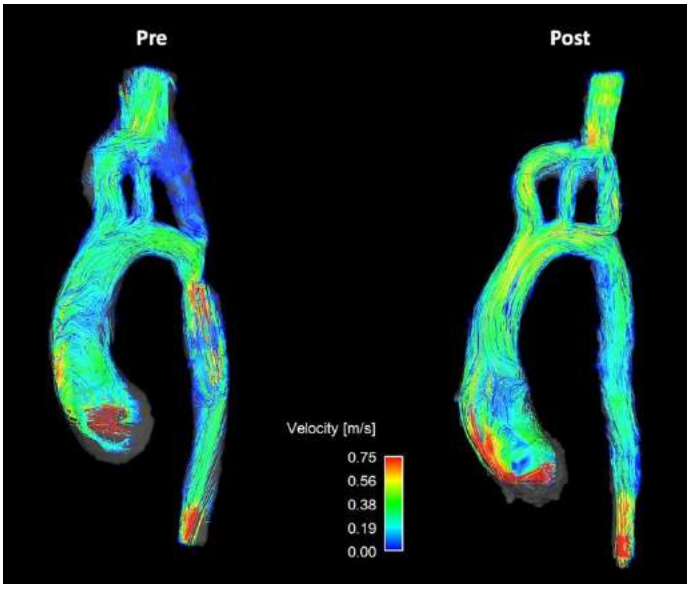

**Figure 2:** Comparison of pre- (left) and post-repair (right) in vitro model flow fields derived from 4D flow MRI for patient 2. High velocity COA jet observed in pre-repair case is relieved with repair.

**DISCUSSION:**

This study utilized patient-specific, in vitro models and 4D flow MRI for hemodynamic analysis of different presentations of COA. In cases where narrowing is observed (patient 1 and 2), velocities in the stenosis are shown to reduce after intervention. This agrees with expectations for treatment, suggesting in vitro modeling can shed light on the effect of surgical intervention on post-repair hemodynamics. Imposing the same inlet flow induced similar model inflow conditions for comparison of the effect of presentation on overall COA hemodynamics. It is noted that this does not reflect in vivo flow conditions. Comparisons to in vivo 4D flow MRI datasets are necessary and prescribing patient-specific inflow rates must be carried out in the future. Another aspect of interest is the ability to analyze flow in regions typically inaccessible with in vivo PC-MR imaging: areas that contain both high and low velocity flow (patient 1, aortic aneurysm) and regions with high susceptibility to MR artifact (patient 3, stent). This is seen in the flow fields for patient 1 and 3, respectively. These results hint that in vitro modeling can be used in other cases where flow information is lost due to a high $V_{enc}$ setting or medical device influence. Results from volumetric flow analysis yielded an average difference between in- and out-flow of 8.95%, agreeing with previously published studies validating the consistency of 4D flow MRI [9].

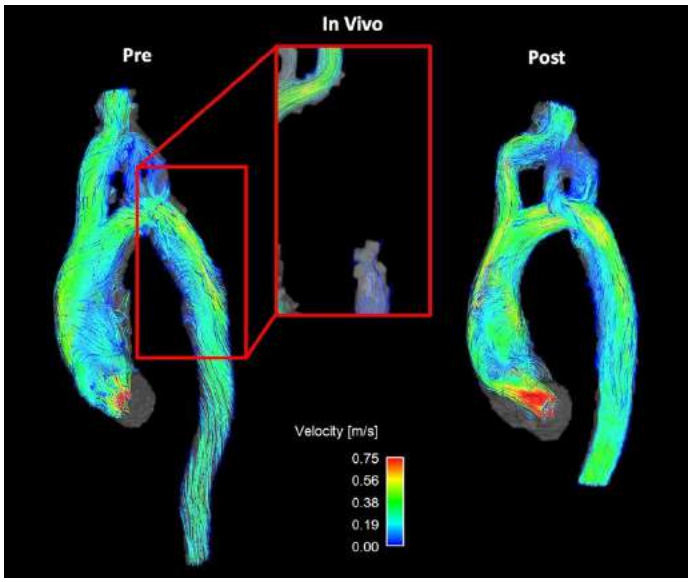

**Figure 3:** Comparison of pre- (left) and post-repair (right) in vitro model flow fields derived from 4D flow MRI for patient 3. Highlighted is a comparison of the in vitro and in vivo flow profiles in the stent, where velocity information is clearly missing in the in vivo dataset.

# A COMPARTIVE STUDY OF BONE TISSUE GROWTH BETWEEN BIOINSPIRED AND SQUARE SCAFFOLDS

**Marco A. Fielder (1, 2), Arun K. Nair (1, 2)**

(1) Materials Science and Engineering, University of Arkansas, Fayetteville, AR, USA

## INTRODUCTION

Several studies have investigated combining tissue scaffolds with ultrasound stimulation to enhance bone growth [1-4]. However, one challenge that remains is designing a scaffold with a high porosity to enable more tissue ingrowth without compromising structural integrity of the scaffold is to withstand the necessary mechanical loads [5]. A study by Gu et al. showed that a bioinspired scaffold derived from the atomic structure of hydroxyapatite was more resistant to deformation compared to a scaffold with uniform square pores [6]. A recent study also found that this bioinspired scaffold structure allows a higher transmission of ultrasound wave energy than the square pore scaffolds [7]. Our study hypothesizes that the bioinspired scaffold from Gu et al. can additionally maintain a level of cell growth compared to the square pore scaffold of the same porosity when subjected to ultrasound stimulation. This would be useful for addressing the issue of designing a scaffold structure with a high structural integrity that also does not impede tissue growth while being stimulated by ultrasound. Our study also hypothesizes that the initial distribution of mesenchymal stem cells (MSCs) in the scaffold can significantly affect the growth and differentiation of the tissue. Figure 1 shows the two scaffolds studied.

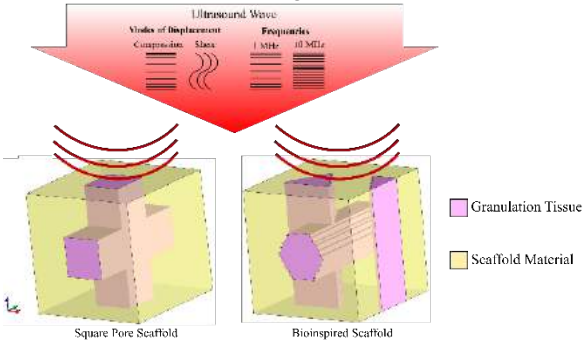

**Figure 1: Ultrasonically stimulated tissue scaffolds**

## METHODS

The finite element method (FEM) simulations of the scaffolds were performed using FEBio [8]. The pores of the scaffold, whose diameters are 400 μm, are filled with granulation tissue and the structure undergoes ultrasound stimulation from the top of the scaffold with the wave propagating in the negative *y*-direction with an amplitude of 0.1 μm, as seen in Figure 1. We test the effect of ultrasound frequencies of 1 MHz and 10 MHz on the tissue growth, as well as the ultrasound wave type between compression and shear waves. The scaffold is modeled as an isotropic solid while the granulation tissue is modeled as a biphasic material of an isotropic solid and Newtonian fluid. Table 1 shows the material properties used in the FEM simulations.

**Table 1: Material Properties of the Finite Element Models**

| Material | Scaffold | Granulation Tissue |
|---|---|---|
| Elastic Modulus, $E$ (MPa) | 1000 | 0.2 |
| Poisson's Ratio, $\nu$ | 0.3 | 0.167 |
| Solid Density, $\rho_{solid}$ (kg/m$^3$) | 400 | 300 |
| Fluid Density, $\rho_{fluid}$ (kg/m$^3$) | NA | 997 |
| Solid Volume Fraction | NA | 0.2 |
| Permeability, (m$^4$/N/s) | NA | constant, 1 x $10^{-14}$ |

The tissue growth algorithm used is from Byrne et al. [9] and is written in MATLAB [10]. Initially, the granulation tissue is randomly seeded at 1% with mesenchymal stem cells (MSCs). These stem cells can then proliferate or differentiate into fibroblasts (fibrous tissue), chondrocytes (cartilage), or osteoblasts (bone) based on the mechanical stimulus. We test the effect of initial MSC distribution on the tissue growth by testing a second random initial MSC distribution, and by localizing random MSCs to be randomly distributed near the bottom of the bioinspired scaffold. Visualization of the differentiated tissue distributions is done using Paraview [11].

## RESULTS

Figure 2 (a) shows the maximum bone tissue growth after 60 days for the bioinspired and square pore scaffolds. Increasing the wave frequency from 1 MHz to 10 MHz increases the amount of bone formation. A compression wave also produces more bone compared to a shear wave for both scaffolds. Overall, the square scaffold produces more bone than the bioinspired scaffold. From Figure 2 (b) this is likely due to more cartilage and fibrous tissue in the bioinspired scaffold. For a compression ultrasound wave of 10 MHz frequency, the calculated percent difference in bone tissue formation between the two scaffolds is 4.7%.

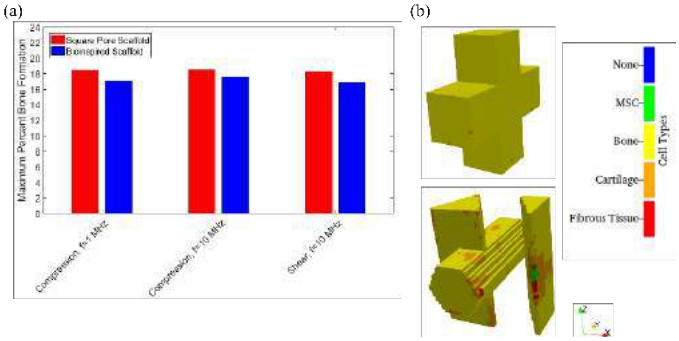

**Figure 2: Square pore and bioinspired scaffolds: (a) Maximum bone formation, (b) Tissue distribution for stimulation by compression wave ultrasound with f = 10 MHz**

Figure 3 shows the maximum bone formation rate for the two scaffolds. For all ultrasound parameters the bioinspired scaffold has a lower maximum bone formation rate than the square pore scaffold. For a compression ultrasound wave of 10 MHz frequency, the calculated percent difference in maximum bone tissue formation rate between the two scaffolds is 41.2%.

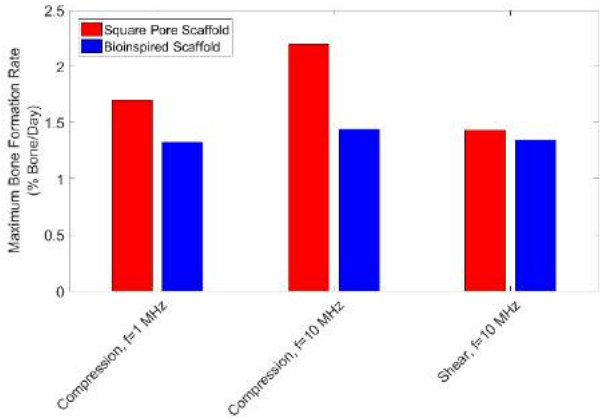

**Figure 3: Maximum bone formation rate for square pore and bioinspired scaffolds**

Figure 4 shows the effect of the initial MSC distribution on bone growth in the bioinspired scaffold stimulated by a compression ultrasound wave with a frequency of 1 MHz. The two random MSC distributions have a negligible difference in maximum growth rate and bone formation. In contrast, localizing the MSC distribution significantly reduces the maximum growth rate and percent bone formation. Between the localized and random MSC distributions there is a calculated percent difference of 178.3% in maximum growth rate and 128.7% in maximum percent bone formation. This is likely due to the amount of space available for the MSCs to proliferate, and the level of mechanical stimulation they receive to differentiate, as can be seen in the tissue distributions in Figure 4 (c).

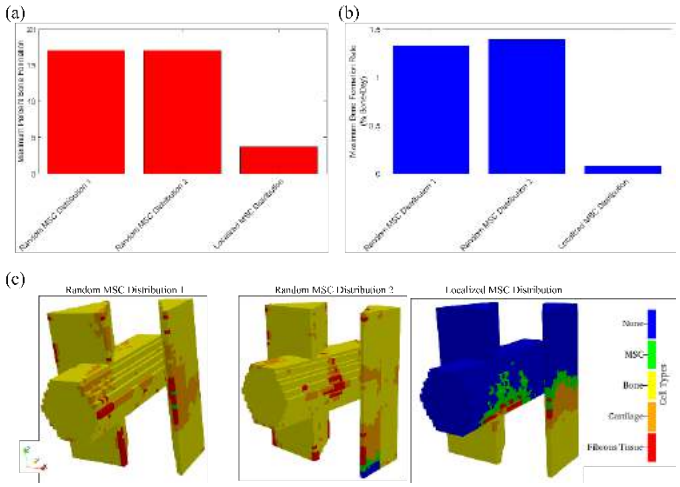

**Figure 4: Effect of MSC distribution: (a) Maximum bone formation, (b) maximum bone formation rate, (c) tissue distribution**

## DISCUSSION

This study demonstrates that, while the bone tissue growth in the bioinspired scaffolds is slower, it can produce amounts of bone tissue comparable to the square pore scaffold. Previous studies show the bioinspired scaffold also has a higher fracture resistance and ultrasound wave transmission than the square pore scaffold, making the bioinspired structure ideal for ultrasonically stimulated tissue scaffolds to enhance cell growth. Our study further shows that the initial MSC seeding of the tissue scaffolds can significantly affect the growth rate and amount of tissue formation. This warrants further computational and experimental study on controlling MSC seeding of tissue scaffolds, and optimal seeding patterns to maximize tissue growth rate amount.

# VESEEL WALL ENHANCEMENT IS ASSOCIATED WITH INCREASED WALL STRESS IN INTRACRANIAL ANEURYSMS

**Sricharan S. Veeturi (1,2), S. Mostafa Mousavi J. S (1,2), Ammad A. Baig (2,3), Andre Monteiro (2,3), Adnan H. Siddiqui (2,3), Vincent M. Tutino (1,2,3,4,5)**

## INTRODUCTION

Vessel wall enhancement has emerged as a potential imaging biomarker for risk stratification of intracranial aneurysms (IAs). This is a phenomenon wherein the presentation of the aneurysm wall on contrast-enhanced MRI (CE-MRI) exhibits markedly higher signal intensity as compared to its presentation on the baseline or non-enhanced MRI (NE-MRI). Vessel wall enhancement (VWE) of the aneurysm wall has been correlated with inflammation in the IA, as well as growth and rupture [1]. However, the underlying tissue mechanobiology in regions of high VWE, which could be related to rupture, remain poorly understood.

Stress in the aneurysm wall tissue could be related to the VWE phenomenon, as aneurysm growth and remodeling are thought to be driven, in part, by vascular smooth muscle responses to abnormal arterial stresses [2]. To measure mechanical stress in the IA wall, finite element analysis (FEA) is a particularly useful tool. Previous studies have shown that IAs exhibiting VWE had a significantly higher 95$^{th}$ percentile wall tension as compared to IAs that did not, showing a potential correlation between mechanical forces in the aneurysm wall and VWE [3]. However, their model used generic assumptions about the internal pressure as well as the IA wall thickness. Variations in thickness and pressure could influence stress distributions in the IA.

In this preliminary study, we investigate the effect of using patient specific internal pressure as well as patient specific wall thickness on the potential correlation between VWE and the Von-mises stress in the aneurysm wall.

## METHODS

In the current study, approved by the IRB (Study 00004370), we collected patient specific 3D Time of flight TOF-MRA image as well as T1 weighted NE-MRI and CE-MRI. The MRA image was used to segment and generate 3D stereolithographic (STL) geometry file for the aneurysm. We then used OpenFOAM V6 to perform hemodynamics as described in previous studies [3]. Assuming the time-averaged inlet pressure to be 90 mm Hg, we generated pressure maps on the IA wall, which were used as loads in FEM simulations.

We then used the NE- and CE-MRI to manually reconstruct the aneurysm wall. This was then used as a point cloud in an in-house MATLAB code (R2021) to generate thickness for each triangulated surface on the STL file. The reconstructed volume of the aneurysm wall was used as input for the FEA simulation. We assumed a location based uniform thickness of 0.58 mm for the parent artery [5].

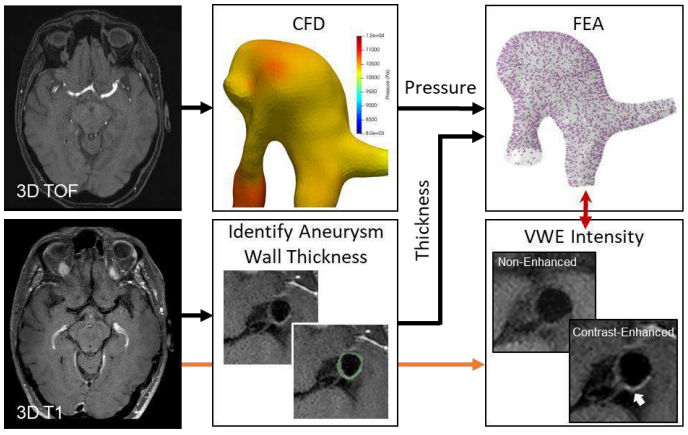

**Figure 1: Modeling Workflow.** From 3D TOF images we reconstruct aneurysm geometry, find blood flow characteristics using CFD, and implement variable pressure on the geometry. From 3D T1 imaging, we find aneurysm thickness and map it on aneurysm geometry. Also, from latter imaging modality we find VWE and compare it to FEA results.

We used Abaqus CAE/2019 to perform FEA models on the aneurysm in four different models: (1) uniform thickness and uniform pressure of 90 mm Hg (UTUP) (2) patient-specific thickness and uniform pressure (PTUP) (3) uniform thickness and patient-specific pressure (UTPP) (4) patient-specific thickness and patient-specific pressure (PTPP). Aneurysm wall was modeled as shell elements. Material models follow a nonlinear hyperelastic model describe previously [6]. For the variable pressure cases, average pressure of one cardiac cycle at different coordinates of aneurysm wall was withdrawn from CFD analysis and implemented on the inside of aneurysm wall. For the uniform pressure, we used the values from a previous study [7]. To map the variable thickness, nodal distribution was used.

Finally, we used previously established method to map the MRI signal intensity in CE-MRI onto the aneurysm wall [8]. We used the intensity at the genu of corpus callosum for normalization of MRI signal intensity ($CC_{ratio}$). Enhancing regions in the sac were defined as areas with $CC_{ratio}>1$. We performed univariate analysis to investigate the differences in Von-Mises stress in enhancing and non-enhancing regions in all the 4 FEA models after isolating the aneurysm sac manually. Furthermore, we also evaluated the potential correlation between $CC_{ratio}$ and Von-mises stress in all the models.

## RESULTS

The aneurysm sac was 8.3 mm in size and was located at the middle cerebral artery. The thickness map generated is shown in figure 3A. We observed that enhancing regions had a significantly higher wall thickness as compared to non-enhancing regions ($p<0.001$) which is also shown in previous literature.

In our FEA analysis, we found that enhancing regions had significantly higher Von-Mises stress as compared to non-enhancing regions ($p<0.001$) in all the models. Qualitatively, we observe that the type of pressure loading used has negligible effect on the stress contours ($R^2>0.99$) in both fixed thickness as well as variable thickness models. However, using aneurysm specific thickness values does indeed have an effect on the stress distributions ($R^2=0.54$) as shown in figure 2.

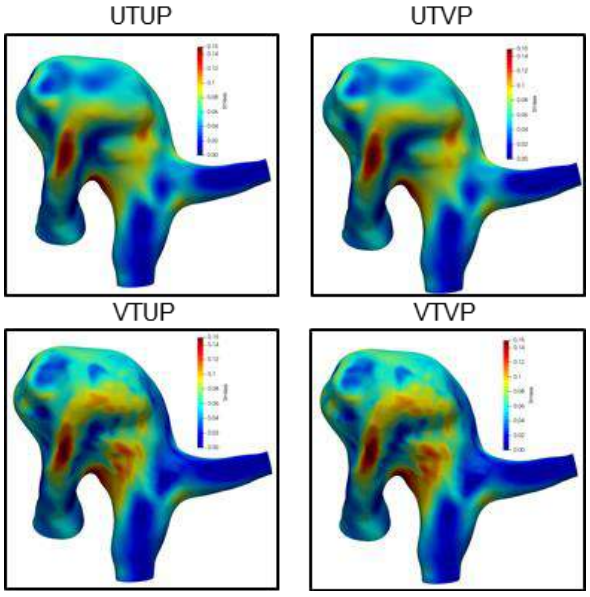

**Figure 2: Contours of Von-Mises stress distribution across different models.** We observed no noticeable change in the stress values when varying pressure was used across the aneurysm as compared to generic uniform pressure loading. However, we do find changes in stress values when varying values of wall thickness are used.

We also found that enhancing regions had significantly higher stress values than non-enhancing regions as was found by previous studies [3]. However, we found that there was only a weak linear correlation between $CC_{ratio}$ values and Von-mises stress in all the models. The correlation of intensity and stress values for different models was as follows: UTUP: 0.094, UTPP: 0.096, PTUP: 0.139 and PTPP: 0.14.

## DISCUSSION

In this study we developed a pipeline for investigation of the potential relationship between aneurysm wall stress and the vessel wall enhancement phenomenon. We found that enhancing regions in the aneurysm had a significantly higher stress than non-enhancing regions. VWE is an indication of inflammatory cell infiltration and neovascularization which have been associated with aneurysm instability and rupture. Hence, it is possible that the regions that have high stress and exhibit enhancement could indicate a damaged wall which is under high stress. Eventually, these regions may degrade further and cause an imbalance in forces which could lead to rupture of the aneurysm. Additionally, we also observed that thickness of the aneurysm has an effect on the stress distributions and using varying pressure does not. Thus, using patient specific aneurysm thickness is advised when possible.

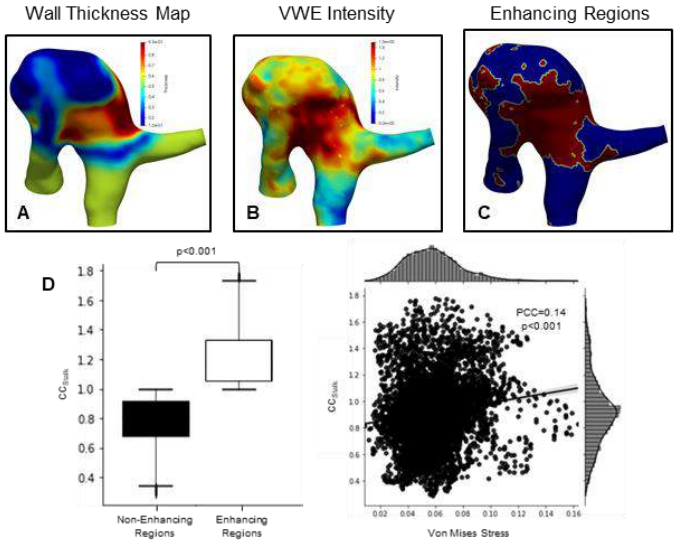

**Figure 3: Contours of wall thickness, VWE mapped intensity and enhancing regions. A).** Heat map of wall thickness. We observed higher thickness in enhancing regions. **B).** Heat maps of mapped vessel wall intensity ($CC_{ratio}$) across the aneurysm. **C).** Visualization of enhancing and non-enhancing regions in the aneurysm. **D).** Univariate analysis and correlation plots of stress values in enhancing and non-enhancing regions.

# AN ULTRASOUND BASED ONE-DIMENSIONAL MODELING FRAMEWORK FOR THE ASSESSMENT OF PERIPHERAL ARTERIAL DISEASE

**Milan Gillissen (1), Frans N. van de Vosse (2), Marc R.H.M van Sambeek (1,3), Richard G.P. Lopata (1)**

## INTRODUCTION

Cardiovascular diseases (CVDs) are a leading cause of death, representing an estimated 32% of all global deaths in 2019. It is a group of diseases that involve the heart and the circulatory system, including peripheral artery disease (PAD) which affects over 230 million people worldwide. With atherosclerosis the most common underlying mechanism, lower extremity peripheral arterial occlusive disease (PAOD) is an increasingly common condition in all countries. Currently, the length of the occlusion is used as criteria for endovascular therapy or surgical bypass [1]. However, main challenges of endovascular therapy include the durability of stents in the femoro-popliteal region where the artery is very mobile and the more typical restenosis, which can occur within six to twelve months [2]. Several studies have shown that finite element analysis (FEA) can predict restenosis regions in different arteries [3, 4]. Despite promising results, these patient-specific models are not used in the clinical setting yet. The current computed tomography (CT) or magnetic resonance (MR) approaches suffer from several drawbacks, e.g. ionizing radiation and high cost. Moreover, patient-specific material properties are unavailable in these approaches. The most important drawback of US, besides the low contrast compared to CT and MR, is the limited field-of-view (FOV). An in-house developed framework is demonstrated, which segments US images automatically, and meshes the geometries obtained for computational fluid dynamics (CFD) analysis. We propose a framework based on time-resolved two-dimensional ultrasound (US), which tackles the aforementioned disadvantages as well as acquire the vessel's motion during the cardiac cycle. Furthermore, a reduced order model is created based on the segmented geometries which provides more information about the circulatory system outside the bounds of the obtained US images.

