## INTRODUCTION

Endotracheal intubation (ETI) is the gold standard for the life-saving intervention of securing a patient's airway. In a combat setting, assessing the patient's airway is the second in priority when determining treatment. In a clinical setting, there is a large learning curve for clinicians to conduct proper intubations [3]. Additionally, the current clinical standard is a generic polymer endotracheal tube (ET) with significant drawbacks that has not had any substantial design advancements beyond materials used in almost 125 years [3]. Patients undergoing prolonged intubations, those being maintained on mechanical ventilation (e.g., en route care), or in prolonged field care, frequently experience health complications such as tracheal stenosis, pneumonia, and necrosis of the tracheal tissue [3]. Most of these complications arise from the current design of the ET tube. The current design is a mass-produced, large, inflexible, fixed-diameter, polyvinylchloride ventilation tube. Sizing is determined through patient's size and age. The current ET utilizes a thin filmed, pneumatically inflated cuff to secure the airway. This cuff is recommended to be inflated to a recommended pressure range of 20-30 $cmH_20$ and exerts radial pressure to the tracheal wall [3]. The current ET is not designed to be in place for more than 24 hours, although in practice it is frequently required by clinical need. The shape and actuation of the donut-shaped pneumatic cuff creates a relatively narrow ring-shaped interface with the trachea and concentrates most of the tissue pressure (and mechanical sealing) in a small annular anatomic area, which has been demonstrated to cause downstream complications [1-2]. Our research proposes a redesigned ET that replaces the standard ET cuff with a novel expanding cylindrical lattice enclosed in a thin silicone sheathing tube. The lattice removes the need for multiple sizes since it can expand through the entire range of adult standard ETs sizes. We hypothesize that this will enable the same fluid tight seal necessary to secure the airway with a lower maximum pressure due to more distributed contact forces.

## METHODS

The expanding lattices were made from an array of individual strips combined into a planar lattice that is rolled into a cylinder [3]. All lattices are composed of two sets of strips that are attached utilizing annular snap-fitting elements that secure the lattice while allowing actuation of the mechanism, which is radial expansion during axial contraction. Small ring shuttles are attached to the middle of the lattice by going over both sets of strips. The lattices were designed in SolidWorks and 3D printed using FormLabs Form 2 printer with their Durable Resin. Sheathing material was casted utilizing Ecoflex 00-20 silicone to have a thickness of 0.5 mm. The lattice is mounted onto a flexible, hollow aluminum rod by guiding the rod through the ring shuttles. A fishing line is run inside the aluminum rod and tied onto the top end of the lattice, creating a pulley system. The lattice is then actuated by applying tension to the fishing line.

A series of leak and pressure tests were conducted with the prototype lattice and the standard ET. For these tests, size 8 Shiley ETs were used for testing. Leak tests were conducted by inflating the ET cuff to a pressure of 20, 25, and 30 $cmH_20$ inside of 20 ml syringes for 10 trials conducted over a 1-hour period, as previously done in Mariyaselvam et. al. Once inflated, 4 ml of water was added on top of the seal and water was collected at the bottom after the hour period. The prototype was also inserted into 20 ml syringes and actuated to match the seal performance of the standard ET using an Instron 3345 Universal Tensile Tester. The experimental setup for both leak tests is shown in Figure 1. Fresh swine tracheas were chosen as pre-clinical models to examine the pressure applied by the lattice. Digital Image Correlation (DIC) was used to evaluate the forces exerted by the lattices and standard ET on the swine trachea. Strain measurements of the external surface of the phantom was collected and used to relate to internal pressure applied. The prototype and the standard ET were submerged into a phosphate-buffered saline (PBS) bath in a 4x4 in. acrylic container, as shown in Figure 2.

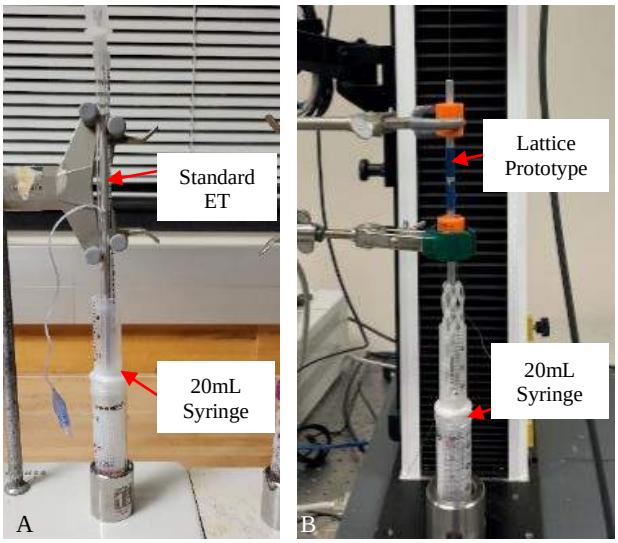

**Figure 1: Experimental setup for leak tests. A) Standard ET, B) Prototype Lattice.**

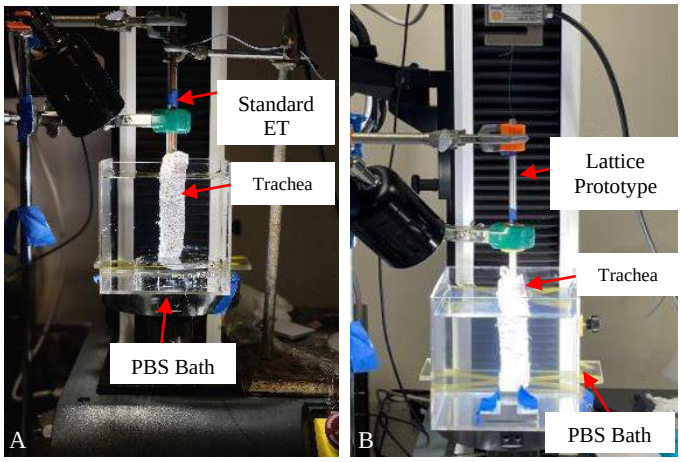

**Figure 2: Experimental setup for DIC experiment. A) Standard ET, B) Prototype Lattice.**

## RESULTS

From the leak tests, it was observed that the standard ET did not create a proper seal at the recommended range of 20-30 $cmH_20$. Utilizing the prototype, the leak performance was then evaluated by actuating to the tension needed to create a proper seal. The prototype was then expanded inside the tracheas by matching the tension needed to create a proper seal. The strain map results from the DIC experiments showed concentrated regions of deformation in the trachea as shown in Figure 3.

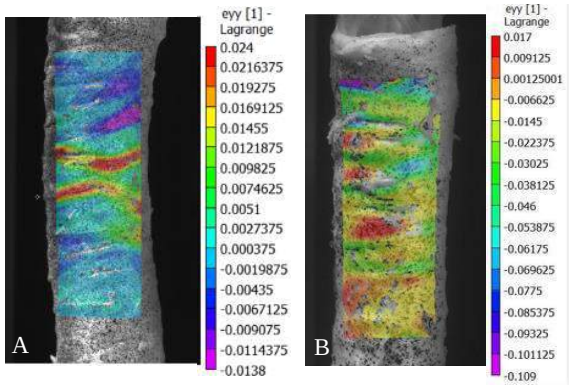

**Figure 3: Strain maps ($e_{yy}$) results from DIC experiments. A) Standard ET, B) Prototype Lattice.**

## DISCUSSION

The leak results observed using the standard ET does not match previous studies. Thus, the lattice prototype was not possible to accurately match the leak performance of the standard of care. These results may need to be further evaluated in order to make a proper comparison between the lattice prototype and standard ET. Previous studies showed small leaks for other brands while the results in this study show a complete leak. This might be due to using a different brand that has not been evaluated in previous studies.

The strain map results showed concentrated regions of pressure in the trachea for both devices. In the case of the standard ET cuff, the pressure is seen in a small, concentrated region. This supports previous studies where it has been described that this concentrated pressure may cause complications to the patient in prolonged intubations. In the case of the prototype lattice, the strain concentrations are distributed along a wider surface area. Different tracheas were used for each device, which could account to some small discrepancies in our results due to the different trachea sizes and geometries.

These results are insufficient to fully evaluate our hypothesis due to the discrepancies between the leak results in this study and previous studies. Future works will further examine the leak tests to assess the differences between our results and previous studies. Other brands of standard ETs will be tested to further compare the lattice prototype. However, this study shows that the novel expanding lattice has the potential to reduce the maximum pressure required to achieve a fluid-tight seal by distributing forces over a wider area. Due to the experimental issues encountered, additional studies will be necessary to properly assess this potential.

## ACKNOWLEDGEMENTS

This grant was funded in part by the San Antonio Medical Foundation. The authors would also like to extend thanks to Robert Brothers, Isaac Trevino, and Darnell Campbell for their support in the prototype development and background research of this work.

# A COMPUTATIONAL RULE-BASED SEMI-AUTOMATIC METHOD FOR CREATING LEFT ATRIAL FIBER ARCHITECTURE

## INTRODUCTION

With an aging population, atrial fibrillation (AF) affects 2.7 million to 6.7 million people in the United States. [1] Although, the $CHA_2DS_2VASC$ score is the most used risk-stratification scoring system to guide AF treatment, the measurement lacks personalization. To overcome this limitation, many researchers have started creating patient-specific computer simulations of AF. [2,3]

One of the challenges faced in the creation of patient-specific computational models of AF is the complexity of the atrial muscle arrangement.[4] While some studies have proposed rule-based models, others have created atlas-based models that require data mapping among anatomies.[5-8]

This work proposes a semi-automated rule-based algorithm for left atrial (LA) myofiber construction. The main fiber LA bundles are created in two layers: the endocardium, and the epicardium. The notable advantage of our approach is the ability to capture the main LA fiber bundles while solving only seven harmonic fields, leading to a straightforward and reproducible approach.

## METHODS

The anatomical regions and muscle fiber were created using seven harmonic fields, solutions of the partial differential equation:

$$-\Delta\phi_i = 0 \text{ on } \Omega \quad (1)$$

$$\phi_i = g \text{ on } \Gamma_D \quad (2)$$

$$\frac{\partial \phi_i}{\partial \boldsymbol{n}} = 0 \text{ on } \partial\Omega. \quad (3)$$

In which $i = 1, \dots, 7$; and $\Gamma_D$ is a side set. The side sets include landmarks such as lines (e.g., pulmonary vein, mitral valve), and points (e.g., the tip of the left atrial appendage, a point on the fossa ovalis). **Figure 1** shows the solutions of Equations (1)-(3) for a patient-specific geometry.

Given these seven harmonic fields, we construct an algorithm that subdivides the left atrium into subregions. To achieve the final region segmentation, we introduce thresholds that are used to control the extent of each subdomain. In the following, we use the gradients of the fields to define a local frame of reference, denoted as {**f**, **s**, **n**}, for each point in $\Omega$.

To compare the resulting fiber field **f** with other models available in the literature, we perform electrophysiology simulations. More specifically, we solve the monodomain equations:

$$\chi\left(C_m \frac{\partial V}{\partial t} + I_{ion}(\boldsymbol{y}, V) + I_{stimulus}\right) = \nabla(\sigma \nabla V), \quad (4)$$

$$\frac{d\boldsymbol{y}}{dt} = g(\boldsymbol{y}, V, t), \quad (5)$$

in which $\chi$ is the surface-to-volume ratio of cells, $I_{ion}$ is the transmembrane current density, $\sigma$ is the conductivity tensor and $C_m$ is the specific membrane capacitance. $I_{ion}$ is defined by a system of nonlinear ordinary differential equations, g, that depends on state variables $\boldsymbol{y}$. More specifically, Equation (5) is characterized by the Cherry-Ehrlich-Nattel-Fenton [9] human atrial ionic model.

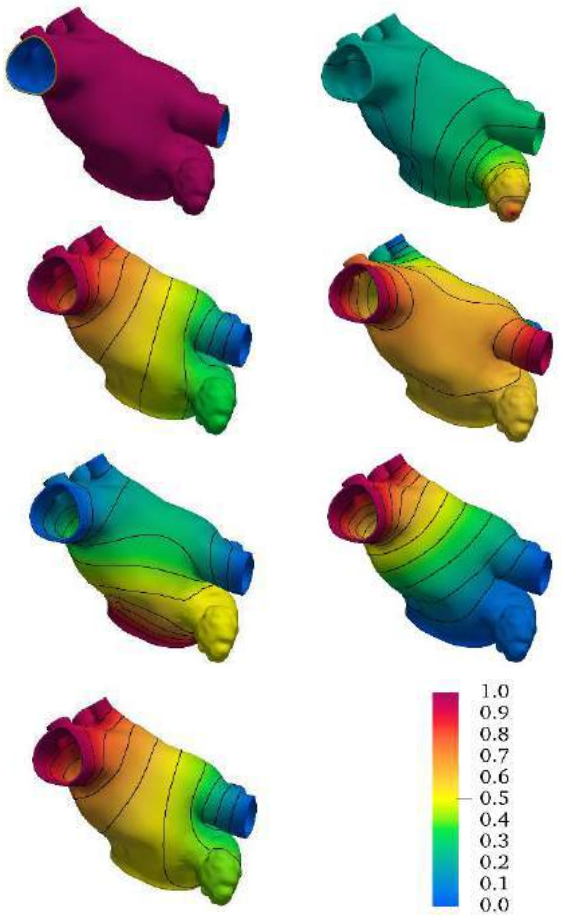

**Figure 1: Harmonic fields for a patient-specific anatomy.**

## RESULTS

The resulting fiber field on the endocardial and epicardial surfaces is shown in **Figure 2.** The interface between them is continuous and smooth.

**Figure 2: Endocardial fiber field (left panel), and epicardial fiber field (right panel) for a patient-specific anatomy.**

The electrophysiology simulation uses an activation function to initialize the signal. The support of this function lies on the anterior wall of the LA, and is defined by the intersection of a sphere centered at (-0.31, 3.35, 3.65) with radius 0.4 and the domain $\Omega$. **Figure 3** shows the comparison between local activation times using the fiber structure presented in this work and more complex fiber architecture developed by Fastl et al. [5]

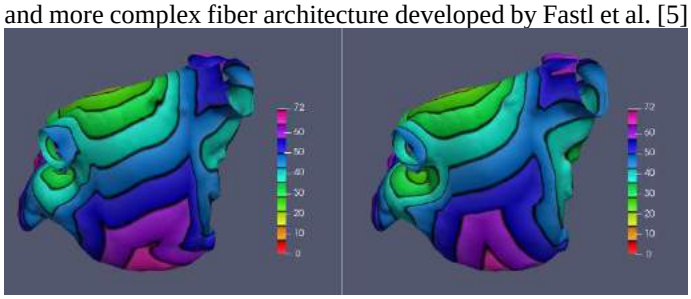

**Figure 3: Local activation times (milliseconds) for using the fiber model by the Fastl et al. [5] (left panel) in comparison to our approach (right panel).**

## DISCUSSION

This work developed a semi-automated rule-based method for fiber construction on left atrial anatomies. To compare our novel algorithm with those currently available, we simulated the propagation of the action potential using the monodomain model. Transmural fibers produced by our algorithm generate similar electrical activation patterns compared to the patterns generated using the more complex model by Fastl et al.[5]

Current approaches for defining the orientation of the atrial fiber bundles either require the definition of hundreds of landmarks or are overly simplistic. The notable advantage of our approach is the ability to capture the main LA fiber bundles while solving only seven harmonic fields, leading to a straightforward and reproducible approach.

Common approaches are well defined for common atrial geometries with four distinct pulmonary veins. However, most patients with AF do not fall in this category and have different pulmonary vein configurations. Our method extends to these scenarios easily.

# PERTURBED CYCLIC STRAIN IN CARDIAC FIBROBLAST CULTURES RESULTS IN A MECHANICALLY-INDUCED SENESCENT PHENOTYPE

**Stephanie E. Schneider (1), Adrienne K. Scott (1), Corey P. Neu (1,2)**

(1) Mechanical Engineering, University of Colorado Boulder, Boulder, CO, U.S.

## INTRODUCTION

Though initially characterized as an arrest in cell cycle, the cellular senescence phenotype has become more complex as we begin to understand the induction of senescence. Extrinsic factors such as oncogene disruption, irradiation, chemotherapy, developmental cues, and tissue damage have been shown to generate a new form of senescence, stress-induced senescence [1]. With exposure to these stresses, the cell will express an array of biomarkers intended to promote regeneration and repair. However, if the stress continues a senescent phenotype emerges, often characterized by cell cycle arrest, morphological changes, chromatin reorganization, and secretion of proinflammatory factors. This phenotype is linked with disease states such as cancer, osteoarthritis, and cardiac disease [1-3]. Furthermore, disease states often lead to changes in both biochemical and mechanical environments in the tissue. While the biochemical effects that induce a premature-stress senescent state are currently under significant exploration [2], the influence of how mechanical perturbations in disease states might influence this induction are still unclear.

Our objective of this study was to examine if perturbed strain magnitudes similar to those described with cardiac disease could induce a premature senescent-like state. In cardiac disease, cardiac fibroblasts (CFs) are one of the main cell types involved in the adaptive response to environmental cues in heart tissue. CFs regulate the remodeling and repair process, and the balance between healthy or fibrotic tissue [4]. To study how changes in the mechanical environment influence the CF, we chose a model system in which the cells have been shown to have immediate strain-dependent response. Studies have estimated heart contractility at 8% strain with decrease contractility to approximately 2% strain with injured or stiffened tissue [5]. Our simplified model examines the cardiac fibroblast phenotype during the mechanical transition observed in cardiac pathology with established senescent markers for biophysical alterations (i.e. nuclear area and Lamin B expression), cell cycle arrest, and cellular damage response [1,2]. For comparison, we used ROS (reactive oxygen species)-induced senescent CFs to investigate a premature senescent phenotype in stretched cells.

## METHODS

***Cell Culture***: Primary cardiac fibroblasts (CFs) were harvested from wild type *Lmna* mice (Jackson Lab #009125) between 4-8 wks old. Minced perfused tissue was digested with CollagenaseP with DNaseI for 30 mins at 37°C. Cells were filtered, RBC lysed, and then plated in petri dishes for 2 hrs. After 2hrs, dishes were washed in warmed DPBS to remove any nonadherent cells, and D10 (DMEM/F12 + 10% FBS + 1X Pen/Strep) medium was added. CFs were grown to confluency and then plated on Geltrex-coated CellScale MCFX membranes at 4 x $10^3/cm^2$. Cells were allowed to adhere for 12 hrs prior to treatment for

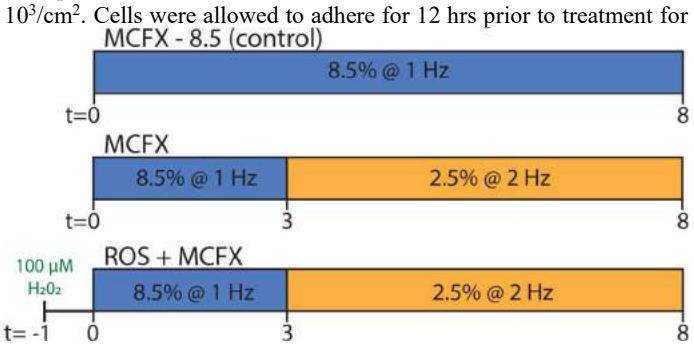

**Figure 1. Cardiac fibroblasts (CFs) loading protocol. A) CFs received uni-axial strain for 8 days in a CellScale MCFX device. Controls for the mechanical stretch treatment were stretched cyclically for 8 days at 8.5% strain at 1 Hz (MCFX-8.5) where time (t) is in days. The two treatment groups, MCFX and ROS + MCFX, had the same cyclic loading protocol. At time t=0, cells were stretched for 3 days at 8.5% strain at 1 Hz. At time, t=3, the loading scheme was changed to 2.5% strain at 2 Hz for 5 days. ROS + MCFX CFs received 100µm $H_20_2$ for 24 hrs prior to stretching.**

both chemical and stretch. Tissue culture plastic (TCP) controls were plated at the same density and allowed to grow to 95% confluency before fixing (4% PFA in DPBS). ***Mechanical Stretch***: Cells received cyclic uni-axial stretched for a total of 8 days in a CellScale MCFX device with daily medium changes (see **Figure 1** for stretch protocols) in a 37°C incubator. On day 8 *in vitro*, cells were fixed for imaging or lysed for RNA (Qiazol). ***ROS treatment:*** Cells plated on TCP received 300µm $H_20_2$ in D10 for 2 hrs at 37°C, and were washed in DPBS prior to replacing the D10 medium. After 24 hours, cells were passaged and replated. Four days after the first dose, the cells received a second dose of 300µm $H_20_2$ for 2 hrs. Plates were observed for increased confluency (typically 5-7 days) before fixation or RNA collection. ***Immunofluorescence/Microscopy***: Cells were stained with DAPI (405nm), Phalloidin Texas-Red (561nm), Lamin B1 (640nm), mounted and imaged with NIKON A1R confocal 60x oil objective. ***Image Analysis***: Images were process in ImageJ and analyzed using a custom MATLAB code for morphological feature extraction (i.e. nuclear area). ***Gene Expression***: RT-qPCR was used for gene expression analysis with targets: p16, p19, p53, and p21 [2]. Expression was first normalized to reference genes *Actb* and *Gapdh*, prior to calculating the fold change compared to treatment controls.

## RESULTS

We first confirmed the senescent phenotype by comparing ROS-induced senescent CFs to CFs plated on TCP. We found ROS-induced senescent CFs showed decreased Lamin B intensity and an inconsistent ring around the nucleus (Fig. 2A). Similarly, CFs which experienced MCFX or ROS + MCFX treatment showed a decrease in Lamin B fluorescent intensity and a discontinuous Lamin B ring around the nuclear periphery compared to control, MCFX–8.5 (Fig. 2A). Additionally, nuclear envelope wrinkling was visualized through Lamin B in ROS + MCFX CFs.

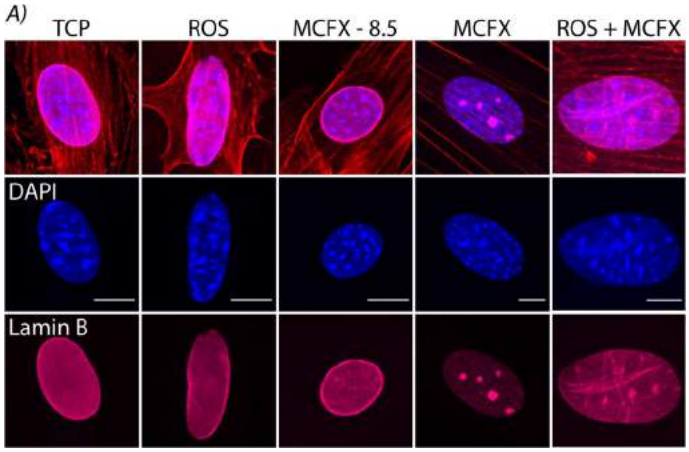

**Figure 2: MCFX and ROS + MCFX loading treatments results in altered Lamin B expression. A) Representative images of CFs from controls (TCP or MCFX – 8.5) and chemical or stretch treatments. ROS-induced senescent CFs have a non-uniform Lamin B ring around the nuclear periphery compared to TCP. MCFX and ROS + MCFX CFs show decreased Lamin B fluorescence and nuclear wrinkling, respectively, compared to MCFX–8.5. Scale bar = 10µm.**

Examining nuclear area, ROS-induced senescent CFs showed no increase in nuclear area compared to TCP (Fig. 3A). However, preliminary data from MCFX and ROS + MCFX CFs show an increased nuclear area compared to CFs which received continuous 8.5% strain (MCFX - 8.5, Fig. 3B). Further assessment of a senescent phenotype was examined with genes upregulated in cell cycle arrest, *Cdkn2A* (p16 and p19), and cellular damage response activation, *Cdkn1a* (p21) and

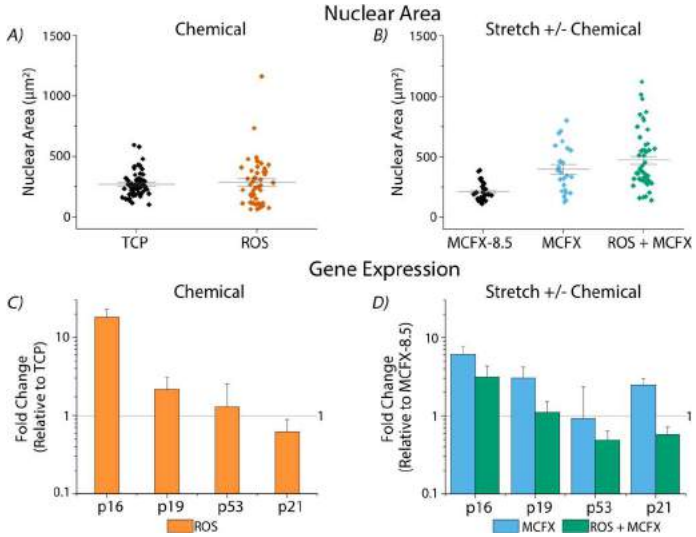

**Figure 3: Biophysical features and gene expression of stretched CFs have senescent-like phenotype. A) ROS-induced senescent CFs do not show increased nuclear area compared to TCP controls. B) MCFX and ROS + MCFX CFs show modest increase in nuclear area compared to constant MCFX – 8.5. C) Gene expression of ROS-induced CFs for cell cycle markers and damage response marker, p53, are increased compared to TCP controls. D) Compared to MCFX-8.5 CFs controls, MCFX and ROS + MCFX CFs have increased expression of cell cycle arrest and damage response marker, p21. N=1-2 animal(s)/treatment, n= 25 nuclei/treatment. All error bars = s.e.m.**

*Tp53* (p53). ROS-induced senescent CFs had upregulated expression of p16, p19, and p53 compared to TCP controls (Fig. 3C). Similarly, preliminary data showed MCFX and ROS + MCFX CFs had increased expression of p16, p19, and p21 compared to MCFX-8.5 CFs (Fig. 3D).

## DISCUSSION

In our work, we show preliminary evidence that perturbing strain in an *in vitro* model to study CFs in cardiac pathology induced a senescent-like phenotype. Compared to ROS-induced CFs, MCFX and ROS + MCFX CFs displayed similar biomarkers of senescence. This premature mechanically-induced senescent phenotype shows increased nuclear area, increased expression of cycle cell arrest, and damage response markers with perturbed cyclic strain compared to continuous strain. While this preliminary evidence demonstrates the importance of maintaining homeostasis of the tissue microenvironment, there are several limitations of this simplified *in vitro* model. One caveat is the length of time the cells spend in the device stretching. This long culture duration could be "prematurely aging" the cells, especially in a 2D environment. Additionally, while 2% strain is reported in the literature with tissue stiffening, this change occurs gradually allowing cellular adaption [5]. Future work will further examine the DNA damage response pathways and potential mechanisms which might induce the transformation observed in this study.

# EFFECT OF HELMET SIZE AND VELOCITY ON CERVICAL SPINE SEGMENTAL RESPONSES UNDER REAR IMPACT ACCELERATION

**Yuvaraj Purushothaman, Hoon Choi, Narayan Yoganandan**

Department of Neurosurgery
Medical College of Wisconsin
Milwaukee, WI

## INTRODUCTION

Numerous studies have been conducted to determine the biomechanics of impact loading to the cervical spine under postero-anterior accelerations, and this rear impact loading vector is used in civilian and military for advancing injury criteria and occupant safety. Experiments with whole-body human cadavers and isolated head-neck complexes are used as validation tools to develop computational models as they can determine parameters such as the range of motion at each segment of the cervical spine and, also extract spinal loads at each level [1]. The advantage of the former metric is its applicability to clinical measures as motions in radiographs are a hallmark for treatment. Experimental studies have been limited to cadaver studies without the use of the head supported mass (HSM), typical in military use. Any data obtained from human cadaver studies should be modulated to delineate the effect of the head supported mass, example, army combat helmet used by Soldiers during operational activities. The objective of this study was to determine the effect of different sizes of the head supported mass (miliary helmets) on male cervical spine responses under two different impact velocity severities.

## METHODS

Our mid-size male head-neck finite element model was used in the study. The cervical spine included the seven vertebrae from the axis to the first thoracic level, intervening discs that consisted of the nucleus and anulus fibers and ground substance, and the ligaments, i.e., anterior and posterior longitudinal, capsular, interspinous, and flavum at each vertebral level. The trabecular bone, cortical bone, and endplates were included for each vertebra. The anterior and posterior regions of the disc consisted of sixteen and eight layers, mimicking the human intervertebral component of the neck. The material properties of the components were obtained from literature. The anulus fibers were defined using membrane elements with tension-only directional fibers embedded in the ground substance. The fibers in the anterior annulus were defined in a crisscross manner, while fibers in the posterior region were defined in the vertical direction. The head to axis structure was attached to the subaxial cervical column. The head center of mass was located using coordinate system based on the location of the occipital condyles. The spinal musculature was simulated using the respective anatomical origin-insertion locations and expressed as one-dimensional beam elements. A coordinate measuring machine was used to describe the geometry of the three different helmets. A collection of coordinates was registered at each point of contact of the probe with the external component surface. The inner component of the helmet was lined with seven foam pads. The helmet and inner foam were modeled as solid hexahedral elements, and the material properties were based on literature studies [1]. The size and mass of the helmet are shown in the Table 1 [2].

**Table 1:** Size and mass of the helmet used in the study.

| Helmet Size | Length (mm) | Width (mm) | Height (mm) | Weight (Kg) |
|---|---|---|---|---|
| Small | 246.38 | 231.14 | 177.80 | 1.33 |
| Medium | 261.62 | 236.22 | 177.80 | 1.40 |
| Large | 266.70 | 241.30 | 177.80 | 1.50 |

**Figure 1: Head-neck finite element models without HSM on the left and with HSM on the right.**

The helmet model was strapped using a chinstrap, modeled using solid elements. Automatic surface-to-surface contact was defined between the head and helmet. The models were exercised under rear impact ($G_x$ accelerative loading) by inputting pulses at velocities of 1.8 and 2.6 m/sec to the T1 vertebra, and these pulses were also used in the experimental validation studies [3]. The input pulses are shown (Figure 2). The model without helmet were validated with the experimental data at both velocities for segmental motions at all levels. The range of motion data from the helmeted models were normalized with respect to the no HSM case to quantify the effect of helmet, and with respect to the low velocity to quantify the effect of impact pulse on the change dur to HSM use. Helmet and HSM are used synonymously.

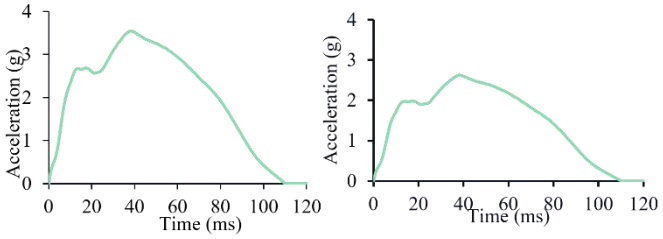

**Figure 2: Input acceleration-time histories for the high (left) and low (right) impact severity simulations for four cases: no-HSM, and small, medium, and large size HSM finite element models. All segmental motions were validated for the first case with human cadaver experimental results.**

## RESULTS

The finite element model without the presence of any HSM was validated using kinematics data from human cadaver tests conducted in our laboratory [3]. The model-predicted range of motion at each subaxial segment was within the mean ±1 standard deviation corridors of experimental motions, at both impact velocities. Segmental motions increased with increase in velocity at all segments of the spine. Angulations ranged from 1.3 deg to 10.3 deg at the higher and from 0.9 deg to 9.3 deg at the lower velocity for the no HSM case. For the small size HSM, they ranged from 1.7 deg to 11.6 deg and 1.4 deg to 10.4 deg, respectively. For the medium size HSM, they ranged from 1.9 deg to 12.3 deg and 1.5 deg to 11.1 deg, respectively. For the large size HSM, angulations ranged from 2.3 deg to 13.2 deg, and 1.7 deg to 11.7 deg, respectively. The maximum increase was at the C5-C6 segment in all cases with the exception of the no HSM case that had a slight increase at the C6-C7 segment. These results are shown in Figure 3.

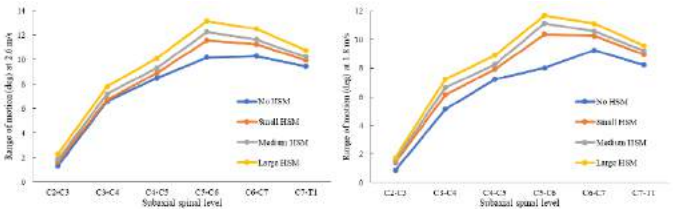

**Figure 3: Segmental angulations for the four cases, without and with different size HSM at the high (left) and low (right) impacts.**

## DISCUSSION

The objective of the study was to determine the effect of HSM on the range of motion of the cervical column for military applications. Three helmet sizes chosen in the study represented Army Combat Helmets [2]. It is customary to validate any computational model with matched pair experimental data. This was accomplished in this study with the model that did not have any HSM, i.e., no helmet condition. This because human cadaver tests with HSM under the accelerative loading vector used in the study is not published in literature; however, matched pair tests without the HSM were available. The range of motion at all segmental levels were within the experimentally determined mean plus/minus one standard deviation corridors, demonstrating that the model was validated at both impact velocities.

This model was then used to add different size HSM to evaluate the size/mass of on neck motions, indirectly considering the addition of HSM as parametric. As expected, increasing velocity increased spinal motions and this was true for all three HSM conditions. Under each HSM condition, as described in the results section, motions increased from the axis to the C5-C6 level and then decreased, and this was true for both impact velocities. The motion was the greatest with the large HSM, and this was expected as the large helmet has greater mass, greater inertial properties, reflecting an anterior shift in the center of gravity of the head from its original non-HSM center of mass. Because large size helmets are a better to fit large size Soldiers, the increased motions may be better tolerated with the change in the spinal anthropometry, although this issue was not specifically addressed in this study. Simulating necks with small, medium, and large anthropometries may be needed to clearly delineate these effects, and this should be pursued in the future.

The increase in the motion at the C5-C6 level with any HSM may have clinical implications. For example, this is the most common site of spinal disorders such as spondylosis/pain in military patients, and some receive surgical treatment with conventional fusion and or arthroplasty [4,5]. From this perspective, the use of a larger HSM than necessary may predispose to the added mobility of the spine under this mode, and to the C5-C6 segment, in particular. The second most common level for surgery in military patients is the C6-C7 level [5,6]. This is also borne out by this study as it is the segment with the second highest increased motion regardless of helmet size.

In summary, the lower cervical spinal region appears to sustain greater motions at both velocities and in an increasing magnitude with the use of the small to medium to large HSM. Common cervical spine disorders in military populations as reported in clinical studies appear to connect increased motion with the disorder. The use of HSM affects spinal responses and increased motions may contribute to clinical observations of neck pathology in the lower spine.

## INTRODUCTION

The zebrafish is a widely used model for studying cardiac development due to its optical transparency, fast development in culture, and ease in applying genetic modifications or pharmacological treatments. Bulk cardiac performance metrics, such as cardiac output and stroke work have recently been obtained for the developing zebrafish [1], but the material properties of the zebrafish heart that underlie these metrics are less studied. Due to the small size of the zebrafish heart, traditional experimental techniques for material characterization are challenging to apply. Experimental characterization of the zebrafish myocardium is limited, and existing work has for the most part studied only the passive mechanical response of *ex vivo* hearts or hearts in otherwise non-physiological states [2], [3]. In this work, we apply an inverse finite element analysis (FEA) to estimate the passive material parameters of the zebrafish ventricle under physiological conditions. This pipeline provides a means for researchers to connect pharmacological and genetic treatments to changes in myocardial material properties during development, potentially revealing new links between cell-level processes and bulk cardiac performance.

## METHODS

Our framework uses 4D light-sheet images of developing zebrafish acquired at 5 days post fertilization (dpf). We use the open-source SimVascular framework (www.simvascular.org) to manually segment the zebrafish myocardium at a single cardiac phase (mid-diastole) and construct a computational model of the ventricle. We then use deformable image registration to extract myocardial displacements and morph the initial segmentation to create a computational model of the beating heart [4]. This approach efficiently and robustly yields a segmentation of the myocardium for each time step, minimizing manual user input. This "moving" segmentation of the ventricular myocardium derived from light-sheet images constitutes the ground truth for the calibration process, and we henceforth denote this data the *"in vivo* configurations."

We model the zebrafish ventricular myocardium as an incompressible, hyperelastic material using our recently developed unified variational multiscale method for incompressible solid mechanics [5]. In this study, we explore multiple material models for developing ventricular myocardium, including the commonly-used Guccione model [6], Ogden model, and Gent model [7]. We were inspired to explore the latter two models because of an unusual diastolic ventricular pressure-volume relationship during development [1], discussed later.

We perform a quasi-static inflation simulation of the ventricle, applying diastolic pressure load measured *in vivo* from previous experiments [1] to a computational model at mid-diastole. We then calibrate the material parameters of each constitutive model such that the FEA loaded configuration matches the *in vivo* configuration at a given pressure load. We compare two calibration procedures. In the first, we seek only to match the volumes of the FEA loaded configuration and the *in vivo* configuration at a given pressure and employ a simple iterative algorithm to estimate material parameters. In the second, we seek to minimize the sum squared differences in nodal point positions between the FEA loaded configuration and the *in vivo* configuration and employ the derivative-free surrogate management framework to achieve this.

## RESULTS

The modeling pipeline produces realistic ventricular displacements that match the collected imaging data as well as volume vs. time data from previous studies (Fig. 2). These agreements serve to validate the process used to construct the ground truth *in vivo* computational models.

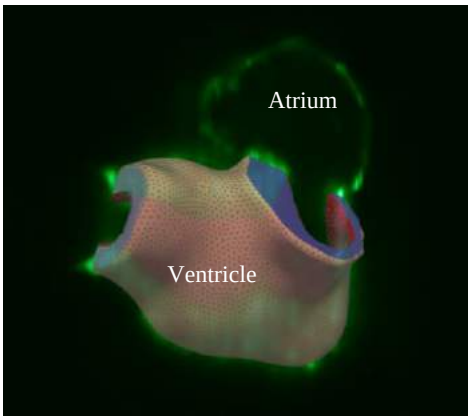

**Figure 1: Computational model of zebrafish ventricular myocardium overlaying one slice of raw light-sheet image.**

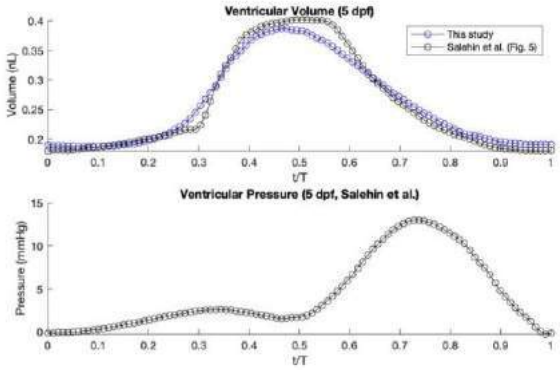

**Figure 2: Ventricular volume vs. time (normalized to cardiac cycle). In this study, volume was calculated from the *in vivo* configurations [4]. In Salehin et al., volume was calculated from manual segmentations at each time point. We note the qualitative agreement in volume vs. time curves. Additionally, pressure vs. time from Salehin et al. is reproduced here.**

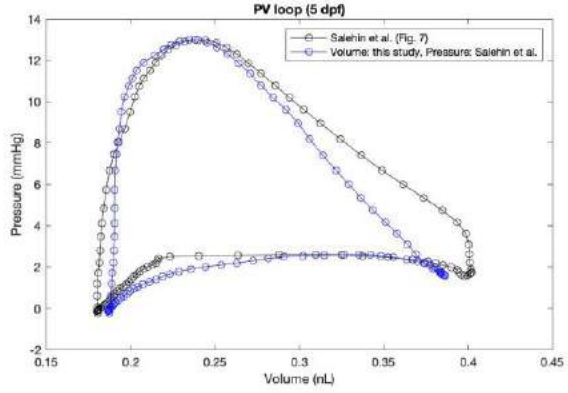

**Figure 3: Pressure-volume loops. The PV loop in blue was obtained by synchronizing pressure data from Salehin et al. to volume data obtained via our modeling pipeline. Note the atypical behavior of the filling curve (lower portion of the loop): pressure initially increases with volume, then plateaus, and finally decreases.**

The simpler volume-based calibration algorithm determines the material parameters such that the pressure-volume relation from the FEA matches the desired diastolic pressure-volume relation (Fig. 3), obtained using the volume of the *in vivo* configurations, synchronized with pressure data from [1]. Synchronization was performed as described in [1]. Since the second calibration procedure is more demanding (imposes nodal point agreement), we expect it to be more accurate for the transversely isotropic Guccione model.

We apply the above framework to estimate myocardial parameters in multiple wild type zebrafish ($N \geq 5$) acquired at 5dpf. In a follow-up study, we discuss the extension of this technique to other stages during zebrafish development (2dpf – 5+dpf) and conduct an analysis of changes in myocardial material properties in response to genetic and pharmacological interventions.

## DISCUSSION

We present an inverse finite element modeling approach for estimating zebrafish myocardial material properties under physiological conditions, using light-sheet imaging that is commonly used to study zebrafish cardiac development. Our approach will allow researchers to study not only the bulk changes in cardiac morphology and function associated with genetic mutations or drug treatments, but also the underlying changes in material properties. Such an added dimension to studying zebrafish development has the potential to reveal new links between cellular biology and tissue mechanics during cardiac morphogenesis.

In addition, we explore the validity of several different material models for the ventricular myocardium of developing zebrafish. While the Guccione model has been used successfully to model the myocardium across many species [6], [8], recent experimental studies on the developing zebrafish suggest a significantly different behavior. Specifically, in the diastolic pressure-volume relationship presented in [1], the myocardium appears to become more compliant with increasing strain, to the point that the pressure plateaus and eventually decreases with volume (Fig. 3). In the "typical" diastolic pressure-volume relation, pressure increases linearly or weakly exponentially with volume [9]. The filling curve in Figure 3 is reminiscent of the so-called "limit-point instability," a phenomenon observed in some rubber-like pressure vessels in which there is a maximum in pressure as a function of volume. The existence of this phenomenon depends on the chosen constitutive model and values of the constitutive parameters, as well as the geometry [7]. This study evaluates the applicability of different material models to zebrafish ventricular myocardium, particularly as it relates to capturing this behavior.

## ACKNOWLEDGEMENTS

# VIT-FNO; A ROBUST MODEL FOR TRACKING MOTION IN 4D-MRI

**A. Chopra (1), A. Pionteck (2), J. Abderezaei (2), M. Kurt (2)**

## INTRODUCTION

The primary objective in this experiment is to develop a novel deep learning-based image registration algorithm that can accurately and efficiently extrapolate displacement fields for 4D MRI sequences while being robust against landmark changes and flow related artifacts that hamper the usability and generalizability of these algorithms for clinical applications. The networks presented here have been trained to be applied to brain motion tracking. However, the network architecture can be adapted to track motion in a wide variety of clinical cases that involve 4D sequences. For example, the network parameters can be adjusted to match new image modalities for cardiac movements.

The development of the algorithm was done in 2 steps: 1) by iteratively modifying and evaluating existing state-of-the-art 3D UNet [1] algorithms [Fig. 1] and 2) using insights from these results to develop a novel algorithm, the ViT-FNO [Fig. 2], that performs part of the calculations in the frequency domain instead of the traditional temporal only approach, in combination with Convolution-Transformer hybrid architecture, allowing for a much efficient and robust image registration pipeline.

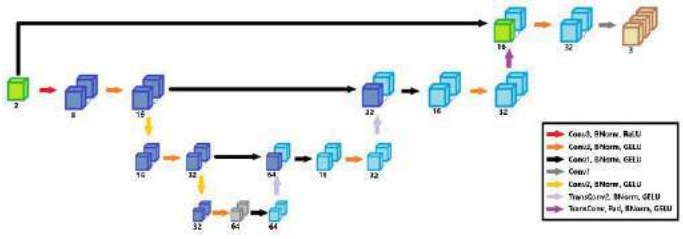

**Figure 1: Modified 3D UNet architecture.**

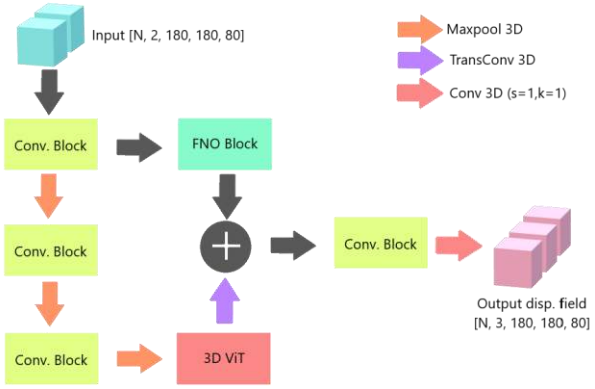

**Figure 2: ViT-FNO architecture.**

Recently, Vision Transformer and Convolution based hybrid models such as the ViT VNet [2] have shown promising results in outperforming traditional Convolution only architectures such as the 3D UNet. But training such models can be quite tedious and often plagued with overfitting for niche tasks where training data is limited. Our proposed model, the ViT-FNO, combines the architecture of ViT VNet with a modified Fourier Neural Operator [3] such that the resulting model is much simpler and more resilient to overfitting.

## METHODS

We generated the training dataset with data from 10 patients. Each patient dataset was made of a series of 3D MRIs volumes, each volume corresponding to a timestep of an MRI cine-sequence. For each patient, the reference image was extracted from the first timestep (t=0) of the sequence, and for each time step from t=1, the displacement field was extracted by a conventional method such as the Demons registration algorithm. These displacement fields were filtered, resized, and used to

deform the other patient's reference images by warping. The process was repeated for all patient sequences, generating approximatively a thousand deformed images with known displacement field and initial image. We split each patient sequence by pairing each timestep to its corresponding reference frame to generate the final dataset used for training and validation. The training set contains data from 8 patients while the remaining 2 patient data is reserved for validation of the models. The data is randomly augmented (rotated in random directions by random amounts) during training.

We iteratively trained a 3D UNet model with Huber Loss and modified the architecture by identifying possible architectural improvements to the previous model by comparing the predicted displacement fields against the ground truth displacement fields using Structural Similarity Index (SSIM).

Finally, drawing from these insights, we propose a novel architecture, ViT-FNO [Fig. 2.] to address some of the pitfalls of the 3D UNet techniques. The ViT-FNO network contains several subunits. Namely, 1) Convolution blocks, that consist of 3 Convolution operations with kernel size of 3 and stride of 1, each followed by a ReLU nonlinearity and batch normalization. 2) FNO block, that consists of first transforming the data into the frequency domain, picking the first 3 modes, applying the weights and biases, transforming back to the time domain, and lastly applying ReLU nonlinearity and batch normalization. 3) 3D ViT block that first encodes the features into 4x4x4 patches unrolled to a single dimension and then passes these vectors to a vision transformer. The data is then reshaped back into the 3D domain and passed through a ReLU nonlinearity and batch normalization function. A Convolution operation of kernel size of 3 and stride of 1 is applied followed by ReLU and batch normalization. 4) Maxpool operation that is used to down sample the data and has kernel and stride size of 2. 5)Transposed Convolution that up samples the data followed by padding to get to the same size as the FNO output. The FNO and Transposed data are concatenated and passed through another padding function such that the resulting final Convolution block output is of the desired size. A final convolution is applied with kernel and stride size of 1 and the output channel size is set to 3 to construct the predicted displacement fields.

## RESULTS

For the Validation set, the average SSIM score was 0.763 and the Loss was 0.0169, while the training Loss was in the range of $10^{-5}$. Our final 3D UNet variant appears to overfit on the training dataset.

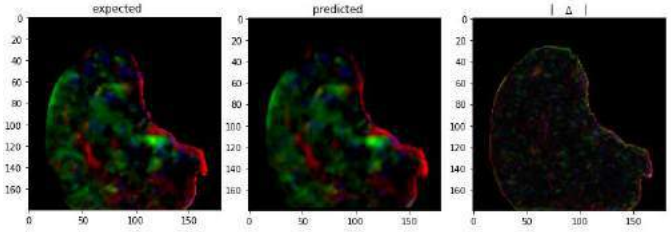

**Figure 3: Displacement field for relatively healthy sample.**

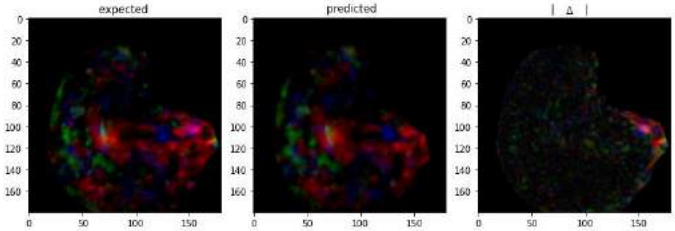

**Figure 4: Displacement field for structural abnormality.**

## DISCUSSION

Although Fig. 3 shows a prediction produced by our 3D UNet model that is almost equal to the ground truth, in Fig. 4, we observe that the same 3D UNet model does not produce a reliable displacement field for a sample with some prominent structural abnormality. This is one of the biggest issues with the 3D UNet model that depends heavily on the training data landmarks to construct reliable displacement fields. This issue could be a biproduct of overfitting.

Reducing model complexity can be one way to minimize overfitting but this may not be an ideal solution in many real-world scenarios. To address this issue, our proposed model, ViT-FNO, will be significantly more robust than previous state-of-the art models while achieving similar performance at a fraction of the computational overhead. Since we transform the paired data into the frequency domain at the FNO block and only apply the nonlinear transformation to the first 3 modes, we can infer that the FNO block is able to accurately extrapolate coarse features such as the structural changes and major landmark changes between the reference frame and the timestep t-frame. Corollary, we suspect that the 3D ViT block can extrapolate features related to much finer details and motions, depending on the patch size. The final block should combine these features and produce the desired displacement field. This novel architecture should be able to produce more reliable displacement field estimations for samples with prominent malformations and other structural abnormalities. Since the model is significantly smaller than traditional algorithms, training should be much faster and vanishing gradient problem should also be minimized, improving performance, and further improving training times. The implications of the proposed ViT-FNO model need to be validated by further testing on the dataset.

## INTRODUCTION

Osteoarthritis (OA) is a multi-tissue joint disease that affects more than 32 million adults in the United States [1, 2]. It is characterized by the degeneration of articular cartilage and causes joint pain, inflammation, and permanent alteration of the cartilaginous structure. Changes to the structure of the joint can adversely affect load distribution and cause mechanically-mediated advancement of the disease. Understanding the mechanical breakdown of articular cartilage would lend insight into the progression of the disease.

OA is often attributed to wear associated with aging or as the pathological response to acute damage to the cartilage. The exact mechanisms by which stress results in tissue degeneration has yet to be elucidated. Disruption of the extracellular matrix (ECM) compromises the integrity of the tissue and promotes degeneration via mechanical aggravation [3].

Few studies have been conducted to determine the initiating factors of structural wear in human cartilage. In the biotribology literature, the friction coefficient ($\mu$) has often served as a proxy for understanding wear in cartilage, with an abrupt change in $\mu$ possibly indicating a loss of cartilage integrity [4]. In previous studies from our lab, Durney et al. [5] and Oungoulian et al. [6] showed that in immature bovine cartilage, $\mu$ for cartilage-on-cartilage contact and cartilage-on-glass remained low over sustained frictional sliding in a migrating contact area configuration, despite the emergence of delamination wear. In the porcine model, Vazquez et al. found that cyclic compression loading in cartilage-on-cartilage contact can cause tissue softening and damage [7]. Regarding human articular cartilage, Weightman reported early signs of fibrillation following cyclic compressive loading [8]. Additionally, Kaplan found that human articular cartilage plugs under cyclic unconfined compression testing resulted in loss of thickness and integrity of the ECM [9]. Other studies have reported fatigue failure in human articular cartilage during tensile cyclic loading [10, 11, 12].

In this study we explored the hypothesis that wear of human articular cartilage could be initiated under reciprocal frictional sliding, using testing conditions that promote loss of interstitial fluid pressurization to exacerbate reciprocal frictional forces on the cartilage extracellular matrix. We hypothesized that applying a supra-physiological contact pressure under static loading and reciprocal sliding for 24 hours leads to wear from delamination of the superficial zone, as observed by Oungoulian et al. in immature bovine cartilage [6].

## METHODS

Sample Preparation: Three fresh frozen human knee joints were obtained from a tissue bank (31-48 y.o., 485 - 756 N, female, two right knees and one left knee) and dissected to expose the articular cartilage on the distal femur. The knee joints were sectioned into medial condyle (MC) and lateral condyle (LC) samples of approximately 50 mm length and 25 mm width, producing five samples. No joints showed visual evidence of cartilage degeneration. Condyles were mounted in custom cylindrical acrylic holders and the bony end was fixed in dental cement (Buff Stone, Whip Mix), leaving the femoral articular cartilage exposed (Fig. 1).

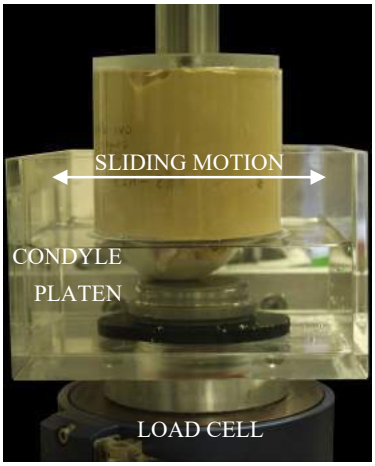

**Fig. 1: Femoral condyle mounted in dental stone articulates against a stainless steel platen.**

Friction Testing: The fixed samples were mounted on a custom testing device described earlier [13] sliding against a stainless steel platen mounted on a 6-axis load cell (JR3, Inc.; Fig. 1). A constant contact force of 439 ± 12 N load was applied under load control. Sliding was prescribed under displacement control with a 5 mm stroke length at 5 mm/s (4 s/cycle) for a duration of 24 hours (21,600 cycles). Samples were immersed in phosphate buffered saline with 0.04% isothiazolone-base biocide (Proclin 950, Sigma-Aldrich) and 0.1% protease inhibitor (0.05 M ethylenediaminetetraacetic acid, EDTA, Sigma-Aldrich) for the duration of the test. Before and after the test, samples were submerged in the same solution, kept at 4 ˚C, and refreshed daily.

Experimental Measurements: Prior to friction testing surface scans were obtained of the samples for topological assessment using a Keyence Profilometer (LJ-V7080), which captured a dense point cloud of 50,000 points/cm$^2$. Additional scans were taken immediately after loading, and again after a 120 hour recovery period. Pressure-sensitive film (Fujifilm, prescale 4LW; 0.05 – 0.2 MPa) was used to determine the average contact area under the 439 N load.

## RESULTS

Friction Testing: The friction coefficient $\mu$ increased over time, from a minimum value of 0.009 ± 0.004 to a final value of 0.095 ± 0.013 after 24 h (Fig. 2A). The final creep deformation across all samples was 1.03 ± 0.09 mm (Fig. 2B).

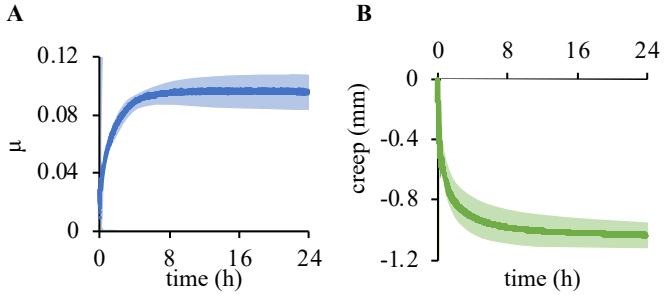

**Fig. 2: Mean and standard deviation of (A) friction coefficient and (B) creep displacement for all five samples**

Experimental Measurements: The mean cartilage thickness was measured with a needle probe to be 1.49 ± 0.30 mm. After 120 h recovery, samples recovered to an average of 99.3% ± 2.34% of their original thickness. Representative photos and scans of a sample before, immediately after, and 120 h after friction testing are shown in Fig. 3.

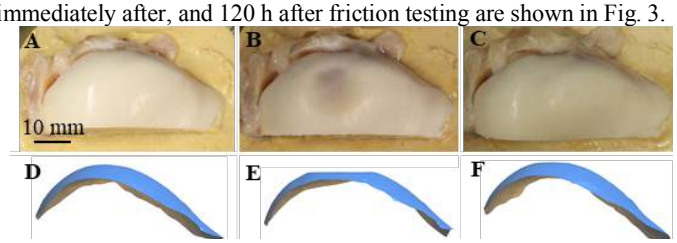

**Fig 3: Photos (A-C) and scans (D-F) of one representative sample before friction testing (left), immediately after the 24 hour test (middle), and after 120 hours of recovery (right).**

The average contact area before the 24 h test, immediately after the test, and after 120 h recovery was 69.0 ± 12.8 mm$^2$, 124 ± 33.3 mm$^2$, and 85.1 ± 13.1 mm$^2$ respectively. Thus, the mean contact pressure during the test decreased from 6.51 ± 1.29 MPa to 3.79 ± 1.05 MPa. At test completion there was no histological evidence of superficial zone delamination or fibrillation in any of the samples (Fig. 4).

**Fig 4. Representative Safranin-O and Fast Green staining of tested sample after 120 h recovery, showing no evidence of wear**

## DISCUSSION

This study tested the hypothesis that supra-physiologic contact pressures sustained statically for 24 h under reciprocal frictional sliding would induce delamination wear in human articular cartilage due to sustained frictional forces resulting from loss of interstitial fluid pressurization. Temporal responses showed that steady friction coefficients $\mu$ and creep displacements were achieved over the test duration (Fig. 2), confirming loss of interstitial fluid pressurization [14] and relatively elevated values of $\mu$ consistent with prior reports [6]. Creep deformation was supra-physiologic as cartilage was compressed nearly to the bone in all cases (Fig. 3B,E), but recovered significantly each time (Fig. 3C,F). Despite these harsh testing conditions, no evidence of delamination wear was observed from histology (Fig. 4). These results strongly suggested that reciprocal frictional forces are not responsible for initiating fatigue wear in articular cartilage. Thus, we must consider alternative mechanisms for understanding mechanically-induced tissue degradation.

In our previous work on immature bovine articular cartilage, Durney et al. reported surface delamination to the tibial cartilage strips, which were articulated against opposing femoral condylar plugs [5]. The condylar plugs did not have delamination. While the tibial cartilage strips and the condylar plugs both underwent frictional cyclical forces, the compressive forces were cyclical for the tibial strips and static for the condylar plugs. This prior result, when taken in conjunction with the current study and [7,8], suggests that delamination wear is induced by fatigue due to cyclical compressive forces, rather than cyclical frictional forces.

We conclude from our study that human articular cartilage is resilient to reciprocal sliding and that cyclical friction alone does not cause delamination. Moving forward, we will modify our experimental design to test the hypothesis that delamination wear in human articular cartilage is mediated by cyclic compressive loading.

## INTRODUCTION

Bicuspid aortic valve (BAV) patients make up 1-2% of the population and present more frequently with aortic disease than the general population. Among these diseases, a common one, ascending aortic aneurysm (AsAA), often precedes the onset of potentially fatal complications such as aortic dissection or rupture [1]. Despite the severity of these outcomes, the cause and progression of BAV-associated aortic disease is not well understood, which has motivated research into the biomechanics and microstructure of BAV-AsAA tissue. This research has shown that certain properties of AsAA tissue vary regionally, suggesting that the tissue degeneration and remodeling that is widely associated with aortic aneurysms does not occur homogenously throughout all areas of the aneurysm [2,3]. These studies, however, have generally considered the aortic wall as a homogenous material, even though the three layers of the wall – intima, media, and adventitia – have been known to exhibit significantly different mechanical properties and microstructural composition [4]. Considering that aortic dissection initiates as a tear in the inner layer of the aortic wall followed by propagation of the dissection between the layers, it becomes important to consider the heterogeneity of the aortic wall layers and their individual contributions to the composite wall. It is possible that tissue remodeling processes are not homogenous through the wall thickness, but rather vary in severity and effect for individual layers or at layer interfaces. Studying the individual layers of the composite aortic wall in BAV-AsAA may provide new insight into the mechanisms of AsAA disease progression and its associated complications.

This study proposes to investigate layer-specific and inter-layer biomechanical properties of BAV-AsAA tissue to further explore the heterogenous nature of aortic tissue degeneration and remodeling. Specifically, exploring the relationship between the primary load-bearing layers – the media and adventitia - and their interfacial strength.

## METHODS

Whole aneurysms were removed from ten BAV patients undergoing elective surgery. Aneurysms were cut first into regions (greater curvature, lesser curvature, posterior, and anterior), and then further divided into specimens based on region size. From each specimen, one circumferential (11) and one longitudinal (22) test strip was removed for delamination testing. The remainder of the specimen was separated into two layers - media (including intima), and adventitia - using the methods described in [4] for biaxial tensile testing.

Delamination testing was conducted using a uniaxial tensile testing device (CellScale Biomaterials Testing, Waterloo, ON) with a 10N load cell. The unloaded width and thickness of the specimen was measured using digital calipers. Layer separation was initiated manually, and the free flaps were attached vertically in the grips of the testing device as per the methods in [5]. The sample was submerged in a PBS bath warmed to a temperature of 37°C, and uniaxial elongation was imposed at a rate of 1 mm/min for a duration of 10 minutes or until full delamination was achieved. The data was processed into delamination tension, which is the recorded tensile load divided by the unloaded width of the specimen. From this, delamination strength was found as the average value of delamination tension after the initial peak [5].

Biaxial tensile testing was conducted using a four-motor biaxial testing system (ElectroForce Systems, TA Instruments, Springfield, MO) with two 22N load cells. The adventitia and media were tested separately, subjected to a series of displacement-controlled test protocols (1:1, 1:0.75, 1:0.5, 1:0.2, 0.2:1, 0.5:1, 0.75:1), where 1 indicates the maximum defined displacement in the circumferential or longitudinal direction based on the original specimen dimensions. These test protocols were carried out in a PBS bath warmed to 37°C, first to a maximum 60% displacement, followed by a maximum 80% displacement if the specimen survived all 60% displacement protocols. Local tissue deformation was recorded through camera tracking of five dots placed in the center of the specimen, and force was recorded in both

SB³C2022-423

directions. Finally, global force, local deformation, and initial specimen dimensions were used to calculate the Cauchy stress and stretch for each specimen. This data was further processed for biomechanical descriptors to compare behaviour across specimens. Specifically, the stress-stretch curve for each sample was plotted and analyzed for a low-strain tangential modulus (LTM), a high-strain tangential modulus (HTM), and the stress and strain values at the transition zone onset and end points, which mark the start and end points of the non-linear portion of the stress-stretch curve (*Figure 1*). These values were obtained for both circumferential and longitudinal directions. Methods for data processing and analysis were performed as in [6].

The biaxial and delamination properties were then matched by specimen location and compared to determine if there was any relationship between the performance of the individual layers and their strength at the interface.

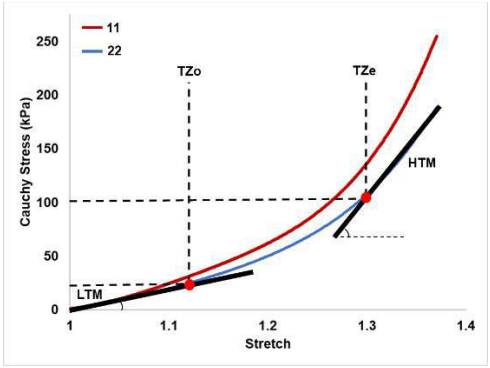

**Figure 1: Example of biaxial tensile test analysis for biomechanical properties including low-strain tangential modulus (LTM), non-linear transition zone onset and end points (TZo, TZe), and high-strain tangential modulus (HTM).**

## RESULTS

Initial results were found based off a subset of seven patients, from which 30 specimens were tested. From these specimens, 50 delamination tests, 29 adventitial biaxial tests, and 22 medial biaxial tests were completed successfully. No significant relationship was found between the LTM of the media and adventitia, or between the LTM of either layer and delamination strength. A paired t-test showed significant difference between the LTM's of the layers in the circumferential direction, but not in the longitudinal. The most noticeable difference was in the HTM's of the layers, where the media and adventitia were significantly different in both directions (*Figure 2*).

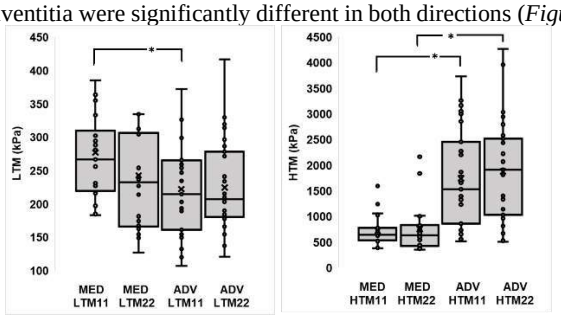

**Figure 2: Comparison of LTM between the layers showed difference in the circumferential direction (p<0.01) (LEFT) and significant difference between the HTM's of the layers in both directions (p<0.001) (RIGHT).**

A positive correlation was found between delamination strength in the circumferential direction and the intima-media HTM in both directions (Pearson's r = 0.774 p < 0.001 for HTM-11; Pearson's r = 0.489, p = 0.039 for HTM-22) (*Figure 3)*. A similar relationship was found for delamination strength in the longitudinal direction, again showing positive correlation with medial HTM in both directions (Pearson's r = 0.715, p <0.01 for HTM-11; Pearson's r = 0.568, p = 0.027 for HTM-22) (*Figure 3*). Delamination strength in both directions was also positively correlated with the biaxial transition zone end point (TZe) stresses in the media but had no correlation with adventitial biaxial properties.

Adventitial HTM and medial HTM were found to be positively correlated in both directions (Pearson's r = 0.484, p = 0.049 for HTM-11; Pearson's r = 0.792, p <0.001 for HTM-22). However, when comparing delamination strength to the ratio of adventitia and media properties, no correlation was found, suggesting that delamination properties are more strongly associated with the condition of the media.

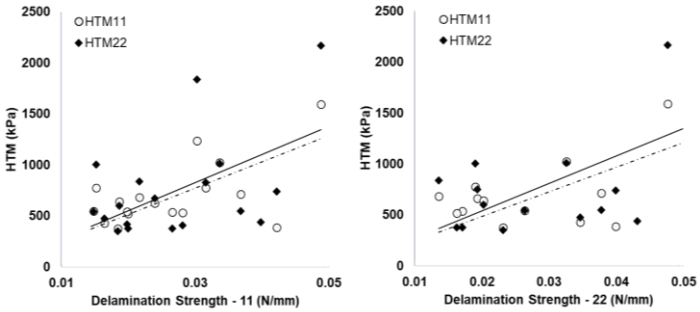

**Figure 3: Delamination strength had a positive correlation with media HTM11 and HTM22. This relationship was seen in both the circumferential delamination strength (LEFT) and the longitudinal delamination strength (RIGHT).**

## DISCUSSION

The present study is one of few that has investigated the heterogenous characteristics of the aortic wall layers and interface. Preliminary results confirm findings that adventitial and medial properties are significantly different in high-strain conditions, however this is the first study to realize a possible relationship between medial stiffness and interfacial strength that appears to be independent of adventitial behaviour. However, the significance of the preliminary findings is currently limited by sample size, preventing statistical analysis that can account for inter-patient and inter-region variability.

Previous literature findings cite the importance of studying aortic wall delamination strength and layer-specific properties to better understand the heterogenous wall remodeling process in AsAA [4,5]. The distinct mechanical behaviour found in each of the layers can be largely attributed to their unique structure and composition, which also strengthens the idea that layers may have independent remodeling or degeneration characteristics. Future investigation of the biomechanical properties in partnership with microscopy or histology may help further our understanding of the mechanisms behind AsAA tissue degeneration.

# BIOPROSTHETIC LEAFLET STRESS FOLLOWING TRANSCATHETER AORTIC VALVE REPLACEMENT IN BICUSPID AORTIC VALVES

**Breandan Yeats (1), Aniket Venkatesh (1), Milad Samaee(1), Pradeep Yadav (2), Venkateshwar Polsani (2), Vinod Thourani (2), and Lakshmi Dasi (1)**

## INTRODUCTION

Bicuspid aortic valve (BAV) disease is the most common congenital heart defect present in 2-4% of the general population and is associated with calcific aortic valve disease [1]. Historically, BAV patients have been treated with surgical replacement however, patients are transitioning to transcatheter aortic valve replacement (TAVR) which is a minimally invasive alternative. Currently, long-term durability in BAV patients is unknown due to the lack of long-term clinical data. Due to the elliptical shape and often high volume of calcium in BAV patients the transcatheter aortic valve (TAV) stent is often elliptical and underexpanded and is hypothesized to impact durability.

Bioprosthetic leaflet stress has not been measured in a cohort of BAV patients which is not possible in the clinical setting. However, this is possible through computational methods. Additionally, the impact of various TAVR strategies including balloon filling volume has not been evaluated in its impact on bioprosthetic leaflet stress in patient specific anatomies. Lastly, it is unknown how bioprosthetic leaflet stress relates to anatomical characteristics. This study aims to quantify bioprosthetic leaflet stress in BAV patients treated with TAVR with varying balloon expansion volumes and compare stress with calcium volume and the shape of the native valve opening through computational techniques.

## METHODS

10 CT scans taken of patients being evaluated for TAVR with BAV and calcific aortic valve disease were analyzed. The aortic valve including leaflets and calcium nodules, ascending aorta, and part of the left ventricle were segmented in Materialise Mimics (Leuven, Belgium) (**Figure 1A**). The total calcium volume in the landing zone for the TAV stent was measured. The angle between the free edges of the two leaflets was measured to quantify the shape of the opening. An angle closer to 120 degrees signifies a tricuspid-like shape and an angle closer to 180 degrees signifies bicuspid-like shape (**Figure 1B**). Finite element analysis (FEA) models of the Edwards SAPIEN balloon-expandable TAV were created for the 23, 26, and 29 mm sizes and were performed in Abaqus (Johnston, RI, USA). Each stent was generated from microCT measurements in Solidworks (Waltham, MA, USA) of the actual device and meshed in Hypermesh (Powell, OH, USA) (**Figure 2**). A balloon was then generated and meshed from benchtop measurements of the actual balloons. Verification of each TAV size was performed by crimping the stent and balloon followed by a volumetric expansion of the balloon until the stent reached the manufacturer specified diameter (**Figure 2C**). Stent deployment was validated previously in a post-TAVR CT scan to reasonable agreement [2].

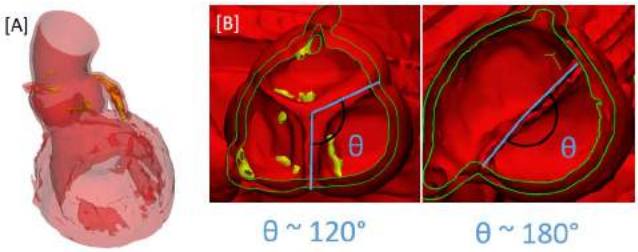

**Figure 1:** Reconstruction of the aortic valve including leaflets and calcium nodules, ascending aorta, and left ventricle (A) and free edge angle measurement depicting tricuspid-like (120°) and bicuspid-like (180°) BAV anatomical shapes (B).

The SAPIEN FEA model was deployed in each anatomy using the manufacturer recommended size. Following deployment of the stent, the bioprosthetic leaflets were mapped onto the stent by displacing the sutured edge of the leaflets to match the sutured edge of the deformed stent. They were then pressurized under peak diastolic physiological pressure and the maximum principal stress was recorded. This process was repeated in various balloon volume scenarios consisting of

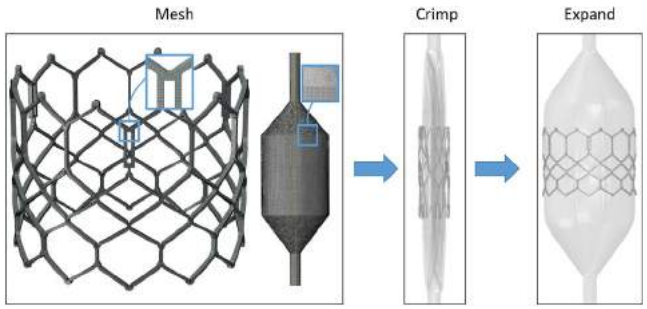

**Figure 2:** Process of developing the SAPIEN FEA 23, 26, and 29 mm models including meshing of the stent and balloon, crimping, and expansion to the manufacturer specified diameter.

underexpansion, nominal expansion, and overexpansion. Material properties used for the native tissues and TAV were extracted from previous studies [3-6]. Statistical analysis consisted of regression analysis between stress and anatomical variables and comparison between means of stresses between expansion configurations with statistical significance considered when $p < 0.05$.

## RESULTS

Geometry of the TAV deployment at nominal expansion and the bioprosthetic leaflet stress under physiological loading for two anatomies, one with high calcium volume (490 mm^3) and one with low calcium volume (58 mm^3) are shown (**Figure 3**).

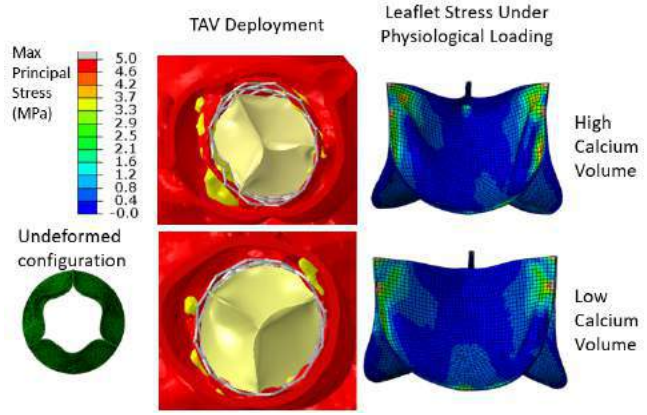

**Figure 3:** TAV deployment geometry (left) and bioprosthetic leaflet stress under physiological loading (right) in an anatomy with high calcium volume (top) and an anatomy with low calcium volume (bottom).

Increased stent ellipticity, increased leaflet stress, and leaflet folding near the commissural points are observed in the anatomy with high calcium volume. The peak stress from each anatomy with nominal expansion was compared to the total calcium and was found to have statistical significance ($R^2 = 0.53$, $p = 0.017$) (**Figure 4**). The free edge angle was also compared to leaflet stress but did not have statistical significance ($R^2 = 0.25$, $p = 0.137$).

The average peak leaflet stress values were 2.26, 2.34, and 2.49 MPa for the nominal expansion, overexpansion, and underexpansion deployments but their differences were not found to be statistically significant. Qualitatively, the leaflets were observed to have increased rates of folding and pinwheeling in the underexpansion deployments.

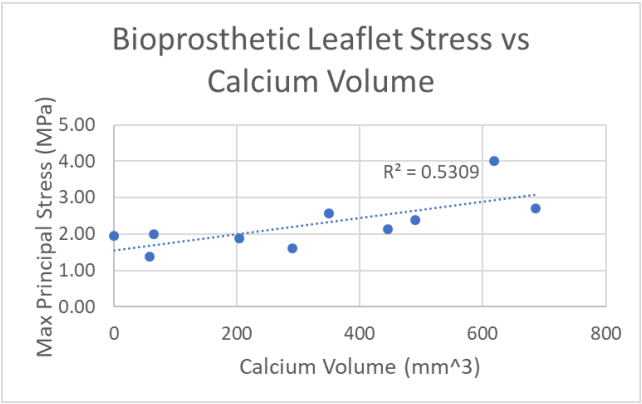

**Figure 4:** Bioprosthetic leaflet stress vs calcium volume with $R^2 = 0.5309$ and statistical significance ($p = 0.017$).

## DISCUSSION

The goal of this study was to investigate the bioprosthetic leaflet stress following balloon-expandable TAV deployment in BAV patients with severe calcific aortic valve disease. Calcium volume was shown to have a statistically significant correlation to the bioprosthetic leaflet stress ($p = 0.017$). The shape of the native valve, quantified by the angle between the free edges of the two leaflets, was not found to have a statistically significant correlation to leaflet stress. Underespansion of the TAV was seen to increase the stress on the leaflets on average however, did not have statistical significant differences from the nominal and overexpansion states.

These results indicate calcium to be the dominant controller of bioprosthetic leaflet stress. This is likely due to calcium high stiffness resisting the uniform deployment of the stent thus causing the leaflets to be deformed increasing their stress under diastolic loading. Other anatomical factors likely also contribute but require a larger patient cohort to find statistical significance. The results also show changes in balloon volume, which is controlled by the operator, does not impact leaflet stress however, qualitative observations of leaflet folding and higher average stress in the underexpanded configuration indicate significance may be found with a larger patient cohort.

The main limitations of this study are the lack of patient specific material properties due to it being difficult to extract from medical imaging alone and validation of the bioprosthetic leaflet stress which currently cannot be measured in a clinical setting. Future directions include investigating the impact of other deployment strategies on leaflet stress. This includes altering the deployment depth and commissural alignment with the native commissures. Additionally, the results of this FEA model can be used in a computational fluid dynamics model to assess for paravalvular regurgitation which is a concern in heavily calcified BAV patients.

# IN SILICO INVESTIGATION OF CONTRALATERAL EMBOLIC STROKE RISKS FROM CAROTID ARTERY DISEASE

**Ricardo Roopnarinesingh[1], Debanjan Mukherjee[1]**

[1]Department of Mechanical Engineering
University of Colorado Boulder
Boulder, CO, USA

## INTRODUCTION

Stroke is one of the leading causes of death worldwide. Embolic stroke accounts for a majority of all ischemic stroke patients, and a significantly large proportion are categorized as Embolic Stroke of Undetermined Source (ESUS) [1]. Identifying embolic stroke etiology is a critical step in improving treatment efficacy and reducing incidence of recurring stroke events [1]. However, the ability to definitively identify embolus source based on occlusion location remains limited. One critical source of emboli are the carotid arteries, where build up of vulnerable atherosclerotic plaques can generate thromboemboli that move into the cerebral arteries. While the prevailing notion is that carotid emboli directed into the Circle of Willis (CoW) cause ipsilateral cerebral embolic events only, there are many reported instances of non-intuitive contralateral embolic strokes in patients with prominent carotid disease lesions. Despite such contralateral events being less frequent, they comprise a critical category of cases owing to the inherent difficulty in disambiguating stroke etiology and the disproportionately severe adversities in terms of treatment outcomes. There is a lack of proper understanding of how emboli released from the left and right carotid arteries intermix across the hemispheres into the CoW; whether particles originating from the left carotid will flow into the right hemisphere of the CoW and vice versa. This inspires a comprehensive investigation of how carotid emboli travel to the six major cerebral arteries, as function of CoW anatomy, embolus size, and laterality of release. Here, we present an in silico study addressing this question, using a custom patient-specific embolic stroke model outlined in several prior works [3, 4].

## METHODS

**Image-Based Modeling of Anatomy:** A patient-specific model from the aortic arch to the cerebral arteries connected at the CoW was created using artery lumen segmentation from patient CT images using SimVascular [3, 5]. Starting from a patient model with a compete CoW, five common variations in CoW anatomy were modeled by removing the absent artery in that variation from the complete CoW model [3]. The anatomical variants include an absent anterior communicating artery (AcoA), absent left or right posterior communicating arteries (LComm and RComm), and absent left or right P1 connectors (LP1 and RP1). Together with the complete CoW variant, a total of six different variations were used in this study, as illustrated in Figure 1.

**Hemodynamics simulation:** Hemodynamics across the aorta-CoW model was simulated using a stabilized finite element method for incompressible Navier-Stokes equations in SimVascular [5]. Blood was assumed to be a Newtonian fluid with a bulk density of 1.06 g/cc, and viscosity of 4.0 cP. At the aorta inlet, a validated pulsatile flow profile is specified over a cardiac cycle spanning 0.83 seconds [6]. Resistance based boundary conditions were applied to the outflow arteries to account for downstream vascular beds. These resistance values were acquired by calculating a total arterial resistance and allocating this resistance proportionally to each outflow artery based upon target flow divisions. 65% of the the flow was set to exit the descending aorta [7]. The six cerebral artery outflows were accordingly split based upon data reported in [8]. The remainder fraction of flow was assigned to the subclavian and external carotid arteries based on their cross-sectional area [9].

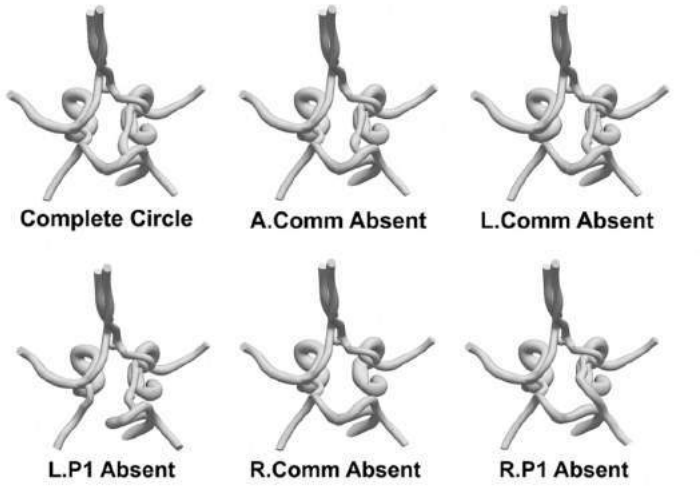

**Figure 1: The six patient-specific CoW models. The absent structures of the CoW are shown for each variation. Each variation model is based upon a modified patient-specific model with complete CoW anatomy to properly represent each variation [3].**

**Embolus Transport:** Embolus transport was modeled using a custom modified version of the Maxey-Riley equation [10]. These modifications included incorporating near-wall shear gradient lift forces, particle collisions with the walls of arteries, and elastohydrodynamic effects near-wall [3]. The emboli were assumed to be spherical particles with a one-way coupled fluid interaction in which the fluid affects the particle but the particle does not affect the fluid. Particles were assigned the mechanical properties of thrombo-emboli [4] and three embolus sizes of 1000$\mu$m, 750$\mu$m, and 500$\mu$m were considered to gain a range of insight on travel. For each model, approx. 12,000 emboli were released along artery wall (mimicking release from plaque wall) around the left and right carotid bifurcation. Resulting embolus distribution data spanning 36 simulations including 432,000 emboli were synthesized to illustrate contralateral trans-

port of carotid emboli into the brain.

## RESULTS

Embolus transport was quantified as the percentage of particles that reached each of the six major cerebral arteries, and the resulting distribution of emboli for each embolus size and each CoW anatomical variant have been presented in Figure 2. The data supports the notion that majority of left/right carotid emboli distribute ipsilaterally into the left/right cerebral arteries. Specifically, the middle cerebral arteries receive the highest proportion of carotid emboli across all sizes and anatomical variants . This is expected owing to the anatomical route of the internal carotid arteries into the middle cerebral arteries. However, when aggregated across all CoW variants, we observed an increased probability of emboli exiting the anterior and posterior cerebral arteries as emboli sizes reduced. This was associated with greater mobility of the emboli across the communicating arteries of the CoW. While the majority trend of ipsilateral carotid embolus distribution was observed as expected, we also observed that across all CoW variants, a smaller but non-zero proportion of emboli crossed hemispheres to distribute contralaterally from their carotid release site. Figure

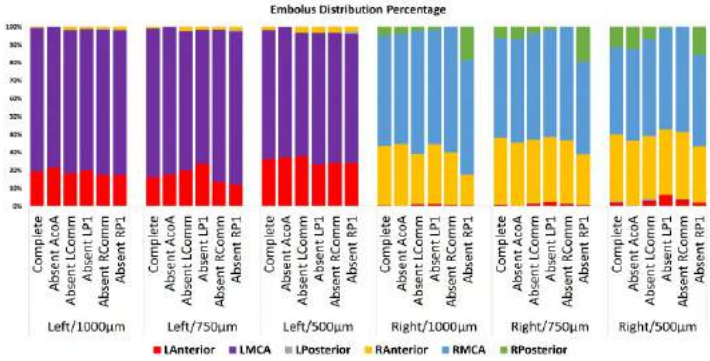

**Figure 2: Percentage of embolic particles moving through the six cerebral output arteries for each variation. Output percentage is given for combinations of both carotid arteries and the three particle sizes.**

3 presents the distribution of emboli that crossover contralaterally into the opposite hemisphere of the CoW with respect to the left or right carotid release. The data illustrates that small fractions of contralateral crossover occurs for all sizes and CoW anatomical variants considered, providing evidence that left carotid artery disease can lead to right cerebral hemisphere embolic events and vice versa. Furthermore, availability of detailed embolus trajectory data enabled viewing the route taken by these contralaterally traveling emboli. A snapshot for the ensemble of 12,000 emboli for the absent RComm CoW variant studied here illustrates that the communicating arteries of the CoW provide the conduit for a small fraction of emboli to move contralaterally into the left cerebral arteries, while the majority remains ipsilaterally distributed into the right cerebral arteries as can be seen in Figure 4 with the usage of the AcoA.

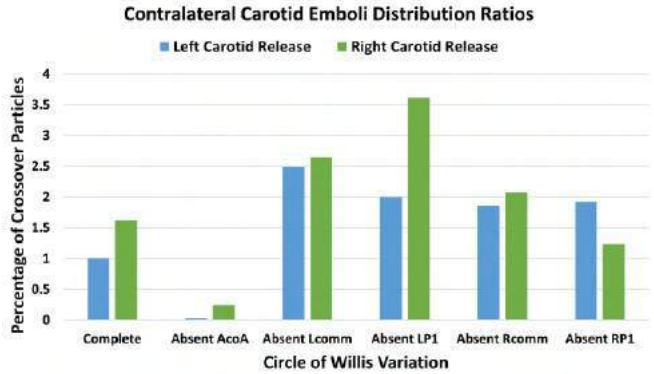

**Figure 3: Percentage of embolic particles that have contralateral movement for both carotid release areas and all six CoW variations.**

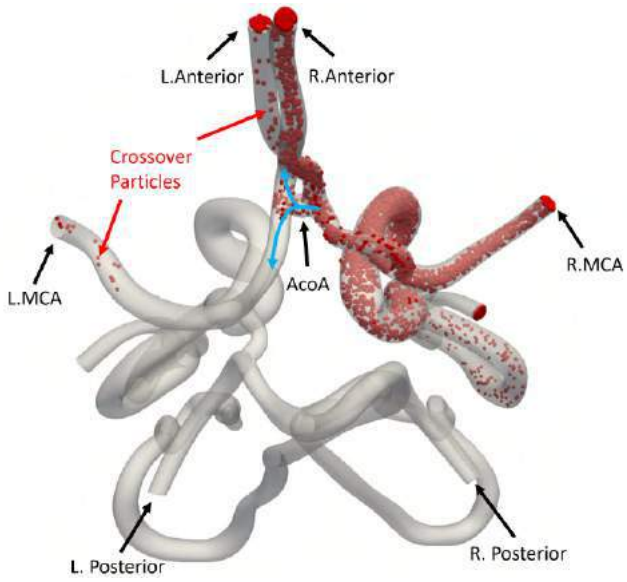

**Figure 4: The simulated movement of embolic particles into the absent R.Comm CoW variation released from the right carotid. The embolic particles are shown in red and a small amount of particles can be seen moving into the left hemisphere heading towards the left anterior and left middle cerebral artery outlets. The blue arrow indicates emboli routing through the AcoA and into left hemisphere arteries.**

## DISCUSSION

Using a patient-specific embolus transport model for stroke, we were able to obtain quantitative data on how particles travel contralaterally from the left and right carotid arteries to the cerebral arteries to cause embolic stroke. We considered systematic simulations including 6 CoW anatomical variations, 3 thromboembolus sizes, and an ensemble of 432,000 embolus samples. The findings are of high clinical relevance, as it enables disambiguating embolus source-destination relationship for contralateral carotid artery disease sites. Despite their lower occurrence as also seen here, such contralateral cases are of high importance as the etiology is difficult to establish and treatment can be adversely impacted. In continuing work, we seek to further characterize the occurrence risks and trends for such contralateral cases by considering more patient anatomy models. Furthermore, this study provides additional evidence on CoW anastomosis and its role in stroke. Specifically, the communicating arteries of the CoW are known to play a key role in determining proximal collateral capacity in occlusive cerebrovascular events such as stroke. Here, we illustrate that this network of vessels can play a secondary role in routing emboli across destination cerebral artery beds, thereby enabling the contralateral conduit for left/right carotid emboli to crossover and reach right/left cerebral arteries.

## INTRODUCTION

Protease-activated receptor type 2 (PAR2) is a G-protein coupled receptor involved in inflammation and pain sensitization [1]. It is canonically activated by irreversible proteolytic cleavage of its N terminus by proteases such as thrombin and tryptase [2]. Importantly, PAR2-mediated calcium response can further sensitize transient receptor potential vanilloid (TRPV) receptor ion channels such as TRPV1 and TRPV4 [1,3], and thereby induce sustained inflammatory response and hyperalgesia. As such, interrupting PAR2 activation and signaling can yield therapeutic relief of protease pain sensitization and inflammation.

Recently, our lab demonstrated that PAR2 could be selectively and remotely photoinactivated in live cells by molecular hyperthermia (MH) [4], which was induced by optical stimulation of gold nanoparticles with ultrashort nanosecond laser pulses. When gold nanoparticles are stimulated by an ultrashort nanosecond laser pulse they act as nano heaters with a nanoscale localized heat distribution that denatures nearby proteins. Although MH treatment was able to significantly reduce cellular calcium response to a PAR2-specific agonist, it's unclear what proportion of each cell's receptors were targeted and photoinactivated by the treatment.

In this work, we use mathematical modeling of the PAR2-mediated calcium signaling cascade to quantify the proportion of receptors photoinactivated by MH and understand how it affects the downstream calcium response (**Figure 1**). From the model we found that the calcium response for a given PAR2 agonist concentration decreased non-linearly with the proportion of photoinactivated PAR2 and provide new insight into how receptor photoinactivation by MH modulates intracellular calcium response to a PAR2 activating stimulus.

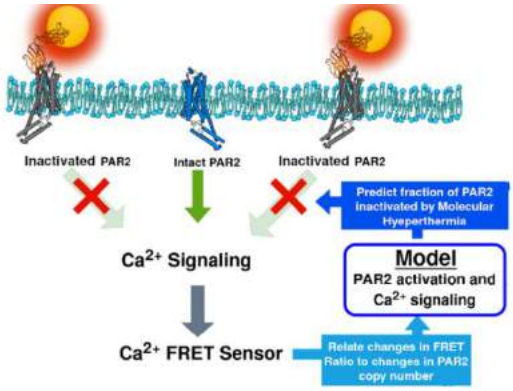

**Figure 1: Schematic depicting how the PAR2 signaling model is used to relate changes in Förster resonance energy transfer (FRET) signal during PAR2-mediated calcium signaling to PAR2 photoinactivation.**

## METHODS

To model PAR2 signaling we created a rule-based ordinary differential equation model of the PAR2 activation-mediated calcium signaling cascade (github.com/NTBEL/PARM). The model was encoded as a Python program module using the PySB framework [5], and it incorporates key elements of the PAR2-mediated calcium signaling cascade including PAR2 activation, PAR2 coupling with and activation of G-protein alpha, and calcium signaling via the phospholipase C and IP3 pathway (**Figure 2**), as well as the Förster resonance energy transfer (FRET) ratio signal generated by a genetically encoded calcium sensor to allow for direct comparison to experimental data. Unknown model parameters were inferred using Bayesian parameter estimation with the PyDREAM software [6], calibrating the model against previously published dynamic calcium

FRET sensor signal from PAR2 expressing HEK293 cells in response to different concentrations of the PAR2 agonist aminothiazol-4-yl-LIGRL-$NH_2$ (2AT) [4].

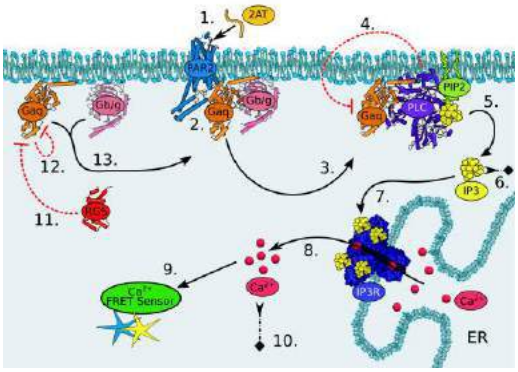

**Figure 2: Schematic of PAR2 activation and calcium signaling.**

*Model calibration:* DREAM$_{(ZS)}$ sampling was executed via PyDREAM with 4 chains and 50000 sampling iterations. The first 25000 iterations were taken as sampler burn-in, leaving a total of 100000 posterior samples (before any sample thinning). Each posterior sample corresponds to a parameter set that fits the calibration data reasonably well. Convergence of the posterior distribution was monitored using the Gelman-Rubin diagnostic.

## RESULTS

To quantify the relationship between PAR2 photoinactivation and changes to the calcium response the PAR2 signaling model was simulated with a wide range of PAR2 copy number values (number of receptors per cell) and the corresponding peak FRET signal in response to 330 nM 2AT agonist was computed for each case (**Figure 3**).

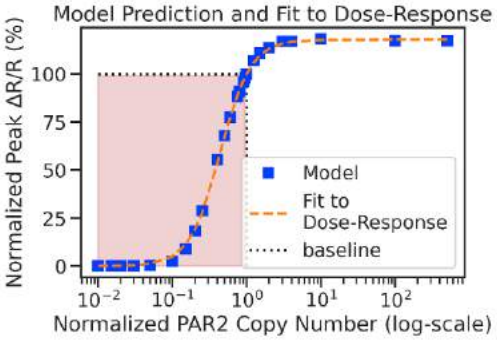

**Figure 3. Dose-response curve relating the normalized PAR2 copy number to the normalized peak FRET signal (ΔR/R) in response to 330 nM 2AT agonist; the quantities were normalized relative to the value of PAR2 copy number estimated by model calibration and the corresponding peak FRET signal at 330 nM 2AT. The dotted lines show the normalized baseline values of 1 and 100% for the PAR2 copy number and FRET signal, respectively. The orange dashed line shows the fit to Equation 1. The region shaded in red corresponds to cases where a fraction of the receptors is inactivated.**

The model results were then fit to a sigmoidal dose-response function:

$$E = iE_{max}/(1 + (EC_{50}/N_{PAR2})^n) \quad (1)$$

where $E_{max}$ is the maximum normalized peak FRET signal response, $EC_{50}$ is the dose at half-maximal response, and $N_{PAR2}$ is the normalized PAR2 copy number which is the dose in this case, and n is the Hill coefficient. The parameters determined when fitting Equation 1 to the model data were then used to map reductions in the normalized peak FRET signal to the percentage of inactivated receptors corresponding to that reduction in calcium response (Equation 2).

$$I_{PAR2} = i100\% - iEC_{50}/\left(1 + i(E_{max}/E)^{1/n}i\right) \quad (2)$$

where $I_{PAR2}$ is the percentage of inactivated PAR2 for any given normalized peak FRET signal $E \leq 100\%$. The percentage of inactivated PAR2 deviated from a linear response relationship (**Figure 4**), decreasing non-linearly with reductions in the peak FRET signal response from calcium signaling.

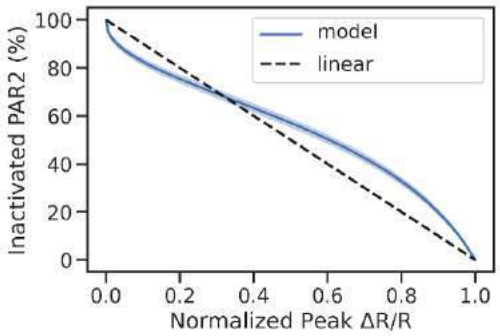

**Figure 4: Predicted relationship of the amount of inactivated PAR2 to the peak FRET signal (ΔR/R) determined from Equation 2 after fitting Equation 2 to the model responses. The dashed line shows a linear relationship for comparison.**

## DISCUSSION

Our results suggest calcium signal in response to a fixed agonist concentration decreases non-linearly with the proportion of photoinactivated PAR2. This result contrasts with enzyme systems which exhibit a linear reduction in the reaction rate with the proportion of enzyme photoactivated by MH [7], providing new insight into the relationship between PAR2 activation and calcium signaling. One current limitation of the model is that the experimental cellular expression level (protein per cell) of PAR2 is unknown. If the actual expression level is significantly different than the model value, the simulated results for the sensitivity of the FRET response to changes in PAR2 may be inaccurate. As a first step, we have experimentally quantified the number of gold nanoparticles that bind to each cell to help explain the fraction of inactivated PAR2. Going forward, we will incorporate this new data into our model analysis and better constrain the PAR2 number per cell. We are also working towards estimating an overall efficiency for MH-induced PAR2 photoinactivation on the cell surface.

# THE IMPACT OF STIFFNESS GAIN ON SPINE STABILITY

**Valerie R. Jardon (1), Sara E. Wilson (1,2)**

(1) Bioengineering Graduate Program, University of Kansas, Lawrence, KS, USA
(2) Department of Mechanical Engineering, University of Kansas, Lawrence, KS, USA

## INTRODUCTION

Low back pain and injury are costly health conditions that are prevalent in our society. Consequently, researchers have developed trunk models to investigate the functions and behaviors of the spine, focusing specifically on spine stability.

After the onset of a perturbation, it is crucial that the muscles adequately respond to assist in the stabilization of the spine and that the system return to equilibrium. If the system is unable to reach equilibrium after a perturbation, this may result in injury.

While intrinsic stiffness of the muscles has proven to be satisfactory for stability of many loading conditions on the spine, Franklin *et al.* [1] determined that there may be loading conditions that cannot be stabilized by only this mechanism, and reflex stiffness is necessary to achieve stability.

Models examining spine stability require representation of short-range muscle stiffness. Bergmark's model for short-range muscle stiffness (Equation 1) has been utilized by many researchers to model the spring-like behavior of the muscle crossbridges [2]:

$$K = q\frac{F}{L_o} \tag{1}$$

where $F$ is the muscle force, $L_o$ is the neutral length of the muscle and $q$ is the stiffness gain.

Panjabi and Crisco [3] defined a range of 0.5 to 42 for the stiffness gain ($q$), with an average value of 10. Correspondingly, the stiffness gain $q$ utilized has varied between research studies (Table 1).

**Table 1: Dimensionless Stiffness Gains in Key Literature**

| | q |
|---|---|
| Bergmark [2] | 40 |
| Cholewicki *et al.* [5] | 30 |
| Franklin *et al.* [1] | 10 |
| Granata & Wilson [8] | 5 |
| Stokes & Gardner-Morse [9] | 5 |

This investigation focuses on the influence that the stiffness gain has on stability and how this potentially affects our ability to adequately model the behavior of the lumbar spine.

## METHODS

To continue our investigation of the impact of stiffness gain on spine stability, a model based on the work of Franklin *et al.* has been developed and utilized [1]. This 18 degree-of-freedom trunk model consists of a fixed pelvis, a rigid body representing the cervical and thoracic regions of the spine, and a rigid body for each of the lumbar vertebrae. There are 90 Hill-type muscle fascicles [4] with curved paths based on Cholewicki *et al.* [5]. The muscle model consists of a damper, spring and contractile element in parallel (Equation 2):

$$F_m = F_{CE} + K_{PE}x + B\dot{x} = f_{max} * \alpha + \left(\frac{q * f_{max} * \alpha}{x_o}x(t)\right) + \left(\frac{b * f_{max} * \alpha}{x_o}\dot{x}(t)\right) \tag{2}$$

where $K_{PE}$ is the stiffness coefficient, $B$ is the damping coefficient, $x$ is the muscle length, $\dot{x}$ is the muscle stretch rate, $f_{max}$ is the maximum muscle force, $q$ is the stiffness gain, $b$ is the damping gain, $x_o$ is the equilibrium muscle length and $\alpha$ is the muscle activation.

The muscle activation can incorporate both the steady-state muscle activation and the reflex activation, with the reflex activation similar to a PD controller providing feedback (Equation 3):

$$\alpha(t) = \alpha_o + \alpha_r = \alpha_o + \alpha_o * \left(G_P * \frac{x(t-\tau) - x_o}{x_o} + G_D * \frac{\dot{x}(t-\tau)}{x_o}\right) \tag{3}$$

where $G_p$ is the proportional gain, $G_d$ is the differential gain and $\tau$ is time delay.

After linearizing the system, with the assumption $\tau = 0$ if reflex activation is included, a constrained optimization was performed to solve for the muscle activations that minimized metabolic power while

requiring that the system is stable and in equilibrium. The total metabolic power utilized is determined through use of Equation 4 from Anderson [6] with an equivalent magnitude of fast and slow twitch fibers:

$$P = \sum_{n=1}^{90} \frac{m_n * 74}{2} * \sin\left(\frac{\alpha * \pi}{2}\right) + \frac{m_n * 111}{2} * \left(1 - \cos\left(\frac{\alpha * \pi}{2}\right)\right) \quad (4)$$

where $m$ is muscle mass and $\alpha$ is steady-state muscle activation.

For a simulation with reflexes, the eigenvalues of the Jacobian matrix and the method by Chen [7] can be used to determine the time delay in which the system becomes unstable. A nonlinear verification procedure was then performed to ensure that the linearized system adequately predicted the behavior of the nonlinear system.

Simulations were completed for q=5, 10, 15, 20, 25, 30, 35, 40 for the following loading conditions: 0 N and 200 N vertical load applied to T4. The resulting metabolic power and muscle force required to stabilize the spine was determined for each simulation. Initial simulations did not include the incorporation of reflexes (i.e $G_p$=$G_d$=0). Reflexes were included in the model and nonlinear analyses were performed if intrinsic stiffness alone was not sufficient for stability of a trial ($G_p$=20, $G_d$=0).

## RESULTS

The resulting metabolic power and muscle force required to stabilize the spine for each of the simulations are provided in Figure 1 and 2. As shown in Figure 1, for both loading tasks, as the stiffness gain ($q$) increases, the necessary metabolic power decreases. Additionally, at smaller stiffness gains, the difference between the metabolic power from one gain to the next was greater. As the gain increases in magnitude, there is less of a decrease in metabolic power between gains. These trends can also be seen for the muscle force required to stabilize the system (Figure 2).

For the stiffness gain magnitude of 5 and 10, the system was unstable with the applied external load of 200 N (Figure 2). When reflexes were included and these simulations were run again, the resulting delay margins were 0.102 and 0.1015 seconds for the stiffness gain of 5 and 10 respectively (Table 2). The resulting metabolic power for the stiffness gain of 5 was 39.8 Watts and 38.1 Watts for the stiffness gain of 10 (Table 2).

**Figure 1: Metabolic Power vs. Stiffness Gain**

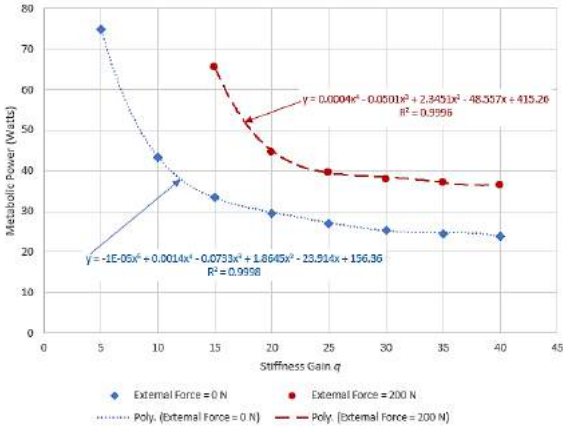

**Table 2: Simulation Results with Reflexes**

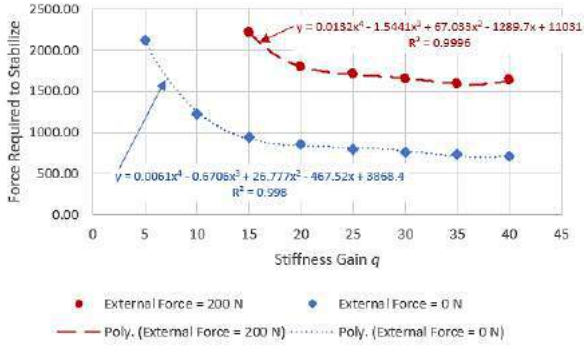
| Stiffness Gain | Time Delay (sec) | Metabolic Power (Watts) |
|---|---|---|
| 5 | 0.102 | 39.8 |
| 10 | 0.1015 | 38.1 |

**Figure 2: Muscle Force Required to Stabilize vs. Stiffness Gain**



## DISCUSSION

It is evident from Equation 2 that an increased stiffness gain would result in a greater muscle force than a muscle with the same activation and a lesser stiffness gain. Based on this relationship, it makes sense that more metabolic power and force would be required to stabilize the system for muscles with smaller stiffness gains. In order to stabilize the system with the smaller gain, more muscles would need to be activated or have increased activation to generate the force needed to stabilize the system. Additionally, it is important to notice the difference between the predictions made at q=5 and q=40. It is crucial to know that based on the stiffness gain used, the results may differ between studies. This would be important for validation of results. Additionally, the results in this study can be used as guidance for which results can be compared reasonably.

For the simulations with reflex stiffness, the calculated delay margins were greater than 0.06 seconds [9], the minimum physiological time delay of reflexes. This indicates that the reflexes would be able to reasonably act at this time to stabilize the system. Using the state variables and through the calculation of their displacement from equilibrium, we determined that that the system was approaching equilibrium in the simulation, verifying the linear analysis results.

# THE INTERPLAY BETWEEN ELASTIN AND PROTEOGLYCANS AND THEIR EFFECT ON ASCENDING AORTIC ANEURYSMAL BIOMECHANICS

**Miriam Nightingale (1,2), Amy Bromley (3), Jehangir J Appoo (4), Elena S Di Martino (1,2)**

## INTRODUCTION

The biomechanics of ascending aortic aneurysmal tissue are primarily dictated by the content and arrangement of the extra-cellular matrix [1]. While the fragmentation and decrease of elastin has long been established a sign of disease progression, the role of proteoglycans in this process has remained elusive [2]. Previous research into the role of proteoglycan in vascular disease paints a complex picture, with both positive and negative effects attributed. Specifically, for aortic aneurysms, it has been shown that in abdominal aneurysms there is a reduction in proteoglycan content in aneurysmal vs. healthy tissue, suggesting a positive regulative role associated with healthy tissue functioning [3]. From the negative side, it has been theorized that the structure of proteoglycans themselves may be associated with disease progression; increasing stress concentrations and reducing tensile strength when accumulated/pooled [4]. This study attempts to shed some light on this complex relationship by examining the effects of proteoglycan content and pooling on the mechanical and histopathological properties of ascending aortic tissue.

## METHODS

Tissue samples from the anterior region of the aorta were collected from 28 patients undergoing elective ascending aortic replacement surgery. Inclusion criteria included: greater than 18 years of age, tricuspid (TAV) or bicuspid aortic valve (BAV), no known or suspected connective tissue disorders, and no previous aortic dissections or ruptures. The sample were subjected to planar biaxial testing to assess mechanical properties such as low strain tangent moduli (physiological stiffness) and energy loss. These methods have been described previously [5]. For this study, a displacement-controlled protocol with a maximum displacement of 60% of the edge length of effective testing area of the sample for both the circumference and axial direction was used. The mechanical behavior of the tissue was characterized by the 2nd Piola-Kirchhoff stress and Green strain both locally at the center of the specimen (through optically measured dot-displacement) and globally (through displacements measured through the testing device) in both directions via a MATLAB Program. Aortic mechanical behaviors were determined under the assumption of homogeneity and incompressibility. A combination of testing methods and post-processing data selection ensured the shear stress on tested samples was low and could be considered negligible in the analysis. The histopathology evaluation of proteoglycan accumulation, elastin fragmentation, and collagen alteration was completed by a pathologist, in accordance with the consensus statement from Society for Cardiovascular Pathology [6]. The samples also underwent a quantitative histopathological analysis to determine proteoglycan and elastin content in the media. A subset of samples was subjected to uniaxial testing until failure to determine tissue strength

For statistical analysis, the normality of continuous variables was assessed through the Shapiro-Wilk Test. The Pearson correlation (if a normal distribution) or Spearman rank correlation (if a non-normal distribution) were used to assess the relationship between continuous variables. Categorical variables were assessed for equivalence of variance through the Levene test. An ANOVA (normal distribution), Mann-Whitney test (non-normal, two categories) or Kruskal-Wallis test (non-normal, > 2 categories) were used to assess the relationships between categorical and continuous/categorical variables. The significance threshold for all tests was set to 0.05.

## RESULTS

Proteoglycan content and accumulation showed a significant inverse relationship ($p=0.002$) where overall content decreased while areas/severity of accumulation increased. This interplay was seen in

both the mechanical and histopathological properties. Both Elastin and collagen were seen to be significantly associated with proteoglycan content and accumulation. Decreased elastin content was significantly associated with decreased proteoglycan content (Figure 1A: $p<0.001$, rho=0.91) and severe proteoglycan accumulation (Figure 1B: $p=0.029$). While increased elastin fragmentation was significantly related to a decreased PG content ($p<0.001$). Proteoglycan content was also seen to significantly decrease in the presence of collagen alteration ($p=0.019$).

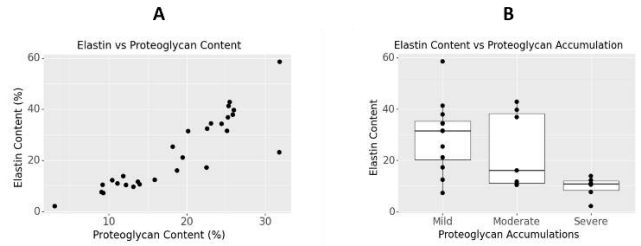

**Figure 1: Scatterplots and boxplots showing the significant associations between elastin content and proteoglycan content/arrangement. Elastin content vs Proteoglycan content (A), Elastin content vs Proteoglycan Accumulation (B)**

A decrease in physiological stiffness was found to be significantly associated with a decrease in both proteoglycan content (Figure 2A: $p=0.038$, rho=0.39) and elastin content ($p=0.041$, rho=0.38). While severe proteoglycan accumulation also led to a significant decrease in physiological stiffness (Figure 2B: $p=0.034$). A trend was also found to be associated with increased elastin fragmentation and decreased physiological stiffness ($p=0.089$). A decrease in proteoglycan content also significantly correlated with increased energy loss ($p<0.001$, rho=-0.61). For decreased elastin content, a trend was associated with increased energy loss ($p=0.065$, rho=-0.35). Both severe proteoglycan accumulation and elastin fragmentation were significantly associated with an increase in energy loss ($p=0.001$ and $p=0.03$ respectively). Finally decreased proteoglycan content was seen to significantly correlated with a reduction in strength ($p=0.032$, rho=0.43). Severe proteoglycan accumulation and collagen alteration were also significantly associate with a reduction in strength ($p=0.023$ and $p=0.016$ respectively).

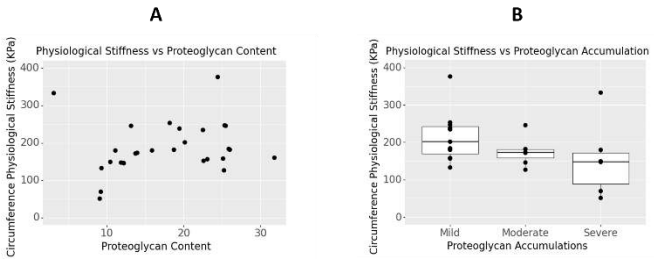

**Figure 2: Scatterplots and boxplots showing the significant associations between physiological stiffness and proteoglycan content/arrangement. Physiological Stiffness vs Proteoglycan content (A), Physiological Stiffness vs Proteoglycan Accumulation (B)**

## DISCUSSION

The media/middle layer of the aortic wall is thought to be the main contributor to the overall mechanical properties [1]. It is composed of equally spaced elastin lamellae, with each lamella perpendicularly connected by elastin as well [1]. Smooth muscle cells and collagen are interspaced between the elastin layers [1]. The elastin lamellae structure is supported by ground substance consisting mostly of Mucopolysaccharides (usually referred to as proteoglycans) [7]. Proteoglycans are thought to be associated with intercellular communication and regulating homeostasis in the aortic wall [7].

These results suggest a complex interplay between proteoglycans and histopathologic and mechanics changes associated with aneurysmal disease progression. High proteoglycan content appears to be associated with healthy tissue functioning, significantly associating with high elastin content, low elastin fragmentation, low collagen alteration, higher physiological stiffness, lower energy loss and higher strength – all histological and mechanical properties previously associated with healthier tissue structures and mechanics [8]. Conversely, proteoglycan accumulation was associated with weakening tissue: low elastin content, high elastin fragmentation, high collagen alteration, lower physiological stiffness, higher energy loss, and lower strength [8] – all histological and mechanical properties previously associated with disease progression.

These results reinforce the interconnection between proteoglycans and elastin and collagen as well as the effect these proteins have on aortic biomechanics. Interestingly, the localized accumulation of proteoglycan appears to be a mechanism separate from the fluctuations of proteoglycan content, existing simultaneously with an overall reduction of proteoglycans within the tissue. These results corroborate previous research illustrating a positive role being associated with content and a negative role being associated with accumulation [1,2]. Increased proteoglycan accumulation alongside decreased content could potentially be utilized as sign of disease progression and weakening.

Several limitations exist for this study. There were no measurements taken from normal aortic tissue to function as controls. Though we included both BAV and TAV patients, we did not have enough samples to determine differences between the two patient populations. Finally, as with all ex-vivo approaches, this study is limited to the passive mechanical properties, missing any changes associated with the interactions of living cells (such smooth muscle cells).

# COMPARING IN-PERSON BIOMEDICAL ENGINEERING LABORATORY TEACHING TO VIRTUAL REALITY TEACHING APPROACH

**Anita Singh (1), Sriram Balasubramanian (2)**

(1) Biomedical Engineering, Widener University, Chester, PA, USA
(2) School of Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia, PA, USA

## INTRODUCTION

Biomedical Engineering laboratories are designed to create hands-on experience that help student's ability to design an experiment while applying engineering principles. They learn to perform data acquisition, analysis while considering safety aspects and apply required engineering standards. They also learn to apply modern technical skills, perform teamwork, and develop communication skills practice [1,2]. Several new teaching modalities resulted from recent COVID-19 pandemic limitations and there is a need to investigated them for their continued implementation in enhancing engineering educational experience and learning . Our team has previously reported the efficacy of virtual reality (VR) videos in explaining the lab procedures. This modality has resulted in enhanced student learning of experimental protocol when compared to the standard online modality that uses traditional 2D videos. In this study, we aim to directly compare the efficacy of VR videos when compared to the in-person lab session.

## METHODS

A total of 18 Junior-level biomedical engineering (BME) students enrolled in BME 303: Biomedical Engineering Lab 1 participated in this study. During a bone-biomechanics lab, students were asked to watch a VR video of the lab and then take a quiz (Figure 1). The instructor then demoed that lab for the students and the students were asked to take another quiz. The questions in the two quizzes were shuffled between the two takes among these students. They were also asked to provide feedback on the ease of use of VR videos and their preference between VR sessions and in-person sessions.

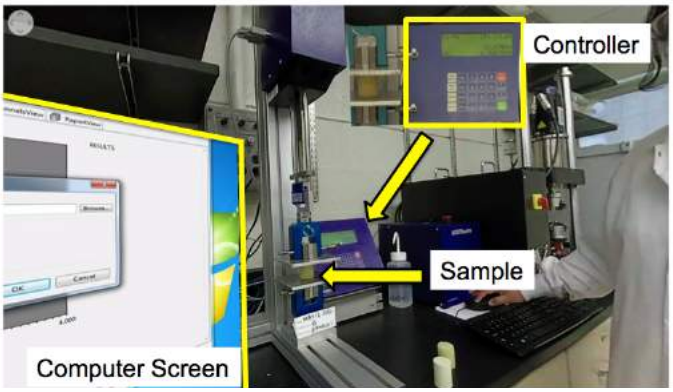

**Figure 1: Bone compression lab with zoomed controller and computer screen display in VR.**

## RESULTS

Student's quiz scores after VR video followed by in-person lab demo were slightly higher than after watching VR video only and before the in-person lab demo (Figure 2). However, no significant differences were reported. This confirms that between the two teaching modalities (VR versus in-person), the student learning attained was comparable. Student feedback also reported VR glasses to be user-friendly. However, students did prefer in-person sessions over VR-only sessions. They highly supported the VR videos as a critical supplemental learning tool since the videos could be watched even after the in-person lab session as they prepared their lab reports.

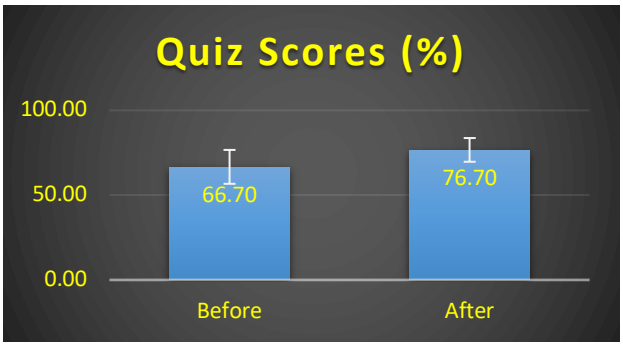

**Figure 2: Quiz scores after watching VR videos only and after watching VR videos followed by in-person lab demo.**

## DISCUSSION

The benefits of using VR technology in teaching biomedical engineering labs exist and it should further be explored as a supplemental teaching tool. It is also noteworthy that while in-person sessions were the preferred format of hands-on experience, the student learning was not different between the VR videos and in-person learning modalities.

## INTRODUCTION

Articular cartilage is a highly specialized tissue that lines the ends of long bones. Cartilage mechanical performance is highly dependent on its biochemical and structural properties: the extracellular matrix (ECM) is comprised of water and highly sulfated anionic glycosaminoglycans (GAG) constrained by fibrous network of type-II collagen that provide tribological material properties essential to supporting applied joint loads and maintaining a nearly frictionless shear interface between articulating joint surfaces. Osteoarthritis (OA), a painful, chronic, condition that damages diarthrodial joint function, is characterized by initial depletion of GAG, loss of collagen organization, and accompanying tissue softening, followed by more severe erosion of the collagen matrix. Promising therapies to treat OA include disease modifying drugs that mitigate or reverse cartilage degeneration and chondroregnerative tissue engineering platforms that recapitulate the composition and structure or healthy hyaline cartilage. The R+D pipeline for assessing the efficacy of treatments consists of a hierarchy of model systems: *in vitro* cartilage organ culture, *in vivo* preclinical animal studies, and randomized clinical trials. However, measurement of the effectiveness of therapies to preserve or regenerate cartilage is burdened by a lack of standardized biomarkers that can be applied across the spectrum of testing platforms. Evidence-based evaluations of the utility of OA therapies should be predicated on measuring biomarkers that reflect OA pathophysiology and portray the structure and composition of regenerated or neo-cartilage repair tissue relevant to its function. Arthroscopic-based cartilage grading systems (Outerbridge) and MRI (dGEMRIC, T1rho, T2*) are only moderately correlated with quantitative assessments of the tissue's material properties [1]. Therefore, robust methods capable of measuring changes in the functional properties of damaged cartilage are requisite for advancing OA treatment.

Raman spectroscopy is an inelastic optical light scattering technique that can provide a quantitative, point-wise optical fingerprint of a tissue's molecular building blocks (amides, sulfates, carboxylic acids, and hydroxyls), thus allowing recognition of the predominant molecular constituents of articular cartilage: GAG, collagen (COL), and $H_2O$. In our prior work, we developed a Raman arthroscopic needle probe and real-time spectral analysis platform capable of measuring ECM-specific compositional biomarkers of hyaline cartilage over the hierarchy of tissue model systems—*in vitro* analysis of enzymatically degenerated cartilage explants and *in vivo* ovine cartilage analysis via intraarticular Raman arthroscopy measures [2]. In this work, we aim to further advance this platform by investigating the capability of our Raman probe to assess the composition and material properties of cartilage in health and disease using ex vivo bovine and human osteochondral specimens over a range of degenerative states.

## METHODS

**Tissue specimens**: Bovine specimens were harvested from the medial femoral condyles (N=5). The first four knees (J1-J4) had no macroscopic degeneration on any of the articular surfaces (Outerbridge grade (OB0) (Fig 1A). The last knee (J5) exhibited a ~∅15mm focal chondral lesion (OB2) within the medial condyle load bearing (LB) region, but no macroscopic degeneration (OB0) in the surrounding LB and non-load bearing (NLB) cartilage (Fig 1B). Specimens were further harvested from the condyles of two cadaveric human knees (NDRI; age/sex: 32/M, 65/F). The 32/M exhibited no macroscopic degeneration (OB0, Fig 1C). The 65/F joint exhibited severe degeneration

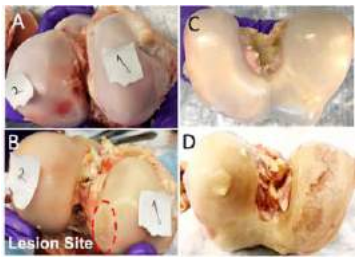

**Fig 1: (A) Healthy and (B) chondral lesion afflicted bovine femoral condyles. (C) Healthy (32yr) and (D) OA (65yr) human femoral condyles.**

(OB4) on the medial condyle, but grossly intact lateral condyle cartilage (OB0, Fig 1D). For both bovine and human models, rectangular osteochondral blocks (~5x5x5mm) were sectioned from the LB and NLB regions for analysis. **Raman analysis**: The Raman platform consisted of an NIR diode laser (ex=785nm, 500mW, B&W Tek), fiber-coupled spectrograph (QEPro, Ocean Optics), and needle probe with a 2mm sapphire ball lens (Fig 2)[2]. Raman spectra were acquired with the probe lens in gentle contact with the chondral surface over 30s acquisition time. The spectral fingerprint range (800-1800cm$^{-1}$) was preprocessed and subjected to a multivariate least-squares linear regression model to decomposition of Raman spectra to calculate the relative contribution of the predominant cartilage constituents (GAG, COL and $H_2O$) to the composite cartilage Raman spectra (Equation 1).

$$\mathbf{Cartilage_{spectra}} = GAG_{score}*(\mathbf{GAG_{REF}}) + COL_{score}*(\mathbf{COL_{REF}}) + H_2O_{score}*(\mathbf{H_2O_{REF}}) \quad (1)$$

where $GAG_{REF}$, $COL_{REF}$, and $H_2O_{REF}$ are the component spectra of purified reference chemicals for each ECM constituent.

**Property measures**:
The elastic modulus of the chondral layer for each tissue block was derived by indentation using a ∅3mm spherical indenter and the slope of the loading curve (Hertzian). The central ∅3mm chondral core of each block was sub-punched and GAG content determined by DMMB assay.

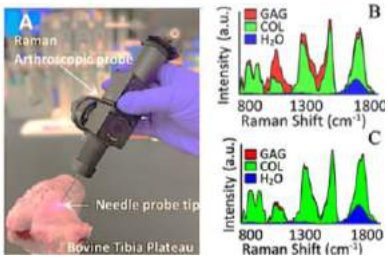

**Fig 2: (A) Raman needle probe in direct contact with cartilage surface. Representative 2D stacked area plot showing cumulative contribution of GAG, COL, $H_2O$, to composite Raman spectra of (B) healthy and (C) degenerative bovine cartilage.**

## RESULTS

The multivariate regression model accounted for 91±1.5% of the variation in composite Raman spectra (Fig 2B&C). Compared to healthy bovine specimens (J1-J4), tissue from the J5 specimen was degraded as evidenced by significantly reduced GAG content and elastic modulus within both the focal lesion (OB2) and surrounding tissue (OB0) (p<0.001; Fig 3A-B).

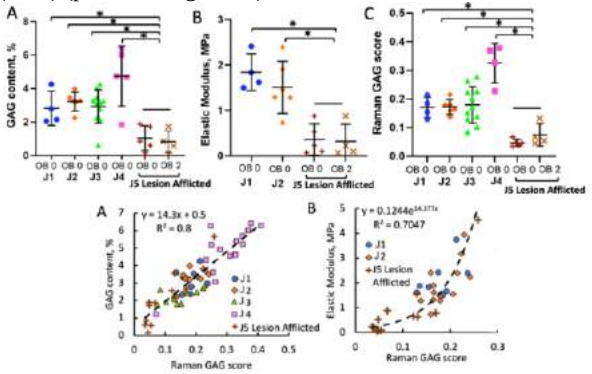

**Fig 3: (A) GAG content, (B) elastic modulus, and (C) Raman GAG scores for cartilage from LB regions of healthy (J1-J4) and lesion-afflicted (J5) bovine tissue blocks. Regression Raman GAG score vs. (D) DMMB-assay GAG content, and (E) elastic modulus for bovine blocks (n=59) * p<0.001: significant differences.**

Similarly, Raman derived biomarkers revealed significantly lower Raman GAG scores in both the lesion and surrounding tissue (p<0.001; Fig 3C). For all bovine specimens, results demonstrated that Raman GAG scores predicted 80% of the variation in GAG content (Fig 3D) and 70% of the variation in elastic modulus (Fig 3E). For the human model, specimens from both condyles of the 65/F-OA were degraded as evidenced by significantly reduced elastic modulus within the OB 4 and intact (OB 0) specimens (p<0.001; Fig 4A). Significantly lower Raman GAG scores were also measured in specimens from both condyle regions of the 65/F-OA joint compared to the 32/M (p<0.001; Fig 4B). For all human specimens, Raman GAG scores predicted 70% of the variation in elastic modulus (Fig 4C).

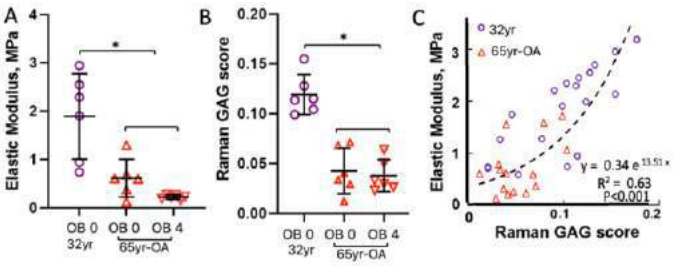

**Fig 4: (A) Elastic modulus and (B) Raman GAG score in LB regions of 32/M and 65/F human tissue blocks. (C) Regression Raman GAG score vs elastic modulus for all human tissue blocks (n=34). * p<0.001: significant differences.**

## DISCUSSION

GAG "scores" derived from multivariate regression spectral analysis represent the relative contribution of GAG to the composite Raman spectra of cartilage acquired in real-time, using Raman probe platform. The GAG score accounted for 80% of the variation in the measured GAG composition and predicted 60-70% of the variation in the elastic modulus of cartilage specimens over a range of cartilage morphologies including intact (OB 0), focal chondral lesion (OB 2), and severely degraded cartilage (OB 4). Raman GAG scores revealed depleted GAG composition and diminished tissue stiffness in regions where there was no visual macroscopic degeneration: "intact" cartilage from human 65/F and tissue surrounding the focal lesion in bovine J5. These outcomes support the feasibility of developing a Raman-based needle probe that maps real-time non-uniform and reduced sGAG distribution within the lesion and peripheral cartilage that was otherwise visually normal. Therefore, Raman spectroscopy of the joint can show molecular signatures of damaged tissue, even if it is invisible to the eye. Raman spectroscopy can "optically biopsy" cartilage and quantify the relative contribution of key biochemical constituents that serve as biomarkers for determining cartilage composition, structure, and material properties in normal and pathological tissue and in response to chondroprotective and/or chondroregenerative treatments. This work supports the use of Raman spectroscopy as a research platform to objectively assess the efficacy of emerging OA therapies across the hierarchy of in vitro, in vivo, and clinical model systems. In the future, Raman arthroscopy can serve as a transformative clinical platform for discrimination of healthy versus degraded tissue, diagnosing early OA, and guiding clinical treatment courses.

## INTRODUCTION

The brachial plexus (BP) is an intricate network of nerves responsible for providing motor and sensory innervation to upper extremities [1]. A common BP nerve injury in infants is neonatal brachial plexus palsy (NBPP) [2]. NBPP is defined as over-stretching of BP during complicated birthing scenarios [3]. Despite obstetric care improvements, NBPP continues to significantly impact infants' lives, with a worldwide incidence of 1 to 4 per 1000 live births [3, 4]. Current available treatment strategies for infants who do not fully regain function by three months after BP injury during a complicated delivery is surgical intervention, such as nerve transplantation surgery [2, 3]. However, surgical intervention remains controversial since timing and type of surgery highly rely on understanding structural changes observed after a neonatal BP injury [3]. Therefore, objective of this study was to relate structural changes at varying degrees of stretch of neonatal BP using a neonatal large animal model.

## METHODS

Ten neonatal piglets (3-5 days old) were anesthetized and BP was exposed using an axillary approach per approved procedures by Institutional Animal Care and Use Committee (IACUC). *Biomechanical Studies*: A custom-built mechanical testing device was used to perform *in vivo* stretch at a displacement rate of 500 mm/min to predetermined strains of <15% and >15% to represent mild and severe stretch injury, respectively (Fig. 1A). BP nerve segments were cut and anchored at the distal end. Three to five black acrylic paint markers were placed along the length of nerve segment and a stereo-camera (ZED Mini) was positioned above to measure real-time strain (Fig. 1B). Load and displacement data was acquired at a sampling rate of 1000 Hz. Images were captured at 100 frames/s.

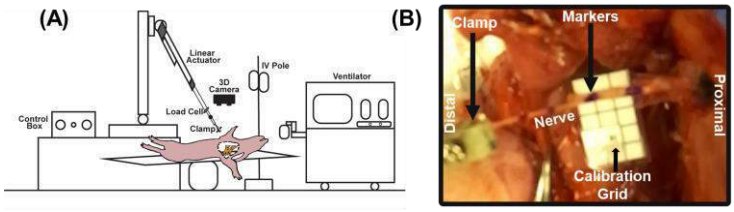

**Figure 1.** (A) Schematic of mechanical testing set-up. (B) A BP terminal nerve branch was clamped and stretched to failure at a rate of 500mm/min. A camera was placed above the BP along with a calibration grid for 3D strain analysis.

*Histology*: BP nerves were harvested post-stretch and OCT-embedded. Ten-µm-thick serial longitudinal sections were stained with Hematoxylin-Eosin (H&E) and neurofilament (NF) immunofluorescence. Using Leica DMI 4000 B microscope, stained slides were imaged at 10x along nerve length. Each image was scored by an independent-blinded observer for vascular damage and fiber disruption using an adaptive scoring system for each. Vascular damage was scored on scale of 0-2 (0-no damage, 1-torn vessel, 2-scattered blood cells) (Table 1).

**Table 1.** Blood Vessel Scoring System

| Score Value | Definition | Staining Method | Notations |
|---|---|---|---|
| | | Hematoxylin–Eosin | |
| 0 | None to minimal damage |  | Intact blood vessel wall (**black arrow**); compact RBCs (**red arrow**) |
| 1 | Moderate damage |  | Intact blood vessel wall with spacing (**black arrow**); minimal scattered RBCs (**red arrow**) |
| 2 | Severe damage |  | Broken blood vessel wall with scattered RBCs (**black arrow**) |

RBCs: Red Blood Cells

Fiber damage was scored on a scale of 0-4 (0-no to minimal damage, 1-straightening, 2-increased spacing, and 3 and 4-torn to scattered fiber disruption, respectively) (Table 2).

**Table 2.** Fiber Damage Scoring System

| Score Value | Definition | Staining Method | Notations |
|---|---|---|---|
| | | Neurofilament Immunofluorescence | |
| 0 | Normal/Control |  | The fibers hold their wavy pattern (**white arrow**) with no increase in space or breakage |
| 1 | Straightening of fibers |  | The uniform wavy pattern begins to straighten (**white arrow**), while fibers remain intact |
| 2 | Increased spacing |  | The fibers are still intact, with loss of wavy pattern (**white arrow**) and increased amount of spacing (**red arrow**) |
| 3 | Fiber disruption |  | The fibers begin to fragment (**red arrow**) while the spacing increases (**white arrow**) |
| 4 | Complete disruption |  | The fibers are no longer intact and there is more space between them (**black arrow**) |

Extent of fiber disruption was measured at thickest fascicle by binarizing image and measuring area of a 100x100 pixel region of interest.

## RESULTS

Using the modified scoring systems, vascular damage (**Fig. 2A**) and fiber damage (**Fig. 2B**) increased with increasing stretch.

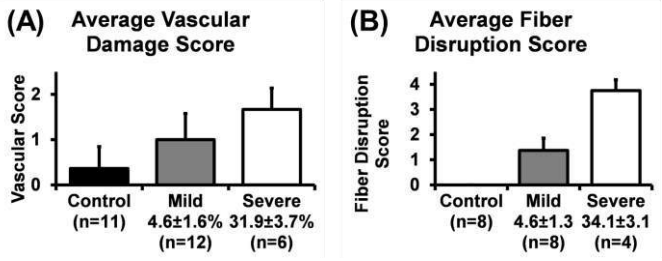

**Figure 2.** Bar graphs of average (A) increasing vascular damage, (B) increasing fiber damage, with increasing stretch.

Extent of fiber disruption decreased with increasing stretch (**Fig. 3**).

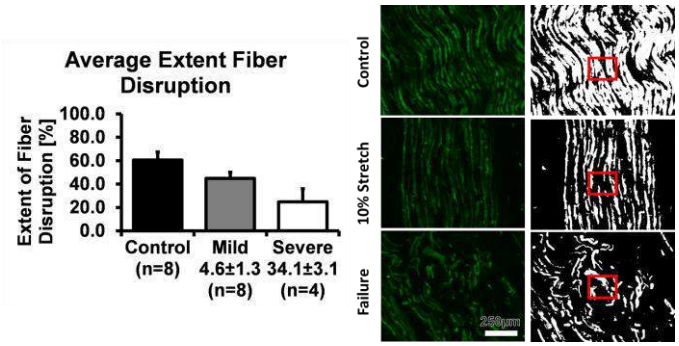

**Figure 3.** Bar graphs of average decreasing extent of fiber disruption with increasing stretch with representative images.

## DISCUSSION

The current study is a novel contribution to understanding the neonatal BP structural response to a stretch injury that may aid the understanding of injury thresholds in human neonatal BP because neonatal piglet BP and neonatal human BP share anatomical similarities [5]. This study is the first to report structural changes of neonatal BP with respect to varying degrees of stretch. Characterizing structural changes as a result of stretch injury is of importance to understand the extent of injury. Future functional studies may further contribute to the understanding of NBPP injury mechanism.

# AUTOMATED 4D MESHING OF EX-VIVO FILLING OF THE MURINE URINARY BLADDER

**Eli Broemer (1), Sara Purdue (1), Pragya Saxena (2), Nathan Tykocki (2), Sara Roccabianca (1)**

(1) Mechanical Engineering, Michigan State University, East Lansing, MI, USA

## INTRODUCTION

The urinary bladder is a highly distensible organ capable of expanding to over twice its initial volume while accommodating urine volume increases at low pressures. For mechanical analysis, the bladder is often modeled as an idealized spherical pressure vessel. In reality, the shape of the bladder is closer to an ellipsoid. Indeed, in the clinical setting, bladder volume is often approximated by measuring the 3 major axes via ultrasound [1]. However, even this is a simplifying proposition, and the true shape changes throughout filling due to the anisotropic and heterogeneous material properties of the soft tissue. The bladder has been shown to have different material properties in the apex-to-base vs circumferential directions [2] as well as distinctive contractility between the dome, bladder wall, and trigone (i.e., top, sides, and lower neck) [3]. This is all to say, the urinary bladder has complex mechanical characteristics that drive a constantly shifting geometry during filling. Accurately modeling the shape of the bladder during filling is necessary to better understand the unique mechanical features of this organ.

In this study, a novel method has been developed for reconstructing accurate 3D geometries/meshes from *ex-vivo* bladder filling experiments, with a time resolution of 0.1 sec (4D). The method is highly automated and utilizes open-source software. 4D meshing of the bladder, as shown here, provides a vectorized organ representation from empty to full capacity. These techniques will be used to further study the anisotropic mechanical behavior of the urinary bladder.

## METHODS

*EXPERIMENTAL SETUP* A mouse bladder was extracted, cleaned, and mounted on a cannula connected to a pump and pressure transducer. A custom testing device was built to allow multiple views (i.e. top, left, right, front, & back views) of the organ to be imaged throughout filling (**Figure 1**). The bladder was empty when mounted, submerged in 37°C saline, and then filled at a rate of 30 µL/min until a measured inner pressure of 25mmHg was reached.

A camera captured the bladder throughout the pressurization. Camera and pressure recordings were synchronized, so that images and pressure measures were collected at the same instant. The output was a video of the experiment at 10 frames/sec, and a spreadsheet of bladder pressure where each measure corresponds to a frame in the video.

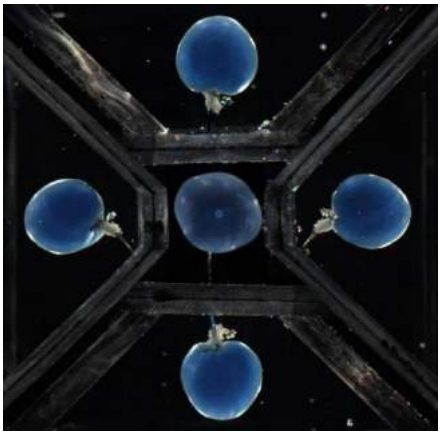

**Figure 1: Experiment setup. Bladder is mounted in the center (viewed from the top), and is surrounded by 4 mirrors which show front, back, left, & right views of the tissue.**

*IMAGE PROCESSING* The data was processed with python. Custom code locates tissue boundaries and segments bladder silhouettes from the top, left, and front views (**Figure 1**) in each frame. First, a region of interest was selected in the final frame with the Paint.NET software. This task creates a window for the code to search for exact tissue boundaries, and takes ~1 minute to perform by a researcher for each sample. The region of interest and the experiment video are then passed into the code, and no more input is needed from the researcher.

SB³C2022-432

Within the region of interest, a Canny algorithm [4] is used to locate the tissue boundaries of each view (**Figure 2A**). In short, the brighter soft tissue in contrast to the dark background creates a sharp gradient along its edge—this gradient is detected, some smoothing and continuity is enforced, and the result is a line denoting the bladder edge.

The edge line is not guaranteed to be a closed curve (**Figure 2A**), so an Open Curve Filling algorithm was developed [5]. This algorithm seeds a pixel at the center of the bladder view, and then pixels "grow" outwards in all directions until an edge is hit. In directions which are open (i.e., no edge will be found) the algorithm draws a connection between the two nearest edges. The result is a solid silhouette of the bladder view (**Figure 2B**). These silhouettes are used to generate a 3D reconstruction of the bladder at each time point in the experiment (4D).

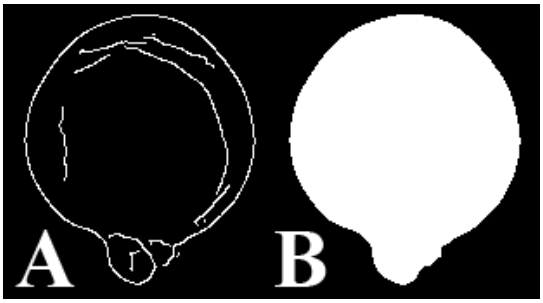

**Figure 2: Segmentation of bladder front view. A) Output of Canny edge detection. B) Output of Open Curve Fill algorithm.**

*MESHING* A 3D solid shape is created by the space carving method [6]. The method begins with a primitive rectangular prism, and then the two side views (**Figure 1**) are used to cut away from the primitive in the direction normal to their plane. These first two carves produce a bicylinder-like shape (intersection of 2 cylinders). The top view is then used to form the final shape by carving in the Z direction (**Figure 3 left**). However, in this case, for each unit in the Z direction, the top silhouette is scaled to fit the rectangular slice of the bicylinder. Phrased another way, the top-down view is mapped along the entire height of the bladder. If this technique was not used, a tricylinder would be obtained instead, and the final bladder shape would have sharp corners. This is an approximation of the actual bladder 3-dimensional volume, yet it is necessary given the type of experimental data available.

Finally, the voxel (3D pixel) representations of the tissue, obtained from space carving, were transformed into surface meshes (**Figure 3 right**). The marching cubes algorithm [7, 8] was employed for this step. Each mesh was verified to be defect-free and watertight, and then smoothed. The final result gave a set of bladder meshes at every time point imaged, which have a corresponding internal pressure measure that may be used for mechanical analysis.

## RESULTS

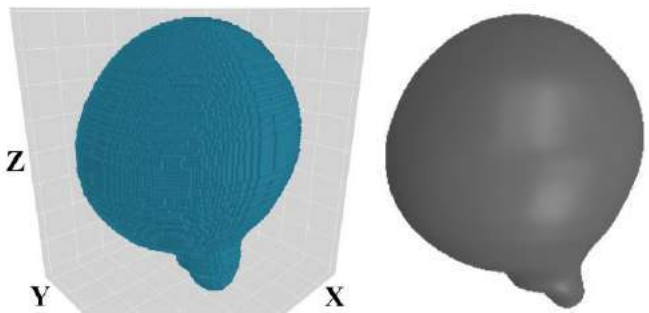

**Figure 3: Left) Voxellized bladder. Right) Meshed bladder.**

Accuracy of automated segmentation was validated by comparing the volume result to a manual segmentation at points throughout the experiment (**Figure 4**). Both manual and automated segmentation produced a linear volume increase correlating to the constant fill rate.

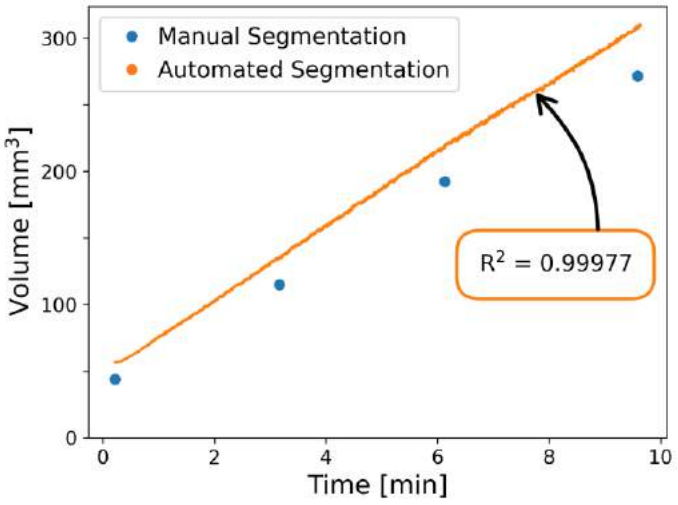

**Figure 4: Bladder volume comparison between fully automated segmentation (Figure 2) and a comparable manual method in which the bladder was isolated from background by a researcher (not shown).**

## DISCUSSION

The methods described here were shown to generate accurate 3D bladder volumes in either voxel or mesh forms. Effort to automatize this process allowed these geometries to be easily rendered at all time points captured during filling. Volumes were compared to a manual method, and the automated process was shown to over-estimate (**Figure 4**). This discrepancy is likely due to the inclusion of the bladder neck, which was removed during manual segmentation. Steps are being made to exclude the neck from automated geometries by obscuring it in the experimental setup. The source code for all image processing and meshing described here is publicly available for use [5].

The work shown here is a step towards fully describing the unique and transient shape of the urinary bladder during filling. Future work will develop more techniques so that bladder deformations in these volumes can be quantified to study the anisotropic behavior of this tissue.

## ACKNOWLEDGEMENTS

Thanks to Sara Purdue for the manual segmentations, and Pragya Saxena for performing the experiments. This work was supported by the National Institutes of Health (grant numbers K01DK103840, R01DK119615, NIH P20DK127554).

# CHARACTERIZATION OF BIOENGINEERED TISSUES BY DIGITAL HOLOGRAPHIC VIBROMETRY AND MACHINE LEARNING

**Colin Hiscox (1), Juanyong Li (2), Ziyang Gao (3), Dmitry Korkin (3), Cosme Furlong(1), Kristen Billiar (2)**

## INTRODUCTION

Mechanical properties are critical and often overlooked factors defining the quality of bioengineered tissues. Current tests used to measure the physical properties of engineered tissues, such as uniaxial tensile tests and nanoindentation, tend to be invasive and destructive and thus not applicable for in-process quality control, requiring aseptic non-destructive assessment.

The goal of this work is to develop a noncontact nondestructive method to measure the properties of bioengineered tissues during production. We apply acoustic vibration to Apligraf living skin substitute and measure the modes and displacements of vibration of the entire surface of the tissue within its packaging. We then utilize Finite Element Methods (FEM) and supervised machine learning algorithms to relate the measured vibrations to the mechanical properties.

## METHODS

Our methodology used three components to measure important information of the sample: optical coherence tomography (OCT), digital holographic vibrometry (DHV), and nanoindentation. All measurements and experiments were performed on samples of Apligraf generously donated by Organogenesis Inc. [1]

First a sample was measured with OCT (Telesto SD-OCT, Thorlabs). A b-scan taken at multiple points was used to estimate the thickness of each layer of the Apligraf nondestructively.

DHV, the primary tool, uses a speaker and a holographic sensor to induce and measure vibrations [2]. The sensor (Fig. 1) uses a 532 nm light to illuminate the sample while it is still in its packaging. In DHV, a subwoofer placed above the sample outputs single tone frequencies and sweeps between 70 Hz and 500 Hz. We identified vibrational modes of the $0^{th}$ order and imaged the sample at 12 equidistant points within a single vibration curve by modifying the phase of camera strobing for image acquisition. This gave a full-field-of-view video with 12 frames that showed the nm-scale waveforms oscillating in the sample.

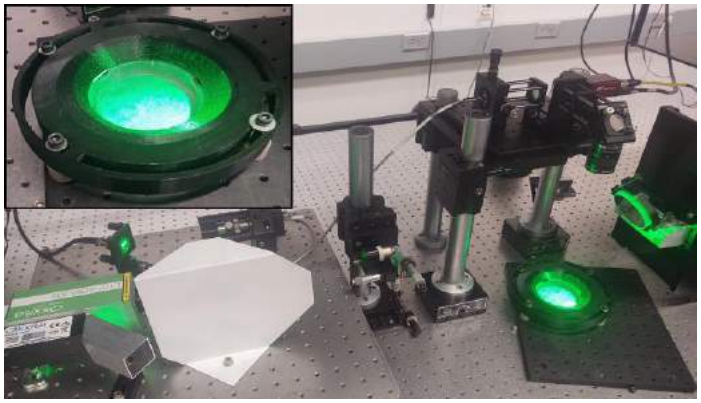

**Figure 1: DHV sensor with inset of tissue during measurement [3]**

Samples were also measured with nanoindentation at 4 multiple random points with a 51 μm-radii probe on a 3.45 N/m stiffness cantilever (Chiaro, Optics 11). During indentation, the sample was covered by a lid with a small opening to minimize evaporation. The epidermis was measured then peeled back with a scalpel and forceps, and the tissue's dermis was measured the same way. This was used to validate the modulus of the epidermal and dermal layers to compare to simulated results and to algorithm predictions.

To demonstrate the utility of the method, two experiments were performed. In the first experiment, a single sample was measured with nanoindentation then with DHV. Four different speaker volumes were measured at each mode, measuring different pressures applied by the acoustic waves to the sample, to test for linearity of the tissue response.

For the second experiment, the sample was subjected to controlled drying to change the thickness and/or stiffness of the sample and measure the resulting change in frequency of vibrational modes over time. Due to the destructive nature of the drying, two different samples from the same production batch were used for nanoindentation and

DHV. Each sample was dried for 90 minutes in a 23 °C oven (Isotemp, Fisher Scientific) for controlled humidity and temperature, and measured at several time points: 0, 3, 6, 10, 15, 30, 60 and 90 minutes. Each sample was put back into the oven with an open lid after measurement until the next time interval is reached.

To integrate future machine learning algorithms into the methodology, we developed a composite linear-elastic Finite Element (FE) model in Ansys APDL. The model includes three layers: the epidermis, dermis, and porous plastic membrane on which they sit. A modal analysis was performed in which the stiffness and thickness of the epidermal and dermal layers were modified across a range of expected values. This model output the frequencies of several modes for each combination of stiffness and thickness values.