## METHODS

Ultrasound (US) scans were made using a MyLab70 scanner (Esaote Europe B.V., Maastricht, The Netherlands). The images were automatically segmented by an in-house developed framework, created in Matlab (2020b, Mathworks Inc., Natick, MA, USA). These segmentations were extended to ensure flow was fully developed at the measured inlet. The final coordinates encapsulating the geometry were imported into Python (3.7, Python Software Foundation, Wilmington, DE, USA) where the Visualisation Toolkit (8.1.2, Kitware Inc., Clifton Park, NY, USA) was used to construct a surface from the scattered coordinates. Finally, the extended geometry was converted to a 3D tetrahedral volume mesh in Ansys (Fluent 19.2, Ansys Inc., Canonsburg, PA, USA) by using the built-in Fluent meshing tool.

To create the reduced order, one-dimensional (1D), model the cross-sectional area from the segmented geometry was used. The minimum calculated area, along with the mean of the healthy in- and outlet areas were used to define a one-dimensional stenosis element which is based on the work of Heinen et al. [5]. This element was placed in the Boileau model [6], in the middle of the scanned vessel. The full Boileau model can be seen in Figure 1. The pressure waveform resulting from the one-dimensional model was used to define two new parameters, the stenosis-brachial index (SBI, Equation 1) and the ankle-stenosis index (ASI, Equation 2). These parameters provide insight of the rest of the circulatory system and any other possible anomalies. The pressure at positions 1 and 2 are represented by the peak systolic pressure, proximal to the stenosis and distal to the stenosis respectively.

$$SBI = p_1/p_{brachial} \quad (1)$$

$$ABI = p_{ankle}/p_2 \quad (2)$$

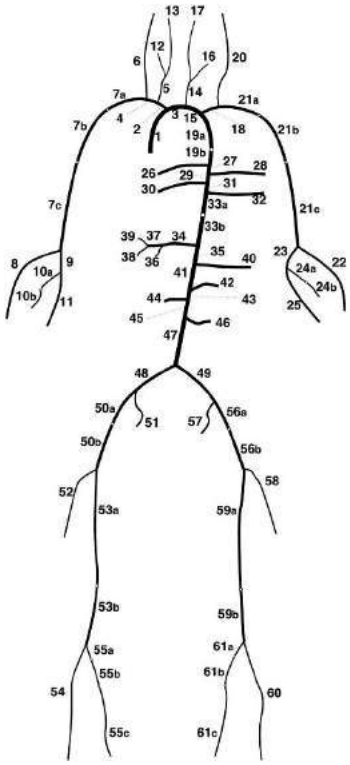

**Figure 1: Topology of the Boileau [5] model.**

## RESULTS

Preliminary results (Table 1) show that the calculated pressure drop in 1D is not in the same order as the calculated pressure drop from a three-dimensional computational fluid dynamics simulation. The proximal pressure is high for the 3D model with respect to the 1D model. The distal pressure is in the same order for both models. Furthermore, the newly introduced SBI and ASI are calculated and displayed. The SBI is high for the 3D model, and within acceptable range for the 1D model. The ABI values are in acceptable range for both models.

## DISCUSSION

Although these first results of the models do not coincide proximal to the stenosis, it does show the feasibility of the technique in an ideal geometry. The high $p_1$ and resulting SBI value for the 3D model could be due to the of the rigidness of the model, a smoothed flow waveform or a parabolic velocity waveform which all will be addressed in the near-future. The ASI values for both models indicate that there are no other stenotic areas in the distal circulatory system. This coincides with the fact that only one stenosis has been implemented in this example.

**Table 1: Preliminary results of both the three-dimensional model as the one-dimensional model. Pressures and pressure drop are in mmHg. SBI, ASI en ABI are dimensionless.**

| Model | $p_1$ | $p_2$ | $\Delta p$ | SBI | ASI | ABI |
|---|---|---|---|---|---|---|
| 3D | 352 | 89 | 263 | 2.82 | 0.82 | 0.58 |
| 1D | 150 | 76 | 74 | 1.20 | 0.97 | 0.58 |

## INTRODUCTION

Radiation cystitis (RC) is a chronic bladder condition characterized by frequent urination, nocturia, urinary incontinence, pelvic pain, and hematuria. RC is the result of radiation therapy used to treat pelvic cancers. such as prostate, cervical, colorectal, and ovarian cancer. Approximately 10% of cancer survivors treated with pelvic radiation therapy will develop RC [1]. Current treatment options are focused on arresting bleeding, however, no therapies are currently available to treat other symptoms of RC, like urinary frequency and nocturia [2-4].

We previously developed a preclinical RC model that mimics the human condition [5,6]. In this model, we have shown that radiation exposure results in increased deposition of collagen (i.e., fibrosis) within the bladder detrusor muscle. In irradiated bladders, the extracellular matrix (ECM) consists of a higher concentration of collagen type I and III fibers when compared to controls. By 12 months post-irradiation, radiation exposure still resulted in increased expression of collagen I in comparison to littermate controls, supporting the notion that RC is a progressive condition [5].

It has been suggested that bladder fibrosis alters bladder compliance, resulting in lower urinary tract symptoms such as urinary frequency and nocturia [7]. However, no study has been done to investigate changes in mechanical properties of the bladder in response to radiation. This study aims to identify alterations to the mechanical behavior of urinary bladder tissue following radiation exposure in a murine model. Specifically, we aim to characterize these changes through mechanical testing and analysis, by employing a continuum mechanics model to estimate material parameters.

## METHODS

*Radiation cystitis mouse model.* This study was performed, in compliance with the NIH Guide for the Care and Use of Laboratory Animals. RC was induced in the mouse bladder as previously described by our group [5] (untreated mice were also anesthetized for a consistent amount of time). Forty 8-week old female C57Bl/6 mice were purchased from Charles River (Wilmington, MA). Mice were randomly assigned to an irradiated or control treatment group (n = 20/group). Radiation was delivered to the mouse bladder using the Small Animal Radiation Research Platform (SARRP) using a two-beam approach. Mice received a single dose of 40 Gy, evenly divided over the two beams, using a 5 x 5 collimator.

*Void Spot Assay.* Bladder function was assessed at baseline, and 3- and 6 months post irradiation using the Void Spot Assay [5]. In short, mice were singly housed for 4 hours in a cage lined with thick filter paper. After 4 hours, the filter paper was collected and urine spots were visualized under TransUV light. Using Fuji Software, urine spots were counted, and total and average void volumes were calculated. Statistical significance was determined through 2-way ANOVA followed by Bonferroni's post-hoc multiple comparison test.

*Mechanical testing.* At the same time points, animals were euthanized, bladders collected and cut into ring-shaped samples. After decellularization [8], we performed uniaxial mechanical stretch test. Cyclic loading, adapted from a previously published protocol [9], was applied to the samples as follows (all at a strain rate of 0.01 s-1): 5% stretch for 10 cycles (preconditioning), 10% stretch for 5 cycles, 15% stretch for 5 cycles, and 20% stretch for 5 cycles. Before each set of cycles, a pre-load of 2 ± 0.25g was placed onto the sample. Samples were assumed to be incompressible and isotropic, resulting in a deformation gradient of $\boldsymbol{F} = diag\left[\lambda; {}^{1}/_{\sqrt{\lambda}}; {}^{1}/_{\sqrt{\lambda}}\right]$ where $\lambda$ is the stretch in the direction of testing (i.e., circumferential).

*Constitutive modeling framework.* For each tested sample, the final loading curve of the last loading cycle (i.e., target stretch of 20%) was used for mechanical analysis. Tissue mechanical behavior was described employing a two-parameter, exponential constitutive model [10]

$$W = c\{exp[k(I_1(\boldsymbol{C}) - 3)] - 1\}$$

where $c$ and $k$ are material parameters ($c$ has the dimension of a stress and $k$ is nondimensional), $\boldsymbol{C}$ is the right Cauchy-Green deformation tensor defined as $\boldsymbol{C} = \boldsymbol{F}^{\boldsymbol{T}}\boldsymbol{F}$, and $I_1(\boldsymbol{C}) = tr(\boldsymbol{C})$ is $\boldsymbol{C}$ first invariant. Following, the definition of Cauchy stress for an incompressible material is:

$$\boldsymbol{T} = -p\boldsymbol{I} + 2\boldsymbol{F}\frac{\partial W}{\partial \boldsymbol{C}}\boldsymbol{F}^{\boldsymbol{T}}$$

where $p$ is a Lagrange multiplier and $\boldsymbol{I}$ is the identity tensor.

## RESULTS

At 3 months post-radiation, there were no significant differences between the untreated and irradiated tissues mechanical behavior (**Fig. 1A**). At 6 months, the stress-stretch curve showed an upward shift between irradiated and untreated tissue, indicating a decrease in distensibility of the ECM induced by radiation (**Fig. 1B**).

The material parameters estimated support this finding. While there were no changes to parameter $c$ (**Fig. 2A**), parameter $k$ was higher in the irradiated tissue compared to untreated tissue (**Fig. 2B**). This result was slight at the 3 months timepoint ($P < 0.1$) and significant at the 6 months timepoint ($P < 0.05$). An increase in $k$ is consistent with an increase in tissue stiffness for larger values of stretch/stress.

To determine if irradiation-induced bladder stiffness alters bladder function, we performed Void Spot Assays. Over a four-hours period, mice exposed to irradiation had an increased number of urine spots (**Fig. 3A**) accompanied by a decrease in voided volume per spot (**Fig. 3B**) in comparison to littermate controls. The change in micturition behavior started at 3-months post-irradiation ($P < 0.1$) and became significant by 6-months ($P < 0.05$).

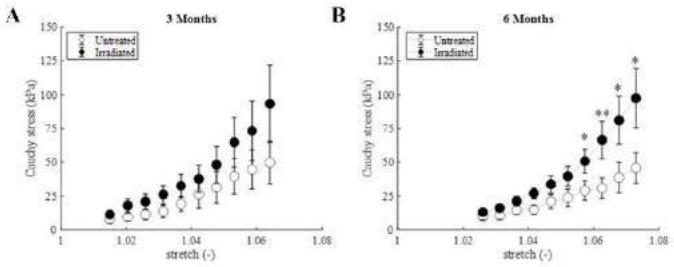

**Figure 1: Average ± SE stress-stretch curves for bladders ECM from untreated (empty) and irradiated (filled) animals at 3- (A) and 6-months (B) post-treatment; *P < 0.1, **P < 0.05 when comparing untreated and treated animals at each time point.**

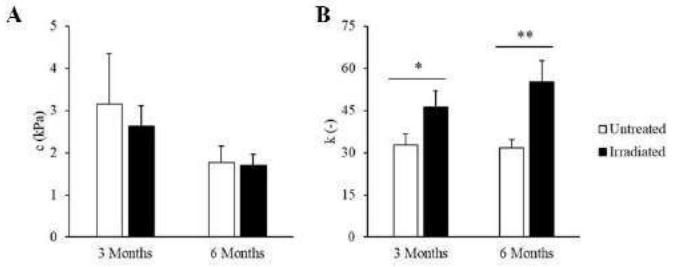

**Figure 2: Average ± SE constitutive model parameters, $c$ (kPa) and $k$ (-), calculated for irradiated and untreated animals at (A) 3- and (B) 6-months post-treatment; *P < 0.1, **P < 0.05 when comparing untreated and treated animals at each time point.**

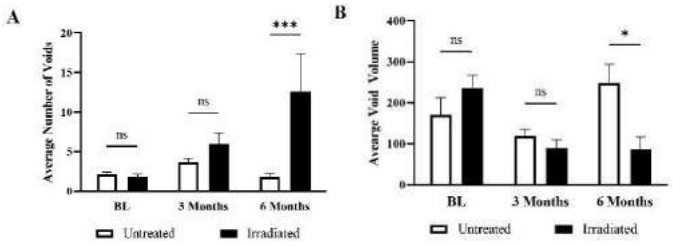

**Figure 3: Average ± SE of (A) number of voids and (B) void volume in untreated and irradiated at 3- and 6-months post-treatment; *P < 0.1, **P < 0.05 when comparing untreated and treated animals at each time point.**

## DISCUSSION

Radiation treatment can impact bladder function and induce lower urinary tract dysfunction in pelvic cancer survivors [1-4]. We sought to determine if radiation altered the mechanical properties of the bladder in response to stretch in a murine model. This study specifically examined ECM remodeling and mechanical behavior of the bladder ECM. To do so, we measured several mechanical and physiological parameters.

Average stress-stretch curves of the irradiated animals showed overall lower distensibility as compared to untreated (**Fig. 1 and 2**). This was accompanied by the constitutive model parameters analysis, which showed no changes to parameter $c$, which dominates mechanical behavior in the low-stiffness region, and at the same time highlighted an increase of the parameter $k$ in irradiated tissues, which dominates behavior in the high-stiffness region. Overall, these results indicate that RC causes a progressive increase in stiffness in the ECM of the bladder that is focused on the upper-end of the stress-stretch curve, when the bladder would be nearing maximum distension from urine filling.

This type of alteration to the stress-stretch behavior of the ECM could be indicative of a decreased bladder capacity, a common hallmark of RC [11], as the tissue is reaching maximum in vivo stress at a much lower stretch. This is supported in that the irradiated mice also voided smaller volumes of urine per void event, without significantly changing their total urine output (**Fig. 3B**).

This study is the first to show the mechanical properties of the bladder, as well as bladder function, are altered after irradiation. Radiation, and subsequent changes in ECM content, significantly increases the stress on bladder tissue as the bladder fills with urine and subsequently stretches, resulting in potentially reduced functional bladder capacity and more frequent urination.

## INTRODUCTION

Patency of the upper airway (UA) is required for critical functions such as breathing and speech production. Under healthy conditions, minimal effort is required to drive airflow through the UA, but even minor obstructions can significantly increase breathing resistance [1]. Robin Sequence (RS) is a congenital craniofacial anomaly characterized by small mandible, posteriorly displaced tongue, and subsequent upper airway obstruction (UAO). This is associated with significant morbidity and mortality in up to 11% of patients [2].

Reliable localization of UAO and characterization of UAO severity are critical to determine clinical airway management strategies [2]. Currently, there is no gold-standard for severity assessment and, therefore, severity is based on subjective evaluations of available diagnostic studies. Additionally, severity is typically assessed from anatomic features characterized via static imaging modalities which do not accurately represent the highly dynamic respiratory cycle [3] and provide no quantitative information on airflow dynamics.

Computational fluid dynamics provides a means of investigating and quantifying the airflow in healthy and diseased airways [1,4]. Four-dimensional computed tomography (4DCT) obtains multiple 3D images throughout the respiratory cycle, resolving the time-evolution of the airway's caliber. In this study, we combine 4DCT and CFD to analyze airflow dynamics in RS infants. By quantifying the fluid mechanics environment of RS patients, we provide a method for quantitative assessment of UAO severity, which is used to identify locations of maximum obstruction and risk-stratify patients. We hypothesize that these advanced modeling tools will improve the clinical understanding and management of UAO in RS patients.

## METHODS

Airflow dynamics were analyzed in five infants with RS, between the ages of 0-6 months. 4DCT scans were obtained with 3D reconstructions performed every 0.1s (SOMATOM Force Dual SourceCT, Siemens, Germany). Between 1 and 3 respiratory cycles were obtained for each patient, and each 3D image was segmented to obtain airway geometries extending through the upper trachea.

An idealized sinusoidal breathing waveform was generated for each patient using a tidal volume based on weight at the time of the scan and the respiratory period, calculated from the 4DCT image sequences. The point of peak exhalation in the idealized respiratory cycle was synchronized with the location of maximum oropharynx volume [5]. Quasi-steady CFD simulations of peak inhalation and peak exhalation were run to evaluate conditions of maximum respiratory resistance [6]. Second-order, unsteady RANS simulations were performed in StarCCM+ (v16, Siemens, PLM Software, Plano, TX, USA) with a K-$\omega$ SST model. Polyhedral meshes with approximately 2.5 million cells were generated for each patient at the airway geometries corresponding to peak inhalation and exhalation. Mass flowrates are prescribed at the trachea based on values computed from the respiratory waveform timepoints corresponding to peak inhalation and exhalation. Unsteady simulations were carried out for 0.15s with a dt of 5E-5s. Computed airflow metrics were averaged over the last 0.075s.

For each patient, breathing resistance ($R = \Delta P \,/\, Q$), where $\Delta P$ and $Q$ are the inlet-to-outlet pressure drop and flowrate respectively, maximum velocity, and viscous dissipation ($\Theta$) were computed. Viscous dissipation is defined as:

$$\Theta = 0.5\,\mu_t \int S : S\, dV + \int \rho\epsilon\, dV \qquad (1)$$

Where $\boldsymbol{S}$, the stress tensor, is defined as $[\boldsymbol{\nabla u} + \boldsymbol{\nabla u^T}]$, $\boldsymbol{\mu_t}$ is the effective viscosity, $\boldsymbol{\rho}$ is the fluid density and $\boldsymbol{\epsilon}$ is the turbulent dissipation rate. Additionally, local resistance and the rate of energy flux ($\boldsymbol{E_f}$) are computed along the airway centerline. Energy flux, is defined as:

$$E_f = \int (P + 0.5\rho|u|^2)(u \cdot \mathrm{n})dA \qquad (2)$$

where P is the local pressure, $u$ is the velocity field, and n is the normal vector of the extracted plane. Subtracting the energy flux at each point

along the centerline from the energy flux at the airway inlet provides the energy loss along the airway. The airway cross sectional area (CSA) is also measured at each centerline point.

Clinical metrics including hospital status, level of respiratory support, and blood CO2 levels were also obtained for each patient.

## RESULTS

Breathing resistance, viscous dissipation, maximum velocity, and minimum CSA are shown for all 5 patients in Figure 1, with patients organized from left to right in order of severity based on metric magnitude. Ranking is consistent regardless of metric or breathing condition chosen. A significant range is seen across the patients for all three computed airflow metrics, with Patient A (most severe) presenting 40x, 20x, and 6x greater values than patient E (least severe) for breathing resistance, viscous dissipation, and maximum velocity, respectively. The minimum CSA follows an inverse trend to the computed airflow metrics with the minimum CSA increasing as resistance decreases, although the differences are less differentiating.

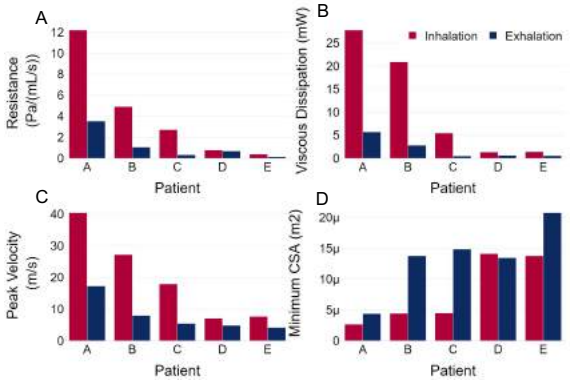

**Figure 1: Breathing resistance (A), viscous dissipation (B), maximum velocity (C), and minimum CSA (D) plotted for each patient at peak inhalation and exhalation**

In Figure 2 the flow field of the patients with the lowest and greatest values of airway resistance, E and A respectively, are highlighted via contours of velocity magnitude extracted along the centerline (3D image) and centerline computed values of respiratory resistance and accumulated energy loss (line graphs). For both patients, sharp increases in breathing resistance (blue curves) are found at local minimums of airway CSA (locations are highlighted by red spheres). A typical laryngeal jet is shown to exist downstream of the larynx in patient E, while in patient A, the dominant jet feature of the airway is found within the tongue base and has significantly higher velocity. As air accelerates through these constrictions, energy dissipation increases due to increased shear at the airway walls and internally as jet breakdown occurs downstream. The energy loss curves show that the dominant flow constriction at the larynx in patient E adds a minor increase to the overall dissipation, while in patient A, a significant increase in dissipation is generated through the tongue base constriction. This mechanism explains the large differences in airway resistance and suggests that the severity of UAO for patient E is minor compared to that of patient A.

At the time of scan, all patients, with the exception of patient E, were hospitalized for critical airway status and respiratory monitoring. Patient E required no respiratory support and was breathing room air. Patients C and D required extreme positioning maneuvers, patient B required high flow oxygen, and patient A required placement of a nasopharyngeal airway stent, the most severe non-invasive level of support. CO2 was elevated above normal values in all patients except patient E.

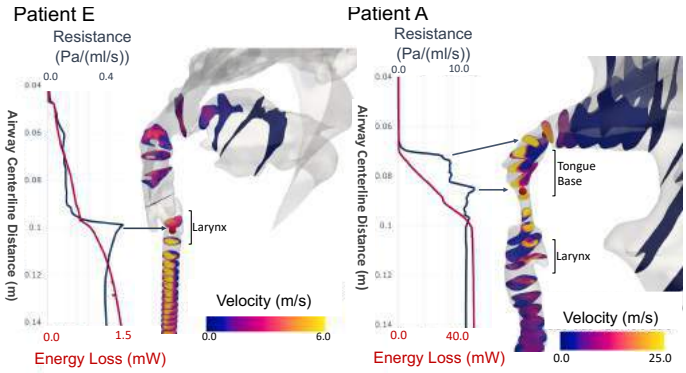

**Figure 2: Energy loss (red) and resistance (blue) computed along the airway centerline (line graphs) and contours of velocity magnitude (3D plot) for patient E and patient A.**

## DISCUSSION

This is the first study to combine 4DCT and CFD to analyze airflow dynamics in RS infants. CFD simulation results were used to retrospectively risk-stratify patients and identify the anatomic features primarily responsible for airway resistance. Large differences in computed airflow metrics were found between patients with airway resistance values ranging from those reported for healthy infant airways [7] to severe sleep apnea patients [8]. The dramatic range in airflow resistances across RS patients is due to the non-linear dependence on CSA and subsequent shear generation from accelerated flow, and a risk-stratification based solely on CSA would be less distinct (figure 1, panel D). CFD results also highlight that the location of maximum resistance is not always localized to the same anatomic subsite, suggesting that surgeries and interventions may need to be tailored specifically to meet the needs of each individual patient.

From a clinical perspective, airway resistance, peak velocity, and viscous dissipation all correlated with the severity of respiratory status defined by the level of intervention support. The patient with the most severe airflow resistance (patient A) also required the highest level of respiratory support. Patients who demonstrated obstruction at the tongue base had elevated blood levels of CO2, indicating their respiratory gas exchange was compromised by the UAO. Conversely, the patients who demonstrated maximum obstruction at the level of the larynx (patient E) required minimal respiratory support. The larynx represents the standard narrowest point in the upper airway, indicating this patient was functioning closer to what is physiologically normal.

The significant differences in airflow metrics and locations of obstruction highlight the variability in UAO in RS patients and the need for quantitative assessments of severity that include airflow dynamics. 4DCT and CFD has the potential to provide the quantitative metrics that lead to individualized surgical and medical treatment for RS patients.

## INTRODUCTION

The Transcatheter Aortic Valve Replacement (TAVR) is a minimally invasive procedure that has been performed at higher rates than in the past, yet certain complications still persist, for example the 90-day mortality rate is higher than surgical replacement procedures for Medicare beneficiaries [1]. The cause of this trend is unknown, and the underlying mechanisms have not been well studied. Some possible reasons for this trend include wear and tear on the aortic artery or even stresses caused by the implanted valve. To study the underlying mechanisms in vitro, our group is designing a 3D printed silicone model of the aorta artery with flow and pressure sensors surrounding the area of interest. The sensors will be made of polyvinylidene fluoride (PVDF).

PVDF is a piezoelectric material that has applications as an implantable biomedical device [2]. PVDF has been used to track changes in blood flow and pressure in various settings. For example, McLaughlin used PVDF as a non-invasive sensor to measure peripheral arterial pressure pulse wave velocity in humans [3]. Using a derivative of PVDF, PVDF-TrFE, Sharma was able to design a system to measure pressure around a catheter in a vascular testing model [4].

While PVDF has been used as a biosensor, there are few studies that show that PVDF being used to detect changes in blood flow and pressure in the aortic artery, which is necessary for our application. Specifically, PVDF needs to be subjected to conditions that similar to the aortic artery. These conditions include pressures peaking around 120mmHg in a healthy adult, and flow rates around 330mL/s [5]. Creation of an environment under these conditions in necessary to design the optimal sensor for investigating the TAVR procedure complications. The goal of this study is to design a flow chamber that mimics the environment of the aortic artery and to calibrate a PVDF sensor to those conditions.

## METHODS

Aortic Artery Model:

A flow chamber was designed and built to mimic the dimensions of the aortic artery. The section of interest of the aorta artery is around 12” in length and 1” in diameter [6], and clear tubing was used as the aortic segment for the purpose of testing the PVDF biosensor in this apparatus. A 12” portion was cut from clear PVC tubing (Abbot Rubber Company, Elk Grove Village, IL), and two copper wires were inserted into the walls of the clear tube to act as electrodes for the sensor.

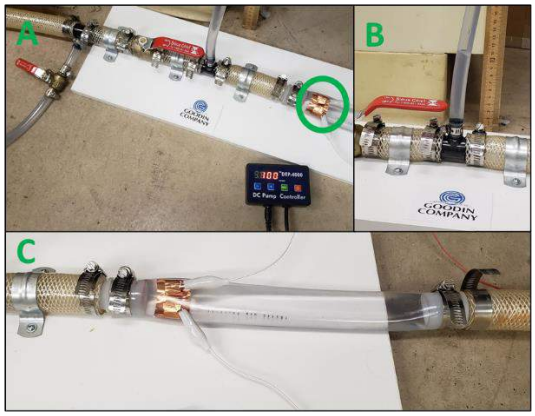

**Figure 1: A) Flow chamber for measuring PVDF response to changes in pressure and flow from a DEP-4000 water pump. The PVDF sensor, covered in copper tape is circled. B) Manometer used to measure head of fluid at various flow rates C) Aorta section of the flow chamber.**

A vertical tube manometer was connected right before the tube section to measure the head of fluid in the flow chamber. A bypass before the manometer and tube segment allows flow to be directed away

from the tube segment to determine if the sensor was detecting vibrations of the pump without water flowing through the segment. A Uniclife DEP-4000 submersible pump was used to vary the flow rates.

Flow rate of water was determined by collecting and weighing the water exiting the setup after 2 seconds. The pressure was determined by measuring the head of fluid in cm $H_2O$, later converted to mmHg, the standard measurement for blood pressure. The flow chamber and measurement of head of fluid can be seen in figures 1A and 1B.

Signal Acquisition:

A 1"x1" square was cut from the PVDF membrane (PolyK Technologies, State College, PA) and copper tape was placed on either face. The sensor was then placed in the flow chamber, with the copper tape touching the copper wire electrodes (figure 2A). The voltage from the PVDF sensor was collected using a National Instruments cDAQ-917 and 9215 Voltage Input module at a rate of 1,000Hz. Data acquisition would start with the flow of water running through the bypass, which was redirected to the aorta tube with PVDF sensor after two seconds.

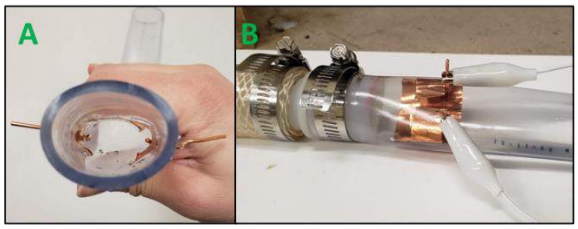

**Figure 2: A) PVDF Sensor held in place from copper wire electrodes. B) The PVDF sensor in flow chamber**

## RESULTS

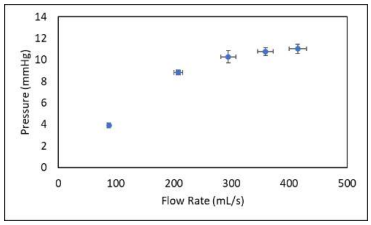

**Figure 3: Flow and Pressure in aortic heart model flow chamber. Figure 3 shows the flow rate and pressure from the Uniclife DEP-4000 pump. The error bars represent standard deviation of each replicate trial (n=3 for pressure, n=5 for flow rate).**

Figure 3 shows the relation between pressure and flow in the aorta. As the flow rate increases, the pressure increases nonlinearly. However, the rate of pressure increase drops with increasing flow rate, as observed by the gradual plateauing of pressures.

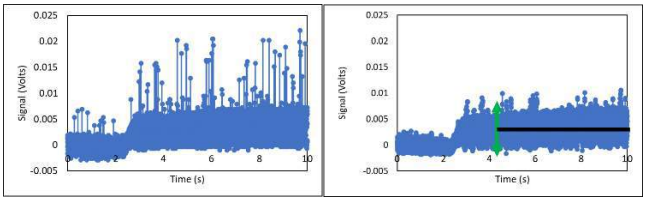

**Figure 4: Signal from PVDF sensor in Flow Chamber. The plot on the left shows the raw voltage from the sensor. The plot on the right is the voltage filtered through a 7-point Savitzy-Golay fit.**

Figure 4 shows the raw and filtered voltage from the PVDF sensor. The calculated signal was determined by taking the average voltage value from the 4 second mark to 10 second mark from the signal that had been filtered using a 7-point Savitzy-Golay [8] fit, after the flow was directed from the bypass to the flow chamber, as shown by the black line, with the signal amplitude shown in green.

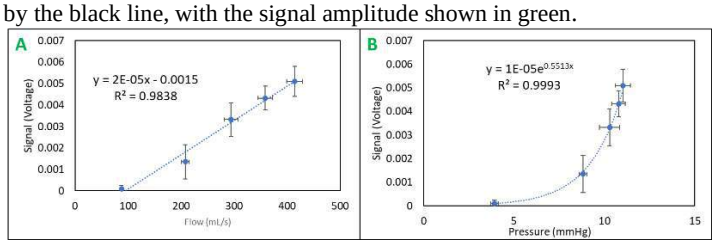

**Figure 5: A) Signal from PVDF sensor at various head pressure. B) Signal from PVDF sensor at various flow rates. The error bars designate standard deviation from triplicate data acquisitions.**

Figure 5 shows the signal generated from the PVDF sensor under various pressure and flow conditions in the aorta flow chamber. Figure 5A shows that as the pressure increases in the flow chamber, the corresponding voltage from the PVDF sensor increases. This is expected, as the force applied to the piezoelectric material increases, the corresponding signal should increase as well. The voltage from the sensor increases exponentially with increased pressure. The signal generated from the PVDF sensor also increases with higher flow rates. This follows a linear trend rather than the exponential trend seen with the increase in pressure.

## DISCUSSION

The flow chamber that was built to mimic the aortic artery did create an environment adequate for testing a sensor for use in studying the TAVR procedure. The flow rates generated from the Uniclife pump are in range of blood flow in the aorta. The pressure generated from the pump is a lot lower than expected, but since the PVDF sensor generated signal that was differentiable at these lower pressures, it is still useful for our application. One possible complication from the TAVR procedure is that the replacement valve could leak around the diseased valve. This could cause small changes in pressure relative to human blood pressure. The PVDF in the current set up is able to detect changes in pressure between 8-10mmHg, which could hypothetically detect leakages in the replacement valve.

The current flow chamber and biosensor set up presumably capture all the deformations which include fluid pressure and flow shear stress. In a native aorta, cyclic distension from pulsatile flow of blood will add to the complexity of the deformations on the aorta. These will have to be decoupled using our flow setup to fully understand the actual changes in the mechanical microenvironment around the TAVR implant as tracked by the PVDF sensor.

## ACKNOWLEDGEMENTS

I would like to thank Mike Danley, Master Plumber, for assistance in designing the flow chamber and George Behr, Goodin Company, for gathering parts and materials for the flow chamber.

# DEVELOPMENT OF A MULTI-TIMESTEP APPROACH FOR MICROPARTICLE AND ERYTHROCYTE IMAGE VELOCIMETRY

**Simon Tupin (1), Joseph van Batenburg-Sherwood (1)**

(1) Bioengineering, Imperial College London, London, UK

## INTRODUCTION

Numerical modelling techniques for simulating blood flow in microvessels have advanced significantly in recent years, but advances in experimental methods have been limited. Experimental measurements of microscale blood flow are needed to provide insight into blood behavior in the microcirculation, particularly in cases where the properties of the red blood cells are altered in complex ways, such as malaria and diabetes. While numerical models can make predictions, experimental data is required for optimisation and validation [1]. However, high quality experimental data is scarce.

Using microfluidics, it is straightforward to fabricate channels that mimic idealised sections of the microvasculature. The velocity in such branching networks is characterised by a wide range of velocities. For a given branch, the velocity increases from 0 at the wall to a peak value near the channel centre. As the network bifurcates, the peak velocity and the velocity in the important near wall region decrease. Accurately capturing this wide range of velocities is challenging.

Micro particle image velocimetry (µPIV) can be used to measure velocities with high spatial resolution in such microchannels [2]. Image correlation is then used to calculate the most likely displacement of the particles in a region of the image between two frames, separated by timestep $\Delta t$ (typically ~0.1-10 ms). A velocity vector can then be calculated for that region using the displacement and $\Delta t$. A limitation of this approach is that the accuracy of the measurement is dependent on the number of pixels that particles move between images. If particles move by one pixel or less between images, a strong correlation peak will be identified, but small differences in sub-pixel resolution can lead to large errors in the estimated velocity. Conversely, if particles move by too many pixels between frames, the correlation will struggle to identify the same group of particles and there will many spurious vectors.

The same difficulties arise in macro PIV in flow fields that include large velocity gradients. To address this problem, a number of authors have proposed multi-$\Delta t$ PIV algorithms. [3,4] In these approaches, image pairs are captured in a sequence of increasing $\Delta t$ values and indices of the signal to noise ratio are used to select the optimal $\Delta t$ for each vector. In the present study, we extend these approaches to µPIV acquisition of flow in branching networks that mimic an ideaslised section of an arteriolar network. First, we consider µPIV, with fluorescent particles suspended in a glycerol solution. We then apply the approach to brightfield illuminated images of erythrocytes flowing in the same branching microchannel.

## METHODS

### Fluidics

Standard techniques were used to fabricate microchannel masters with SU8-based photolithography, and PDMS microchannels were cast and bonded to glass coverslips. The channels had a 50µm square cross section throughout and featured two sequential branches inclined at 45° and on alternating sides of the main channel. A pressure controller (OB1 MK3+, Elveflow) was used to perfuse either 0.5µm diameter fluorescent particles suspended in glycerol solution (PS-FluoRed-PEG/Fi142-1, microParticles GmbH) or human erythrocytes suspended in an Optiprep (Sigma Aldrich) and phosphate-buffered saline solution at a haematocrit of 25%.

### Image Acquisition

A custom µPIV system designed specifically for microscale blood flow experiments was developed. The setup comprises an inverted microscope (IX73, Olympus) equipped with two illumination methods: a dual head pulsed Nd:Yag laser (532nm, NanoPIV, Litron) to image fluorescent microparticles and a red LED (623nm, Solis-623C, Thorlabs) to image erythrocytes (Fig 1).

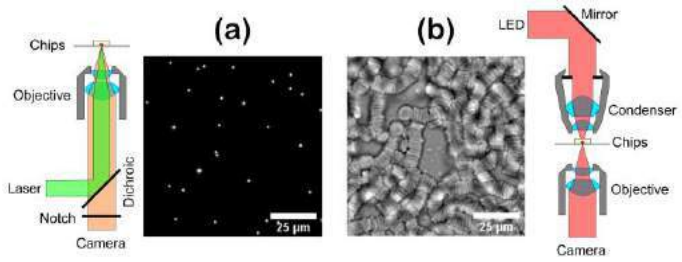

**Figure 1: Optical system schematics and typical image of (a) microparticles and (b) red blood cells.**

An sCMOS camera (Zyla 5.5, Andor) was used to record pairs of images at a resolution of 0.325 µm/px with a 20X objective (UPLXAPO20X, Olympus). The system is controlled using a custom LabVIEW program that enables interleaved recording of images pairs with multiple $\Delta t$ values. For the particle data, 5 values of $\Delta t$ = 0.1, 0.2, 0.5, 1 and 2 ms were acquired, for 50 image pairs at each $\Delta t$. For the demonstratin with erythrocytes, three timesteps ($\Delta t$ = 0.5, 1 and 5 ms) were sufficient to reconstruct the flow field (the different range of $\Delta t$ corresponds to lower flow rates).

**PIV processing**

Velocity magnitude fields for each $\Delta t$ were measured using the ensemble average algorithm implemented in PIVlab [5]. For each $\Delta t$, a two-pass algorithm was implemented. For the particle images, we used 48px then 24 px interrogation windows (IW), with 50% overlap, yielding a final spatial resolution of 3.9µm. For erythrocyte images, 32 then 16 px IWs were used, yielding a spatial resolution of 2.6 px, enabled due to the nature of the erythrocyte images offering more features that can be correlated in smaller IWs.

A method for selection of $\Delta t$ for each vector location was implemented based on the general PIV principle that optimal particle displacement between frames should be ~ IW/4 [6]. For each vector, the $\Delta t$ that yielded the highest displacement that was ≤ IW/4 was selected. We refer to the resulting vector field as 'optimised'.

In addition, the correlation (C) signal-to-noise ratio (SNR) was evaluated by measuring the peak to correlation energy (PCE) [7], defined as:

$$PCE = \frac{|C_{max}|^2}{\int_{-\infty}^{\infty}|C|^2 dx} \quad (1)$$

**RESULTS**

Figure 2a shows the optimised velocity field, with velocity magnitudes that vary by more than a decade. The selected $\Delta t$ values are shown in Figure 2b, and vary both between and within branches. Figure 2c presents the percentage differences between the optimised velocities and those calculated using the shortest $\Delta t$ (0.1ms). The latter approach led to a significant underestimation of >20% in the lower velocity regions, including near the wall. Use of longer $\Delta t$ values performed comparably better in such regions, but failed in higher velocity regions (Figure 2d).

The signal-to-noise ratio (PCE) field was found to be maximal when using the shortest $\Delta t$ throughout the domain, despite the fact that the displacement between frames was less than 1 pixel in the low velocity regions, indicating it is not appropriate for the present application.

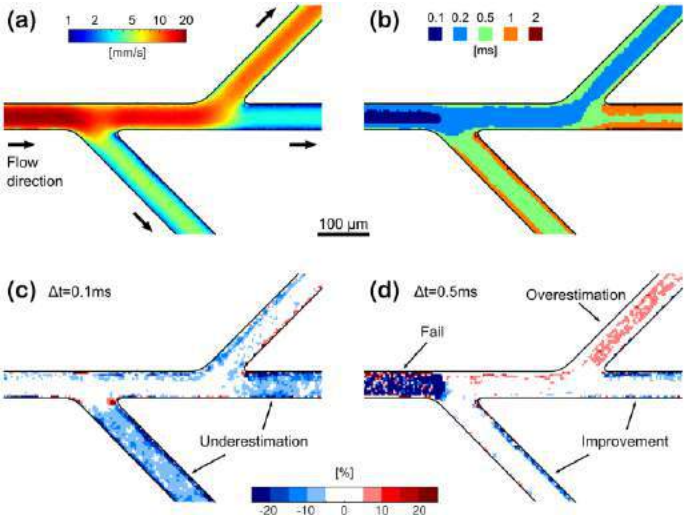

**Figure 2: Multi-timestep approach applied to the microparticle experiment: (a) optimised velocity field, (b) local $\Delta t$ selection. Percentage difference in velocity between the optimised field and (c) $\Delta t$ =0.1ms, (d) $\Delta t$ =0.5ms.**

The developed framework was then applied to erythrocytes (Figure 3). The velocities varied significantly throughout the channel, with clear asymmetries that arise due to asymmetric haematocrit distributions [1]. The inset demonstrates the high resolution with which the velocity was measured.

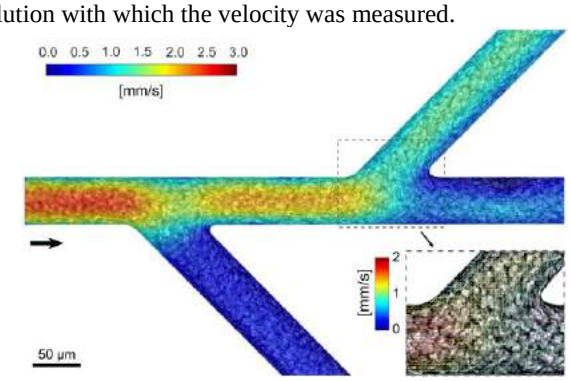

**Figure 3: Multi-timestep approach applied to the erythrocytes experiment.**

**DISCUSSION**

The multi-timestep approach developed in this study was found to be effective for the velocity measurement in branching geometries exhibiting large velocity gradients. Optimisation of the local timestep allows maintenance of an ideal displacement between frames, which improves the accuracy throughout the network. The accuracy of the near wall velocity was notably improved, which is particularly important when estimating the shear stress acting on the channel walls, or the endothelium for vascularised channels.

The proposed method was found to be more efficient than the correlation SNR in the selection of the local timestep. SNR values were high even when the particle displacement was small, as a strong correlation peak is identified, but the corresponding outcomes were not accurate. A larger displacement is demonstrated here to achieve a higher accuracy in the velocity estimation.

The current results demonstrate proof-of-principle, but further work is required to validate the reconstructed velocity field. For a range of input velocities and flow splits between branches, the accuracy of the approach will be determined by evaluating conservation of mass errors at each bifurcation, and by measuring the flow rates for each branch for direct comparison.

Once validated, this approach will be applied to the simultaneous velocity measurements of particles and erythrocytes. This multiphase characterisation will better describe the complex blood behavior in the microcirculation.

**ACKNOWLEDGEMENTS**

# HEMODYNAMIC CHANGES IN THE AORTIC ROOT UPON TRANSCATHETER AORTIC VALVE (TAV) IMPLANTATION

## INTRODUCTION

Aortic stenosis (AS), the most common type of valvular heart disease, is characterized by a narrowing (stenosis) of the aortic valve (AV) orifice caused by progressive calcification and restricted opening of the aortic valve leaflets [1-2]. This results in significant obstruction of blood flow from the left ventricle outflow tract (LVOT) across the aortic valve into the ascending aorta and amplifying the ventricular pressures required to maintain normal cardiac output. If untreated, this obstruction can cause life-threatening complications such as cardiac arrhythmias, heart failure, and stroke. The primary treatment for AS is aortic valve replacement. The surgical aortic valve replacement (SAVR) procedure has been the gold standard for treating symptomatic AS. However, the transcatheter aortic valve replacement (TAVR), a procedure in which a stented valve is deployed into the aortic valve position via arterial catheter, introduced a novel, less invasive option for at-risk patients.

Although TAVR procedures have quickly become the standard of care for many patient subgroups [3], hemodynamic alterations in the aortic root induced by TAVR implant are not fully understood. Several prior studies have investigated this topic [4-5], however, there remains a need for an end-to-end pipeline for computational modeling of pre- and post-TAVR hemodynamics which is validated against clinical data.

The aims of this research are twofold: elucidate hemodynamic changes in the aortic root after TAV implantation by developing a patient-specific modeling pipeline that enables the simulation of fluid flow through a model of the aortic root; and validate these data against clinical patient data. Specifically, we examine the ability of our pipeline to non-invasively estimate measures of relative pressure and flow pre-operatively (under stenotic conditions) as well as post-operatively (after TAVR implantation). Understanding and predicting local hemodynamic changes within the aortic root upon TAV implantation provides a powerful tool for surgical planning and the clinical treatment of AS patients.

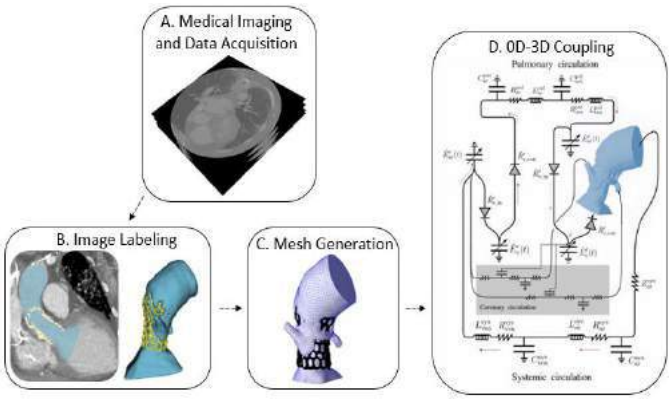

**Figure 1: Novel aortic root modeling pipeline. (A) Pre- and post-TAVR CT images and echocardiogram data is collected. (B) The aortic root is segmented (blue) and the TAVR (yellow) is subtracted from the segmented volume. (C) The remaining blood volume of the aortic root is meshed (blue) in SimModeler. (D) The 3D model (blue) is coupled to a closed loop 0D model and patient specific data is integrated into the CFD model**

## METHODS

In order to predict hemodynamic outcomes post TAVR, we developed a novel pipeline to create patient-specific computational fluid dynamic models of the aortic root. Computed tomography (CT) images were collected for each patient pre- and post- TAV implantation (Fig. 1a). The aortic root blood volume was segmented in 3DSlicer with the anatomic aortic valve orifice area (AVOA) defined from the CT and doppler flow data (Fig. 1b). Segmented models were imported into SimModeler for smoothing, inflow and outflow boundary generation, tetrahedral mesh generation, and the creation of a 3D boundary layer (Fig. 1c). Newly smoothed and meshed 3D models were coupled to a

closed loop 0D model (Fig. 1d) that represents the remaining vasculature and that provides continuous feedback to the 3D model [6]. Heart rate (HR), volumetric flow from the left ventricle, AVOA, and stroke volume (SV) provide the data for model assimilation using direct constraints on the 0D model. The finite element-based solver *CHeart* was used to perform CFD simulations of aortic root flow [7].

This pipeline (Fig.1) was used to analyze six different models: a pre-TAVR and post-TAVR aortic root model for three different patient-specific geometries.

**Pre-TAVR Models.** This modeling pipeline can be used to model the diseased state of patients with AS. For these models the location and orientation of the AV was determined from segmenting the preoperative CT images, however poor image resolution convoluted the process of obtaining a reliable AVOA. The AVOA was adjusted such that the area approximated the ratio of maximum left ventricle (LV) volumetric flux into the aortic root (calculated from dynamic CT images) to peak velocity across the valve plane.

**Post-TAVR Models.** Postoperative imaging and echocardiogram measurements allowed for assessment of patient hemodynamics post-TAVR. A TAV (composed of valve stents and skirt) and an aortic root model were created from the CT images. The valve skirt, which is not visible in the CT images, was manually segmented using stent landmarks. The TAV model was subtracted from the aortic root model to generate a post-TAVR aortic root blood volume. The AVOA was defined similarly to the pre-TAV case, however no dynamic post-operative CT data was available to calculate a maximum LV volumetric flux. Instead, the pre-TAV volumetric flux was adjusted such that the SV of the LV corresponded to the post-operative SV registered in the patient chart.

CFD results are validated using data taken directly from the patient's pre-procedural echocardiogram and their echocardiogram taken 24-48 hours post-TAV implantation.

## RESULTS

Figure 2 depicts the velocity field for a representative case across the aortic valve at peak systole for both pre- and post-TAVR models. At peak systole, the pre-TAVR model has a peak velocity magnitude of 4.7 m/s (compared to 4.1 m/s measured by doppler). The post-TAVR model has a peak velocity magnitude of 2.6 m/s (compared to 2.9 m/s measured by doppler) which is a 55.3% decrease in velocity magnitude after TAV implantation.

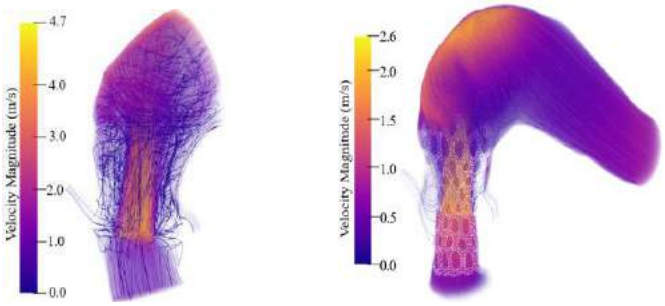

**Figure 2: Velocity field of aortic root models at peak systole. The pre-TAVR model (left) has a high velocity, centralized jet crossing the valve plane. The post-TAVR model (right) has a lower velocity, decentralized jet crossing the valve plane and into the ascending aorta. Extension of the ascending aorta included in order to highlight uniform flow patterns past the valve plane.**

Important hemodynamic parameters are shown in Table 1. The pre-TAVR model had a peak aortic valve pressure gradient, mean aortic valve pressure gradient, and peak velocity measurement percent errors of 8.21%, 3.86%, and 14.6%, respectively. The post-TAVR model had a peak aortic valve pressure gradient, mean aortic valve pressure gradient, and peak velocity measurement percent errors of 5.76%, 16.5%, and 10.0%, respectively. These results show good agreement between the CFD data generated *in silico* and the invasively measured patient data for both pre- and post-TAVR models of the representative case (Table 1).

**Table 1: CFD simulation data validation for representative case.**

| **Pre-TAVR** | | | | | |
|---|---|---|---|---|---|
| | *Data for constraining CFD model* | | *Data for model validation* | | |
| | HR (bpm) | SV (mL) | Peak AV pressure gradient (mmHg) | Mean AV pressure gradient (mmHg) | Peak velocity (m/s) |
| Patient Data | 71 | 85.6 | 67 | 44 | 4.1 |
| CFD Output | 71 | 85.6 | 72.5 | 45.7 | 4.7 |
| **Post-TAVR** | | | | | |

| CFD Output | 80 | 81.3 | 31.1 | 19.8 | 2.61 |

## DISCUSSION

In this study, we developed a novel modeling pipeline whose output includes a 0D-3D coupled patient-specific model that can be used in CFD simulations and the TAVR procedure. The predictive results of these simulations were then validated against velocity and pressure measurements.