## RESULTS

The maximum positive displacement measured at the first four vibration modes for four different acoustic forces applied by the speaker show roughly linear relationships (Fig. 2) indicating that the tissue is within the linear region at these low displacements. For these analyses, the largest displacement is taken from the point in the 12-image set of measurements that reflects the top of the sinusoidal curve.

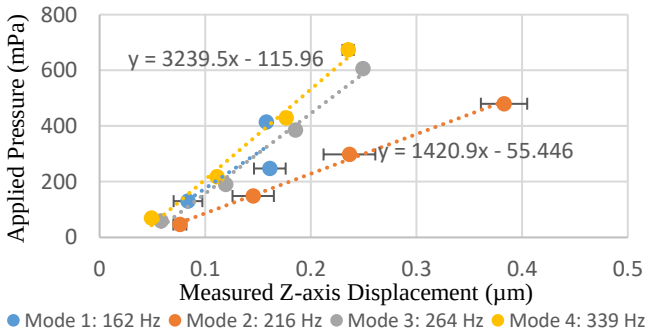

**Figure 2: Amplitude of tissue displacement for multiple applied pressures during vibration [3]**

In the second experiment, OCT measurements of thickness for both epidermal and dermal layers of the Apligraf tissue decreased with drying time (Fig. 3).

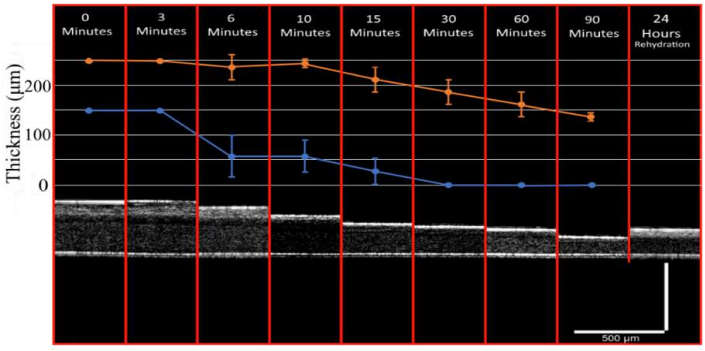

**Figure 3: OCT measurement of tissue thickness during drying [3]**

The frequencies at which each of the 1st four modes of vibration occur decrease monotonically with drying (Fig. 4). The modal FEA in which the layer thickness was decreased to match the measured data show the opposite trend in frequency of the fundamental mode (Fig. 5). This result indicates that it is more likely that the increase on modulus with drying dominates the vibratory behavior.

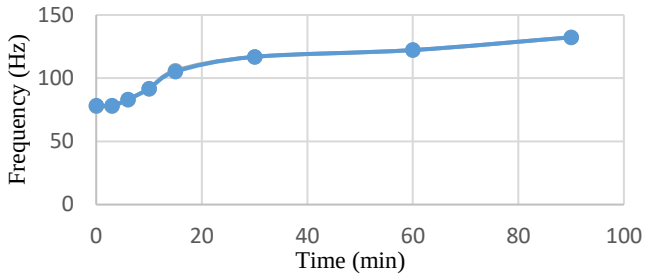

**Figure 4: Expected frequency of vibration from FEM [3]**

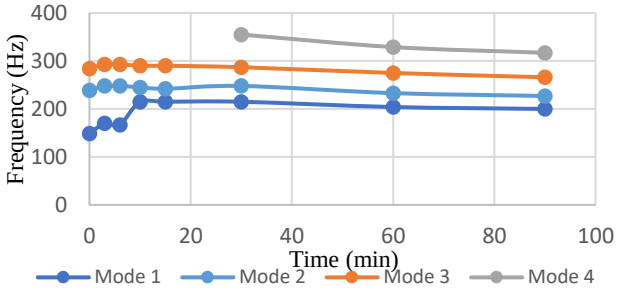

**Figure 5: Frequency location for each mode during drying [3]**

## DISCUSSION

This study demonstrates the ability to measure the full-field surface displacements of engineered skin tissue nondestructively and aseptically within its packaging using stroboscopic holographic vibrometry. By utilizing multiple acoustic pressures, the linearity of the tissue behavior was confirmed. Drying the tissue demonstrated the ability of the system to detect changes in the physical properties, and the FE analysis indicates that the changes in modal frequencies are due to stiffening of the tissue. However, due to the complexity of the layered system which includes the agar and stiff membrane on which the tissue is grown, it is not currently possible to extract the precise mechanical properties of the Apligraf layers from vibrometry alone. Further, the interferometric images output from the holographic system are very large and complex and can take multiple hours to analyze. Machine learning models are being constructed to relate finite element results to experimentally measured results and to more quickly analyze the full-field surface displacement data to predict the mechanical properties.

Once completed, this non-invasive measurement technique and associated analysis method would likely take around 5 minutes allowing for in-line measurement during production. This QC assay has the potential to enable identification of faulty batches before the full growth time is reached, increasing efficiency of manufacturing.

## ACKNOWLEDGEMENTS

# QUANTIFYING TISSUE-SPECIFIC DIFFERENCES IN COMPRESSIVE MATERIAL BEHAVIOR OF PORCINE GASTROINTESTINAL TISSUE

**Samantha J. Barr (1), Alexander J. McGuigan (1), Caroline Karczewski (1), Alexander W. Caulk (1)**

(1) Surgical Innovations, Medtronic Inc., North Haven, Connecticut, United States

## INTRODUCTION

Surgical stapling is a common intervention used in gastro-intestinal (GI) applications to resect and repair damaged or diseased tissue. Despite significant technological advancements in surgical stapling, rates of adverse postoperative outcomes such as anastomotic leak remain high in some applications [1]. Clinicians and medical device manufacturers alike remain interested in design improvements to surgical staplers which may aid in improving postoperative outcomes. One key design parameter of interest is identification of the optimal compression profile of tissue which is highly dependent on tissue geometry and material properties. Currently, staplers compress tissue to a predetermined thickness, and manufacturers offer a variety of stapling products with differing final compression thicknesses to provide surgeons the opportunity to account for different tissue characteristics during stapling procedures. However, the opportunity remains to further improve device performance through design enhancements which better account for patient- and tissue-specific differences in compressive material properties of tissue.

*Ex vivo* mechanical characterization of GI tissues has been performed extensively in tension. While compressive properties of some GI tissues have been reported in minimal contexts [2], there remains a pressing need to perform material testing of GI tissues which adequately supports constitutive modeling and material parameter estimation in applications which recapitulate the large compressive strains commonly imposed during surgical stapling.

In the present study, porcine GI tissues were subjected to uniaxial compressive testing to evaluate loading and stress relaxation behavior. We focused on GI tissues which are commonly subjected to procedures involving surgical stapling: colon, small bowel, and stomach.

## METHODS

*Tissue harvest and preparation.* Fresh porcine colon, small bowel, and stomach were obtained from Animal Technologies (Tyler, TX). All tissues were tested within 72 hours of harvesting. Samples were cut into 1 $cm^2$ pieces and secured to a standard material testing device (Electropuls Model E3000, Instron, Norwood, MA, USA) using sandpaper (220 grit) and tissue glue to minimize slipping during testing. Reference thickness was determined by applying a load of 0.01 lbs. to the tissue. After reference thickness was determined, the entire fixture was submerged in a 37°C saline bath.

*Mechanical testing.* For all tissues, each sample was preconditioned for 3 loading and unloading cycles to the target strain. Target strains were chosen for each tissue type to reach sufficiently high stress without inducing structural damage as defined by a decrease in the stress-strain curve. Colon was compressed to 75%, small bowel to 71%, and all stomach samples to 45% strain. The protocol for small bowel included remeasurement of reference thickness after preconditioning, which was not performed for other tissues. Target strain was calculated based on the remeasured thickness, but to facilitate comparison with other tissues, strain was recalculated based on the original thickness, which introduced variation in the target strain ($\epsilon = 0.71 \pm 0.025$). Stomach tissue was further divided into anatomical region (i.e., fundus, body, antrum) based on preliminary testing and literature reports of significant material heterogeneity across regions; however, an applied strain of 45% was implemented across all regions to facilitate data comparison. Preliminary testing suggested minimal regional differences within colon and small bowel.

All testing was performed at 0.5%/sec. In the fourth cycle, the sample was compressed to the tissue-specific target strain and held for 600 seconds before unloading to quantify the relaxation response of the tissue.

*Data analysis.* Stress and strain were calculated according to Equations 1 and 2,

$$\sigma = \frac{F}{A} \tag{1}$$

SB³C2022-434

$$\epsilon = 1 - \frac{h}{H} \quad (2)$$

where $\sigma$ is the 1st Piola Kirchoff stress, $F$ is the applied load, $A$ is the reference cross-sectional area, $\epsilon$ is the strain (noting a positive sign convention for compression to aid in visual interpretation), $h$ is the current or deformed thickness, and $H$ is the reference thickness.

Stresses during loading were compared at a common strain value of 0.45 ($\sigma_{\epsilon=0.45}$) to aid in interpretation of differences in stiffness. To quantify the stress relaxation response, stress during the 600 second relaxation period of cycle 4 was normalized to the peak stress, i.e., the stress developed in the tissue at the maximum applied strain, and normalized values were compared at the 600 second time point.

*Statistics.* A one-way ANOVA with a Tukey's post hoc significance test was performed across groups for all metrics to determine statistical significance, defined as $p < 0.05$. All data are presented as mean ± SEM.

## RESULTS

Material metrics for all tissues are reported in Table 1. Small bowel was significantly thinner than colon (0.071 ± 0.004 in. vs. 0.116 ± 0.014 in., respectively, $p < 0.05$), but both tissues exhibited similar material behavior in compression at a strain of 0.45 (Table 1).

**Table 1.** Material metrics derived from mechanical tests for porcine GI tissue. Data are presented as mean ± SEM.

| | Small bowel (n = 6) | Colon (n = 5) | Stomach | | |
|---|---|---|---|---|---|
| | | | Fundus (n = 3) | Body (n = 3) | Antrum (n = 2) |
| $h$ (in) | 0.071 ± 0.004 | 0.116 ± 0.014 | 0.139 ± 0.008* | 0.166 ± 0.016* | 0.134 ± 0.009* |
| $\sigma_{\epsilon=0.45}$ (psi) | 6.2 ± 2.2 | 1.9 ± 1.0 | 55 ± 5.6 | 83 ± 17 | 88 ± 34 |
| $\sigma_{relax\|600s}$ (%) | 26 ± 2.1 | 9.2 ± 4.0 | 6.6 ± 2.2 | 10 ± 4.1 | 5.3 ± 0.2 |

Notably, the small bowel exhibited qualitatively stiffer behavior overall, which was not evident at strain of 0.45 but was apparent at strains nearing 0.60 (Figure 1). All regions of the stomach were thicker than small bowel ($p < 0.01$), but only the body region was statistically thicker than colon ($p < 0.05$). All regions of the stomach were stiffer than colon and small bowel, defined as higher stresses at a common strain of 0.45 ($p < 0.05$). Regional differences within the stomach were observed, with the fundus being more compliant, but these differences were not statistically significant, possibly due to low sample sizes.

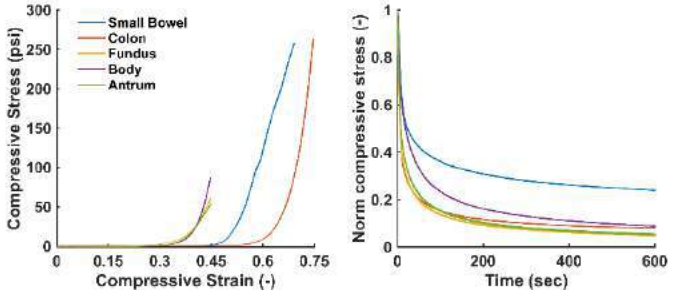

**Figure 1:** (Left) Representative curves of compressive loading to target strain for each tissue type. (Right) Representative curves of normalized stress relaxation for each tissue type at target strain.

All tissues exhibited a remarkable degree of relaxation despite a low strain rate of 0.5%/sec. Stress relaxation profiles were similar across all groups except small bowel, which exhibited less relaxation than colon and fundus ($p < 0.001$). As stress relaxation was observed following compression to different strains, it is difficult to assert whether differences in small bowel are due to inherent tissue-specific differences or differences in testing protocol. The body exhibited less relaxation than other regions, but this was not statistically significant, possibly due to low sample sizes. Further stress relaxation testing should be performed for all tissues at equivalent target strains to facilitate further comparison.

## DISCUSSION

Quantifying tissue-specific material properties in compression is of critical importance in surgical stapling. Though various models of surgical staplers are designed for different tissue thicknesses to prevent ischemia and tissue damage, these models do not inherently account for differences in tissue material properties between tissue types or patient characteristics (e.g., sex, age, disease state). Thus, beginning to understand and characterize compressive tissue mechanics for each tissue type can inform future design parameters in surgical stapling in pursuit of improving patient outcomes through patient-specific treatment of tissue.

An optimal compression profile may be defined not only by intraoperative metrics such as minimization of structural damage, but also postoperative metrics such as reduction of maladaptive tissue remodeling. Previous studies have demonstrated increasing inflammation and apoptosis in GI tissue with increasing applied load [3], suggesting a link between mechanics and postoperative tissue remodeling. Proper understanding of tissue-specific material properties in compression may better inform critical thresholds of applied loads which can prevent undesired mechanobiological responses and thus adverse tissue remodeling.

These data were obtained in unconfined uniaxial compression, but applied loads in surgical stapling are significantly more complex. Future studies may include combinatorial loading in compression and shear [4], which can better inform clinically relevant loading scenarios. Such data may also inform constitutive modeling for studies implementing finite element analyses for more detailed analyses of spatial differences in loads which develop during surgical stapling. The data presented herein provide the foundation necessary for beginning to develop a robust understanding of tissue-specific differences in material properties under clinically relevant scenarios for surgical stapling. Further testing is necessary to increase sample sizes, adapt protocols to facilitate comparisons in stress relaxation data, and expand to additional tissue types (e.g., esophagus, liver, pancreas).

In conclusion, these results demonstrate clear differences in viscoelastic compressive properties of different organs of the GI system. These results can inform necessary design parameters in surgical stapling to improve intraoperative performance of staplers and postoperative clinical outcomes.

## INTRODUCTION

The tricuspid valve ensures the unidirectional flow of blood between the right atrium and the right ventricle of the heart. However, nearly 1.6 million Americans suffer from clinically significant leakage, or regurgitation, in the valve. In most patients, the origin of regurgitation is extrinsic to the valve itself and occurs as a result of right ventricular (RV) remodeling. RV remodeling displaces the papillary muscles and dilates the tricuspid annulus thereby distorting the shape and disrupting the dynamics of the normal valve. Notably, current repair strategies for regurgitant tricuspid valves have a significant rate of failure. As such, almost 10-30% of patients redevelop leakage within a few years [1].

We submit that an incomplete understanding of tricuspid valve mechanics is, in part, responsible for this shortcoming in treatment. Highly-detailed computer models of the tricuspid valve may be critical tools to better understand the valve. Specifically, they may be used to uncover the etiology of the valve's morphology and structure. Furthermore, they may be used to optimize medical devices and surgical procedures. Existing models of the valve are often based on idealized or population-averaged geometries. Furthermore, they often employ material and structural properties from other subjects or species. Additionally, existing models of the human tricuspid valve have not been made publicly available as a research tool.

In this study, we seek to overcome these shortcomings of existing models. Namely, our goal is to build an openly-available, high-fidelity, subject-specific model of the human tricuspid valve.

## METHODS

Towards building a highly detailed subject-specific model of the human tricuspid valve we developed an extensive pipeline to combine ex vivo and in vivo measurements from a healthy, beating human heart, see **Figure 1**. Briefly, we reperfused and electrically paced a donor heart in an organ preservation system (TransMedics, Andover, MA). This heart was rejected for clinical transplantation but deemed otherwise structurally sound. In the beating heart, we recorded tricuspid annular dynamics via sonomicrometry crystals (Sonometrics Inc., London, Ontario) over multiple cardiac cycles. Additionally, we measured right atrial and ventricular pressures via miniaturized pressure sensors. Moreover, we recorded epicardial echo images of the tricuspid valve in the beating heart.

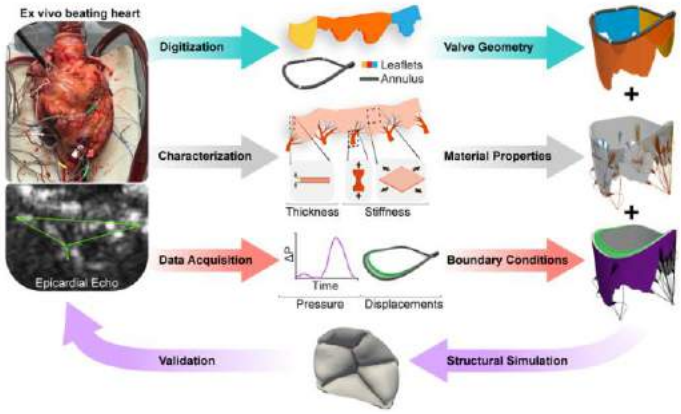

**Figure 1: The reverse-engineering pipeline. We combine measurements from an ex vivo beating human heart with in vitro material characterization to build a highly-detailed, subject-specific finite element model of the human tricuspid valve. We then simulate valve closure with boundary conditions derived from ex vivo data. Finally, we validate our predictions against echo images of the tricuspid valve in the same beating heart.**

Upon conclusion of the ex vivo experiments, we arrested the heart and explanted the tricuspid valve apparatus. Next, we made an incision

in the valve annulus at the postero-setpal commissure and laid the valve on a calibrated grid. We then took detailed photographs of the atrial and ventricular surfaces of the valve. Subsequently, we biaxially tested the valve leaflets and uniaxially tested the chordae. We modelled the constitutive behaviour of the leaflets via a hyperelastic material model as suggested by Kamensky et al [2]. Similarly, we model the hyperelastic response of the chordae using the Ogden model.

To recreate the model geometry, we first fit a 3D cubic spline to the annulus sonomicrometry data. Next, we used a custom MATLAB code (MathWorks, Natick, MA) to digitize leaflet geometry from photographs taken previously. We then non-rigidly transform the leaflet geometry onto the reconstructed 3D annulus to rebuild the valve in a stress-free state. To assemble the sub-valvular apparatus, we inform chordal insertion sites through in vitro images and existing literature [3]. Furthermore, we fix papillary muscle positions from sonomicrometry data. Additionally, we iteratively adjust chordae lengths to achieve leaflet coaptation similar to Kong et al [4].

We subsequently discretized the valve leaflets and chordae tendineae with C3D8R hexahedral elements and T3D2 linear elements, respectively. We then imported the models into Abaqus/Explicit (Dassault Systemes, Velizy-Villacoublay, France) where we assigned subject-specific material properties to all three leaflets and their chordae tendineae based on in vitro measurements. Furthermore, we assigned transvalvular pressure gradients and annular displacements, measured ex vivo, as Neumann and Dirichlet boundary conditions to our model, respectively. Note, we modeled contact between the valve leaflets using the kinematic predictor-corrector algorithm in Abaqus.

To showcase the predictive capabilities of our model, we use it to examine disease- and repair-induced changes to valve mechanics. To this end, we first create a regurgitant tricuspid valve by non-uniformly dilating the valve annulus, tethering the chordae tendineae, and applying pathological pressures to the ventricular surface of the leaflets. We then virtually repair the valve using two different techniques: ring-annuloplasty and clip-based repair.

## RESULTS

To validate our model, we quasi-statically loaded the valve to the end-systolic state. Our model faithfully captures the deformation of the leaflets when compared to echocardiographic images of the tricuspid valve in the beating heart, see **Figure 2**.

We then demonstrate the utility of our model through two virtual case studies. We observe that disease induces greater stresses the valve

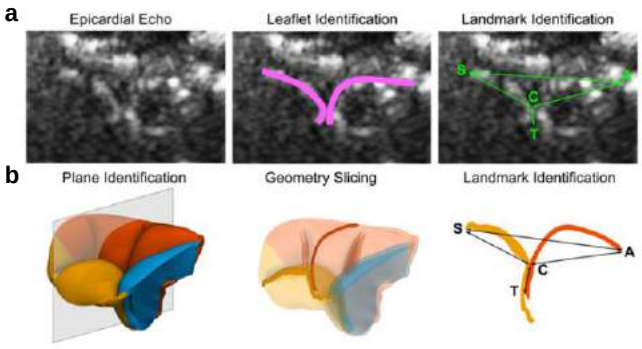

**Figure 2: Model validation against beating heart echocardiography. (a) We measure distances between anatomic landmarks: the anterior (A) and septal (S) leaflet hinge points, coaptation point (C), and coaptation length (T). (b) We then identify the corresponding plane in the valve model and compare distances between those same landmarks.**

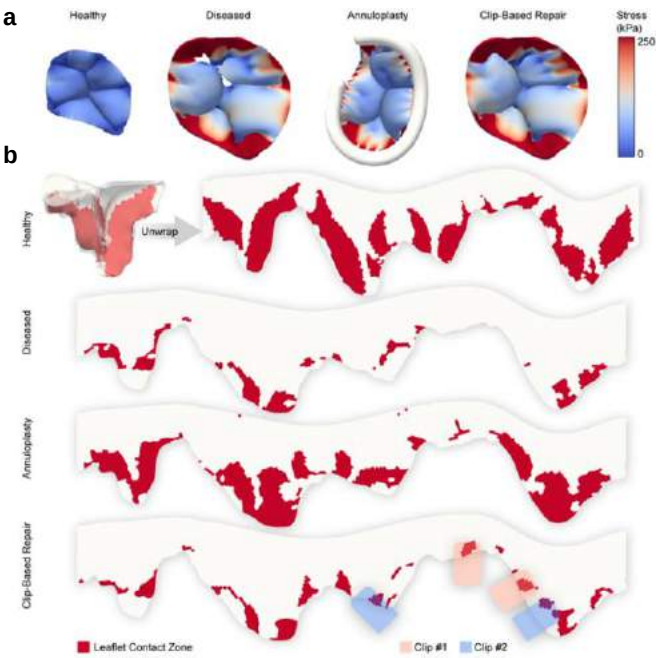

**Figure 3: Outcomes of simulated valve repair strategies. (a) Neither annuloplasty nor clip-based repair can completely resolve stress increases induced by disease. (b) Leaflet contact areas (in red) projected onto a 2D representation of the valves at end-diastole show the loss in coaptation area under disease. While annuloplasty restores this, clip-based repair is unable to.**

leaflets in comparison to the healthy valve (**Figure 3a**). While ring-annuloplasty and clip-based repair reduce these stresses, they are unable to restore the valve to its original stress state. Additionally, we observe a sizeable loss of leaflet contact area in the diseased valve leading to leakage (**Figure 3b**). Ring-annuloplasty restores this lost contact area to a large extent. In contrast, clip-based repair provides only modest gains in contact area.

## DISCUSSION

In our current work, we present a validated, openly-available, high-fidelity model of the human tricuspid valve informed by subject-specific geometries, material properties, and boundary conditions. Furthermore, we showcase the utility of our model through two virtual case studies. Models such as ours may be crucial in future efforts to optimize medical devices and improve patient outcomes.

## DATA AVAILABILITY

The Abaqus input files for all models are available at https://github.com/SoftTissueBiomechanicsLab/Texas_TriValve.git

## ACKNOWLEDGEMENTS

We appreciate support from the AHA via awards 18CDA34120028 and 902502, and from the NIH via awards 1R21HL181632-01 and F31HL145976. We would also like to thank the Living Heart Team at Abaqus for their courtesy software license.

## INTRODUCTION

The headbanging first started in 1968 when Led Zeppelin played a set at the Boston Tea Party on their first US tour [1,2]. Currently, headbanging is mostly referred to the rhythmic shaking of the head synchronous with the music, most commonly heavy metal and rock music [3]. It comes with many different styles such as the up-down, the circular swing, the full body, and the side-to-side motion [4]. Even though headbanging in its current form has been around for a few decades, there is still no consensus whether this level of head shaking could carry any minor brain injury implications. Despite being considered by some as a routine and daily activity, the biomechanical and neurological consequences of headbanging is largely unknown, mainly due to a lack of data in this field.

Even though, several health issues including traumatic aneurysm of cervical vertebral artery or subdural hematoma [3, 5, 6] have been reported to be possibly related to headbanging, little research has been conducted on this phenomenon so far. Previous works have analyzed the kinematics of voluntary head motion by instrumenting subjects with sensor-laden mouthguards and measuring six-degree-of-freedom head accelerations for rapid voluntary head rotations [7]. Baseline and post-experiment neurological tests revealed no significant deficits, and the authors suggested that high velocity, low-acceleration rotational inputs are unlikely to cause concussion in the subjects [7]. In another study, the effects of vigorous voluntary head shaking was analyzed on the head and neck motion [8]. Subjects were asked to vigorously shake their heads 5–10 times in a completely unconstrained manner, while recording the kinematics and kinetics of their head and neck [8]. The subjects shook their heads at self-selected tempos ranging from 1.9–4.7 Hz over a 20–91º range of motion, which resulted in low peak head accelerations of 4.3 ± 1.1 g and 250 ± 103 rad/s2 for men, 3.0 ± 0.9 g and 182 ± 58 rad/s2 for women [8]. Even though, these new studies have analyzed the voluntary head motion and the vigorous head shaking [7,8], not many studies have analyzed the kinematics of the head during headbanging in a concert event. In this work, we created a platform to study headbanging patterns in a concert environment and tested it during a simulated heavy metal/hard rock virtual concert. In short, this platform was designed to study the effect of 1) the song's tempo, 2) participant's familiarity with the song, and 3) the type of headbanging with associated head kinematics.

## METHODS

The aim of this study was to create a protocol to record and compare the different head kinematics involved in different headbanging patterns during a concert. The study was deceptive, as participants were not aware of the true objectives of the experiment prior to participation, i.e., the study of headbanging. The protocol was validated by an IRB board.

First, volunteers were selected based on their response to a prescreening form based on their heavy metal/hard rock music listening and concert habits, and to ensure that they have no history of neurological or neck injuries or allergies. Participants were encouraged to participate with friends to create an atmosphere conducive to dance and headbanging demonstrations. However, sessions were limited to 3 people to meet social distancing requirements due to the COVID-19 pandemic.

During the concert, volunteers wore instrumented mouthguards which needed to be custom fit for each subject. Instrumented mouthguard devices are made of a soft plastic material and fit onto the upper teeth of participants [10], who were invited in the days preceding the experiment to obtain their dental impressions. The custom fit provided a conforming, rigid coupling to the participant's skull through the maxillary (upper) dentition. Mouthguards were instrumented to record 6 degrees-of-freedom (DOF) translational and rotational head kinematics. Each mouthguard sensor board were equipped with a tri-axial accelerometer (ST H3LIS331), a tri-axial gyroscope (Invensense ITG-3500A) measuring rotational velocity in

the coronal, sagittal, and horizontal planes, and a digital proximity sensing module for near-field proximity sensing (AMS TMD2771).

Simulated concert sessions of 60 minutes were organized during which head kinematics were tracked with the mouthguard. A series of concert footage were collected and merged to simulate a live concert session and to cover a range of 90 to 180 BPM. Sessions were video recorded to classify the different headbanging patterns into the categories defined below. The real conditions of a concert were simulated as best as possible, including lighting and sound system, and the concert footage were projected on a giant screen.

Instructions were given to the participants to replicate their usual behavior when attending hard rock/heavy metal concerts. No mention was made of headbanging to avoid encouraging this behavior and introducing bias into the study. Mouthguard acquisition and camera recording were synchronized by performing a series of flicks on the mouthguard in front of the cameras.

Before starting the session and after the end of the concert, the participants were asked to perform neurocognitive testing. The Sports Concussion Assessment Tool-5 (SCAT5) was used to determine if the headbanging induced temporary neurocognitive changes. After the session, participants received a debriefing document revealing the true purpose of the experiment, the study of headbanging, and asking for their consent to participate in the study with knowledge of these new conditions. Participants also completed a postscreening form to assess their familiarity with the various music tracks to verify if the occurrences and intensity of headbanging were higher when subjects were familiar with the songs played, as reported in [11].

The video recordings were detailed to classify the different types of head motion. The different types of headbanging were classified as:

1. up and down: it is the most common style, and consists in shaking the head up and down in the sagittal plane
2. circular swing: swinging the head in a circular motion, approximately in the coronal plane
3. full body: swinging backwards and forwards from the waist, in sagittal plane
4. side-to-side: shaking the head from side to side, rotating around the longitudinal axis
5. random style: head moving in random directions

## RESULTS

10 participants were selected based on their response to the prescreening form. All participants were successfully fitted with instrumented mouthguards and no issues were encountered during the recording of the sessions. Preliminary results showed a great heterogeneity of behavior and dancing intensity among the volunteers, but only one of them did not show any motion that could be considered as headbanging. All types of headbanging were successfully identified, but a majority of up and down shaking was observed. Preliminary results of one volunteer were analyzed in detail and showed high velocity and acceleration values, with peaks reaching 5 rad/s for rotational velocity in the sagittal plane and linear acceleration of 8g along the superior-inferior axis (Figure 1). This volunteer also demonstrated synchronization with the music, with his headbanging patterns adopting the tempo of the song being played. In addition, the amplitude of the movement was greater when the volunteer indicated the track as being known and/or appreciated.

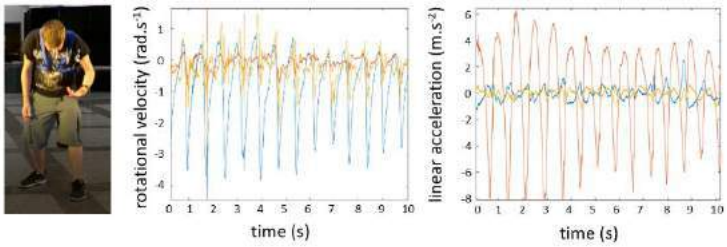

**Figure 1: Portion of the head kinematics data corresponding to an up and down movement, video recording (a), rotational velocity (b) and linear acceleration (c). The blue line corresponds to the rotation around the left-right axis for rotational velocity, or to the acceleration along the same axis for the linear acceleration. The yellow line corresponds to the antero-posterior axis, and the red line to the superior-inferior axis.**

## DISCUSSION

The developed platform was successfully tested during simulated concerts and allowed us to acquire the head kinematics of 10 volunteers, as well as the data necessary for the study of the effects of familiarity with the sound and tempo. Detailed analysis of the results for one volunteer showed that acceleration and velocity values were below the brain injury thresholds. The results of the corresponding SCAT5 test did not show any degradation after the session. However, these first results have already revealed the effects of tempo and familiarity with the sound on the intensity of headbanging. Since this preliminary study showed promising results with the developed testing platform, in the future, we can consider the implementation of this testing protocol on a larger scale, in the context of a real concert for example.

## INTRODUCTION

Incorporating perfusable vascular networks within engineered tissues and organs remains a grand challenge and precludes advancement towards artificial tissues at clinically relevant scales. Recent techniques in 3D biofabrication demonstrate the ability to manipulate living matter at resolutions and speeds necessary for viable tissues. However, there are currently no comprehensive algorithms to generate, model, and simulate biomimetic vascular networks for tissues of varying shape, vascular complexity, and perfusion conditions. Without a unified approach, efforts to vascularize tissues rely on simplified perfusion networks which poorly recapitulate pressure and flow distributions of native vasculature. To address these limitations, we present a unified framework through the open-source software package, SimVascular (simvascular.org), and validate predicted flow behavior in 3D printed bioreactors[1].

## METHODS

Our framework extends previous methods in constrained constructive optimization (CCO) by partially binding local optimization routines and triaging vessel collision repair to ensure efficient, accurate vascular generation for multiple vascular trees Fig1. Further, new methods for implicit volume reconstruction are presented to efficiently vascularize nonconvex tissue and organ shapes with and without cavities using a based on the Duchon's function (1) and variational point set surfaces[2]. We implement this reconstruction procedure as a partition of unity to avoid memory and complexity reported in literature for global approaches[3]. Resulting vascular networks

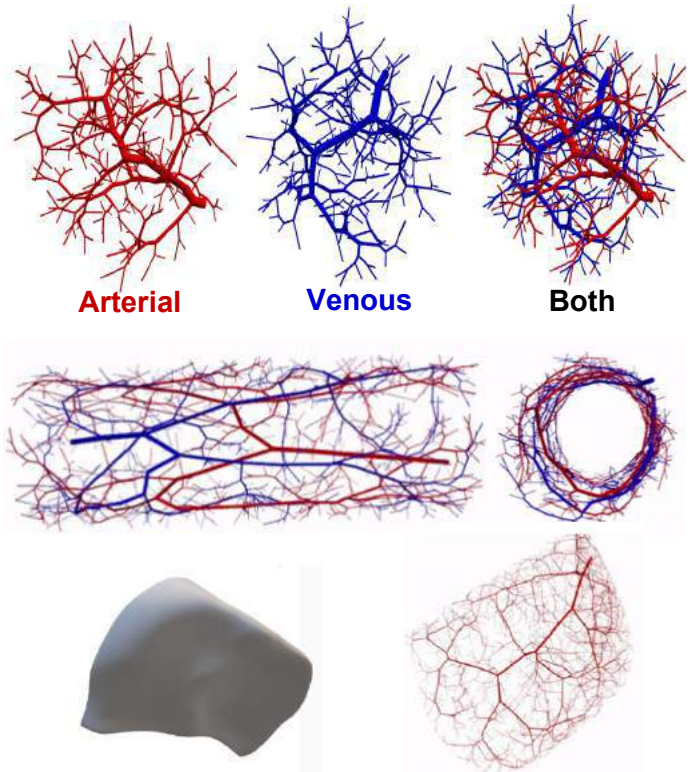

**Figure 1: Arterial (top left), venous (top middle), and arterial-venous circuit (top right) are CCO constructed collision-free for a cube volume. Arterial-venous network approximating the vasa vasorum (middle). Liver hepatovenous segment IV requiring perfusion (bottom left) and arterial network (bottom right)**

are exported for SWIFT and FRESH 3D bioprinting as well as multiscale (0D, 1D, 3D) hemodynamic simulations[4,5].

**Duchon Interpolant**

$$f(\boldsymbol{x}) = \sum_{i}^{N} a_i \phi_1(||\boldsymbol{x} - \boldsymbol{x_i}||) + \sum_{i}^{N} \boldsymbol{b_i^T} \frac{\partial}{\partial \boldsymbol{x_i}} \phi_1(||\boldsymbol{x} - \boldsymbol{x_i}||) + \boldsymbol{c^T x} + d$$

**Subject to**: $\sum_i a_i = 0, \sum_i a_i \boldsymbol{x_i} + \sum_i \boldsymbol{b_i} = 0$ (1)

Networks are constrained to meet desired bioreactor perfusion specifications (i.e. time-average wall shear stress, inlet/outlet diameters) and printing limitations (>100μm vessel spacing) for each technique. Geometric integrity of printed networks is assessed through optical coherence tomography and epifluorescence imaging which obtain 3D reconstructions. Flow splits, pressure distribution, and wall shear stress characteristics are simulated before and after printing using model and reconstructed geometries to determine flow deviations between ideal and printed networks. Experimentally, flow splits and diffusion are measured via fluorescence particle tracking and 10-70kDa dextran perfusion assuming a Darcy law relation. In addition to soft (hydrogel) type material, models are 3D printed using stereolithography a rigid, plastic resin to ensure wall assumptions are satisfied for the underlying assumptions of homogeneous, incompressible, fully-developed, steady, laminar, axisymmetric blood flow in rigid-walled cylinders. These assumptions are necessary for CCO methods but not necessarily subsequent CDF simulations which may better match physical systems given known material behaviors.

## RESULTS

Computational complexity of collision detection verifies that simple sphere proximity checks can decrease the average number of oriented bounding box (OBB) evaluations to 1 or 2

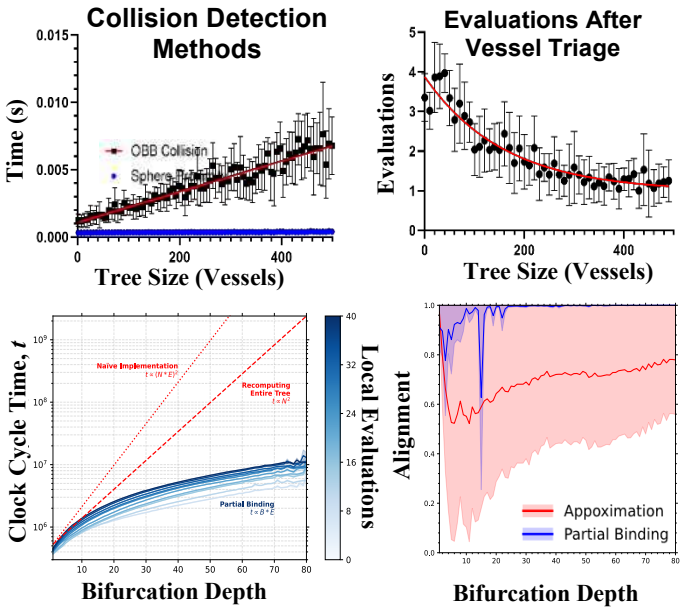

**Figure 2: Comparison of collision detection methods (top right) and performance from triaging detection with sphere proximity. Computational complexity (CPU clock cycles) for local bifurcation optimization (bottom left) alignment performance against finite difference ("ground truth") compared to previous literature[6].**

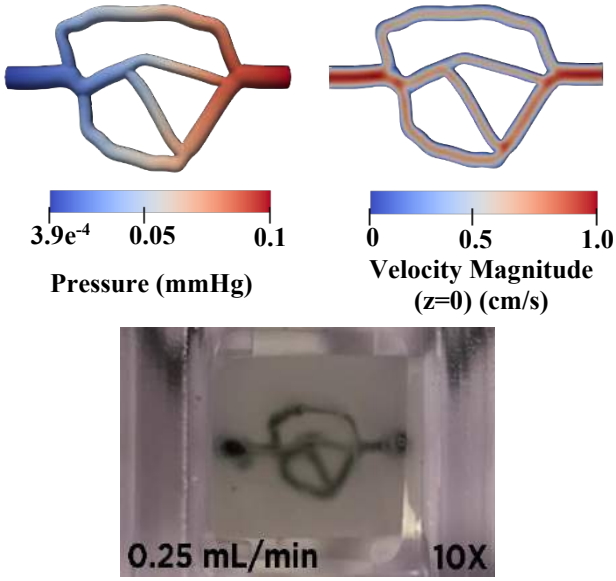

**Figure 3: Pressure (top left) and velocity magnitudes (top right) obtained during hemodynamic analysis and 3D FRESH bioprint in collagen (bottom) generated from the same 3D model file. Generic dye shown flowing through patent vessels.**

per vessel addition as trees extend into hundreds of vessels. Partial binding similarly accelerates CCO vascularization while increasing accuracy of bifurcation placement Fig2 with logarithmic scaling of bifurcation depth over more expensive implementations scaling on number of vessels[6]. Steady-state hemodynamic simulations show uniform pressure distribution through vascular circuits with qualitatively uniform flow splits which are also observed in 3D bioprints Fig3 which serve as an initial validation of this fully automated pipeline in rational vascular design, simulation, and fabrication.

## DISCUSSION

Our unified framework enables effective, efficient vascularization of engineered tissues and simulation of flow behavior within 3D bioprinted networks. Preliminary experimental bioprinting results provide initial validation of this framework for rapid vascular design from first principals of mammalian vasculature. Further work is needed to account for variability of bioinks when approximating wall deformability and permeability for nutrient considerations of metabolically active engineered tissues approaching significant functional densities.

## INTRODUCTION

Bone quantity (bone mass) is the clinical indicator for risk of fracture; however, this metric explains less than half of bone fragility fractures. In diseases such as type 2 diabetes mellitus (T2DM), bone mass can be normal, if not slightly elevated, while risk of fracture is higher compared to the risk of the healthy population. This elevated risk of fracture points to the role of bone quality in addition to bone quantity when determining fracture risk.

Bone quality, an admittedly broad term, describes many aspects of bone health outside of bone quantity that contribute to the unique mechanical properties of bone. Common aspects of bone quality include bone's matrix and collagen properties as well as its multiscale hierarchical structure. At the microstructural scale, canals are vascular porosities responsible for transporting nutrients throughout the bone. Osteocytes, the most abundant cell in bone, are intricately connected to canals and each other via a dense, nanoscale network of dendritic processes called canaliculi. This network of osteocytes and canaliculi is known as the lacunocanalicular network (LCN).

One process by which bone quality is maintained is known as perilacunar/canalicular remodeling (PLR). This process involves osteocyte cells resorbing and replacing bone matrix directly surrounding the LCN. PLR is not only a response to metabolic stress and disease, but also a hallmark of healthy bone homeostasis. The effects of PLR are seen in the bone matrix and osteocyte lacunae, which are voids in the bone matrix that osteocyte cells reside within.

PLR performed by osteocytes is signaled by transforming growth factor beta (TGF-β). Ablation of TGF-β signaling in osteocyte cells is known to induce bone fragility while maintaining bone mass [1]. Furthermore, circulating TGF-β is significantly elevated in obese and high-fat diet (HFD) induced obese mice or humans and is associated with insulin resistance [2]. While recent work has elucidated the role of TGF-β in signaling osteocytes to orchestrate PLR, a critical gap in knowledge remains in determining whether T2DM and obesity impact osteocyte-intrinsic TGF-β signaling in bone.

To address whether T2DM and obesity impact TGF-β signaling in osteocytes to reduce bone's mechanical properties, we tested the hypothesis that HFD-fed mice possess exacerbated osteocytic-TGF-β signaling. We also hypothesize that with an osteocyte-intrinsic inhibition of TGF-β receptor type II, this exacerbated TGF-β signaling can be downregulated in the HFD mice.

## METHODS

**Study Design and Mouse Model.** This work was performed in collaboration with the Alliston Lab at the University of California, San Francisco. To determine whether HFD-induced obesity adversely affects bone quality and to determine whether inhibiting TGF-β signaling will impact bone quality, two genotypes of mice are considered: a control, wild-type (WT) mouse model and a TGF-β receptor type II gene knockout ($T\beta RII^{ocy-/-}$) mouse model. To begin, WT and $T\beta RII^{ocy-/-}$ mice are raised to an age of 12 weeks, where they will take on a diet challenge. Mice from each genotype were randomly assigned to a HFD or a control, low-fat diet (LFD). Following 18 weeks of diet treatment, the mice were sacrificed and mice tibia were extracted for synchrotron radiation tomography and silver nitrate stain imaging.

**Synchrotron Radiation Micro-Computed Tomography (SRμT).** SRμT image acquisition was performed at beamline 8.3.2 at the Advanced Light Source. SRμT is an imaging modality that captures micro-scale internal morphology and material composition using high-flux x-rays. Mouse tibia were mounted on a rotating stage and transmission radiographs were taken over a range of 180°. A beam energy of 18 keV with 1313 projections and a 500 ms exposure time was used to acquire images. Full 3-dimensional (3D) image volumes were reconstructed at a final resolution of 1.3μm/pixel using open-source python code Tomopy.

Following image reconstruction and segmentation, the size and density (#/bone volume) of canals and lacunae were calculated in Dragonfly (ORS) to compare the genetic model and diet models. All statistics compared each group to each other using an ANOVA with a Tukey multiple comparison test. The distribution of mineralization in each bone was calculated from ImageJ by directly converting image grayvalues to a volumetric tissue mineral density (vTMD) using a relationship with beam energy.

**Ploton Silver Nitrate Stain.** Silver nitrate staining of the LCN was used to visualize canaliculi and osteocytes as described by Jáuregui et al [3]. For this study, four sections from each mouse were analyzed. Canalicular length and number were measured individually using ImageJ. Average LCN area was calculated by thresholding grayscale images of silver-stained bone sections. The resulting LCN area is then normalized per osteocyte cell in the image.

## RESULTS

**Canals and Canaliculi are Concurrently Altered with High-Fat Diet and TβRII$^{ocy-/-}$.** Alterations to canal morphology were observed with both HFD and TβRII$^{ocy-/-}$ (Figure 1). HFD treatment tended to increase canal diameter compared to LFD groups for both WT and TβRII$^{ocy-/-}$ genotypes. Additionally, canal diameter tended to increase in TβRII$^{ocy-/-}$ groups when compared to WT groups. These effects together resulted in a significant increase in canal diameter between WT-LFD and TβRII$^{ocy-/-}$-HFD groups ($p < 0.01$). Canal density tended to increase with HFD compared to LFD in WT groups but not with TβRII$^{ocy-/-}$. As such, TβRII$^{ocy-/-}$-HFD possessed a Ca.Dn similar to that of the LFD groups. The WT-HFD group possessed significantly higher Ca.Dn than the TβRII$^{ocy-/-}$-LFD group ($p < 0.05$).

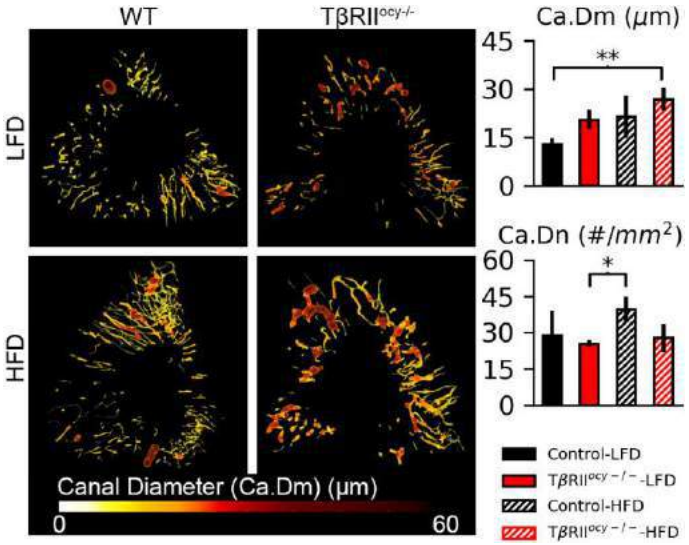

**Figure 1: Representative SRμT canal volumes (left), average canal diameter (top right), and average canal density (bottom right). Error bars denote one standard deviation.**

Silver nitrate staining and quantification of the LCN revealed that changes in the LCN occur in parallel with changes to canals (Figure 2). LCN area demonstrated a similar trend to Ca.Dn, with HFD tending to increase LCN area and TβRII$^{ocy-/-}$ tending to decrease LCN area. Canalicular number and length tended to remain constant with each respective diet model but decreases with TβRII$^{ocy-/-}$.

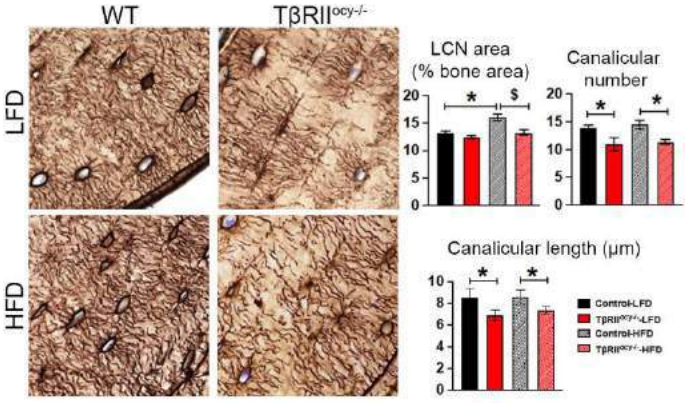

**Figure 2: Silver nitrate staining (left) reveals that TβRII$^{ocy-/-}$ decreases LCN area, canalicular number, and length (right). Error bars denote one standard deviation.**

**High-Fat Diet Induces Hypomineralization in Wild-Type Mouse Bone.** Hypomineralization is present in high-fat diet mice compared to low-fat diet mice (data not shown for brevity). In this study, mineralization in bone tissue was analyzed in four quantile ranges to capture low and high regions of mineralization. These quantile ranges were 1300-1660, 1660-2015, 2015-2375, and 2375-2725 mgHA/cm$^3$. The WT-HFD group possessed a significantly higher percentage of bone in the lowest region of mineralization (1300-1660 mgHA/cm$^3$) than all groups ($p < 0.05$). The WT-HFD bone model still possessed more bone in the second-lowest region (1660-2015 mgHA/cm$^3$) of mineralization than the WT-LFD group ($p < 0.05$). Other groups in each mineralization quantile were not significantly different.

## DISCUSSION

Because canal diameter at the microscale increased with both HFD and TβRII$^{ocy-/-}$, it is possible that both these alterations reflect an increase in the need to transport nutrients or perform PLR. Similar changes in LCN area and canalicular number and length may indicate that transport systems at both microscale and nanoscale are simultaneously influenced by diet and TβRII$^{ocy-/-}$. Because Ca.Dn, LCN area, canalicular number, and canalicular length follow similar tendencies with genotype and diet, it may follow that ablation to osteocyte-intrinsic TGF-β signaling affects the transport system at all length scales through the mechanism of PLR.

Furthermore, hypomineralization in the WT-HFD group indicates bone is being remodeled, with new bone material possessing lower vTMD [4]. Per quantile in each group, mineralization follows the trend of Ca.Dn and LCN area, where TβRII$^{ocy-/-}$ tends to "recover" the HFD model to levels akin to LFD groups. Both SRμT data and histology images point to the phenomena of PLR exacerbation in HFD, as well as to potential recovery of PLR exacerbation with TGF-β receptor II inhibition.

The effect of HFD-induced obesity on the transport system, LCN, and mineralization in bone tends to be mitigated with TβRII$^{ocy-/-}$. These metrics of PLR suggest potential protection of bone quality with TβRII$^{ocy-/-}$ in HFD mice. Although inhibition of TGF-β receptor II shows promising results in recovering the effects of HFD-induced obesity, further investigation of PLR through a comprehensive analysis of lacunar volume is necessary to completely illustrate the effect of HFD and TβRII$^{ocy-/-}$ in this mouse model. Additionally, a correlation between the impact of PLR and mechanical properties of bone remains to be fully examined, though salient mechanical properties have been obtained and will be analyzed in the context of data presented here. Despite these current limitations, present results indicate that PLR may indeed be exacerbated, as shown in histological data, placing a burden on microscale transport systems (canals). TGF-β receptor II inhibition shows promise in reducing the negative impact of HFD on osteocyte-intrinsic TGF-β signaling.

## ACKNOWLEDGEMENTS

We would like to acknowledge the Advanced Light Source at Lawrence Berkeley National Lab for assistance in SRμT data acquisition at beamline 8.3.2. – microtomography.

## INTRODUCTION

Coarctation of the aorta (CoA) is a congenital defect characterized by a constriction of the aorta, typically just beyond the left subclavian artery, which accounts for 6-8% of congenital heart defects[1]. The narrowing of the aorta causes a drop in blood pressure (BP) across the stenosis region which can be alleviated using surgical approaches or catheter-based interventions using stents. The current guideline for treatment is a BP gradient $\geq$ 20 mmHg at rest.

Computational fluid dynamics (CFD) simulations are used to characterize local hemodynamics in patients with CoA. Previous studies have showed the capability of three-dimensional (3D) simulations in modeling aortic coarctation and predicting the trans-coarctation pressure gradient.[2,3] However, 3D simulations are computationally expensive and time-intensive which can prevent them from being used routinely in clinical applications. Reduced-order models, in our case zero-dimensional (0D) models, that are less expensive, therefore become crucial for patient-specific applications of cardiovascular flow simulations. 0D circuit analogy models have no spatial dependency; they only depend on time but can be evaluated at different locations along the cardiovascular system by creating models comprising multiple circuit elements.

The objective of this study was to non-invasively predict the pressure drop across the coarctation, comparing patient-specific CFD simulations to 0D models. Both 0D and 3D simulations were performed using the open-source software SimVascular. The pressure drops measured across the coarctation using both models were compared and validated using invasive cardiac catheterization measurements.

## METHODS

**Acquisition of Patient Data:** 4D-Flow MRI datasets were acquired for two patients with CoA who thereafter underwent a catheter intervention and stent placement. Invasive measurements of pressure via cardiac catheterization in the ascending and descending aorta were also acquired, in addition to BP measured using a sphygmometer cuff within 48 hours of the catheterization.

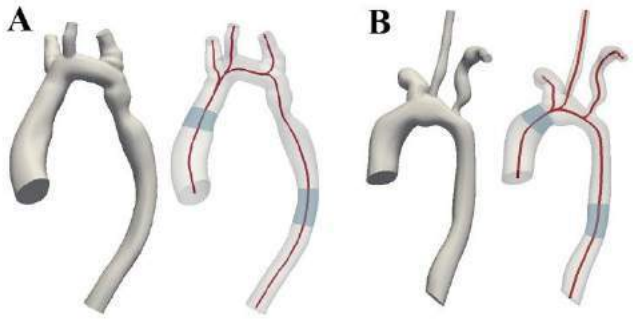

**Figure 1. 3D geometry (left), with centerlines (right) for Patient A and Patient B. Blue shaded regions in the ascending and descending aorta indicate where pressure was measured.**

**Anatomic Model Generation:** MRI magnitude images were imported into SimVascular (simvascular.org)[4] and manually segmented to generate 3D geometries of the aorta and branches arising from the aortic arch: brachiocephalic trunk, left carotid artery, and left subclavian artery. Centerlines were automatically extracted from the 3D geometry for use in creating the 0D model which consists of individual lumped-parameter elements (resistors and capacitors) that connect to form a complex lumped parameter network. The 3D volume was meshed using tetrahedral elements and contained ~1.5 million elements. A boundary layer mesh consisting of three layers was also incorporated to resolve large velocity gradients at the wall.

**Boundary Conditions:** Boundary conditions were tuned using 4D-Flow MRI and cuff BP measurements. Eddy-current corrected images from the 4D-Flow MRI dataset were analyzed to measure 2D time-resolved flow at the inlets and outlets using Arterys (Arterys, San

Francisco, USA). A patient-specific temporally varying parabolic flow profile was prescribed to the inlet of the 0D and 3D models. Flow from the brachiocephalic trunk, left carotid artery, left subclavian artery and descending aorta were used, along with BP data, to tune outflow boundary conditions. A three-element Windkessel model (proximal resistance $R_p$, capacitance C, distal resistance $R_d$) was imposed at each of the outlets. Total resistance ($R_p + R_d$) for each of the branches was calculated using the cuff BP and the flow split determined from MRI. 0D simulations were performed first and used to fine-tune the prescribed boundary conditions. An approximate value of $10^{-4}$ for C was used as a starting point. The value of C, along with $R_p/R_d$ ratio, were adjusted to fine-tune the boundary conditions until the calculated pressures matched the patient's systolic and diastolic cuff BP within 5 mmHg.

**0D and 3D simulations:** For the 0D simulation, the value of each of the lumped-parameter elements was determined from the geometric and material properties of the blood and blood vessel: fluid density 1.06 g/cm$^3$, viscosity 4cP, Young's modulus 3 MPa[5] and thickness of the vessel defined as 20% of the radius of the vessel.. Simulations were run for ten cardiac cycles to reach a periodic state of the solution. Inclusion of a stenosis model did not affect results. Results from the last time step of the 0D simulation were projected onto the model's 3D mesh and this was used as the initial condition for the 3D simulation[6].

3D simulations were performed using a coupled-momentum method using the same boundary conditions as the 0D simulation. Deformable walls with Young's modulus 3 MPa, Poisson ratio 0.5 and shear correction factor 0.8333 were used. Simulations were run for ten cardiac cycles until a periodic state of the solution was reached.

Pressure along the centerline before and after the coarctation were measured at peak systole in both the 0D and 3D models. The drop in pressure was calculated as the difference in pressure between the mean of the pressure measured in a region defined by 80% of the length to 100% of the length of the ascending aorta, and the mean of the pressure measured in a region defined by 50% of the length to 70% of the length of the descending aorta, shown in Figure 1. This drop was compared to the invasively acquired measurements during cardiac catheterization.

## RESULTS

Anatomy and hemodynamics reflective of coarctation were observed and captured in the simulation. Figures 2 and 3 show a comparison of the pressure obtained from the 0D simulation to that of the 3D simulation over the normalized vessel path for the inlet and some outlets for Patient A and B respectively.

The non-invasively computed peak-to-peak pressure drop was lower using 0D than using 3D (10 mmHg vs. 15 mmHg). The 0D estimate correctly estimated pressure drop and 3D estimate overestimated pressure drop compared to the catheter-based measurement of 10 mmHg for Patient A.

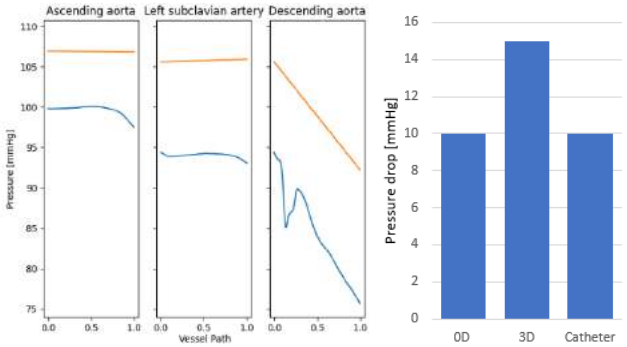

**Figure 2: Pressure over the vessel path (scaled with the length of the vessel) for 3D (blue) and 0D (orange) simulations of Patient A's geometry (left). Comparison of pressure drop measured using 0D, 3D and catheter (right)**

In Patient B, since the coarctation is located in a junction region, the 0D model estimate (7 mm Hg) was a poor estimate of the pressure drop measured using the catheter (30 mmHg). The 3D model estimate (31 mmHg) slightly overestimated the pressure drop compared to the catheter-based measurement of 30 mmHg for Patient B.

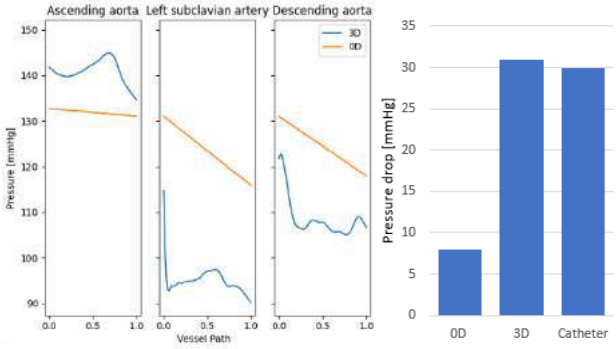

**Figure 3: Pressure over the vessel path (scaled with the length of the vessel) for 3D (blue) and 0D (orange) simulations of Patient B's geometry (left). Comparison of pressure drop measured using 0D, 3D and catheter (right)**

## DISCUSSION

This study demonstrates the capability of 0D models constructed automatically from 3D models in computing flow and pressure in a patient-specific model of aortic coarctation. Pressure drop measured from 0D and 3D simulations validated using invasive catheter measurements showed that the 0D and 3D model estimated pressure gradient within 5 mmHg in the case where the coarctation was located in a non-junction region, as seen in Patient A.

The significantly lower computational time of the 0D models makes them more feasible to use in a clinical setting. 0D models, however, currently cannot resolve flow and pressure when the coarctation is located at the junction of two vessels (as seen in Patient B) which reduces the number of patients that this model can be applied to. A limitation with validation using catheter measurements is that the specific location at which the pressure was measured clinically is unknown. This would be of interest since the location at which the pressure is measured in the simulation is sensitive and can alter results.

This study is currently being extended to include more patients with aortic coarctation. Future studies can explore the prediction of the trans-coarctation gradient before and after stent intervention, as well as in exercise conditions.

# LEARNING WHOLE HEART MESH GENERATION FROM PATIENT IMAGES FOR COMPUTATIONAL SIMULATIONS

**Fanwei Kong and Shawn C. Shadden**

Department of Mechanical Engineering
University of California, Berkeley
Berkeley, California, USA

## INTRODUCTION

Patient-specific cardiac modeling combines geometries of the heart derived from medical images and biophysical simulations to simulate various aspects of cardiac function. It can provide useful physiological information non-invasively to facilitate understanding, diagnosis and treatment planning of cardiac diseases for individual patients [1]. However, generating simulation-suitable meshes of the heart from patient image data often requires complicated procedures and significant human efforts, limiting clinical translations. We are thus motivated to develop fast and automated methods to construct simulation-ready meshes of the heart from medical images.

Deep learning methods can train neural networks from existing data to automatically process medical images and generate whole heart reconstructions. While most prior deep learning methods have focused on image segmentation, our recent approaches directly reconstructed surface meshes from patient image data [2-3]. By deforming a surface mesh template, our previous methods eliminate the intermediate segmentation step that sometimes introduce extraneous regions containing topological anomalies that are unphysical and unintelligible for simulation-based analyses [2]. We have also combined free-form deformation (FFD) with deep learning to predict the displacement of a control point grid to deform the space enclosing a simulation-ready whole heart template, thus enabling direct reconstruction of simulation-ready meshes from image data [3].

However, since FFD has limited capability for complex shape deformation, our prior method requires a dense control point grid including thousands of control point to achieve acceptable whole heart reconstruction accuracy [3]. Here we propose a new deep-learning approach that leverage biharmonic coordinates to deform the whole heart template to fit the target image data with higher accuracy and using far less control points. We also introduce a few effective learning biases as objective functions to produce meshes that better satisfy the modeling requirements for computational simulation of cardiac flow.

## METHODS

**Dataset**: We trained our method with 87 contrast-enhanced CT images and 41 MR images that cover the whole heart [3]. 15 CT images and 6 MR images were used for validation. The final performance of our model was evaluated on the MMWHS held-out test dataset that contains 40 CT and 40 MR images [4], as well as time-series CT images.

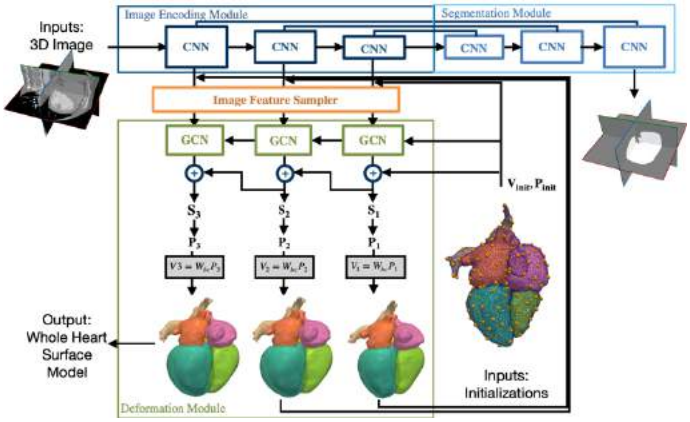

**Figure 1: Proposed automatic whole heart reconstruction approach**

**Shape Deformation Using Biharmonic Coordinates**: Our approach constructs whole heart meshes by deforming a pre-defined whole heart mesh template. We parameterize the deformations with the translations of a small set of deformation handles uniformly sampled from the mesh template. Given a set of mesh vertices $V \in R^{n\times 3}$ and a set of control points $P \in R^{c\times 3}$, we compute the biharmonic coordinates $W \in R^{n\times c}$, which is a linear map, $V = WP$. $W$ is pre-computed by minimizing a quadratic deformation energy function while satisfying the handle constraints with linear precision [5].

**Neural Network Architecture**: As shown in Fig 1, our framework

first uses an image encoding module that extracts and encodes image features. These features are used as inputs to graph convolutional layers to predict the displacements of mesh vertices ($S \in R^{n\times 3}$) from their previous locations. We then select control handles ($P \in R^{c\times 3}$) from the updated mesh vertex locations to deform the template. The shape deformation module consists of three deformation blocks that progressively deform mesh templates, using increasing number of control handles (75, 150 and 600, respectively). We also use a segmentation module that predict a binary segmentation map to enable additional supervision using ground truth annotations.

**Neural Network Optimization**: 3D ground truth meshes of the whole heart extracted from manual segmentations were used to supervise the training of the neural network model. We used point and normal consistency losses to supervise the geometric consistency between the prediction and the ground truth. In contrast to [2], which uses edge length and Laplacian regularization losses, the smoothness of the mesh prediction is naturally constrained by the biharmonic coordinates used to deform the template. For CFD simulation of cardiac flow, the inlet and outlet vessel geometries need to be trimmed to have planar faces orthogonal to the vessel walls. We thus applied a co-planar loss on the cap that penalizes the L2 differences of surface normal vectors among mesh vertices on the caps. For mesh vertices that are on the vessel walls near the caps, we minimize the absolute value of the dot products between their surface normal vectors and the surface normal vector of the caps to encourage orthogonality. As geometries of inlet vessels are important to the accuracy of CFD results, we applied a higher weight of the geometric consistency loss on mesh vertices that are located on vessel walls near the inlets.

## RESULTS

We compare the performance of whole-heart reconstructions from our method against two mesh reconstruction methods, HeartFFDNet [3] that learns FFD to deform mesh template of the heart, MeshDeformNet [2] that learns to predict displacements from sphere mesh templates, as well as two segmentation methods, 2D UNet [6] and a modified 3D UNet [7].

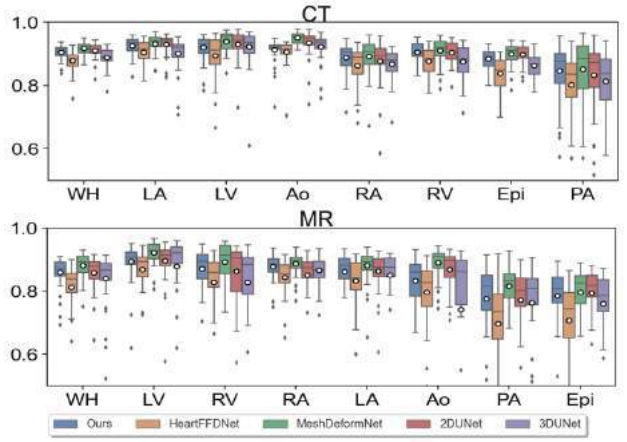

**Figure 2: Dice scores of different methods on MMWHS test set**

Figure 1 shows the average Dice score (a similarity index) of the reconstruction results of both the whole heart and individual cardiac structures for the MMWHS test dataset. For both CT and MR data, our method consistently outperformed HeartFFDNet and 3D UNet and achieved comparable performance with MeshDeformNet and 2D UNet. Figure 3 compares the reconstructed whole heart geometries from different methods for time-series CT images. From end-diastole to end-systole, mesh-based methods produced more anatomically and temporally consistent geometries than segmentation-based methods (the UNets). MeshDeformNet is prone to gaps between adjacent cardiac structures since it deforms uncoupled spheres to represent separate structures. Our method avoids this issue by deforming a realistic whole heart template. Compared with HeartFFDNet, we used far less control points (600 vs 4096) and achieved better accuracy.

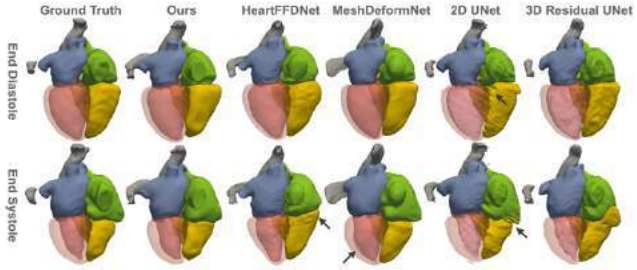

**Figure 3: Qualitative comparisons for time-series CT images**

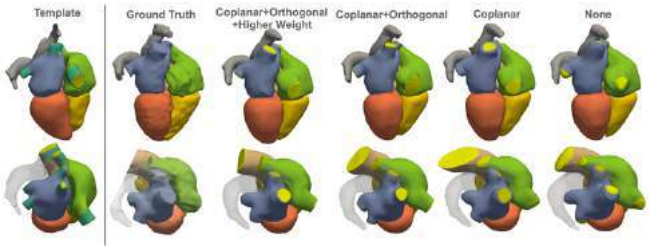

**Figure 4: Contribution of different loss components on vessel inlet geometries. 1st column shows the template mesh with caps tagged in yellow and walls tagged in turquoise.**

Figure 4 demonstrates the effect of adding individual loss components on the predicted inlet and outlet geometries (pulmonary veins, vena cava, and aorta). The coplanar loss and the orthogonal loss succeeded in producing planar cap geometries that are orthogonal to vessel walls. Applying a higher weight on the inlet mesh vertices in the geometric consistency loss improved the accuracy of inlet geometries.

## DISCUSSION

Automated image-based reconstruction of cardiac meshes is important for computational simulation of cardiac physiology. We have demonstrated a novel approach for automated image-based cardiac model reconstruction that is generally more geometrically accurate than our prior approach [4] while at the same time better satisfying modeling requirements for cardiac flow simulations. Our approach can automatically construct whole heart meshes within seconds on modern desktop computers. Once being trained on the whole heart template, the network can deform alternative template meshes that represent a subset of the geometries in the template to accommodate different modeling requirements, by interpolating the biharmonic coordinates onto new template meshes. Future work will focus on validating the reconstructed meshes for CFD simulation of cardiac flow.

## INTRODUCTION

Surgical intervention for congenital heart diseases (CHD) remains a significant challenge for cardiothoracic surgeons because of the wide variation of anatomy and physiology. Traditional methods for presurgical planning involve multimodality imaging methods and interdisciplinary consultations. Current standard imaging still fails to fully reflect the actual intraoperative inspection of the open and cardioplegic heart, particularly with respect to anatomical distortion of the non-physiologic condition, spatial orientation, and dimensional perception. Previous studies have shown that it is possible to use modern visualization software to recreate 3D anatomical models of the heart with different degrees of fidelity [1]. Understanding the complex anatomy and hemodynamic patterns of each CHD is critical to making clinical decisions involving surgery and post-operative treatment.

To further support the translation of 3D models into clinical decision-making, we report prospective and retrospective modeling efforts in patient-specific models of two different presentations of atrial septal defects (ASDs). The two specific variations of ASD studied herein are sinus venosus atrial septal defect (SVASD) and biatrial drainage of the superior vena cava (SVC). SVASD comprises about 10% of all ASDs, and embryologically originates as a deficient inward folding of the atrial wall that forms the posterior wall of the SVC and upper right pulmonary veins; in such presentations, the pulmonary veins drain into the right atrium (RA) at the root of the SVC instead of the left atrium (LA) [2]. ASDs with biatrial drainage of the SVC is a very similar defect but is distinct from SVASD in that biatrial drainage does nmot have a true interatrial shunt; that is the defect is superior to allow shunting from one atrium to the other [3].

In this work, we applied 3D modeling to compare the anatomy of the two types of ASDs to justify the choice between deploying a cardiac stent-graft shunting the SVC into the RA with minimally invasive methods versus implementing a cardiac baffle draining the pulmonary veins through the ASD into the LA with open-heart surgery.

## METHODS

**Data Collection.** Anonymized datasets were provided by the team of cardiologists and surgeons at the Children's Hospital of Richmond (CHoR) acquired prior to surgical intervention for clinical purposes as part of the follow-up of each patient. Each imaging dataset consisted on several MRI series comprising 3D angiograms with and without contrast, long and short axis planes with cine MRI, and several 2D and 3D phase-contrast MRIs (Figure 1).

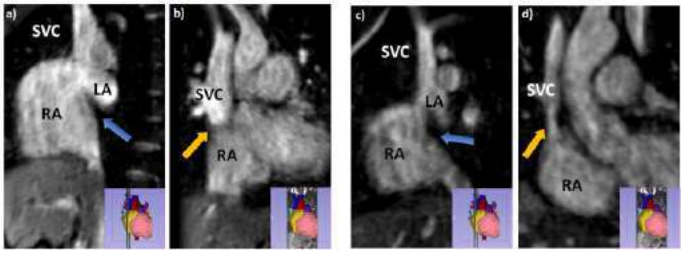

**Figure 1.** Multiplanar Magnetic Resonance Angiography (MRA) of SVASD a) Sagittal view, b) Coronal view, and Biatrial Drainage c) sagittal view, d) coronal view. (blue arrows: atrial septal wall, yellow arrows: junction between the SVC and RA) Location of each plane within the entire 3d anatomical model is shown in small insert in the bottom right.

**3D anatomical model generation.** Slicer3D software and 3D angiograms were used to segment and model the blood pools and walls of the major heart chambers and vessels. Cine3D planar views and feedback from CHoR collaborators were used to refine and ensure the anatomical precision of the models (Figure 2). Since the surgical intervention is focused around the SVC-RA junction and how the right pulmonary veins connect to the heart, we selected the anterior quadrant of the heart containing the SVC, right-sided pulmonary veins, and portions of the RA, left atria and right ventricle as our region of interest (Figure 3). The finished models were 3D-printed with acrylonitrile

butadiene styrene (ABS) to demonstrate the differences between their respective interventions and assist in physician understanding of the anatomical differences.

Additionally, the 3D models were uploaded into an augmented reality platform to further facilitate the model exploration and use for didactic and teaching purposes (Figure 4).

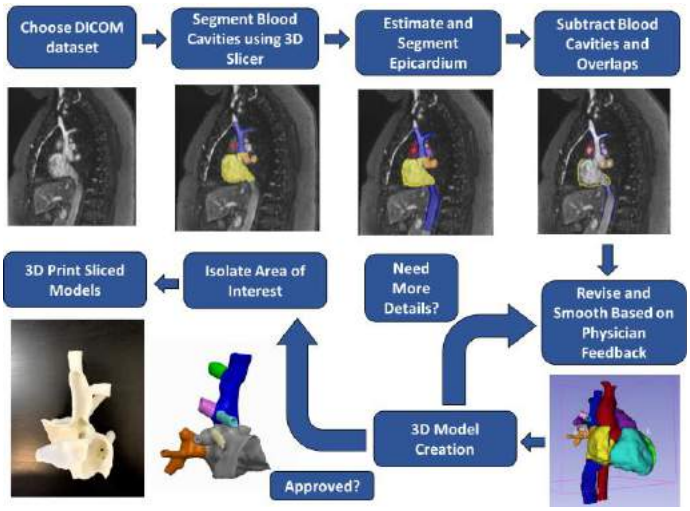

**Figure 2.** Medical imaging processing and 3D modeling pipeline.

**Assessment of modeling impact on treatment planning.** The models were then presented at the Pediatric Cardiology Conference at CHoR and a survey to assess the efficacy of 3D modeling in clinical decision making was distributed among its members.