Given the close agreement between hemodynamics measured by CFD and the patient specific data, we conclude that the computational modeling methods undertaken in this study are suitable to simulate aortic root hemodynamics pre- and post-TAV implantation. This outcome is supported by the conclusion of previous work which highlights the predictive information that is acquired from patient-specific computational models after device implantation [8].

A limitation of this work is that post-TAVR anatomies were taken from CT images rather than directly simulating the TAV implantation. Future work includes expanding this methodology to allow for investigation into the hemodynamic effects of implant depth and rotation orientation (e.g., commissural alignment) with valve types. Furthermore, we plan to expand this modeling framework to examine the hemodynamic effects of a repeat TAVR procedure (TAV-in-TAV) considering the growing need for advanced procedural planning techniques for such procedures due to patients outliving the durability of the original transcatheter valve [9].

# ROLE OF MIDLEVEL CONSTRAINT IN REDUCING MIDFLEXION LAXITY AFTER ADDITIONAL DISTAL FEMORAL RESECTION IN POSTERIOR STABILIZED TKA

## INTRODUCTION

Surgeons resect additional distal femur during primary posterior-stabilized (PS) total knee arthroplasty (TKA) to correct for flexion contracture [1]. We previously demonstrated that utilizing this approach to alleviate a 10° flexion contracture, which elevates the joint line, induces significant increase of coronal laxity in the mid-flexion ranges, and, therefore, may contribute to knee instability; a common cause of patient dissatisfaction and revision surgery [2]. It has been postulated that a midlevel constrained (MLC) insert, an insert compatible with TKA implant components, provides more coronal stability than a PS insert due to a thicker and wider post [3]. However, the effect of MLC on tibiofemoral kinematics in the presence of joint line elevation is not well understood. Therefore, the goal of this study was to determine whether an MLC insert reduces mid-flexion laxity after additional resection of the distal femur in TKA.

## METHODS

Six computational knee models were developed via 3D reconstructing of bony geometries for the tibia and femur from CT scans of six cadaveric knees. A measured resection TKA was conducted and a standardized capsular and collateral ligament properties that produces a balanced knee at full extension were incorporated to the model (Fig. 1.a) [4]. PS and MLC inserts were subsequently installed on each of the six models (Optetrak Logic®, Exactech, FL, USA) (Fig. 1.b). A compliant contact formulation between the articulating surfaces of the femoral component and the polyethylene insert was defined [4]. A 10° flexion contracture was modeled by reducing the slack in the spring elements representing the posterior capsule while simulating a standard clinical exam of knee extension [5]. Additional bone resections of the distal femoral of +2 mm and +4 mm were simulated with the PS and MLC models (Fig. 1.c).

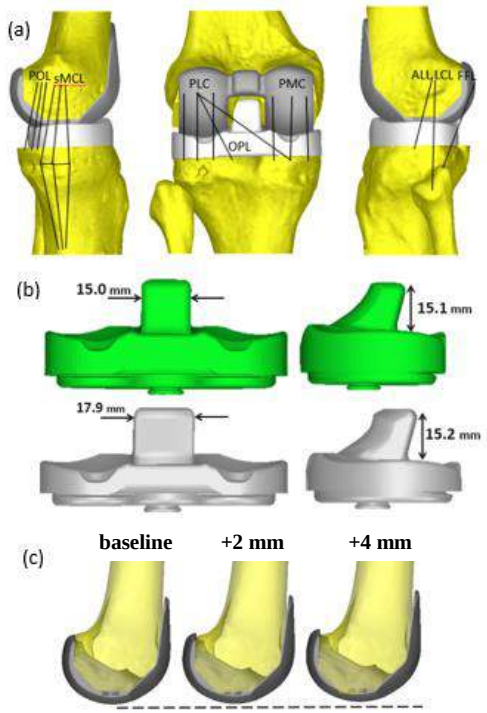

**Figure 1:** (a) The TKA model included 20 ligament fibers representing the collateral ligaments and posterior capsule. (b) The geometry of the PS insert (green) and the MLC insert (gray). (c) Three bone resections Subsequently, varus and valgus (VV) moments of ±10 Nm under 50 N of compression were applied to the tibia as the knee was flexed from 0°

Subsequently, varus and valgus (VV) moments of ±10 Nm under 50 N of compression were applied to the tibia as the knee was flexed from 0° to 90° at baseline (i.e., no additional resection) and after additional distal resections of +2 mm and +4 mm. The coronal laxity, defined as the sum of VV angulations in response to the VV moments, and coupled axial rotation, defined as the sum of coupled internal and external rotation in response to the VV moments, were measured at 30°, 45°, and 60° of flexion and compared between PS and MLC using RM-ANOVA with α set to 0.05.

## RESULTS

At 30° of flexion, the coronal laxities with the PS insert at the +2 mm and +4 mm resections averaged 7.9 ±0.5° and 11.3 ±0.6°, respectively. With the MLC insert, the coronal laxity decreased by 0.8° (p= 0.06) and 1.0° (p= 0.07) with the +2 mm and +4 mm resections, respectively (Fig. 2 and Table 1). With the PS insert, the coupled axial rotation at the +2 mm and +4 mm resections averaged 11.1 ±3.9° and 12.5 ±4.6°, respectively. With the MLC insert, the coupled axial rotation decreased by 5.6° (P= 0.01) and 7.1° (P=0 .02), respectively, (Fig. 3 and Table 2). Similar patterns were observed at 45° and 60° of flexion (Tables 1 & 2).

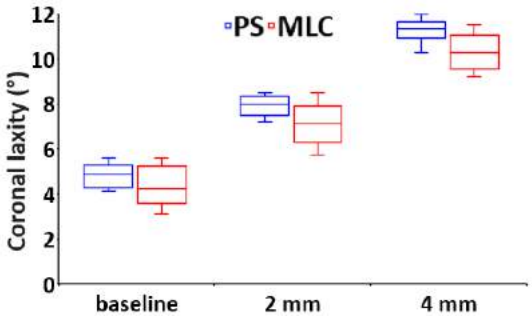

**Figure. 2**: Coronal laxity in PS and MLC models at the baseline, +2 and +4 mm of additional resections at 30° of flexion.

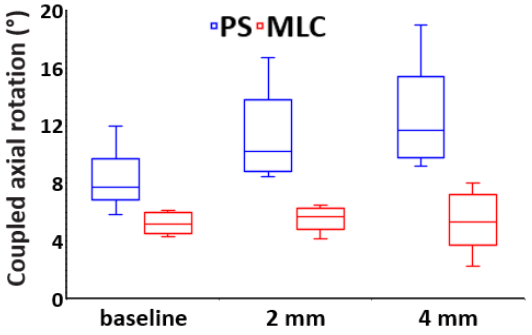

**Fig. 3**: Coupled axial rotation in PS and MLC models at the baseline, +2 and +4 mm of additional resections at 30° of flexion

## DISCUSSION

We found that with additional resections of the distal femur resulting in joint line elevation in primary TKA, utilizing an MLC insert reduced coupled axial rotation (up to 7.1°) but had a minimal impact on coronal laxity (only up to about 1.0°) in mid-flexion compared to that occurring with a PS insert. Midflexion instability could be attributed not only to increased primary motions, like coronal laxity, but also coupled rotations of the knee at midflexion [6]. Compared to the natural knee, the coupled axial rotations predicted by the model with joint line elevation were greater than those of the native knee in mid-flexion, which averaged at most 5° in valgus [7]. Our findings might suggest that MLC insert could contribute to reducing the incidence of midflexion

instability by reducing the coupled axial rotation induced with the PS insert. However, the increased constraint provided by the post in MLC may also increase the mechanical burden on the bone-implant interface. Therefore, understanding the trade-offs between constraint, joint-level stability, and bone-implant loading are critical considerations when selecting the insert design. Importantly, MLC design differs among manufacturers, so these findings are specific to the simulated implant system. In conclusion, with additional resections of the distal femur in primary TKA to alleviate a flexion contracture, utilizing an MLC insert substantially reduced coupled axial rotation but had a minimal impact on coronal laxity compared to PS insert. These findings may help guide surgeons for the indications and potential kinematic impact of joint line elevation and utilization of MLC inserts.

## INTRODUCTION

Nanoparticle (NP) formulations have been extensively studied as a carrier of poorly water-soluble drugs[1]. However, many formulation schemes[2-5] are typically developed in a drug-specific manner, it is still challenging to adapt NP formulation schemes for a wide variety of hydrophobic drugs.

In this context, metal-phenolic network (MPN), a supramolecular structure formed by the rapid coordination between metal ions and polyphenols[6], has been considered a promising coating scheme because it can be easily deposited on various substrates with different sizes, shapes and compositions[7]. The MPN can adhere to aggregates of hydrophobic drugs and suppress their Ostwald ripening[8, 9] to produce NPs with high drug loading capacity. In addition, the MPNs display unique features such as pH and redox responsiveness, which can facilitate drug release control and combination therapy[10]. The MPN shell is also conducive to conjugation of biofunctional molecules via diverse molecular interactions; thus, tannic acid (TA)-$Fe^{III}$ nanocapsules, one of the MPNs, has been used to immobilize an endotoxin adsorbent for systemic use[11]. However, the application of MPN coating on different hydrophobic drug types needs empirical adjustment and optimization of synthesis parameters. Mechanistically designed manufacture schemes are essential to diversify the application of NP formulation with MPN coating.

In this study, a mechanistic guideline is proposed to synthesize NP with TA-$Fe^{III}$ coating for various hydrophobic drugs using hydrodynamic flow focusing (HFF) on a microfluidic platform. This method is based on a hypothesis that the drug NP with TA-$Fe^{III}$ coating can synthesized by controlling the mixing time scale of HFF as illustrated in Figure 1. Specifically, if the mixing time scale is shorter than the induction time scale of hydrophobic drug, small and uniform size NP with TA-$Fe^{III}$ coating will be formed. We test this hypothesis by investigating the NP formulation of several drugs with varying water solubility.

## METHODS

*Selection of drugs*.

We investigated the effects of flow conditions of HFF on the synthesis of NPs of several hydrophobic drugs with varying water solubility. These include vitamin D ($VD_3$) (< 1 ng/mL), curcumin (CM) and paclitaxel (PTX) (> 1 μg/mL).

*Microfluidics of HFF*.

As illustrated in Figure 1A, HFF is the crucial step of the microfluidics which controls the subsequent step of solvent exchange for NP formation. Drug and TA in the organic solvent is introduced to the central channel, and $FeCl_3$ in water is introduced to both side channels. The central organic stream is squeezed by the outer aqueous stream which flows at higher flow rates. Figure 1B shows HFF enables short diffusion length, leading to shorter mixing time scale ($\tau_m$) than the induction time scale ($\tau_i$) of a given hydrophobic drug. This leads to the formation of drug NPs with TA-$Fe^{III}$ coatings with small and uniform size.

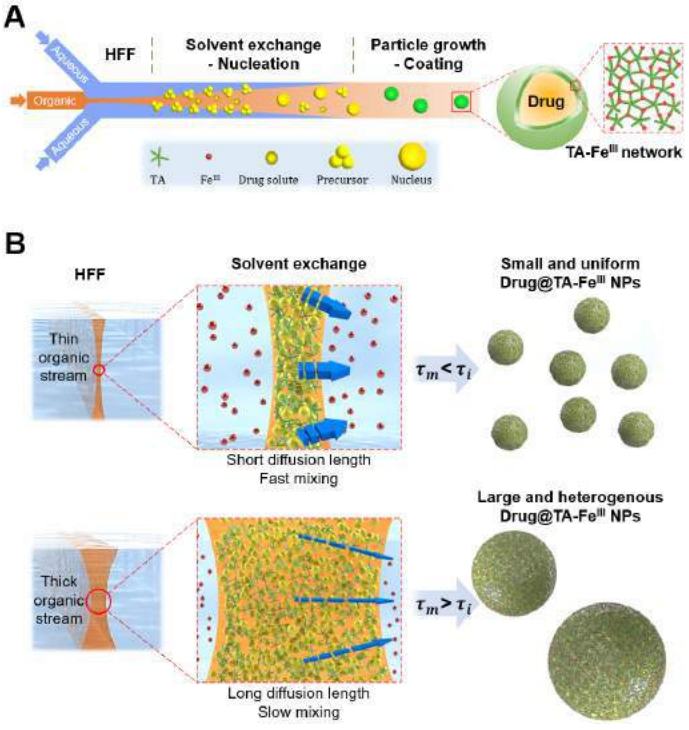

**Figure 1. Schematic illustration of the microfluidic synthesis method of hydrophobic drug NPs with TA-$Fe^{III}$ coating.**

*Characterization of NPs.*
The synthesized TA-$Fe^{III}$ network coated drug NPs of curcumin, paclitaxel and vitamin D are characterized by dynamic light scattering (DLS) measurement, the transmission electron microscopy (TEM) imaging, as well as the HPLC analysis of the drug loading contents.

## RESULTS

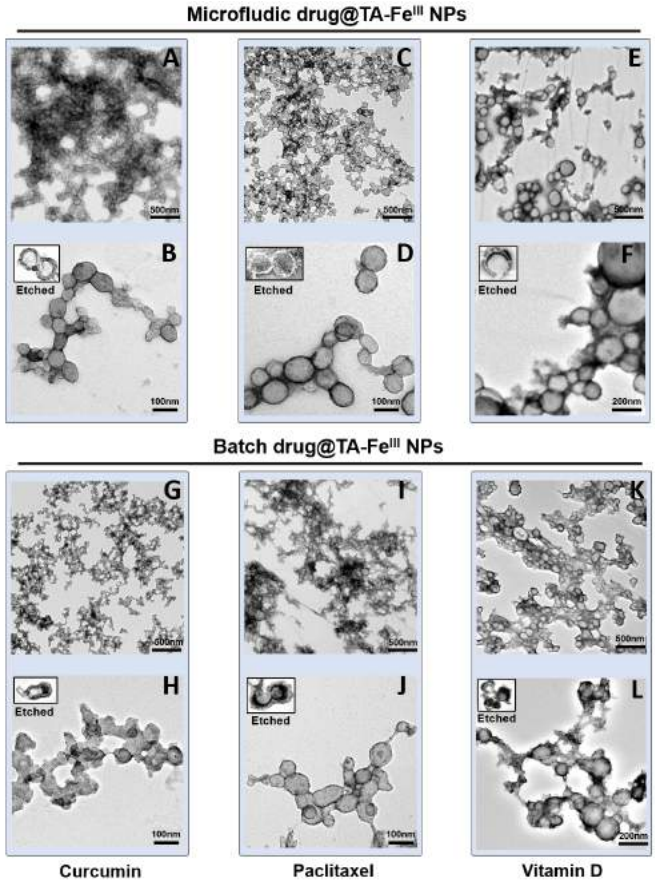

**Figure 2. Transmission electron microscopy images of drug NPs with TA-$Fe^{III}$ coatings synthesized by microfluidic and batch methods**.

Following our timescale-guided microfluidic method for the continuous production of drug NPs with TA-$Fe^{III}$ network coatings, we can produce size-controlled NPs of CM, PTX and $VD_3$. TEM images of the microfluidic NPs are shown in Figures 2A – 2F. Figures 2A, 2C and 2E show the low magnification TEM images of CM, PTX and $VD_3$ NPs, respectively, which were generally uniform in morphology and size. $VD_3$ NPs are significantly larger than CM or PTX NPs. More clearly exhibited in the high magnification TEM images in Figures 2B, 2D and 2F, $VD_3$ NPs are around 200 nm in diameter while CM and PTX NPs are around 100 nm in diameter. In the images (inserts) of the etched NPs, TA-$Fe^{III}$ coatings are clearly visible. Compared to the TEM images of the batch NPs in Figures 2G - 2L, the microfluidic NPs have more regular shapes.

According to the DLS measurement, microfluidic CM NP has the mean diameter of 140 ± 5 nm with the polydispersity index PDI of 0.1 ± 0.05, microfluidic PTX NP 121 ± 10 nm (PDI of 0.15 ± 0.03), and microfluidic $VD_3$ NP 233 ± 11 nm (PDI of 0.19 ± 0.03). Batch CM NP has the mean diameter of 199 ± 5 nm (PDI of 0.07 ± 0.02), batch PTX NP 166 ± 2 nm (PdI of 0.1 ± 0.03) and batch $VD_3$ NP 228 ± 7 nm (PDI of 0.08 ± 0.01). The DLS data agree reasonably well with the TEM images of microfluidic PTX and $VD_3$ NPs but overestimate the microfluidic CM NP size by approximately 30%. Figure 2B indicates that microfluidic CM particles are less spherical than microfluidic PTX or $VD_3$ particles, which results in a relatively large interfacial area between the particles, making the microfluidic CM particles more prone to aggregation during the DLS measurement. Similarly, the DLS data overestimate the size of batch NPs by more than 50%.

According to the HPLC analysis, for the microfluidic synthesis, CM, PTX and $VD_3$ are encapsulated with a loading content of 44 ± 7.2 wt%, 61 ± 8.4 wt%, 70 ± 9.9 wt%, respectively, and by comparison, these are 35 ± 10 wt%, 44 ± 0.2 wt%, 34 ± 3.7 wt%, respectively, for the batch synthesis. The NP production yield of the microfluidic synthesis is approximately 10 mg/hr, 9 mg/hr and 7 mg/hr for CM, PTX and $VD_3$, respectively, equivalent to approximately 5 mg/hr for all three drugs, which is comparable to or higher than the production yield of the batch synthesis.

## DISCUSSION

This work expands the proof of principle to the mechanistic study explaining the size control of the NP with a drug core – MPN shell structure, which provides a guideline for the future application to various hydrophobic drugs. We demonstrated the efficiency of this method via the synthesis of different drug NPs of CM, PTX and $VD_3$ with well controlled sizes of 100-200 nm and high drug loadings of 40-70%. Our microfluidic method enables continuous production of the MPN coated drug NPs at a relatively high yield of 7-10 mg/hr for these three drugs to facilitate scale-up efforts. Our work on this new microfluidic method lays the foundation for the well-controlled continuous production of MPN-coated NPs for a large variety of hydrophobic drugs.

## INTRODUCTION

There are an ever-increasing number of pediatric athletes through middle and high school sports, accompanied by an increase in pediatric anterior cruciate ligament (ACL) injuries [1]. Furthermore, there is a stark difference during adolescence in the rate of ACL injuries between males and females, with females being 3 times more likely to tear their ACL [2]. Several groups attribute this difference to aspects of puberty, including spikes and cycles of sex hormone serum concentrations of estradiol and progesterone in females [3,4]. Despite several groups showing correlations between estradiol and progesterone concentrations and overall joint laxity, there is still much debate over the effect of these sex hormones on changes within specific tissues, like the ACL [3]. Even less information exists on the influence of testosterone, the primary male sex hormone, on the developing male ACL. Surgical castration is known to drastically decrease total serum testosterone values, and there is some evidence that testosterone may play a protective role in ligament function [5]. One study showed that castrated rats had significantly less testosterone and similar-sized ACLs as intact rats, yet the ACL had a lower load to failure and ultimate stress [6]. Currently, there are no large animal models that have looked at the influence of surgical castration on the developing male ACL, which will be useful in identifying effects in the ACL, specifically, as opposed to overall joint laxity. Our group has also shown that the size of the porcine ACL diverges in males and females near the point of sexual maturity [7], similar to humans [8], suggesting the pig as a good model to study changes during adolescence. Therefore, the objective of this study was to use an established porcine animal model for the human ACL to determine how castration influences the structure and function of the male ACL during adolescence.

## METHODS

Twenty-four male Yorkshire crossbreed pigs were raised to 4.5 months (pre-puberty) or to 6 months (early puberty). Half of each age group were left sexually intact (boars), while the other half were castrated (barrows) at an early age (n=6 animals/age/treatment; Fig. 1A). All animals were bred at the North Carolina State University Swine Education Unit, and all experimental protocols were approved by the NC State University IACUC. Following euthanasia, hind limbs were removed, and the stifle (knee) joints were stored at -20°C in saline-soaked gauze. To determine structural data, stifle joints were thawed and imaged using a 7.0-T Siemens Magnetom MRI scanner (Siemens Healthineers) using a double-echo steady-state sequence (DESS, flip angle: 25°, TR: 17ms, TE: 6s, voxel size: 0.42 x 0.42 x 0.4mm). Joint size data, including bicondylar width, anterior-posterior (AP) tibial width, and cross-sectional areas (CSA) of the anteromedial (AM) and posterolateral (PL) bundle of the ACL, were recorded after segmentation using a commercial software (Simpleware ScanIP, Synopsys) and processing using MATLAB scripts (Fig. 1B).

Then, stifle joints (with the exception of two 4.5 month barrows) were biomechanically tested using a 6 degree-of-freedom force sensing robotic testing system (Kuka, SimVitro) as previously described [7]. AP loads of 80 N and 100 N for the 4.5 month and 6 month joints, respectively, were applied at 60° of flexion in force control mode and the kinematic paths were recorded. The kinematic paths were then repeated after removing the AM and PL bundles of the ACL to determine tissue-specific contributions during anterior drawer under the principle of superposition [9]. Normalized joint laxity was calculated as AP tibial translation divided by AP tibial width. ACL stiffness values were calculated as the slope of the linear region of the AP force-translation curve. Two-way ANOVAs were used to determine overall effects of age and castration on bicondylar width, CSA, joint laxity, ACL stiffness, and ACL bundle contributions. Sidak post-hoc tests were used for multiple comparisons between boars and barrows ($\alpha$=0.05). Data presented as mean ± 95% CI as each point representing an animal.

## RESULTS

Both age (p=0.002) and surgical castration (p=0.03) had significant effects on overall knee joint size (Fig. 1C). The average boar and barrow bicondylar width increased by nearly 9% from 4.5 to 6 months. Between boars and barrow, there was no significant difference at 4.5 months, but the barrows at 6 months had an 8% smaller width (adjusted p=0.04).

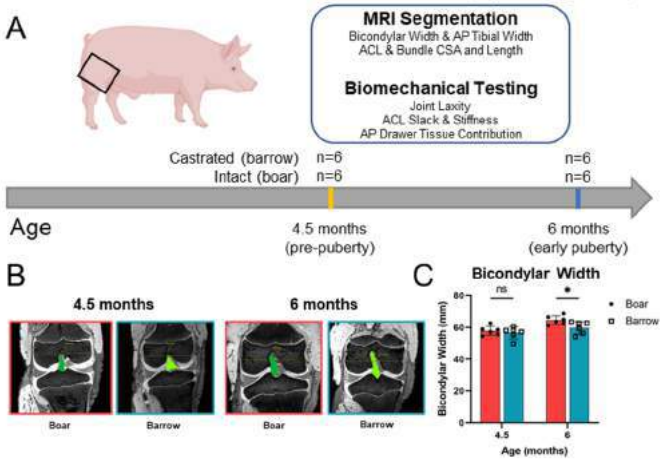

**Figure 1: (A) Joints were collected from boars and barrows at 4.5 or 6 months. (B) Representative MRI scans of joints. (C) Bicondylar width data. *indicates adj p<0.05 from post-hoc test.**

Raw ACL and AM bundle CSA values averaged 13% and 20% smaller in the barrows across both ages (ACL: p=0.08; AM: p=0.07; Fig. 2A-C). Raw PL bundle CSA values showed no differences between the boars and barrows across the ages (p=0.94). Once the raw CSA values were normalized to the bicondylar width, these minor size differences largely disappeared (ACL: p=0.79; AM: p=0.23; PL: p=0.77; Fig. 2D-F). Age, however, has a significant effect on all three CSA values, which persisted after normalizing to the bicondylar width (ACL: p=0.008; AM: p=0.008; PL: p=0.003).

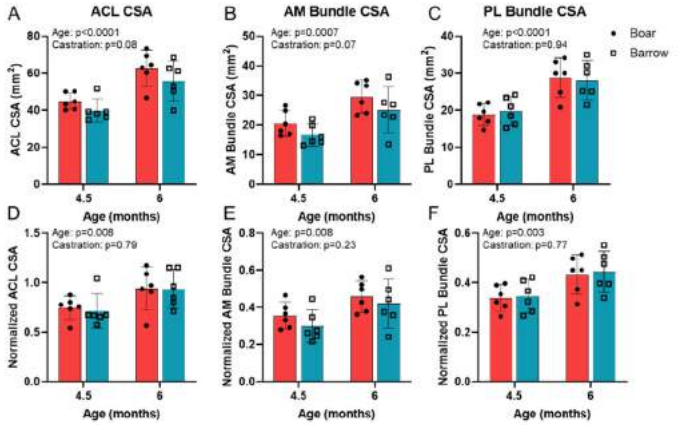

**Figure 2: Cross-sectional area of the (A) ACL, (B) AM bundle, and (C) PL bundle. Cross-sectional area normalized to bicondylar width of the (D) ACL, (E) AM bundle, and (F) PL bundle. P-values shown for main age and castration effects.**

Biomechanical analysis revealed that normalized joint laxity did not significantly differ between age (p=0.06) or castration status (p=0.94; Fig. 3A). There was no significant main effect of castration on ACL stiffness (p=0.55), although mean values were higher in the barrows at 6 months, but not 4.5 months (Fig. 3B). The AM bundle resisted the majority of the anterior drawer applied to the tibia in both the barrows (72%) and boars (88%) across 4.5 and 6 months (Fig. 3C). The difference in bundle contribution (Fig. 3D) did not significantly change because of castration (p=0.06), but the boars did have slightly higher bundle difference than the barrows (76% vs. 45%).

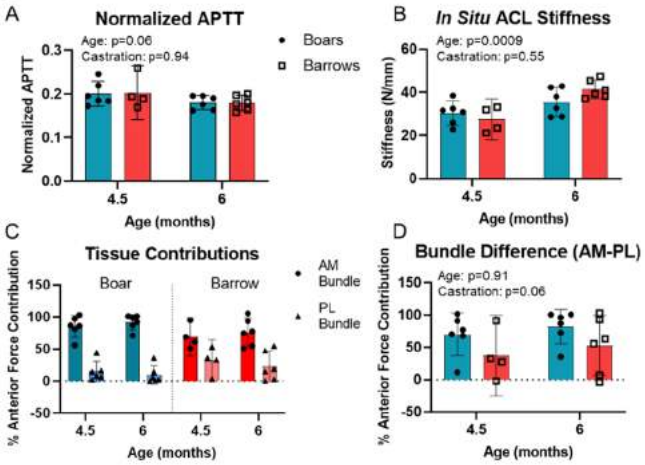

**Figure 3: (A) Normalized APTT and (B) *In situ* ACL stiffness. (C) AM and PL percent contribution to resisting anterior drawer. (D) Difference between AM and PL bundle contributions.**

## DISCUSSION

This study found that while surgical castration influenced overall joint size, it had only minor effects on ACL size and morphology as well as on mechanics. When looking at ACL CSA, these results are in agreement with other groups who have shown that surgical castration in rats does not change ACL size [6]. Raw structural values did show some minor differences, but these were mainly a result of smaller joints in the barrow groups. There were some interesting differences between boars and barrows when looking at function, though. After the point of sexual maturity (5-6 months) [10] the barrows had slightly stiffer ACLs that were not present pre-puberty. A possible explanation may be that there are less active muscle forces surrounding the knee in castrated animals that typically stabilize the knee joint. This might then result in greater force transmission in the ligaments and thus, stiffer ACLs via remodeling. When looking at load distribution between the AM and PL bundles, the boars seemed to be more AM-dependent, whereas the barrows have more variable load distribution between the bundle, which more closely resembles data in female pigs [7]. A larger sample size, older ages, and testosterone levels are necessary to fully tease out these effects. This and future work will help determine the role of sex hormones on ACL structure and function across development.

# AN EXPERIMENTAL APPROACH TO QUANTIFY THE PRE-STRAINS OF THE TRICUSPID HEART VALVE LEAFLETS

**Devin W. Laurence (1) and Chung-Hao Lee, Ph.D. (1,2)**

(1) Biomechanics and Biomaterials Design Laboratory, School of Aerospace and Mechanical Engineering, The University of Oklahoma, Norman, Oklahoma, USA
(2) Institute for Biomedical Engineering, Science, and Technology, The University of Oklahoma, Norman, Oklahoma, USA

## INTRODUCTION

The importance of pre-strains in soft biological tissues was first emphasized by Dr. Y.C. Fung and colleagues in the 1980s [1,2]. Their seminal works showed that the pre-strains within the arteries are heterogeneous and influence the *in vivo* stress and strain distributions of the tissue. These findings sparked interests in this important topic over the past three decades, and our understanding of the topic has improved accordingly. For example, *in-silico* approaches have been employed to understand how pre-strains influence the behavior of thin membranes (e.g., heart valve leaflets) [3], how to best implement pre-stresses into simulations of abdominal aortic aneurysms [4], and the role of growth and remodeling in the formation of pre-strains in the left ventricle [5].

Despite the significant advancements in the topic of pre-strains since Dr. Fung's fundamental arterial studies, much remains to be further explored. This is especially true for the heart valve leaflets that have received considerably less attention in this topic compared to arterial or ventricular tissues. One key area of improvement is the experimental methodologies to quantify the pre-strains of these soft biological tissues. Exemplary investigations oftentimes involve some type of opening angle experiment. However, opening angle experiments are only easily performed on cylindrical tissues (e.g., arteries) and may not be directly applicable when considering planar tissues, such as the heart valve leaflets. Researchers have overcome this limitation by using fiducial markers to track configurational changes of the tissue following removal from the *in vivo* configuration, including the work by Amini *et al*. [6] that experimentally captured the central region pre-strains of the mitral valve leaflets. Although this has provided the foundation for our current understanding of heart valve leaflet pre-strains, experimental data that demonstrate the essential microstructural [7] and mechanical [8] heterogeneities suggest that these pre-strains are also heterogeneous. Thus, the objective of this study is to establish an experimental approach that provides a novel, rich, spatial description of the pre-strain to inform heart valve leaflet tissue biomechanics.

## METHODS

***Heart Retrieval and Preparation*:** Five porcine hearts ($n$=5) were acquired fresh from a local slaughterhouse (Chickasha Home Meat Co., Chickasha, OK) and promptly transported to the laboratory. Upon arrival, the right auricle was removed, and the right ventricle was opened by cutting along the posterior-septal leaflet commissure to the apex of the heart. The tricuspid valve (TV) leaflets were then briefly rinsed and visible coagulated blood was removed from the heart. Finally, a surgical pen was used to apply approximately 100 fiducial markers in a uniform unstructured grid on the leaflet surface.

***Stereo Image Acquisition and TV Excision*:** Following fiducial marker application, the heart was placed beneath two cameras arranged in a calibrated stereo configuration. The cameras were then used to capture two images (**Fig. 1**) of the valve in the *ex vivo* configuration for 3D registration. Following image acquisition, the TV was carefully dissected from the heart while maintaining the native annulus and chordae attachments. This dissected valve was floated in a bath of phosphate buffered saline and placed under the stereo camera for imaging of the explanted configuration.

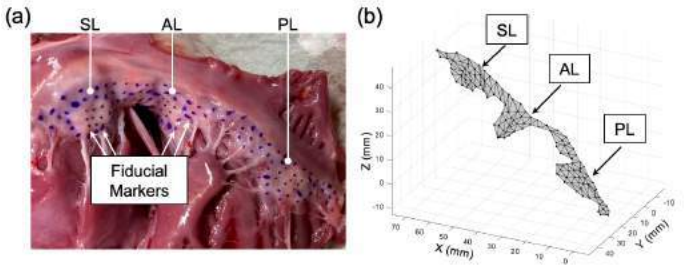

**Figure 1. (a) Representative image, and (b) 3D-registered leaflet surface. (SL: septal, AL: anterior, PL: posterior leaflets)**

***3D Fiducial Marker Registration via Discrete Linear Transform*:** The two sets of images of the valve in the *ex vivo* configuration were imported into MATLAB (MathWorks, Natick, MA). Next, the pixel locations of each fiducial marker in both images were manually determined using the `drawpolygon()` function. The two sets of pixel locations for each fiducial marker were then used with the calibrated discrete linear transformations of each camera according to [9] to determine the physical 3D marker locations. This process was repeated with the two offset images of the valve in the explanted configuration.

***Computation and Evaluation of Pre-Strains*:** The overhead view of the 3D fiducial marker locations were used with the MATLAB `delaunay()` function to construct a triangular mesh of the *ex-vivo* (reference) and explanted (deformed) leaflet surfaces. For each element, both the reference and deformed nodal coordinates were shifted so the centers of geometry were at the origin and rotated so each element's normal vector aligned with the +*Z*-axis. The 2D nodal displacements for each node $(u_i, v_i)$ were then used to compute the deformation gradient

$$\mathbf{F} = \mathbf{I} + \begin{bmatrix} \sum_{i=1}^{3} B_{Xi} u_i & \sum_{i=1}^{3} B_{Yi} u_i \\ \sum_{i=1}^{3} B_{Xi} v_i & \sum_{i=1}^{3} B_{Yi} v_i \end{bmatrix}. \quad (1)$$

Herein, **F** is the deformation gradient, **I** is the 2nd-order identity tensor, and $B_{Xi}$ and $B_{Yi}$ are the derivatives of the shape functions in the *X*- and *Y*-directions, respectively. The deformation gradient was then used to compute the Green-Lagrange strain $\mathbf{E} = 0.5(\mathbf{F}^T\mathbf{F} - \mathbf{I})$. Next, the principal strains were determined and classified as the circumferential or radial principal strain based on their principal orientations. These principal strains were finally rotated back to the undeformed configuration for visualization purposes.

## RESULTS

***TV Leaflet Residual Strains are Heterogeneous*:** The circumferential and radial principal residual strains for one representative heart are provided in **Figure 2**. These results clearly show the pre-strains vary across the tricuspid valve leaflets in both principal directions. However, the septal leaflet and posterior leaflet generally have positive circumferential and radial principal strains, respectively. In addition to the quantified principal pre-strains, these vectors within the visualizations show the how aligned the principal strains are near the circumferential direction (**Fig. 2a**) or the radial direction (**Fig. 2b**). These orientations are generally consistent across the three leaflets.

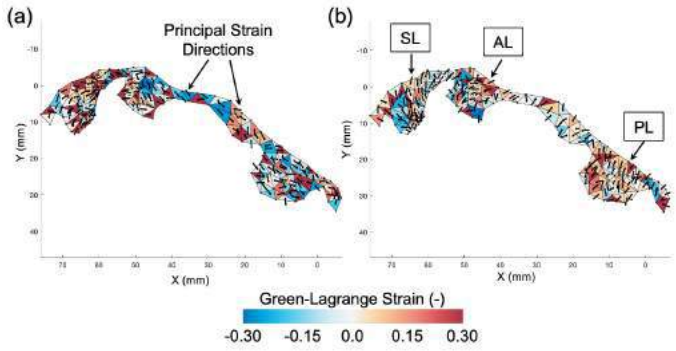

**Figure 2. Computed principal pre-strains and directions for a representative TV in the (a) circumferential, (b) radial directions.**

***Comparisons of the Average Leaflet Pre-Strains*:** The average principal pre-strains for each leaflet are shown in **Fig. 3**. These results indicate large variations across the three TV leaflets, further suggesting that the pre-strains are *leaflet-specific* and could be stemmed from the microstructural differences in the leaflets. Among the three leaflets, the posterior leaflet (PL) appears to exhibit the greatest variability while the anterior leaflet (AL) has the smallest variability in the radial direction.

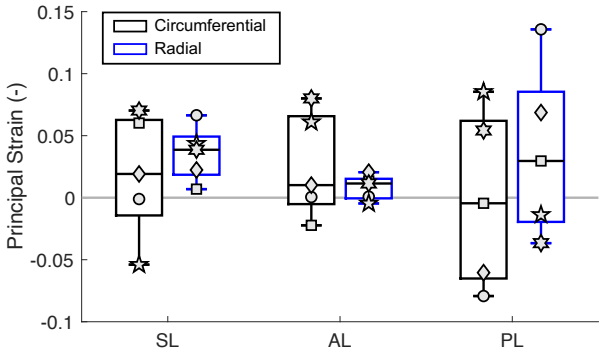

**Figure 3. Average circumferential and radial pre-strains for each TV leaflet. The individual heart is indicated with a unique symbol.**

## DISCUSSION

This study has provided the first experimental characterization of the TV leaflet pre-strains. This new approach allows us to determine the 3D configurational changes in the tricuspid valve following excision from the heart. As a result, we can obtain a rich description of the tricuspid valve leaflet pre-strains that was previously unobtainable. Our analysis has shown the pre-strains are heterogeneous and but generally align with the two anatomical directions – the circumferential direction and the radial direction. Furthermore, these pre-strains were found to be leaflet-specific, which agrees with the previous microstructural and mechanical observations in the literature [7-8].

One key extension of the present work is the incorporation of the quantified pre-strains into *in-silico* simulations of the TV [10]. By considering the accurate pre-strains, we can acquire more realistic predictions of the tricuspid valve behavior. Further, the acquired pre-strain information can be compared to information acquired from polarized spatial frequency domain imaging [11] to relate the quantified strains to the underlying collagen fiber architecture. This would be an important first logical step to establish the mechanics-microstructure relationship as well as the underlying growth and remodeling [5].

## INTRODUCTION

Tracheal stenosis is a rare congenital anomaly that most commonly occurs due to improperly formed tracheal cartilage rings.[1] It generally presents with long segment airway narrowing that leads to respiratory restriction as an infant. It is estimated that only 10-17% of patients can be managed with observation, while most undergo surgery.[2] Slide tracheoplasty (ST) is the preferred option for long segment tracheal stenosis (LSTS) due to its high success rates.[3] The procedure itself is technically challenging and involves complete transection and reconstruction of the trachea.

Due to relatively low surgical volumes and a heterogeneous patient population, it is difficult to study outcomes and compare techniques in ST. Prior anatomic studies have shown that all types of ST increase the diameter and volume of the stenosis, and that a beveled tracheal transection incision as opposed to a straight incision results in a longer post-operative tracheal length.[4] From a physiological perspective, little is understood about how surgery changes tracheal airflow. There are no studies examining pre- and post-operative airflow after ST. While increased length is optimal from a surgical and healing perspective, it is unknown how varying surgical techniques affects airflow.

Computational fluid dynamics (CFD) has been increasingly used in the past decade to investigate and quantify airflow dynamics in healthy and diseased airways [5,6]. In this study, we use 3D printed trachea models and CFD to analyze the airflow dynamics before and after ST and compare airflow between different surgical techniques. By leveraging these advanced modeling tools, we aim to improve the clinical understanding of LSTS and demonstrate which surgical technique yields the optimum anatomy and airflow physiology.

## METHODS

A high-resolution (0.357x0.357x 0.6mm slice thickness) computed tomography (CT) imaging scan was obtained (SOMATOM Force Dual Source CT, Siemens Healthineers, Erlangen Germany) from a two-year-old patient with complete tracheal rings and LSTS. Data from this scan was converted to a stereolithographic (STL) file and the lumen, cartilage, and soft tissue were modeled in Mimics/3-Matics (Materialise, Leuven Belgium). Model printing was performed on a Stratasys J750 digital anatomy printer (Stratasys Ltd., Rehovot Israel) using multi-materials (Agilus 30 for the wall, Structural-Frame 4 [pre-set] for cartilage rings, and Gel-matrix for the lumen). ST was performed on the models by a single pediatric airway surgeon using a combination of surgical technique variables. The main surgical variable was the type of tracheal transection incision angle (90º [straight], 45º anterior-superior to posterior-inferior bevel [AP bevel], and 45º posterior-superior to anterior-inferior bevel [PA bevel]. After transection, ST was completed on the models using standard instruments and suture. Post-operative CT scans of the models were obtained for analysis. Luminal surfaces were analyzed by single rates to derive measures of length, area, and volume measures.

For each surgical technique (straight, AP bevel, PA bevel) and the pre-treatment control, quasi-steady CFD simulations of peak inhalation were run to evaluate conditions of maximum respiratory resistance. Unsteady RANS simulations were performed in StarCCM+ (v16, Siemens, PLM Software, Plano, TX, USA) with a K-omega SST model. Polyhedral meshes with approximately 1 million cells are generated from the CT scans of each condition. Flow extensions equal to 20x the airway branch diameter were added to the trachea and bronchi. To model inspiratory flow, a mass flow boundary condition was applied at the trachea equal to 100 mL/s, and a flow-split ratio of 0.32:0.62 is applied at the R:L bronchus, respectively. The inflow rate is based on an estimated tidal volume for a patient of this age and the bronchi flow-splits were derived from the volume ratio of the patients segmented right and left lung. Simulations were run for 0.15s with a dt of 5e-5s. Computed airflow metrics are averaged over the last 0.075s.

For each surgical technique, we computed the total airway resistance, ($R = \Delta Pi/iQ$), where $\Delta Pi$ and $Q$ are the inlet-to-outlet

pressure drop and flow-rate respectively, maximum and average velocity, and viscous dissipation (Θ). Viscous dissipation is defined as:

$$\Theta = 0.5\,\mu_t \int \boldsymbol{S} : \boldsymbol{S}\, dV + \int \rho\epsilon\, dV \qquad (1)$$

Where $\boldsymbol{S}$, the stress tensor, is defined as $[\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^{\boldsymbol{T}}]$, $\mu_t$ is the effective viscosity, ρ is the fluid density and $\epsilon$ is the turbulent dissipation rate.

## RESULTS

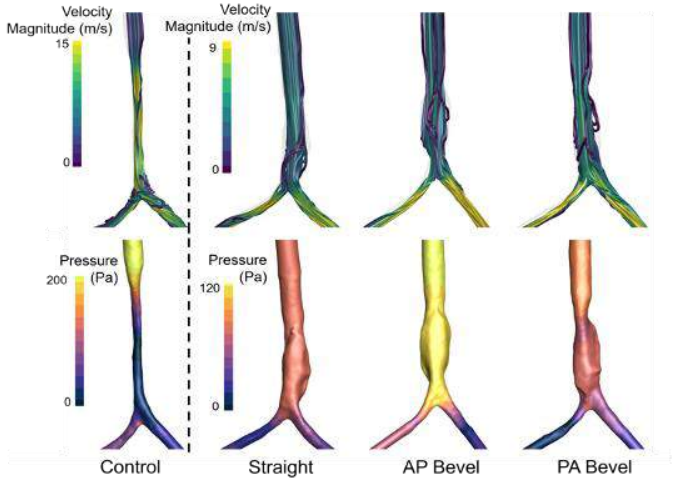
Nine STs were performed including three replicates of each incision. Pooling all combinations, ST decreased total tracheal length by 36% ($p<0.0001$), decreased the length of the stenotic segment by 43% ($p<0.001$), increased cross-sectional area at the midpoint of the stenosis by 397% ($p<0.0001$), and increased total tracheal volume by 53% ($p=0.003$). Comparing all beveled incisions to all straight incisions, beveled incisions resulted in a longer final trachea by an average of 3.9mm (95% CI: 2.7-5.0), corresponding to about 9.5% of total post-operative tracheal length ($p<0.0001$).

CFD simulations of peak inspiratory flow were performed for each surgical technique and the pre-operative control (Table 1, Figure 1)

**Table 1: Computed airflow metrics for each surgery condition. For each metric, both the value and percentage change as compared to the control condition are shown.**

| | Total Airway Resistance (Pa/(mL/s)) | Maximum Velocity (m/s) | Average Velocity (m/s) | Viscous Dissipation (mW) |
|---|---|---|---|---|
| Control | 2.3 | 19.9 | 5.1 | 14.2 |
| Straight | 0.8 (64%) | 11.2 (44%) | 3.9 (24%) | 4.2 (70%) |
| AP Bevel | 0.9 (60%) | 13.2 (34%) | 42 (18%) | 5.2 (63%) |
| PA Bevel | 0.9 (57%) | 14.0 (30%) | 4.0 (20%) | 5.5 (61%) |

**Figure 1: Velocity streamlines (top row) and pressure contours (bottom row) of the pre-operative condition and each surgical technique. Colormap ranges are identical for all operated models, but different from the control.**



Each of the three surgeries was shown to reduce total airway resistance, maximum and volume averaged velocity, and viscous dissipation compared to the pre-operative condition with median reductions of each metric of 59%, 34%, 21%, and 63%, respectively. Relative differences between of each of the three surgeries was not significant.

The velocity streamlines and pressure contour maps (Figure 1) highlight the accelerated flow and pressure-drop through the primary tracheal stenosis. The flow conditions of each of the surgically repaired models exhibit similar behavior with a significant reduction of velocity and pressure-loss along the trachea, as compared to the pre-operative condition. The locations of maximum velocity and contributions to overall breathing resistance moved to the mainstem bronchi, representing a change to a more physiologically normal location.

## DISCUSSION

This is the first study to use CFD to analyze respiratory airflow changes in tracheal stenosis before and after ST. Additionally, it is the first to use CFD to analyze differences in ST surgical technique. As previously demonstrated, a beveled tracheal transection incision increased post-operative tracheal length and volume as compared to straight incisions.[4] There were no statistically significant CFD differences between surgical techniques, including straight incision compared to bevel, or between differing directions of incision bevel (45º AP versus PA). ST overall significantly decreased tracheal airflow pressure drop, velocity, and resistance. Computed energy expenditure during breathing decreased by 63% after surgery. These results mirror the clinical benefit observed from ST, reiterating it as a helpful treatment for patients suffering respiratory compromise from LSTS.

From a surgical technique standpoint, improving post-operative tracheal length without compromising airflow has important clinical implications. Due to the length preserved with improved tissue conservation, beveled incision tracheal segments require less distance to slide and therefore have less tension at the site of repair than straight incision tracheal segments. Relieving tension wherever possible may result in lower rates of complications such as anastomotic dehiscence, granulation, and re-stenosis, which can be life threatening.[7,8]

This study also represents the first reported use of 3D printed tracheal models used in combination with CFD. These models provide several advantages. They eliminate the variability that exists in the heterogeneous LSTS patient population. Using the same model for all procedures allows for direct comparison of simulated surgical variables on a single patient, which cannot be done in an in vivo model. Utilizing 3D printed models also allows for study of morphological and physiological changes immediately before and after surgery. Live comparisons rely on patient-based imaging or procedures, which can have inconsistent timing and are often avoided when possible in the pediatric population.

Overall, 3D modeling is an easy and safe way to study surgical variables in airway surgery. Adding CFD analysis allows for a more comprehensive understanding of the physiological changes introduced in tracheal stenosis after surgery. Our data show that a beveled tracheal incision has the added benefit over a straight incision of preserved tracheal length and does not compromise physiological airflow improvements. Taking these factors into consideration, we conclude that a beveled incision is the optimal surgical technique for ST.

# 3-DIMENSIONAL IMAGING OF THE MURINE VAGINA USING TO-PRO-3 IODIDE AND EOSIN WITH DUAL INVERTED SELECTIVE PLANE ILLUMINATION MICROSCOPY

**Jasmine X. Kiley (1), Mari J.E. Domingo (1), Guang Li (1), Diego R. Gatica (1), J. Quincy Brown, Ph.D. (1), Kristin S. Miller, Ph.D. (1)**

## INTRODUCTION

Pelvic floor disorders, such as pelvic organ prolapse (POP), and increased trauma risk are associated with increasing age and loss of elastic fibers [1]. While the etiology of pelvic floor disorders is not fully understood, disruption of elastic fibers and changes in the vaginal microstructure likely contribute. In clinical practice, the standard stain for two-dimensional (2-D) vaginal imaging is Hematoxylin and Eosin (H&E), which allows quantification of basic metrics such as layer thickness, collagen content, and elastin content [2]. However, 2-D histology involves sectioning three-dimensional (3-D) tissues into thin 2-D slices, limiting the ability to identify critical spatial relationships and orientations of extracellular matrix (ECM) components found in native tissues that are critical for tissue structural integrity and function.

Towards this end, dual-view inverted selective plane illumination microscopy (diSPIM) enables 3-D imaging of large samples with high resolution, more accurate cellular quantification, and increased image detail [3,4]. Similar approaches have been used to image human prostate tissue [4,5] and *C. elegans* embryos [6], utilizing stains such as TO-PRO-3 Iodide and Eosin (T&E). To date, how the 3-D vaginal architecture changes with pregnancy and other biological processes is not well defined. Further, it is unknown whether T&E stained vagina tissues are direct analogs of tissues stained with H&E.

Therefore, this study first sought to investigate the validity of T&E as an analog to H&E in murine vaginal tissue. In addition, T&E staining was utilized in diSPIM imaging to visualize vaginal morphology before and after pregnancy. It was hypothesized that pseudo-colored images from T&E fluorescent images would be analogous to H&E images and that diSPIM imaging with T&E staining will allow visualization of the 3-D architecture of the vagina. If successful, 3-D diSPIM imaging of the vagina will be an integral component of understanding changes in vaginal microstructure during pregnancy, aging, and POP.

## METHODS

**Stains.** TO-PRO-3 Iodide (Thermo Fisher Scientific, Waltham, MA) was dissolved to [0.1% v/v] solution with PBS and [0.2% v/v] Triton X-100. The tissue was stained with TO-PRO-3 Iodide, dehydrated, stained with Eosin Y, then optically cleared with Ethyl Cinnamate. Stains were applied directly to tissue sections without further modification.

**Animal Use.** A total of n=12 mice were used in this study. For H&E and T&E comparison, n = *9* nulliparous Fibulin-5 C57BL/6 x 129 SvEv female mice were used (IACUC approved). The mice comprised three different genotypes: wildtype (*Fbln5* ), haploinsufficient (*Fbln5* ), and deficient (*Fbln5* ) with n = 3/group. To evaluate the feasibility of 3-D imaging, three female CD-1 mice aged 2-3 months were used with nulliparous (n=1), day 18 gestation (n=1), and five days postpartum (n=1) (IACUC approved).