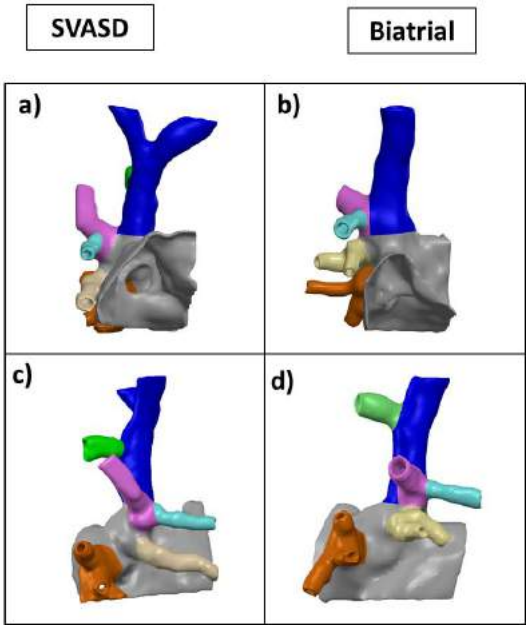

**Figure 3.** Four Panel Cut Model 3D Rendering, blue: SVC, pink: upper right pulmonary vein, turquoise: middle right pulmonary vein, green: azygous vein, beige: lower right pulmonary vein, orange: normal pulmonary veins draining into LA.

## RESULTS

Two 3D computational heart models were created, showcasing the subtle differences between the two CHD cases. The biatrial drainage ASD showcased an anteriorly tilted septal wall which caused a stenotic channel into the right atrium. This narrowing justified the choice of minimally invasive repair with a stent-graft placement, which could be deployed and expanded to properly anchor it distally shunting the SVC into the narrowing entrance of the RA. Additionally, computational modeling allowed the surgical team to realize that enough clearance would remain underneath the proximal placement of the stent-graft in the SVC to allow for proper drainage of pulmonary veins into the left atria. The SVASD heart showcased anatomy more appropriate for surgical repair with a patch closing the ASD and Warden procedure transecting the SVC connecting to the RA appendage. Both surgeries proceeded successfully. Eighty-six percent (86%) of physicians surveyed reported that the models "helped immensely" in their understanding of the differences between the two types of CHDs.

## DISCUSSION

3D models of two distinct CHDs have been created and shown to positively aid in pre-surgical planning and justifying a stent placement with a minimally invasive procedure rather than the deployment of a cardiac baffle with open-heart surgery in one of the cases that demonstrated biatrial drainage ASD. In addition to aiding in clinical decision-making, these models can serve as powerful educational tools for healthcare professionals. Current limitations include accounting for the movement of the vessels during the heart cycle and improving the semi-automatic processing pipeline in which these models are constructed. In future studies, 4D-Flow MRI data can be extracted and be used to estimate hemodynamic parameters, like wall shear stress (WSS), which can aid in understanding the onset and progression of cardiovascular disease.

# RECENT UPDATES ON THE GHBMC HUMAN HEAD FINITE ELEMENT MODEL – DEVELOPMENT OF CRASH INJURY INDEX FOR MULTIPLE BRAIN INJURIES

**Ding Lyu (1), Shirin Phadke (1), Abhijeet Kumbhare (1), Liying Zhang (1)**

(1) Department of Biomedical Engineering, Detroit, MI, United States

## INTRODUCTION

Each year, an estimated 1.5 million Americans sustain a Traumatic Brain Injury (TBI). Motor vehicle crashes are the leading cause of TBI resulting in hospitalization. Mathematic modeling of a traumatic event has become a powerful tool to study biomechanical processes of head injuries that are difficult to investigate experimentally on living human subjects. The Global Human Body Modelling Consortium (GHBMC) 50$^{th}$ percentile human adult male head model (M50) based on the Finite element (FE) technique has been developed and validated extensively. Most recently, GHBMC M50 head model was updated with an anisotropic hyperelastic brain model to enable its capability to predict axonal injury in various white matter structures and identify the impact direction-dependent injury risk. This updated GHBMC head model v6.0 was rigorously validated against 63 head impact experiments conducted on Postmortem Human Subject (PMHS) to ensure the accuracy of the prediction of the kinematic, kinetic, stress and strain responses as experienced by the human head from a variety of loading conditions.

To utilize the FE model's predictive power to delineate the injury process and predict injury severity by relating types of injury to material failure of tissues, tissue level predictors based on model parameters need to be established. Previously, FE head model simulation of 56 helmet impacts involving concussed and non-concussed American Football players suggested that the local brain response in the form of maximum principal strain (MPS) and product of MPS and maximum principal strain rate (MPSR) were predictors that corelated better to neurological symptoms, memory impairment and return to play than the HIC15 (Head Injury Criterion) and rotational acceleration alone[2,3,4]. FE reconstruction of limited real-world vehicle crashes involving brain injuries implied that MPS was a potential injury parameter for AIS 4+ diffuse brain injury while the intracranial pressure (ICP) and bridging vein (BV) strain were predictive for brain contusion and ASDH[5].

The objective of this study was to develop Crash-Induced Injuries indices (CIIs) for the GHBMC M50 head model v6.0 based on tissue response measures for predicting multiple brain injuries, skull fractures and facial fractures.

## METHODS

The GHBMC M50 head model v6.0 was applied to reconstruct a total of 49 PMHS impact tests and real-world injury cases (Table 1). The correlation of the model parameters for various injuries were determined according to logistic regression and Weibull survival analysis or the overall average values.

**Table 1: Cases reconstructed to determine various CIIs**

| CIIs (Test | Parameter | Injury, Noninjury |
|---|---|---|
| Facial Fractures[6,7] | MPS / MPST# | 6 fractures |
| Skull Fractures[8,9] | MPS / MPST | 9 fractures |
| Cerebral | ICP in ROI | 8 injuries, 5 noninjuries |
| ASDH[12] | BV Strain | 6 injuries, 9 noninjuries |
| Diffuse Brain | MPS, MPS × MMPSR | 4 injuries |

#MPST: Maximum principal stress

Development of CIIs for Facial and Skull Fracture of Various Regions

A series of cadaveric facial and skull impacts on the nasal, maxilla, zygomatic, frontal, temporal, and parietal bones were simulated[6,7,8,9]. To predict fractures of the cortical and spongy bones, the MPS and MPST failure limits were specified respectively to initiate the fracture predictions by using *MAT_ADD_EROSION (LS-DYNA R12.0). The final failure thresholds were determined while all resulting fracture forces fell well within the reported range of experimental results.

Development of CIIs for Various Brain Injuries

A set of frontal head impact tests[11,12] were simulated to determine the ICP for cases with and without cerebral contusion. Eighteen occipital head impacts were simulated to determine the ASDH[12]. The logistic regression and Weibull survival analysis were conducted to develop the injury risk curves of cerebral contusion and ASDH. The injury threshold

for diffuse brain injury was based on the simulation results of four real-world crash accidents which covers a range of different levels of head injuries (AIS0, AIS4, AIS5, and MAIS5)[5].

## RESULTS

CIIs for Fractures

For skull impact, the model predicted fracture forces for frontal, temporal and temporal-parietal bones were 5.09, 6.39, and 7.52 kN, respectively and were comparable to the experimental data in the corresponding regions. The predicted fracture force in the facial bones were 1.78, 1.88 and 0.97 kN for nasal, zygomatic and maxilla impact, respectively and fell well within the range of experimental results (Figure 1). 0.88 MPS and 0.78 MPS were the fracture CIIs for the outer/inner tables and facial cortical bone, respectively. 20 MPa MPSR was the CII for both skull diploe and facial spongy bone.

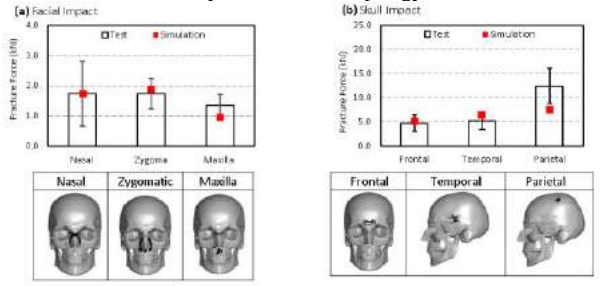

**Figure 1: Comparison of fracture forces and predicted facture location (a) facial impact and (b) skull impact**

CIIs for Cerebral Contusion

The cerebral contusion injury risk functions based on ICP were determined in equations (1) and (2) from Logistic regression and Weibull survival analysis:

$$P(Contusion)_{Logistic} = \frac{1}{1 + e^{-0.02394 \times coup + 3.8606}} \quad (1)$$

$$P\ Contusion\ _{Weibull} = 1 - e^{-\ coup/244.92\ ^{5.29}} \quad (2)$$

Receiver Operating Characteristic (ROC) curves were reconstructed and the Area Under the ROC Curve (AUC) was 0.8 for both models indicating excellent discrimination of the model (Figure 2). Based on logistic regression model, the peak ICP values at 50% and 5% risk of contusion were 161kPa and 38 kPa, respectively.

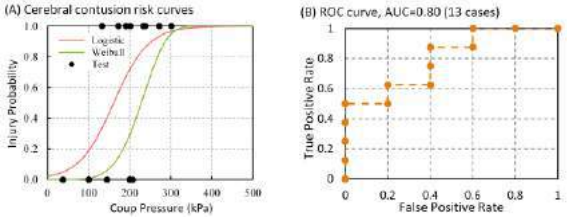

**Figure 2: (A) Cerebral contusion risk curves and (B) AUC**

CIIs for ASDH

The strain in the BV was highly related to the occurrence of ASDH based on the AUC of 0.82 (Figure 3) evaluated for both injury risk functions. The ASDH injury function based on Logistic regression and Weibull survival analysis are described in equations (**3**) and (**4**):

$$P(ASDH)_{Logistic} = \frac{1}{1 + e^{-9.184 \times stretchiratio + 4.195}} \quad (3)$$

$$P(ASDH)_{Weibull} = 1 - e^{-(stretchiratio/0.6181)^{5.3232}} \quad (4)$$

The BV strained at 0.46 and 0.14 would respectively result in 50% and 5% risk of BV rupture leading to ASDH according to the Logistic regression function.

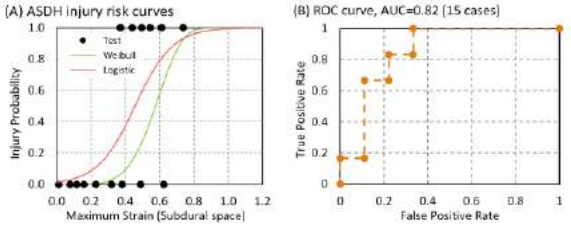

**Figure 3: (A) ASDH risk curves and (B) AUC**

CIIs for Diffuse Brain Injury

The MPS was the averaging of the top 10 elements with highest MPS. The MPSR was the derivative of MPS time-histories. The peak product of the MPS and MPSR was obtained by multiplying MPSR by MPS curves. The peak MPS, MPSR, and MPS × MPSR responses from brainstem, corpus callosum, and subcortical white matter were averaged to predict the risk of diffuse brain injury for AIS 2 and AIS 4+ injury. It appeared that MPS×MPSR had better predictability than MPS alone for differentiating serious diffuse brain injury from concussion.

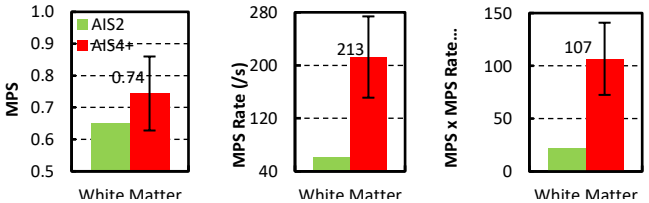

**Figure 4: Diffuse brain injury CIIs based on (a) MPS, (b) MPSR, and (c) MPS x MPSR in the white matter**

## DISCUSSION AND CONCLUSIONS

The CIIs of the GHBMC M50 head model in all prior versions for predicting various brain injuries were based on an average value of the predictions from injury cases. In this study, the risk functions were developed for assessing the probability of cerebral contusion and ASDH injuries. For diffuse brain injury, it was found that the product of strain and strain rate in the white matter might be a more sensitive injury predictor than the strain alone, consistent with the finding from previous studies[3,4]. For skull/facial fractures, established strain and stress limits at failure enables the model to simulate tensile failure of the compact bone as well compressive failure of the cancellous bone. All CIIs show improved capability over previous versions of the GHBMC M50. The authors believe that this tool can be used for testing of various hypothesis advanced as the mechanisms of brain injuries, prediction of injuries and developing countermeasures to reduce risk of injuries in many environments, e.g., falls, transportation, sports and military.

## INTRODUCTION

Pulmonary artery hypertension (PAH) is a progressive pulmonary vascular remodeling disease and increased pulmonary vascular resistance leading to right ventricular dysfunction. The introduction of medications, such as calcium channel blockers and endothelin reception antagonists, has significantly improved the treatment and prognosis of PAH. [1] An acute vasodilator challenge is performed to assess a patient's responsiveness to these treatments. This is conventionally performed by right heart catheterization (RHC) whereby pressure, cardiac output, and vascular resistance are measured in response to a short-acting vasoactive agent such as inhaled nitric oxide (iNO). RHC is an invasive and relatively expensive procedure with inhered risks, making this method's serial characterization of pulmonary artery hypertension a challenging task. [2]

Phase-contrast magnetic resonance imaging (PC MRI) is a non-invasive technique that allows the resolution of blood flow and its velocity. As with any other MRI sequence, it poses no radiation exposure and unlike RHC, does not require vascular instrumentation. Originally, PC MRI was applied for the time-resolved assessment of through and in-plane blood velocity components at a given MRI slice; the technique has now evolved to allow time-resolved 3D resolution of blood velocity components (4D Flow MRI) by sacrificing some of the voxel size resolutions. Herein, we study the hemodynamics of patients with PAH undergoing an acute vasodilator challenge with inhaled nitric oxide by the analysis of both 2D through-plane PC MRI and 4D Flow MRI data of pulmonary artery hemodynamics. This study aims to explore the capacities of non-invasive MRI techniques to assess the vasoreactivity of PAH patients, which could eventually decrease the costs and risks associated with the characterization, diagnosis, and treatment of PAH.

## METHODS

**Data collection.** Retrospective anonymized data from ten adult patients with PAH undergoing the iNO vasodilator challenge. Each dataset consisted of respiratory-gated phase-contrast MRI for time-resolved 2D cross-sections (~1.5 mm/px) of the ascending aorta (AA), the proximal main, left, and right pulmonary artery (MPA, LPA, and RPA, respectively), and a thoracic 4D Flow MRI with a voxel size of 2.5 x 2.5 x 2.5 before and after 10 minutes of iNO administration. Typical sequence parameters were as follows: echo times, 2.4 to 2.6 ms; repetition times, 4.2 to 5.0 ms; flip angle, 10°; temporal resolution, 38 to 48 ms, and VENC set at 150 cm/s.

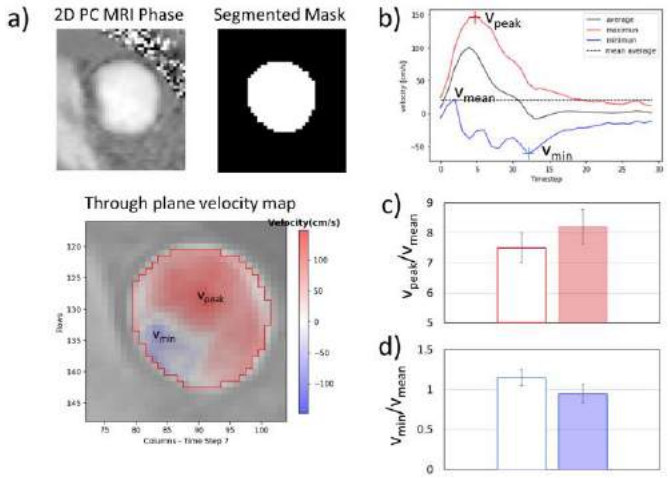

**Figure 1.** a) PC MRI data and processed velocity map. b) time resolved velocity metrics, c) statistics of peak over mean velocity ratio, and d) statistics of peak backflow velocity over mean velocity ratio.

**Image Processing.** Phase data offset error was corrected following the method proposed by Lankhaar et al. [3] assuming this error to be time-dependent and varying linearly within each scanned slice. Time-resolved segmentation masks were built semi-automatically with

custom-developed segmentation pipelines with ImageJ for planar PC MRI scans by two independent observers, and a fixed volumetric mask at systolic configuration was generated with Slicer3D for each 4D Flow dataset.

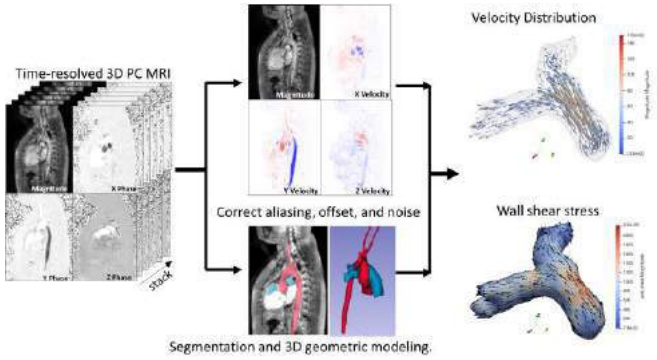

**Figure 2.** 4D Flow processing pipeline.

**PC MRI Postprocessing.** 2D PC MRI pixel-wise data was integrated to generate time-resolved area and flow curves that were smoothed with Python Scipy library tools. Smoothed data was used to generate the following hemodynamic parameters: Ratio of Area Change (RAC), peak and average net flow, peak retrograde flow, peak-net to peak retrograde flow time delay, onset time of retrograde flow, ejection time, acceleration time, acceleration volume, and volumetric-flow branch distribution (Figure 1). Pulse-wave velocity (PWV) was estimated with the slope of the flow vs. area curve at early stages of systole as proposed by Vullieamoz et al. [4]

**4D Flow Postprocessing.** A smooth surface was generated from 3D segmentation mask at systole, surface spatial information and voxel-wise 4D Flow data was used to generate time-resolved wall-shear stress distribution using the B-spline method proposed by Potter et al.[5] Wall shear stress has been previously shown to be significantly lower in pulmonary arteries of PAH patents compared to normal controls [6]. Then, voxel-wise data was exported to Paraview in .vtk format files and a 3D Delaunay mesh was generated with offset and α parameters set to 0.1mm and 2 respectively (figure 2). The Delaunay mesh was used to estimate velocity gradients and estimations of time-resolved vorticity. Paraview filters were applied to identify magnitude and location of regions with highest wall shear stress and vorticity.

**Statistics.** Statistics were performed with JMP® Pro 15.1.0 (SAS Institute Inc.) and assumed a significance level of $p^* < 0.05$. Standard ANOVA was used to study the effect of treatment, location, case and observer on hemodynamic parameters. Then a case paired Student t-test was applied to explore the effect of iNO treatment on hemodynamic parameters.

## RESULTS

Resulting velocity distributions and derived hemodynamic parameters showed good agreement with previous studies on PAH on adults. Notably, PWV estimations were $4.3 \pm 0.3 \dot{m}/s$, $3.2 \pm 0.4 \dot{m}/s$, and $1.7 \pm 0.3 \dot{m}/s$ at the MPA, LPA and RPA respectively. Blood flow is distributed in the pulmonary branch such that $55 \pm 10\%$ of the volume is directed to the LPA.

For all cases studied, PC MRI suggests that normal peak forward velocity normalized to the mean time-averaged velocity is on average 10% larger at the MPA after iNO inhalation, and 40% larger at the LPA, a trend that requires further study to explore potential statistical significance ($p<0.2$). Retrograde peak velocity normalized to mean time-averaged velocity was 20% lower at the MPA after iNO inhalation, a difference that approached statistical significance ($p=0.12$). However, statistical analysis showed that, for the cases studied here, iNO treatment does not affect PC MRI derived measurements of area change, net blood flow, retrograde flow, blood flow distribution or pulse wave velocity. These results were on agreement with findings from 4D Flow MRI data, that revealed that peak velocity and wall shear stress were on average 15% and 10%, respectively, larger after iNO inhalation (figure 3). Peak velocities were found on consistently within the MPA. Wall shear stress peaked at the superior wall of the MPA product of the interaction with the flow ejected from the right atrium, and at the posterior side of the main pulmonary branching.

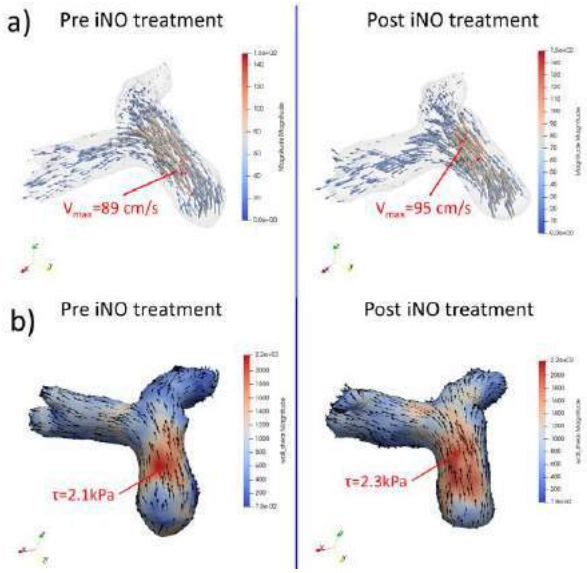

**Figure 3.** a) Velocity distribution b) Wall shear stress distribution.

## DISCUSSION

PC MRI and 4D Flow MRI are useful tools to quantitatively, and qualitatively assess patient-specific pulmonary artery hemodynamics in PAH. Herein, these tools were applied to explore potential effects of iNO inhalation for vasoreactivity tests on pulmonary artery hemodynamics. The method did show differences on velocity and velocity-gradient distributions, suggesting that iNO inhalation treatment reduces the intensity of retrograde flow velocity, wall shear stress, and flow vorticity. The statistical analysis showed that case-to-case variability dominated over the effects of iNO treatment. Nevertheless, the trends found here motivate us to pursue future studies with a larger cohort of recruited patients to further explore the effects of iNO treatment on PAH hemodynamics. The developments of non-invasive tools to assess PAH severity and responsiveness to vasoactive agents has the potential to reduce costs of diagnosis and treatment of this disease, with a positive impact on patients quality of life.

# EFFECT OF BULGING SINUS ON HEMODYNAMIC PERFORMANCE OF POLYMERIC RV-PA CONDUIT FOR PEDIATRIC AND ADULT PATIENTS

## INTRODUCTION

Congenital heart defects (CHD) are among the most common birth defects in the United States and a leading contributor to infant mortality rates across the globe. In 2017, CHD caused about 181,000 deaths in infants, accounting for 70% of the total CHD mortality rate worldwide[1]. A right ventricle to pulmonary artery (RV-PA) conduit is often used in procedures for various congenital heart defects such as pulmonary atresia, Tetralogy of Fallot, truncus arteriosus and right ventricle outflow tract reconstruction. This device helps restore the pulmonary blood flow from the heart. Currently available conduit options include homografts, decellularized allografts, commercial xenografts (Contegra and Hancock by Medtronic), prostheses made from expanded polytetrafluoroethylene (ePTFE) and/or polyethylene terephthalate (PET) that are hand sewn intraoperatively, and a newly developed tissue engineering conduit, the Xeltis pulmonary valve[2-6]. The challenges with these existing conduits include thrombus formation, calcification, stenosis, regurgitation and sternal compression, which affects the device's longevity leading to surgical reinterventions[7]. Therefore, there is a critical need to investigate biocompatible materials, optimize the design for these conduits, and introduce geometrical modifications that can alleviate these issues.

Our group has demonstrated the use of a novel biomaterial made of an interpenetrating polymeric network of hyaluronan (HA) and linear low density polyethylene (LLDPE) for cardiovascular devices, owing to its biocompatibility, anti-calcific and anti-thrombotic properties[7,8]. In addition to these advantages, HA-LLDPE has good hemodynamic performance due to low bending stiffness, high tear and tensile strengths, as well as excellent handling characteristics, and is inexpensive. Therefore, the objective of this pilot project is to demonstrate the potential of the HA-LLDPE conduit for pediatric and adult populations to address many of the drawbacks of the available options. We will look at HA-LLDPE conduit as an alternative to existing options and understand the difference in hemodynamics post geometrical modifications. Particularly, we will investigate the introduction of a bulging sinus ad its effect on the conduit's performance characteristics.

## METHODS

### Conduit Design

LLDPE conduits of diameters 14 mm and 26 mm were designed with and without a sinus, having the same leaflet geometry as shown in Figure 1. In order to incorporate the sinus geometry, the correlation between body surface area (BSA) and sinus of Valsalva, which is 26.79  6.59 mm/m$^2$ (r – 0.886, p < 0.001) when BSA is between 0.5 and 1.0 m$^2$, was used[9]. Equation 1 gives the relationship between the main pulmonary artery (MPA) and body surface area (BSA)[10]:

$$MPA=(1.653)(BSA0.5)+0.033\text{MPA}=1.653\text{BSA}0.5+0.033\ldots \quad (1)$$

Based on the above relationship, the sinus diameter for each of the designs was calculated and incorporated into their respective designs.

**Figure 2: Top view and side view of valved conduit (A) With bulging sinus and (B) Without bulging sinus**

**Valve Fabrication and Conduit Assembly**

LLDPE (80um thick) sheet was mounted on a vacuum former, preheated for 30 seconds, and vacuum formed into a valve using a 3D printed mold. The process was repeated with another LLDPE sheet thermoformed around a tubular mold that it mounted on the valve, which created the conduit. Further heating of the valved conduit along its wall fused two LLDPE layers together. In order to incorporate a sinus geometry into the valve, the molds used to create the valved conduits will be altered. Figure 1 shows the two conduit designs after thermoforming.

***In vitro* Hemodynamic Assessment**

LLDPE valved conduits, with and without a sinus of Valsalva, of two diameters (14 and 26 mm) were fabricated and mounted in an in-vitro model as shown in Figure 2 and tested under pulsatile flow conditions (8/25 mm Hg diastolic/peak systolic pressure). The 14 mm and 26 mm conduit were tested at pediatric and adult conditions, respectively. A working fluid of 60/40 water to glycerin (99% pure glycerin) was used as a blood analog to provide required density and kinematic viscosity of 1060 kg/m$^3$ and 3.5 x 10-6 m$^2$/s, respectively. Pressure gradient and flow waveform were collected. From this data, mean transvalvular pressure gradient (ΔP), peak transvalvular pressure gradient (peak ΔP), effective orifice area (EOA), and regurgitant fraction (RF) were computed for each of the valved conduits.

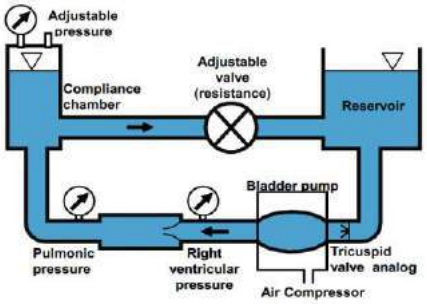

**Figure 2: Schematic of physiological right heart simulator**

**RESULTS**

The ΔP, peak ΔP, and RF for the 14 mm and 26 mm straight conduits without a sinus are shown in Table 1. The EOA for all samples is close to the minimum device performance required value for the appropriate valve size, between 1.45 cm$^2$ for 26 mm ID and approximately 0.47 cm$^2$ for 14 mm ID as extrapolated from the ISO 5840. Additional data for the 14 mm and 26 mm conduits with bulging sinus is being generated for the presentation.

**Table 1: Hemodynamic data and in-vitro setting of the LLDPE pulmonary valved conduit**

| Size (mm) | ΔP (mmHg) | | Peak ΔP (mmHg) | | (RF) (%) | |
|---|---|---|---|---|---|---|
| | mean | std | mean | std | mean | std |
| 14 | 13.6 | ±0.72 | 24.9 | ±1.17 | 2.83 | ±0.74 |
| 26 | 18.1 | ±0.25 | 24.7 | ±0.28 | 9.53 | ±0.49 |

**DISCUSSION**

The HA-LLDPE valved conduits proposed in this study will be a positive step towards developing a biocompatible conduit that has excellent hemodynamics and durability. The pressure gradients of the LLDPE conduits are comparable to that of Contegra bovine jugular conduits[10]. The incorporation of a bulging sinus can improve the overall hemodynamic performance characteristics of the conduit, increasing the longevity of the device. Thus, the development of this conduit would help in the treatment of various complex congenital heart defects.

# PERFORMANCE OF THE BALLOON-EXPANDABLE VALVE IN A SELF-EXPANDING VALVE AT DIFFERENT IMPLANTATION HEIGHTS

**Milad Samaee (1), Huang Chen (1), Pradeep Yadav (2), Vinod Thourani (2), Lakshmi Prasad Dasi (1)**

(1) Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

## INTRODUCTION

Transcatheter aortic-valve (TAV) replacement (TAVR) is currently approved for all risk categories of patients [1]. Following the use of TAVR at younger ages, the life expectancy may go beyond the durability of the TAVs [2], which have been raised by the structural heart community. As a result, implantation of a second TAV inside a prior TAV (which is known as redo TAVR or TAV-in-TAV) procedure may be considered to treat patients with failed TAVs due to regurgitation, stenosis, or a combination of the two. However, depending on the patient anatomy (such as coronary access due to risk of coronary obstruction) and the initial TAV status and characteristics, the second TAV's selection and implantation height will be crucial. Moreover, the second TAV performance, such as leaflet fluttering, pinwheeling, effective orifice area (EOA) size, and the downstream flow pattern can be affected by the implantation height compared with the initial TAV. The current in vitro study investigates the effects of the second TAV implantation height in a TAV-in-TAV procedure by comparing the hemodynamics and performance of the second TAV at different implantation heights.

## METHODS

A 26 mm SAPIEN 3 Ultra (Edwards Lifesciences, Irvine Calif) was deployed in a 29 mm Evolut PRO+ (Medtronic Inc, Irvine, Calif) within a transparent distensible aortic chamber at four different heights ($H_1$ = 24.5mm, $H_2$ = 20.5mm, $H_3$ = 16mm, and $H_4$ = 12.5mm) as shown in **Figure 1**. The aortic chamber was implanted in a left heart simulator, which was designed and used in our previous studies [3]. The flow loop imposed physiological hemodynamics (peak aortic flow = 25±0.2 L/min; heart rate = 60 bpm; systolic/diastolic aortic pressure = 120/80±1 mmHg) in all four sets of experiments. 60 consecutive cardiac cycles were recorded for calculating hemodynamic parameters, namely EOA and regurgitant fraction (RF). EOD and RF percentage were calculated as Equitation 1 and Equation 2, respectively.

$$RF = \frac{Regurgitant\ Volume\ [ml]}{Stroke\ Volume\ [ml]} \times 100 \quad (1)$$

where regurgitant volume was the sum of closing volume and leakage volume; stroke volume was considered as forward flow volume.

$$EOA = \frac{Q\ [cm^3/s]}{51.6\sqrt{PG\ [mmHg]}} \quad (2)$$

where Q represents the root mean square aortic valve flow and PG is the mean transvalvular aortic pressure gradient in a cardiac cycle.

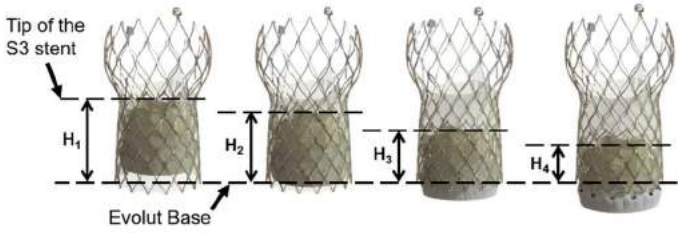

**Figure 1: Deploying a 26 mm SAPIEN 3 Ultra in a 29 mm Evolut PRO+ at four different heights**

En face images were recorded using a 1 kHz frame rate high-speed camera. Geometric orifice area (GOA) and pinwheeling index (PI) were calculated using the en face images. PI was calculated as Equation 3.

$$PI = \frac{L_{actual} - L_{ideal}}{L_{ideal}} \times 100 \quad (3)$$

where $L_{actual}$ and $L_{ideal}$ represent the deflected and unconstrained free edge of the leaflet, respectively. Fluid flow patterns downstream of the TAV were assessed using high spatial and temporal resolution particle image velocimetry (PIV). 200 consecutive image pairs were acquired at 3 time points: mid acceleration, peak systole, and mid deceleration.

Velocity vector field, vorticity dynamics, and Reynolds shear stress (RSS) were also evaluated distal to the TAV.

## RESULTS

The obtained mean pressure gradients (PG) for four conditions was 11.84±0.27 mmHg, 11.61±0.48 mmHg, 12.46±0.52 mmHg, and 12.26±0.47 mmHg for $H_1$, $H_2$, $H_3$, and $H_4$, respectively, which is comparable to each other. The RF for all cases is shown in **Figure 2**.

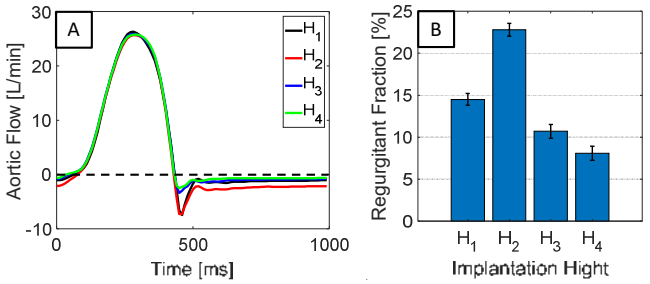

**Figure 2: Aortic Flow and regurgitant fraction Comparison between different implantation heights**

Similarly, calculated EOAs were comparable with all cases (1.72±0.02 $cm^2$, 1.57±0.03 $cm^2$, 1.55±0.06 $cm^2$, and 1.69±0.04 $cm^2$) for $H_1$, $H_2$, $H_3$, and $H_4$, respectively. The en face view of the valve at peak systole and during diastole for different implantation heights are shown in **Figure3**. As shown in **Figure 3**, PI cannot be calculated for $H_3$ and $H_4$ since the Evolut valve is fully closed during diastole and blocks the SAPIEN 3 en face view. The PI values for $H_1$ and $H_2$ were 12.42% and 18.31%, respectively.

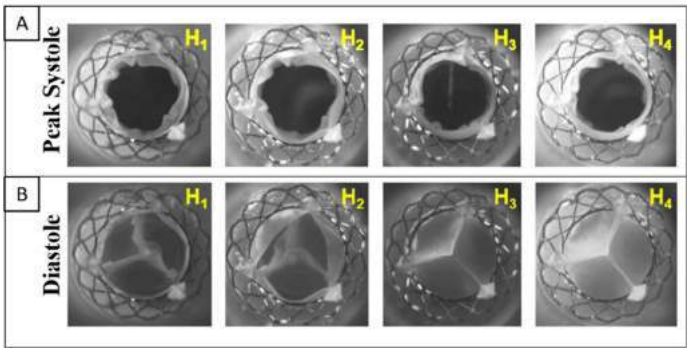

**Figure 3: En face view of TAV at A) peak systole and B) diastole**

RSS and velocity vector fields overlaid with z-vorticity contours at peak flow and acceleration phase are plotted as shown in **Figure 4**. Results for the mid-decelerations will be presented.

## DISCUSSION

With the highest implantations of SAPIEN 3 in Evolut ($H_1$) the stent frame of the SAPIEN 3 pushes the Evolut leaflets and generates a neo-skirt. Therefore, the Evolut leaflets stay fully open during diastole and may cause a coronary obstruction that needs further investigation. Evolut leaflets remain half-open in $H_2$ during diastole and fully closed in lower implantation heights, $H_3$ and $H_4$. Therefore, PGs were lower in $H_1$ and $H_2$ than $H_3$ and $H_4$ since both SAPIEN 3 and Evolut leaflets need to be open in early systole in $H_3$ and $H_4$.

The closing volume and leakage volume are reduced in lower heights of implantation ($H_3$ and $H_4$) due to having two valves closing in series, unlike those higher implantation heights ($H_1$ and $H_2$). This result can be beneficial from the fluid mechanical point of view; however, the clinical aspects need to be justified.

The RSS looks very high in $H_1$ and shows the lowes in $H_3$. A vortex ring is generated in $H_3$ and $H_4$ during the acceleration phase (early systole), which is due to having the closed Evolut leaflets opening and will be beneficial for mixing fluid flow.

Another important point that needs to be investigated is incorporating the stiffness of the Evolut valve in this study. The TAV-in-TAV is usually proposed to be performed on a calcified TAV. The stiffness of the Evolut will play an important role in the amount of pressure gradients and will be highly dependent on the implantation heights. Therefore it seems to be beneficial to open up the Evolut valve ($H_1$ or $H_2$), but at the same time can cause coronary obstructions. Another important future study is washout investigations in the sinus area since the geometry of the neo-sinus is highly dependent on the implantation height.

Results suggest that the implantation height in TAV-in-TAV is an important factor. A detailed hemodynamics comparison between cases will be discussed.

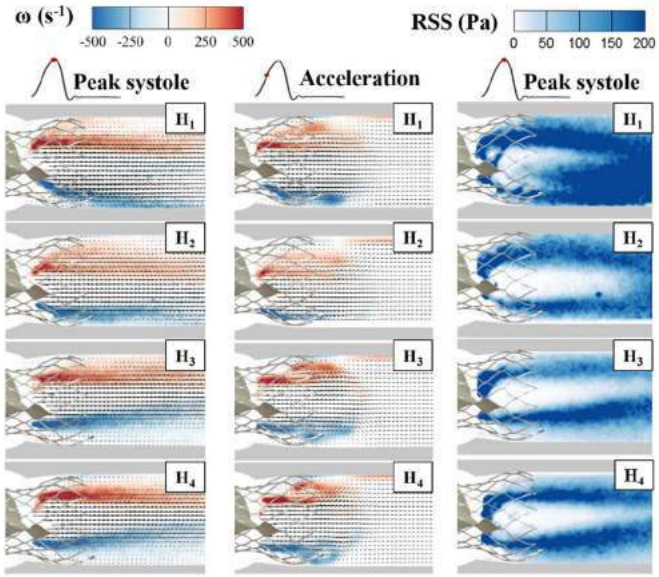

**Figure 4: En face view of TAV at A) peak systole**

# CHANGES IN THE IN-VIVO FUNCTIONAL STATE OF THE MITRAL VALVE IN PERCUTANEOUS MITRACLIP REPAIR

**Hao Liu (1), Natalie Simonian (1), Sneha Vakamudi (3), Mark Pirwitz (3), Joseph H. Gorman III (2), Robert C. Gorman (2), and Michael S. Sacks (1)**

## INTRODUCTION

Mitral regurgitation is the most common valvular disease in the United States affecting over 2% of the population and is expected to double by 2030 due to population aging [1, 2]. The preferred treatment strategy for MR is undersized ring annuloplasty (URA), but the long-term outcomes of this repair are mixed [3, 4]. Recently, minimally invasive edge-to-edge leaflet clipping methods (e.g the MitraClip) have been of great clinical interest as the technique is generally effective, particularly for patients at high surgical risk with no suitable alternatives [5]. However, outcomes as compared to other treatment options have been unclear, as well as long-term outcomes (>5 years) after surgical procedures. Furthermore, the details of the procedure (the number, size, and placement of the clips) are dependent on the clinician's experience, and these configurations are adjusted heuristically in real-time during the procedure until maximum reduction of MR grade on echo has been achieved. Therefore, there is clearly an urgent need for quantitative, patient-specific treatment optimization. In particular, we seek to develop models which consolidate the highly variable clinical metrics of each individual into predictive factors of future repair efficacy.

In this study, we focused on the MitraClip percutaneous edge-to-edge repair (Abbott Inc.) used to correct ischemic mitral valve regurgitation (IMR). Our long-term objective is to develop an understanding of the functional consequences of minimally invasive edge-to-edge leaflet approximation methods using clinically available imaging data to accurately assess and predict the efficacy and longevity of MitraClip procedure for individual patients. In the present study, as a first step we examined the leaflet deformation patterns of pre- and post-surgical post-IMR state mitral valves (MV) to develop an improved understanding of how point loads generated by the MitralClip affect both the local and more distant leaflet deformation patterns.

## METHODS

Real-time three-dimensional echocardiography (rt-3DE) images of 20 patients before and after MitraClip procedure were performed and 3D volume data was then converted to the Cartesian coordinates system. MitraClip devices were clearly visible in rt-3DE images using ITK-snap software (Figure 1).

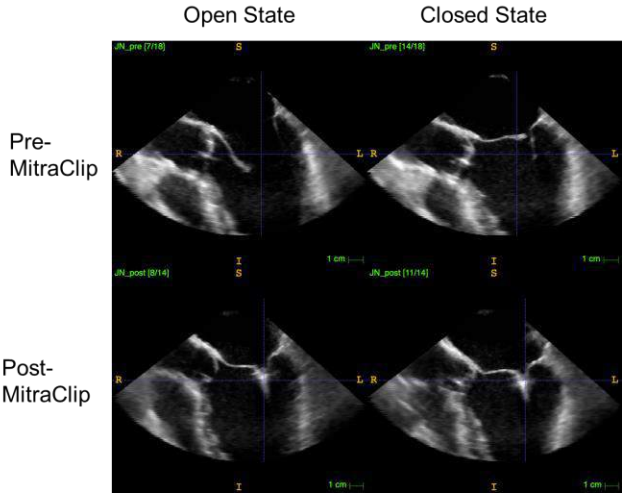

**Figure 1: 3D echocardiography (parasternal long-axis view) of one patient in pre- and post- MitraClip state**

Then, these rt-3DE images were segmented with our previous established segmentation pipeline in MATLAB [6, 7] (details are shown in Figure 2). Afterwards, in-vivo strain estimation of pre-MitraClip state was analyzed using our extensively validated pipeline [6, 7] (Figure 3A). The simulation was conducted in the commercial FE software Abaqus by applying an annular displacement boundary

condition, a physiological ventricular pressurization, and a downward chordal-mimicking force. After the leaflets have initially coapted, a local corrective pressure field was applied to penalize any mismatch between the simulated geometry and the true closed-state rt-3DE reconstruction. For post-MitraClip state simulation, we improved the in-vivo strain estimation pipeline by introducing axial and beam connectors which are functionally equivalent to the MitraClip (Figure 3B). First, six axial connectors were created by connecting the anterior and posterior leaflets where MitraClip located. Secondly, two nodes on each connector were activated to minimize its distance to zero similar to MitraClip actuation. Next, the axial connectors were replaced with beam connectors to fix these points of leaflets and the same shape-matching technique as in the pre-MitraClip state was utilized to generate the global radial and circumferential strain fields.

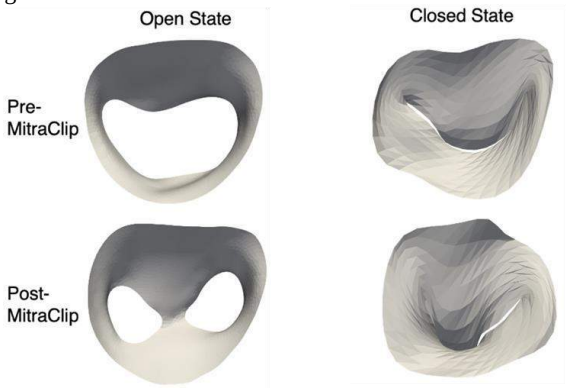

**Figure 2: rt-3DE Image segmentation of a patient MV before and after percutaneous repair. In the open state, the double orifice and pinching of two leaflets is clearly visible, and in the closed state, the excessive posterior distension of the anterior leaflet is delineated by the mesh element edges**

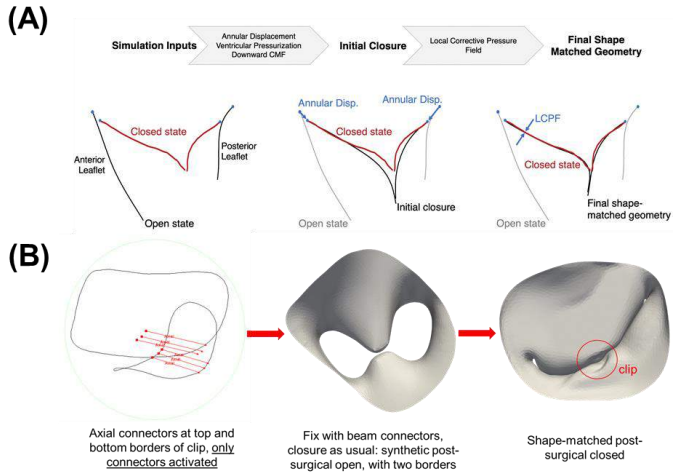

**Figure 3: (A) Shape matching method for pre-surgical simulation: starting from MV open state geometry, annular motion and transmural pressure were applied to have a transitional state. Then, local corrective pressure forces were implemented to match MV closed state geometry; (B) Improved shape matching technique by introducing axial and beam connectors as MitraClip device in post-MitraClip cases**

## RESULTS

Results firstly demonstrated a clear distortion in leaflet geometry due to leaflet edge-edge repair. The anterior leaflet was dramatically displaced towards posterior side which is confirmed with notable increase in radial strain of anterior leaflet. In the meantime, the posterior leaflet moved towards the posterior side and induced a decrease of radial direction of posterior leaflet. An increase of circumferential strain was observed around free edge area mainly due to the grippers of the MitraClip grabbing the leaflets. However, circumferential strain in the belly area had an overall decrease after repair (Figure 4, left panel).

Then, we compared the stress distributions between pre-surgical and post-surgical states. Clearly, stress concentration in both circumferential and radial directions were observed and locations were confirmed with where dramatic change of strain occurred (Figure 4, right panel).

## DISCUSSION

Application of the MitraClip was shown to clearly induce major alterations in MV leaflet strain and stress behaviors. This work confirms that such techniques dramatically alter the MV functional behaviors, which may elucidate the underlying reasons long-term MV remodeling occurs in response to the observed stress concentrations, possibly leading to limited repair durability. We are currently conducting analyses on 20 patients to: (1) establish the pre-operative state of MV across the mitral regurgitation spectrum and (2) elucidate overall consequences of MitraClip on MV leaflet geometry, behavior, and remodeling. This study will allow us to develop an anatomically faithful patient specific model of MV apparatus to predict post-surgical outcomes strictly from pre-surgical information. Such studies are critical since clinical long-term outcomes of MV repair are quite poor, yet our knowledge on how to improve surgical outcomes is very limited. Our long-term goal is to inform the optimal treatment for each patient, including of repair or replacement is the best treatment of choice.

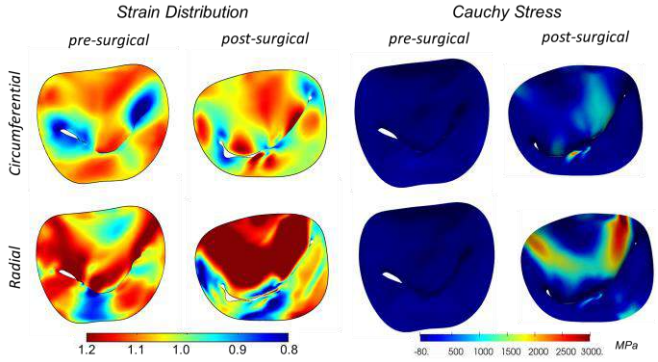

**Figure 4: In-vivo strain and Cauchy stress estimation of pre-surgical and post-surgical states: an increase of radial strain on anterior leaflet and a decrease of radial strain on posterior leaflet due to excessive posterior distention for both leaflets; an increase of circumferential strain around contact area and a decrease in the belly area; stress concentration were captured where dramatic changes of MV strain occurred.**

## INTRODUCTION

Pancreatic ductile adenocarcinoma (PDAC) is a dismal disease whose 5-year survival rate is only 10%. [1] PDAC comprises a complex and heterogeneous tumor microenvironment (TME) with a strong desmoplastic stroma, including cancer-associated fibroblast, which causes inherent resistance to anti-cancer therapy. Among stromal cells, cancer associated fibroblast (CAFs) play a central role in PDAC progression and drug resistance, but their interplay with pancreatic cancer cells (PCCs) remains elusive. [2] Specifically, CAFs can also hinder drug delivery to PDAC tumors and escalate therapeutic resistance. [3] Therefore, it is essential to have a reliable tumor model that allows for the systematic study of the complex disease to make advances in anti-cancer therapeutic strategies.

In the present study, we used a tumor microenvironment on-chip (T-MOC) model, which reconstitutes PCC and CAFs in the 3D perfused TME context, to discover the efficacy of drug candidates targeting the redox function of Ref-1 in PDAC. The Ref-1 has been recognized as a redox signaling protein regulating redox metabolic activity of cancer in hypoxia, known to induce drug resistance and metastasis. [4] The inhibition of the redox activity has been recognized as effective in reducing PDAC tumor growth. Our group already synthesized multiple analogs of Ref-1 inhibitors [4]. Here, we investigated the efficacy of the Ref-1 inhibition on PCC in the presence of CAFs by using the T-MOC model to test its capability of screening the drug efficacy difference between the cell types. The results are analyzed to test whether the T-MOC model can provide a reliable testbed to study the potential cancer-selective targeting drugs for the complex and heterogeneous TME in a controlled manner.

## METHODS

The tumor-microenvironment-on-chip (T-MOC) is a 3D *in vitro* microfluidics platform composed of three channels – an interstitial and two side channels. The 1mm-wide interstitial channel includes cells embedded in the 3D extracellular matrix (ECM), sided with two 300μm-wide channels allowing for drug perfusion mimicking the actual interstitial transport in PDAC TME. The microfluidic platform was fabricated by soft-lithography techniques using PDMS. Details of fabrication and preparation were described previously. [5] The interstitial channels were filled with cell-collagen mixture fulfilling the 3D culture condition. We used a human pancreatic cancer cell line (Pa03C, transfected with Td-tomato) and cancer-associated fibroblast cell line (CAF19, transfected with GFP) for the model. [4] The cell-collagen mixture was composed of Pa03C and CAF19 cells, and 6 mg/ml of type I collagen with 10X PBS, NaOH, HEPES buffer, FBS, Glu, P/S, and cell culture grade distilled water. PCCs (Pa03C) and CAFs (CAF19) were mixed into the cell-collagen mixture at a 1:1 cell ratio. The initial cell concentration was $2 \times 10^6$ cells/mL for each cell type. After loading, the chips were incubated at 37°C for 1 hour for collagen polymerization. Then, the culture medium was introduced through the side channels. The loading process was controlled by pressurizing channels.

To assess drug efficacy, we followed the experiment timeline shown in **Fig 1**. The PDAC T-MOC were cultured for 48 hours before the experiments. Then, the drugs were perfused through the side channels (DAY0). We initially applied a pressure difference between two side channels to ensure the drug perfusion to cells encapsulated by the collagen matrix. The pressurization was achieved by varying a medium level in the side channel reservoirs. The drug solutions were prepared in the culture medium as 0 μM (control), 3, 10, and 30 μM for APX2009 (Ref-1 inhibitor). On day 3, the channels were washed with a drug-free medium and re-perfused with the same drug-containing medium. On day 6, we finalized the treatment and measured drug efficacy.

Drug efficacy was analyzed in two ways, cell growth and cell survival. Cell growth was determined by quantifying the fluorescent cell area. Fluorescence of transfected Pa03C (Td-tomato) and CAF19 (GFP)

was measured with an inverted microscope (Olympus IX71, Japan) with TRITC and FITC filter on days -2, 0, 3, and 6. Cell growth was analyzed by normalizing the corresponding fluorescent pixel counting by day 0.

$$\text{Cell growth} = \frac{[\text{Fluorescent area of cells}]_{\text{DAY } n}}{[\text{Fluorescent area of cells}]_{\text{DAY0}}} \quad (n = 0, 3, \textit{and } 6)$$

Cell survival was determined by evaluating cell viability at the end of the experiment. The cell survival was defined as the cell growth at day 6 of drug treatment groups normalized by the cell growth of the control groups (absence of drug) as following:

$$\text{Cell survival} = \frac{[\text{Cell growth}]_{treatment}}{[\text{Cell growth}]_{control}}$$

## RESULTS

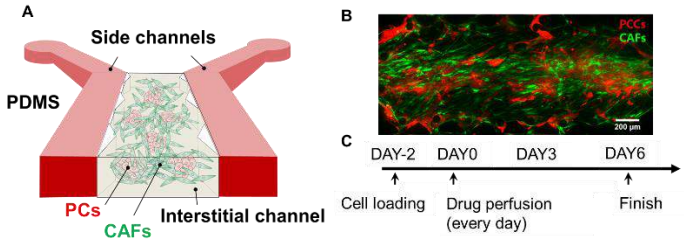

**Figure 1: (A) Schematic of functional structures of PDAC T-MOC (B) Fluorescent microscopic observation of PCCs (red) and CAFs (green) in PDAC T-MOC (C) Experimental timeline**

To assess the potential effect of Ref-1 inhibition as a cancer-selective target drug, the PDAC T-MOC model was utilized with co-culture of Pa03C and CAF19 cells. (**Fig.1A**) The T-MOC platform was developed to reconstitute the heterogeneity in the tumor microenvironment as described in our previous publication. [5] In the present study, we integrated the human PCCs with CAFs in the T-MOC platform. [4] Each cell type was transfected, having distinguishable fluorescence. The red fluorescent PCCs were clearly distinguished over the green fluorescent CAFs as shown in **Fig.1B**, highlighting the capability of T-MOC to capture the cell-cell interactions *in vitro*. The treatment schedule was also designed to mimic an animal treatment schedule (**Fig.1C**).

We tested the efficacy of Ref-1 inhibitor (APX 2009) for Pa03C (red fluorescence) and CAF19 (green fluorescence) co-cultured in tumor-stroma PDAC T-MOC to compare the differential response to the drug. Representative fluorescence micrographs of the T-MOC samples during the experiment are shown in **Fig. 2A**. In the control group (0μM), both cell types grew significantly over time, as indicated by the increasing red and green fluorescence. On the other hand, the treatment groups showed a differential effect of the APX 2009 between Pa03C and CAF19. The Pa03C cells treated by APX 2009 proliferated significantly slower than CAF19 from 3μM. The red fluorescence indicating Pa03C notably diminished over time, whereas no notable fluorescence change in green fluorescence of CAF19 even at the higher concentration of 30μM. We confirmed our observations by quantifying the cell growth and survival. (**Fig. 2B**) In terms of cell growth, the cancer cell growth treated by APX 2009 started to be slightly slower than the control from DAY3. On Day6, a significantly notable difference was observed in cancer cell growth among the experimental groups ($p<0.05$). The cell survival at DAY6 showed the cancer cell growth was suppressed as 0.48 in the 3μM treatment group while the control group was denoted as 1. For the CAF growth rate, no difference was noted among the experimental groups even at the 30μM treatment group. The resulting survival confirms that the efficacy of the combination treatment is notably high on PCC but not for CAF, indicating the tumor-selective targeting potential of the Ref-1 inhibition.

Dots and bars; mean ± S.E. *: p<.05 (Tukey *post hoc* in ANOVA).**

## DISCUSSION

The present results demonstrate the capability of the T-MOC platform. We investigated the effect of the Ref-1 inhibitor as a potential tumor-selective targeting therapeutics by reconstituting the tumor-stroma TME in T-MOC. The results confirmed that the Ref-1 inhibition suppressed cancer cell growth whereas CAF growth was consistent even at the high concentration of 30μM APX 2009. The T-MOC platform provides a unique testbed to mimic the TME and pharmacokinetics and bridge high throughput spheroid models and *in vivo* animal models. In fact, most previous *in vitro* tumor models have not demonstrated distinct tumor microenvironment features. Both 2D monolayers and 3D spheroid tumor models inadequately recapitulate biophysical interactions in the complex TME. Animal models, including the complex feature of TME, are cost-ineffective and limited to control the biophysical and biochemical interactions in the complex TME. In this sense, the microfluidic technique has an advantage in bridging the conventional models with their controllability and easy accessibility.

# EVALUATION OF SHEAR STRESS VARIABILITY ALONG CAPILLARIES IN ANGIOGENIC RAT MESENTERIC MICROVASCULAR NETWORKS

**N. Hu (1), B. Lomel (1), P. Balogh (2), W. L. Murfee (1)**

(1) J. Crayton Pruitt Family Department of Biomedical Engineering, University of Florida, Gainesville, Florida, U.S.A.

## INTRODUCTION

Shear stress is commonly implicated in angiogenesis, defined as the formation of new vessels from existing vessels. The role of shear stress as a regulator of endothelial cell dynamics during capillary sprouting is supported by the influences on cell phenotype, proliferation and function [1,2]. For example, exposure of endothelial cells to 10-30 dyne/cm$^2$ laminar shear stress *in vitro* can result in the secretion of angiogenic growth factors (i.e. bFGF) and the upregulation of growth factor receptors (i.e. VEGF-R2) [3,4]. The appreciation of the physiological relevance of these models, however, is challenged by not knowing the actual shear stress values along vessels in an angiogenic microvascular network. Computational modeling based estimates in quiescent, adult microvascular networks suggest that shear stresses in individual capillary segments can range from 0.1 to over 500 dyne/cm$^2$ [5]. The potential heterogeneous distribution suggests that the range of relevant shear stresses might be different from those commonly used in *in vitro* studies and motivate critical questions. What is the shear stress experienced by endothelial cells along capillaries? Do all capillaries experience similar shear stress magnitudes? Can variations in shear stress along different capillary segments explain vessel-specific responses? The objective of this project was to estimate shear stress values in regions of angiogenic microvascular networks using measurements from real networks and a network segmental flow model.

## METHODS

**Angiogenic Microvascular Network Stimulation and Vessel Specific Measurements** Rat mesenteric tissues were harvested from adult male Wistar rats post the stimulation of angiogenesis via 48-80 mast cell degranulation. Microvascular networks were identified by perfusion of a 40kDa fixable dextran prior to harvesting and immunolabelling for PECAM. Dextran presence identified perfused segments along the hierarchy of microvascular networks, which were characterized by increased vessel density indicative of angiogenesis. Three representative network regions with arteriole input and venule output vessels were selected for analysis. Vessel segments were defined by nodes, branch order position, and the measurements of lengths and diameters.

**Computational Modeling** A network segmental flow model was used to computationally estimate vessel-specific shear stresses and velocities similar to previous studies [5,6]. Using the boundary conditions (i.e. input arteriolar pressure and output venular pressure), our segment measurements (length (L), diameter (D), and nodal pressures, segmental flows were estimated assuming a modified Poiseuille Flow relationship. An apparent viscosity per vessels was defined based on empirical data derived from the rat mesenteric microcirculation [5]. Initially, vessel viscosity ($\mu$) was set to 4 cP. Then conductance, C, was calculated per segment using equation (Eq. 1):

$$C = \frac{\pi D^4}{128 \mu L} \qquad (1)$$

With the segmental conductances and assuming 75 mmHg inlet pressures and 10 mmHg outlet pressures, the nodal pressure (P) and the flow going through each node (Q) was calculated using the following matrix equation: **CP = Q**. The discharge hematocrit (HD) was set to 0.45 at first and then be updated with the segmental flow, flow fraction ($\psi$) and cell flux ($\varphi$) entering a daughter segment, the diameter of parent segment (D) and daughter segments ($D_1, D_2$), based on an empirical red blood cell distribution law (Eq. 2-3) [6]:

$$A = -\frac{6.96 l \frac{D_1}{D_2}}{D}, \quad B = 1 + \frac{6.98(1-HD)}{D}, \quad X_0 = \frac{0.4}{D} \qquad (2)$$

$$\log it \varphi = B \log it \frac{\psi - X_0}{1 - 2X_0} + A, \quad \log it x = \ln \frac{x}{1-x} \qquad (3)$$

The updated hematocrit was then used to calculate segmental viscosity based on (Eq. 4-6) [6]:

$$C = (0.8 + e^{-0.075D})\left(-1 + \frac{1}{1 + 10^{-11}D^{12}}\right) + \frac{1}{1 + 10^{-11}D^{12}} \quad (4)$$

$$\mu^* = 6e^{-0.85D} + 3.2 - 2.4e^{-0.06D^{0.645}} \quad (5)$$

$$\mu = \{1 + (\mu^* - 1)\frac{(1-HD)^C - 1}{(1-0.45)^C - 1}(\frac{D}{D-1.1})^2\}(\frac{D}{D-1.1})^2 \quad (6)$$

With the updated segmental-specific viscosity, the segmental conductance, nodal pressure, and segmental flow was re-calculated, leading to another updated viscosity and a calculation loop. The calculation loop was stopped upon meeting the conversion requirement defined as total ratio of nodal pressure difference from previous iteration being less than 1%.

## RESULTS

Three angiogenic microvascular regions with clearly identified arteriole inputs and venule output vessels, as well as the loop connected by the arterioles and venules were selected for analysis (Fig. 1). For region 1, shear stresses along capillaries ranged from 0.3 to 708 dyne/cm$^2$ (average = 73± 98 dyne/cm$^2$). For region 2, shear stresses along capillaries ranged from 0.2 to 1509 dyne/cm$^2$ (average = 91± 120 dyne/cm$^2$). For region 3, shear stresses along capillaries ranged from 0.1 to 1645 dyne/cm$^2$ (average = 127± 178 dyne/cm$^2$). For the three regions, the maximum shear stress along capillary segments was greater than the maximum shear stress in the initial arterial branches.

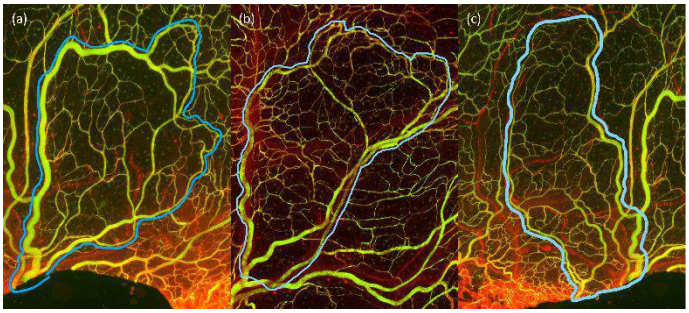

**Figure 1: Angiogenic Microvascular Network Regions. Perfused vessels were identified by perfusion of a 40kDa fixable dextran prior (Green). PECAM immunolabelling identifies all vessels (RED). (a) Region. 1 (b) Region 2. (c) Region 3.**

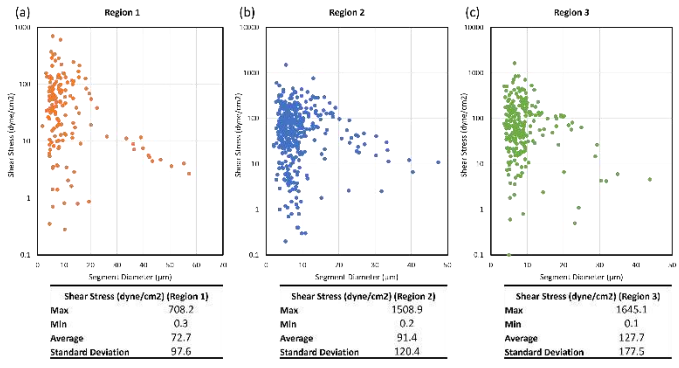

**Figure 2: Segment-Specific Shear Stress Estimates per Network Region. (a) Region 1 (b) Region 2 (c) Region 3.**

Vessel specific estimates allowed for comparing of shear stresses values for different vessel locations within the region. The maximum shear stresses in proximal capillary segments connecting the high-pressure arterial sides to the lower pressure venous sides in a network were increased compared to stresses for segments in more distal network regions. In order to evaluate the sensitivity of the vessel specific estimates to different network pressure drops, the shear stress distribution was evaluated for different pressure boundary conditions. Inlet vessel pressures were varied from 45 mmHg to 105 mmHg with the same outlet vessel pressure of 10 mmHg. Shear stress distributions per pressure scenario displayed a similar trends with high variability at the capillary level (Fig. 3).

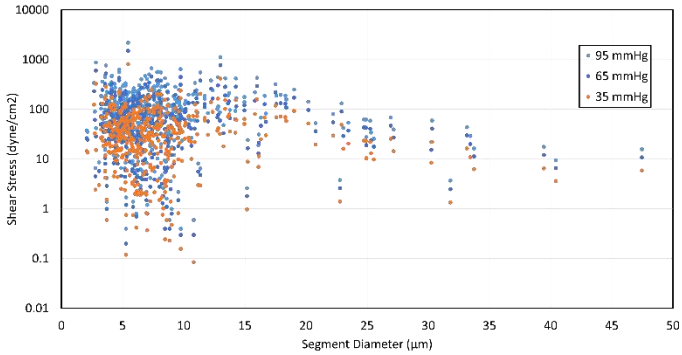

**Figure 3: Segment-Specific Shear Stress Estimation for Region 1 per Different Pressure Drop Scenarios. Inlet pressures were equal to 105 mmHg, 95 mmHg, and 45 mmHg. Outlet pressures were equal to 10 mmHg for each scenario.**

## DISCUSSION

The main contribution of this study is the estimate of vessel specific shear stress values in angiogenic microvascular networks. Consistent with previous cauterization, angiogenic remodeling in the 48-80 stimulated networks was supported by increased vessel density and capillary branching [7]. In the context of understanding the role of shear stress as a regulator of endothelial dynamics involved in capillary sprouting and to make sense of effects reported in the literature based on *in vitro* studies, we need to know the relevant shear stresses experienced *in vivo*. The results of this study highlight the potential heterogeneity of shear stresses at the capillary level in angiogenic microvascular networks and provoke questions related to how vessel-specific hemodynamic environments regulate endothelial cell function.

# FABRICATION OF POLYMERIC HEART VALVES THROUGH ADDITIVE MANUFACTURING

**Hieu T. Bui (1), Adam S. Verga (1), Srujana S. Joshi (1), Scott J. Hollister (1), Lakshmi P. Dasi (1)**

(1) The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA

## INTRODUCTION

Approximately 30 million people are affected by valvular heart disease in the United States. About 182,000 heart valve replacements are conducted each year. Current solutions include replacing the native heart valve with either a mechanical valve or a bioprosthetic valve, both of which have significant downsides. For the mechanical valves, the major problem arises due to thrombogenicity, whereas for the bioprosthetic valves, issues arise because of the immune rejection by the host and low durability which reduces the longevity of the device and may require surgical reinterventions in the future.

In recent years, 3D printed heart valves are being developed to overcome these drawbacks [1]. With the help of 3D printing, intricate geometries representing the anatomy of native leaflets can be incorporated into the valve design to create patient-specific valves. Some of the advantages of customized valves are improved hemodynamic performance, higher durability and ease of surgical implantation. In addition to this, the recent advancements made in additive manufacturing techniques can enable printing leaflet materials with anisotropic mechanical properties, which mimic the properties of the native leaflets. This pilot study is the first attempt to design, manufacture and test 3D printed heart valves. Different 3D printed materials and leaflet thickness were investigated.

## METHODS

### Valve Design

The valve design is based on works described in the literature [1]. Computer-aided design (CAD) (Solidworks) was used to create valves. Figure 1 shows the fabrication process. Figure 2 shows an example of a valve leaflet with heterogeneous thickness. The valve assembly is presented in figure 3.

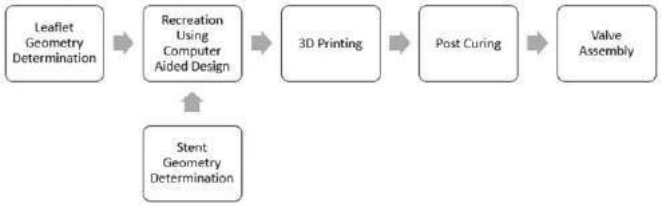

**Figure 1:** Flowchart of valve design and manufacturing process

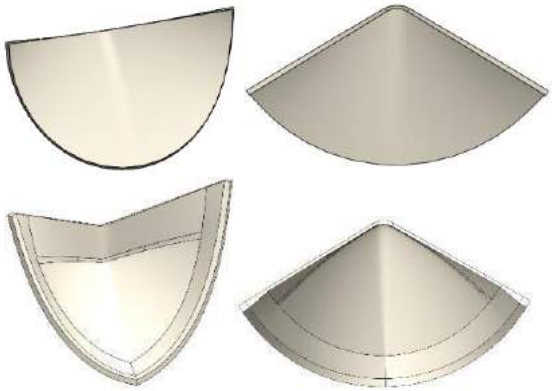

**Figure 2:** Isometric (top left) and top (top right) views of a leaflet with a low profile and homogenous thickness of 300 um. Isometric ( bottom left) and top views ( bottom right) of a leaflet with varying thickness where 1.5 mm radial outer portion is 500-um while the inner portion is 200 µm thick. The top and bottom leaflets were made in the v4 and v5 valves, respectively.

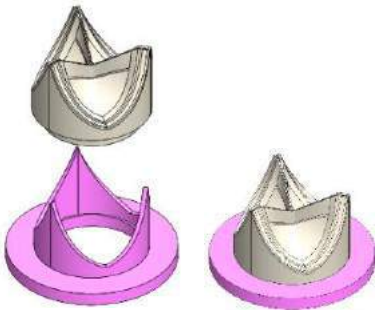

**Figure 3:** rendering of 3D printed valve assembly where the leaflet portion (beige) can be easily mounted on top of the frame (purple).

### Valve Production and Assembly

Valve prototyping was conducted using 3D printers and materials purchased from Stratasys. Shore-A materials are composed of mixes, in varying proportions, of soft Agilus material and rigid Vero material. Leaflets composed of shore-A materials and frames composed of pure Vero material were printed, as full assemblies, on a Stratasys J750 polyjet printer. Leaflets composed of polyurethane were printed on a Stratasys F370 FDM printer and assembled by hand, utilizing cyanoacrylate adhesive, to Vero frames printed on the J750.

### Pulsatile Flow Test

Valve samples were tested under pulsatile flow conditions (80/10 mm Hg diastolic/peak systolic pressure, 1.5 L/min cardiac output). A working fluid of 60/40 water to glycerin (99% pure glycerin) was used as a blood analog to provide required density and kinematic viscosity of 1060 kg/m$^3$ and 3.5 10-6 m$^2$/s, respectively. The average simulated cardiac output was 5 L/min, and the heart rate was 60 bpm. The mean systolic gradient (ΔP), effective orifice area (EOA), and a regurgitant fraction (RF) were calculated. ΔP is the transvalvular pressure gradient across the valve during systole. The EOA was calculated using the Gorlin equation, the recorded systolic gradient, and the flow rate. RF is the fraction of backflow over forwarding flow volume [2].

## RESULTS

Figure 4 shows the various valve designs and their 3D printed counterparts. The hemodynamic data can be found in Table 1. The gradient was lowest with the v4 design using Agilus to make leaflets. The EOA was also highest with a valve made from Agilus. The effect of valve design is evident when comparing the v4 and v5 valves, each printed with the shore-A 70 leaflet material. The significantly higher RF of v5 indicates more undesirable leakage than the v4. The v6 design was printed with polyurethane, and the valve was deemed too rigid during in vitro testing, as the leaflets barely opened during the systolic phase. Overall, the 3D printed valves have higher ΔP and lower EOA than native human aortic valves, though RF is comparable.

**Figure 4:** The CAD models of heart valves with different geometry (top row) and the 3D printed counterparts (bottom row). Designs were labeled (from left to right) as v4, v5, and v6.

**Table 1:** Results from the pulsatile flow test.

| Leaflet | Design | Gradient (mmHg) | Effective Orifice Area | Regurgitant Fraction (%) |
|---|---|---|---|---|
| Shore-A 85 | v4 | 30.6 | 0.95 | 4.26 |
| Shore-A 70 | v4 | 36.2 | 0.9 | 3.36 |
| Shore-A 70 | v5 | 34.7 | 0.87 | 21.9 |
| Shore-A 30 | v4 | 30 | 1.08 | 7.78 |
| Physiological | physiological | < 5 | 0.95 | < 15 |

## DISCUSSION

The results show that heart valves can be fabricated with variable performance using additive manufacturing. A more comprehensive study will be conducted to compare all the valve designs and 3D printed material. Although further optimization is needed to ensure comparable performance with the native heart valves, the results reveal that hemodyanmics can be manipulated easily through valve design and material selection. In addition to implantable devices, additive manufacturing can be used for disease modeling for surgical practice or the testing of other devices. Future work could involve replicating patient-specific aortic roots with complex geometry and simulating valve diseases such as the presence of calcium nodules, bicuspid aortic leaflets, and aortic insufficiency.

## INTRODUCTION

Pulmonary hypertension (PH) is the increased pressure in the vessels that carry blood from the heart to the lungs. This disease may be inherited or can be developed because of other illnesses. Patients with chronic kidney disease (CKD) and end stage renal disease (ESRD) may develop pulmonary hypertension. The presence of pulmonary hypertension in patients with CKD and ESRD is linked to increased mortality rate [1]. The prevalence of pulmonary hypertension in end stage renal disease is reported to be between 30-60% based on echocardiography measurements [2]. The pathophysiologic mechanism underlying development of pulmonary hypertension in ESRD patients is still an open question and according to WHO pulmonary hypertension classification, is categorized in group 5 (miscellaneous effects) [2]. This uncertainty comes from the fact that patients with CKD and ESRD often have other coexisting diseases that might be the cause of developing pulmonary hypertension. Cardiac dysfunction, fluid overload, endothelial dysfunction due to increased oxidative stress, increased venous return and increased cardiac output due to arteriovenous fistula placement and vascular calcification are suggested as the possible mechanisms of pulmonary hypertension development in CKD patients although not confirmed by clinical studies [3, 4].

Computational fluid dynamics (CFD) is used to assess the blood flow through the cardiac system. Images from magnetic resonance imaging (MRI) or computed tomography (CT) from patients can be used in software to produce the geometry and inlet velocity waveforms. The fluid flow and structural equations are solved to compute parameters of interest over these geometries.

There are several studies in which the fluid-structure interaction problem of blood flow in pulmonary arteries were investigated. Kong et al. studied the unsteady problem of blood flow interaction with the arterial wall in pulmonary arteries with a Newtonian fluid assumption [5]. It is shown in the CFD analysis of pulmonary arteries by Tang et al. [6] that wall shear stress is decreased over the pulmonary arterial walls in PH patients. Their approach does not include the effect of vasculature wall deformation. Zambrano et al. [7] also developed a fluid-structure interaction model of pulmonary artery hypertension. The primary goal of this study is to perform the fluid-structure interaction analysis and characterize blood flow in the pulmonary arteries of patients diagnosed with pulmonary hypertension and who are undergoing arteriovenous fistula hemodialysis.

## METHODS

The data acquisition from patients was approved by East Carolina University Internal Review Board (UMCIRB 19-000708). Due to the pandemic restrictions, the MRI data was acquired from one patient who was a 41-year-old African American male with PH diagnosed through right heart catheterization and undergoing hemodialysis with arteriovenous fistula.

The MR imaging was performed using a Siemens Aera 1.5 T scanner which uses a gradient echo (GR) imaging sequence. The subject's pulmonary artery geometry was reconstructed using 22 slices with 8 mm thickness from short axis cine scan. The echo time of 1.34 ms and the repetition time of 289.5 ms was used for image acquisition. Pixel spacing was given to be 1.61 mm. The transient velocity waveform of the cardiac cycle just past the leaflets of the pulmonary artery was obtained using phase-contrast magnetic resonance imaging (PCMRI). The blood flow rate through the pulmonary artery and vessel diameter were calculated from PCMRI images.

The 3D geometry of the vessel was then reconstructed in Mimics 20.0 (Materialise, Inc.; Plymouth, MI) using the image segmentation techniques. The thresholding segmentation method identifies the pixel

values below a specified threshold in order to separate the anatomical structure from its background. The 3D geometry of the pulmonary artery was reconstructed using the "calculate 3D" feature of Mimics. It was then further trimmed in Solidworks 2017 (Dassault Systemes; Waltham, MA) to generate the solid shell with a defined thickness. The fluid domain was created in SpaceClaim using the 'volume extract' feature.

The transient linear fluid-structure interaction model (ANSYS, Inc.; Canonsburg, PA) was used to model the coupled blood flow and vessel wall mechanics. The fluid domain was discretized using 557559 elements of size 1 mm while the solid domain consisted of 55768 elements of size 2 mm. Both the fluid and solid domain have been examined for mesh convergence. The mesh created for fluid and solid domains is depicted in Figure (1)

The blood was taken to be a non-Newtonian fluid with a variable viscosity modeled using the Carreau model and a density of 1200 kg/m$^3$. The solid domain was modeled as a linear elastic material with E= 2 MPa and Poisson's ratio ν=0.48 [5, 7]. The transient velocity waveform in Figure (2) was implemented at the inlet boundary and the outlets were taken to be zero gauge pressure outlets. In the structural model the inlet and outlets were assumed to be fixed.

**Figure 1: (a) Fluid domain meshing (b) Solid domain meshing**

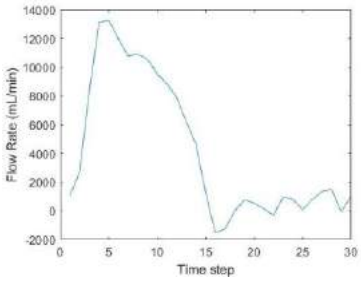

**Figure 2: Inlet fluid flow rate waveform calculated from MRI data**

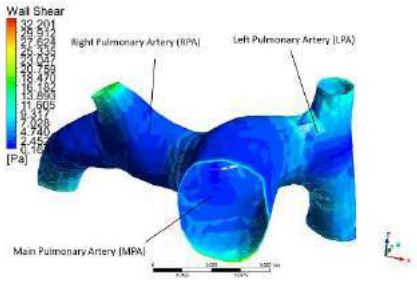
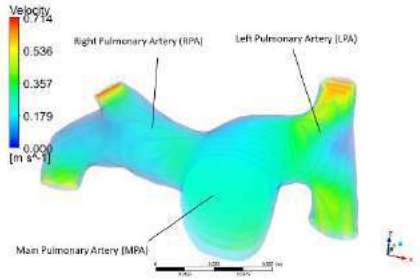
## RESULTS

The contours of wall shear stress and velocity at peak systole are shown in Figure (3). The maximum velocity is found to be 0.714 m/s and the maximum wall shear stress to be 33.3 Pa. The contour of total deformation is shown in Figure (4). The structural analysis yields the value of maximum deformation to be 0.01 mm, maximum stress to be 0.03 MPa and maximum strain to be 0.0013 at peak systole.



(a)



(b)

**Figure 3: (a) Wall shear stress (b) Flow velocity at peak systole**

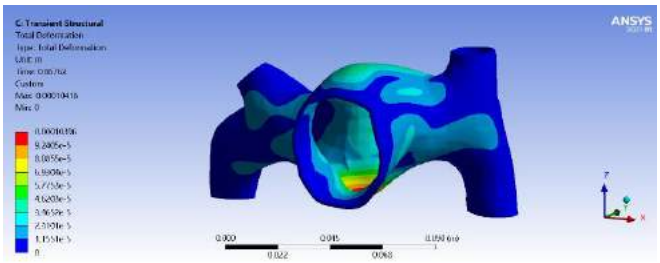


**Figure 4: Contours of total deformation at peak systole**

These values are in good agreement with the data reported in the previous studies for different PH populations.

## DISCUSSION

The coupled analysis of blood flow and vasculature wall mechanics has been conducted in the pulmonary artery of a patient with pulmonary hypertension undergoing arteriovenous fistula hemodialysis. Clinical data from more patients should be acquired to perform better analysis and reach strong conclusions. The application of other wall mechanical models will be explored and compared with the results from linear elastic model. In the future, the outcome of this research may provide clinicians with data to monitor the function of pulmonary artery and intervene to prevent the incidence of pulmonary hypertension. Early diagnosis of PH development in ESRD patients will improve the patients' quality of life, outcome of healthcare procedure, and potentially prevent the patients' removal from the kidney transplant list.

# EFFECT OF BREAKING CALCIFICATION ON THE COMPLIANCE OF CORONARY ARTERIES

## INTRODUCTION

Atherosclerosis leads to coronary artery disease (CAD) which is one of the leading causes of death in the United States. Calcified atherosclerotic plaque is common in CAD and hinders therapeutic interventions such as balloon angioplasty and stenting. Intravascular Lithotripsy has been used to break calcifications [1, 2]. Breaking the plaque and calcification to increase vessel compliance is crucial for effective therapeutic interventions.

Therefore, the objective of this study was to determine the effect that cracks in calcification and intimal tear had on the compliance of heavily calcified arteries.

## METHODS

Calcified cross-sections were created in SOLIDWORKS® based on a histology image of a calcified coronary artery segment (Fig. 1a) and the 2D cross-sections were extruded for 3 mm to create 3D models. The pre-cracking intact cross-section was created by artificially "healing" the cracks and breakage in the calcification and plaque. Both arterial wall and atherosclerotic plaque were assumed to be isotropic, incompressible, hyperelastic material with reduced polynomial strain energy density function:

$$W = C_{10}(\bar{I}_1 - 3) + C_{20}(\bar{I}_1 - 3)^2 + C_{30}(\bar{I}_1 - 3)^3 + C_{40}(\bar{I}_1 - 3)^4 + C_{50}(\bar{I}_1 - 3)^5 + C_{60}(\bar{I}_1 - 3)^6 \quad (1)$$

Where $I_1$ is the first invariant of deformation tensor and $C_{10}$ to $C_{60}$ are the material constants are given in Table 1. Density of the arterial wall and stiff plaque (calcification) were assumed to be the same and equal to 1120 kg/m³ [3].

Pressurized inflations of the calcified arteries were simulated using commercial FEA package ABAQUS®. Arterial wall and atherosclerotic plaque were meshed using eight-node linear brick reduced integration (C3D8R) elements. A uniform pressure up to 15 kPa was gradually applied to the lumen mimicking balloon expansion. Both ends of the artery were free to expand radially but fixed in other directions to prevent free movement as a rigid body. Additionally, tie constraint was defined to eliminate the relative motion between arterial wall and atherosclerotic plaque.

In addition to the pre- and post-cracking models, more models with different number of cracks in calcifications and intimal tears were simulated to determine how they would affect arterial compliance.

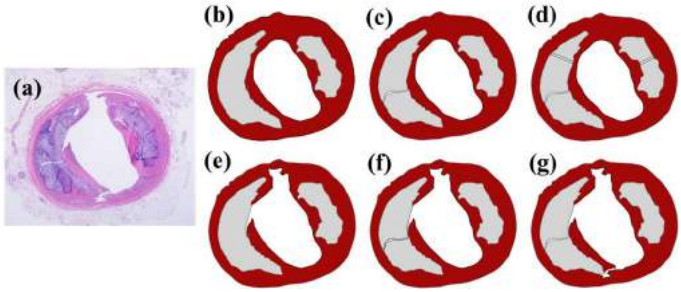

**Figure 1: Cross-sectional image of a coronary artery post cracking and 6 corresponding models. (a) Histology image, (b) intact model, (c) intact tissue+ 1 Ca crack, (d) intact tissue + 3 Ca Crack. (e) 2 intimal tears+ intact Ca. (f) 2 intimal tears+ 1 Ca crack. (g) 3 intimal tears + 1 Ca crack.**

**Table 1: Material coefficients for arterial wall and calcified plaque [3]. Units of all constants are in kPa.**

| | C10 | C20 | C30 | C40 | C50 | C60 |
|---|---|---|---|---|---|---|
| Arterial Wall | 6.52 | 4.90 | 9.26 | 760 | -430 | 87.0 |
| Calcification | 12.1 | 1540 | 2190 | 2.14E5 | -3.35E6 | 1.34E8 |

## RESULTS

A total of 6 different models with intact and cracked calcification and intimal tears were analyzed (Figure 1). The changes in the lumen area of the middle cross section of the calcified coronary artery were calculated and plotted as functions of lumen pressure to illustrate vessel compliance (Figure 2).

Our results showed that the compliance of the artery with either crack in calcification or intimal tear is higher than the intact artery. However, cracked calcification with intact tissue has an insignificant effect on vessel compliance, even when multiple cracks were added to the calcification. In contrast, intimal tears significantly increased the compliance of the artery (Figure 2).

## DISCUSSION

The effect of calcification and tissue lasing on the compliance of the coronary artery were investigated. Our results showed that cracking calcification, while keeping tissue intact, has little effect on improving the compliance of the artery. Cracking the surrounding plaque tissue increased the compliance significantly. Combining intimal tears and cracks in calcification would further increase the compliance of the artery.

There are a few limitations in this study. First, variation of the calcification and arterial wall along the length of the artery were not considered. Second, the arterial wall was assumed to be homogenous and isotropic though the arterial is anisotropic [4,5].

While limitations exist, these results shed light on how lithotripsy of calcification and plaque affects the compliance of the artery and provides guidance for targeted treatment.

## INTRODUCTION

Lung cancer is the primary cause of cancer related death worldwide. Even when detected early, the 5-year survival is poor (1). To improve patient outcomes, a better understanding of the factors that drive early lung tumor progression is needed.

Lung cancer progression is driven by both biochemical and mechanical signals. Cancer initiates from mutations in lung epithelial cells that line the alveoli to cause aberrant proliferation and survival. As the transformed cells grow into tumors that fill the alveoli, additional mutations and alterations in the tumor microenvironment contribute to the tumor's progression to invasive cancer. Signals from local fibroblasts and the deposition of new extracellular matrix correlates with and promotes progression toward invasive and metastatic cancer (2). The fibrotic remodeling associated with late stage lung cancer is similar to that observed in other solid tumors, in which increased tumor stiffness promotes metastasis (3).

In addition to the alterations associated with tumorigenic remodeling, lung cancer is also subjected to the mechanics of cyclic expansion during respiration. During normal respiration alveoli expand 5-20% (4), with a change in surface area at total lung capacity of ~50% (5). *In vitro*, lung epithelial cells subjected to strain exhibit increased proliferation, differentiation, and growth factor production (6). Lung fibroblasts also exhibit strain-sensitive proliferation, myofibroblast differentiation, and matrix production (7). While mechanotransduction associated with abnormal forces has been recognized in many cancers, strain is a previously unappreciated mechanical signal in early lung cancer lesions.

We aimed to map the strain in the early lung tumor environment and probe its contribution to tumor progression. Understanding the role of mechanical signaling in lung cancer is challenged by the lack of good experimental models that capture early tumorigenesis. The direct measurement of strain in lung tissue during respiration and tumor heterogeneity pose additional challenges. To address this, we adapted previous models of the lung that incorporated the stress-strain behavior (8) and architecture (9) to develop a model that predicts the strain in the local tissue when a tumor modifies the architecture.

## METHODS

We created an idealized geometric finite element model of the lung. A mesh was prepared in MATLAB as a hexagonal lattice of 100 units horizontally and vertically that mimics the alveolar architecture in the lung (Fig. 1A). Each measured ~100 μm in diameter, which represents the approximate size of alveoli in the human lung, twice the size of mouse lung (Fig. 1B, C). To account for variability in lung architecture, a randomization algorithm was applied to the initial geometry, followed by simulated annealing through energy minimization (9). The randomized lattice was imported into FEBio and modeled with z-height of 30 μm. Shell elements were used to represent alveolar walls, 10 μm in width. A neo-Hookean constitutive model was used for the lung matrix and the modulus was set by parameter optimization using FEBio to match the behavior of a constitutive model previously reported to for bulk lung tissue (8). The resulting optimized modulus for the alveolar walls was 35 kPa with a Poisson's ratio set to 0.25. A simulated rigid body indentation experiment using a 30 μm thick volume assigned the bulk lung constitutive model confirmed that the modulus is consistent with atomic force microscopy (AFM) measurements the of lung tissue, ~1.8 kPa (10).

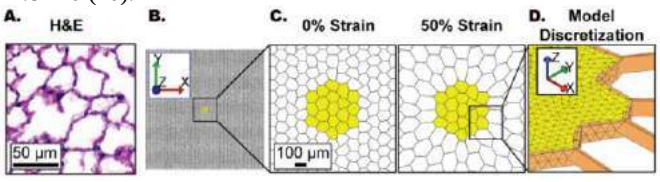

**Figure 1: A) Normal mouse lung tissue, inflated before fixation, and stained with hematoxylin and eosin (H&E). B) A zoomed-out**

**view of the human lung model. C) Inset to visualize tumor and adjacent matrix under 0% and 50% globally applied strain. D) Discretization of the lung model. The lung matrix is represented by shell elements. The tumor is discretized using tetrahedral elements with a surrounding material layer of triangular elements.**

A tumor was incorporated as 20 filled alveolar units in the center of the lattice and discretized as solid 4-noded tetrahedral elements (Fig. 1C, D). The tumor was represented as neo-Hookean with a Poisson's ratio of 0.49 (3) and the tumor modulus was varied parametrically. Early tumor was modeled with modulus of 1 kPA, matching the normal lung. Late tumor with fibrotic stiffening was represented with a modulus of 35 kPA, and this base value was varied between 0.2 kPa and 350 kPa to represent the range for tumor or fibrotic tissue (3, 11). Using FEBio, the final discretized mesh was subjected to 50% biaxial prescribed elongation to mimic respiration with plane strain boundary conditions (Fig. 1C and D). We considered the amplification at 5%, 20% and 50% to represent the baseline lung, the strain associated with normal respiration, and the strain expected at total lung capacity.

## RESULTS

In order to understand strain in the early lung tumor environment, we calculated the strain expected during lung expansion in normal lung and around a lung tumor. In the normal lung, at 20% globally applied strain we observed a relatively homogenous strain distribution in the alveolar walls (Fig. 2A, Normal lung). To assess how the lung model amplifies strain, we calculated the strain ratio [1st principal strain/globally applied strain] (Fig. 2B, normal lung). We found strain amplification increased with applied strain. Around the tumor, strain was largest directly adjacent to the tumor and increased with increasing stiffness (Fig. 2A). Strain was amplified adjacent to the tumor in both early (1 kPa) and fibrotic (35 kPa) tumor conditions; however, the amount of strain amplification was dependent on both distance from the tumor and tumor stiffness, with the highest amplification associated with the stiffer tumor and greater applied strain (Fig. 2B).

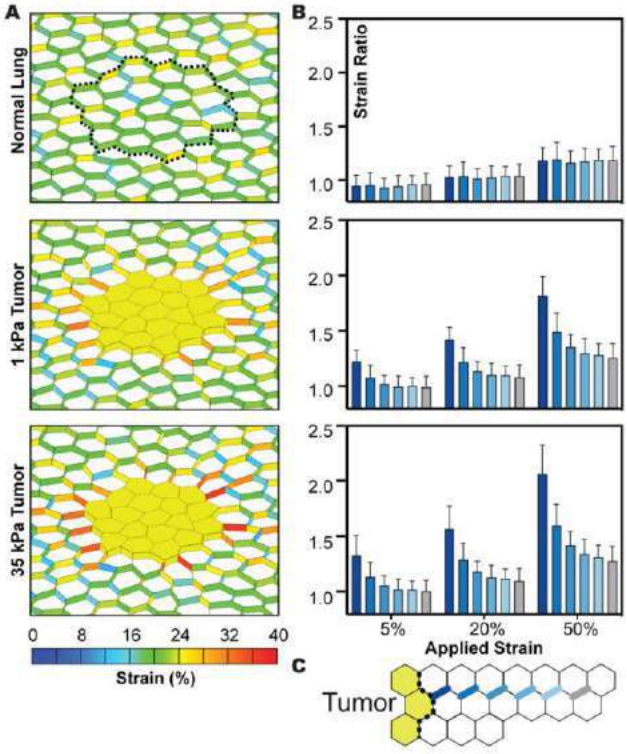

**Figure 2: A) 1st principal strain in alveoli walls surrounding the tumor at 20% applied strain for normal lung and tumors with 1 and 35 kPa modulus. B) The strain amplification ratio at 5%, 20%, and 50% applied strain, showing amplification in matrix shell elements in normal and tumor lung model as a function of distance from the tumor boundary. The schematic, (C) indicates the distance from the tumor where line color corresponds to the shell layer indicated. Strain ratio = globally applied strain / 1st principal shell strain. Error bars are SD of all elements at the indicated distance.**

## DISCUSSION

Our results demonstrated that the strain experienced by alveolar walls near the tumor is larger than that experienced in healthy lung tissue. The model predicts that tumor stiffening associated with tumor progression will lead to additional strain amplification that would exacerbate the altered mechanical environment.

Our modeling approach represents the first geometric tissue scale model of a tumor in a lung matrix. This model design allowed us to test the magnitude of change and spatial distribution of strain in lung tissue. We selected geometries that reflected our observations from mouse models of lung cancer and human histopathology. By applying an established constitutive model of normal lung tissue to our geometric model, we mapped the amplification of strain associated with the presence of a small early tumor and stiffened late tumor.

The poor prognosis of lung adenocarcinoma, even when caught small and seemingly localized, suggests that early tumor cells invade away from the tumor and metastasize. Our finding of strain amplification at even the earliest stage of lung cancer suggests that mechanical signaling may contribute to early tumorigenesis and invasion. Strain amplification directly adjacent to the tumor would be sensed by tumor cells at the invasive front. Thus, the epithelial cell proliferation and growth factor production response to strain observed in vitro may occur in vivo at the tumor edge. Additionally, fibroblasts at the tumor edge may respond to changes in strain and stiffness with increased matrix production to further promote progression.

This model underscores the importance of future research to interrogate how strain influences mechanotransduction in lung cancer. Future adaptations of the model can be used to test the role of other mechanical changes in the tumor microenvironment, such as matrix remodeling and tumor growth, contribute to changes in stiffness, tumor progression, and invasion.

# COMPUTATIONAL ANALYSIS OF PAPILLARY MUSCLE APPROXIMATION FOR FUNCTIONAL MITRAL REGURGITATION REPAIR

**Gediminas Gaidulis (1,2), Daisuke Onohara (1,2), Muralidhar Padala (1,2)**

(1) Structural Heart Research and Innovation Laboratory, Carlyle Fraser Heart Center at Emory University Hospital Midtown, Atlanta, GA, USA

## INTRODUCTION

Functional mitral regurgitation (FMR) is a heart valve lesion that perturbs mitral valve (MV) geometry resulting in inadequate closure and backward leakage of the valve. It is a common complication of myocardial infarction, which develops in approximately 50% of patients [**1**]. In such condition, the MV leaks because of distortion of its geometry by the dysfunctional and dilated left ventricle which tethers the valve. The constant pulmonary venous return, when combined with the mitral regurgitant volume, increases total blood volume that fills the left ventricle and thus causes a volume overloaded state. Wall stresses are elevated, and ventricular dysfunction ensues, altogether accelerating heart failure hospitalizations and doubling mortality [**2**].

It is now well established through randomized controlled trials that correcting FMR can reduce both heart failure hospitalizations and mortality, and significantly improve the functional capacity in these patients [**3**]. Papillary muscle approximation (PMA) is a novel surgical technique that aims to restore the configuration of subvalvular apparatus by drawing papillary muscles (PMs) together and subsequently relieving tethering forces and improving mobility of the MV leaflets [**4**] (**Figure 1**). Our recent bench work on FMR repair demonstrated that PMA not only relieves tethering forces in the chordae, but it also preserves the twisting motion of the left ventricle, thus improving the ventricular mechanics [**5**].

Patient-specific computational simulations of the MV behavior before and after surgical repair can be extremely useful in procedure planning. Such approach is particularly valuable while investigating the impact of novel treatment strategies since computational simulations can help surgeons to assess interventional outcomes. However, up to date, only a single simplified 2D computational study was performed to investigate PMA and its impact on the MV function [**6**]. Therefore, in this study, we present patient-specific PMA simulations performed using realistic 3D computational MV models that allow to assess the outcomes of PMA and therefore can aid in surgical planning.

## METHODS

Two patient-specific computational models of the MV affected by FMR were created from 3D epicardial echocardiography data obtained in two pigs that received a myocardial infarction via percutaneous occlusion of the left circumflex artery, and as a result developed FMR. The modeling workflow used in this study was based on the approach developed and validated previously in our lab, which allows to create a realistic computational model of the MV with subvalvular apparatus.

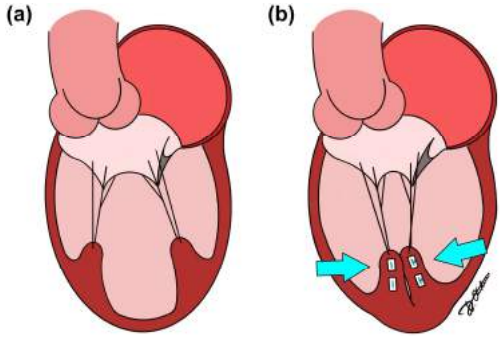

**Figure 1: Schematic of MV before (a) and after (b) PMA.**

For each case, a geometry of the MV annulus, leaflets, and PMs in diastole was reconstructed from echo images. Each MV model was completed by adding a branched network of chordae, connecting the MV leaflets to the PMs. To create FMR state of the MV, the PMs were displaced further from the annular plane, thus stretching the chordae and imposing a pre-strain on both chordae and MV leaflets (**Figure 2a**). By adjusting this pre-strain, we were able to simulate the restricted motion of the leaflets and obtain a realistic systolic configuration of the valve for both MV models used in this study.

To simulate the MV closure before the repair, physiologic transvalvular pressure gradient was applied to the leaflets, and patient-specific annular contraction and movement of the PMs were prescribed as kinematic boundary conditions. For each model, explicit dynamic simulation was performed and pre-repair peak systolic configuration of the MV was obtained. PMA repair was achieved by bringing the PMs together laterally and fixing them in diastole (**Figure 2b**). The simulations were repeated and for each model post-repair peak systolic configuration of the MV was obtained. In addition, the following parameters were calculated: stress distribution on the leaflets, tension forces in the chordae, reaction forces on the PMs, and coaptation area of the leaflets. Moreover, to investigate the mobility of the leaflets, tenting height, tenting area, and tenting angles for both MV leaflets were computed. Post-repair systolic results were compared with pre-repair values.

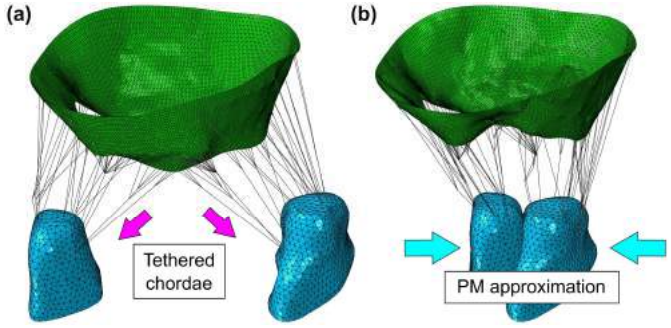

**Figure 2: MV model with FMR (a) and after PMA (b) in diastole.**

## RESULTS

Simulation results for both investigated cases are presented in **Table 1**, while stress distribution across the MV leaflets in peak systole for each model is shown in **Figure 3**. In both pre-repair models, regurgitant gaps at A1-P1 and A3-P3 segments of the leaflets were noticed, while high stress distribution areas were observed near the insertion sites of the strut chordae. After PMA, the elimination of regurgitant gaps was seen, and high stresses were abolished in both post-repair models. Similarly, the overall chordal tension forces were greatly reduced, as shown by the decrease of reaction forces acting on the PMs. In addition, a reduction of tenting height, tenting area, and tenting angles was observed after PMA, whereas leaflet coaptation area increased significantly.

**Table 1: Simulation results in peak systole.**

| | Case 1 | | Case 2 | |
|---|---|---|---|---|
| | **FMR** | **PMA** | **FMR** | **PMA** |
| Max stress AL (MPa) | 0.79 | 0.85 | 5.32 | 1.04 |
| Max stress PL (MPa) | 2.04 | 0.64 | 1.56 | 1.32 |
| Max strut force (N) | 2.82 | 1.96 | 6.62 | 1.80 |
| Max marginal force (N) | 0.60 | 0.89 | 1.25 | 1.09 |
| Max basal force (N) | 0.72 | 0.42 | 0.37 | 0.74 |
| APM force (N) | 11.26 | 8.38 | 13.26 | 8.71 |
| PPM force (N) | 10.77 | 7.39 | 14.95 | 8.75 |
| Coaptation area ($mm^2$) | 105.0 | 189.1 | 133.0 | 191.9 |
| Tenting height (mm) | 10.4 | 5.0 | 11.4 | 6.8 |
| Tenting area ($mm^2$) | 166.1 | 79.7 | 166.3 | 98.4 |
| Tenting angle AL (deg) | 24.8 | 12.3 | 29.9 | 21.0 |
| Tenting angle PL (deg) | 48.4 | 29.6 | 51.1 | 30.5 |

**AL**, anterior leaflet; **PL**, posterior leaflet; **APM**, anteroposterior PM; **PPM**, posteromedial PM.

## DISCUSSION

In this study, we presented an application of computational modeling approach, used to create a realistic patient-specific MV model and simulate the outcomes of PMA. The bench work recently done in our lab demonstrated that in the presence of FMR there is an increase in MV tethering forces and leaflet tenting parameters [**5**]. The simulation results of FMR affected MV function showed similar trend: high leaflet stresses and chordal tension forces, as well as increased tenting height, tenting area, and tenting angles for both leaflets were observed. After PMA, these elevated values were greatly reduced, relieving leaflet and chordal tethering, and enabling better leaflet mobility and coaptation.

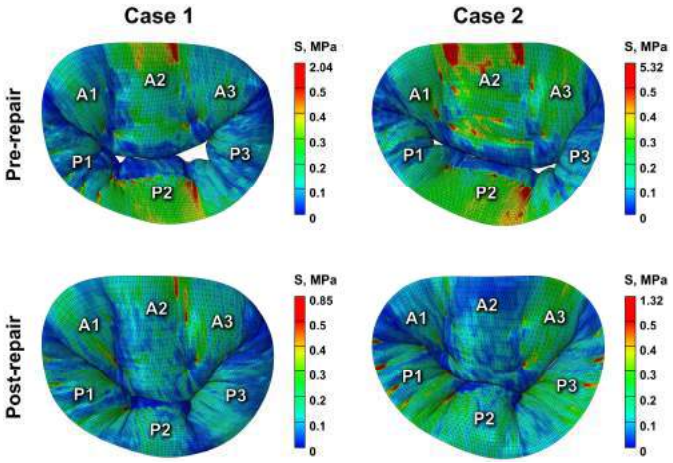

**Figure 3: Stress distribution on MV leaflets in systole.**

In post-repair models, both leaflet stresses and chordal tension forces decreased. While a slight increase of maximum stress value was observed on the anterior leaflet in case 1, high stress areas on the posterior leaflet were abolished, and more even stress distribution across the whole surface of the leaflets was achieved, thus showing the overall relief of leaflet tethering. Similarly, a slight force increase was noticed in marginal (case 1) and basal (case 2) chordae. Still, the overall chordal tension forces were greatly reduced, as shown by the reduction of reaction forces acting on the PMs. Thus, a more even force distribution across the whole chordal network was achieved.

In addition, increased leaflet mobility after PMA was observed. The values of tenting parameters (tenting height, area, and angles) in pre-repair models were elevated, if compared to the data on healthy valves recently measured in our lab [**7**]. In general, the increased tenting parameters show reduced leaflet mobility, which leads to insufficient leaflet coaptation. After PMA, all tenting parameters were greatly reduced, thus leaflet mobility and coaptation were increased.

To sum up, patient-specific PMA simulations performed using realistic 3D computational MV models showed that PMA was effective in not only improving coaptation but also in reducing leaflet stresses and chordal tension forces. Our computational results indicate that PMA could be an effective technique to repair FMR.

# REPLACEMENT HEART VALVE SIMULATIONS USING A NEURAL NETWORK FINITE ELEMENT SURROGATE MODEL

**Shruti Motiwale (1,2), Christian L. Goodbrake (1), Wenbo Zhang (1), Michael S. Sacks (1,2)**

(1) James T. Willerson Center for Cardiovascular Modeling and Simulation, Oden Institute and the Department of Biomedical Engineering, University of Texas at Austin, Austin, Texas, USA

## INTRODUCTION

Our understanding of heart valve structure and function, though still limited, has advanced significantly over the past decade. With the advances in computation power we are now able to perform robust heart valve simulations, addressing such problems as longterm cyclic loading to estimate replacement heart valve structural degradation over time. Such simulations can account for detailed features such as fiber distributions, through thickness variations, coupling between material phases etc. However, even with the latest computational resources, the computation times are still too slow for extensive parametric studies, let alone being conducted in a clinically relevant time frame for patient specific applications. We thus need to develop computational methods that can run thousands of simulations within a very short time.

Neural networks (NN), in their capacity as universal function approximators, can serve as a useful tool as 'surrogate' models for finite element simulations. NN have been trained to represent parametric PDEs using either a data-driven approach or a physics-informed approach [1-3]. Our group has developed a hybrid approach that couples a neural network to a differentiable finite element domain map to create a neural network finite element (NNFE) surrogate model [4].

In this work, we have developed a NNFE surrogate model of a tri-leaflet heart simulation model under valve quasi-static loading. The neural network is directly trained using a potential function corresponding to the parametric PDE, and thus does not require any 'training dataset' in the form of experimental data or other simulation results. Although neural networks can be computationally expensive to train, a trained model takes a few seconds at most to provide simulations results. Thus, our approach effectively shifts the computational expense offline, allowing for rapid simulations in clinical settings. Such a model paves the pathway for bridging the gap between computational research and real clinical applications in this field.

## METHODS

The NNFE surrogate model can be specified as

$$\mathcal{N}(\mathbf{u}(\mathbf{x}); \mathbf{m}) = 0 \qquad (1)$$

where, $\mathcal{N}$ represents a differentiable surrogate model, $\mathbf{u}(\mathbf{x})$ represents the displacement function, and $\mathbf{m}$ represents the boundary condition. The NN takes parametrized boundary conditions as inputs and provides control points and weights of the displacement function as output

$$\hat{\boldsymbol{u}} = f_{NN}(\mathbf{m}) \qquad (2)$$

where, $f_{NN}$ represents the neural network, and $\hat{\boldsymbol{u}}$ are the control points and weights of the NURBS displacement function. The Dirichlet boundary conditions are strongly imposed by replacing the corresponding control points and weights. The updated control points and weights $\hat{\boldsymbol{u}}$ along with the NURBS basis functions are used to obtain the solution $\mathbf{u}(\mathbf{x})$. Once $\mathbf{u}(\mathbf{x})$ is obtained, its gradient is computed using automatic differentiation, which is then used to calculate the potential function used for minimization in the neural network training algorithm (Fig 1). The neural network is developed to be a fully differentiable model and is coded using JAX python library [5].

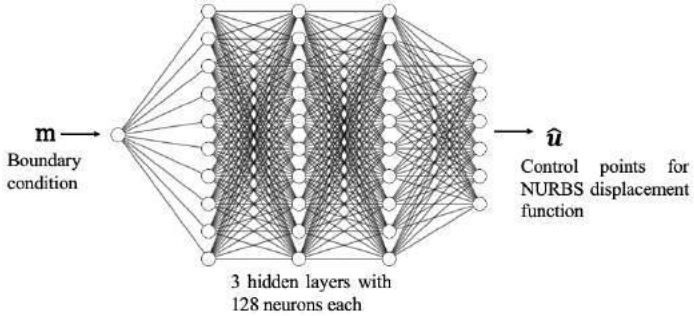

**Figure 1: Neural network surrogate model mapping boundary condition to displacement control points and weights**

The network parameters were trained using the gradient descent algorithm with momentum [6]. Assuming a pressure boundary condition, the cost function for training is given by the total potential

$$\Pi(\mathbf{u}) = \Pi_{int} - \Pi_{ext} = \int_{\Omega_0} \Psi \, d\Omega - p \int_{\Delta\Omega} dV \qquad (3)$$

where, $\Pi_{int}$ and $\Pi_{ext}$ are the internal energy and work done by external forces respectively, $\Psi$ is the strain energy of the domain and describes its material behavior, p is the pressure acting on the surface, and $\Delta\Omega$ represents the displaced volume. As an initial study, we trained a NNFE surrogate model to simulate a pressurized membrane with fixed edges. We modeled the membrane geometry as a flat square sheet (1 cm x 1 cm x 1 mm) with solid elements and linear basis functions. The strain energy was modeled using a neo-Hookean material model. We trained the model for a fixed geometry under a range of pressures from p=0 to p=50 MPa.

As the next step, we trained a NNFE surrogate model to simulate a tri-leaflet heart-valve geometry for varying pressures. We used a full structural model that accounts for fiber architecture to represent the internal potential energy. The strain energy for the heart valve leaflet is given by

$$\Psi = \phi_{\mathrm{m}}\Psi_m + (1 - \phi_{\mathrm{m}})[\Psi_c + \Psi_{int}] - p(J - 1) \qquad (4)$$

where $\Psi_m, \Psi_c, \Psi_{int}$ are the strain energies of the matrix, collagen fibers and their interactions respectively and $\phi_{\mathrm{m}}$ is the volume fraction of the matrix. The material model is described in further detail in our previous publication [7]. The heart valve geometry is represented as shell elements using 2nd order NURBS basis functions (Fig. 4a inset). We developed a custom method to simulate contact between the leaflets using related energy potential function.

## RESULTS

We evaluated the trained NNFE surrogate model for the pressurized membrane at different pressure values and compared the results against results from FE simulations done in FEniCS (Fig 2).

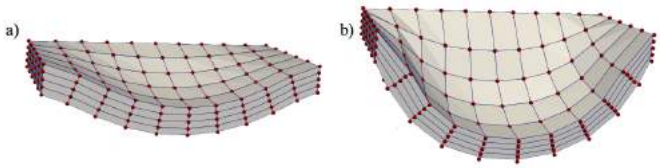

**Figure 2: Cut-section view of a pressurized membrane with fixed edges. Solid elements represent the NNFE surrogate model results and red dots represent FEniCS results. a) p=10 MPa b) p=50 MPa. The maximum displacement error among all nodes was < 1%.**

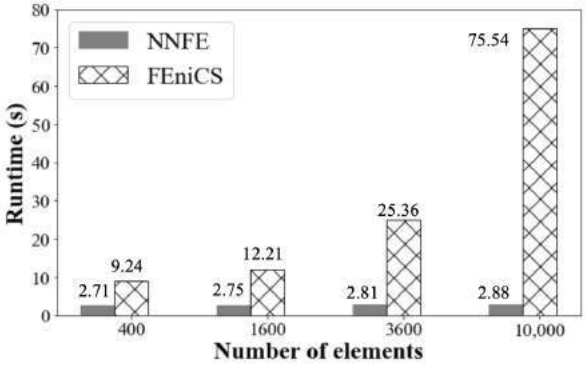

**Figure 3: Simulation time comparison between FEniCS and NNFE surrogate model for pressurized membrane.**

The pressurized membrane NNFE surrogate model took 25 min for training. However, once trained, the surrogate model took only 2-3 secs to simulate a problem irrespective of the number of elements, whereas FEniCS took 26x longer to run a simulation consisting of 10,000 elements (Fig 3). We also evaluated the results of the tri-leaflet heart valve NNFE surrogate model against the results published previously [8] and found that it gives visually indistinguishable results (Fig 4). Even with the greater model size in this problem, the NNFE computational times did not increase, whereas the FE solutions increased to ~20 minutes on the same computer.

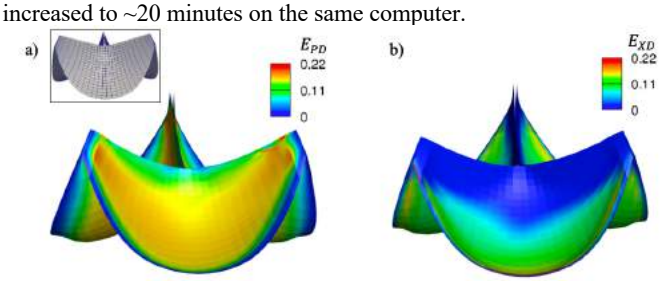

**Figure 4: Strain in the a) preferred and b) cross-preferred fiber direction obtained from replacement heart valve simulations for a fiber splay of $\sigma = 30°$ with the NNFE surrogate model.**

## DISCUSSION

We have demonstrated that we can develop neural network finite element surrogate models that can simulate heart valves within a few seconds with no loss of accuracy or related limitations due the use of aggressive approximation methods. Furthermore, these models are trained on the potential function describing the physical laws of the problem, and not on any experimental or simulated data. The material model used for training takes detailed fiber architecture information into account. Thus, these models are extremely high-fidelity and obey the physical principles within the training range.

The use of NURBS for both the geometric descriptions and NNFE basis functions provide two key advantages. First, they allow for exact representation of heart valve geometry without any discretization errors. This is also a crucial advantage for solving contact problems. Secondly, they allow for quick modifications to the geometry that is important for parametric studies. While we have used shell elements in the model presented here, we are currently developing the solid element model. The use of solid elements can allow us to capture through thickness variation of material properties that evidently exists in heart valves. In this work, we have considered a fixed fiber distribution. However, we are extending our approach to include fiber distribution data as an additional input to the neural network. In the future, we would also like to include geometry information as inputs to the neural network. With regards to the material model, we have only considered elastic effects in the model at this stage. However, our goal is to extend the model to also include plasticity effects [9] and simulate time-evolving behavior of the native and replacement heart valve under long-term conditions.

## INTRODUCTION

Articular cartilage is a specialized tissue lining diarthrodial joints in the body, where it serves to reduce friction while sustaining contact forces for over 108 million cycles of loading in a 60-year lifespan. As with any mechanical system, cartilage must experience some normal 'wear and tear' over normal activities of daily living. This routine damage initiates in the superficial zone (SZ) of cartilage tissue [1,2], where its resident chondrocytes have been shown to die even under normal physiologic loading conditions [3, 4, 5]. This counter-intuitive observation suggests that there must exist a cell replenishment mechanism in diarthrodial joints, most likely from the synovium lining [6]. The objective of the current study is to better understand mechanical factors that may lead to SZ chondrocyte death, as part of a broader effort of understanding the mode of repair of normal 'wear and tear'.

The SZ is known to exhibit lower compressive and shear moduli compared to the middle and deep zones (MZ, DZ) of the articular layer [7], likely resulting in excessive SZ compaction under physiological loading. Such compaction may wring out the interstitial fluid of SZ chondrocytes, significantly altering their fluid transport properties and possibly causing their death. Chahine et al. [8] showed that SZ chondrocytes died after sustained 12-hour compaction of live cartilage explants by 50-80% strain. Using suitable control experiments they reported that SZ chondrocyte were more vulnerable to loading than their MZ and DZ counterparts.

Albro et al. [9] showed that chondrocytes can survive a volume loss of 50%, induced by hyperosmotic loading, for a short period of time (up to 1 h). However, lasting changes in cell volume can affect the ability of the cell to regulate its volume via ion channel transport, significantly affecting its homeostasis and viability [10]. Tissue compaction, especially of the pericellular matrix (PCM), and reduced cytoplasm permeability as fluid volume is lost, may also decrease diffusivity of glucose, insulin, other nutrients, and waste products between the cell and the synovial fluid, harming cell metabolism and potentially resulting in cell death.

In this study we performed a multiscale finite element analysis of articular contact to understand the fate of a SZ chondrocyte, by tracking the temporal evolution of its interstitial fluid pressure, hydraulic permeability, and volume change under physiologic loading conditions.

## METHODS

A multiscale finite element model was constructed in the open-source FE software FEBio (www.febio.org). A model by Zimmerman et al. [11] of biphasic frictional sliding contact between a cartilage plug and strip, accounting for symmetry, was modified by replacing one element in the cartilage strip SZ with a finite element domain containing an embedded 15×15×5 μm [12] ellipsoidal chondrocyte (Fig. 1). The finite element mesh of the strip, plug, and PCM + cytoplasm respectively included 7743, 3780, and 9728 8-node hexahedral elements; the cell membrane consisted of 384 4-node porous shell elements [13] (Fig. 1).

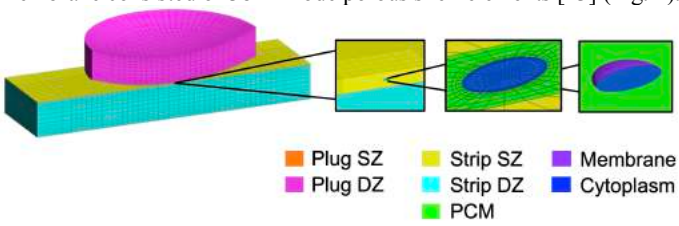

**Figure 1. Multiscale model of a cartilage plug in contact with a cartilage strip, containing a chondrocyte in the strip SZ.**

The properties of the cartilage matrix were described previously [11]. The cell cytoplasm was modeled as a biphasic material with a solid volume fraction of 0.4 [9], porous neo-Hookean solid matrix with E=0.78 kPa [13], and a Holmes-Mow strain dependent hydraulic permeability ($k=0.002$ mm$^4$/N·s [13], $M=2.2$, $\alpha=2$), to account for decreasing permeability as the cytoplasm gets compacted. The cell membrane was assigned a thickness of 10 nm. Its elasticity was

modeled with a Mooney-Rivlin solid with a shear modulus of 0.5 kPa and bulk modulus of 2.5 MPa. Its hydraulic permeability was set to $7\times10^{-10}$ mm$^4$/N·s [13]. The PCM kept the same properties as the SZ.

The model was subject to the following two loading conditions: Migrating Contact: Reciprocal displacement of the cartilage plug with an amplitude of 10 mm at 6 mm/min was prescribed for 15 minutes under a constant prescribed compressive load of 3.15 N and an equilibrium friction coefficient $\mu_{eq}$=0.201 [11]. This model ran for 12 hours (wall clock) on a high-performance cluster. Static Contact: A static compressive load of 3.15 N was prescribed on the plug for 3 hours. This model ran for 7 h (wall clock).

## RESULTS

The cell volume relative to its reference state (t=0) was recorded as a function of time (Fig. 2a). In both loading configurations, the cell volume decreased steadily throughout loading, following the same trend. In the stationary contact model, after 30 minutes of loading, a cell volume loss greater than 20% and a PCM volume loss of ~10% were observed (Fig. 2b, center). After 3 hours of stationary contact loading, the cell volume had reduced to 50% of its initial value, indicating that almost all the cytoplasmic fluid had left the cell. The PCM volume decreased by 20%, but notably remained higher in regions directly adjacent to the cell membrane (Fig. 2b, right).

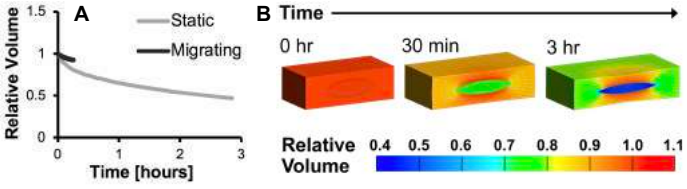

**Figure 2. (a) Relative volume of the cytoplasm versus time (b) Visualization of cell and PCM compaction in the stationary contact model, at time 0, after 30 minutes, and after 3 hours of loading**

The fluid pressure in the cytoplasm decreased as fluid flowed out of the cell and the tissue. (Fig. 3a). The cytoplasm progressively became compacted, decreasing its hydraulic permeability (Fig. 3b). In the stationary contact model, permeability decreased by four orders of magnitude over the loading duration due to compaction.

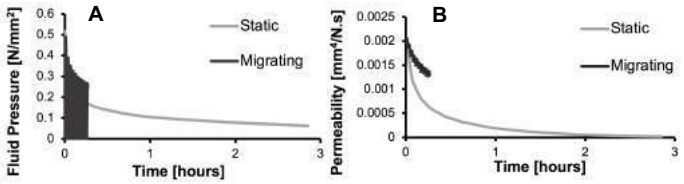

**Figure 3. (a) Fluid pressure in the cytoplasm versus time (b) Minimum principal permeability in the cytoplasm versus time**

As interstitial fluid flowed out of the tissue, its pressure decreased and the stresses were transferred to the solid matrix, exhibiting significant creep deformation (Fig. 4).

## DISCUSSION

This study showed that loading articular cartilage under physiological conditions and durations resulted in significant changes in the volume of SZ chondrocytes (Fig. 2), producing cell compaction and considerable reduction in the fluid transport properties (Fig. 3b). The drastic decrease in permeability of the cell cytoplasm and the creep deformation of the soft SZ also support the hypothesis that compressive loading may reduce the diffusivity of nutrients from the synovial fluid to the cell. Durney et al. [2] demonstrated that culturing explants with physiologic levels of the metabolic mediators found in synovial fluid, including glucose, cortisol, insulin, and ascorbic acid, is critical in maintaining tissue homeostasis. Further, Cigan et al. [14] showed that insulin and ascorbic acid are essential for chondrocyte viability in engineered construct culture, and that glucose has a dose-dependent effect on cell metabolism and proliferation. Together these results support our premise that access to nutrients at the proper dosage is critical to maintaining cell function. Reduced transport of these nutrients during loading may cause SZ cell death. DZ and MZ chondrocytes may be less sensitive to changes in nutrient transport, as they are accustomed to low nutrient access and may be more phenotypically mature. Thus, the results of this study provide a cogent hypothesis for the normal occurrence of SZ chondrocyte death reported in prior *in vitro* and *in vivo* studies [3,4,5].

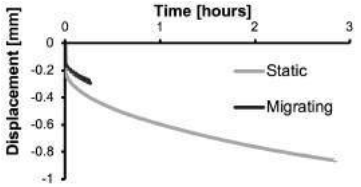

**Figure 4. Creep deformation of the cartilage tissue versus time**

It should be noted that intrinsic differences in cell properties, metabolism, or other mechanobiological signaling pathways in response to loading are other possible causes for the vulnerability of SZ cells to normal loading. Understanding these mechanisms may elucidate how OA initiates and progresses, possibly providing therapeutic targets.

Several factors influence the compaction time of SZ chondrocytes due to loss of interstitial fluid. In addition to the tissue material and transport properties, the most significant factor is the path length for the pressurized fluid to escape the loaded regions of the articular layer. In a contact configuration this means that the size (radius) of the contact area influences the compaction time, with larger contact areas requiring longer times. In this study the contact radius increased from 2.7 mm to 5.0 mm over 3 hours of loading. In the experimental study of Guilak et al. [12], loaded cartilage explants with a radius of 1.5 mm required only 20 minutes to produce steady-state values for their chondrocyte volume. These outcomes are self-consistent in the context of porous media mechanics and interstitial fluid transport.

A potential limitation of this computational analysis was the inability to compute the response to migrating contact for more than 15 minutes of loading. Though migrating contact is more representative of physiological loading, the computational challenge of solving this configuration was apparent from the disparity in the wall clock solution times between the two models. However, since both contact configurations led to consistent changes in cell volume (Fig. 2), fluid pressure and permeability (Fig. 3) and creep deformation (Fig. 4), it is reasonable to assume that the conditions achieved under stationary contact loading would be reproduced under migrating contact at later times, while remaining consistent with loading durations for activities of daily living (~ 8 hours).

## INTRODUCTION

Residing within the heart valve leaflets, the valvular interstitial cells (VICs) are at the center of maintaining valve competency. The primary role of VICs revolves around the production and remodeling of the extracellular matrix (ECM). The two primary constituents of the ECM, i.e., collagen and elastin fibers, function in synergy to provide the mechanical integrity necessary for the valve to handle physiological loads. The expression and remodeling of the ECM is mediated through the mechano-transduction of the VICs. The ability to sense their environment and any deviation allows VICs to alter their protein expression [1]. Repeated high cyclic strain, for example, is known to increase collagen production in aortic valves [2].

Certain genetic mutations pose a risk to a structurally sound ECM, nevertheless. Marfan syndrome (MFS), for example, is characterized by having fragmented elastin fibers in the ECM heart valves among other tissues. Because collagen and elastin fiber configuration depend on one another, MFS has the potential to result in a cellular morphology that differs from native ECM when the ECM micro-architecture is compromised.

aim was to characterize the nuclear aspect ratio of VICs of native leaflets and those of leaflets devoid of elastin across the thickness of the tricuspid valve leaflets. To establish an initial baseline, this study focused on anterior leaflet specimens in a stress-free state. This approach offered an insight into how cellular morphology was affected as a result of MFS. We hypothesized that leaflets devoid of elastin would display a higher nuclear aspect ratio, a result of a relaxed collagen fiber configuration.

## METHODS

Porcine hearts were acquired from a slaughterhouse and delivered to our laboratory within 24 hours after the animal was sacrificed. The anterior leaflet was carefully excised. The leaflet was then trimmed to a 7.6-mm small square. A small fiducial marker was attached at a specified location on the atrial surface of the leaflet such that the orientation of the leaflet could be recalled after the tissue was trimmed.

Fixation took place in 10% formalin overnight in a no-load state. After fixation, tissue specimens were embedded in paraffin before obtaining 20-µm-thick sections along the transmural-circumferential direction. Sectioned specimens were then deparaffinized and permeabilized with Triton-X, at a concentration of 1:1000, for 25 minutes. Next, the VIC nuclei were stained with SYTOX Green (Thermo Fisher Scientific, Cat: S7020), at a concentration of 1:2000, for 15 minutes before finalizing mounting with Fluoromount-G (Thermo Fisher Scientific, Cat: 00-4958-02).

Imaging on the processed sections was performed on a Zeiss LSM 880 NLO using a 10x objective with a field of view sufficient to cover the entire thickness of the specimen. Stained VICs were imaged using 488 nm as an excitation wavelength. The acquired z-stacks were then segmented using in Imaris (Bitplane, Zurich, Switzerland), as seen in Fig. 1A.

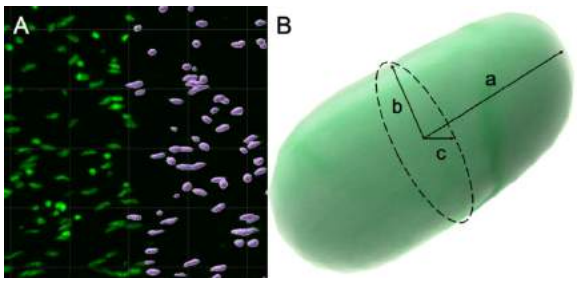

**Figure 1: (A) Representative ellipsoid fit of a VIC where axes a, b and c, are the three semi-axes lengths calculated using Imaris. (B) Stained (green) and segmented (purple) VIC images of a representative sample. Segmentation performed in Imaris.**

The abovementioned procedure was repeated for two groups: the control group (n=3) and the elastase-treated group (n=3). Similar to a previous study, elastase at a concentration of 7.5 U/ml for 20 minutes was used in the elastase-treated group [3].

Segmentation took place for a region of interest which was located in the center field of view of the acquired z-stack. An average number of X nuclei was segmented per each sample. The semi-axes for each fitted ellipsoid (corresponding to each segmented VIC, see Fig. 1B) were obtained in addition to the number of total segmented VICs in each sample and the nuclear aspect ratio (NAR) for each segmented VIC was obtained by dividing the major semi-axis a, by the minor semi-axis c.

To evaluate the overall morphology pertinent to each imaged sample, the average NAR was calculated across every sample along the entire transmural-circumferential thickness of the leaflet. For statistical testing, a two-sample *t*-test was performed to detect any significance of NAR in between the total segmented VICs of both groups.

## RESULTS

Figure 3 shows that the nuclear aspect ratio of the VIC increased in the specimens that were treated with elastase. The mean value of NAR for the control group was 2.44, whereas the mean value for the elastase-treated group was 2.63. Further, the calculated standard error of the mean was higher in the elastase-treated group (±2.70%) than that of the control group (±1.51%).

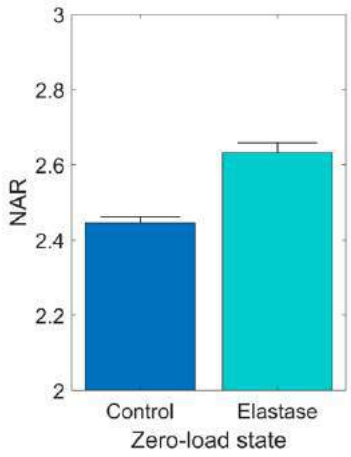

**Figure 3: Average NAR for Control and Elastase-treated groups. Error bars represent standard errors of the mean.**

Because of the inherent presence of variation across specimens, the thicknesses of each sample varied. In particular, the control samples were thicker than the elastase-treated samples. As such, the total VIC nuclei count in the control group was 2360, whereas 1297 nuclei were identified in the elastase-treated group. A significant difference was observed between the NAR values of the control and elastase-treated groups ($p < 0.01$, two-sample *t*-test).

## DISCUSSION

The purpose of this study was to understand how the landscape of VICs are modified when there is a degradation of native elastin fibers. The NAR in the control group represent the VICs that are residing within a native micro-structural environment of the leaflet. It is important to note that through focal adhesions, said VICs are connected to the extra cellular matrix (ECM) and have a "sense of mechanical awareness" of their residing environment [4]. Further, while the tricuspid valve leaflets undergo dynamic deformation, the main load-bearing constituents of the ECM (i.e., elastin and collagen) provide coupled responses, intrinsic to the mechanical response of leaflet [4].

When native tissue is treated with elastase, the original ECM micro-architecture is clearly altered as collagen undulation is reduced (Fig. 4). With the shift in ECM landscape coupled with focal adhesions of the VICs, one would expect that VICs morphology would also alter. As shown in Fig. 3, we noticed a significant increase of 7.78% in the elastase-treated NAR from that of the native tissue, suggesting a close link between collagen fibers micro-architecture (including reduced fiber crimp) and VIC nuclear morphology once elastase was applied. Using two-photon microscopy, we have previously observed the effect that elastase has on decreasing the undulation of collagen fibers in the tricuspid valve anterior leaflet (Fig. 4).

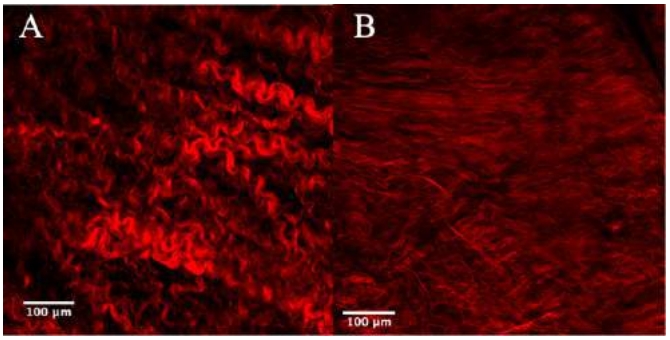

**Figure 4: Two-photon images of collagen fibers obtained from (A) a native tricuspid valve anterior leaflet as compared with (B) less-undulated collagen fibers in an elastase-treated sample.**

Nevertheless, to establish a trend between the NAR of control and elastase groups future investigation would have to include further load ranges. While results presented are for a zero-load state, additional loading protocols would include biaxial loads that concentrate mostly in the lower stress ranges which offer a wider strain range as seen in previous publication from our research group [6]. It should be noted that MFS, and its detrimental effects to elastin occur over a longer timeline than what is simulated in our investigation, as such, remodeling of the ECM may vary compared to what has been demonstrated here.

In summary, to simulate the effects of MFS on native tricuspid valve anterior leaflet tissues, the NAR of zero-load native specimens were calculated and compared with that of elastase-treated specimens. The average NAR, across all three samples per group, were 2.44 and 2.63 for the control and elastase-treated groups, respectively. The increase in NAR, was statistically significant at the zero-load state.

## INTRODUCTION

Mouse animal models are attractive for their ability to perform genetic studies of the disease process and test potential pharmaceutical treatments. While mouse models have been used for cellular level studies of heart valve disease, their small size and fast heart rates has hindered our ability to utilize them for tissue and organ level studies. We have recently developed a novel small animal imaging technique based on high-frequency four-dimensional ultrasound (4DUS) [1]. Using this method, we have developed a pipeline for reconstructing, for the first time, the *in vivo* geometry of the mouse aortic valve (mAV). This method was guided and validated using high-resolution µCT images of *ex vivo* mouse mAV geometric modeling.

## METHODS

**Data acquisition.** A Vevo 3100 (FUJIFILM VisualSonics) instrument with MX550D linear array transducer (Fig. 1) was used to acquire 4DUS images of the aortic valve of three C57BL/6J mice (healthy, male, 3 months old) with spatial voxel size and temporal resolution to be 40µm$^3$ and 2ms, respectively. Segmentation was performed using an in-house MATLAB GUI in which the imaging volume was first oriented orthogonal to aortic valve opening to ensure true short axis (SAX) view and then rotated to ensure that the right and left coronary cusp (RCC/LCC) were on the left and right side of the image, and non-coronary cusp (NCC) pointing downward. To overcome the motion of mAV within chest cavity and isolate leaflet motion, the center of the mAV was tracked throughout the cardiac cycle, and motion was offset across time in three axes. At each time point, the following geometric features were manually segmented (Fig. 2) including points along the free edges $\mathbf{P}_{FE}$ (black squares) including the commissure points, the midpoints of the basal attachment $\mathbf{P}_{BA,mid}$ (green squares), the lowest points of each leaflet $\mathbf{P}_{lowest}$ (red squares) along the SAX, and the horizontal cross sections of each leaflet at the height of the triple point ($\boldsymbol{\ell}_{triple}$).

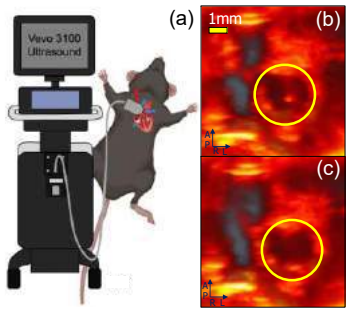

**Figure 1: 4DUS images of mAVs (highlighted) were acquired at fully closed (b) and open (c) states.**

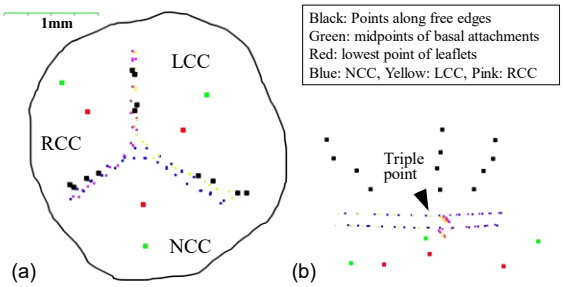

**Figure 2: Top (a) and side (b) views of the 4DUS-segmented geometric features of a mAV at the closed state. The contour represents a slice of the aortic wall.**

A Thermo Scientific Heliscan µCT instrument was used to obtain the *ex vivo* images of the aortic valve of a C57BL/6J mouse (healthy, male, 10 months old). The mAV was excised and fixed at the closed state under 100 mmHg. This was achieved by elevating a reservoir of solution to a

height relative to the mAV [2]. The polyethylene pressure monitor tubing was anastomosed to the aorta with polyamide sutures. Transvalvular hydrostatic pressure was applied from the arterial side with saline solution initially to ensure proper pressurization of the aortic trunk. Segmentation of the µCT images was performed using Synopsys' Simpleware ScanIP software (Version 2018.12-SP2).

**In vivo closed-state surface reconstruction.** To reconstruct the *in vivo* closed-state geometry, we used a generic NURBS-based geometric model (Fig. 3) to fit the 4DUS-segmented geometric features. The geometric model used 33 independent parameters to control the position of a grid of NURBS control points with which the size and shape of the midsurface geometry was determined. The controlling geometric parameters include but not limited to the valve height, leaflet span angle, position of the triple point, etc. A two-step fitting scheme was then adopted to ensure proper fitting to the segmented features. In the first step, only $\mathbf{P}_{FE}$ and $\mathbf{P}_{BA,mid}$ of all leaflets were fitted which set the size and rigid body translation of the mAV from the model to the lab coordinate. In the second step, $\mathbf{P}_{lowest}$ and $\ell_{triple}$ were included to further characterize the profiles of the free edge and belly curve.

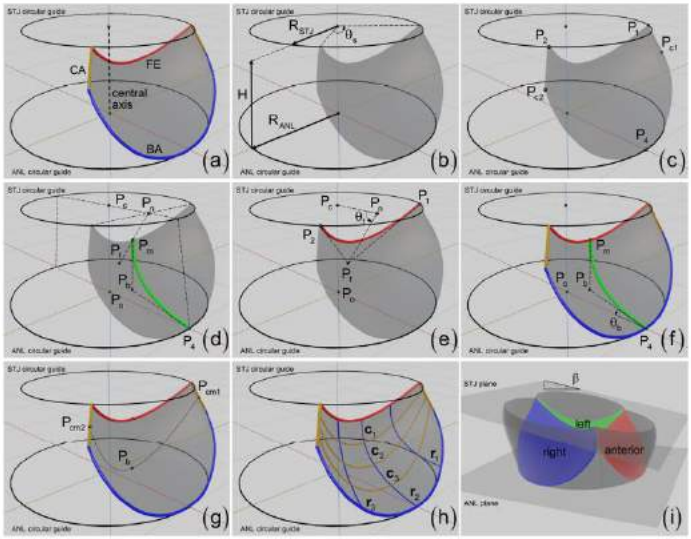

**Figure 3: NURBS-based geometric model was used to fit the *in vivo* closed-state geometry of mAV.**

**In vivo open-state surface reconstruction.** The *in vivo* open-state geometry was developed by morphing the control points of the closed-state geometry to match the 4DUS-segmented geometric features at the open state. The morphing process was governed by the displacement vectors of control points at the two commissure lines $\mathbf{u}_{comm,line1}$, $\mathbf{u}_{comm,line2}$, the midpoints of the basal attachment $\mathbf{u}_{BA,mid}$ and free edge $\mathbf{u}_{FE,mid}$. In particular, for a control point associated with NURBS parameter $(\xi,\eta)$, $0 \le \xi \le 1$, $0 \le \eta \le 1$, the following displacement vector $\mathbf{u}$ was introduced to morph the geometry from the closed-state to the open-state:

$$\begin{aligned}\mathbf{u}(\xi,\eta) = {} & (1-\eta)^2 \mathbf{u}_{comm,line1} + \eta^2 \mathbf{u}_{comm,line2} + \\ & 4(1-\xi)\eta(1-\eta)\mathbf{u}_{BA,mid} + \\ & \alpha\xi\eta(\eta-c)(\eta-1+c)(\eta-1)\mathbf{u}_{FE,mid}\end{aligned} \quad (1)$$

Here, $\xi$ and $\eta$ are the coordinates of the NURBS parametric domain along the radial and circumferential directions, respectively.

## RESULTS

In both states, the final *in vivo* geometry was rendered as volumes by assigning µCT-measured thickness to the fitted midsurface with a uniform thickness value to the belly region and a realistic thickness model to the nodulus position (Fig. 5). It was found that the limited segmented geometric features were sufficient to characterize the geometry at both states indicating that the geometric model could substantially lower the amount of segmentation load in reconstruction. Compared with the *ex vivo* geometry, the reconstructed *in vivo* closed-state mAV geometry showed reasonably good agreement (Fig. 4a and Fig. 5b, d). Particularly, the *in vivo* and *ex vivo* mAV geometry indicated similar dimensions and dipping profile of the free edges, a characteristic seen in mouse heart valves [2] but not in bioprosthetic heart valves [3]. By morphing the control points of the closed state, we also reconstructed the geometry at the open state although no µCT counterpart was available at this stage (Fig. 5a, c).

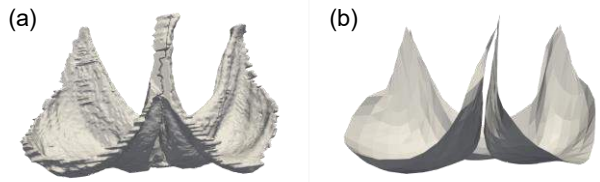

**Figure 4: The *ex vivo* µCT-segmented geometry (a) and reconstruction of the midsurface using the geometric model (b), which was used to guide the *in vivo* geometric model form.**

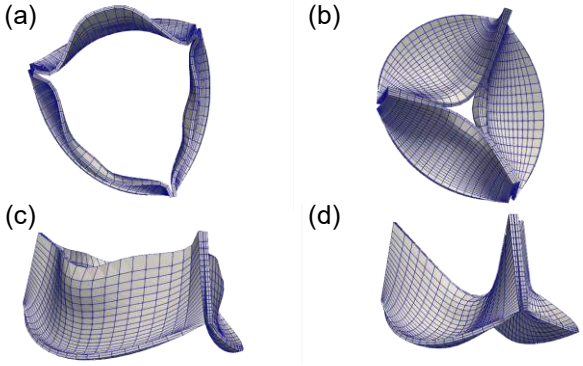

**Figure 5: Final reconstructed *in vivo* mAV geometry at open (a, c) and closed (b, d) states.**

## DISCUSSION

In this work, we have demonstrated the ability to use high-frequency 4DUS to reconstruct *in vivo* mAV geometry. *To our knowledge, this is the first time such reconstruction was ever achieved*. By using a geometric model based on µCT data, we were able to reconstruct mAV geometry given limited amount of 4DUS segmentation data. Looking forward, we are working on increased number of frames to develop a more accurate picture of mAV motion over the cardiac cycle. This will allow for longitudinal characterization of mouse models of aortic heart valve disease in long-term mechanistic studies.

# CYSTEINE CHEMICAL MODIFICATIONS AS THE REGULATORY RESPONSE TO DIMETHYL SULFOXIDE EXPOSURE

## INTRODUCTION

Cysteine is a key amino acid in proteins with a chemical composition of three functional groups - amino, carboxyl, and thiol - all highly abundant among different organisms [1]. Specifically, the presence of highly reactive thiol group and its structural feature to form disulfide bonds under oxidative conditions makes cysteine an ideal compound for investigation of oxidation induced chemical modifications in biologically relevant models [2-4]. On the other hand, dimethyl sulfoxide (DMSO) is a low molecular weight cell permeating compound that is widely used in the pharmaceutical industry as a solvent, and it is a very well-known cryoprotective agent that is routinely used to preserve cells at cryogenic temperatures. Particularly, DMSO is the major component of many vitrification solutions [5-7] due to its ideal property of eliminating ice formation and preventing freezing damage during organ transplantation; however, organ transplantation is currently hindered due to cell death that occurs during the cryopreservation process. Therefore, in this work, we proposed to identify whether DMSO exposure modulates cysteine properties as part of its cytotoxicity effect. Various parameters, such as the number of free thiol groups, were assessed following immediate exposure of cysteine to DMSO and upon treatment with a reducing agent Dithiothreitol (DTT) post removal of DMSO using a series of designed ad hoc ideally simplified experiments. The observed chemical modifications of cysteine after DMSO treatment indicate that DMSO would irreversibly alter the activity and function of many proteins in signaling pathways consequently affecting the ultimate cell survival rate.

## METHODS

L-Cysteine (Sigma-Aldrich, 30089) solution was prepared in phosphate buffer saline (Sigma-Aldrich, P5368) and exposed to 30% v/v DMSO to the final concentration of 2 mM, followed by 1 hour incubation at 37 °C. Then, DMSO was diluted out to 0.5% v/v and samples were second incubated with 150 µM DTT for another hour at 37 °C. The number of free thiol groups were quantified at the end of the first and second incubation steps using Ellman's reagent (Thermo Scientific, 22582) according to the manufacturer's protocol and reading absorbance at 412 nm. All experiments were performed in triplicates to determine the mean ± standard deviation (SD) of each group. Student's t-test was used to evaluate the significantly different groups among pairs. p value of $< 0.05$ was considered significant.

## RESULTS

The absorbance values obtained from Ellman's reagent-based colorimetric assay for cysteine samples exposed to DMSO is shown in Figure 1. Total number of free thiol groups decreased significantly (50%, $p < 0.05$) compared to the cysteine untreated group. Control and DMSO exposed samples were then diluted and second incubated with DTT to investigate the effect of a reducing agent on the DMSO induced cysteine modifications. The absorbance data is shown in the same Figure 1. Interestingly, the reducing agent did not change the number of available thiol groups compared to the DMSO exposed alone samples, which suggests that the nature of chemical modifications that DMSO induces is unlike the formed intramolecular disulfide bridges upon oxidation when the thiol group is exposed to the traditional oxidizing agents, such as hydrogen peroxide.

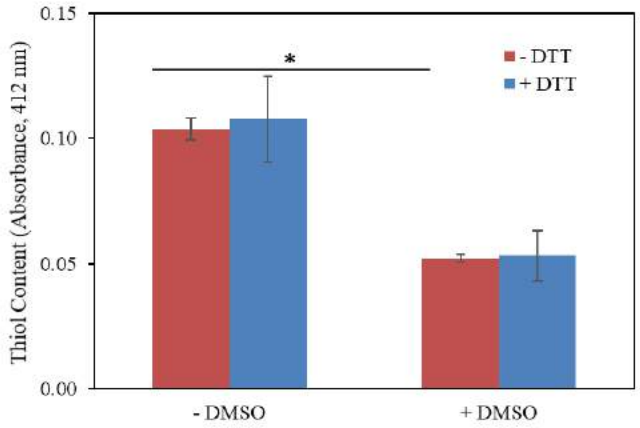

**Figure 1: Thiol content of cysteine samples post exposed to (+) DMSO and (+) DTT using Ellman's reagent-based colorimetric assay. Negative control samples are shown as (-) indicating no exposure to DMSO or DTT. Values are presented as mean ± SD of n = 3, $p < 0.05$.**

## DISCUSSION

The loss of free thiol groups, which is shown by the significant reduction of absorbance of the treated samples, indicates that cysteine directly interacts with DMSO. The observed chemical modification suggests that the thiol groups of the cysteine solution may have been oxidized by DMSO, which might have induced the formation of disulfide bonds. This phenomena along with the fact that the interaction was not reversed with the reducing agent, DTT, lead to the conclusion that maybe the toxic effect of DMSO on cells is caused by exerting extensive severe damage to proteins' cysteine content and ultimately irreversibly disturbing major oxidative signaling pathways/mechanisms during organ cryopreservation for transplantation purposes.

# A DEEP LEARNING APPROACH TO INVESTIGATE THE HIDDEN LINKS BETWEEN CANNABIS AND CARDIOVASCULAR HEALTH

## INTRODUCTION

While cannabis has been legalized in many U.S. states, its impact on cardiovascular health is still unclear and remains to be explored. On one hand, some studies have shown that no association could be made between cannabis use and cardiovascular diseases [1,2], but on the other hand other studies have suggested a negative correlation between the two. A study conducted in the United States by Desai et al. [3] using the National Inpatient Sample (NIS) database has shown that 0.23% of cannabis users were admitted for acute myocardial infarction (AMI) while non-users had a lower frequency of admission for the same disease (0.14%). Overall, the current literature is still divided on the impact of cannabis on cardiovascular health. In this work, we take a step towards a better understanding of the issue by exploring a potential correlation between cannabis use and cardiovascular magnetic resonance (CMR) images.

Cardiovascular magnetic resonance (CMR) imaging is a non-invasive imaging technique used to diagnose different cardiovascular diseases such as congenital heart disease and myocarditis [4]. While most cardiovascular disease (CVD) studies use long-axis and short-axis image sequences displaying the heart during a cardiac cycle [5], some studies focus on another sequence of CMR images that measures relaxation time of myocardial tissue: native T1 mapping images [6]. Here, we take a similar approach in order to build a fast model that only uses a single T1 mapping image instead of a stack of long-axis and short-axis images.

To explore the potential correlation between cannabis use and CMR images, we used the UK Biobank platform [7], a large-scale biomedical database containing both CMR images and cannabis use information obtained through a survey. In this survey, volunteers were given the option to report if they have used cannabis in the past, how often, and the last age at which they used it.

In this work, (1) we explore the UK Biobank and identify individuals with CMR data and cannabis use information, (2) we segment T1 mapping images of regular cannabis users and non-users, and (3) we train and test a deep learning model to distinguish T1 mapping images of regular cannabis users and non-users.