**2D Verification of Fluorescent Analog T&E.** Mice were euthanized via carbon dioxide inhalation, and the vagina was dissected. The vagina was then perfusion fixed in 10% formalin at the physiologic length and mean *in vivo* pressure for 24 hours. Physiologic length and *in vivo* pressure values were obtained from previous work [7]. Next, tissue samples were embedded in paraffin. 4μm thick sections were obtained in the circumferential plane and randomly allocated for either standard H&E or fluorescent T&E staining. To resemble H&E, the dual-channel fluorescent images were then pseudo-colored through a MATLAB algorithm.

**3-D diSPIM Imaging.** Mice were euthanized by guillotine without anesthesia and vaginas were extracted and stained as described above. The vagina was then mounted and imaged using lasers with wavelengths of 488 nm (eosin) and 640 nm (TO-PRO-3). The diSPIM imaging process was adapted from prior work [8]. The resulting images were pseudo-colored to resemble H&E. After 3-D diSPIM imaging, vaginal samples were sectioned (4 μm) and stained for H&E. The 2-D

slices were obtained at matched depths from the 3-D samples to identify key structures within the tissue.

**Data Analysis.** For the 2-D T&E images, qualitative analysis was performed by comparing key structures with the corresponding H&E tissue slice (Figure 2). Additionally, 3-D diSPIM images were viewed with Amira (Thermo Fisher Scientific) software. 2-D cross-sections were extracted to visualize morphological features before and after pregnancy (Figure 3).

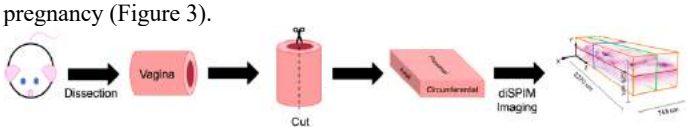

**Figure 1. Dissection and preparation of murine vaginas to obtain 3-D diSPIM images. Vaginas were cut axially and unrolled from cylindrical to rectangular geometry before mounting onto the diSPIM system [8].**

## RESULTS

A qualitative comparison between images stained with H&E versus T&E showed similar structures using both stains on FFPE tissue sections (Figure 2). Epithelial rugae were observable in the proximal view of the vagina in both the nulliparous (Figure 3A) and five days postpartum (Figure 3B) samples. Layer identification was possible in the cross-sectional images extracted from the 3-D diSPIM images (Figure 3A and Figure 3B). Upon qualitative observation, muscularis layer thickness was greater in the circumferential and axial views of the five days postpartum sample compared to the nonpregnant sample.

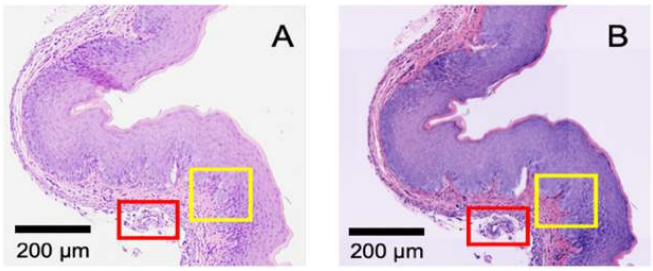

**Figure 2. Representative H&E (A) and T&E (B) images of Fibulin 5. demonstrated that fluorescent analog T&E was similar to the standard H&E stain. Specific regions of interest, including epithelial rugae (yellow) and a large vessel in the adventitia (red) showed further similarities between stains.**

## DISCUSSION

The qualitative and quantitative comparisons demonstrated that T&E staining was a high fidelity H&E analog (Figure 2). By applying the pseudo-color process within MATLAB, the same morphological features were visualized in both H&E and T&E images. This finding agreed with prior work that validated DRAQ5 and Eosin against H&E as a fluorescent analog [9].

The destructive nature and limited sampling frequency of standard 2-D histology techniques limits ability to identify spatial relationships and orientation of important ECM components such as collagen and elastic fibers. Volumetric histological imaging with the diSPIM system permitted visualization of T&E-stained vaginal tissue with easy sample mounting and isotropic resolution in three dimensions, thus enabling the analysis of structural relationships between cells and ECM components. Upon qualitative observation, the muscularis in the postpartum sample was thicker than the nulliparous sample. This observation was in agreement with findings in ovine samples [10].

Further imaging of multiple samples at both time points is needed to account for individual variation in vaginal morphology. A limitation to T&E was the inability to differentially stain collagen and elastin, which are proteins of high interest in the vagina. Further studies are needed to validate a fluorescent stain specific to these proteins compatible with diSPIM. To employ T&E's use in 3-D imaging of the vagina using the diSPIM system, future investigations include identifying changes in vaginal morphology throughout pregnancy, postpartum healing, and prolapse progression.

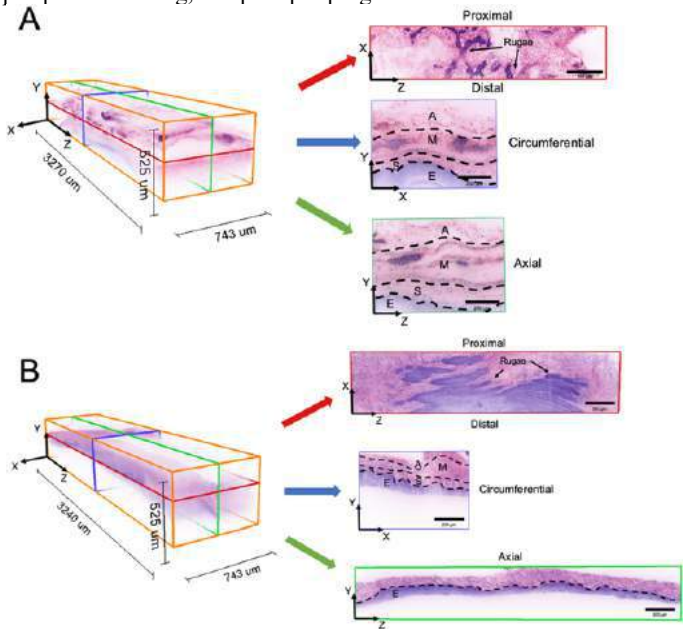

**Figure 3. XZ, XY, and YZ orthoslices extracted from 3-D diSPIM volumetric images of the nulliparous (A) and 5 days postpartum (B) vaginal samples. The XZ plane represented the vaginal plane from the proximal to the distal section. In this plane, the rugae of the epithelial layer was identifiable according to the purple staining of the nuclei of the epithelial cells (A, B). Along the Y direction from top to bottom of the sample, the rugae observed first in the XZ planes signify a section of epithelium which was thicker than other adjacent sections. The next observable layer along the Y direction was the sub-epithelial layer, which indicated that these rugae are "penetrating" into the sub-epithelium. The XY plane represented the circumferential plane of the vagina after being cut, and the vaginal layers were outlined as follows: E=epithelium, S=subepithelium, M=muscularis, A=adventitia, (A, B). The YZ plane represented the axial plane of the vagina across sample depth and the nulliparous vaginal layers were outlined (A), while the 5 days postpartum sample showed an identifiable epithelial layer (B).**

# DESIGN AND INITIAL OPTIMIZATION OF A CENTRIFUGAL LEFT VENTRICULAR ASSIST DEVICE

**Huang Chen (1), Shweta Ashishkumar Karnik (1), Jeyan Kirtay (1), Lakshmi Prasad Dasi (1)**

(1) Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA

## INTRODUCTION

Left Ventricular Assist Device (LVAD) is used as an effective treatment for end-stage heart failure patients. However, severe complications, including thrombosis, stroke, and bleeding, are common. Past studies have shown that the blood damage associated with the supraphysiologic shear stress [1, 2] in the device is the cause for those complications. The mechanical forces generated by the rotating components destroy blood cells, leading to hemolysis; and activate platelets, causing thrombus formation. It is crucial to optimize the LVAD design to achieve minimal blood damage. In this work, we first designed a parametric centrifugal LVAD model and built a computational framework to assess blood damage. Subsequently, preliminary design optimization was carried out. Results from two models are compared and discussed.

## METHODS

An experimental parametric centrifugal LVAD has been developed at Georgia Tech (Fig.1a), based on the industry-proven design concept [3]. A Matlab script was used to generate the LVAD blade profile and the volute shape with different parameters. As illustrated in Fig.1b, the parameters that control the geometry and their ranges are: inlet diameter ($D_1$=10-15mm), rotor diameter ($D_2$=20-35mm), leading-edge angle ($\beta_1$=5-30°), trailing edge angle ($\beta_2$=10-60°), number of blades (z=3-8), blade thickness (d=1-4mm), blade tip gap size (distance between the blade tip and cutwater) (h=1-4mm), blade wrap angle ($\varphi$=30°-200°), and outlet diameter ($D_3$=10-20mm). Current optimization has been focused on the rotor, and the targeted quantity is the hemolysis index, a measure for blood damage, at the design condition of 5L/min and 3000 RPM. Three sample blade profiles generated by the code are shown in Figure 2. The rotors are named by their leading-edge angle followed by the trailing-edge angle ($\beta_1$-$\beta_2$). The inlet/outlet diameters are $D_1$=10mm and $D_2$=30mm, respectively. The initial design (20-60) is shown in Figure 2a, while

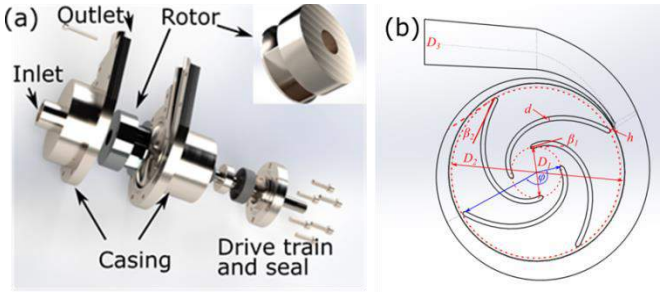

**Figure 1: (a) The experimental LVAD model and (b) design parameters.**

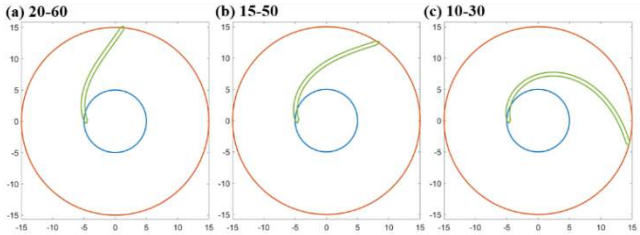

**Figure 2: Parametric rotor blade profiles.**

Figure 2c shows the rotor after optimization (10-30). There are four blades per rotor and the magnet attached to the top of the rotor was omitted in this initial optimization study.

A CFD model was developed in Ansys Fluent (Canonsburg, PA) to assess the performance and blood damage using the mesh motion method. The rotor and casing are defined as separate domains, and the interface between them slides freely to create the rotating motion. The 3D mesh was generated with mostly unstructured tetrahedral elements in Ansys Meshing. Boundary layer mesh was created by inflating the surface mesh, and the inner mesh layers were able to resolve the

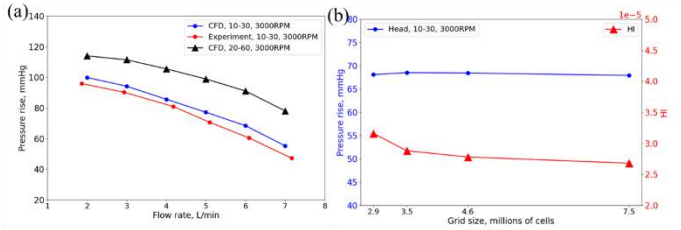

**Figure 3: (a) Performance comparison between experiments and CFD simulations. (b) Head rise and HI computed on different mesh grids.**

viscous sublayer. Blood was modeled as a Newtonian fluid with a density of 1060kg/m$^3$ and a viscosity of 3.5cP. Turbulence was modeled by the *k-ω* SST model. The reported quantities were the average of 3 consecutive rotor revolutions. A benchtop hydrodynamic testing was carried out to validate the CFD simulation. The results in Figure 3a have shown good agreementbetween the CFD and experiment for the 10-30 rotor at 3000RPM.

A hybrid Lagrangian/Eulerian hemolysis model was used, which is described in [4] as the model $C_E$. The hemolysis index (HI) is defined by the ratio of free hemoglobin to the total hemoglobin ($H_b$), $\mathrm{HI}(\bar{\tau}, it) = \Delta H_b / H_b$. The scalar stress $\bar{\tau}$ is defined by Eq1, where $\sigma$ is the stress tensor.

$$\bar{\tau} = [\frac{1}{6}\sum_{i,j}(\sigma_{ii} - \sigma_{jj})^2 + \sum_{i,j}\sigma_{ij}\sigma_{ij}]^{0.5} \quad (1)$$

The HI is calculated by a power law that includes the scalar stress and exposure time as defined in Eqn.2. The constants (a, b, c) are defines as (0.77, 3.075, $3.31\times10^{-6}$) following [5].

$$\mathrm{HI}(\bar{\tau}, it) = c\bar{\tau}^a t^b \quad (2)$$

Note that these constants and relations are empirical, and Reynolds stresses are not considered. Although the model might not provide the exact results, it is sufficient for the current optimization purpose. The HI is reported as the mass-weighted average at the outlet. A mesh independence study was carried out, and the results are shown in Figure 3b. The performance predicted by the CFD model is not affected much by the mesh size, while HI is very sensitive to it. In the following study, a mesh size of around 5 million was used.

## RESULTS

The current optimization step focuses on the blade leading and trailing edge angles, and two models: the original rotor design (20-60) and the optimized rotor (10-30), are compared. The head rise curve (Figure 3a) has shown the performance of the 20-60 rotor is much higher throughout the entire flow rate range. However, the 10-30 rotor causes much less blood damage (Figure 4), especially at low flow rates. For both models, HI is high at a low flow rate and decreases drastically at around 5L/min before rising again at high flow rates. The trend seems to be consistent with that for the efficiency, which peaks around 5L/min for both models. However, if HI and efficiency are compared across the models, higher efficiency does not suggest lower blood damage. For example, at 2L/min, both models have similar efficiency, but the 10-30 rotor causes much less blood damage.

The contours of velocity magnitudes (in the stationary reference frame) and HI at 5L/min are shown in Figure 5. This cross-section is located at the center of the rotor span. The vectors in the rotating reference frame have shown large recirculating regions for the 20-60 rotor (Figure 5a). HI is high in the recirculation region (Figure 5c) due to the long exposure time. While for the optimized rotor, the flow follows the blade profile without separation (Figure 5b). As a result, there is much less associated blood damage (Figure 5d). The velocity near the casing wall is high for the 20-60 rotor (Figure 5a), which is consistent with the higher performance for the model. However, the HI near the casing is significantly higher for the 20-60 rotor (Figure 5c) when compared with the optimized one (Figure 5d).

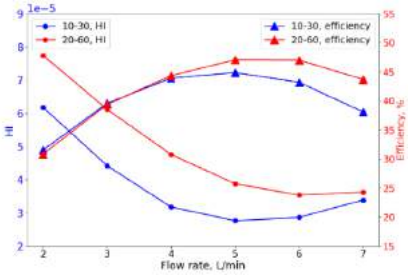

**Figure 4: HI and efficiency comparisons between the initial design and the optimized rotor.**

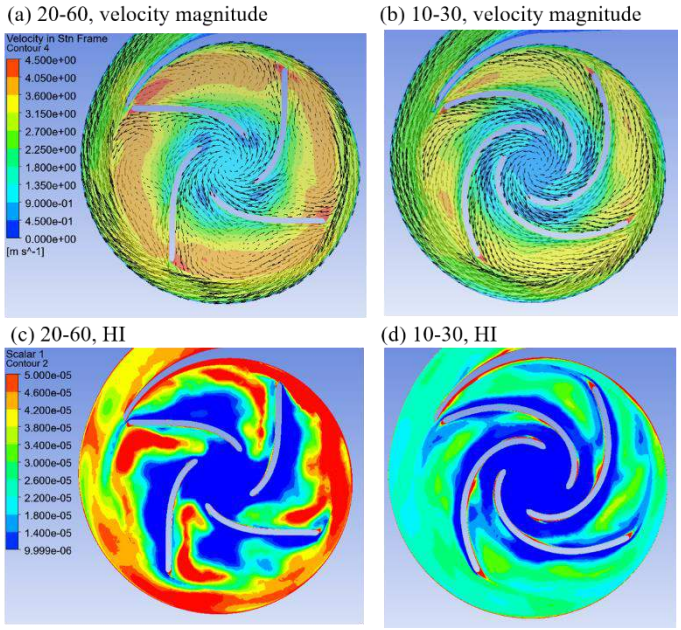

**Figure 5: (a, b) Flow and (c, d) HI comparisons between (a, c) the initial design and (b, d) the optimized rotor at 3000RPM and 5L/min. The color contour in (a, c) are computed in the stationary reference frame and the unit is m/s. The vectors in the rotor domain are plotted in the rotating reference frame.**

## DISCUSSION

A parametric LVAD model was design at Georgia Tech and initial optimization aimed at reducing the hemolysis has been carried out. Results have shown that the performance predicted by the CFD model matches well with experiments. It was found that the hemolysis index is very sensitive to the mesh grid size through a mesh independence study. The increase in blade angles increased both the performance and HI. The high HI is caused by the higher velocity near the casing and the large-scale separation in the rotor passage for the original rotor. The optimized rotor eliminates the flow separation thereby reducing the blood damage. Future work will focus on using advanced machine learning strategies to optimize the LVAD design.

# AN IN-VITRO STUDY OF THE FLOW PAST A TRANSCATHETER AORTIC VALVE USING TIME-RESOLVED 3D PARTICLE TRACKING

**Huang Chen (1), Yasaman Farsiani (1,2), Lakshmi Prasad Dasi (1)**

(1) Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA
(2) Nationwide Children's Hospital, Columbus, OH

## INTRODUCTION

Three-dimensional flow field downstream of a transcatheter aortic valve was studied using time-resolved 3D particle tracking velocimetry. A fully refractive index matching imaging setup allows for unobstructed optical access downstream of the valve. Around 4,000 particles are tracked through three cardiac cycles. Velocity fields in a Cartesian mesh are obtained and analyzed by implementing a constrained interpolation algorithm.

## METHODS

An idealized aortic root model with three sinus lobes was made by cast PDMS. The wall thickness is at least 10mm to ensure minimal deformation during the cardiac cycle. A 26mm Edwards SAPIEN 3 (Edwards Lifesciences, Irvine, CA) transcatheter aortic valve was mounted inside the aortic chamber, with commissures aligned with the sinuses. The aortic root model was placed in the vertical left heart pulse duplicator flow loop shown in Figure 1. The model was tested under physiological conditions of 60 beats per minute, 120/80 mmHg, and an averaged cardiac output of 5 L/min. The working fluid was a mixture of water, glycerin, and urea, matching the viscosity of blood and the refractive index of the PDMS silicone. Undistorted optical access was achieved in the aortic root. The aortic flow rate was measured by a Transonic ultrasonic flow probe (Transonic Inc., Ithaca, NY) upstream to the aortic valve chamber. Aortic pressures were monitored across the valve using two Deltran transducers (DPT-200, Utah Medical) to ensure physiological conditions. The pulsatile pump used in this flow loop was a custom-built pneumatic bladder pump connected to a compressed air supply and controlled by a LabVIEW program.

Time-resolved 3D-PTV was used to measure the trajectories of the tracer particles in a 3D volume covering the entire aorta model downstream of the valve stent. The model was placed in a chamber filled with the same working solution (Figure 1). Four Phantom high-

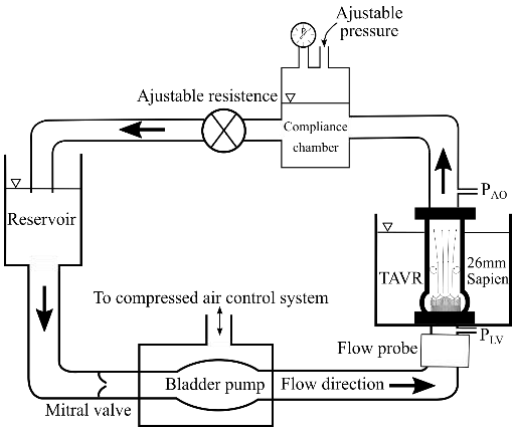

**Figure 1: Sketch of the pulsatile left heart simulator with the aortic root model.**

speed cameras (VEO 440l, 2560×1600 Pixels, 10μm pixel size) with 60mm Nikon lenses were used to record the particle images through four optical windows (Figure 2). The inner two cameras were separated by 60 degrees, while the outer two were separated by 140 degrees, satisfying 3D imaging conditions. The aorta was illuminated by a thick laser volume, expanded by a series of optics from a high-speed Nd:YLF double cavity laser beam. Scheimpflug adapters were used to ensure proper focus was achieved throughout the entire field of view. The imaging system and the laser were synchronized by a programmable timing unit (LaVision GmbH) and controlled by a desktop computer. The flow was seeded with fluorescence particles, and corresponding band-pass filters were used to filter out unwanted reflections. The data was acquired at 1,100 frames per second, and the flow in 3 consecutive cardiac cycles was recorded. The imaging

system was carefully calibrated in a two-step calibration process. First, rough calibrations of the cameras were obtained by placing a 3D

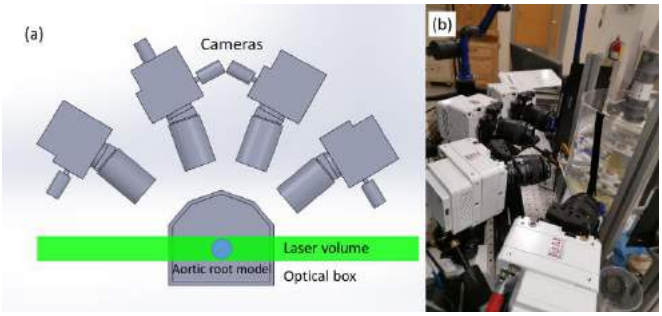

**Figure 2: 3D PTV experimental setup**

calibration target at the center of the laser volume. Second, a fine volume self-calibration [1] was carried out to reduce the residual calibration error to below 0.2 pixels. The optical transfer function (OTF) was calculated and used in subsequent particle detection algorithms [2]. Particles were tracked throughout the entire flow field by the Shake-the-box algorithm [3] implemented in DaVis 10 (LaVision GmbH). The tracking error of a single particle can be as low as 0.1px, much more accurate than the cross-correlation-based particle image velocimetry

## RESULTS

Around 4,000 individual particles were tracked in the $30\times30\times50mm^3$ volume. Two sample snapshots of the particle tracks are shown in Figure 4, representing the early systole (Figure 4a) and diastole phases (Figure 4b), respectively. The shear layer between the forward aortic jet and the surrounding fluid is clearly visible.

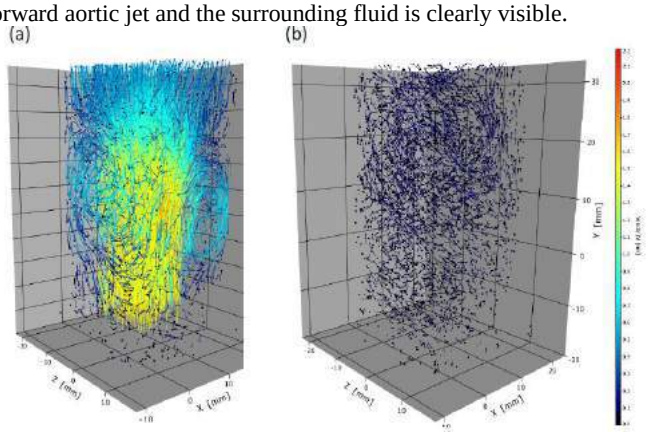

**Figure 3: Sample particle tracks color-coded by instantaneous velocity magnitude at (a) early systole and (b) diastole phases.**

The discrete velocity fields from the particle tracking were interpolated onto regular Cartesian grids using the second-order constrained cost minimization method described in [4]. The final 3D grid spacing is 0.8mm. Figure 4 shows the flow field at peak systole. At this phase, the flow field is dominated by a strong aortic jet, whose peak velocity exceeds 1.5m/s. Strong shear exists between the jet and the ambient fluid. The star-shaped jet shown in Figure 4b resembles the valve opening geometry. While the jet is developing downstream, it entrains the fluid surrounding it. This entrainment process is shown more clearly in the cross-section view (Figure 4b), where the velocity vectors are pointing from the wall towards the jet. Apart from the antegrade aortic jet, there is a strong retrograde flow near the wall, whose magnitude can reach 0.5m/s. The flow is driven by the positive pressure gradient associated with the attachment of the aortic jet at the wall downstream. The retrograde flow eventually enters the sinus region of the valve, contributing to the washout there.