## METHODS

Before investigating the correlation between cannabis use and T1 mapping images, we first explore the UK Biobank dataset. To avoid extracting features that might be related to a particular disease and focus on the correlation between cannabis use and T1 mapping images, we remove individuals with 96 common diagnoses (diagnoses that affect more than 1% of the dataset) and other cardiovascular diagnoses (dilated cardiomyopathy, cardiomyopathy, preexcitation syndrome, heart failure, and cardiomegaly). We then select the cohort of individuals that would be classified as regular cannabis users. As shown in Figure 1, we define regular cannabis users as individuals who have used cannabis at least 100 times, once a week or more, and with a most recent use no longer than 1 year before taking the survey.

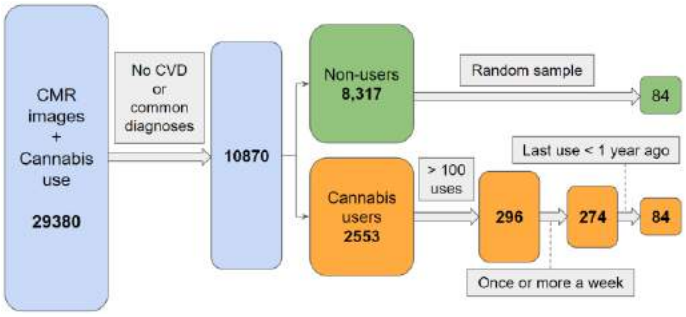

**Figure 1: UK Biobank cannabis use exploration**

After obtaining the final dataset consisting of 168 T1 mapping images, with 84 images from regular cannabis users and 84 images from "healthy" non-users, each image is manually segmented as seen in Figure 2 by identifying pixels belonging to the LV myocardium and the RV.

We then split the 168 T1 mapping images coupled with their segmentations into a 60:15:25 split, yielding 100 training images, 26 validation images, and 42 test images. To avoid training issues due to class imbalance, the splits are done for each class individually before putting the data back together.

After exploring different architectures available in PyTorch [8], we choose ResNet18 [9], a deep learning model widely used for image classification, and change the last fully connected layer to output 2 predictions. We finetune the hyperparameters on the validation set and finally select a batch size of 16 and an initial learning rate of 0.01 that is divided by 10 every 30 epochs. With these parameters fixed, we then select for the inputs shown in Figures 2.B and 2.D the 3 fully-converged models that perform the best using 5-fold cross validation.

## RESULTS

Figures 2.B and 2.D show the different types of input used during training and testing depending on the model. Figure 2.A is the full T1 mapping image and Figure 2.C is its corresponding heatmap. Figure 2.B is obtained by changing all the positive values of the manually segmented mask to 1 and multiplying the result with Figure 2.C. Figure 2.D is obtained using a similar process where only the mask of the left ventricle (LV) myocardium is kept.

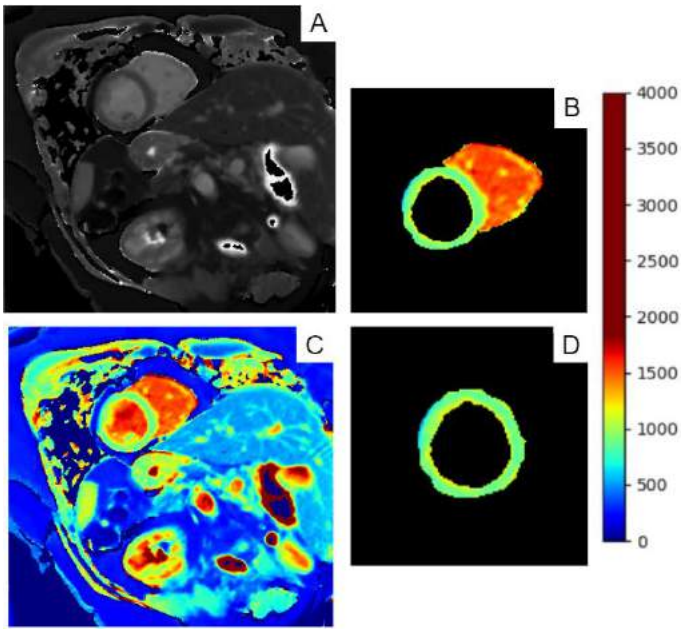

**Figure 2: (A) T1 mapping image; (B) Segmented Left Ventricle (LV) myocardium + Right Ventricle (RV); (C) T1 mapping heatmap; (D) LV myocardium**

Figure 3 shows the results obtained on the test set. Since our validation set is small and might not be fully representative of the test set despite 5-fold cross validation, for each type of input, we select the 3 models that converged and performed the best on the validation set.

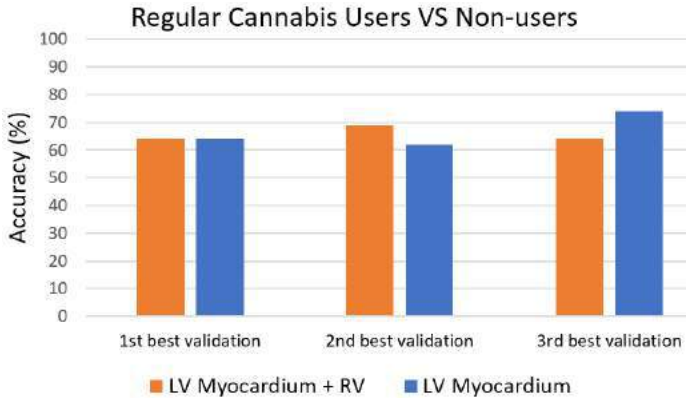

**Figure 3: Test set classification accuracy for each type of input**

## DISCUSSION

Figure 3 shows that the model trained on the LV myocardium performs the best (73.8%), which is well above a random binary classification of 50%. This result aligns with most methods that analyze T1 mapping images using global and regional T1 values of the LV myocardium [6]. While adding the RV allows the network to see more pixels, it seems that it cannot leverage this extra information, including the location of the septum to give a better classification accuracy. Overall, our experiments show that the LV myocardium in T1 mapping images could be used with a deep learning model to distinguish between the T1 mapping images of some regular cannabis users and non-users.

One limitation of our study is the limited number of available images to train our deep learning model. With only 26 validation images, our validation results do not directly transfer to our test set. To avoid selecting a model biased towards the validation set, we select the best 3 models for each input type and report their results on the test set. With more images, we could train a more robust model that could handle outliers. Since the UK Biobank is continuously accruing data, we hope to address this issue as more data becomes available.

While the impact of cannabis use on cardiovascular health is still unclear, this preliminary study shows that deep learning algorithms might be used to distinguish between T1 mapping images of regular cannabis users and non-users. This useful tool for non-invasive image-based diagnostics might help shading some lights on potential hidden links between cannabis use and major cardiovascular events.

# THE INFLUENCE OF PERSONAL PROTECTIVE EQUIPMENT ON MALE AND FEMALE SPINAL LOADS IN VERTICAL IMPACT

**Sagar Umale (1), Prashant Khandelwal (1), John R. Humm (1), Narayan Yoganandan (1,2)**

## INTRODUCTION

Mounted Soldiers are subjected to vertical loads, transmitted from the seat to the pelvis to the torso regions during underbody blast events. The use of personal protective equipment (PPE) adds to the weight of the torso, influencing the load transmission within the vertebral column. Due to the loading direction and proximity to the seat, during blast events, the thoracolumbar spine is at a higher risk of injury, and injuries to this region are reported in clinical literature [1]. With increase in the female population, and with the acknowledgment that this group has different biomechanical injury tolerance limits, the objective of the present investigation was to determine the forces and sagittal bending moments in male and female spines with the PPE and head supported mass using human body finite element models.

## METHODS

The detailed Global Human Body Models Consortium (GHBMC) mid-sized male [2] and the small female model [3] were used in the study. The simulation environment consisted of the human body model, a rigid seat, and a footrest. As the models represented the posture of automotive occupants, to mimic the posture of a seated soldier, the male and female occupants were seated close to the seat and were then settled under the 1 g acceleration along the z (vertical) and x (antero-posterior) directions. The final postures of the two models were extracted from the positioning simulations such that the models represented an upright seated soldier in a military vehicle (Figure 1).

The positioned models were restrained in the seat with a five-point seatbelt, typical of a military harness. They were updated with PPE, which consisted of a 1.4 kg military Army Combat Helmet and 11 kg body armor vest. The vest consisted of carrier plates (3.6 kg) with arms protective inserts (5 kg) and side ballistic inserts (2.4 kg) [4]. Cross-sectional sets along the transverse axis were defined at the L5 and T12 mid-intervertebral bodies to obtain loads in the spine at the lumbar and thoracic end, termed distal and proximal regions [5]. Three acceleration ($G_z$) pulses with peak velocities of 4.8 m/s, 6.5 m/s and 7.9 m/s, termed as low, medium, and high severity) were derived from acceleration pulses. They were applied to the seat and the footrest to determine the effect of impact severity on spine loads. A total of twelve cases were simulated for the two models (with and without PPE) and three severities. The peak forces and moments were extracted at the proximal and distal regions of the spine for the low, medium, and high severity impacts.

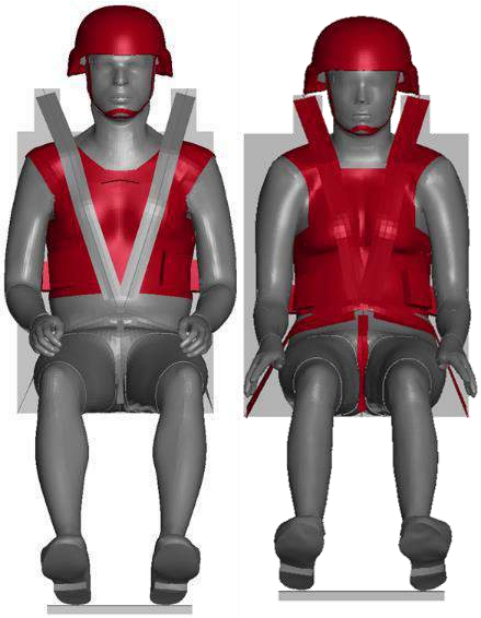

**Figure 1: The male (left) and female (right) models positioned in the seat with PPE (body armor and army combat helmet).**

## RESULTS

The kinematic analysis showed that the thoracic and lumbar spines responded with compression-flexion in both male and female models, and this was true for with and without PPE cases.

*Effect of impact severity:* The increasing severity of impact increased forces more in males than females. For PPE cases, compared with the low severity, at the proximal and distal regions, force increased by 31% and 36% for the male spine while for the female spine the increase was 18% and 20%, for high severity respectively. At the medium severity, increases in the male spine were 25% and 28%, and in the female spine they were 24% and 26%, respectively. Compared with the low severity, at the proximal and distal regions, moments increased by 34% and 36% for the male spine while for the female spine the increase was 20% and 21%, for high severity respectively. At the medium severity, increases in the male spine were 25% and 30%, and in the female spine they were 27% and 26%, respectively. These results for with and without PPE increase in force are shown in Figure 2.

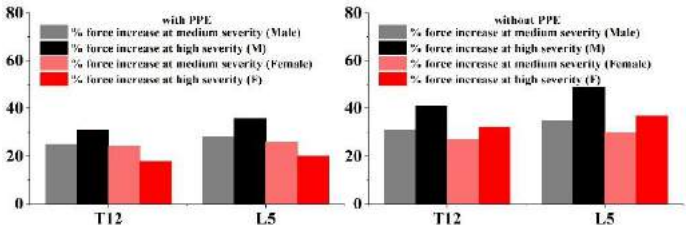

**Figure 2: The % increase in force for medium and high severity velocity compared to low severity.**

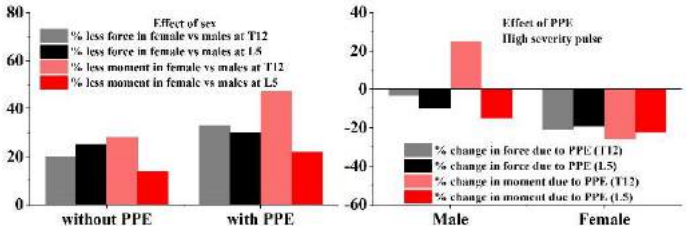

**Figure 3: The effect of sex (left) and PPE (right) on spinal loads.**

*Effect of sex:* With the use of the PPE, forces in the female spine were lower than those in male spine. Across the three impact severities, on average, forces were lower by 33% at the proximal and 30% at the distal regions, and moments were lower by 47% and 22%, respectively. As a comparison, without PPE the female spines had lower changes than with PPE. These results for without and with PPE are shown in Figure 3 (left).

*Effect PPE:* With PPE the forces decreased in both spines: up to 10% at the distal region in the male spine and up to 21% at the proximal region in the female spine. Bending moments decreased by 26% and 22% for the female spine at the distal and proximal regions, and in the male spine, moments decreased by 15% at the distal and increased by 25% at the proximal regions (Figure 3 - right).

## DISCUSSION

In this study, male and female human body models were used to determine the thoracolumbar spine kinetics simulating underbody blast loading, and three impact severities were used. Because the original models were developed for automotive occupants, and the currently intended application is for Soldiers, PPE was added to each torso, and in addition, the posture was altered. The PPE simulated in the models represented the equipment currently used in the military. A head supported mass was added, and it simulated the midsize Army Combat Helmet. These changes rendered the modeling and output responses more realistic and are considered as a first step in the analysis of spinal kinetic for vertical loading from underbody blast events.

From an overall kinematics perspective, both male and female spines responded similarly, as expected; however, the internal load transmissions were different, and these metrics depended on the type of the metric, force versus moment, spinal region, distal versus proximal, and male versus female. The kinematic patterns showed that the mechanism of loading was compression combined with flexion. This mode of loading parallels injuries such as wedge compression fractures in military environments [6]. While not the focus of the present study, similar kinematics and mechanism without PPE is applicable to the civilian automotive environments, as similar inferences have been reported from field data [7]. Thus, the results based on the overall kinematics indicate that the present analysis is applicable to both automotive and military scenarios.

As expected, increase in impact severity increased spinal loads at both regions; however, the use of the PPE reduced forces in both spines. Bending moments were reduced with PPE in the female spine at both regions. Whereas in the male spine, they reduced at the distal and increased at the proximal region, suggesting that the PPE is more effective in female. The increase in the bending moment at the proximal region may predispose the male spine to compression-flexion injures.

Spinal loads were lower in the female spine than the male spine. This is largely due to the size effect. The vertebral column length, depth breadth along the antero-posterior direction, and intervertebral disc depths along the superior-inferior direction are lower in the female spine than the male spine [8]. Although not investigated here, curvature also plays a role in the load transmission. They are different between men and women, and the female pelvis anatomy orients the dorsal spine differently in women in a seated position. The male vertebral body cross-sectional areas are 20% greater on an average [9]. The female vertebral body cross-sectional areas in the present model were 43% lower at T12 and 20% at L5 than the male model. These parameters contributed to the differences in the force and moment pattern changes between the male and female spines.

The present human body modeling study showed that increase in vertical impact velocity increased spinal forces and moments for both PPE cases, the PPE decreased the spinal force and moments, except the bending moment at thoracolumbar junction in the male spine, and the spinal loads in males were greater than females. These results delineate the effects of PPE, male-female, sex and impact severity on proximal and distal spinal forces and moments under simulated underbody blast loading.

# 3D MICROFLUIDIC CELL ARRAYS WITH RECIRCULATION AND TUMOR-STROMA INTEACTIONS FOR THE DEVELOPMENT OF IMMUNOTHERAPEUTIC DRUG

**Chun-Wei Chi (1), Yeh-Hsing Lao (2), A.H. Rezwanuddin Ahmed (1), Kam W. Leong (2) and Sihong Wang (1)**

## INTRODUCTION

Recent studies have demonstrated cancer immunotherapy's feasibility in treating triple-negative breast cancer, the most aggressive breast cancer type with worse survival, as two of immune checkpoint blockades have received FDA approval. Since there are many checkpoint proteins involved in adaptive immunity, and more candidates of inhibitory receptors being discovered, more and thorough studies are warranted to explore and validate their clinical potentials.[1] However, generation of a proper murine model to mimic human tumor microenvironment (TME) for immunotherapy validation is difficult, costly, and complicated. There is therefore an unmet need for novel approaches to replicate TME for pre-screening these drug candidates. Moreover, several studies have demonstrated that the immune response observed in 2D monolayer culture is significantly different from that in 3D culture. [2, 3] Microfluidic platforms further provide a spatial control of cell distribution as well as the TME construction, thereby allowing a more precise flow control to better mimic the transport conditions *in vivo*.

We previously developed a three-layer microfluidic cell array (μFCA) to reconstruct the physiologically spatial structure of tumor microenvironment by co-culturing cancer cells with microvascular endothelial cells (EC) in two compartments, separated by a thin layer with patterned pores.[4, 5] Cancer-associated fibroblasts (CAFs), the most abundant stromal cells in TME, were cocultured with cancer cells in Matrigel to reconstruct more physiologically relevant TME. Compared with conventional 2D *in vitro* assays, in our platform, the spatial configuration of endothelial monolayer on the top channel represents an EC barrier against lymphocyte infiltration to mimic the *in vivo* scenario occurring during the cancer immunotherapy treatment. Continuous flow in the endothelial channel provides nutrient supply as well as waste removal in TME. It also mimics the mechanical and chemical stimulations of bloodstream. Indeed, evidence has shown shear stress affects lymphocyte attachment and migration across endothelium through mediating the expression of E-selectin and ICAM-1 in endothelium.[6] In this study, we further develop a recirculation circuit to enable the on-chip immune cell circulation with unidirectional flow by a syringe pump with functions of infusion and withdraw. With these designs, we are able to study effects of tumor-endothelium and tumor-stroma interactions in cancer drug responses and kinetics in a scenario close to real physiological conditions. The observation of the $CD8^+$ T cell infiltration and cytotoxicity to the cancer cells on this platform further demonstrates this platform's potential for prescreening cancer immunotherapy candidates in a high throughput manner.

## METHODS

**Figure 1A** illustrated our μFCA platform configuration and the recirculation circuit constructed by microfluidic check valves. Both were fabricated by standard soft lithography techniques. Briefly, the selective bonding in the region of check valves was carried out by transferring PDMS residual oligomers from a PDMS stamp to the stopper region of an oxidized bottom layer before bonding with the bonded top and middle layers. The feasibility of recirculation circuit was firstly evaluated by the viability of human monocytes circulated in the system using calcein AM and ethidium homodimer-1.

For the T cell infiltration experiment, GFP-expressing MDA-MB-231 breast cancer cells and CAFs, differentiated from human MSC by culturing with cancer-conditioned media for 30 days, were encapsulated in Matrigel and introduced to the bottom chambers of our µFCA. ECs were then seeded on the top channels on the second day, and a continuous flow of media was given 5 h after. On the fourth day, the recirculation circuit was connected to the cell array, and CellTracker CM-DiI stained cytotoxic T cells (TALL-104) were introduced to the platform. At the end of experiment, cells were incubated with 2µM NucView®405 Caspase-3 substrate for 1 h and then fixed with 4% paraformaldehyde for 60 min. The Z-stacked images for monitoring T cell infiltration and/or caspase-3 activity were captured by an epi-fluorescent microscope (Zeiss AxioObserver) and/or a confocal microscope (Zeiss LSM800).

## RESULTS

As shown in **Figure 1B**, human monocytes could follow the flow direction guided by check valves in the recirculation circuit. In addition, there was no negative effect on their viability after 3-day recirculation in the microfluidic platform. Thus, we further circulated human $CD8^+$ T cells with this design to investigate T cell infiltration into regenerated micro-tumors and their cytotoxicity in different coculture conditions.

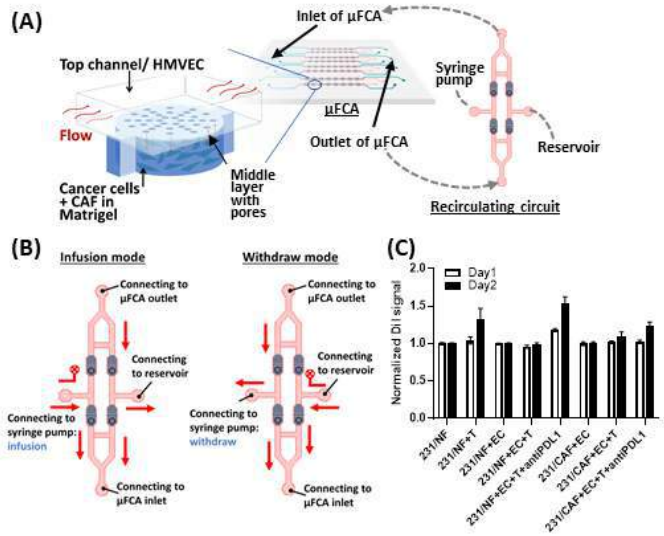

**Figure 1. Microfluidic cell array (µFCA) integrated with tumor-stroma microenvironment and recirculating circuit for studying T cell infiltration and cytotoxicity. (A)** Scheme of the connection between µFCA and the recirculating circuit. **(B)** Working mechanism of the recirculation circuit **(C)** DiI-stained T cell infiltration in the tumor chamber.

As shown in **Figure 1C**, T cell infiltration could be observed after one-day recirculation, and the difference between culture conditions became more significant after a two-day recirculation. Compared with the coculture of MDA-MB-231 and normal fibroblasts with endothelial cells (231/NF+EC+T), the condition with the absence of endothelial cell (231/NF+T) had a significant DiI signal increase in the bottom chamber, indicating that the endothelial monolayer in the µFCA hampered the T cell infiltration. Anti-human PD-L1 antibody treatment increased T cell infiltration and even overcame the interference from the endothelial monolayer, resulting in the highest DiI signal in the coculture with normal fibroblasts among all conditions. We further analyzed the caspase-3 activity in the tumor chamber of our µFCA via fluorogenic caspase-3 substrates (data not shown). The caspase-3 activity in the coculture with normal fibroblast was higher than the one with CAF. Although T cell alone did not lead to significant cytotoxicity, additional anti-PD-L1 treatment increased the caspase-3 activity. However, the enhancement by anti-PD-L1 in coculture with CAFs cannot reach the same level of caspase-3 activity in coculture with normal fibroblasts without any treatment.

## DISCUSSION

In this study, a microfluidic cell array, which reconstructs tumor-stroma microenvironment and is integrated with a recirculation circuit, has been developed for studying T cell infiltration and cytotoxicity. The recirculation circuit provides unidirectional flow in µFCA, primarily through manipulation of flow from a reciprocating syringe pump coupled with check-valves; immune cells directly travelling in this recirculation circuit retain uncompromised viability. Furthermore, this design enables to study the dynamics of cytotoxic T cells in continuous flow with a more physiologically relevant TME. The reconstructed endothelium plays a role as a barrier to the T cell infiltration into the tumor compartment. Blockade of anti-human PD-L1 enhances T cell infiltration and even overcomes the interference from the endothelial monolayer. The tumor stroma strongly influences $CD8^+$ T cell infiltration and cytotoxic activity. Compared with the coculture with normal fibroblasts, the CAF coculture attenuates T cell infiltration and leads to lower caspase-3 activity. Treatment of anti-PD-L1 enhances the caspase-3 activity but is not enough to compensate the influence from CAFs, when compared with the normal fibroblast coculture conditions without any treatment. Collectively, these results reveal that our µFCA could serve as an *in vitro* tool for studying cancer immunotherapeutic strategies with precisely mimicked TME, paired with a high throughput adaptation.

# EFFECT OF STATURE AND LORDOSIS ON FEMALE LUMBAR SPINE LOADS IN VERTICAL IMPACT

**Sagar Umale (1), Prashant Khandelwal (1), John R. Humm (1), Narayan Yoganandan (1,2)**

## INTRODUCTION

It is well known that female spines are different from male spines although clinical options do not have specific targets for the surgical treatment of traumatic injuries. The lumbar spines of women are generally smaller in terms of parameters such as column length, disc height, and vertebral anteroposterior depth than men spines. The stature, sitting height, and body mass of men and women for the same anthropometric definitions (mid-size male versus mid-size female, for example) are also different [1]. A clinical measure of the spine is the curvature, defined as the Cobb angle between various vertebrae of the lumbar spine, e.g., the angle formed between L1 and L5 endplates in the midsagittal plane [2]. As the lumbar spine responds to the external loading via interaction within the various joints of the column, and with the aforementioned differences between men and women, it is expected that the load carrying capacity and hence, tolerance of female spines are lower than men [3]; specifically, for the same categorization such as equivalent stature and curvature, forces and moments will be lower than the male spine. The share of the forces and moments load also depends on the external mechanical load vector. The objective of this study is the parametrically determine the loads on the female spines.

## METHODS

A validated finite element model of the human lumbar spinal column was used in the study [4]. The T12-S1 model consisted of three-dimensional hexahedral solid elements representing the cancellous bone, intervertebral disc (annulus and nucleus), spinous process, transverse process, and facet joints at each vertebral level. The two-dimensional quadratic shell elements represented the cortical bone, endplates, and annulus fibers at each level. One-dimensional beam elements were used to represent the anterior and posterior longitudinal ligaments, ligamentum flavum, interspinous ligament, transverse ligaments, and supraspinous ligaments. The model consisted of 273 beam elements, 98,978 shell elements and 289,586 solid elements. The mapping blocks/hex-boxes technique was used to develop the mesh [5]. To incorporate the variation in the length and curvature, the hex boxes were converted to morphing boxes. The range for the variation of length and curvature parameters was obtained from the literature [6,7]. The morphing of the model for these parameters was automated using the Latin Hypercube Sampling parametrization technique in the LS-Dyna software. A routine was developed in LS opt using the ANSA software and the models were solved using LS-Dyna. The spine model was constrained at the T12 level by constraining all nodes, and displacement was applied to S1 in a vertically upward direction. The displacement pulse corresponding to 6.5 m/s was applied to the sacrum [8]. One-hundred finite element 100 models were simulated, and the vertical forces and moments were extracted using pre-defined cross-sectional planes defined at the mid-vertebral body level of L1.

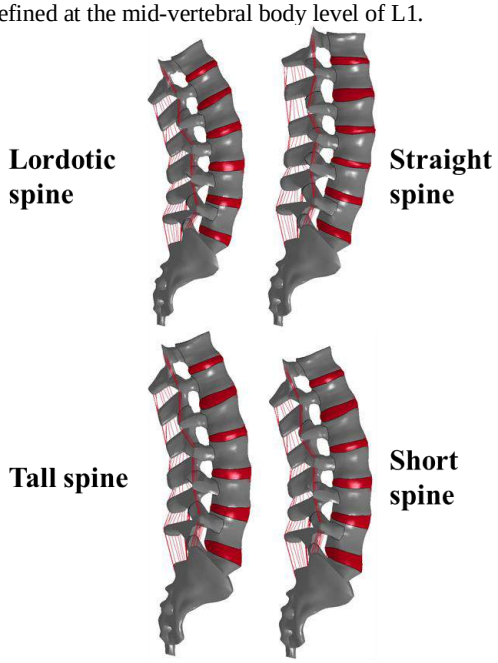

**Figure 1: Lordotic, straight, tall and short spine models generated by morphing using the developed technique.**

## RESULTS

The overall length of the 100 lumbar spines ranged from 158 to 193 mm. The overall lumbar lordosis defined as the Cobb angle ranged from 34 to 65 deg, where the less value represents higher lordosis, and the greater value represents less lordosis, i.e., inverse relationship to angle. The peak force, moment for the shortest and tallest spine was 5.6 kN, 82.1 Nm and 4.1 kN, 82.4 Nm. The overall spine forces decreased, and moments remained the same with increase in stature. Independent of the stature, the peak L1 force, moment for the most lordotic and straight spine was 4.3 kN, 73.7 Nm and 5.7 kN, 110.2 Nm. Thus, with the increase in lordosis, the spinal forces and moments decreased.

The models were analyzed based on two groups, spinal column length representing the short and tall population, and curvature representing the lordotic and straight spine configurations. For the short and tall groups, the spinal column length ranged from 158 to 176 mm and 176 to 193 mm, respectively. For the short population models, the lordotic spine Cobb angles ranged from 42 to 49 deg, and for the straight spine ranged from 49 to 62 deg. For the tall population models, the lordotic spine Cobb angles ranged from 34 to 56 deg and the straight spine ranged from 56 to 65 deg. The breakup was done such that all subgroups had equal number of finite element simulations under the same vertical loading. The average and standard deviation of the spinal loads for each group were calculated (Figure 2).

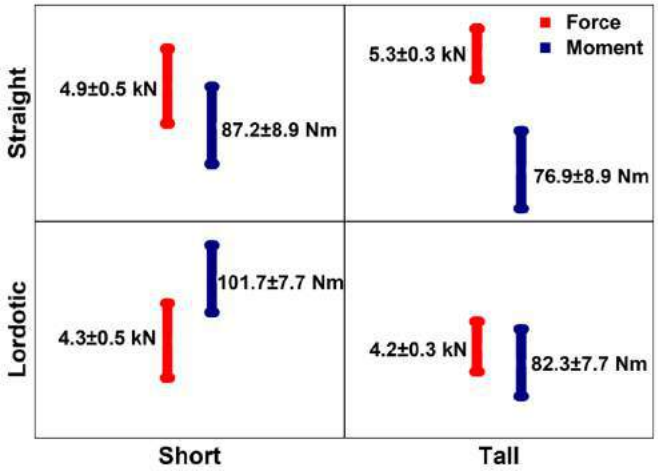

**Figure 1: Female lumbar spine loads based on stature and lordosis.**

Comparing the stature, the forces for lordotic spine were marginally (2%) decreased from short to tall females. Whereas, for straight spine, the forces for the tall stature were 8% higher. The moments were greater for short stature compared to the tall stature (23% for lordotic and 13% for straight spine), irrespective of the lordosis. The lordotic spine forces were lower for both short (14% lower) and tall (26% lower) stature spines, whereas the moments were higher (16% for short and 7% for tall).

## DISCUSSION

In this study, a validated lumbar spine model was used to investigate the effect of stature and lumbar lordosis in females [4]. The model was validated under all physiological modes. A parameterized morphing technique was used to generate 100 models to cover a wide range in the anatomical spectrum of female lumbar spines. An initial study was conducted to determine the most sensitive geometrical parameters on spinal loads and the Pearson's correlation coefficients between the parameters and the spinal forces were determined. Results while not shown indicated that the curvature and column length were sensitive parameters. The Pearson's correlation values for L1 force with lumbar lordosis and column length were -0.87 and 0.75.

The models were simulated for vertical impact from the seat to the spine via pelvis, representing underbody blast loading. The spinal loads were extracted at the cranial end of the column, representing the transmitted biomechanical metrics, reflecting the energy absorption of the structural system. Individual investigation of stature and lordosis demonstrated that forces decreased, while moments were less variant with an increase in stature, whereas with an increase in lordosis both force and moments decreased.

Further, the spinal loads were grouped based on short and tall stature and lordotic and straight spines. Decrease in lordosis increased spinal forces. It can be attributed to the lack of shearing in the straight spine and resulting in more axial force, and this fits well with the Euler theory of columns. The greater moments in the straight spine compared to the lordotic spine may be due to the selected distribution in the stature subgroups. Straight models in short and tall subgroups were marginally longer than the lordotic models, and perhaps a further subdivision between the two stature and or between the angular ranges may shed light on this observation. This is a future study. The lumbar spinal forces increased with stature for straight spine, and it can be attributed to the lordosis bias in the tall spine models. The moments decreased with increase in stature. As stated above, further subdivisions in these parameters for additional understanding is a future study.

In summary, this finite element modeling study provides a range of spine loads that a female spine experiences during vertical loading simulating underbody blast impacts, and data were grouped on the external anthropomorphic metric, i.e., stature, and clinical measure of Cobb angle, i.e., curvature. As the study is specific to females, these results are applicable to this group of our population, and as the loading is vertical, it is applicable for the military scenarios [9] and civilian events such as falls and vehicle crashes [10,11]. The results may be useful to develop independent women injury criteria for the lumbar spine. A comparison between male spines can be made with the present approach of simulating male-specific stature and curvature to delineate the response differences between male and female spines.

# CHARACTERIZATION OF CELLULAR RESPONSE TO ENDOVASCULAR ABLATIVE THERAPIES

**S. Brocklehurst (1), D. Stolley (2), N. Ghousifam(1), E. Cressman(2), D. Fuentes(2), M.N. Rylander(1)**

## INTRODUCTION

Curative therapies are not available to greater than 80% of the patient population with hepatocellular carcinoma (HCC). There is a well-recognized need for novel methods that can intricately balance (1) treatment of the disease extent with (2) preservation of liver function and minimize the risk of recurrence and metastasis. Ablation and embolization are the two most common minimally invasive methods used in treating unresectable HCC. These are established therapies with a known survival advantage [1]. Thermally ablative therapies include radiofrequency ablation (RFA) and microwave ablation (MWA) and utilize thermal energy to destroy the disease. Embolization techniques utilize a direct injection of a chemotherapeutic agent or radiation into the hepatic artery with or without lipiodol and a procoagulant material to promote intratumoral retention. Thermoembolization (TE) provides a novel conceptual endovascular approach in which a bolus of acid chloride dissolved in an inert oily solvent delivers an exothermic chemical reaction. Recent investigations of TE indicate that it might offer unique advantages versus current techniques [2]. This approach is unique and combines the benefits of embolic and thermal- and chemical-ablative therapy modalities. The target tissue and vascular bed are subjected to simultaneous hyperthermia, ischemia, and acidic environments in a single procedure.

These complex conditions caused by the injection of acid chloride into the target tissue must be understood thoroughly in order to develop techniques to effectively destroy the intended cancerous tissue without negatively affecting the surrounding parts of the body. Accurate predictions of cell death are important towards these goals, and we have developed and calibrated preliminary mathematical models of the TE procedure using *in vitro* platforms that mimic vascularized liver. Validated cell damage models will accurately estimate the cellular damage as a function of hyperthermia, ischemia, and low pH stress that occurs during TE. The work presented in this paper focuses on the evaluation of how the conditions in the target tissue affect cells in order to develop an appropriate cell damage model.

## METHODS

To understand the independent contribution of hypothermia, ischemia, and acidic environments that work in concert during TE, we first isolated the decrease in local pH and localized hyperthermia to determine their individual impact *in* vitro for computational model development. These conditions were later combined to identify any synergistic effects between them. Normal human dermal fibroblasts were cultured in flasks and then passaged and seeded into 96-well plates for use in experiments. Each plate had 20-25 wells with a confluent monolayer of adherent cells coating their bottom surfaces. Cell survival ratios were determined 24 hours after exposure to hyperthermia and diminished ph using Cell-Titer blue assays. Additional unexposed control plates were measured alongside the exposed samples. The survival ratio was calculated as the ratio of absorbance between exposed and unexposed samples after subtracting the background absorbance observed from an acellular plate.

A temperature-controlled water bath was used to expose cells to hyperthermia. Cell culture media was removed from cell-seeded plates, and it was replaced with only 40 µL of media per well to reduce heating times. The plastic skirt of the plates was broken with pliers in 6 places around the circumference to allow water to flow under and cover the bottom surface without trapped air. At the start of the experiment, plates were taken from the incubator and placed directly into the water bath, and held down with aluminum plates at the same temperature as the water. One cell-bearing plate was tested simultaneously with a second, acellular plate with the same fluid volumes and a thermocouple placed in the bottom of one well. Temperatures were recorded throughout the exposure, and water bath settings were adjusted to maintain the target temperature within the plates. At the end of the experiment, plates were removed and shaken upside-down to remove the warm media rapidly,

then fresh media was added, and the plates were stored in an incubator. Cells were exposed to temperatures of 43, 45, 47, and 50 $^{o}$C for 10 to 60 minutes.

Phosphate-buffered saline (PBS) solutions with added glacial acetic acid were used to expose cells to acidic pH. Solutions with a pH of 6.00, 6.25, 6.50, 6.75, and 7.00 were prepared and passed through sterile filters. Media was removed from each well of a plate, then a timer was started, and 150 µL of acidified PBS was added to each well. The plate was kept in an incubator for between 10 and 60 minutes, then the acid solutions were removed in the same order they were added. A small pH probe was used to record the pH over time in identical cell-bearing plates. Combined pH and hyperthermia testing were performed using the pH exposure protocol listed above with heated solutions, then placing the plates into cell culture incubators set to 43 or 45 $^{o}$C.

Arrhenius damage models are used to provide a first-order estimate of the cell death resulting from the thermal and acidic pH exposure. Cell kill as a function of exposure to temperature is known to approximately follow an Arrhenius rate process [3]. Here, parameters of the Arrhenius damage model will be considered dependent on the presence of the acid as well. Arrhenius parameters are calibrated to the pathology response observed from *in vitro* cell damage testing. The Arrhenius parameters follow a log-linear relationship [4]. Regardless of the type of damage process being examined, a plot of the activation energy versus the log of the frequency factor that defines the Arrhenius model approximately follows a straight line. This empirical relationship has been measured independently by Wright[5] and He[6] and is used to constrain the damage model under variations in temperature and acidic ph exposure. A constrained optimization formulation is numerical solved to fit model parameters to the cell viability data. The parameters corresponding to the temperature-only data are recovered first. The parameters corresponding to pH are then recovered given the known Arrhenius parameters that fit temperature.

## RESULTS

Preliminary *in vitro* testing results have been applied toward the creation of cell death models based on exposure to hyperthermia and acidic solutions. As seen in Figure 1, a steady decline in cell survival was observed for acidic solutions, with the rate of death increasing with lower pH and longer exposure times.

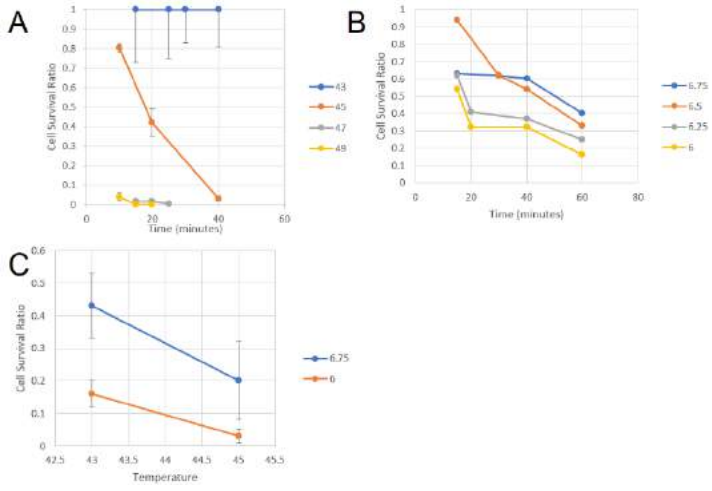

**Figure 1 – Experimental viability. A – Hyperthermia exposure B – Acidic pH exposure C – Combined hyperthermia and acidic pH**

Cell death was gradual during hyperthermia, until temperatures rose above 46 $^{o}$C after which cellular death was rapidly accelerated. Similar results were observed when hyperthermia and acidic solution exposure were combined in the same experiments under various conditions, with the combined cell death greater than each condition separately. These results further confirm the benefit of the combined effect of multiple mechanisms of cell injury implicity to TE.

Numerical optimization of cell damage model fits to viability data recovered an Arrhenius activation energy of 1.99e5 [J/mol] with a linear correction for pH as .994e4 [J/mol/pH] and frequency factor of 1.18e30 [1/s] as shown in Figure 2. The model fit of the predicted damage vs. measured damage achieves an $R^2$ values of .42.

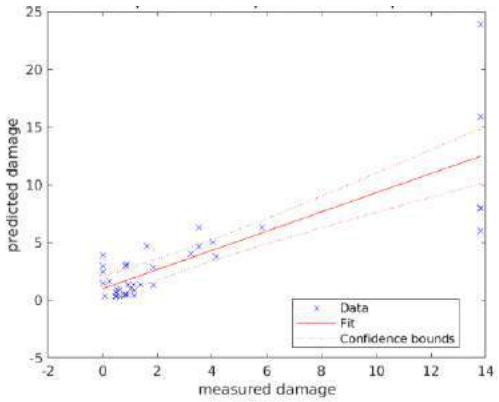

**Figure 2 – Fitting of Arrhenius model to viability data**

## DISCUSSION

The work presented in this abstract has successfully broken down the conditions present in the target tissue during TE in separate and combined experiments to observe the resulting cell death. In this way, the contribution of each variable to the therapeutic effect of TE can be quantitatively studied, and the synergistic interactions between multiple conditions can be identified. Initial results demonstrate the feasibility of calibrating a temperature and pH-dependent cell damage model to the observed viability data. Further studies will cross-validate the results to study the prediction accuracy of our cell damage modeling approach.

The results from this study will enable the development and calibration of mathematical models to understand and predict the independent and synergistic effects of hyperthermia and acidic environments caused by TE. Deeper insight into effective delivery of this new therapy will provide valuable knowledge applicable to the treatment of other cancers (e.g. renal cell, soft tissue sarcomas, metastatic colorectal, and neuroendocrine), immunotherapies, and other diseases beyond cancer

# CHARACTERIZING THE MECHANICAL RESPONSE OF CORNEA USING BIAXIAL TESTS

**M.E Emu, H. Hatami-Marbini**

Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, USA,
Email. hatami@uic.edu

## INTRODUCTION

The cornea is a transparent tissue that covers the front of the eye and has unique mechanical properties. The cornea and sclera protect internal parts of the eye globe, i.e., iris, pupil, and lens. The cornea is a tissue that is exposed to the outside environment; thus, it could undergo significant amount of external pressure that is, for example, caused by eye rubbing and sudden injuries. The cornea is composed of five layers, i.e. epithelium, Bowman's layer, stroma, Descemet's membrane, and endothelium. The stroma is its thickest layer and comprises about 90 percent of the corneal thickness. The corneal stroma is mainly composed of water, collagen fibers, and proteoglycans that are found in the form of many superimposed lamellae. The uniform diameter and regular arrangement of collagen fibers in the corneal stroma are essential for its transparency and unique optical properties. In addition, the stromal layer is responsible for the structural properties of the cornea.

The mechanical behavior of the cornea has been mainly investigated using the in vitro uniaxial tensile testing method and inflation method [1-3]. In the tensile experiments, uniaxial tensile force or displacement is applied to cornea strips for investigating their stress-strain behavior. In the inflation testing method, the deformation of corneal samples subjected to posterior pressure is determined. These testing techniques showed that the cornea has a rate-dependent and anisotropic mechanical behavior. However, the exact relationship between the corneal microstructure and anisotropic mechanical properties has not yet been fully characterized. The ability to understand and predict anisotropic corneal response is of significant importance for developing a proper material model that is able to accurately capture the corneal mechanical response. The biaxial tensile test is an experimental testing method that has been used to characterize the mechanical properties of biological tissues; however, it has not been commonly employed to investigate corneal biomechanics. The biaxial testing is particularly useful for characterizing the mechanical response of anisotropic materials, i.e. it could determine the influence of collagen fiber orientation on the mechanical response of a material. It is known that collagen fibers in the healthy human cornea have two preferred orientations orthogonal to each other, i.e. they are primarily in the horizontal (nasal-temporal) and vertical (inferior-superior) directions. The primary objective of the present work was to conduct biaxial tensile experiments to determine the anisotropic biomechanical response of the corneal samples.

## METHODS

Five porcine eyes were brought to the laboratory and corneal rings with sclera were dissected carefully from the eyeballs. A square sample was then prepared from the center part of each cornea-scleral ring. The samples were allowed to air–dry or were allowed to swell in solution until their thickness was about 800 um. A pachymeter (DGH Technology Inc., Pennsylvania) was used to measure the thickness of

specimens. The samples were mounted into the planar biaxial machine (ElectroForce TestBench), Figure 1. The samples were stretched along the nasal-temporal (NT) and superior-inferior (SI) directions at a stretch ratio of 1:1 with a displacement rate of 2 mm/min. A tare force was initially applied to remove slack, and ensure the firm grip of samples, and have a complete contact with the specimens. The samples were then strained up equally in each direction. The stress was defined as the measured force divided by the initial cross-sectional area of the samples in order to determine the stress-strain curves. The data was reported as mean ± standard deviation and one-way ANOVA with a significance level of 0.05 was used for the statistical analysis.

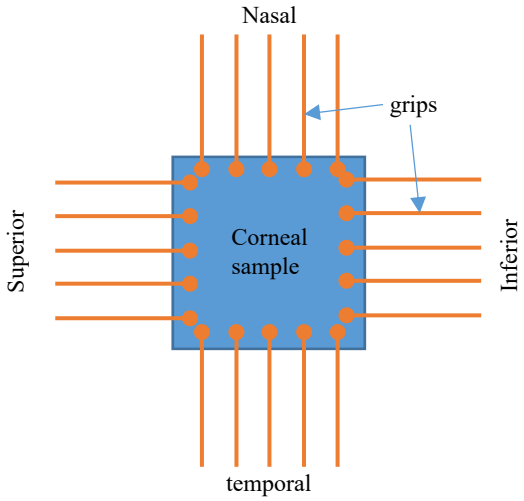

**Figure 1:** *The corneal specimens were gripped into the planar biaxial machine such that nasal-temporal (NT) and superior-inferior (SI) directions were aligned in the vertical and horizontal axes, respectively.*

## RESULTS

The experimental stress-strain curves are shown in Figure 2. From the stress-strain curves, the elastic modulus at 6% strain was calculated. The mean maximum stress was 0.09 MPa and 0.07 MPa in NT and IS directions, respectively. The variation in the maximum stress of NT and SI directions was statistically significant but the variation in the elastic modulus was not statistically significant.

## DISCUSSION

The primary purpose of this study was to characterize the anisotropic mechanical response of porcine cornea using the biaxial tensile testing method. A different nonlinear stress-strain curve was observed for each direction (Fig. 2). The collagen fibril orientations and arrangements inside the corneal stroma are responsible for the observed variation in tensile stress-strain curves.

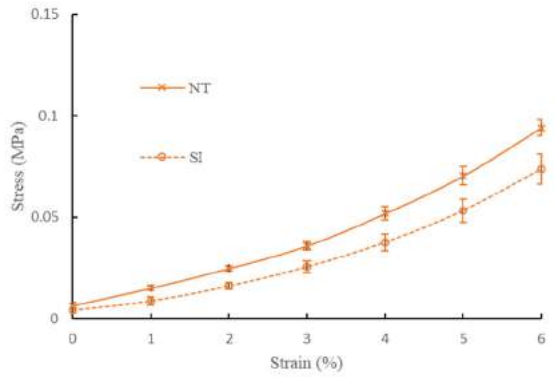

**Figure 2:** *Stress-strain curve of porcine corneal samples obtained from the biaxial experiments. The symbols show the average response and the error bars indicate one standard deviation.*

Previous imaging studies have shown a clear preferential orientation of collagen fibrils in the vertical and horizontal directions [4-5]. The mechanical measurements of the present study can be used along with these imaging results to relate the macroscopic response of the cornea in terms of its microstructure. The biaxial testing has a number of limitations. For example, the specimens were initially curved and they had variable thickness. The number of samples used in the present study was also small and future experiments are undergoing in our laboratory to decrease the variability in the measurements. Despite these limitations, the present work showed that biaxial experiments could be used to characterize the nonlinear anisotropic mechanical response of the corneal samples.

# PRECISE MEASUREMENT OF MICROPARTICLE VISCOELASTIC PROPERTIES USING A MICROFLUIDIC EXTENSIONAL FLOW DEVICE

**S. Ghanbarpour Mamaghani, J.B. Dahl**

Department of Engineering, University of Massachusetts Boston, Boston, Massachusetts, USA

## INTRODUCTION

Several studies have shown the clinical potential of mechanophenotyping or grouping of cells based on mechanical properties, for disease diagnostics and therapeutics. However, accuracy and precision of these measurements needs to improve before reliable clinical products are possible. Comparing measured cells stiffnesses across studies is challenging due to lack of standard calibration procedures, and uncertainty in the experiment parameters, namely the force that deforms cells [1]. Many microfluidic platforms that measure the mechanical properties of suspended single cells rely on approximations and empirical calibration due to complicated cell deformations and viscous stresses arising from close proximity to or contact with channel walls [2,3]. Our objective here is to develop accurate microfluidic mechanical measurement techniques using non-contact hydrodynamic deforming forces along with validation checks to confirm that experimental conditions closely match the mechanical model.

This work builds off our published proof-of-principle study demonstrating the first use of extensional flow device to measure average cell mechanical properties from the maximum observed stretch [4]. Here we improve our technique to measure single cell mechanical properties from an elongation test that captures the transient stretching and the steady-state strain plateau. We also use particle trajectory information to check that the suspended particle is entrained in the fluid and experiencing the viscous forces assumed in the mechanical model.

## METHODS

A microfluidic extensional flow device, commonly called a cross-slot, consists of two channels that intersect at 90 degrees, generates a linear planar extensional flow field. The initially spherical microparticles elongate into prolate ellipsoids in the extensional flow region that has a uniform extensional strain rate (Fig. 1a). Channel dimensions are 300 µm wide and 165 µm deep.

Agarose microparticles are fabricated using an emulsion technique from 0.5% (w/v) low melting point agarose. The agarose hydrogels are spherical and isotropic. The average particle diameter is approximately 45 µm. For microfluidic experiments, particles are suspended in aqueous 0.97% (w/v) methylcellulose ($\mu \sim 81.9$ mPa·s)

To measure mechanical properties, microparticles are observed stretching in the extensional flow region of the cross-slot. Videos are captured in phase contrast at 10x (Zeiss Axiovert 200 M) using a high-speed camera (JetCam, 9000 fps). In this study, two fluid flow rates are used, 10 and 15 mL/hr. Microparticle deformation and trajectories are analyzed using a custom MATLAB (MathWorks) analysis code. Microparticle strain over time is measured from ellipses fitted to detected particle edges. Kelvin-Voigt viscoelastic parameters for individual microparticles are obtained by fitting the mechanical model (described below) to the strain history (Fig. 1b).

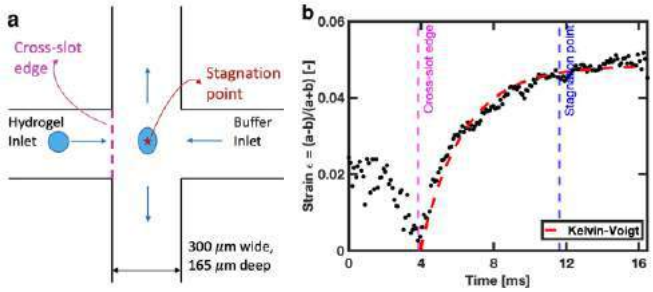

**Figure 1: a) Schematic of the extensional flow experiment to measure microparticle viscoelastic properties. b) An example of hydrogel deformation analysis. For this hydrogel, the fitted model yields $G_0$ = 1.519 kPa and $\tau$ = 0.0023 s**

Using the viscoelastic correspondence principle [5], the Laplace-transformed viscoelastic solution of a sphere deforming in planar extensional flow is obtained directly from the corresponding elastic

solution [6]. The result for a viscoelastic sphere is obtained upon taking the inverse Laplace transform:

$$\varepsilon(t) = \frac{5}{2}\frac{\mu\dot{\varepsilon}}{G_0}(1 - \exp i(-\frac{t}{\tau})) \quad (1)$$

Here we employed the Kelvin-Voigt constitutive model for a viscoelastic solid. $\varepsilon = (a-b)/(a+b)$ is the strain of the stretched microparticle where $a$ and $b$ are the long and short axes, respectively, of an ellipse fitted to the outer edge of the microsphere. $\dot{\varepsilon}$ is the extensional strain rate, $G_0$ is the relaxation modulus, and $\tau$ is the retardation time.

The actual extensional strain rate experienced by a particle could be different from what is expected based on flow rate and channel geometry, possibly due to subtle pressure fluctuations or a particle being too close to a wall. At midchannel height, deep cross-slot devices produce planar extensional flow with a stagnation point located at $(x_{sp}, y_{sp})$ has a velocity defined as:

$$\mathbf{v} = i\dot{\varepsilon}(-(x - x_{sp})\hat{\mathbf{x}} + (y - y_{sp})\hat{\mathbf{y}}) \quad (2)$$

By integrating the velocity components $u = \frac{dx}{dt} = -\dot{\varepsilon}(x - x_{sp})$ and $v = \frac{dy}{dt} = \dot{\varepsilon}(y - y_{sp})$, we obtain equations that relate the strain rate to the microparticle trajectory points ($x$, $y$) as it flows through the extensional flow region:

$$\ln\left(\left|\frac{x-x_{sp}}{x_0-x_{sp}}\right|\right) = -\dot{\varepsilon}t, \qquad \ln\left(\left|\frac{y-y_{sp}}{y_0-y_{sp}}\right|\right) = \dot{\varepsilon}t \quad (3)$$

$x_0$ and $y_0$ are the initial hydrogel coordinates at the video start. With Eq. 3, the extensional strain rate around the suspended particle can be computed from the linear regression slope of these functions of particle $x$ and $y$ coordinates vs. time.

## RESULTS

The box plots in Fig.2 shows similar distributions of relaxation moduli and retardation times for 0.5% w/w agarose microparticles stretched at two flow rates that differ by a factor of 1.5. We expect these parameters to be in close agreement between the two flow rates because the same concentration of agarose is used. However, inherent variation in small particle mechanical properties is expected due to slight differences in how they were polymerized.

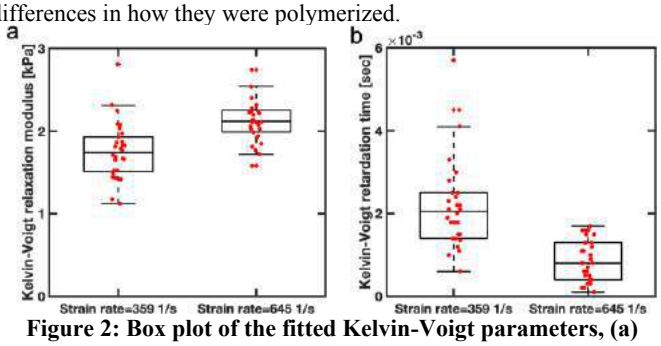

**Figure 2: Box plot of the fitted Kelvin-Voigt parameters, (a) relaxation modulus $G_0$ and (b) retardation time ($\tau$) for 0.5% w/w agarose microparticles at two strain rates. $N = 30$ hydrogels were analyzed for each experiment.**

To confirm the accuracy of the results, we compared the extensional strain measured from the microparticles' trajectories to the expected flow field in this device. Guillou et al. [4] and Foster et al. [7] have indicated that the strain rate inside the cross-slot is proportional to the average velocity ($U$) in the straight channels and inversely proportional to the channel's width ($w$):

$$\dot{\varepsilon} \approx \frac{2U}{w} \quad (4)$$

Fig. 3a shows the computing extensional strain rate experimentally using $x$ coordinates (orange line), and y coordinates (blue line) of one microparticle's trajectory. Both coordinates resulted in similar strain rate. The measured strain rates measured are in good agreement with the strain rates computed using the theoretical Eq. 4 (Fig. 3b). This agreement means that the particle is entrained in the fluid and flowing at midchannel height and experiencing the forces that we assume in the mechanical model used to extract the Kelvin-Voigt parameters.

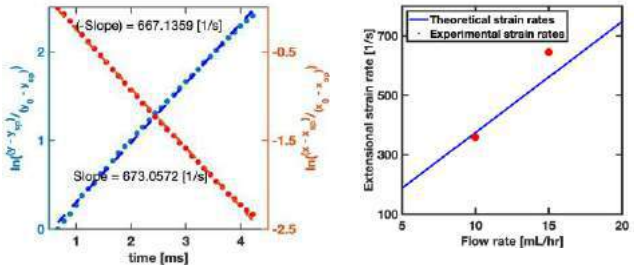

**Figure 3: a) Strain rate computed experimentally using the $y$ coordinates and $x$ coordinates of one hydrogel trajectory. Strain rate is obtained from the slope of the line of best fit. b) Comparison of strain rates computed theoretically using Eq.4 (blue line) and experimentally using microparticles' trajectory.**

## DISCUSSION

Our agarose microparticle mechanical property results agree with other non-contact microfluidic devices in which particle are deformed by hydrodynamic forces only and do not contact walls. Mietke et al. [8] measured an average modulus of 2.15 kPa for 0.5% w/w agarose microparticles. We measured an average relaxation modulus of 1.75 kPa, and 2.12 kPa in two experiments with different strain rates microparticles made of the same 0.5% w/w agarose formulation.

Accuracy of microfluidic measurement techniques can be improved by confirming that all controllable experimental parameters are the same values used in mechanical model that extracts mechanical properties from the observed deformation. That means independently measuring these parameters and quantifying the precision of control as opposed to relying on theoretical predictions or calibrations. Here we are used auxiliary particle kinematic information to confirm that the particles are entrained in the fluid and experiencing the extensional strain rate that we expect the device to generate. We will continue to validate our technique by independently measuring flow velocities with particle image velocimetry to further confirm extensional strain rates. We will also compare our viscoelastic property measurement technique to traditional methods on bulk agarose (rheometer) and agarose microparticles (atomic force microscopy). These comparisons will help us further prove our technique's ability to reproduce the standard creep test at the microscale and at high-throughput.

In addition to the creep test performed in this work on particles approaching the stagnation point, cross-slot microfluidic devices can perform relaxation test as particles leave the stagnation point. Next we will measure microparticle relaxation as they exit the extensional flow region towards the outlet channels.

## INTRODUCTION

Vascular contributions have been implicated with numerous disease states including cancer, heart failure, and neurodegenerative diseases, such as Alzheimer's Disease (AD). With each heartbeat, our distensible arterial system and circulating cerebrospinal fluid (CSF) within the brain act to dampen an otherwise damaging pulse wave. Studies have demonstrated that in disease states, the transmission of excess energy from cardiac pulsations to the cerebral microvasculature can lead to the formation of white matter lesions or hyperintensities (WMH) observable on T2-weighted MRI[1]. WMH have been linked to neurodegenerative disease states including dementia, Parkinson's disease, and AD. Further, WMH have proven to be better indicators of preclinical AD than any other conventional evaluation method[2]. Critical insight into the formation of WMH, as well as their early detection and risk mitigation could provide clinicians with a window of opportunity to treat aging individuals.

The presence of a sensitive microvasculature in the brain makes it particularly susceptible to damage. The established correlation of the lateral ventricle wall movement with the cardiac cycle suggests that this serial contraction/expansion elicits biomechanical stress within the periventricular white matter. Brain tissue is a highly organized, anisotropic material with viscoelastic properties that dissipates energy across each cardiac pulse and requires a delicate biomechanical balance of forces to maintain healthy brain clearance. Additionally, the unique shape of the ventricular system makes a 3D modeling analysis necessary for capturing true *in vivo* behavior.

We have developed a modeling pipeline to quantify stress in the brain over each cardiac cycle by employing a computational model informed by patient-specific anatomy and spatiotemporally resolved lateral ventricle wall movement. Using information obtained across multiple scales and modalities, we hope to provide insight into the biomechanical progression of WMH and enable early risk stratification.

## METHODS

### Imaging

MRI data was obtained for a healthy volunteer with temporally resolved motion of the lateral ventricle walls assessed using a single slice, fast echo-planar imaging (EPI) sequence (Siemens Prisma 3T scanner). This sequence provided spatial resolution of 1.97x1.97x4mm with a repetition time of 86ms, resulting in 1500 frames of dynamic lateral ventricle movement from the 129s scan. Wall movement was assessed by extracting an intensity profile across the parenchyma and ventricles. Additionally, structural MRI (T1- and T2-weighted) sequences were used to obtain high spatial resolution images of the brain tissue, 1x1x1mm, for segmentation.

### 2D Computational Modeling

T1-weighted images were used to generate image segmentations at the widest level of the lateral ventricles using ITK-SNAP. Following surface geometry creation in Geomagic (3D Systems), finite element meshes were generated and simulations were conducted using an in-house python code incorporating DOLFIN and the FEniCS open-source software[3]. Viscoelastic properties of human white matter were obtained from literature sources with homogenous conditions of Poisson ratio of 0.48, short term modulus of 0.25 kPa, long-term modulus of 1.5 kPa, and viscosity parameter of 3.87 kPa-s[4]. CSF was also modeled as a soft, viscoelastic solid with a Poisson's Ratio of 0.48 and constant Modulus of 0.2 kPa and viscosity parameter of 0.1 kPa-s to mimic fluid-like distension. 2D modeling boundary conditions include (1) Neumann boundary condition assigned to the inner wall facets of the lateral ventricle – simulations were iteratively repeated to produce spatiotemporally varying displacement fields most similar to EPI-measured displacement fields; (2) zero displacement Dirichlet boundary condition prescribed on the facets of the outer dura - to represent fixation of the skull.

## 3D Computational Modeling

We have also implemented a previously developed 3D brain modeling pipeline that enables construction of patient-specific geometries and accounts for 3D anisotropic properties using Diffusion Tensor Imaging (DTI)**.** The in-house pipeline shown in Figure 1 automatically processes T1-weighted and DTI scans to generate the following patient-specific outputs: (1) 3-label tissue segmentation, (2) 133-label deep brain labeling, (3) whole-brain tractography, (4) 3D nested geometry including idealized skull and skin layers using in-house MATLAB/Python code, and (5) whole-head finite element mesh with embedded fiber orientations using a combination of commercial meshing software and in-house MATLAB/Python code. This modeling pipeline is currently being extended to conduct automatic finite element analysis in 3D. A transversely isotropic hyperviscoelastic 3D material model will be informed by patient-specific fiber orientations and published values of relevant parameters. Boundary conditions will seek to replicate in-vivo brain loading as informed by time-resolved MRI.

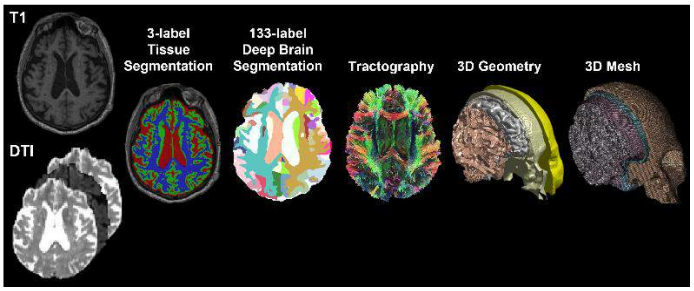

**Figure 1:** Patient-specific 3D Modeling pipeline. Inputs of T1-weighted and Diffusion Tensor Magnetic Resonance Imaging are used to generate segmentations, tractography, nested geometry, and finite element mesh with embedded fiber orientations and idealized skull.

## RESULTS

Preliminary results of the 2D model demonstrated stress clustering around the horns of the lateral ventricles, as shown in Figure 2. These locations align with commonly reported locations of periventricular WMH formation. The 3D modeling pipeline has demonstrated the ability to process large cohorts of patients from T1-weighted and DTI scans through generation of a finite element mesh with embedded fiber orientations.

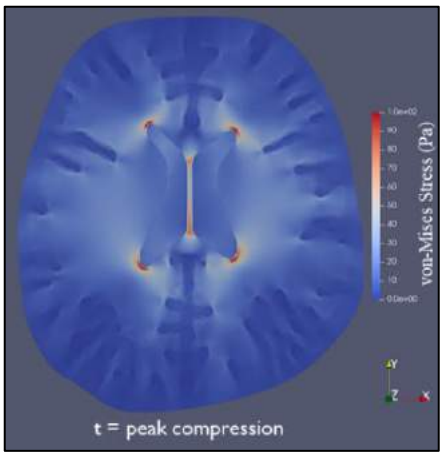

**Figure 2:** Normalized von-Mises stress at peak compression showing regions of elevated stress around the horns of the lateral ventricles.

## DISCUSSION

The effect of the cardiac pulse on highly anisotropic brain tissue depends on subject-specific brain geometry which can vary greatly across individuals. Our modeling pipeline allows to maximize patient-specificity and account for anisotropic, variable brain volumes based on T1-weighted and DTI scans. Preliminary data has demonstrated that there is merit in further investigating the underlying biomechanical drivers of tissue damage that lead to neurodegeneration. This modeling methodology provides the fundamental groundwork required for a larger scale study seeking to identify biomarkers of WMH formation in a cohort of neurodegenerative and aging individuals.

The 2D approximations of biomechanical stress distribution in a healthy volunteer represent a significant simplification made in the current study. 2D computational models of the brain fail to capture the non-symmetric 3D organization of the brain which is likely to reduce the model's predictive capability. We are extending our modeling approach to simulate various degrees of disease and neurodegeneration in 3D. Additionally, modeling patient-specific fiber orientations will allow for new computational parameters, such as axonal strain, to be incorporated along with more accurate material models.

Combining a multimodality imaging approach with state-of-the-art computational modeling, will allow us to elucidate the biomechanical mechanisms by which mid-life cardiovascular disease promotes degeneration of periventricular white matter in late-life, as well as and develop clinical risk stratification metrics.

# MECHANICAL ANCHORING DRIVES STEM CELL DIFFERENTIATION AND TISSUE MATURATION IN TISSUE ENGINEERED LIGAMENT-TO-BONE ENTHESES

## INTRODUCTION

Ligament-to-bone attachments, or entheses, are structurally complex tissues that transfer load from elastic ligament to stiff bone via a compliant fibrocartilage region with gradients in organization, composition, and cell phenotype. These gradients are not restored in healing, repair, or in engineered replacements, resulting limited repair options and high failure rates [1]. Previously, we developed a novel culture system that guides anterior cruciate ligament (ACL) fibroblasts to form postnatal-like ligament-to-bone entheses via a zonal tensile-compressive culture environment [2]. Specifically, compressive restrains at the edge of the constructs produce a tensile-compressive environment which guides cells to produce 3 unique zones of organization and composition, with zone specific cell morphologies, recapitulating early postnatal enthesis properties [2]. While these engineered entheses are promising replacements, ACL fibroblasts are not an optimal clinical cell source. Human mesenchymal stem cells (hMSCs) are more clinically relevant; however, it remains a challenge to guide hMSCs to form the complex zonal and cellular gradients necessary for functional entheses [1]. The objective of this study was to investigate if the tensile-compressive nature of our culture system is sufficient to drive zonal differentiation of stem cells and produce zonal ligament-to-bone entheses similar to ACL fibroblast seeded constructs.

## METHODS

Engineered constructs were made by individually mixing human MSCs (hMSCs) from 3 donors or bovine immature ACL fibroblasts with rat tail type I collagen to form 20 mg/mL sheet gels at $5x10^6$ cells/mL as previously described [2]. Rectangular constructs (30x8 mm) were cut from the sheet gels and cultured in our clamping device (Fig 1A) for up to 4 weeks. At completion of culture, constructs were cut into half-samples for analysis of organization and mechanics or middle (M), transition (T), and clamped (C) regions for analysis of matrix composition and gene expression (Fig 1A). Zonal collagen organization was analyzed via confocal reflectance. DNA, glycosaminoglycans (GAGs), and collagen content were measured via Picogreen, DMMB, and hydroxyproline assays. Quantitative RT-PCR was performed on 4 week hMSC constructs to measure gene expression of types I and X collagen, Ihh, Gli1, Runx2, ALPL, Scx, and Sox9, normalized to GAPDH. Mechanical testing was performed across the transition zone via tensile tests at 0.75% strain/sec to failure. All data are expressed as mean ± SD. Significance was determined by 2-way ANOVA and 2-way repeated measures ANOVA with Tukey's post-hoc ($p < 0.05$).

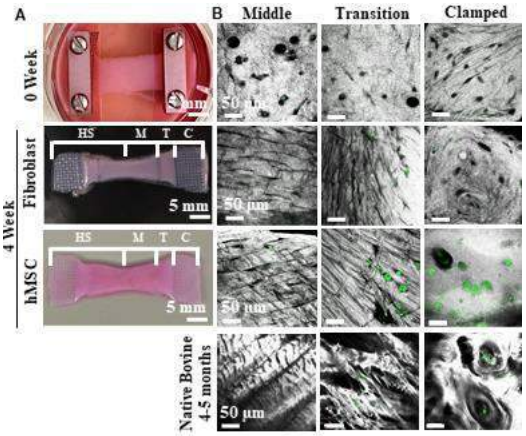

**Figure 1: A) Clamping device and constructs at 0 & 4 weeks with analysis regions depicted. B) Confocal reflectance of zonal collagen organization. Collagen = grey, cells = green.**

## RESULTS

Confocal imaging revealed samples begin as unorganized matrix for both hMSC and ACL fibroblast seeded constructs. By 4 weeks, ACL constructs develop early postnatal-like zonal collagen organization with aligned parallel fibers in the mid-section, perpendicular fibers in the transition, and unorganized collagen under the clamp. hMSC constructs developed similarly, however had accelerated zonal organization by 2 weeks (data not shown), and by 4 weeks fibers in the transition shifted

from perpendicular alignment to more direct insertions, indicative of more mature organization and later stage development (Fig 1B, [3]).

Analysis of zonal matrix composition revealed hMSC constructs had no changes in zonal DNA concentration throughout culture, while ACL constructs had significant increases in DNA content in the middle and transition regions by 4 weeks (data not shown). Both hMSC and ACL constructs maintained steady collagen content across all regions at ~60% of native tissue throughout culture (data not shown) [4]. Finally, hMSC constructs had significantly increased GAG/DNA in all regions by 4 weeks with significantly more GAG accumulation in the clamped region, while GAG/DNA remained constant in all zones for ACL constructs (data not shown).

Tensile tests across the transition region revealed hMSC constructs significantly increased the elastic modulus of the enthesis region to ~5.5 MPa by 4 weeks, while ACL constructs remained under 2 MPa throughout culture (Fig 2A). Additionally, hMSC constructs had a 2-3 fold significant increase in toe modulus, ultimate tensile strength (UTS), and transition stress (Fig 2A-B). There were no differences in strain properties between hMSC and ACL constructs by 4 weeks (Fig 2C).

Gene expression analysis of 4 week hMSC constructs revealed that key genes associated with enthesis development such as Ihh, Gli1, Scx, Sox9, and type X collagen were upregulated in all regions in relation to day 0 cell controls (data not shown). Normalizing zonal gene expression to the middle region revealed zonal differences at 4 weeks with clamped regions having significantly upregulated expression of Indian Hedgehog (Ihh), Gli1, Runx2, and type I and X collagen compared to middle regions (Fig 3). Additionally, ALPL expression was trending in upregulation compared to middle ($p$ = 0.06) and transition ($p$ = 0.08).

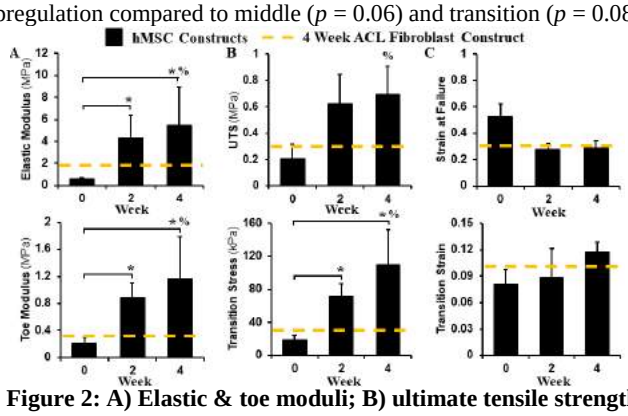

**Figure 2: A) Elastic & toe moduli; B) ultimate tensile strength (UTS) and stress at toe to linear region transition; and C) strain at failure and transition. *Significance to bracket, %Significance to 4 week ACL construct mechanics ($p$<0.05). N=2-3 donors, n=3-4.**

## DISCUSSION

Four weeks of static tensile-compressive culture hMSC seeded high density collagen gels resulted in enhanced zonal collagen organization, zonal composition, and significantly increased mechanical properties compared to ACL constructs, as well as zonal expression of key enthesis developmental markers. Both hMSC and ACL constructs developed similar collagen organization in the middle and clamped regions, mirroring immature native tissue organization; however, hMSC constructs demonstrated a marked shift in collagen organization from perpendicular fiber alignment in the transition to more direct fiber insertions. This shift in organization resembles more mature enthesis organization where fibers shift from being perpendicular to the ligament to more parallel with the ligament, while maintaining a degree of disorganization [3]. This organization in mature entheses is critical for proper mechanical function and reduction of stress concentrations [5]. Previously, we have observed similar organizational shifts in the transition region after 10 days of dynamic

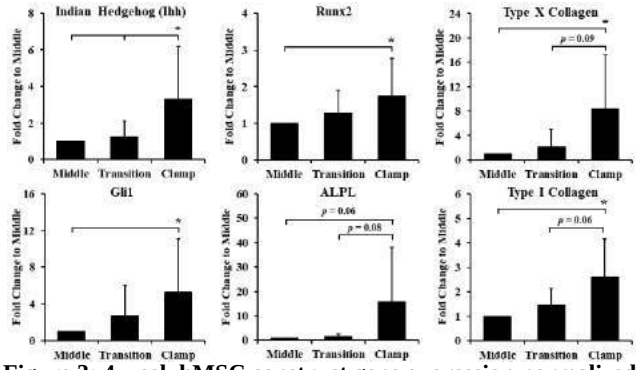

**Figure 3: 4 week hMSC construct gene expression normalized to middle region for enthesis markers Ihh and Gli1, mineralization markers Runx2 and ALPL, and matrix markers type X and I collagen. *Significance to bracket ($p$<0.05). N=2 donors, n=3-4.**

mechanical stimulation in ACL constructs [6]. These organizational changes in ACL constructs also resulted in a significant 2-3 fold increase in moduli and stress properties [6]. Interestingly, while ACL constructs require further mechanical stimulation to reach this level of maturation, hMSC constructs develop these properties with simple static clamping, suggesting mechanical forces of the clamping system may be sufficient to drive hMSC differentiation into appropriate cell phenotypes that can more readily facilitate these changes.

Interestingly, only hMSC constructs had zonal GAG/DNA changes throughout culture, with significantly increased GAG/DNA under the clamp compared to the middle region. This indicates that the compressive environment under the clamp drives the hMSCs to shift to a more chondrocyte-like phenotype similar to that observed in early postnatal enthesis fibrocartilage [3,7]. Mirroring compositional changes, hMSC constructs also had zonal gene expression differences for key enthesis developmental markers. In particular, significant upregulation was observed under the clamp for Ihh and Gli1, known to be critical for proper development of the fibrocartilage regions of the enthesis [8,9]. Additionally, markers commonly associated with mineralization of the fibrocartilage tissue, such as Runx2, ALPL, and type X collagen, were upregulated in the clamp region as well [8]. Collective upregulation of these key markers under the clamp suggests zonal differentiation of hMSCs into fibrochondrocytes or hypertrophic fibrochondrocytes, cells known to populate the fibrocartilage regions of late postnatal entheses [1,2]. Evaluation of gene expression at 0 and 2 weeks, and evaluation of zonal types I, II, and X collagen accumulation are ongoing. This study provides insight into how tensile-compressive culture conditions can drive zonal hMSC differentiation and tissue maturation in engineered ligament-to-bone tissues, ultimately producing the complex gradients of the enthesis. These constructs hold great promise as ACL replacements and provide an *in vitro* model to investigate driving stem cell regeneration for ligament-to-bone repair.

# DIRECT NUMERICAL SIMULATION OF BLOOD FLOW WITH CELLS IN RETINA VASCULAR NETWORK

**Kacper Ostalowski (1), Jifu Tan (1)**

(1) Department of Mechanical Engineering, Northern Illinois University, DeKalb, IL, USA

## INTRODUCTION

Blood flow in capillary network is important for delivery of oxygen, water, nutrient, and removal of waste substance. Modeling the blood flow in capillary network is important for both fundamental understanding the multiphase flow and clinic applications. However, it is challenging because of the complex network structure with branches and loops and deformable cells, which needs to be explicitly considered due to the size of cells is comparable to capillary vessel. Previously, Balogh et al. presented the first direct numerical simulation of 3D cellular-scale blood flow in physiologically realistic microvascular networks using the finite volume method coupled with finite-element method[1]. Bernabeu et al. coupled the lattice Boltzmann method (LBM), finite element method, and immerse boundary method to study the hematocrit in cancer vascular network and found uneven hematocrit split in the downstream branching point[2]. However, these works either did not consider the heterogeneous blood cell suspensions in vascular network or did not study the blood cell transport in vessel blockage in vascular network. This paper tried to bridge the gap in studying the transport of cells in the complex vascular network and with stenosis. To the best of authors' knowledge, this is the first time to simulate blood cell transport in a patient-specific vascular network with stenosis.

## METHODS

In this work, the multiphase flow in a patient-specific retina capillary network, as shown in Figure 1(a)Figure 1, was simulated by the LBM coupled with particle-based cell membrane models through the immersed boundary method. Both the red blood cells (RBCs) and white blood cells (WBCs) were modeled as cell membranes.

Briefly, the LBM was used to approximate the incompressible fluid flow with governing equations

$$\nabla \cdot \boldsymbol{u} = 0 \quad (1)$$

$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot (\nabla \boldsymbol{u}) = -\frac{1}{\rho}\nabla p + \nu \nabla^2 \boldsymbol{u} + \boldsymbol{g} \quad (2)$$

where $\boldsymbol{u}$ is the velocity, $t$ is time, $\nu$ is the kinematic viscosity, $\boldsymbol{g}$ is the external body force. The LBM solver was based on open source packages Palabos (Parallel lattice Boltzmann solver)[3].

The cell membranes are made of interactive particles with potentials resisting stretching, bending, area/volume changes.

$$U = U_{stretch} + U_{bend} + U_{area} + U_{volume} \quad (3)$$

The membrane nodal forces are calculated from potential functions, and the position are updated based on the Newton's law of motion. The detailed potential forms can be found in our previous publication and others[4], [5]. The membrane model was implemented in LAMMPS (large-scale atomic/molecular massively parallel simulator) [6].

The coupling between the cell and the flow was done through the immersed boundary method where the cell interpolated velocity from fluid, and the fluid feel the existence of the cell through spreading the restoring force through the body force term in Eqn (2). Details on the implementation and validations can be found in Ref.[4], [7].

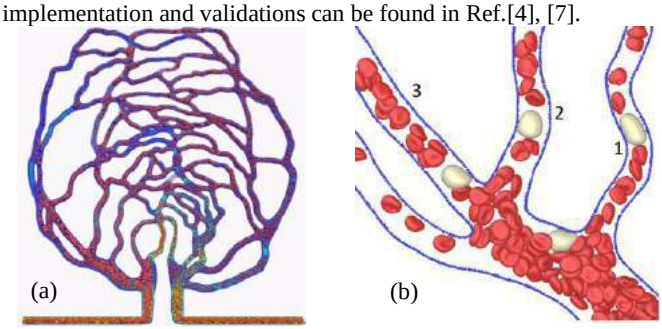

**Figure 1: (a) Snapshot of RBCs in a patient specific retina vascular network. The background color shows the velocity. (b) the zoom-in view of the simulation with both RBCs (red) and WBCs (white).**

## RESULTS

### Dynamic stalling of flow in the network

The complex geometry of the curved vessels and bifurcations can lead to cells temporarily being stuck at the vessel wall near flow stagnation regions. The aggregated cells will increase the size of the stagnation region and change local flow. E.g., RBCs were found to accumulate and create a blockage at a T-shaped bifurcation as seen in Figure 2(a).

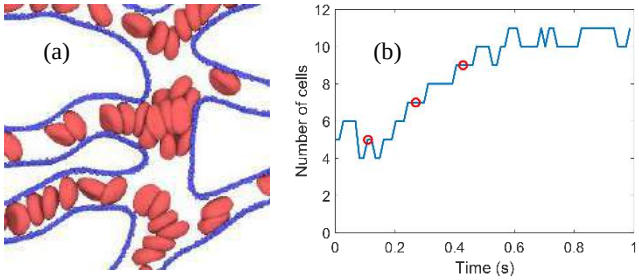

**Figure 2: (a) The aggregation of cells in the T-junction of the vessel network. (b) The growth of the cell aggregation in flow.**

A large stagnation zone was created where the mass of cells built up which remains for the entire duration of the simulation. The size of the blockage varied over time and eventually stabilized during our simulation, see Figure 2(b). At its largest, flow was significantly reduced at the upstream vessel and through the bifurcation region. As a result, the downstream vessel experienced reduced hematocrit compared to surrounding vessels. The cell blockage can affect local flow rate and hematocrit distributions.

The simulation with mixed RBCs and WBCs showed that the flow rate reduced significantly when a WBC was squeezing through the vessel (Data not shown here, a snapshot of the simulation can be found in Figure 1(b)Figure 1). It is expected that the large size of WBC would increase the resistance of the vessel.

### RBCs oscillation in the network with partial blockage

The growth of plaque may narrow the blood vessel, which leads to the investigation of RBC transport in a partially blocked blood vessel. In the simulation, 50% of the cross section in a vessel was blocked, as shown in Figure 3(a). Flow with RBC suspensions was simulated through the partially blocked network. Interestingly, oscillatory flow was observed in a vessel near the obstruction. The cells oscillating in the vessel were shown in different colors in the dashed box in **F**igure 3(b).

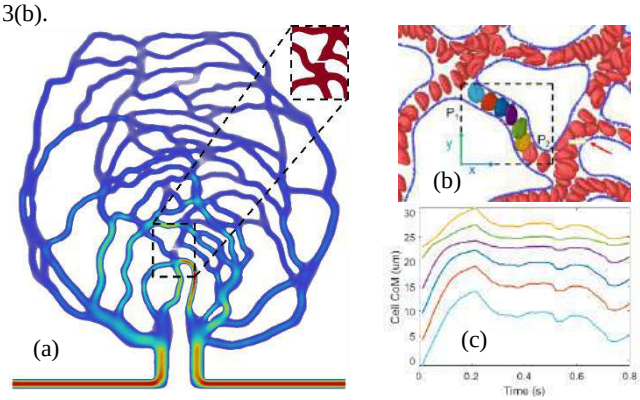

**Figure 3. (a) Simulation of blood flow with a stenosis in one of the blood vessels in the center region, as indicated by the inset. (b) The oscillating cells trapped in the vessel bounded by a dashed box. (c) the oscillating center of mass for each trapped cell.**

The partial blockage reduced the flow in the oscillating vessel by changing the pressure gradient. The pressure at both ending points (P1 and P2 in Figure 3(b)) showed fluctuations (data not shown here). In general, the inclusion of RBCs through the vasculature had a small effect on the pressure distribution, but the effect can be significant near vessels where the pressure gradient was already low. The oscillations in flow direction in a vessel was most likely caused by variations in the local hematocrit at either end of the vessel. The supply of oxygen would be interrupted since no new cells enter the vessel. Indeed, the time history of the center of mass of the six trapped cells in x direction further confirmed the oscillation of cells, as shown in Figure 3(c).

## DISCUSSION

The simulation showed that dynamic stalling can happen in a vascular network with explicit cells in certain branched regions. Without cells, the fluid flow in the retina network is steady without any fluctuations. However, the multiphase nature of blood flow due to cells in the vessel change the flow to be unsteady with fluctuating velocities, see Figure 1(a). In some branched vessel, there is no cell entry due to the plasma skimming effect in capillaries. On the other hand, simulation results with partial blockage showed that cells may be trapped in certain blood vessel due to the narrowing of other vessels. In such cases, the supply of oxygen may be stalled. This could be fatal if the stalling lasts for a long time for cerebral capillaries due to the high metabolic demand of continuous oxygen in brain tissue. In addition, the blood flow rate was reduced significantly when a WBC squeezed into a capillary lumen due to the large size of WBC. Similar results were reported in experimental work too. E.g, the dynamic stalling was observed in cerebral capillary network by obstructing WBCs in experimental strokes[8]. In their work, the adhesion between WBCs and the injured vessel wall contributed to the obstruction. In another study, even in a healthy mouse brain, about 7.5% of ~200 capillaries had at least one stall in awake mice with chronic widows during a 9 min observation under observation[9]. The similar oscillating of RBCs were also reported in a mouse retina vessel network [10]. All these experimental studies confirm that our model can capture blood transport at cell size scale in capillaries including dynamic stalling. The model will provide tools for future investigation of stalling events in capillary pathologies.

Note that the current study only considered the mechanical effect of cells in the flow. The pulsative nature of the flow was not considered, which was shown to affect the RBC flux in capillaries[10]. In capillary networks, the obstruction in blood flow will trigger vasodilation to restore the flow. Further improvement of the model is needed to include chemical signaling to study the mechanobiology in capillaries.

# HETEROGENEITY IN CELL DISTRIBUTION DUE TO COLLECTIVE ORGANIZATION LEADS TO LOCALIZED HIGHER STRESSES.

**M. Jebeli (1), S. P. Lopez (1), Q. Wen (2), K. Billiar (1)**

(1) Biomedical Engineering, Worcester Polytechnic Institute, Worcester, Massachusetts, USA
(2) Physics, Worcester Polytechnic Institute, Worcester, Massachusetts, USA

## INTRODUCTION

Collective cell behavior drives many crucial biological phenomena including morphogenesis, tissue repair, and cancer metastasis. These behaviors arise from cell interactions in addition to individual cell behavior [1], as it has been shown that an individual cell's behavior differs when in communication with other cells [2]. Previous studies on collective cell behavior have focused mainly on epithelial monolayers showing that cells are relatively uniform throughout the monolayer and cells are extruded when the layer become dense. Further, when cultured on protein islands which provide geometrical constraint, non-uniform patterns of proliferation more on edges, and cell alignment emerge due to gradients in mechanical stresses and contact guidance at the edges [3, 4]. Cell-cell transmission and build-up of stresses within these monolayers and constrained cell aggregates have been estimated with computational models since they cannot be directly measured. The models suggest symmetric stress distribution in circular aggregates, higher on the edges and lower in the center yet they assume uniform cell properties.

In our observations of valvular interstitial cells (VICs), we noticed more heterogeneity of cell distribution than reported with other types of cells on micro contact printed islands regardless of the shape. VICs crowd in the middle, yet, in contrast to epithelial cells, they do not extrude as single cells. Rather densification occurs at the center of aggregates which leads to apoptosis, likely driven by collective cell behavior and reduction of stress in the center which is predicted by our computational models when radially varying modulus or contractility are included [5]. We have also observed heterogeneity in the cell distribution and formation of multicellular bands spanning the 200 µm circular 2D aggregates [5]. Further, rather than high tractions around the edge of each pattern, we observed hotspot tractions associated with the cells spanning the aggregates.

We hypothesize that the heterogeneity observed in traction force maps is due to the formation of bands with more elongated cells at the endpoints and the formation of local hyperconfluent regions with rounded cells within constrained cell aggregates. To quantify the mechanical state of the cells within the aggregates, we measure the collective forces that cells apply to the substrate using traction force microscopy (TFM). Further, we utilize relatively large 400 µm diameter microcontact printed circular islands to increase the homogeneity of the cell behaviors and minimize the ability of single cells to span the pattern.

## METHODS

Substrate preparation

Circular collagen patterns of 400 µm were printed onto 19.2 kPa polyacrylamide (PA) gels. We used the size of micropatterns of 400 µm to minimize single cell spanning of the pattens and increase the homogeneity of the collective behavior i.e., obtain a more clear differentiation between edge and center of the cell islands.

The surface of each substrate was sandwiched between glass coverslips coated with fluorescent micro-beads to transfer fluorescent displacement tracking beads to the surface of the gel which were prepared per [5]. To analyze the displacement of the beads, a custom MATLAB code was used[5].

Direct microcontact printing

To form microcontact printed protein islands, collagen was directly printed on the previously described PA gels per [5].

Cells and media

Porcine aortic VICs, isolated per [6] from a heart obtained from a local abattoir (Blood Farm, Groton, MA), were chosen as a primary fibroblastic cell type; porcine VICs are commonly used for CAVD research due to the similarity to human VICs. Cells were cultured in DMEM with 10% FBS and 1% Antibiotic/Antifungal at 37 °C in 10% CO2.

Experimental design

VICs were seeded at passage 3-6 at 12,500 cells per $cm^2$ [7] on microcontact printed substrates. 24 hours post-seeding, the aggregates

were imaged with phase contrast and red fluorescent channels; then utilizing trypsin, the cells were detached from the substrate and a red fluorescent image was captured again. Two red fluorescent images, with cells attached and after cells detachment, were analyzed using the customized MATLAB code, to calculate the displacement on the surface of the PA gel.

## RESULTS

Heterogeneity of cell distribution in microcontact printed aggregates

Despite the large size of the protein islands, we observed heterogeneity in cells distribution and formation of multicellular bands spanning across the protein island diameter. Figure 1 shows a four-day time-series images in which a clear multi-cellular band is formed. From observations of many aggregates, it appears that banding occurs over time when cells have more affinity with lining up with each other than forming symmetric rings due to contact guidance around the edges. The bands do not disappear, rather they strengthen over time. This banding is not predicted by existing computational models and the mechanisms driving this behavior are unclear.

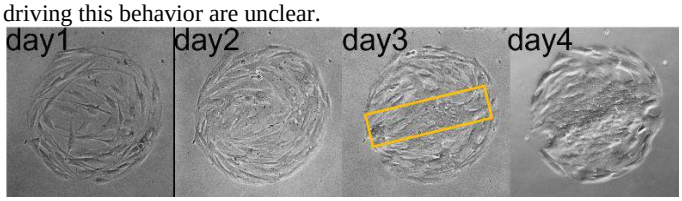

**Figure 1. Phase images of an aggregate of 400 µm over 4 days, showing the heterogeneity of the cell distribution and formation of band crossing over the aggregate surface, yellow rectangle showing the cells alignment and band formation.**

Hyper-confluency and banding changes the mechanical state of the cells in aggregate

Rather than generate high traction stresses uniformly around the circumference of the patter as is observed for epithelial cells, the calculated traction forces for the VICs is significantly higher at the endpoints of the bands (Fig. 2).

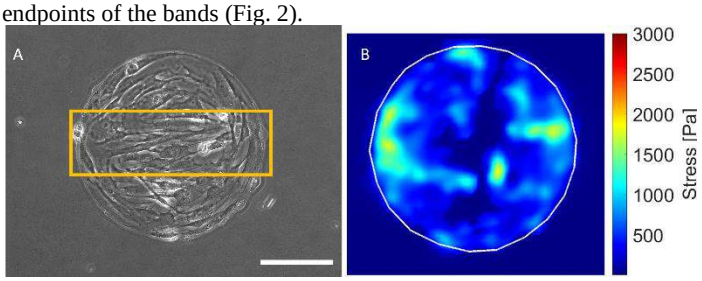

**Figure 2. TFM demonstrates that the cells apply higher forces to the substrate at the endpoints of the bands, shown by yellow rectangle, collectively. A) Phase image of a sparse aggregate. B) TFM analysis of the aggregate in sparse stage. Scale bar = 200 µm.**

Further, to quantify the forces cells apply to the substrate in local hyper-confluent areas, we have imaged a hyper-confluent aggregate, with a clear local hyper-confluent region, Figure 3. In the TFM image, Fig 3B, it is evident that the cells in hyper-confluent regions, even though very high in number and density, apply significantly lower forces to the substrate compared to the endpoints of bandings and the areas with elongated cells.

## DISCUSSION

Multicellular banding creates heterogenous stress patterns

We hypothesized that with the larger protein islands, we would observe more uniform traction force patterns with high stress on the outer circumference and low tractions in the center. Indeed, single cells were no longer able to span the islands; however, we still observed substantial heterogeneity in the traction force maps. To our surprise, large multicellular bands formed across the patterns rather than forming radially symmetric patterns with predominantly circumferentially cell orientation. We observed that the traction stresses were clearly higher at the endpoints of the bands. Interestingly, in the center of the bands the cell density is very high, which is correlated with low stress and increased rates of apoptosis.

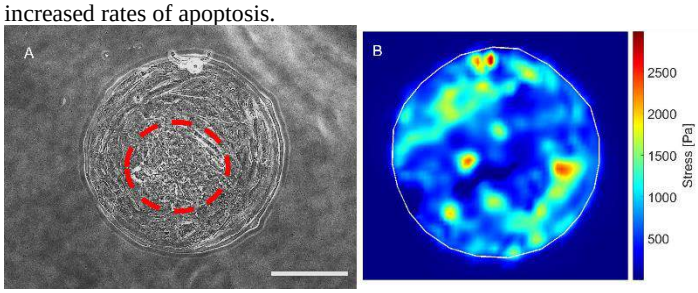

**Figure 3. TFM shows that in hyper-confluent regions, shown by red dotted circle, the cells apply significantly lower forces to the substrate collectively. A) Phase image of a hyper-confluent aggregate. B) TFM analysis of the aggregate in hyper-confluent stage. Scale bar = 200 µm.**

Asymmetric mechanical state

Previous studies have shown that cells require a homeostatic tension to survive; for example, states of low cell stress initiate apoptosis [8, 9]. Furthermore, indicators of high cell tension are localized to the edges of aggregates [10], while indicators of low cell tension are found in central regions [5]. Here we showed that these signals are not symmetric with primary mesenchymal cells and change with heterogeneity in confluency levels; we showed heterogeneity in cell distribution, which leads to asymmetric traction forces, which are higher at the two endpoints and not uniform around the edges.

## INTRODUCTION

The maternal body undergoes multiple physiological changes in the cardiovascular system during pregnancy [1]. During normotensive pregnancy, cardiac output, arterial compliance, and heart rate increase, causing vascular resistance and blood pressure (BP) to decrease [2, 3]. The drop in vascular resistance caused by vasodilation are indicators of increased arterial distensibility [4]. However, attenuations of these physiological changes in maternal cardiovascular system, have been linked to the pathogenesis of maternal cardiovascular disease and mortality [5].

Aortic and hemodynamical properties during pregnancy are commonly evaluated using non-invasive methods in humans or rats, by measuring pulse-wave velocity and augmentation index (AIx), both of which are indicators of structural stiffness [6, 7]. However, the changes in aortic mechanical properties that are responsible for the functional changes in the cardiovascular system during pregnancy are largely unknown. To address this question, we aimed to investigate the structural and functional properties of the thoracic aorta in C57BL7/6 pregnant and virgin female mice. We hypothesized that the mechanical response of the murine thoracic aorta adapts during pregnancy.

## METHODS

*Sample groups.* Pregnant C57BL/6 mice at gestation day 17 (N=2) were purchased from the Jackson Laboratories (Bar Harbor, Maine) and were used for the late-gestation experimental group. Nulligravida female C57BL/6 mice (N=2) at 10 weeks of age served as nonpregnant, age-matched controls.

*Blood Pressure.* Blood pressure measurements were collected on each mouse using a non-invasive tail-cuff system (CODA; Kent Scientific) before sacrifice.

*Sample collection and preparation.* Mice were euthanized and a ~5mm sample of the descending thoracic aorta (DTA) was excised. Samples were cleaned from excess perivascular tissues and fat. Lateral branches on the tissue were tied with 9-0 nylon sutures. DTA specimens were cannulated on the proximal and distal end onto custom-made glass micropipettes. Ring samples were taken from either end of each specimen to measure unloaded thickness.

*Biaxial Mechanical testing.* Prepared samples were mounted onto a custom-made biaxial testing system which is controlled by a computer (Fig. 1) [8]. The outer diameter of the vessel was measured using a camera. Linear actuators controlled the axial stretch, and a load cell measured the axial force. Luminal pressure and axial length were set through a custom LabView Program. Samples were acclimated, pre-conditioned, and their axial stretch was estimated. Cyclic pressure-diameter and force-length tests were done on each sample. Following mechanical testing, a nonlinear regression was implemented to fit a four-fiber family constitutive model to the experimental data. Estimated material parameters were used to predict mechanical variables, including biaxial Cauchy stress, biaxial linearized stiffness and aortic distensibility [8].

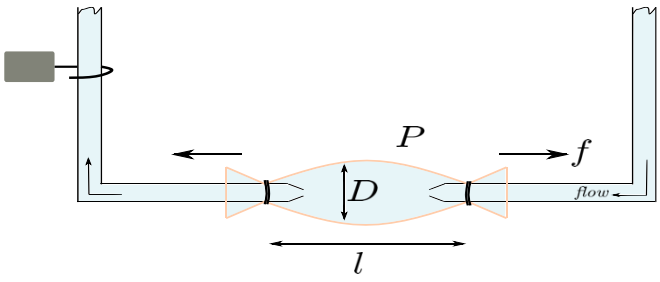

**Figure 1: Biaxial Testing Schematics. DTA sample is connected to glass capillary tubes on both ends. D denoted the diameter of the tubal tissue, l denotes its length, P is the applied pressure, and f denotes the axial force that is applied on both ends of the tubal tissue.**

## RESULTS

Preliminary data on blood pressure measurements suggested a decrease in systolic and diastolic measurements during pregnancy (Fig. 2), with mean values of 119 and 96 mmHg for control mice, and 102 and 75 mmHg for pregnant mice, respectively.

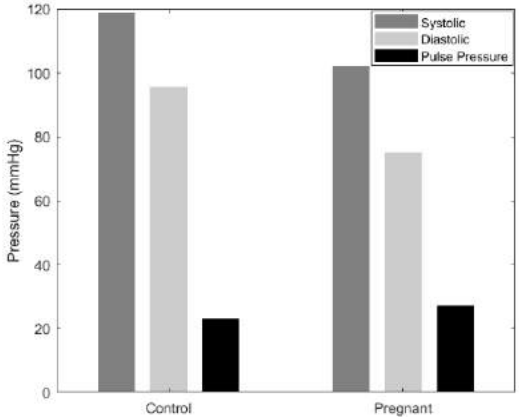

**Figure 2: Measured blood pressure in pregnant mice and age-matched control group**

Figure 3 shows the results of the experimental gathered dring biaxial testing and fitted to the mathematical model. While the focus of this premilinary work was not quantifying the mechanical properties, the excersise of fitting the data demonstrated the feasibility of using such models in further analysis of the experimental data when more samples becomes available.

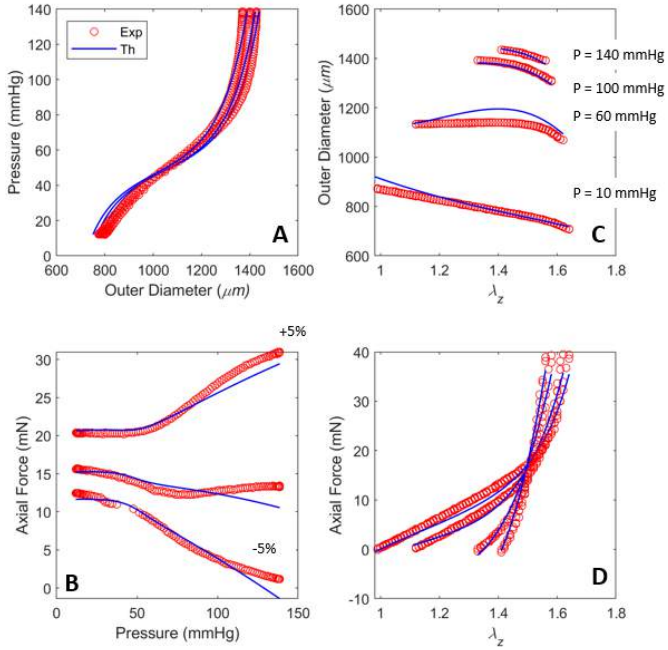

**Figure 3: Results of a typical experiment in the control group shown in red hallow cricles and the mathematical model in blue lines. In (A) and (B) the intitial axial stretch was kept constant for each experimental protocol and the pressure increased whereas in (C) and (D) the pressrure for each protocol was kept constant and the axial stretch ($\lambda_z$) was increased.**

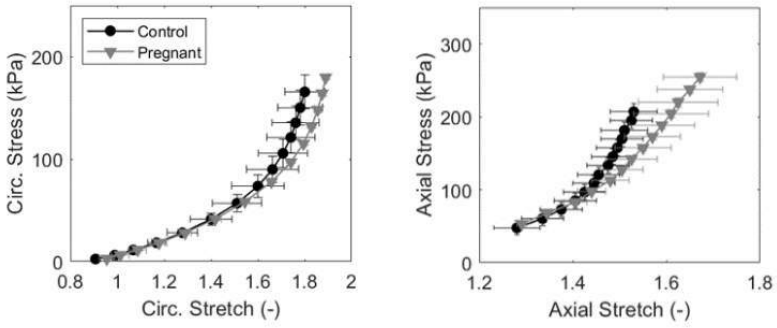

**Figure 4: DTA biaxial stresses for pregnant and age-matched control C57BL/6 mice: (A) circumferential direction, and (B) axial direction**

Stress vs. stretch response of aortic tissues in the circumferential and axial direction is shown in Figure 4. Again, due to the limited number of experiments, a rigorous statistical analysis was deemed impossible at this stage. However, visual examination of the data showed a nonlinear behavior of the tissue consistent with previous observations in murine DTA and other species (including human). In addition, anisotropic response was observed, especially in the control samples. Finally, the pregnant groups seemed to be more compliant at higher levels of mechanical stress.

## DISCUSSION

With cardiovascular disease being one of the major causes of maternal mortality [9], we are motivated to understand the changes in cardiovascular function during pregnancy. In the reported study, we presented our observation and initial analyses of the passive mechanical responses of the descending thoracic aorta in nulligravida and late-gestation pregnant mice.

Preliminary data (N=2 for each group) suggested an increase in circumferential distensibility and axial extensibility in pregnant mice. Our ongoing research is focused on increasing sample size for DTA specimen as well as performing biaxial mechanical testing on the ascending thoracic aorta (ATA) for both groups. We expect to elucidate the changes in the intrinsic stiffness of tissues during pregnancy and to provide insights into the changes in axial and circumferential stretch, the relationship between the thickness of the aortic wall, and the changes in the stored elastic energy of the thoracic aorta, which are all important factors in biomechanical assessment of aortic tissue in health and disease.

## INTRODUCTION

Abdominal Aortic Aneurysm (AAA) is a common cardiovascular disease, causing irreversible enlargement of the lower part of the aorta by more than 50%. An aneurysm can continue to grow and lead to eventual rupture, the 13th leading cause of death in the US [1]. However, surgical intervention can be performed to stabilize an aneurysm using two methods: high-risk open surgical repair (up to 12% mortality) or minimally invasive endovascular repair (~2% mortality). Open surgery requires opening the abdominal cavity and resecting the diseased portion of the abdominal aorta with a graft. Endovascular aneurysm repair (EVAR) involves making a small incision in the femoral artery and deploying a stent-graft using a catheter. The stent-graft in turn would protect the aneurysm by reducing the forces it experiences due to systolic blood pressure. EVAR has become more prevalent due to its lower mortality rate during operation [2].

Complex geometry aneurysms pose significant compatibility issues with traditional endovascular approaches because of their short neck (superior to the aneurysm sac to the lowest inferior renal artery). To accommodate complex geometry aneurysms, a fenestrated EVAR (FEVAR) approach was introduced to overcome the challenges of placing a traditional stent graft superiorly that would block visceral arteries (renal, celiac, and superior mesenteric arteries). Surgeon modified or custom prefabricated endografts are required to restore blood flow to visceral arteries and allow for the placement of bridging stent-grafts.

Currently, there is only one FDA-approved fenestrated stent-graft on the market, the Cook Zenith graft (Cook Medical LLC, Bloomington, Indiana). This prefabricated stent-graft requires a medical image for the placement of fenestrations (up to 8 weeks for custom manufacturing) and can cost up to three times more than a traditional endograft. The lead time for delivery of the customized stent-graft poses a potential for rupture to occur for patients that are in need of immediate repair. Katsarygyris et al. reported that nearly 2% of patients experienced a rupture before a fenestrated stent-graft operation could take place [3].

To alleviate the extended costs and wait times for customized devices, a novel system was introduced to perform *in situ* fabrication of stent-grafts. The proposed system begins with placing a point source on a guidewire into the visceral arteries with a separate device that detects the point source prior to fenestration. The purpose of this study is to develop a prototype that can visualize visceral arteries in an *in vitro* test bench through stent-graft material (woven polyester fabric), a first step in realizing a medical device to perform *in situ* fenestration of stent-grafts.

## METHODS

*Summary:* The feasibility of the sensing device will be determined by its ability to detect an artery from white light imaging. The device consists of a bundle of fiber optic cables for transmitting light and a camera for real-time visualization of the light. A light-emitting diode (LED) connected to an Arduino (Arduino LLC, Boston, MA) is placed into the lumen of a visceral artery of a 3D printed aorta model. A 400 µm, 0.50 numerical aperture – Thorlabs (Thorlabs, Inc. Newton, New Jersey) fiber optic cable bundle was used to retrieve light waves from the visceral artery point source. Fiber optic cables consist

of slim strands of glass that are used to carry information in the form of light. For this experiment they are a means for carrying light a short distance for real-time visualization. A separate MATLAB (Mathworks, Inc. Natick, Massachusetts) script was used for visualization.

*Experimental Setup:* Two models of an aorta with visceral arteries was created using Solidworks (Dassault Systemés, Vélizy-Villacoublay, France) 3D printed using the Form 3 SLA printer (Formlabs, Inc. Somerville, MA) with grey and elastic resin. A 3D model was cut in half through its longitudinal axis in Solidworks to allow for visualization of the probe position while the second model remained intact (**Figure 1A**). A piece of a Zenith stent-graft was cut and placed onto the aorta model. A single LED was placed in the lumen of a visceral artery for emitting white light. The LED was connected to a potentiometer connected to the 5V power source from the Arduino. The experiment was conducted in the air with two different custom-designed and 3D printed probe tips with fiber optics bundles.

*Quantitative Fiber Optic Measurements:* A five fiber-bundle probe (**Figure 1C**) was used along with a custom printed circuit board (PCB) to retrieve analog sensor values emitted from a LED. The PCB had five photoresistors record the amount of light the fiber optic bundle transmitted. The data was recorded using a live data stream connected to MATLAB and the data was post-processed and visualized (**Figure 1B**).

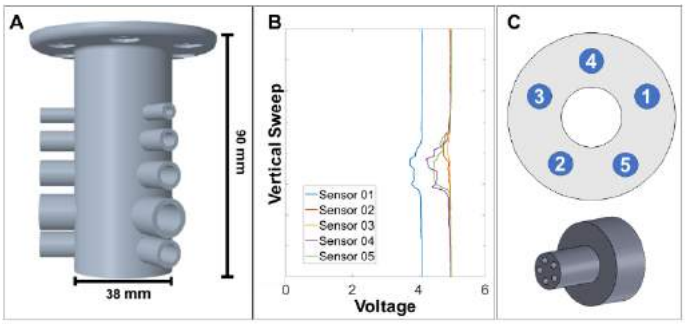

**Figure 1: A) 3D printed experimental test bench with a stent graft placed inside. B) Analog sensor values when the visceral artery was detected. C) Position of fiber optic wire corresponding to sensor values and the CAD rendering of the probe tip.**

*Fiber Optic Visualization:* A probe was designed to hold fourteen fiber optic cables on Autodesk Inventor (Autodesk, San Rafael, CA) and 3D printed. The fiber optic cables were arranged in two circular patterns, an inner and outer ring. The outer ring is 4.8 mm in diameter with 8 fiber optic cables. The inner ring is 2.5 mm in diameter with 6 fiber optic cables, for a total of 14 cables (**Figure 2C**). The cables were cut to 1.5 feet in length each and attached to a block with holes arranged in the same pattern as the probe. The half-cut test bench was used for this experiment to visualize the boundary of the visceral artery (**Figure 2A)**. The fiber optic probe was placed on the North, South, East, West, and center of the artery opening (**Figure 2B**). A video stream taken of fiber optic bundle end was converted to an 8-bit grayscale image ranging from 0 to 255. An image was created using 14 unique gray value points when detecting light. Finally, bicubic interpolation was performed on the 14 fiber bundle to resize the image in MATLAB for visualization (**Figure 2B**).

## RESULTS

Two experiments were successfully developed by designing and 3D printing test benches, probes, and a PCB to record data. The first experiment reported the voltage changes due to the detection of the orifice of a visceral artery where the point source was located. The voltage decrease (percent change) when an orifice was detected was 8.47 ± 2.55%. The results from the second experiment exhibited expected behavior. When the probe was placed on the center of each edge (NSWE), it was found that the fibers receiving light were brighter than when an individual fiber did not detect light.

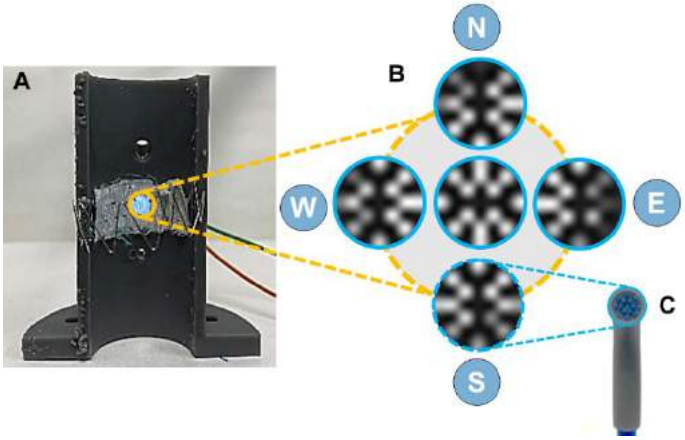

**Figure 2: A) Half-cut test bench with the stent-graft materials placed in front of the opening of the visceral artery. B) Visualization of the probe tip in the NSWE and center positions. C) probe tip with a 14-fiber bundle for visualization.**

## DISCUSSION

Several fiber-optic probes were constructed that had the ability to detect white light with either a photoresistor or a camera to visualize light intensity. Quantitative measurements of the voltage were achieved but did not have accurate spatial information of the probe tip in relation to the opening of the orifice. The half-cut test bench allowed for real-time visualization and accurate placement of the probe tip in several positions. Although the probe exhibited expected behavior, it is unclear whether the grayscale images are sufficient to detect the visceral artery when deployed. The ability to detect the edge of the visceral artery is an important step towards the development of *in situ* fabrication of stent-grafts. Future research and development will include testing the system in chelated sheep blood, testing the reliability of sensor-based measurements vs. camera visualization, and developing a puncturing mechanism to create fenestrations in the stent-graft material.

## INTRODUCTION

Patients with severe aortic stenosis undergo aortic valve replacement (AVR) through surgical or transcatheter approaches to prevent heart failure. Transcatheter AVR has emerged as an alternative mode of AVR for patients deemed high risk to undergo surgical AVR based on age and comorbidities. Transcatheter devices and methods have progressed vastly over the last two decades, showing similar or better outcomes compared to surgical AVR. However, TAVR has its shortcomings as well, with adverse procedural outcomes such as coronary obstruction (1-3% of all cases), aortic root rupture (1-2%), paravalvular leak (20-40%) etc., being reported [1-2]. Understanding the biomechanics of TAVR is crucial to prediction and prevention of such events.

Coronary obstruction (CO) is a procedural complication of TAVR that has been observed in 0.7% of all TAVR cases, and up to 2.3% in valve-in-valve TAVR cases [3]. In the event of CO during TAVR, the failed aortic valve leaflets get displaced and obstruct one or both coronary arteries, thus occluding coronary perfusion, leading to myocardial infarction. Coronary obstruction is associated with a high 30-day mortality rate of 40-50%. Currently, pre-procedural computed tomography (CT) is the imaging modality used to make decisions on valve type, sizing and in the assessment of risk of adverse events. Based on a multicenter registry study, coronary artery height (h) and sinus of Valsalva diameter (SOVd) were derived to be predictors of coronary obstruction with cutoffs of h<12mm or SOVd < 30mm**.** However, given the severity of the complication, these predictors are insufficient in accurately identifying patients at high risk of CO, with reported sensitivity and specificity of only 78% and 66% respectively.

Therefore, the goal of this study is to use high-fidelity computational simulations to overcome the limitations posed by clinical guidelines based on cardiac imaging and develop a highly accurate patient specific predictive tool for coronary obstruction after TAVR.

## METHODS

Pre-procedural cardiac CT images of a patient cohort (n=50) deemed to be at risk of coronary obstruction based on clinical guidelines (h<12mm or SOVd <30mm) was collected retrospectively from multiple TAVR centers. Patient specific aortic root, valve leaflets and calcification were segmented and meshed in Materialise Mimics (Figure 1) (Leuven, Belgium). Geometries for both the balloon expandable Edwards SAPIEN and self-expanding Medtronic Evolut valves were created using Solidworks (Dassault Systems, Concord, MA, USA). Aortic root, leaflets and calcification were meshed with 4-node tetrahedral elements to retain patient specific features and the mesh density ranged from 100K-200K elements per model. Transcatheter heart valve (THV) stent models are meshed using 6-node hexahedral elements in Hypermesh maintaining 4 elements across the stent thickness (Altair, Powel, OH, USA). ABAQUS Explicit (Dassault Systems, USA) was chosen as the finite element solver for this work.

*Material modeling*

The SAPIEN stent was modeled using an elasto-plastic model with a Young's modulus of E = 193 GPa, $\sigma_{yield}$ (0.2%) = 340 MPa, $\sigma_u$ (48%) = 670 MPa and a Poisson's ratio, $\nu$ = 0.29 with a density of $\rho$ = 7760 kg/m$^3$ [4]. The Evolut valve stent was modeled using superelastic nitinol properties and the material model was employed in ABAQUS using a user defined subroutine [5]. The aortic root was modeled using a hyperelastic neo-Hookean material model with the strain energy function represented in equation (1).

$$\varphi = \frac{\mu}{2}(\bar{I}_1 - 3) + \frac{k}{2}(J-1)^2 \qquad (1)$$

$\bar{I}_1$ is the first invariant of the right Cauchy-Green tensor $\bar{C} = J^{-2/3}I_1$ where $J = detF$, $F$ being the deformation gradient tensor. $\mu$ represents the shear modulus in which 0.5 MPa was used and $k$ represents the bulk modulus in which 5 MPa was used to allow compressibility of the material [6].

*FE Simulations*

A quasi-static approach was adopted with a cone propping open the failed native valve leaflets to position the crimped THV in place prior to deployment. The balloon and crimped SAPIEN stent were positioned coaxially inside the aortic root and a fluid-cavity based approach was employed to inflate the balloon and deploy the stent. The Evolut stent was crimped and released inside the native valve by leveraging the shape-memory properties of nitinol. Scaled penalty contact was prescribed for the stent-balloon and stent-AV interactions.

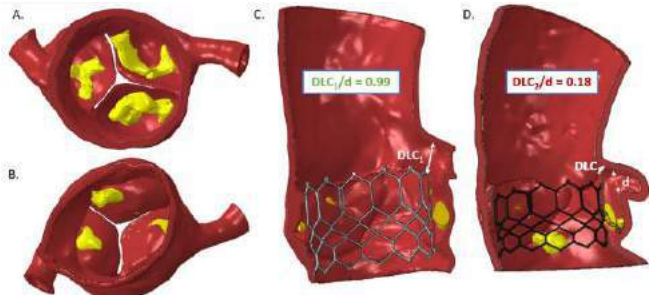

**Figure 1. Patient specific aortic root, leaflets, yellow calcific nodules in aortic and ventricular views (A, B). DLC/d measured in an unobstructed (C) and obstructed case (D).**

TAVR was virtually simulated in these patients based on the corresponding valve type and size received by the patient. The closest distance between the native aortic valve leaflet and the tip of the left coronary ostium is then measured (DLC) and the ratio of this distance to the diameter of the coronary artery (d) is considered as a representative measure of the fraction of occlusion [7] (Figure 1).

## RESULTS

Visualization of the final THV configuration after simulation of TAVR and the measurement of DLC and d was done through post-processing in ABAQUS. Out of the 50 patients in the study, 39 patients received a TAVR without CO and 11 patients underwent TAVR with CO. Mean values of the predictors of CO in the successful and unsuccessful cohorts is presented in Table 1.

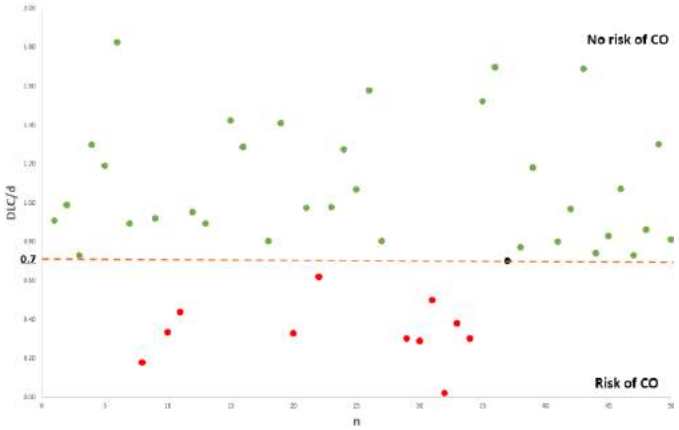

**Figure 2. Study population characterized by DLC/d to predict coronary artery obstruction. Green dots represent patients who successfully underwent TAVR without coronary obstruction, red dots represent patients who had CO after TAVR, and the black dot represents the 1 patient who underwent TAVR successfully but had DLC/d <= 0.7.**

A DLC/d cutoff of 0.7 predicted the occurrence of coronary obstruction accurately in 11/11 confirmed cases (100% sensitivity) and predicted no occurrence of CO accurately in 38/39 cases (97.8% specificity), improving significantly over current clinical guidelines (Figure 3). In comparison, coronary height (h) showed sensitivity and specificity of 72% and 41% respectively in the same cohort.

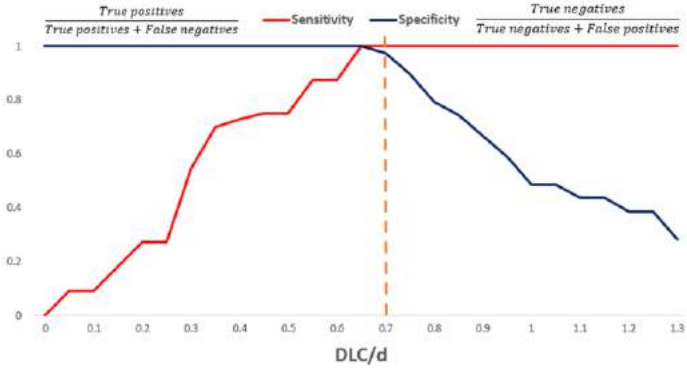

**Figure 3. Sensitivity & Specificity plots for the predictor DLC/d based on TAVR outcomes in 50 retrospective cases.**

**Table 1: Predictors of coronary obstruction in study population**

| Predictors | Successful (n=39) | Unsuccessful (n=11) |
|---|---|---|
| **DLC/d** | **1.23 ± 0.54** | **0.34 ± 0.15** |
| **Coronary height** | **11.33 ± 2.69mm** | **10.82 ± 2.17mm** |
| **Sinus diameter** | **30.09 ± 3.22mm** | **29.32 ± 3.61mm** |

## DISCUSSION

Coronary obstruction after TAVR, despite its low reported incidence, is a catastrophic complication that presents a very high mortality rate. Due to the fatal nature of coronary obstruction, candidacy for TAVR is often dependent on the risk of CO assessed in procedural planning. Therefore, a less sensitive/specific predictor can lead to low CO-risk patients not receiving TAVR and vice versa. In this study, DLC/d derived from computational modeling showed much better stratification between patients who successful and unsuccessful TAVR cases (Table 1) than h or SOVd. The complex interaction between the THV and the aortic root influences the final configuration of the THV as well as aortic valve leaflets, as demonstrated by the superior predictability shown by DLC/d. With TAVR expanded to all patients with AS, there is a need for accurate patient selection to prevent adverse events while improving TAVR accessibility. Computational patient specific modeling of TAVR can lead to better patient selection through accurate assessment of risk of fatal complications such as CO.

## INTRODUCTION

Hypertension, also known as high blood pressure, is a prevalent condition that is associated with many adverse cardiovascular events such as stroke, aneurysm, and end-organ damage. Along these lines, the renin-angiotensin-aldosterone system (RAAS) is an important mediator of hypertensive arterial remodeling, as shown by the ability of angiotensin-II (AngII) to modulate renal function and peripheral resistance while promoting excessive vascular inflammation, which leads to the development and persistence of chronic hypertension [1].

Previous work using an AngII infusion mouse model of hypertension has revealed the existence of spatio-temporal relationships between mechano- and immune-mediated aortic remodeling [2]. Namely, in response to an early increase in blood pressure and mechanical loading of the aortic wall, the thoracic aorta experienced excessive fibrotic remodeling and structural stiffening while the abdominal aorta experienced less remodeling and minimal adventitial fibrosis. Additionally, the amount of remodeling in each region was found to correlate with the extent of immune cell expression in the adventitia and perivascular space [3].

Though geometric and anatomical differences may contribute to the regional variations in hypertensive remodeling between the thoracic and abdominal aorta, there are also variations in the structure and function of perivascular adipose tissue (PVAT) depots along the length of the aorta. Given that PVAT is known to secrete cytokines that regulate vascular contractility, signaling, and inflammation [4], and can be activated by external mechanical stimulation [5], we hypothesize that regional PVAT may contribute to the observed differences in hypertensive vascular remodeling. Using a combination of histology, gene expression, and co-culture analysis, the current study is focused on the mechanobiology of regional PVAT. Our findings reveal that thoracic PVAT (tPVAT) and abdominal PVAT (aPVAT) respond differently to AngII-induced hypertension and that thoracic PVAT secretes factors that lead to changes in fibroblast phenotype *in vitro*.

## METHODS

**Animal Models.** Male wild-type C57BL/6J mice were housed in standard conditions with food (normal chow) and water available *ad libitum*. At ~8 weeks of age, animals received either saline or AngII (490 ng/kg/min) delivered via subcutaneous mini-osmotic pumps (Alzet) for a period of two weeks. Following AngII infusion, mice from each group were euthanized and the descending thoracic aorta (DTA) and infrarenal abdominal aorta (IAA) were isolated with PVAT in-place [6]. For studies on regional PVAT, tissues were separated from the DTA or IAA prior to storage in -80°C for further experimentation.

**Histological Analysis.** Vascular tissues containing PVAT were fixed in formalin overnight at 4°C prior to embedding, freezing, and sectioning at a thickness of 8 μm. Sections were washed with phosphate-buffered saline (PBS) for at least 10 min prior to staining with Oil Red O solution (ORO; Abcam) overnight at room temperature to label adipocytes. PVAT area was quantified from brightfield images of ORO-stained sections using a custom image-processing algorithm (Matlab). For all quantification, a minimum of three sections per sample with a total of five biological replicates per group were analyzed.

**RNA Extraction and Analysis.** Total RNA was extracted from isolated thoracic PVAT and abdominal PVAT using the Qiagen RNeasy mini kit. RNA quantity and purity was measured using a Nanodrop spectrophotometer (ThermoScientific). cDNA synthesis and real-time quantitative PCR (qPCR) were performed using SuperScript IV VILO Master Mix. Expression of genes related to PVAT phenotype (*Ucp1*, *Lep*) and immune cell activity (*Ccl2*, *Mmp2*) were measured.

**Fibroblast-PVAT Co-culture.** To assess the impact of PVAT on fibroblast phenotype, we performed a co-culture of thoracic PVAT and 3T3 fibroblasts in a 0.4 μm pore 24-well transwell setup (Costar). Fibroblasts were seeded ($0.05\times10^6$ cells/well) one day prior to placement of 5 mg of thoracic PVAT in the insert. For a subset of groups, 1mM AngII was added to the media to isolate the effect PVAT

and AngII on the observed phenotypic changes. Together, this resulted in four experimental groups – 3T3, 3T3+PVAT, 3T3+AngII, and 3T3+PVAT+AngII. All cells were cultured at 37°C and 5% $CO_2$ in DMEM supplemented with 10% FBS and 1% penicillin/streptomycin antibiotic. Experiments were performed in triplicate.

**Immunofluorescence Analysis.** Following 48 hours of co-culture, cells were fixed at room temperature in 4% paraformaldehyde and 0.1% Triton X-100 for 10 min prior to staining with a conjugated antibody to α-smooth muscle actin (1:200; Sigma-Aldrich). Staining intensity was quantified for each group using a custom image analysis code (Matlab).

**Statistical Analysis.** Data are presented as means ± SEM. Normally distributed groups were compared with a Student's *t* test and a value of $p < 0.05$ was considered statistically significant. All data points are mean values of at least two technical replicates.

## RESULTS

Given that adipose tissue – and in particular PVAT – has been shown to alter its structure and cellular composition in response to obesity and hypertension [7], we first wanted to confirm if tPVAT and aPVAT are responsive to AngII infusion. Indeed, after two weeks of AngII-induced hypertension we observed an increase in PVAT area in each region. While the increase in aPVAT was not statistically significant, we found that tPVAT increased by ~20% relative to saline control ($p < 0.05$; **Fig.1**). The increase in PVAT area, as shown by ORO positive staining, is consistent with adipocyte proliferation and suggests a hypertension-driven remodeling. Notably, the changes in aortic PVAT are consistent with prior observations of excessive vascular remodeling in the thoracic aorta but not in the abdominal aorta suggesting PVAT may play a role in regional hypertensive vascular remodeling.

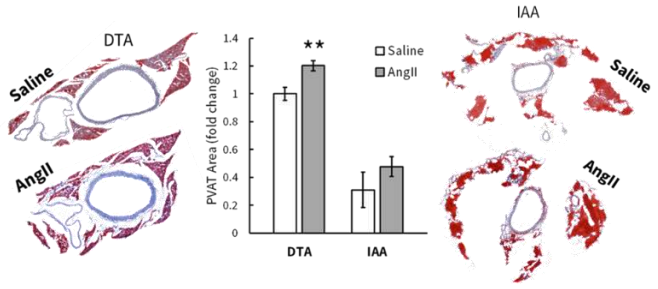

**Figure 1: PVAT is significantly increased around the DTA (tPVAT) and marginally increased around the IAA (aPVAT) after AngII infusion. Red indicates adipocytes labeled by ORO stain.**

Based on the differences in PVAT remodeling, we next investigated the transcriptional differences between tPVAT and aPVAT in response to AngII-induced hypertension. Using canonical genetic markers of fat phenotype, we observed high expression of the brown fat marker *Ucp1* in tPVAT as measured by qPCR ($p < 0.01$, **Fig.2A**), whereas aPVAT had higher expression of leptin (*Lep;* $p < 0.05$, **Fig.2A**) a marker of white fat phenotype. Such phenotypic differences in PVAT may suggest the potential for disparate responses to systemic hypertension. Indeed, gene expression of *Ccl2* – a general marker of immune regulation and inflammatory processes – was increased in tPVAT ($p < 0.01$, **Fig.2B**) and expression of the matrix enzyme *Mmp2* was increased in aPVAT ($p < 0.01$, **Fig.2B**). Together, this suggests a higher immune cell recruitment to tPVAT and increased extracellular matrix turnover in aPVAT, both of which may contribute to the observed levels of vascular remodeling and fibrosis.

Based on the altered transcription between regional PVAT depots, and our observations of regional vascular remodeling, we next hypothesized that tPVAT may alter the phenotype of fibroblasts to promote fibrotic remodeling. To investigate the impact of PVAT on

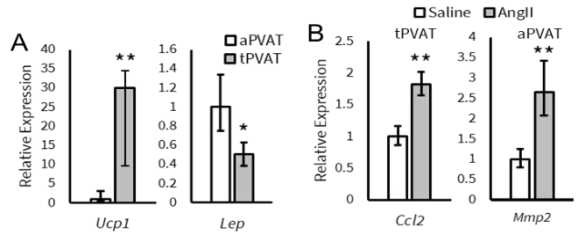

**Figure 2: Gene expression analysis of regional PVAT depots reveals differences in fat phenotype and response to AngII.**

fibroblast phenotype, we performed a co-culture of 3T3 fibroblasts with multiple combinations of PVAT and AngII treatments *in vitro*. Quantification of alpha-smooth muscle actin (αSMA) immunostaining revealed increased staining intensity in cells cultured with PVAT (**Fig.3**). PVAT-treated cells also showed apparent changes in cell morphology (**Fig.3**). Using αSMA as a proxy for a myofibroblast phenotype, this suggests tPVAT can alter fibroblast phenotypes *in vitro* and may promote fibrotic remodeling *in vivo*.

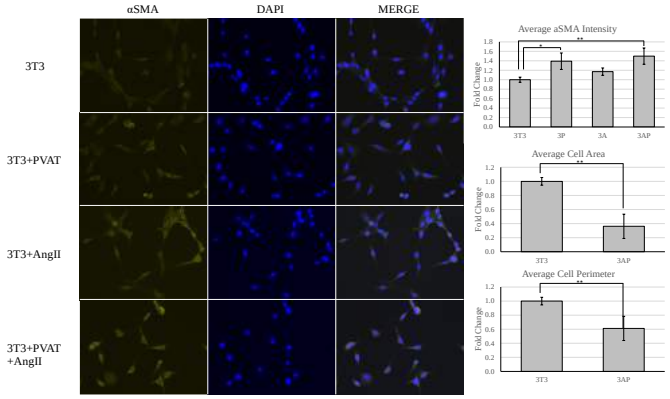

**Figure 3: PVAT-treated cells have an altered shape and increased expression of the contractile protein αSMA, relative to control.**

## DISCUSSION

In this study, we demonstrate that at a tissue, protein, and transcriptional level, aortic PVAT responds differently to hypertension depending on its anatomical location. The regional variations in PVAT phenotype and gene expression, combined with our observations of PVAT area change, suggest a potential relationship to our previously reported regional variations in vascular remodeling. Indeed, higher expression of immune cell recruitment genes and area change in tPVAT is consistent with marked wall thickening and adventitial fibrosis of the DTA in response to AngII-induced hypertension [3]. Our co-culture studies suggest PVAT can alter fibroblast phenotype indirectly. Future work will focus on PVAT secreted factors and specific immune cell populations (macrophages or T cells) as drivers of vascular remodeling. Altogether, this study identifies regional differences in aortic PVAT and highlights the potential of PVAT to regulate vascular remodeling via immune cell recruitment and effector adipokine secretion.

## INTRODUCTION

Thoracic aortic aneurysms and dissections (TAADs) are vascular pathologies responsible for significant morbidity and mortality. While there is a complex network of cellular, molecular, and genetic factors that render the aorta susceptible to TAAD formation, it is ultimately biomechanical factors – such as blood pressure, wall stress, and wall strength – that lead to material and structural failures of the aortic wall [1]. Thus, a better understanding of evolving aortic vulnerability and the biomechanical mechanisms that promote dissection and rupture is needed to develop viable therapeutic strategies for TAAD management.

The ongoing discovery of genetic mutations that predispose the aorta to lesion formation has led to the development of models for TAAD in the mouse. Studies in these models have revealed critical insights into the underlying molecular mechanisms, cell pathobiology, and tissue-level changes in microstructure associated with TAAD [2]. In addition to genetic approaches, previous work has shown that chronic infusion of the pro-inflammatory vasoconstrictor angiotensin-II (AngII) can similarly promote the formation of local mural defects in the ascending thoracic aorta (ATA) of the mouse [3]. Using this approach, the current study seeks to measure the local biomechanical properties of AngII-treated thoracic aortic samples with a specific focus on quantifying the behavior of regions with measurable mural defects.

Herein, we combine a sophisticated ex vivo mechanical testing pipeline – biaxial biomechanical testing (for identification of axial loads), panoramic digital image correlation (pDIC; for identification of surface deformation), and optical coherence tomography (OCT; for identification of wall thickness) – with quantitative histological image analysis [4]. This allowed us to develop spatial correlations between the evolving local microstructural composition, mural defects, and mechanical properties of the ATA over the duration of AngII infusion.

## METHODS

**Animal models.** Hypertension was induced in male, apolipoprotein-E null (*ApoE*$^{-/-}$) mice by Ang II infusion (1000 ng/kg/min) via subcutaneous mini-osmotic pump for up to 28 days. A subset of mice were euthanized at weekly experimental time points of 0, 7, 14, 21, or 28 days of infusion, and the ascending thoracic (ATA) was gently excised and prepared for mechanical testing and analysis.

**Biomechanical phenotyping.** Isolated ATA segments were cleaned of excess perivascular tissues and sutures were placed around the left carotid artery, left subclavian artery, and distal aortic arch to allow for pressurization. Samples were cannulated at each end through the aortic root and the brachiocephalic artery and were placed in a custom computer-controlled extension-inflation biaxial mechanical testing system [5]. Following preconditioning, the *in vivo* axial stretch was estimated based on the axial force-pressure relationship and multiple cyclic pressurization and axial extension protocols about the *in vivo* axial stretch were used to characterize the material response.

**Optical coherence tomography imaging.** Following biomechanical phenotyping, samples were recannulated onto a custom needle composite and high-resolution OCT images (ThorLabs, Inc.) were acquired at a series of fixed pressure and axial stretch values. This not only provides a measurement of the wall thickness profile over the entire ATA [4], but it also enables the identification local mural defects that would otherwise only be detectable using destructive methods.

**Panoramic digital image correlation.** Following OCT imaging, a random speckle pattern of black and white India ink was applied to the outer adventitial surface of the ATA. Speckled samples were then mounted in the center of a concave conical mirror and subjected to the same series of fixed pressure and axial stretch values. Using optics-

based techniques – such as digital image correlation, direct linear transformation, and ray tracing – a discrete grid of points defining the ATA surface was defined, tracked through all deformed configurations, and reconstructed in 3D [6]. Calibration of the conical mirror as well as the pDIC image processing and analysis was performed in Matlab.

**Material property estimation.** A finite element mesh of the ATA (FEBio) was generated from OCT images and displacement boundary conditions on the outer adventitial surface were imposed based on the measured pDIC deformation. The ATA surface was subdivided into 1000 patches and material properties were identified using an inverse analysis based on the principal of virtual power [7]. Using the virtual fields method, and an appropriate hyperelastic constitutive model, material parameters were iteratively identified for each surface patch.

**Histological analysis.** Following the multi-step testing, vessels were fixed overnight in a 10% neutral buffered formalin and stored in 70% ethanol at 4°C prior to paraffin embedding, sectioning, and staining with Movat's pentachrome for proteins of interest (elastin, collagen, etc.). Custom image analysis was developed to isolate constituents based on colorimetric analysis and subdivide images into evenly spaced circumferential segments for spatial correlation with material properties [4]. Localization of histological images was determined based on registration to the OCT dataset using a normalized thickness profile.

## RESULTS

Chronic infusion of AngII resulted in adventitial fibrosis, thickening, and aneurysmal dilatation of the ATA. A *k*-means clustering analysis of the 17 samples included in the current study resulted in the classification of three groups based on diameter: no dilatation (n=3), modest dilatation (n=7), and marked dilatation (n=7) (**Fig.1A**). Identification of mural defects in OCT images revealed some degree of mural degeneration in each AngII-treated sample (**Fig.1B**) and showed that mural defect area tended to increase linearly with the degree of dilatation (**Fig.1C**). This suggests that the energy release associated with elastin fragmentation and mural damage may contribute to aneurysmal dilatation.

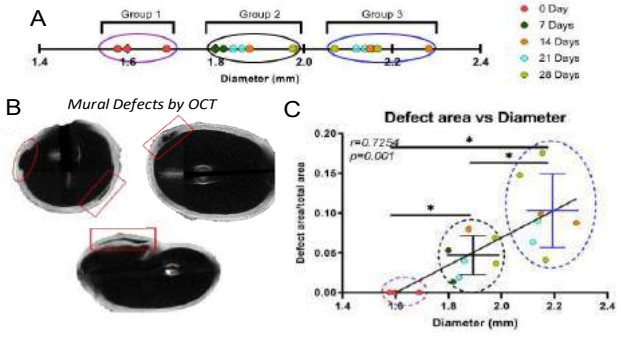

**Figure 1: (A) ATA samples was clustered into three groups and (B) OCT images were used to identify mural defects which were (C) linearly related to the extent of aneurysmal dilatation.**

By combining OCT and pDIC data for each sample, we were able to investigate biomechanical differences between the regions of the ATA that did or did not present with mural defects (**Fig.2A**). While there was substantial sample-to-sample variation in the magnitude of the identified material properties – i.e., stored energy and material stiffness – within each classification group, several trends emerged. Namely, defect regions tended to have reduced stored energy (**Fig.2B**) and increased circumferential material stiffness compared to non-defect regions. These trends held within each ATA sample as well as at a population level across all samples within each classification group.

Finally, spatial correlations between the identified full-field material properties and quantitative histological analysis (**Fig.2C**) revealed

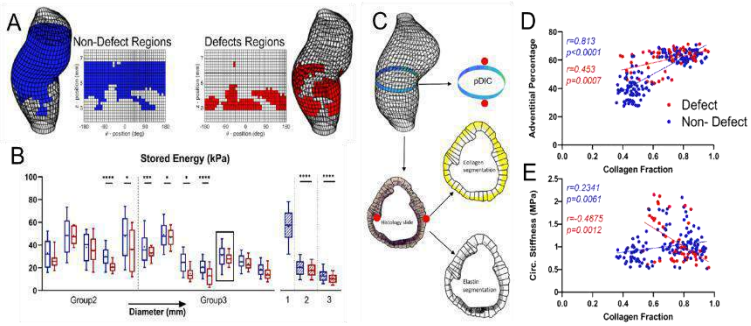

**Figure 2: (A) Spatial maps of defect vs. non-defect regions derived from OCT images allow for (B) biomechanical assessment of mural defects. (C) Spatial correlations with quantitative histological image analysis reveals (D) local collagen content and (E) relationships between collagen and material stiffness in areas with and without mural defects.**

several interesting local structure-function relationships. As mural defects were often associated with medial damage and elastin fragmentation, regions associated with mural defects tended to have higher collagen content and adventitial percentage (**Fig.2D**). Additionally, while non-defect regions showed a nearly constant relationship between circumferential stiffness and collagen content, defect regions appeared to have a negative correlation between stiffness and collagen (**Fig.2E**). Similarly, defect regions had little elastin – and thereby stored energy – compared to non-defect regions. Independent of defect or non-defect region, there was a nearly linear relationship between elastin and stored energy, consistent with the notion that elastin is responsible for providing the elastic recoil associated with diastole.

## DISCUSSION

Using a multi-step experimental biomechanical testing pipeline, we show for the first time that the local mechanical properties of defect regions found in AngII-treated thoracic aortic samples are distinct from non-defect regions in the mouse. While the extent of mural defects are linearly related to aneurysmal dilation of the ATA, they typically present as regions of marked medial damage and elastin fragmentation following AngII infusion. The excessive medial damage is spatially correlated with low levels of elastin area fraction and elastically stored energy. Conversely, defect areas are highly collagenous but tend to have a negative correlation with material stiffness. This suggests that collagen orientation and integrity are critically important aspects of maintaining native tissue stiffness of the ATA, even in extreme cases of remodeling as seen with instances of mural degeneration associated with TAAD [8]. Together, the results from this study indicate that 1) TAAD is a geometrically and materially complex vascular pathology and 2) local collagen reinforcement may be a viable therapeutic option for the management of TAAD and aneurysmal dilatation.

# INFANT SKULL FRACTURE PATTERN CHARACTERISTICS FROM LOW-HEIGHT FALLS

**Yousef Alsanea (1), Tagrid Ruiz-Maldonado (2), Brittany Coats (1)**

(1) Mechanical Engineering, University of Utah, Salt Lake City, Utah, USA
(2) Pediatrics, University of Utah, Salt Lake City, UT, USA

## INTRODUCTION

Approximately 686,000 children are victims of abuse and neglect every year. The highest percentage are children between birth and 1 year of age, and are more likely to experience a recurrence of maltreatment if the abuse is not identified. Accidental falls are the leading cause of non-fatal injury in infants and the most common explanation given by caretakers suspected of abuse. Thus, distinguishing a truthful history of a fall from a false one proves to be a difficult but important task for a clinician.

Skull fracture is a common finding for both accidental falls and abusive injuries, and may provide insight into head impact direction and impact energy. Unique fracture patterns, such as biparietal fractures, may be even more distinctive in their application and provide better insight into the validity of the provided history. The objectives of this study were (1) to determine how child age, fall height, impact surface, and impact location influence skull fracture patterns in infants, and (2) to gain insight into the mechanism and locations of occipital impact that lead to biparietal fracture in infants.

## METHODS

All studies were approved by the University of Utah and Primary Children's Hospital IRB. Infants <12 months of age with skull fracture from a low height fall between 2014-2019 and associated 3D CT reconstruction were retrospectively reviewed. 201 subjects with well-characterized falls, suitable imaging for analysis, and no significant concern for inflicted injury, as determined by a child abuse pediatrics team, were selected for this study. A semi-automated MATLAB routine was created to segment fractures and quantify the Euclidean distance between fracture endpoints (**Fig. 1**), the true line length, and the nonlinearity (true length divided by Euclidean distance). In cases with multiple fractures, each fracture was evaluated individually. The nonlinearity was averaged and true length summed across all the fractures. Fractures spanning multiple bones were excluded from this analysis and will be evaluated at a later date.

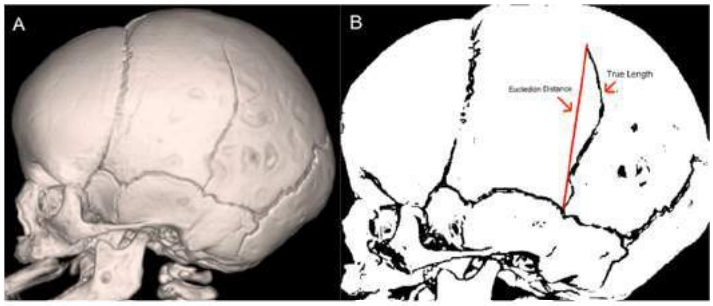

**Figure 1: (A) 3D CT reconstruction of infant skull fracture. (B) segmentation of fracture and calculation of length and linearity**

In each subject, the mechanism of the fall (e.g., fall from bed, drop from arms), impact surface, bone fracture location (parietal, occipital, frontal), and fall height were collected. Fall heights were estimated by 3 independent reviewers based on the mechanism of fall and medical record history. A least squares linear regression was used to evaluate the effect of child age, impact surface, bone fracture location, and fall height on fracture nonlinearity and length.

In the data set, 12 infants had biparietal fracture, 10 that were not aligned across the sagittal suture. Of these fractures, 3 had evidence of soft tissue swelling (all located on the occiput). A parametric finite element analysis was performed to identify the mechanism and occipital location by which biparietal fracture could occur.

Using an infant skull finite element model developed and validated by Coats et al. (2007), and later further validated by Hajiaghamemar et al. (2018), we simulated 1.45m falls onto a rigid surface with 13 different impact locations on the occipital bone (**Fig. 2**). The locations were selected based on the regions of soft tissue swelling identified from the medical history and were arranged symmetrically about the

ossification center of the occipital. The geometry of the model was based off CT images of a 1.5-month-old infant. Therefore, the skull had non-uniform thickness and was asymmetric about the midsagittal plane. The presence of fracture was defined by a stress threshold of 25 MPa across an approximately 10x10 mm localized region of elements (Coats et al. 2007; Hajiaghamemar et al. 2018).

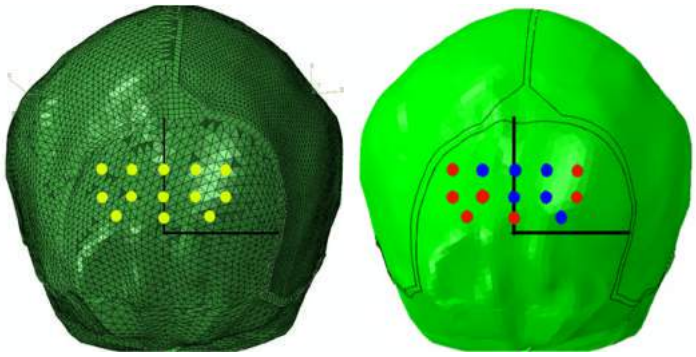

**Figure 2: Thirteen occipital impact locations were selected for the biparietal parametric study. Six of those locations (blue in right image) resulted in biparietal fracture**

## RESULTS

Fall heights averaged 1.0m, with 122 (60.7%) falls between 0.3-0.9 m, and 78 (38.8%) between 0.9 and 1.8 m. Least squares regression revealed a significant increase in fracture nonlinearity with younger infants ($p<0.001$) and with impacts to the frontal or occipital bones ($p=0.032$). Fracture length significantly decreased with increasing age of the child ($p=0.028$), lower fall heights ($p=0.035$), and with impacts to the frontal and occipital bones ($p=0.016$). Increasing nonlinearity with increasing height was also seen (**Fig. 3**), but was only significant in parietal fractures of older infants ($p=0.038$).

Out of the 13 points, 6 points predicted biparietal fractures based on the 25 MPa threshold. Due to the asymmetry of the skull and the non-uniform skull thickness, these points were not symmetric around the ossification center. Points further away from the vertical ossification center axis predicted fracture only on one parietal bone. Points that were near the horizontal axis and below did not predict biparietal fracture. The asymmetry resulted in an asymmetric stress distribution (**Fig. 4**).

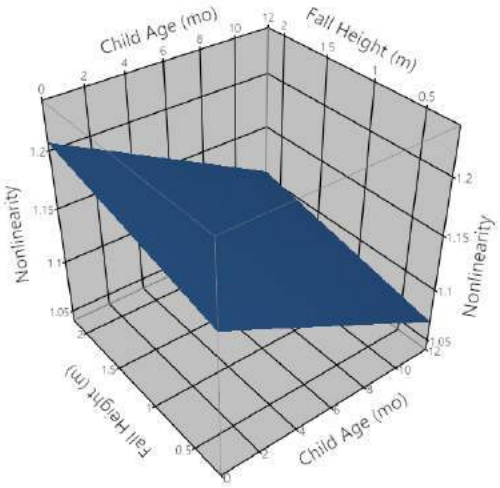

**Figure 3: Surface plot illustrating the linear relationship between child age (mo), fall height (m), and nonlinearity**

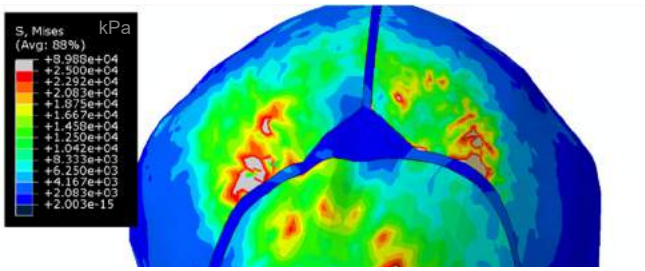

**Figure 4: Stress contour plot of impact to the top of the occiput in the middle**

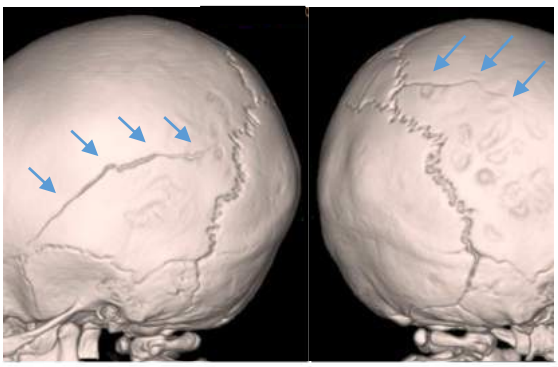

**Figure 5. Asymmetric length of biparietal fracture (arrows) in 7-month old infant**

## DISCUSSION

Fracture characteristics in this large dataset confirm previous computational simulations by our group that fracture length and nonlinearity increase with fall height (He et al.). However, the present study found that younger infants had approximately 10% more nonlinearity compared to older infants. Infant skull is highly transversely anisotropic and begins to become more isotropic with age. The increased anisotropy may contribute to the increased nonlinearity. Frontal and occipital bones exhibited decreased fracture length and nonlinearity, likely due to the greater curvature and thicker structure compared to parietal bones.

We predicted the presence of biparietal fracture in several of our impact locations, particularly those closer to the vertex of the skull and laterally located around the ossification center. The parietal stress was not caused by direct impact to the plate, but was rather due to contact with the occipital bone. The asymmetry of the skull and variability in the skull thickness resulted in asymmetric stress distribution which resulted in one bone having a larger stress field than the other. This would result in a larger fracture on one side, a common finding in the clinical data set (**Fig. 5**). These data highlight the contribution of anatomical variability in skull fracture patterns. Future work will evaluate the effect of skull thickness variability on skull fracture predictions and investigate more complicated fracture patterns.