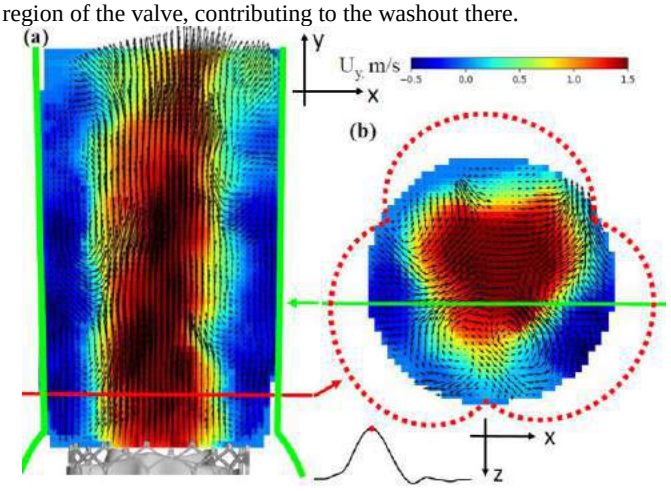

**Figure 4: In-plane vectors over $U_y$ contour at peak systole.**

The flow on the same plane at diastole is shown in Figure 5. The magnitude of the aortic jet has decreased significantly but is still entraining the surrounding fluid (Figure 5b). The scale and the magnitude of the retrograde flow increase, and it is still entering the sinus regions of the valve. However, this fluid has been in the aorta and might already be exposed to high shear associated with the jet. As a result, its contribution to thrombosis formation on the leaflets needs further investigation.

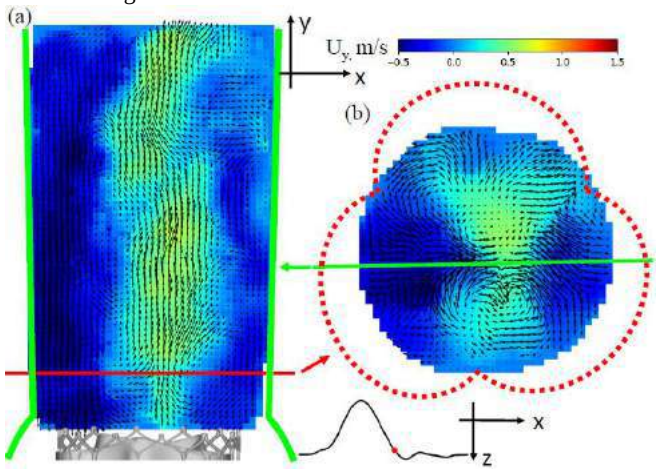

**Figure 5: In-plane vectors over $U_y$ contour at diastole.**

## DISCUSSION

Time-resolve 3D PTV was used in this study to quantify the particle trajectories and flow downstream of a transcatheter aortic valve. Detailed 3D flow features of the aortic jet were obtained and discussed. Future work will quantify the particle residence time and use it to study the effects of the retrograde flow on the washout in the sinus

## INTRODUCTION

Developmental dysplasia of the hip (DDH) is a biomechanical disease of infancy that is the leading cause of early-onset hip osteoarthritis in people >50 years of age.[1] DDH occurs when the femoral head and/or acetabulum is developing incorrectly, requiring intervention in 2 of 1000 infants. Early diagnosis and treatment with a Pavlik harness is used to encourage proper hip development in babies with DDH; however, 20% of these treatments fail, requiring surgery and increasing the likelihood of lifelong complications. Despite the prevalence of DDH and the lasting negative impact on some patients, there are few pre-clinical models that can be used to investigate innovative treatment strategies. Dodds et al. previously developed a knee-stifling technique to study hip instability in a porcine DDH model,[2] but the potential tissue-level changes to the hip joint induced by the stifle were not quantified. In order to understand the localized effect of DDH on tissue remodeling, and to select appropriate constitutive models for future pre-clinical computational studies, the mechanical behavior of the articulating surfaces must be characterized. The objective of this study is to the quantify viscoelastic mechanical properties at the hip between DDH-induced limbs and controls in distinct regions of the acetabulum and femoral head.

## METHODS

*Specimen Preparation*: Articular cartilage was harvested from two pigs: one farm pig that was induced with DDH (3 months old), and one healthy juvenile Yucatan micro-pig (12 months old). The DDH pig had the right knee stifled with a screw for 6 weeks prior to harvest resulting in outcomes consistent with hip dysplasia (e.g., reduced acetabular coverage).[2] After dissection, a 4-mm biopsy punch was used to extract cylindrical cartilage plugs in anatomical regions of the acetabulum and femoral head specified by Athanasiou et al. **(Fig 1A)**[3]. Three plugs were excised per region within the superficial zone of the cartilage for 21 specimens per pig (42 total). Custom-made tooling was used to trim and level the deep surface of the plug to produce a uniform thickness of approximately 0.8 mm (0.79 ± 0.04 mm) (**Fig. 1B**). Specimens were stored in 0.9% saline solution and frozen. On the day of mechanical testing, each sample thawed for 30 minutes and then equilibrated for approximately one hour in a 0.9% saline solution bath (21°C). The diameter of each specimen was measured using ImageJ (4.2 ± 0.1 mm).

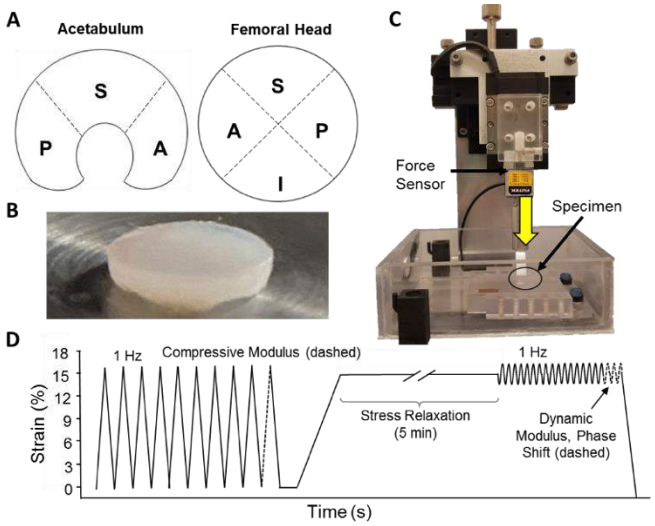

**Figure 1: Mechanical characterization protocol. A) Testing regions (A = anterior, P = posterior, S = superior, I = inferior) for B) porcine cartilage. C) A mechanical test system was used to compress the samples with D) a dynamic loading profile.**

*Mechanical Testing:* A custom mechanical testing system (**Fig. 1C**) applied unconfined compression tests with dynamic mechanical

analysis (**Fig. 1D**). Each of the forty-two cartilage plugs were placed between an acrylic platform and impervious platen (**Fig. 1C**). A preload of 0.05 N was applied to measure the reference thickness after soaking (0.92 ± 0.09 mm). The preload was followed by a preconditioning protocol of ten sinusoidal waves targeted to 16% strain at 0.5 Hz and a ramp to 14.4 ± 0.7% strain at a rate of 1%/s, followed by 5 minutes of stress relaxation. This strain level has been used to characterize articular cartilage in porcine and bovine studies[4,5], and the 5 minutes stress relaxation allowed the force response to equilibrate prior to dynamic testing.[6] Cyclic compression at 1% peak-to-peak amplitude was then applied for 20 cycles at 0.5 Hz.[6] The specimens were saturated with saline solution during mechanical testing but were not submerged. The compressive linear modulus was measured as the slope of stress-strain curve during the final preconditioning cycle. The equilibrium modulus was measured as the ratio of stress to strain at the end of the stress relaxation period. The dynamic modulus was calculated by fitting the last three sinusoidal compression cycles of the stress-time and strain-time data to a four-parameter sine wave function ($R^2 = 0.92 \pm 0.09$). The phase shift was determined by subtracting the fitted phase parameters from the stress-time and strain-time data.[6] The effect of treatment (DDH vs healthy), hip structure (socket vs head), and region on the mechanical properties were measured using MANOVAs in SPSS ($p < 0.05$) with a Bonferroni correction for multiple comparisons.

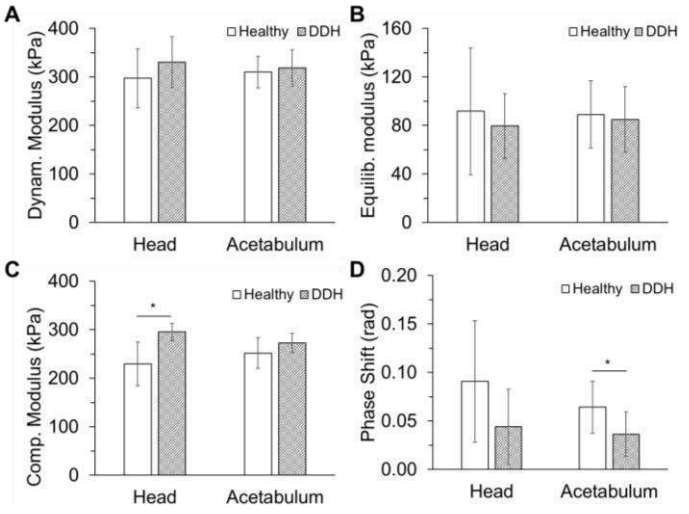

**Figure 2. Compressive properties of DDH and Healthy hip cartilage. No differences were observed in: A) Dynamic modulus, and B) equilibrium modulus, but DDH did have a higher C) compression linear modulus and a lower D) phase shift.**

## RESULTS

Mechanical properties of the cartilage specimens were shown to be similar for healthy and DDH hips (**Fig. 2**). No significance was found between the healthy and DDH hips for both dynamic modulus and equilibrium modulus (**Fig. 2A-B**), although the dynamic modulus for the DDH femoral head was 10% greater than the healthy pig ($p = 0.185$). The compressive modulus of the DDH femoral head was 22% greater than the healthy pig (**Fig. 2C;** $p = 0.01$). The DDH head and acetabulum had 52% and 43% less phase shift than the healthy pigs, respectively, although only the difference in the acetabulum was significant ($p = 0.024$) **(Fig. 2D)**. No significance was detected between regions on both the femur and acetabulum for the healthy and DDH hips. Additionally, no interaction was detected between treatment and region, nor between treatment and hip structure.

## DISCUSSION

This study characterized articular cartilage viscoelastic mechanical properties of DDH within a porcine model using unconfined compression testing. We were surprised to find that the superficial layer of cartilage in the infant DDH hip had mechanical properties similar to a juvenile healthy pig. When excising the cartilage plugs, the DDH hips had notably thicker cartilage and less subchondral bone than the healthy juvenile hips. Nevertheless, the superficial layer (0.8 mm thickness) had similar compressive properties that were largely unaltered in the DDH pig, with the exception of the compressive modulus in the femoral head. We did observe a decrease in the phase shift between the two pigs, which indicates that the DDH pig is less viscous and may suggest a reduction in aggrecan. It was also interesting to find that the mechanical properties did not have significant regional variations within the DDH hip. The acetabulum in the DDH hip experiences posterosuperior elongation,[7] and therefore we would have expected to see structural and mechanical changes within this region. However, the posterior and superior regions had compressive properties that were on average only 3% - 10% different than the other regions. These findings indicate that the structural changes in the hip socket observed in the DDH pig (e.g. reduction in acetabular coverage; data not shown) are not associated with alterations in cartilage mechanical properties. It is important to limit the interpretation of this data to the superficial zone, as we may have measured mechanical differences if cartilage plugs were drilled past the subchondral bone, since the older juvenile pigs experience greater ossification.

The compressive properties found in this study were compared to values reported in the literature. The average equilibrium modulus for the porcine specimens (86.2 ± 35.2 kPa) was about 70-80% less than published values for bovine and human cartilage using unconfined compression.[4,8] One reason for the mechanical differences is likely due to the bovine and human studies using on average thicker plugs (~1.5 mm). The phase shift for the pig specimens (0.060 ± 0.047 rad) was less than the reported phase shift for human articular cartilage (0.17 - 0.26 rad),[4] but was consistent with materials primarily comprised of collagen (0.06 rad).[4] The fact our results are closer to 0.06 rad seems reasonable since the superficial layer of cartilage is composed primarily by tightly packed collagen fibers.[9]

A principal limitation to the current study is that the forty-two experiments we conducted were from two porcine hips. Additionally, the contralateral DDH hip was excluded from this study based on a prior imaging analysis which found that the contralateral limb did not develop as a normal hip; therefore, it would not have served as a healthy control. Future experiments are planned with a greater sample size to calculate material parameters that are representative of a greater population of DDH and healthy porcine infant hips.

This study has established a baseline characterization of the cartilage mechanical behavior in a DDH induced porcine model and has provided new insight into the mechanobiology of DDH. Data from this study will be used for the calibration and validation of a finite element model for DDH hips that can serve as an investigative tool to encourage clinical advancement in this understudied disease.

# WHY DON'T BATS TEAR THEIR ROTATOR CUFFS DESPITE REPETITIVE OVERHEAD MOTION?

## INTRODUCTION

Rotator cuff tears often arise when humans exert substantial forces during repeated overhead motions. Such tears are common in humans, affecting more than 50% of patients over the age of 65 and resulting in pain and loss of shoulder function [1]. Yet, these tears are apparently uncommon in bats, which perform repetitive overhead motions during flight. Despite improvements in surgical techniques and postoperative rehabilitation, restoring glenohumeral joint stability after rotator cuff repair remains a clinical challenge [2]. To gain insight into strategies that might inform improved treatment, we therefore investigated the structure and function of the bat rotator cuff.

Bats and humans share a common quadrupedal ancestor, but evolutionary adaptations likely compromised human glenohumeral stability as posture changed from pronograde to orthograde. Stable glenohumeral joints, with mobility largely restricted to the sagittal plane, evolved into the less stable joints that allow bipedal primate shoulders to rotate and move in the coronal plane [3]. Bats, however, evolved a balance between glenohumeral mobility and stability, enabling a large, multiplanar, overhead range of motion [4]. In this study, we performed comparative anatomy to better understand the functional advantages of the bat shoulder versus that of the mouse, a similarly-sized quadrupedal animal. We hypothesized that the anatomy of the bat glenohumeral joint would differ from that of the mouse in ways that are consistent with improved stability. Results supported the hypothesis, and provided potential insight into techniques for surgical repair of the human rotator cuff.

## METHODS

Sample preparation: All animal procedures were approved by the Columbia and Brown University Institutional Animal Care and Use Committees. Shoulders harvested from adult (12 weeks) C57BL6/J mice (n=5) and *C. perspicillata* bats (n=5) were dissected then fixed in three different positions: full shoulder extension ("P1"), intermediate ("P2"), and full shoulder flexion ("P3"). To consistently identify the angle between the scapular spine and the humerus for each fixation position, gait (mouse) and flight (bat) analyses were used. Species-specific 3D-printed fixtures were used to fix samples at each position. *MicroCT Imaging:* Samples were scanned at 55 kV peaks with 145 mA intensity, and 19.3 μm resolution (Skyscan 1272, Bruker). *Anatomical Measurements:* Images were reconstructed (NRecon, Skyscan), and bone parameters measured (Skyscan CT Analyzer). The scapular linear index was determined as the ratio of scapular width to length. Supraspinatus and infraspinatus linear indices were calculated using the length from the medial aspect of the spine to the superior or inferior angle. Glenoid retroversion was measured via the anterior facing angle between the body of the scapula and the glenoid face on the axial cross section. Supraspinatus outlet area was measured as the area posterior to the coracoid, inferior to the acromion, and within the acromial arch. Supraspinatus clearance, measured as the vertical distance between the humeral supraspinatus insertion and the bottom face of the acromion, was measured for each sample at each of the three positions. Glenoid curvature was measured using the circle tool in ImageJ to create the best fit circle. The arc length of the glenoid was calculated using the angle from the anterior to the posterior glenoid rim. *Modeling:* Using a mathematical model based upon our imaging of the bony anatomy at the enthesis of mouse and bats, we predicted how strength, stiffness and toughness of the tendon enthesis would vary with loading direction and the bony ridge abutting the enthesis [9]. Simulations considered 20 linear elastic, brittle fibers of thickness $w$ = 10 μm and spacing $s/w$ = 1.5 abutting a cylindrical bone ridge of aspect ratio $B/A$=1 (mouse) or $B/A$=0.4 (bat). Strength, stiffness, and toughness were normalized against idealized scenario where tightly packed fibers ($s/w$ = 1) were pulled to failure uniaxially at 90° (Fig. 3). *Statistical Analysis:* All data are shown as mean ± standard deviation. Statistical analysis was performed for all experiments using unpaired t-tests with Welch's

correction (GraphPad Prism 7). The threshold for statistical significance was defined at $p < 0.05$.

## RESULTS

The scapular index and infraspinatus index were both significantly larger in bats than in mice, while the supraspinatus index did not differ (Fig. 1a). Supraspinatus-acromion clearance increased when moving from full shoulder flexion to extension (i.e., from P3 to P2 to P1) in both bats and mice. However, the supraspinatus outlet area was significantly greater in bats compared to mice (Fig. 1b). The glenoid was retroverted in bats and anteverted in mice (Fig. 2a). Glenoid curvature and arc length were significantly higher in bats than in mice (Fig. 2b). Simulations suggested that the strength and stiffness of the supraspinatus tendon attachment are greater for the bat's flatter humeral head for the mouse's more circular mouse humeral head (Fig. 3). The higher strength associated with the bat is maintained over a broad range of loading angles, while toughness was slightly reduced, particularly at very low abduction angles.

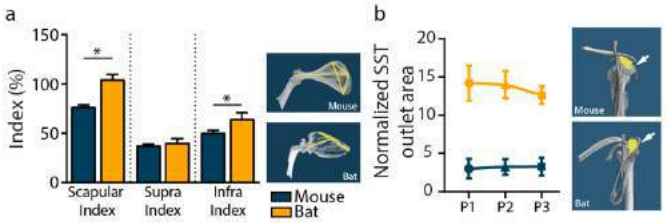

**Figure 1. (a) Scapular, supra and infra indices (b) Supraspinatus outlet area (yellow) normalized by attachment area.**

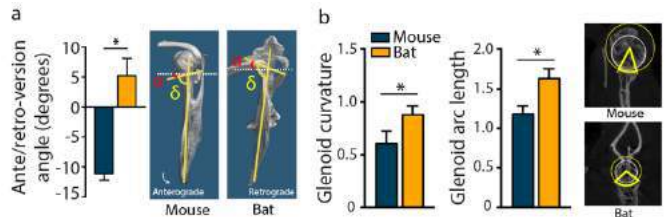

**Figure 2. (a) Glenoid ante/retroversion (α angle; α=δ-90) for mouse and bats. (b) Glenoid curvature and arc length for mouse and bats.**

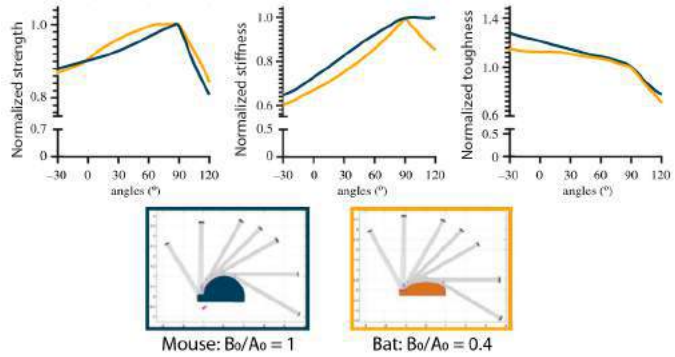

**Figure 3. Mathematical modeling suggested that the flatter bat humeral head may increase strength and stiffness relative to the mouse, across a broad range of abduction angles. This comes at the expense of reduced toughness.**

## DISCUSSION

Comparison of the glenohumeral joints of two similarly-sized species (i.e., bats and mice) suggested functional adaptations of bat shoulder anatomy in relation to the demands of flight.

***Evolutionary perspective.*** From the evolutionary perspective, the bat's enlarged scapular and infraspinatus indices imply changes to muscle size and orientation. The supraspinatus index, however, was conserved across species. Because the infraspinatus and supraspinatus stabilize quadrupedal gait, the bat's enlarged infraspinatus index suggests a larger role for the infraspinatus in the bat's glenohumeral stability. This also hints at adaptation to relieve stress on the supraspinatus, as does the observation that the larger supraspinatus outlet in the bat, providing more space for the supraspinatus to pass under the coracoacromial arch to prevent the supraspinatus shoulder impingement commonly seen in overhead-throwing athletes [5]. Although the glenoid is anteverted in mice, it is retroverted in bats, analogous to the retroverted glenoids reported in high-level overhead-throwing athletes [6]. This may enable more rotation of the joint while limiting capsular tension. The bat glenoid is more concave, encapsulating more of the humeral head when compared to mice. In addition, the bat has a larger glenoid arc length and articulating surface area with the humeral head, thus providing more stability while maintaining mobility.

***Insight from quantitative analysis of the data.*** The idea of the bat's deeper glenoid providing more stability is consistent with shoulder instability patients, who present with loss of glenoid concavity and a flatter glenoid morphology [8]. Our modeling revealed potential reasons why the humeral head shape at the supraspinatus tendon attachment may affect stability. The models suggested that flatter attachment in bats relative to mice lead to increased strength over a wide range of motion, enabling bats to perform high stress flight by optimizing strength over a wider range of motion than needed for walking. The mechanical energy needed to dislocated the humeral head increases with concavity of the glenoid and stiffness of the rotator cuff tendons: compression of the convex humeral head into the concave glenoid fossa stabilizes the shoulder. Dislocation requires displacing the humeral head laterally over the glenoid lip, with a force that increases with tendon stiffness. The energy required for this displacement is thus directly related to the shape of the glenoid. In bat's case, where the glenoid is deeper and more concave, more energy is required for shoulder dislocation.

***Implications for rotator cuff repair.*** From the clinical perspective, adaptations in the bat provide insight into reshaping of the anatomy in surgical repair. Features of bat shoulder anatomy, such as a larger infraspinatus fossa, a larger supraspinatus outlet area, a retroverted and concave glenoid, and the flattened shape of the humeral head attachment may contribute to increased stability of the glenohumeral joint at the extremes of range of the repetitive overhead motions of flight. Bone reshaping to increase the height of the glenoid lip may improve stability, and bone reshaping to increase the area of the supraspinatus outlet may reduce impingement. Future studies of the bat rotator cuff muscles and tendons will further test these hypotheses about passive stabilization of the shoulder and rotator cuff repair techniques to decrease supraspinatus stress.

# EFFECTS OF INTERFACE MATERIAL ON CARTILAGE FLUID LOAD SUPPORT IN THE MIGRATING CONTACT AREA

**Jamie M. Benson (1) and David L. Burris (1,2)**

(1) Department of Biomedical Engineering, University of Delaware, Newark, DE, USA
(2) Department of Mechanical Engineering, University of Delaware, Newark, DE, USA

**INTRODUCTION:** The unique ability of cartilage to withstand contact stresses (0.5-10 MPa) that exceed its modulus (0.1-1 MPa) with minimal strains and friction coefficients is largely attributed to fluid load support (FLS) through interstitial pressurization via the migrating contact area (MCA). According to the MCA theory, cartilage achieves and maintains maximum fluid load support if the contact migrates across the cartilage surface faster (*Pe>>1*) than the fluid can escape [1].

Based on our recent experimental and analytical modelling we have found that not only is FLS dependent on speed, it is also dependent on range of motion [2]. In order to maintain maximum FLS the range of motion, or migration length, needs to be at least 10 times the contact diameter. However, cartilage can sustain non-zero FLS when migration lengths are smaller than the contact diameter—suggesting that small movements (i.e., fidgeting, drifting) can mitigate fluid loss during prolonged period of standing. Our previous work utilized smooth spherical glass probes as the contacting interface between bovine osteochondral explants. This allowed for a well-controlled and idealized experimental environment that allowed us to isolate the interfacial mechanics in each sample. However, this setup is not representative of the joint.

The objective of this study was to replicate our previous study using a cartilage-on-cartilage setup to determine: 1) FLS in an in-vitro setup and 2) if the glass-cartilage setup accurately describes the in-vitro interfacial contact mechanics.

**METHODS:** *Sample extraction:* Full thickness Ø 19 mm (N = 5) and Ø 6 mm (N = 1) osteochondral plugs were extracted along the centerlines of the medial and femoral condyles from 3 adult bovine stifle joints. Samples were rinsed in phosphate buffered saline (PBS) and stored in protease inhibitor solution at 4ºC. All tests were performed within 24hr of extraction to minimize the risk of enzymatic digestion-induced changes in material properties.

*In-situ characterization:* Samples were mounted to a reciprocating stage on a custom tribometer (Fig. 1A) and lubricated in 1X PBS. Normal force ($F_N$) and indentation depth ($\delta$) data were quantified first, under static conditions using a Ø 6.35 mm borosilicate glass probe to obtain sample specific material properties, then during sliding in the migrating contact area (MCA) configuration. Our previous in-situ observations with cartilage [3] showed that the contact geometry is best described by Hertzian mechanics, which we used to relate the contact

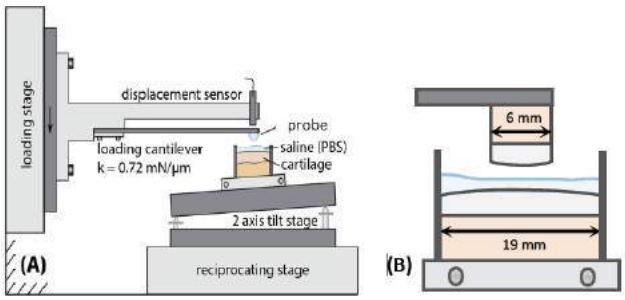

**Figure 1: (A) Schematic of custom tribometer and experimental setup. (B) Cartilage-on-cartilage experimental setup.**

radius ($a$) to the known probe radius ($R$) and the measured indentation depth ($\delta$) with Eq. (1).

$$a = \sqrt{\delta_s \cdot R} \quad (1)$$

The effective contact modulus ($E_c$), which depends on the material properties and sliding speed among other variables, is quantified experimentally with measured/known values of load ($F_N$), equilibrium tissue deformation ($\delta_s$), and probe radius ($R$), as described in Eq. (2):

$$E_c = \frac{3}{4}\frac{F_N}{R^{0.5}\cdot\delta_s^{1.5}} \quad (2)$$

At equilibrium under static contact conditions, load is supported entirely by osmotic pressure. With Eq. (2), the equilibrium contact modulus ($E_{c0}$) can be quantified by the force or deformation response during **static equilibrium** contact. During sliding, interstitial pressurization increases $E_c$ and reduces friction. At **dynamic equilibrium,** interstitial pressure, the fluid load fraction, the effective contact modulus, and the friction coefficient depend on material properties and the sliding conditions. We quantify the magnitude of fluid load support using the fluid load fraction (*FLS*), which varies between 0 and maximum fluid load fraction ($FLS_{max}$). As we have shown in a previous paper [3], fluid load support can be quantified experimentally based on $E_c$ and $E_{c0}$ using Eq. (3):

$$FLS = \frac{E_c - E_{c0}}{E_c} \quad (3)$$

*Tribological testing*: Each sample was first indented with the borosilicate glass sphere to a target load under static conditions until reaching equilibrium. Following equilibration, the next minute of data was used with Eq. (2) to determine the mean and standard deviation of the equilibrium modulus. Following static equilibration, the borosilicate glass probe was replaced with the Ø 6 mm osteochondral plug, as depicted in Fig 1B. Each sample was indented again to a static equilibrium in the cartilage-on-cartilage setup. Immediately following static equilibrium, a lateral stage began reciprocating at 1.5 mm/s ($Pe > 100$) over a maximum migration length ($S = 5$ mm) to establish the large Pe number and long migration length baseline ($FLS_{max}$). Reciprocation continued until a dynamic equilibrium was reached, which is defined < 0.3 $\mu$m/min change in indentation depth. Following dynamic equilibration, the migration length was reduced to $S = 2$ mm until the system reached a new dynamic equilibrium. This procedure was repeated for $S = 1$, 0.5, 0.2 and 0.1 mm in that order.

*Analysis and theoretical framework*: Methods for data analysis are described in depth in our previous publication [2]. Briefly, fluid load support was quantified across each migration length (*FLS*). To remove any sample specific material effects the relative *FLS* ($F^*$) was calculated by normalizing the FLS at each migration length by the maximum $FLS_{max}$ for that sample. Similarly, the relative migration length ($S^*$) was calculated by normalizing the migration length ($S$) by the contact diameter ($d$). The results were fit to our previously derived model equation, Eq. (4).

$$F^* = \frac{FLS}{FLS_{max}} = \frac{S^*}{S^* + \frac{\pi}{4}R^*} \quad (4)$$

We propose that the relative *FLS* ($F^*$) varies between 0 and 1 as a sigmoidal function of the relative migration length ($S^*$). *FLS* reaches 0.5 at a critical migration length, at which the rate of fluid exudation equals the rate of fluid recovery, which we define as the exudation ratio ($R^*$) in Eq. (5).

$$R^* = \frac{R_{exudation}}{R_{recovery}} \quad (5)$$

The relative *FLS* ($F^*$) and relative migration length ($S^*$) for each sample were plotted to obtain the exudation ratio ($R^*$). $F^*$, $S^*$, and $R^*$ values were compared with the values from our previous publication [2] using one-way ANOVAs where significance was determined by $p<0.05$.

**RESULTS:** Raw time-dependent force and indentation depth measurements from a representative cartilage on cartilage sample are plotted in Figure 2 with a representative glass on cartilage sample from our previous publication. Tissue deformation increased and normal force decreased similarly for both datasets starting at static equilibration throughout dynamic MCA testing. At the start of sliding across a S = 5 mm migration track, the system recovered a significant amount of fluid (decreased deformation) until dynamic equilibrium (fluid exudation rate = fluid recovery rate), as illustrated in Figure 2. Additional systematic fluid loss (increased deformation) was observed as the migration lengths

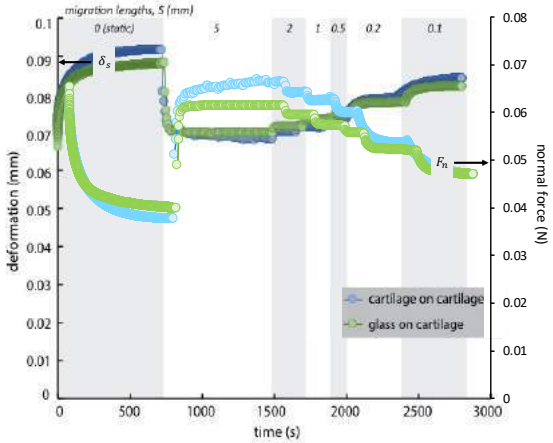

**Figure 2: Raw deformation (left y-axis) and normal force measurements (right y-axis) measurements vs. time for representative cartilage-on-cartilage (blue) and glass-on-cartilage (green) MCA experiments.**

were reduced. The relative *FLS* ($F^*$) vs. relative migration length ($S^*$) for each representative sample is plotted in Figure 3. Similarly, $F^*$ increased when $S^*$ increased for both samples. Using Eq. 4 from our previously described model [2], the exudation ratio ($R^*$) was calculated to be 0.102 and 0.101 for the cartilage-on-cartilage and glass-on-cartilage samples, respectively. There was no significance ($p>0.5$) in $F^*$, $S^*$ and $R^*$ values between the cartilage-on-cartilage setup and the glass-on-cartilage setup.

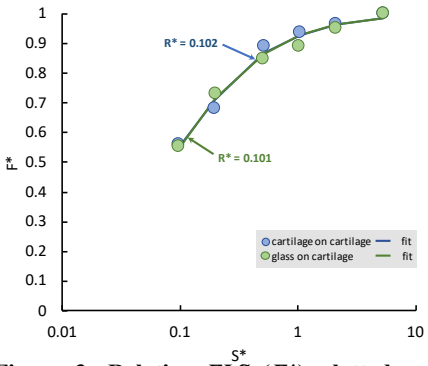

**Figure 3: Relative *FLS* ($F^*$) plotted vs. relative migration length ($S^*$) for representative cartilage-on-cartilage and glass-on-cartilage samples. Each dataset was fit to Eq. 4 to obtain the respective exudation ratios ($R^*$).**

**DISCUSSION:** This study demonstrates that the use of glass on cartilage setups in small-scale MCA experiments is an accurate experimental model of in vitro cartilage mechanics. More importantly, this work suggests that the use of the glass-cartilage setup can be more beneficial than the cartilage-cartilage setup. Unlike the stiff, impermeable glass probe, the cartilage probe was soft, porous and possessed material properties unique to that specific sample. During the cartilage-on cartilage testing, both surfaces were deforming and recovering fluid at different rates—making it impossible to separate the contributions made by each surface. Thus, mechanical properties can only be quantified for the system rather than independently for each surface. While the cartilage-on-cartilage system still provides valuable information, it doesn't allow the ability to isolate 1) the mechanisms driving fluid recovery and 2) which surface is dominant. Furthermore, glass on cartilage setups enable the ability to isolate key variable parameters (i.e. load/BMI, contact stress, etc.) that are vital in order to develop cartilage replacement materials and treatments for OA.

## INTRODUCTION

Rupture of intracranial aneurysms (IAs) is a catastrophic clinical event with a fatality rate of 45% [1]. Published models of rupture risk are based on patient and aneurysm characteristics discernable from current imaging modalities (e.g. aneurysm size and aspect ratio). From a biomechanics point of view, IA wall rupture is the mechanical failure of the wall tissue in the presence of wall stresses in excess of the tissue strength. However, accurate computation of aneurysm wall stress fields requires patient specific wall thickness measurements. Such data are rarely available from clinical imaging data for aneurysm patients due to the resolution of clinical scanners as well as the imaging modality. Wall thickness fields can be obtained ex-vivo from excised tissue and are reported to range from 16 um-550 um [2,3]. In this work, we leverage ten cases in our database for aneurysm patients that includes aneurysm specimens, surgical videos and pre-operative clinical images of the aneurysm and surrounding vasculature. Using high resolution micro-CT, we obtain a 3D model of each specimen, which is then mapped back to 3D model of the aneurysm and surrounding vasculature to create a patient specific 3D model. We then obtain for the first time, patient specific stress distributions in cerebral aneurysms, using the finite element method. We then compare normalized stress distributions to those obtained using constant wall thickness models.

## METHODS

Aneurysm tissue was harvested after surgical clipping from 22 patients with cerebral aneurysm from Allegheny General Hospital, Pittsburgh, USA, Helsinki University Hospital Helsinki, Finland and University of Illinois Hospital, Chicago, USA. Informed consent was signed by the patient before surgery and all study protocols were approved by the Institutional Review Board at both the University of Pittsburgh and respective sites. Before surgery, clinical imaging of the patient was taken, using 3-D rotational angiography (3DRA) or computed tomography angiography. During surgery an intraoperative video was obtained. Following harvest, the aneurysm specimen was kept in a dedicated cooled transport container submerged in HypoThermosol (Biolife Solutions, Bothell, WA), a preservation media, and transported to the University of Pittsburgh. After fixation in using 4% paraformaldehyde or 3% glutaraldehyde the specimen was scanned at a resolution of 6 μm using a micro-CT scanner (Skyscan 1272, Bruker, Belgium). The same protocol was followed for the samples from Helsinki except they were snap-frozen in the operating room and transported to Pittsburgh after fixation in 10% formalin. After 45 minutes of scanning, a stack of 3D images was reconstructed using NRecon reconstruction software (Bruker, Belgium). A series of image processing operations, including thresholding, Gaussian smoothing, and connected components filtering, were performed to clean up the segmentation mask in NRecon. Triangular surface meshes were then generated from the segmentation masks. Finally thickness of the triangular surface meshes were calculated in 3Matics Research (Materialise, Leuven, Belguim). Patient specific luminal surface geometries were created from 3DRA images using MIMICS (Materialise, Leuven, Belguim) [4-5].

Using Paraview (kitware, Clifton Park, NY) the surface mesh from microCT was aligned with the luminal surface mesh from 3DRA. Out of 22 aneurysm samples that were scanned under microCT, 10 samples could be mapped to the vasculature surface with the aid of surgical videos and intraoperative agreement. The thickness map generated from the microCT mesh in 3Matics was then mapped onto the luminal surface mesh using a custom algorithm implemented in both Paraview and MATLAB (Mathworks, Natick, MA). With the exception of one fusiform aneurysm, obtained during bypass surgery, the IA specimens were obtained following clipping and therefore only a subset of the aneurysm tissue was harvested. In the region surrounding the specimen region, a constant thickness of 200 um was prescribed and a two-ring smoothing algorithm was applied to the thickness field variable to remove artificially large gradients in the regions connecting measured

and prescribed thicknesses. Intramural stress values were reported for the region of the IA specimen. The thickness map on the current triangular luminal surface mesh was then mapped onto a quad surface mesh using a custom MATLAB (Mathworks, Natick, MA) script and Trelis (Coreform, Orem, UT). Finally, another custom code was used to extrude volumetric hexahedral elements from the quad luminal mesh for patient specific wall thickness maps. For each patient specific wall model, a second model was created with constant wall thickness by extruding a 200 um thickness volumetric hexahedral mesh from the same quad surface mesh. The IA wall was modeled as an isotropic, homogeneous hyperelastic material- a two constant power law neo-Hookean model, [6]. Material constants ($\alpha$=455 kPa and $\beta$=531 kPa) were regressed from previous uniaxial tests on unruptured aneurysms [7]. Finally, a custom finite element code was used to calculate maximum and minimum principal stresses, directions of principal stresses, and ratio of principal stresses under 120 mmHg of pressure applied on the luminal surface. Nodal values of the maximum principal stress were normalized by the respective sample average of the maximum principal stress. The 95$^{th}$ percentile values of the normalized stress were compared between patient specific and constant wall thickness models. The 95$^{th}$ percentile rather than absolute maximum was chosen to reduce artifacts from spuriously high nodal stress values.

## RESULTS

Average sample wall thickness ranged from 50 um to 800 um with a mean and standard deviation of 310 um ± 180 um, respectively. The average sample thickness was not normally distributed, with 77% of samples less than 300 um. The sample average maximum principal stress varied from 40 kPa to 240 kPa. Contour plots of normalized maximum principal stress for three samples and corresponding wall thickness maps are shown in Figure 1. Normalized 95$^{th}$ percentile

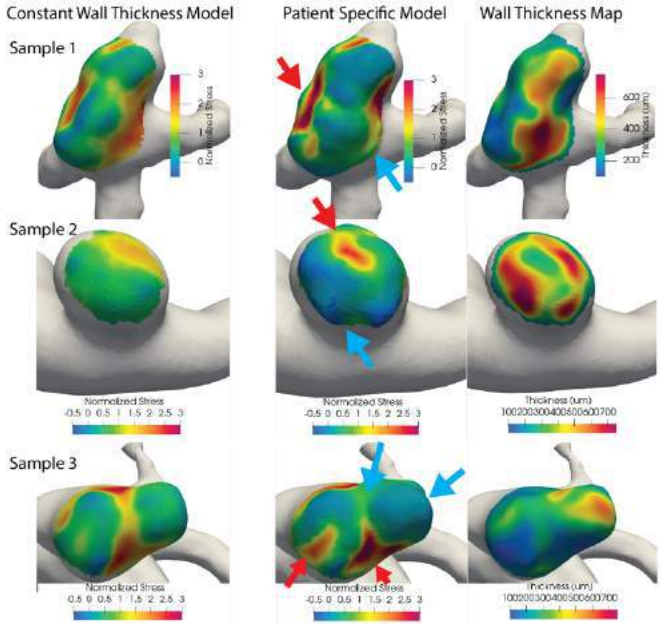

**Figure 1. Normalized maximum principal stress for constant and patient specific wall thickness models for three representative cases, columns 1 and 2. The wall thickness field for the patient specific model is shown in column 3. Blue arrows indicate locations of decreased stress and red arrows indicate locations of increased stress in the mapped versus uniform thickness model. Regions away from region of aneurysm specimen are shown in gray.**

maximum principal stress for each sample is shown in Figure 2. The 95$^{th}$ percentile of the normalized principal stress was elevated in the patient specific wall thickness model for nine out of ten samples, compared with constant wall thickness models (mean value of 2.03 vs 1.64, average difference of 39.79%).

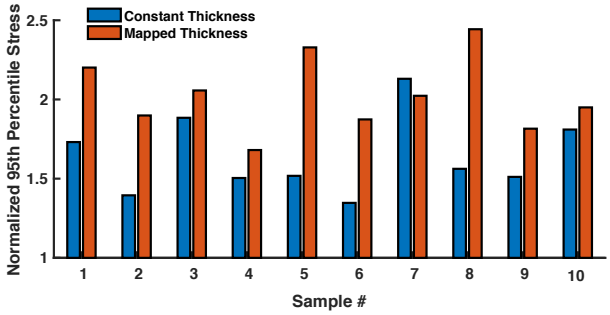

**Figure 2: Bar plot of 95$^{th}$ percentile of the normalized (by sample average) maximum principal stress.**

## DISCUSSION

We leveraged our data base for human aneurysms to calculate for the first time, the intramural stress in human cerebral aneurysms using patient specific values of wall thickness fields. The heterogeneous sample thickness was obtained using high resolution micro-CT analysis of the physical samples harvested during open brain surgery and mapped onto 3D reconstructions of the patient vasculature. As for other works, we found the wall thickness to be highly heterogenous. In this database, wall thickness ranged from 10 um - 1.2 mm and could increase by an order of magnitude within samples. We found the 95$^{th}$ percentile of the maximum principal stress ranged from 90 to 310 kPa. Prior work reported Cauchy failure stress in uniaxial testing for vulnerable aneurysm samples to range from 630 to 730 kPa, while in robust samples to be from 1.2 to 2.2 MPa [7].

Given the larger range in wall thickness in IA samples, in the absence of patient specific wall thickness values, biomechanical studies cannot provide reliable estimates of intramural stress. Here we explore the possibility that such models can provide reliable values of stress ratios (here, normalized stresses). The constant wall thickness model did capture many of the hot spots, Figure 1. However, the constant wall thickness models generally underestimated the intensity of the hot spot, red arrows in Figure 1. This finding is also reflected in results for the 95$^{th}$ percentile stress, which was nearly always higher in the patient specific model due to the existence of thinner regions that were not present in the constant wall thickness model.

There were limitations in this study. The IA sample was, with one exception, a subset of the IA sac and had to be merged to a constant wall thickness region. In the future, we can investigate the sensitivity of the solutions to this choice of wall thickness in the surrounding region.

## INTRODUCTION

The mechanisms responsible for Traumatic Axonal Injuries (TAI) are poorly understood. Mouse models are commonly used together with blunt impact experiments to understand the pathologies and neurophysiological deficits related to TAI [1], but the relationship between the initial impact, the subsequent motion of the mouse head and the brain tissue distortion is not well established. To address this gap, this study leverages a previously validated biomechanical model of the mouse brain to simulate recent CHIMERA (Closed Head Impact Model of Engineered Rotational Acceleration) mouse experiments [1,2]. The benefit of this approach is that the model's calculated strains in specific brain regions can be readily compared to pathological findings of axonal injury in living mice undergoing the same mechanical insult from head impacts. Results from such an analysis can also be compared to tissue-based thresholds of axonal injury taken from previous laboratory testing with different species, such as non-human primate, porcine and human biomechanical models [3]. This will help the biomechanics community gain insight into how TAI develops during injurious events such as a fall or automotive accident, and how mouse models can be leveraged to better understand the neuropathology for similar loading scenarios across multiple species.

## METHODS

In order to simulate the loading condition from the previous mouse CHIMERA experiments [1,2], two different finite element models (FEMs) were used. Each FEM serves a distinct purpose. The first FEM was based on coarsened segmented anatomy from a whole mouse body computed tomography imaging, and was used to simulate the initial skull deflection as the impactor struck the skull. Taking the kinematics of the interface between the skull and brain from this coarse FEM, the rigid body motion was subtracted, which allowed us to estimate the localized skull bending at the impact site over the frontal skull bone.

The second FEM consisted of high-resolution mouse brain anatomy derived from a diffusion tensor imaging atlas. Although this second FEM did not contain a skull, its brain strain response has been previously validated against experimental strain data, thus ensuring a realistic strain field response for dynamic head rotations in the sagittal plane up to 200 rad/s. Taking the skull deflection motion data from the first FEM of the whole mouse body, along with the experimental head marker motion data from the mouse impact experiments [2], the combined motion was applied to the boundary of the high-resolution mouse brain FEM. Brain strains were calculated for each time point of the simulation, with an element size of 125 μm.

Taking the skull motion from the whole-body mouse model (1st FEM) and applying it to the brain atlas model (2nd FEM) allowed for multiple tissue deformation metrics such as Maximum Principal Strain (MPS), strain rate (MPSR) and strain times strain rate (MPSxSR) to be calculated and readily compared to the simulation results of other species for Wu and colleagues [3].

## RESULTS

Figure 1 shows the high speed video of the CHIMERA mouse experiments from McInnes et al. [2], and the corresponding brain/skull kinematics calculated from the whole body FEM (first and second rows of Figure 1). Here, the whole body FEM simulated the initial skull deflection upon impact and the subsequent motion of the head. When the motion at the skull/brain interface was applied as boundary conditions to the high-resolution brain atlas FEM, the MPS distribution varied over time and by brain region. Observing the third row of Figure 1, the bottom left image shows the MPS distribution during the initial impact (t = 0.1 ms) due to skull flexure while the bottom right image shows the MPS distribution due to the subsequent head motion (t > 1 ms). During impact with the piston, the brain shows localized strain near impact location of the skull due to skull bending. As the head continues to move upwards, the strains in other parts of the brain begin

to increase, suggesting that the rapid head rotation following impact produces more severe brain tissue distortion.

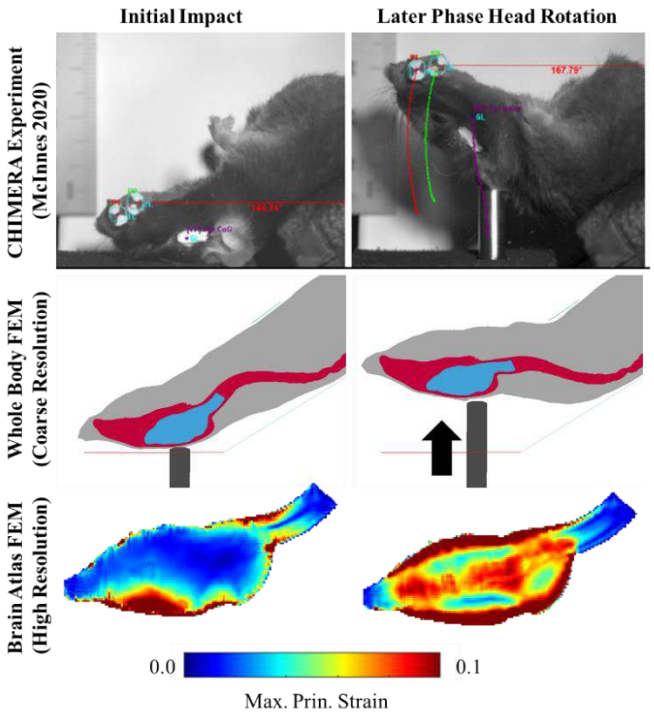

**Figure 1: Top row: High speed camera images CHIMERA experiments [2]. Middle row: whole body FEM simulating the skull deflection during impact. Bottom row: Strain distributions calculated by the high-resolution brain atlas FEM**

When the mouse FEM's 95$^{th}$ percent highest peak MPS, MPSR and MPSxSR values were compared to the non-human primate, human and pig FEM simulations from Wu et al [3], the results were mixed. Figure 2 shows the three deformation metrics from the mouse model (black circles) compared to the distribution of 25$^{th}$, 50$^{th}$ and 75$^{th}$ percentiles of the other species' mild traumatic brain injury FEM datasets (grey box plots). Here, the mouse strains (MPS95) are lower than the Wu 2021 results. However, the peak strain rates are higher than the other species FEM while the product of strain and strain rate (MPSxSR95) were comparable to the primate and pig simulations.

## DISCUSSION

The simulation results presented here have implications for comparing the biomechanical response of the mouse brain during impact experiments to other species, including humans. The first implication is that the brain strain is localized at the site of blunt impact due to skull flexure. As the head begins to accelerate upwards and rotate into flexion, the majority of the brain tissue experiences increased strain. According to the MPS calculations in the current study, the accelerative head rotation is the primary mechanism responsible for increased brain tissue distortion, and thus cellular injury. The diffuse strain patterns calculated by the high-resolution FEM reflect the pattern of axonal pathology examined in the live mouse experiments, where TAI was found in different regions across the entire mouse brain, rather than limited near the impact location of the skull.

The second implication of the current study is that the tissue deformation responses calculated during the CHIMERA simulation of mTBI in the mouse had mixed results when compared to other species. In the Wu study [3], the approximate MPS value of 0.3 was consistent across the three types of species. In the current study simulating mild traumatic brain injury in the mouse, the corresponding MPS was 0.13, which is approximately half the MPS associated with injury from the Wu study. On the other hand, the strain rate from this study was much greater than those in Wu's study (Figure 2). There could be several reasons why the current mouse results potentially differ from the other species. One reason could be the smaller size of the mouse brain which could respond quicker (higher brain strain rate) to a head motion but limit its development of strain magnitude. The porcine and non-human primate FEMs had larger brain masses, but experience similar angular velocities as the mouse during CHIMERA impacts [3]. Given the similar peak angular velocities between the two studies, the larger mass of the pig and primate brains might contribute to the difference in tissue strain experienced during loading.

While the mouse brain tissue strains are lower than those in the other species, the strain rates from the CHIMERA experiments were higher, which may result from differences in tissue material properties between the various species, as well as the mouse head potentially experiencing higher rotational accelerations those reported in [3]. The rate sensitivity of axonal stretching has been previously studied in the biomechanics community, but there is still a lack of consensus about the appropriate threshold for inducing TAI. In summary, the current study is a first step in investigating the mouse brain deformation response during CHIMERA experiments, and the implications for comparison to other species for a more comprehensive understanding of traumatic brain injury. This study adds to the body of knowledge for TBI research using animal models to gain insight for human TBI mechanisms where the having the tissue level equivalences across different species is important for biomechanical understanding and quantification.

## ACKNOWLEDGEMENTS

The National Health Mission Area at the Johns Hopkins Applied Physics Laboratory provided funding for this study as part of an internal research and development project. KTR was supported in part by the Hopkins Extreme Materials Institute during this effort.