# AN ITERATIVE APPROACH TO ASSIGN TUMOR-SPECIFIC FLOW BOUNDARY CONDITIONS FOR LIVER CANCER USING MULTI-MODAL IMAGE ANALYSIS

**S. Andrews (1), P. Trivedi (2), D. Mukherjee (3)**

(1) Paul M. Randy Mechanical Engineering, University of Colorado Boulder, Boulder, CO, USA
(2) Department of Radiology, University of Colorado Anschutz Medical Campus, Denver, CO, USA

## INTRODUCTION

In 2020, liver cancer was the sixth most common form of cancer, and the third leading cause of cancer-related mortality [1]. Transarterial embolization (TARE), a prominent treatment for unresectable hepatic tumors, utilizes a guided microcatheter to deliver radioactive particles intra arterially to a tumor. Undesirable clinical outcomes of TARE, which may be fatal [2,3], can be attributed to unwanted particle delivery to healthy tissue via the hepatic arterial network. Angiogenesis stimulated by tumor growth ultimately alters local flow dynamics, pulling more blood into the tumor, lending to the efficacy of embolization treatments. Flow dynamics are also altered at the site of drug administration and may influence final drug distributions [4]. However, flow information under pathological conditions and during TARE are poorly characterized *in vivo*. Pretreatment planning relies on surrogate tracer particles to predict drug distribution, but these particles differ morphologically and in size compared to treatment particles, limiting pretreatment accuracy [5]. Computational methods offer a more accurate and less invasive approach to dosimetry and treatment planning, but few models have incorporated pathologic and patient-specific flow information in their distribution predictions. Here, we devise a multi-modal imaging-based framework for determining tumor specific flow conditions that can be used to create high resolution *in silico* models for tumor embolization therapy.

## METHODS

**Image based vascular modeling:** Computed tomography angiography (CTA) images were used to create a 3D patient-specific model of the descending aorta and hepatic arteries, using planar 2D segmentation technique as employed in SimVascular (Fig. 1A) [6]. The tumor and its surrounding vessels were located by intersecting the 3D vascular model with CTA images, and cross referencing with cone beam CT imaging of the hepatic tumor vasculature.

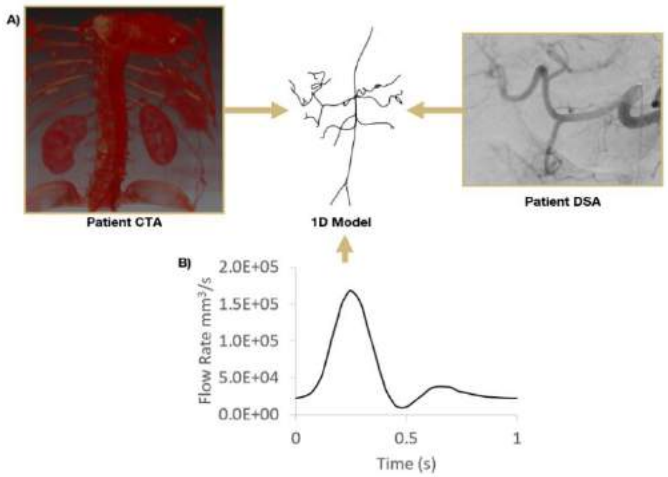

**Figure 1: (A) Patient specific 1D model creation from CTA imaging data, with implementation of DSA based outlet conditions. (B) Aortic inlet flow waveform used as an inlet boundary condition.**

**Image-based quantification of tumor's influence on flow:** Arteries feeding the tumor were located on pretreatment mapping digital subtraction angiography (DSA) images, by aligning the DSA images with a combination of cone beam CT images and patient CTA scans. Contrast intensities from DSA scans were used to quantify preferential flow into the tumor. An affine registration technique was used to stabilize the DSA image stack, and account for patient breathing and movement during the DSA acquisition. Vessels injected with contrast agent were segmented to record contrast intensity over time for key sections of the hepatic arterial network (Fig. 2). The raw intensity values were normalized with respect to the cross-sectional area of the

respective vessels. The ratio of flow rates through the tumor-feeding artery and healthy artery was estimated in terms of the time averaged contrast intensity ratio for these same vessels. This ratio served as a target flow rate ratio for tuning a tumor-specific boundary condition.

**Tuning of resistance boundary conditions:** A numerical framework to tune the boundary conditions was devised using the DSA target flow ratio and a reduced order 1D vascular model as implemented in SimVascular (see 1D model, Fig. 1A). A pulsatile waveform (Fig. 1B) was prescribed at the aorta inlet. The tuning started with baseline vascular resistance values prescribed at the vessel outlets, which were estimated as:

$$R_v\, i = i\frac{MAP}{Q_v} \quad (1)$$

where MAP is the mean arterial pressure (derived from literature [7]), and Qv is the flow rate through the respective vessel outlet. The flow rate was assumed to proportional to the cross-sectional area of the vessel outlet

$$Q_v\, i = ikA_v \quad (2)$$

where the proportionality constant, k, was derived from the time averaged flow ratio of the inlet waveform (Fig. 1B) and the sum of the outlet areas. For subsequent iterations of the tuning algorithm, the resistance of the tumor-feeding vessel was iteratively lowered by increments of 0.01 g/mm$^4$s, and subsequent ratio of flow rates through the tumor-feeding and healthy vessels were compared to the target DSA-derived flow ratio. The segments analyzed in the 1D simulation were taken from corresponding visual portions of the DSA, before either vessel bifurcates (Fig. 2). This process was repeated until the flow distribution ratio from the 1D simulation matched the DSA-derived ratio.

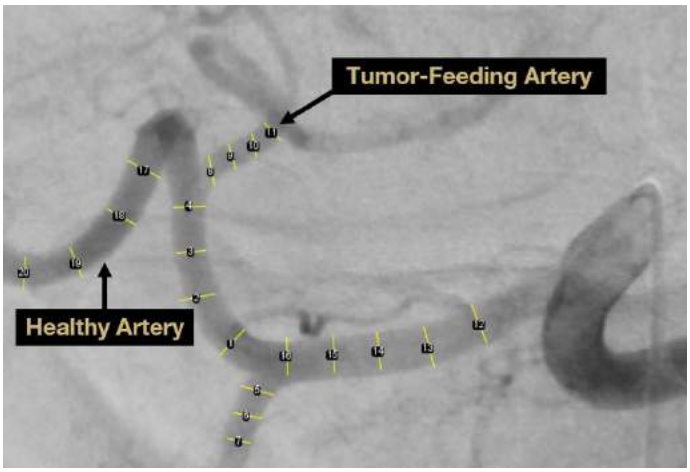

**Figure 2: DSA image of the common hepatic artery (segments 1-4), right hepatic artery (segments 17-20), and left hepatic artery (segments 8-11).**

## RESULTS

The DSA intensity values from the stabilized image processing workflow over time are shown in Figure 3. The normalized intensity values in the tumor-feeding artery (time averaged, μ = 0.98) were greater than the intensity values of the non-tumor artery (μ = 0.64). The tumor to non-tumor intensity ratio is 1.54, which was subsequently used as the target flow ratio to demonstrate the efficacy of proposed approach. The baseline resistance value calculated for the tumor-feeding vessel was 18.96 g/mm$^4$s. Using our tuning framework, the tumor resistance was lowered to a value of 2.78 g/mm$^4$s; for which the computed flow rate ratio between the tumor-feeding artery and healthy artery matched the target DSA ratio. Two sets of reduced order simulations of the entire arterial network leading into the tumor were conducted. One assumed baseline boundary condition values, the other assumed tuned boundary condition values. The resulting flowrates into the tumor-feeding and healthy vessels are presented in Figure 4.

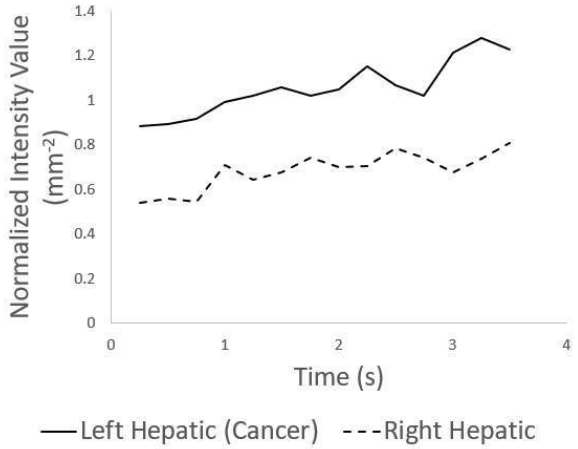

**Figure 3: Vessel intensities normalized to cross-sectional area versus time. DSA scans were captured at 4 frames per second.**

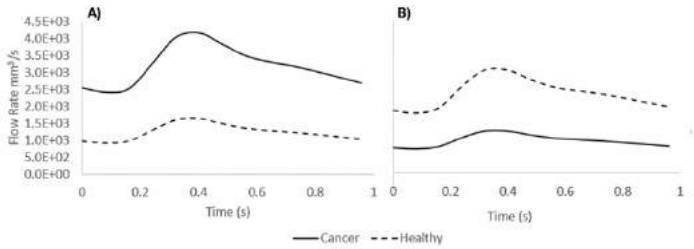

**Figure 4: Comparison of flow rates at outlets of vessels feeding the tumor and healthy tissue for (A) tuned boundary conditions and (B) baseline boundary conditions.**

## DISCUSSION

Here we have presented a systematic numerical approach to incorporate the preferential flow into the tumor into tumor-specific boundary condition for *in silico* modeling of the hepatic arterial network for liver cancer cases. Our approach integrates the multiple modalities of imaging (CTA, cone beam CT, DSA) that are standard-of-care in liver cancer embolization therapy. This enables precise characterization of *in vivo* flow conditions in *in silico* models. We did not consider catheter effects on contrast flow rates in the DSA images, which could potentially alter flow rates. Additionally, this methodology assumes that contrast intensity is a direct quantification of flow rate, but future work can explore a more mathematical relationship between contrast diffusion in the bloodstream and flow.

## INTRODUCTION

Respiratory infectious viruses have burdened millions of people as evidenced by the ongoing COVID-19 pandemic. Simple and sensitive detection of pathogens is critical to screen potential patients and combat infectious diseases spread. Homogeneous immunoassays have simple operation and generate analyte-specific signals without the need of immobilization, separation, and washing, and thus are promising for point-of-care (POC) diagnostics. With unique localized surface plasmonic resonance (LSPR) and coupling properties, gold nanoparticles (AuNPs) have been widely used in homogeneous assays.[1] Upon identifying analytes, they can form aggregates and change color, resulting from the interparticle distance change. Despite the visual recognition and rapid readouts, conventional AuNPs-based homogeneous assays suffer from the low sensitivity as confined by the weak optical response of the AuNPs.[2] As a result, they oftentimes are inadequate to be a standalone diagnostic tool. Previous efforts in enhancing the assay sensitivity focused on the strategies including coupling with dynamic light scattering and metallic enhancement.[3] The requirements of instrumentations and addition operation add complexity to the homogeneous assays. Therefore, it remains an unmet and urgent need for improving the detection performance of AuNP-based homogeneous assay.

Driven by this need, we systematically investigated the effect of AuNP shape on the homogeneous immunoassay with the goal to substantially improve the detection sensitivity. Particularly, antibody-conjugated gold nanosphere (AuNSs), nanorods (AuNRs), and nanourchins (AuNUs) were prepared for the evaluation (**Figure 1**). Using respiratory syncytial viruses (RSV), we demonstrated that AuNUs have the lowest detection limit compared to that of AuNSs and AuNRs. Our simulation based on the boundary element method revealed that the Au urchins have the most significant change in the extinction cross-section upon plasmonic coupling, resulting in more sensitive detection.

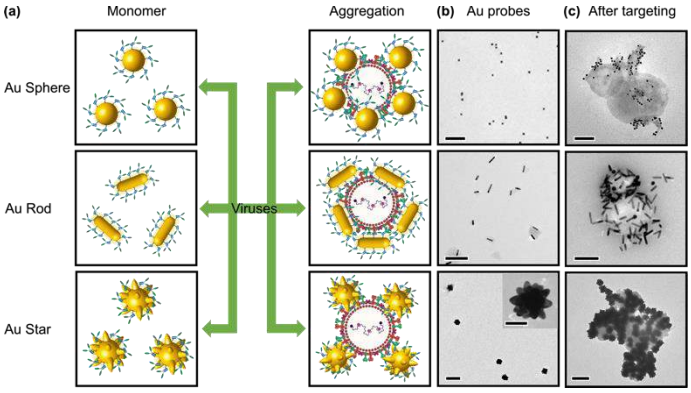

**Figure 1: Concept of the plasmonic coupling assay for diagnosis of infectious viruses.** (a) Antibody-conjugated AuNP probes with different morphologies aggregated on virus' surface due to specific antigen recognition. (b-c) TEM images confirmed the binding of AuNP probes on RSV. Scale bar =200 nm. Inset scale bar = 50 nm.

## METHODS

*RSV detection by AuNPs probes.* Antibody functionalized AuNP probes were prepared and incubated with RSV and other close relative respiratory viruses (e.g., influenza type A virus (IAV), human metapneumovirus viruses (hMPV), and parainfluenza viruses (PIV)) as controls in a volume ratio of 2:1. The extinction of the assay solutions was monitored after 30 minutes.

*BEM simulation of plasmonic coupling properties of AuNPs-based sensors.* Three models of AuNPs (i.e., AuNSs, AuNRs, and AuNUs) were embedded in water as surrounding dielectric environment. The dielectric functions of gold used in the simulations were obtained from Johnson and Christy.[4] All simulations were conducted via the MNPBEM toolbox in MATLAB (version 2021b).[5]

## RESULTS

We first analyzed the extinction spectra monitored for RSV detection using AuNSs, AuNRs, and AuNUs as probes, respectively (**Figure 2a-c**). Obviously, the extinction peak of the measured solution has decreased intensity with increasing RSV concentrations. To quantify the detection results, a ratiometric method was used. Taking AuNSs as an example, we generated the calibration curve by plotting the extinction intensity ($I_{ext}$) ratio of 700 nm to 532 nm against the viral titers (**Figure 2d**). A linear relationship ($R^2$ = 0.98) was observed in the range of 10,000-200,000 PFU/mL (**Figure 2d inset**). The limit of detection (LOD) was determined to be 8,000 PFU/mL by calculating the concentration corresponding to a signal that is 3 times the standard deviation above the blank control calibrator. Same applied to other AuNPs-based sensors (**Figure 2e** for AuNRs and **Figure 2f** for AuNUs). The linear detection range was determined to be 10,000-100,000 PFU/mL and 2,500-50,000 PFU/mL for AuNRs and AuNUs, respectively. Their corresponding LOD was then calculated to be 4,360 PFU/mL and 1,402 PFU/mL, which was about 1.8 and 5.7-times lower than that of AuNSs, respectively. Apparently, AuNUs probes provide the most sensitive detection for RSV.

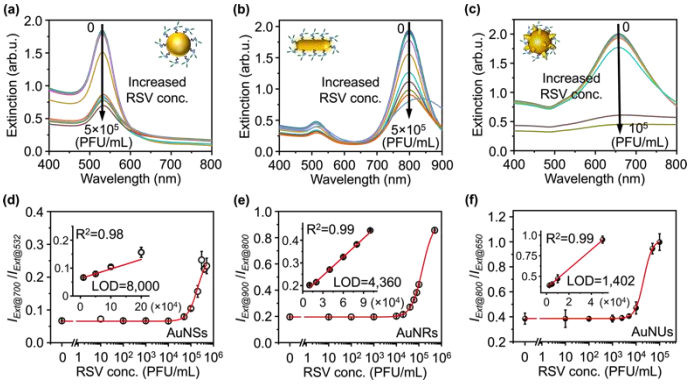

**Figure 2. Plasmonic coupling assay for diagnosis of RSV.** Spectra measurements (a-c) and ratiometric quantification (d-f) for colorimetric detection using AuNSs (a, d), AuNRs (b, e), and AuNUs (c, f).

Next, we performed computational modeling and simulation and aimed to provide optical insights in the plasmonic coupling effect. We applied boundary element method due to its ability to provide simple and fast simulation for AuNPs with complex geometries. As colorimetric assays essentially measure the extinction change of the AuNPs-based probes upon aggregating on the target, we calculated the extinction cross-section area as an index to present the plasmonic activities for all AuNPs of different shapes. For simplicity, we only calculated the plasmonic coupling strength between two coupled AuNPs. We built three sets of models of two identical AuNPs with varied interparticle distance ($d$ = 1-10 nm, **Figure 3a, b, c**). Using a single AuNP as a reference, we calculated the change of extinction cross-section area ($\Delta Ext_{@SPR}$) and peak shift ($\Delta\lambda$). **Figure 3d, e** show the $\Delta Ext_{@SPR}$ and $\Delta\lambda$ of two coupled AuNSs with different sizes. Basically, decreasing the interparticle distance leads to the increase of the extinction cross-section area and a red shift in the plasmonic peak, regardless of the particle size. Nevertheless, larger particle shows higher $\Delta Ext_{@SPR}$ and $\Delta\lambda$. Notably, for d > 5 nm, the $\Delta Ext_{@SPR}$ becomes close for 50 nm and 100 nm AuNSs. This suggests that further increasing AuNP size does not necessarily improve the plasmonic coupling, hence the assay performance. While for AuNRs, two representative coupling models (i.e., side-to-side, STS, and edge-to-edge, ETE) were considered for the simulation. **Figure 3f, g** show $\Delta Ext_{@SPR}$ and peak shift of the coupled rods against that of a single particle. Notably, both STS and ETE modes of two closely coupled AuNRs ($d$ = 0) induce the blue shift of the peaks as compared to a single AuNR. While ETE mode initially develops an increase in $\Delta Ext_{@SPR}$, STS mode shows a decrease on the contrary. Further increasing the $d$ (>1 nm) leads to the increase of $\Delta Ext_{@SPR}$ and peak shift for STS and decrease of $\Delta Ext_{@SPR}$ and peak shift for ETE. Attractively, ETE mode holds higher $\Delta Ext_{@SPR}$ values than the STS mode, regardless of the coupling gap. Lastly, we constructed the model for Au urchins, where the tip number ($n$ = 14), tip length ($L$ = 20 nm), and core size ($D$ = 50 nm) based on the TEM imaging. **Figure 3h, i** show the $\Delta Ext_{@SPR}$ and $\Delta\lambda$ against the $d$, where we found that the interparticle distance barely affects the peak shift but is of great importance for $\Delta Ext_{@SPR}$ in two coupled Au urchins. Under experimental conditions, the interparticle distance is typically larger than 10 nm due to surface conjugation with antibodies (e.g., the size of antibodies ~10 nm).[6] When setting $d$ at 10 nm, AuNUs dimer possesses the highest value of $\Delta Ext_{@SPR}$ among three simulated cases, which is consistent with the best detection sensitivity in the experimental section.

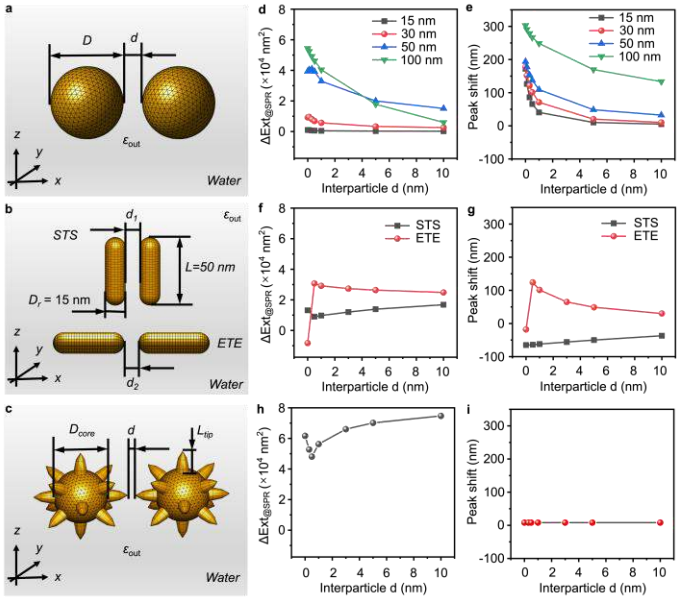

**Figure 3. BEM simulation of plasmonic coupling properties for Au nanosensors with different shapes.** Models built for two coupled AuNSs (a), AuNRs (b), and AuNUs (c). The simulated $\Delta Ext_{@SPR}$ and peak shift as a function of interparticle distance for coupled AuNSs (d, e), AuNRs (f, g), and AuNUs (h, i).

## DISCUSSION

In summary, we have systematically studied the impacts of particle shape on the detection sensitivity of AuNP-based homogeneous immunoassay. Our experimental results suggest Au nanourchins achieve a detection limit of 1,402 PFU/mL for RSV and provide the most sensitive detection compared with nanorods and nanospheres. With BEM simulation, we found that Au urchins have the largest extinction cross-section area change that contribute to the sensitivity enhancement over the other counterparts. Our study advances our understanding of nanoparticle design for rapid pathogen detection.

## INTRODUCTION

Heart disease is the leading cause of death in the developed world and is often characterized by changing contractile mechanics and subsequent cellular remodeling. Hypertrophic cardiomyopathy (HCM) is the most common inherited form of heart disease and is the leading cause of sudden cardiac death in young adults. This condition is characterized by hypercontractility and cardiomyocyte hypertrophy that can obstruct the outflow tract and contribute to heart failure [1].

Approximately one third of known HCM mutations are found in beta-cardiac myosin, the motor protein responsible for contraction in human ventricles. Given the known hypercontractile phenotype of HCM in patients, our biochemical studies have investigated how these mutations alter kinetic rates of myosin function and myosin regulation. Ensemble measurements of myosin interactions with actin as well as single molecule measurements of myosin binding events have revealed a surprising heterogeneity of effects of different myosin mutations (some mutations increase while others decrease or cause no change to rates of myosin activity – Table 1)[2-5]. The ability of myosin to form a super-relaxed state (SRX) associated with folded conformation is important for energy conservation, and is also disrupted by many HCM mutations, including the pediatric mutations P710R and H251N [4,5].

New therapies targeting these properties of myosin regulation and function are currently in clinical trials to assess how changes observed in vitro in molecular assays translate to the more complex in vivo context of the heart. Mavacamten was originally discovered for its inhibitory effect on ATPase rates, but has been shown to alter SRX% and is effective in reducing symptoms, hypercontractility, and hypertrophy in patients with obstructive cardiomyopathy [6]. Omecamtiv Mercabil (OM) is a myosin activator that can potently affect myosin function and muscle contractility in vitro, but its effects in patients experiencing heart failure were less clear [1]. Understanding how these drug and other related compounds affect contraction and cellular responses could accelerate the development of new therapies for cardiac patients. When the effects of mutations and drugs have been well defined, they can be incorporated into computational models that link measurements across scales and predict outcomes and targets.

Studying the impact of specific mutations in primary cardiomyocytes is challenging (especially for rare mutations associated with pediatric onset HCM). Human induced pluripotent stem cell derived cardiomyocytes (hiPSC-CMs) provide a powerful platform for investigating the particular effects of heterozygous mutations in human cells. While these cells are immature compared to adult cardiomyocytes, the use of patterning and engineered environments can improve the functional maturity of these cells and allow for measurement of force production and intracellular organization with various perturbations [7].

## METHODS

We have previously assessed the effects of HCM mutations and myosin targeting therapeutics on myosin function using purified recombinant human β-cardiac myosin protein constructs. The load-dependent detachment rates ($k_{det}$) and step size of wild type and mutant myosin molecules were measured in a dual-beam optical trap using the harmonic force spectroscopy (HFS)[2,5]. Motility measurements and actin-activated ATPase assays of WT, H251N, and P710R assess the motor function of active myosin [3-5]. Additional ATPase assays and single turnover experiments were used to compare the activity of WT and mutant versions of two-headed human ß-cardiac myosin constructs to assess the percentage of myosin in an SRX state [4-5].

To assess the impact of these mutations in living cells, heterozygous mutations (P710R and H251N) were introduced using Crispr/Cas9 gene editing in hiPSCs generated from healthy patients, and these healthy lines were used as isogenic controls. We have previously reported an increase in traction force generation, and cell size, and myofibril disruption in cells with the P710R mutation [5], and treated these cells with mavacamten for 3 weeks to determine its affect on cell hypertrophy. The H251N mutation was edited onto a healthy

SB³C2022-479

background line with a GFP-tagged alpha actinin protein to allow for live cell tracking of cardiac differentiation, cell size, and sarcomeric contraction. These cells were differentiated into cardiomyocytes following established protocols manipulating beta catenin signaling and grown for 30 to 60 days [5]. Some H251N cells were replated onto patterned substrates at day 30 and the remainder replated onto unpatterned coverslips at day 60 and fixed and stained for cardiac troponin after 48 hours. H251N cells plated on patterned glass were imaged before, immediately after and 24 hours after treatment with 300 nM OM, and patterns of sarcomere lengths during contraction was visualized with Kymograph plots generated in ImageJ. We then quantified cell spread area and beta myosin expression.

We have also modified a computational model to incorporate exponential force sensitive detachment rate and fit cellular traction force measurements from representative control and P710R cells. We assessed the sensitivity of predicted force to different muscle properties, and have made preliminary predictions of the expected force generation of cells with the H251N mutation or OM.

## RESULTS

Molecular measurements have revealed a surprising heterogeneity of effects on ATPase rate, unloaded motility, SRX%, basal detachment rate ($k_0$) and the exponential force sensitivity term of the detachment rate ($\delta$) caused by mutations, mavacamten and OM (Table 1).

**Table 1: Molecular measurements of the biomechanics of myosin with HCM mutations and myosin targeting therapeutics.**

| Mutation/ drug | Vel. | $k_{cat}$ | $k_0$ | $\delta$ | Step size | SRX % |
|---|---|---|---|---|---|---|
| **P710R** | -60% | -40% | -15% | -60% | -60% | -50% |
| **H251N** | +40% | +30% | +50% | +10% | +20% | -45% |
| **Mava** | -50% | -50% | ? | ? | ? | +90% |
| **OM** | -80% | -80% | -80% | -85% | -90% | ? |

Our multiscale assessment of the P710R mutation in cells revealed a significant increase in cell traction force generation, in addition to changes in myofibril organization and cell size [5]. Incorporation of measured myosin parameters into a computational model enabled fitting the cell force and predicting the individual effects of the measured changes to myosin function as well as the predicted range in forces that moderate changes in cross bridge density would cause (Figure 1). Our analysis confirmed the significance of the SRX state as a therapeutic target for this mutation and the importance of myofibril organization.

**Figure 1: Model incorporates myosin metrics to predict force.**

The presence of a GFP-tagged alpha actinin in the H251N cells and their isogenic controls enabled live assessment of the sarcomere contraction dynamics in spontaneously beating cells (Figure 2). Initial sarcomere kymographs showed more coordinated motion and more distinct diastolic rest periods in Control cells compared to H251N. Immediately after the addition of OM, both cell types experienced longer duration contractions with no clear relaxed phase and showed evidence of overextension of sarcomeres at sporadic points along the myofibril, especially in the H251N cells. After 24 hours, the magnitude of sarcomere displacements were significantly reduced in both cells, and we observed some evidence of myofibril remodeling and confirmed beta myosin expression via immunostaining.

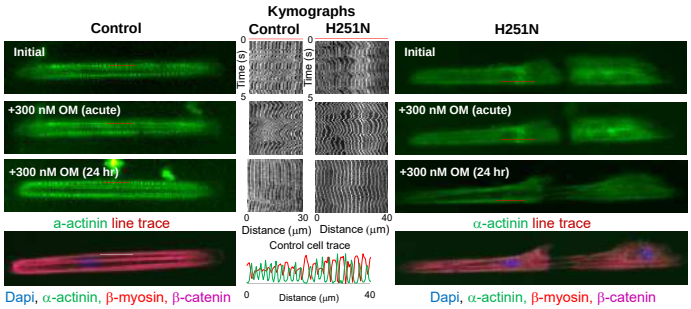

**Figure 2: Analysis of sarcomere structure and contraction in patterned hiPSC-CMs before and after treatment with OM**

Treatment with a moderate dose of mavacamten (0.3 uM) reduced cell area of P710R cells to the level of Control cells. In contrast to cells with the P710R mutation, cells with the H251N mutation had significantly lower baseline cell spread area at day 62, but both patterned and unpatterned H251N cells treated with OM for 24 hours were not significantly different from control cells (Figure 3).

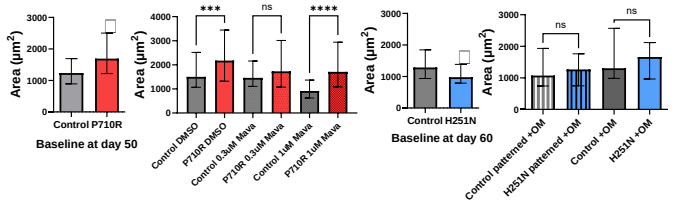

**Figure 3: Median cell spread area varies with different mutations, mavacamten and OM treatment.**

## DISCUSSION

These results confirm the surprising heterogeneity in phenotypes caused by HCM mutations in myosin across scale and highlights the benefits of an integrated, multiscale approach to assess myosin biomechanics and mechanobiology. Analysis of the sensitivity of predicted force generation to model parameters highlighted the importance of both the SRX state and the density of crossbridges, which can be affected by myofibril density and structure. Analysis of myofibril and sarcomere dynamics in control and H251N cells before and after perturbing their homeostasis with OM treatment revealed differences in myofibril structure exacerbated by acutely increased force that may contribute to the myofibril disarray and adverse remodeling which occurs in HCM. Future experiments will determine if inhibiting myosin activity with mavacamten in the H251N cells rescues sarcomeric organization and cell spreading. The ability to predict how different mutations and therapeutics affect contractile function and cellular hypertrophy could provide important clinical insights for personalized medicine and treatment plans, especially for pediatric patients.

## INTRODUCTION

Tissue models grown from cell monolayers can be used for screening of pharmacologic agents, for evaluation of stem cell differentiation potential, and for wound healing and regenerative medicine scenarios including skin, subcutaneous connective tissue, adipose tissue, and periosteum [1]. Connective tissues in the body contain fibrillar collagen. However, achieving an abundant, collagen-rich extracellular matrix (ECM) during *in vitro* culture is challenging, due in part to insufficient assembly and retention of fibrillar collagen.

In comparing the physiological extracellular space where tissues grow in the body to the *in vitro* culture environment, one critical difference is the lack of biological macromolecules within the *in vitro* environment. Macromolecules are a ubiquitous component of all fluid compartments within the body, with some macromolecules moving freely in solution and others present within an interconnected, insoluble, hydrophilic network permeated by the aqueous solvent. These macromolecules, through repulsive interactions, reduce the volume of solvent within which transport, interactions, and reactions of solutes can occur [2]. The effects of macromolecules to influence solute transport and reactions in fluid media through excluded volume effects are generally described by the biophysical concepts of macromolecular crowding and confinement. Crowding applies to fluid environments where macromolecules freely moving in solution are present at a high total volume fraction, while confinement applies to fluid environments in which structural obstacles to solute transport exist [2].

Macromolecular crowding has been shown to enhance the processing of type I procollagen, leading to significant increases in fibrillar collagen assembly and accumulation during *in vitro* culture of a variety of cell types [3]. The confinement approach, while more difficult to implement within the *in vitro* culture environment, has the advantage of avoiding any interactions with the growing tissue layer. Additionally, the "confined" environment can be more easily controlled than the "crowded" environment, since the confinement approach is based upon a macromolecular barrier rather than macromolecules in solution. Limited evidence suggests that a confinement approach can be used to improve *in vitro* collagen deposition [4]. In this study, we developed a carrageenan-based hydrogel confinement approach, evaluated the effectiveness of this approach to increase collagen accumulation by the human MG-63 bone cell line, and characterized the stability of the carrageenan hydrogel in the culture system. Additionally, computational modeling of oxygen transport within the confinement culture model was performed to complement the experimental results.

## METHODS

A modified culture system was developed for the hydrogel confinement approach. A polyethylene washer (2.4 mm thickness) was affixed to the base of a 6-well tissue culture plate, and cells were seeded on the surface inside the washer. The MG-63 bone cell line was used as an immature human osteoblast model to evaluate confinement effects on type I collagen deposition. A sterilized and presoaked CR gel (thickness range of 2 – 3 mm) was placed on top of the washer to provide a confinement barrier, and a medium layer was added above the gel (1.2 mm thickness). For preparation of the CR gels, a kappa-CR or kappa/lambda-CR solution (5% w/v) was prepared with stirring at 100 °C until homogeneous. The solution was cast into layers, with individual gels punched from the layers. Gels were replaced every two days along with replacement of the culture medium. After 7 days in medium containing ascorbic acid-2-phosphate -/+ a CR gel, MG-63 cultures were enzymatically digested and evaluated for hydroxyproline and DNA content, which were used as indirect measures of deposited collagen and cell number, respectively.

To directly measure CR hydrogel degradation, a release experiment was performed. Hydrogels (50 µL) were incubated in 4 mL of PBS/37ºC on a rocking platform. At specified time points, 500 µL of release buffer was collected and replaced with fresh PBS. CR released from hydrogels was quantified by measuring absorbance at 500 nm. Hydrogel mechanical properties were also measured using a rheometer

on CR slabs (1 x 20 mm) following incubation in PBS/37 ºC for 1, 2, or 3 days. Storage modulus, *G'*, and loss modulus, *G"*, were measured as a function of angular frequency from 1 – 10 rad/s. To evaluate whether material released from the CR hydrogels influenced cell viability, MG-63 cultures were incubated in medium that had been in contact with CR gels for 2 days, and a resazurin assay was used to indirectly assess cell viability of the cultures after 48 hours of exposure to the medium.

To determine if hydrogel degradation could influence diffusivity of solutes in the culture medium above the cell layer, fluorescence correlation spectroscopy (FCS) was performed utilizing RNase A fluorescently labeled with Atto 655-NHS ester. Buffer samples were taken from CR hydrogels incubated in PBS/37 ºC for 1, 2, or 3 days. FCS samples were prepared (1 µg/mL final protein concentration in hydrogel releasate or PBS) and loaded (40 µL) into capped perfusion chamber gaskets adhered to #1.5 coverslip for measurements (180 s; 640 nm ps pulsed laser; ~11.4 µW optical power; n≥6 per sample). An autocorrelation function was determined for each measurement and normalized to the initial time point. The effective tracer diffusion coefficient for RNase A in each solution was then calculated.

A computational model of steady-state axial transport of oxygen within the culture model for Fickian diffusion of a dilute species was developed (COMSOL, V5.6). A constant concentration boundary of 0.185 mol/m$^3$ of oxygen was applied to the upper medium surface based upon exchange between the aqueous medium and humidified air at 37 ºC. Oxygen consumption by the cell layer at the lower surface of the model was represented as a flux boundary based upon Michaelis-Menten kinetics and using values for osteoblasts defined in [5]. There was no oxygen flux through any surface of the culture well or the washer. Oxygen diffusivity in both the culture medium and CR hydrogel were approximated as that of oxygen in water. A constant gel thickness of 2.5 mm was used.

## RESULTS

Given the thermoreversibility of CR hydrogels, the initial focus of the study was to determine a CR concentration that would support survival of the hydrogels for 2-3 days in culture at 37°C. We found that a 5% weight per volume concentration of either kappa-CR or a CR mixture of kappa and lambda isoforms produced a hydrogel that remained intact and could be handled after a culture period of three days.

The kappa-CR and kappa/lambda-CR confinement barriers supported a 1.65-fold and 1.25-fold increase, respectively, in collagen deposition compared to the level deposited by control cultures in the absence of a gel overlay. However, both gel conditions significantly decreased the total cell number by about 50% compared to the control cultures without a gel overlay.

A direct measurement of hydrogel degradation was performed using UV-vis spectroscopy. Hydrogel degradation led to a release of polymer molecules, thereby affecting absorbance values. Following six days of incubation, kappa/lambda CR hydrogels showed 14% release, while kappa-CR hydrogels released 10% of original hydrogel concentration. Rheology was used as an indirect measurement of hydrogel degradation. Hydrogel stiffness, *G'*, decreased for both types of CR hydrogels between Day 1 and Day 3 (31% and 43% decrease for kappa and kappa/lambda, respectively). Although hydrogel degradation occurred, it was found that viability of MG-63 cultures exposed to gel-conditioned medium for 2 days was not different from control cultures that received medium only based upon assessment of metabolic activity using a resazurin assay.

FCS was used to assess potential effects of hydrogel degradation on diffusivity of solutes within the culture medium above the cell layer. Both types of CR hydrogel releasates showed slowed diffusivity of Rnase A between Day 1 and Day 3, as expected. A rightward shift of the normalized autocorrelation function was observed in the presence of the releasates, indicating hindered diffusion of protein molecules caused by release of carrageenan molecules into solution. The diffusivities of Rnase A in the hydrogel releasates were quantified and normalized by the diffusion coefficient of the protein in PBS. Kappa/lambda CR solutions showed a 1.45-fold decrease in diffusivity from Day 1 to Day 3, while kappa-CR diffusivity was reduced 1.21-fold.

To complement the cellular experiments, oxygen transport in a steady-state axial model of the confinement culture system was modeled. Because the MG-63 cell line does not exhibit contact inhibition during adherent culture, the transport model included effects of increasing cell number within the oxygen consumption boundary condition. Under baseline conditions in the absence of any hydrogel degradation, the oxygen concentration in contact with the cell layer was found to vary from 0.162 to 0.023 mol/m$^3$ for cell densities ranging from 40,000 to 320,000 cells/cm$^2$, respectively. In additional simulations, oxygen diffusivity was reduced within the culture medium directly above the cell layer to represent the effects of carrageenan macromolecules present in this medium due to hydrogel degradation. Under these conditions, a 10-25% reduction in oxygen diffusivity led to reductions in oxygen concentration for the higher densities, while only larger reductions (75 – 90%) led to reductions at the lower densities.

## DISCUSSION

This study demonstrated the potential for a confinement barrier to enhance collagen deposition in a developing 2D tissue model for a bone cell line. Degradation of the CR hydrogels was characterized by both direct and indirect measurements, with similar levels of degradation found in both types of hydrogels. The degradation of the hydrogels could lead to accumulation of carrageenan macromolecules within the culture medium located above the cell layer. This accumulation could support a localized crowding effect, as indicated by the reduced diffusivities measured with FCS in the hydrogel releasates. Given this consideration, the observed increase in collagen deposition cannot be exclusively associated with confinement effects from the hydrogel barrier. Reductions in cell number were found over the course of a 7-day culture period. An assessment of viability following exposure to gel-conditioned medium suggested that hydrogel degradation products did not have adverse effects on the MG-63 cells. The computational model indicated that the continued growth of the bone cells, coupled with a possible reduction in oxygen diffusivity due to the presence of carrageenan molecules within the medium following degradation, would lead to reduced oxygen available to the cell layer that likely contributed to the reduction in cell number that occurred when the CR gels were used. Future studies evaluating the confinement approach will utilize a stable hydrogel formulation and will evaluate a more in-depth characterization of the developing tissue layer.

## ACKNOWLEDGEMENTS

Funding, including a graduate fellowship for Samuel Stealey, was provided by the Parks College of Engineering, Aviation and Technology. Use of FCS instrumentation was kindly provided by Dr. Nicola Pozzi at Saint Louis University.

# A case study to evaluate pediatric gait speed and effects of Chiari Malformation

**T Streat-Ricchiuti (1), Dr. D Wajda (1) and Dr. B Davis (1)**

(1) Cleveland State University, Cleveland, OH, USA

## INTRODUCTION

The distinction between normal and abnormal gait in growing children is complicated by a number of factors. The formation of characteristic gait patterns is influenced by musculoskeletal growth, central nervous system maturation, and learning capacity. Furthermore, changes in gait characteristics are linked to changes in walking speed and subjects' statures. While the literature is extensive when it comes to gait patterns that are characteristic of cerebral palsy and other pediatric conditions, there is a paucity of information related to gait parameters in Chiari Malformation pediatric patients.

Chiari Malformation (CM) is a condition that affects the skull-spine junction and is linked to the cerebellum protruding into the top of the spine, obstructing the passage of cerebrospinal fluid. Headaches, dizziness, trouble swallowing, muscle weakness, and loss of neuromuscular coordination arise as a result of this increased pressure (Curone, 2017).

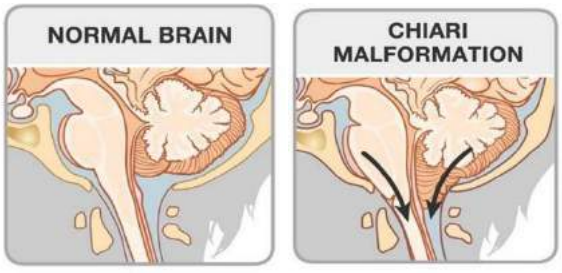

**Figure 1: Diagram of normal neurological and Chiari malformation development in patients (Shah, 2017)**

Our understanding of the functional implications of CM and how it affects gait and posture is hampered by these knowledge gaps. A better knowledge of neuromuscular function will aid neurologists, neurosurgeons devising surgical therapies, and physiotherapists developing pain reduction and rehabilitative balancing approaches. This abstract analyzes walking data collected on 10 control subjects and pediatric CM patient.

Type 2 Chiari Malformation has been diagnosed in the CM patient. The cerebellar tonsils, inferior vermis, fourth ventricle, and brain stem, as well as a small posterior fossa, are herniated in Chiari-Type 2 (Cotes, 2015).

The goal of this research is to analyze the increase in gait velocity in growing children in comparison to CM children. Even though loss of stability and difficulty walking are common symptoms in CM patients, no previous research has investigated these issues.

## METHODS

This study was approved by the Cleveland State University Institutional Review Board. Our Chiari subject was a 14 year old male and 172 centimeters in height. Our control 10 subjects were male and female ranging from 12 to 17 years old, and 60 to 178 centimeters in height. The kinematic parameters of walking, including as gait speed and step/stride parameters, were determined using a 6.1m electronic Zeno walkway (Protokinetics Inc., Havertown, PA). Individual footfalls were distinguished, and spatiotemporal aspects of the subject's gait were quantified using pressure sensors on the Zeno walkway. Participants were told to take four walks: two at their normal walking pace and two at a faster tempo without running. The subjects were instructed to walk as fast as safely possible for the fast walk trial.

**Figure 2: Control patient normal walking trial**

**Figure 3: Chiari patient normal walking trial. Yellow refers to a step that was removed because it was partially off the walkway.**

Gait trials were processed removing any uncompleted steps. Stride velocity for both variation of walking were analyzed to establish the relationship between walking velocity and height.

**Table 1: Heights, walking speed variations, and speed vs height ratio for all subjects. Chiari subject data is indicated in the green highlighted row.**

| Height (cm) | Fast walk mean (cm/sec) | Regular walk mean (cm/sec) | Fast Walking Speed/Ht | Regular Walking Speed/Ht |
|---|---|---|---|---|
| 64 | 188.4 | 125 | 2.94 | 1.95 |
| 172 | 180 | 119 | 1.05 | 0.69 |
| 163 | 181 | 127 | 1.11 | 0.78 |
| 162 | 191 | 108 | 1.18 | 0.67 |
| 161 | 182 | 120 | 1.13 | 0.75 |
| 60 | 189 | 153 | 3.15 | 2.55 |
| 156 | 219 | 167 | 1.40 | 1.07 |
| 178 | 191 | 141 | 1.07 | 0.79 |
| 156 | 192 | 140 | 1.23 | 0.90 |
| 149 | 197 | 130 | 1.32 | 0.87 |
| 158 | 163 | 113 | 1.03 | 0.72 |

## RESULTS AND DISCUSSION

When comparing the Chiari individual to the control data, there was a substantial difference for the speed/height ratio for both fast ($p = 0.035$) and regular walking ($p = 0.034$). The fast walking pace was 67 percent of the expected value for a subject of Chiari's stature, and 63 percent for the ordinary self-selected speed.

Our understanding of the functional implications of CM and how it affects gait and posture is hampered by a variety of factors, including (i) degree of tonsillation at the base of the cerebellum, (ii) presence or absence of syringomyelia, (iii) height, gender and weight influences, (iv) effects of age, (v) medication usage, and (vi) surgical history. A better knowledge of each of these factors and how they influence neuromuscular function will aid neurologists, neurosurgeons devising surgical therapies, and physiotherapists developing pain reduction and rehabilitative balancing approaches.

## CONCLUSION

The Chiari subject displayed slower walking speeds for a person of his stature. This is likely due to lack of stability in his gait. Whilst this is a case study, ongoing research will ascertain the degree to which this is consistent for all pediatric Chiari patients, and the degree to which gross motor control changes over time.

## INTRODUCTION

Abnormal morphological brain development is a symptom of some neurological diseases. For example, a unique cortical folding pattern is known to be a symptom of schizophrenia [1]. Mammalian brain images are important for studying such abnormal development in the brain because it shows how the brain folds into different thicknesses and shapes while unaffected by pathology, providing insight that can untangle the root causes of neurological disorders where abnormal folding is a symptom. A common tool for studying brain shape is magnetic resonance imaging (MRI). MRI captures the 3D gross morphologies. However, standard MRI brain scans do not consistently have an adequate resolution for analyzing cortical thickness and laminar thickness in mammalian brain scans, especially in smaller animals and in brains with a high degree of foldedness [2]. Stained tissue slices of a brain give a higher resolution picture of the white and gray matter of a brain than what is currently available through MRI. However, these images do not typically capture 3D information, and 3D geometry is known to affect thickness [3]. A 3D reconstruction would provide the necessary resolution and structure for highly accurate measurement of common brain folding parameters such as cortical thickness. Additionally, it would enable researchers to study unique brains that are solely found as serial tissue sections. In a step towards full three-dimensional reconstruction of the brain geometry, we segmented the white and gray matter from histology images of serial sections of a manatee brain using the software ImageJ, and wrote a script to align each slice to the adjacent one. The next step is to convert the connected slices into a 3D structure. This pipeline will build 3D structures of given mammalian brains. We determined that the given histology images can be processed, analyzed appropriately, and further developed into 3D models of mammalian brains.

## METHODS

For this study we utilized histology images from the University of Wisconsin and Michigan State Comparative Mammalian Brain Collections (CMBC) [4]. The CMBC has stained brain images from over 100 species in its archive. We selected the manatee brain for development of the automation pipeline because it is relatively large, making it well-defined - this will help us in identifying issues with the pipeline for ideal brains, and then the pipeline can be tailored for more difficult one. Additionally, it is less folded than a human brain, meaning it has implications for the study of human brain diseases involving lissencephaly. During collection, the CMBC sliced the mammal brains into 25-40 micron sections, with every 20th slice available on the CMBC website [4]. The resolution is comparable to the .5 mm cube resolution of an MRI scan, and the resolution in the slice plane is much higher than an MRI scan.

We used the NIH-funded image analysis software platform ImageJ to build an analysis pipeline for the histology slices [5]. The exact goal of this pipeline code is to convert the histology slices into separate 3D structures of white and gray matter. Currently, we are able to align single slices relative to each other, and have developed an ImageJ-based segmentation process that can be implemented automatically. First, we remove the text from the histology images that identifies the slice and scale of the image (Fig. 1A). We use ImageJ's color thresholding tool to separate the white and gray matter, developing masks for both tissues. Next, we make a separate binary mask of the whole brain to use to execute the alignment code. Through this process, we are able to create three separate images - a binary mask of the white matter, a binary mask of the gray matter, and a binary mask of both tissues for use in the alignment code (Fig. 1B). Finally, the binary brain slices are aligned using an optimization algorithm to minimize the differences between slices (Fig. 1C). Once

this is repeated sequentially over many pairs of images, the pipeline can use the displacements calculated from the binary images to build a 3D model of the gray matter, white matter, and whole brain (Fig. 1D).

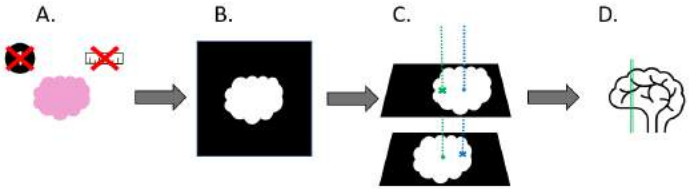

**Figure 1: Summary of pipeline code steps**

The alignment code developed through this research seeks to match two adjacent histology images of a sliced brain so that the centers of the images are aligned as they were in the original 3D brain. The displacement of each brain image from the biological center of the brain must be determined. To do this, we assume that the best alignment of adjacent brain images is the position with the least difference between the two images. The code quantifies the difference between the images by calculating the mean squared error between them. In this case, the variable $n$ represents the number of pixels in each image, and $x_i$ and $y_i$ represent the value of the pixel at each point where the variable $x$ is one binary image and $y$ is the other.

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(x_i - y_i)^2 \quad (1)$$

The slices are roughly centered in the images, so the displacement necessary to align adjacent slices should only be a few pixels. The code loops through displacements for the second image from (-20,-20) to (20,20) pixels and evaluates the mean squared error between the images for each displacement. This code identifies the lowest error displacement, aligning the images. This will allow the user to create a 3D shape from any set of sequential histology images.

## RESULTS

The code's performance can be illustrated by considering a single slice (Fig. 2A) and examining the difference between it and its adjacent slice for different displacements (Fig 2B and 2C). When the images are subtracted from each other, there is a slight mismatch, which we minimize through the alignment code. The fewer yellow pixels in the second image illustrate how the difference between images is minimized through displacement, although not completely eliminated.

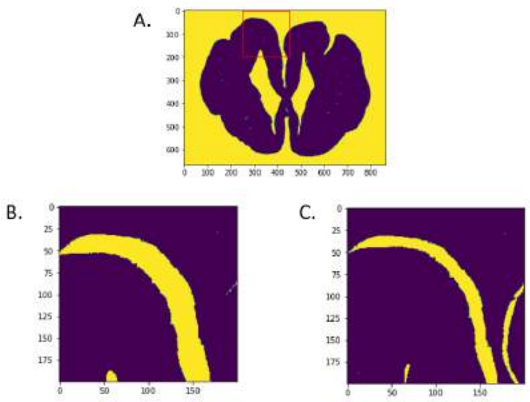

**Figure 2: (A) Brain slice #880 with the detailed portion highlighted in red. (B and C) Detail of slice difference between slice #880 and #900 for displacements [0,0] in B and [12,-9] in C. Yellow pixels indicate unique values between images.**

Our script evaluates the alignment between two sequential images via the mean squared error as a function of relative displacement (Fig. 3). The alignment of the brains is not sensitive to small displacements of a few pixels in any direction from this optimal position. However, differences of more than 5 pixels generate poor alignment.

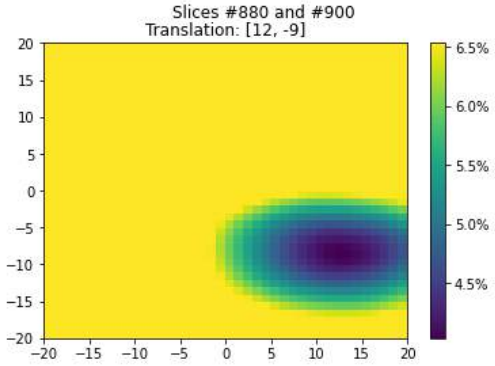

**Figure 3: Heatmap of mean squared error between slices #880 and #900 for displacements in *x* and *y*.**

## DISCUSSION

In this study we develop a code that can determine the optimal displacement between two adjacent brain histology images. Our results indicate that the alignment code can converge on an optimal displacement by minimizing the mean squared error resulting from different displacements. This means that a three-dimensional file of highly detailed gray and white matter can be developed from these images. We note that our script minimizes error between images but cannot completely eliminate it. Further development work will allow for the generation of many such 3D files that compile the highly detailed histology images of rare brains.

# Development of a Sensor-Imbedded Transmetatarsal Foot Amputation Prosthetic (TMAP)

**Jenna M. Munshi[1,2,3], Vinod Rangaprasad[1,2,3], Simon Hasik[1,2,3]**

**1 - Purdue University**

## ABSTRACT

Diabetes and peripheral arterial disease are two prevalent chronic medical conditions afflicting the global population. Lower extremity disease secondary to diabetic microvascular and peripheral vascular disease often result in transmetatarsal foot amputation (TMA). Management after TMA requires extensive rehabilitation, often with the aid of prosthetics. Current prosthetics lack the comfort and suspension patients required; they do not adequately support gait, balance, proprioception, and can negatively impact post-amputation limb health. To address these drawbacks, our team designed a Transmetatarsal Foot Prosthetic (TMAP) that enhances proprioception, balance and gait while improving limb health. The new prosthetic is integrated into a compression sock with contractible strings placed within the sock acting as tendons to distribute the patient's weight evenly as they walk. As the patient steps forward, placing weight on the prosthetic results in the "tendons" extending to redistribute the weight across the foot. Placing weight on the back of the foot results in retraction of the tendons. The prosthetic is flexible and utilizes an elastic band to aid in weight distribution. Sensors embedded in the insoles detect changes in weight distribution across both feet. Heart rate/pulse oximetric sensors within the compression sock monitor the health of the limb. Data is collected and stored in real time on a mobile app, to be retrieved by therapists during scheduled appointments. The prototype, currently in its developmental phase, will be completed by early March. In conclusion, the TMFP will improve gait and balance, increase comfort and proprioception, and improve limb health post-amputation.

## INTRODUCTION

The transmetatarsal foot amputation is one of the most common procedures for patients suffering from diabetes and peripheral neuropathy. Current solutions do not focus on the patient's health and safety, but rather on convenience. Our prosthetic is designed to monitor the patient's biometric data and account for balance and gait. This gives the patient the ability to return to their daily life with ease. Our prosthetic works in conjunction with a mobile app. This allows physicians and physical therapists to see the patient's data (heart rate, blood pressure, etc) and assign the necessary exercises or procedures that will most benefit the patient. It provides individualized care with easy transmission of data from patient to doctor. TMAP would be considered a Class I medical device as it is an improvement of similar prosthetics, while using elements of modern design: sensors and improved comfort for the user. A 510(k) or PMA would likely not be needed. TMAP would follow FDA's General Controls in ensuring safety and effectiveness through provisions regarding adulteration, misbranding, device registration, keeping records, and standard manufacturing practices. The market for TMAP is on the increase. As more and more people acquire comorbidities like diabetes and peripheral neuropathy disease, the TMA will become more common. Our modern

SB³C2022-483

and holistic prosthetic will be the ideal solution to this issue.

**PROBLEM STATEMENT**

The transmetatarsal foot amputation (TMA) is common in patients with diabetic neuropathy, ulcers, and peripheral artery disease. Partial foot amputations such as TMA are the most common type of amputation in the United States, and affects over 600,000 individuals. As the prevalence of diabetes and vascular diseases increase over time, experts say the frequency of TMA could double by 2050. While it is a viable option for limb salvage, TMA is an especially difficult wound to heal. Approximately 15 to 45% of partial foot amputation patients undergo a secondary amputation[1]. One factor in this is post-amputation skin breakdown and subsequent ulceration. Prosthetics can be used as a solution to promote healing and preserve function with respect to weight-bearing and ambulation. Current solutions lack suspension, impair limb health, and do not allow for proper proprioception of users. Our prosthetic is designed to take into account gait and balance, and provide a safer, more comfortable way of walking.

**SOLUTION STATEMENT**

The objective of this prosthetic is to provide a comfortable and safe way for Transmetatarsal foot amputation patients to heal and ambulate again. The sensors in the insoles of the prosthetic detect changes in weight distribution across not only the partially amputated foot, but also the healthy foot. This allows the prosthetic to normalize the patient's gait and ensure that they are walking as they once did. The compression sock contains sensors that take basic biometric data to monitor the limb health. The data is then stored in a mobile app and can be analyzed each time the patient has an appointment with the physical therapist or primary care doctor. This is invaluable because it provides day by day documentation of the patient's progress, allowing therapists and doctors to see each piece of data necessary to assess the patient and recommend the right medication, exercise, or activity with specificity.

# *IN VITRO* HUMAN LUNG FIBROBLAST-TO-MYOFIBROBLAST TRANSITION FROM PROFIBROTIC GROWTH FACTOR STIMULATION

**Catherine S. Sano (1), Julie Leonard-Duke (2), Shayn M. Peirce-Cottler (2)**

(1) Department of Chemical Engineering, University of Virginia, Charlottesville, Virginia, United States

## INTRODUCTION

Idiopathic pulmonary fibrosis (IPF) is a terminal disease characterized by uncontrolled extracellular matrix (ECM) production mediated by fibroblast and myofibroblast activity in the lung.[1] The complex lung microenvironment poses challenges to determining the mechanisms of IPF progression. There are currently only two FDA-approved antifibrotic drugs, Nintedanib and Pirfenidone, which can slow the rate of fibrosis but do not halt it.[2] Fibroblasts have cell surface protein receptors called integrins that bind to the ECM allowing them to sense their environment, a process called mechanosensing.[3] Thy-1, a cell surface glycoprotein, blocks the binding of integrins with the ECM and regulates this mechanosensing.[3] The loss of Thy-1 increases susceptibility to external mechanical stimuli, as the integrin-ECM binding is uninhibited, and triggers the excessive and pathological fibrotic response in IPF.[3]

Fibroblasts additionally respond to signaling molecules in the lung microenvironment, specifically inflammatory cytokines and growth factors, such as TGF-$\beta$, inducing their differentiation into myofibroblasts.[4] Myofibroblasts are characterized by an increase in size, α-smooth muscle actin ($\alpha$-SMA) upregulation, and elevated collagen I production, which increase the stiffness of the lung, reducing compliance and impairing gas exchange, and is exacerbated by increased mechanosensing from Thy-1 loss in IPF.[5] Fibroblasts also produce and secrete additional inflammatory cytokines and profibrotic growth factors, such as TGF-$\beta$, which causes a reduction in their Thy-1 expression levels and further perpetuates the pro-fibrotic pathways and fibroblast-to-myofibroblast transition.[6] **The objective of this study was to quantify the impact of TGF-$\beta$ stimulation on human lung fibroblast f-actin and α-SMA expression, and determine whether the lung fibroblasts can be stimulated to exhibit a myofibroblast phenotype *in vitro*.**

## METHODS

To determine myofibroblast transformation, human lung fibroblast cells were stimulated with the growth factor, TGF-$\beta$, and the expression of characteristic myofibroblast markers were quantified using immunofluorescent staining. Commercially available human lung fibroblasts (CCL-210) were initially plated on a 24-well glass plate in 0.5mL standard culture media, DMEM-F12 with 1% Penicillin-Streptomycin and 10% fetal bovine serum (FBS), at a density of 50,000 cells/well to allow for proliferation and adherence to the wells. The media was changed to media without FBS the following day and the experimental groups were be stimulated with 20ng/mL of TGF-$\beta$. The media without FBS prevents binding of the treatment to factors in the serum, allowing uptake of TGF-$\beta$ by the cells. Additionally, a control group without treatment received media without FBS. Three days after the media change, the cells were fixed and immunostained.

Cells were stained with different colored fluorescent markers to image nuclei (DAPI stain), $\alpha$-SMA (monoclonal antibody), and F-actin (Phalloidin stain). Five representative microscopic images of each well of the culture plate were acquired using a Leica Thunder microscope and a 20x objective. ImageJ software was used to quantify cell numbers and sizes according to DAPI and Phalloidin stains, respectively, as well as the relative fluorescence intensity of the stains for $\alpha$-SMA and Thy-1. The five representative images were cropped to 500x500µm images, which were separated into three images: blue (DAPI), red (Phalloidin), and green ($\alpha$-SMA). The colored images were grey-scaled and each pixel was quantified on a scale from 0-255, proportional to the fluorescence. The median grey values for the Phalloidin and $\alpha$-SMA stains were averaged for the unstimulated and stimulated groups and percent change in the averaged median grey values were calculated. Error was determined by standard error of mean and standard error propagation with a total of 10 images analyzed per experimental group.

SB³C2022-484

## RESULTS

Upon stimulation of the human lung fibroblast cells with TGF-$\beta$ the cells exhibited elevated f-actin and $\alpha$-SMA expression, demonstrated by the percent increase in fluorescence from the Phalloidin and $\alpha$-SMA monoclonal antibodies that bind to those proteins (Figure 1).

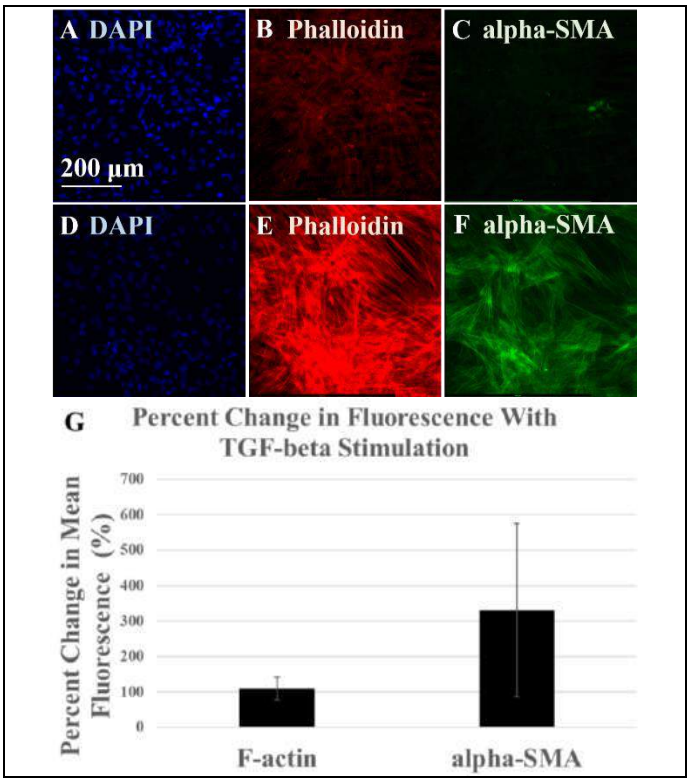

**Figure 1 Stimulation of fibroblasts with TGF-$\beta$ results in cytoskeleton remodeling. A-F: Immunofluorescent images without stimulation (A-C) and with TGF-$\beta$ stimulation (D-F). G: Percent change in mean fluorescence (from multiple wells and fields of view) of Phalloidin stain (109.9±32.1%) and stain for $\alpha$-SMA (330.6±245%) with TGF-$\beta$ stimulation.**

## DISCUSSION

Increased expression levels of f-actin and $\alpha$-SMA are consistent with previous work by Rikard et al. from the Peirce-Cottler lab, where human cardiac fibroblast cells similarly exhibited heightened f-actin and $\alpha$-SMA upon stimulation with TGF-$\beta$.[7] Elevated expression of both f-actin and $\alpha$-SMA indicates enhanced growth of the fibroblasts and contractility in the lung consistent with the myofibroblast phenotype.

Limitations of the study include the small sample size: a total of 20 images were analyzed, 10 stimulated and 10 unstimulated, which likely contributed to the large error in percent increase of $\alpha$-SMA expression. Further repetitions of the experiment should be performed to corroborate these results. Future experiments will test for other myofibroblast marker expressions, such as Thy-1, collagen, and inflammatory cytokines, upon stimulation with combinations of inflammatory cytokines and growth factors. Additional protein expression measurement methods, including qRT-PCR, ELISA, and western blot will also be used to support myofibroblast character.

The results of this experiment are evidence of myofibroblast transition upon uptake of the growth factor present in the lung microenvironment naturally and in greater numbers from the pathological response in IPF. This phenotypic shift, thus likely contributes to the reduced respiration and ventilation as a result of impaired alveolar expansion and contraction in IPF, demonstrating the pathological interaction of lung fibroblasts with growth factor signaling molecules in IPF. Determining how specific intersecting molecular signaling pathways drive pathological fibroblast behaviors has the potential to suggest new treatments that more comprehensively address the interplay between lung fibroblasts and their environment in IPF, as well as other diseases characterized by lung fibrosis, such as long-COVID-19.

# 3D ULTRASOUND IMAGING OF THE MURINE CERVIX DURING PREGNANCY USING PRETERM BIRTH MODELS

**Riley L. Holloway (1), Jennifer L. Anderson (1), Craig J. Goergen (1)**

(1) Weldon School of Biomedical Engineering
Purdue University
West Lafayette, Indiana, USA

## INTRODUCTION

Preterm birth (PTB) is defined as birth before 37 weeks gestation in humans and affects 1 in 10 babies in the United States [1]. These babies face higher morbidity and mortality rates due to their underdeveloped organs. One cause of preterm birth is cervical insufficiency or cervical incompetence that affects every 1 in 100 pregnancies in the U.S. Cervical insufficiency is defined as the inability of the cervix to remain closed until gestation is complete [2][3]. It is widely known that as gestation progresses, the cervix length decreases. This is known as cervical ripening, a normal process of softening and opening of the cervix before labor starts. Premature or extreme remodeling or ripening of the cervix can cause cervical insufficiency and lead to preterm birth.

The current tool to diagnose an incompetent cervix is a uniaxial ultrasound measurement at routine checkups. The ultrasound measurement method utilizes a uniaxial view of the cervix, which does not account for the three-dimensional complexity of the organ. This can lead to incomplete or inaccurate measurements of the cervix. For example, one study found that out of 56.3% of subjects whose cervixes decreased in length between gestation weeks 24-28, only 4.2% gave birth preterm [4]. Other studies have assessed the cervix in a non-pregnant state or have failed to assess the cervix longitudinally over time [5]. This lack of data on the geometric remodeling of the cervix and an assumed uniaxial ultrasound measurement can lead to both over and underdiagnosis, and a larger number of preterm births. Our study aims to capture two and three-dimensional longitudinal ultrasound images of the cervix so that a better understanding of the complex remodeling process can be made.

There are two established mouse models of PTB: one by an inflammatory process, and one by the premature withdrawal of progesterone (P) activity through the administration of lipopolysaccharide (LPS) and RU486, respectively. LPS is an endotoxin derived from the *e. coli* pathogen. RU486 (or mifepristone) blocks progesterone which is needed to keep the embryo attached to the uterine lining. These animal models allow us to study the distinct pathways driving premature cervical remodeling [6]. To address these challenges, our group induced both models of PTB to assess changes in murine cervical geometry and mechanics throughout gestation via *in vivo* ultrasound assessment.

## METHODS

For this study, a similar experimental protocol was used as with previous three-dimensional ultrasound studies that measured the cervix [7]. Five nulligravida female C57BL/6J mice, ages 8-12 weeks were used (initial body mass = 21.6g ± 1.0 g). The mice were anesthetized using 1-3% isoflurane, depilatory cream was used on the pelvic area to remove hair and ultrasound conductive gel was placed on the lower abdomen. Three-dimensional ultrasound images of the murine cervix were acquired before and during pregnancy using a high-frequency ultrasound system (Vevo3100 Imaging system, FUJIFILM VisualSonics, Inc., Toronto, ON, Canada). To take a three-dimensional ultrasound image, a stepper motor was used to acquire successive ECG and respiration-gated B-mode images with a step size of 0.08 mm from the vaginal canal through the bifurcation of the uterine horns. The female mice were then paired with male mice and checked every 3-4 days for pregnancy using standard two-dimensional ultrasound images. Dating of pregnancy was determined by of the appearance of the decidual reaction, gestational sacs, and other features seen in early gestation. Three-dimensional ultrasound was repeated at this pregnancy check (typically gestational stage e6.5), and then again at days e12.5, e15.5, and e16.5.

Between timepoints e15.5 and e16.5, the preterm birth intervention was implemented - either via the inflammatory process from LPS (inflammation group, n = 2), or the premature withdrawal of progesterone via RU486 (non-inflammation group, n = 1). For the inflammation model, we administered 250 μg of LPS (Escherichia coli

serotype 055:B5, Sigma) dissolved in 30 uL sterile water intravaginally [8]. For the non-inflammation model, we administered 0.5 mg of RU486 (Sigma) dissolved in 50 µL of ethanol and brought up in 150 µL of glycerol trioleate (Sigma) subcutaneously [9]. Sham groups used the vehicle, (30 uL sterile water injected intravaginally for the inflammation model and 50 µL of ethanol and 150 µL of glycerol trioleate injected subcutaneously for the non-inflammation model) as a control (inflammation, n = 1; non-inflammation, n = 1).

Three-dimensional volumetric renderings (see Figure 1) were created using SimVascular [10] and analyzed in Python (v3.8.2) and Blender (v2.79b) using the NeuroMorph toolset (v2.0) [11]. Cervical area and height were calculated at all timepoints from the volumetric renderings. At e16.5, the mice were euthanized via isoflurane overdose and cervical dislocation. Upon euthanasia, the intact uterus and cervix were removed and weighed.

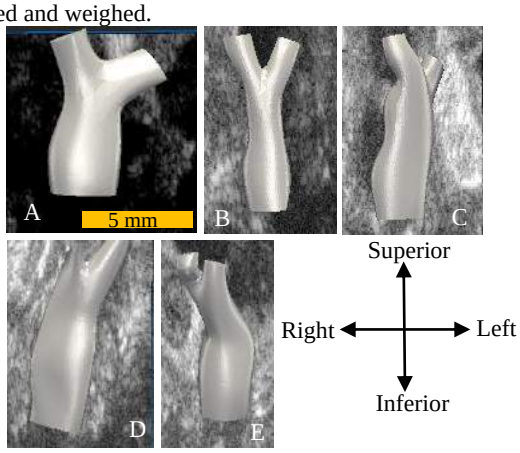

**Figure 1: Three-dimensional volumetric rendering of the murine cervix in the non-inflammation model. (A) Non-pregnant state. (B) Gestational age e6.5. (C) Gestational age e12.5. (D) Gestational age e15.5. (E) Gestational age e16.5.**

## RESULTS

Our results suggest cervical length increases and cervical area decreases after LPS introduction which occurs after e15.5 (Figure 2). In the non-inflammation model, cervical length decreases and cervical area increases after injection of RU486, also occurring after e15.5.

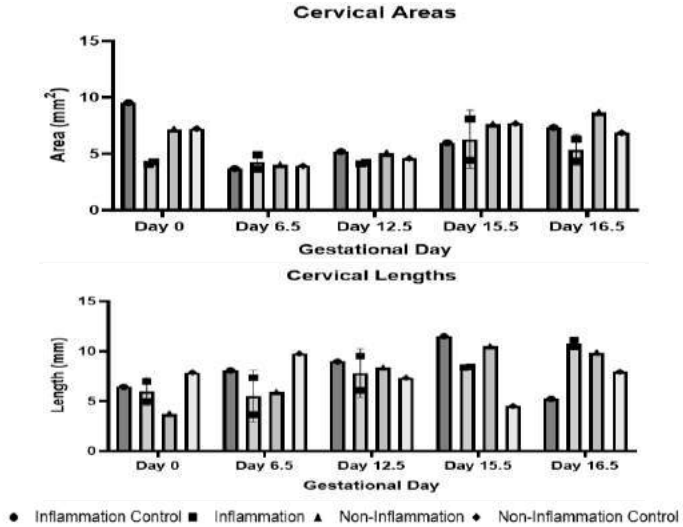

**Figure 2: Cervical area (top) and length (bottom) at multiple gestational timepoints.**

## DISCUSSION

In a typical pregnancy as gestation progresses, cervical length decreases, and cervical area increases. While the non-inflammation model follows this expectation, the inflammation model results do not. This could be because of our very small group sizes or be a potential indicator of differences between groups in respect to how the cervix remodels. Additionally, external factors such as the administration route - intravaginally versus subcutaneously - could affect cervical remodeling. More data is needed to investigate these findings, with work in progress to add additional animals to each group. Future work could also assess both cardiac remodeling and histologic changes associated with both models.

## INTRODUCTION

Skeletal muscle provides the necessary functions required for human locomotion. Computational models – such as musculoskeletal or finite element simulations – are often utilized in clinical settings for a variety of purposes, such as rehabilitative strategies, prosthetic and orthotic device fitting, and determining at-risk groups for certain injuries [1,2]. In most models, muscles are treated as one-dimensional elements that only exert force in a single line of action. However, research has shown that force is transmitted both laterally within skeletal muscle and between surrounding muscles [3,4]. Such findings also highlight the importance of passive properties such as anisotropic stiffness, which allow the force generated by the muscle cells to be transmitted throughout the skeletal system and induce movement [5]. Passive muscle properties are also crucial to proper function, as many neuromuscular impairments can manifest through increased passive stiffness. While this lateral force transmission is known to exist, there is not much information on the specifics - such as when and how much force transmission occurs. Recent studies also show that stretching muscle biaxially may enact certain passive mechanisms relating to force transmission, such as dispersed collagen fibers, that are hidden during uniaxial stretch [6].

Therefore, we conducted biaxial tensile testing to study the stiffness of muscle tissue under uniaxial versus biaxial tensile stretch and hypothesized that skeletal muscle will be stiffer in biaxial stretch. The data gained from this study can help improve future musculoskeletal and finite element models by developing a more comprehensive understanding of lateral force transmission in skeletal muscle. This may drastically alter the assumptions used to drive such simulations.

## METHODS

Fresh porcine skeletal muscle was obtained for experimentation on the day of sacrifice from a local abattoir. No live animal handling was performed by any researchers for this study. Tissue was harvested from the semimembranosus and biceps femoris using standard dissection techniques and prepared into cruciform shapes. The samples were speckled with graphite powder and fitted into a planar biaxial tensile testing machine with integrated digital image correlation. The samples each underwent three tensile tests, including uniaxial stretch in each direction and biaxial stretch. Specifically, the muscle was stretched longitudinally while being allowed to naturally compress in the transverse direction due to the Poisson effect. Similarly, it was also stretched in the transverse direction while being allowed to compress naturally in the longitudinal direction. Finally, the muscle was stretched biaxially at a ratio of 1:1. The testing order was randomized, and all three tests were conducted at a strain rate of 0.5% until 20% nominal strain. Testing was performed on n=25 samples.

Image data was collected and analyzed with VIC2D (Correlated Solutions, Inc.), where engineering strains were calculated and exported into MATLAB along with the raw force and displacement data from the tensile machine. A custom script was written to extract, filter, and smooth the data to obtain stress-strain relationships for all three tests for each sample. The stress-strain curves were plotted, and a mean curve for each testing type and direction was calculated to allow for a visual representation of the stiffness of the muscle. The individual curves were then fit to an exponential equation with parameters a, correlating to stiffness, and b, correlating to nonlinearity, to characterize the general tissue stiffness between testing conditions. These data were exported to Excel and used to a run a statistical analysis, specifically a t-test assuming unequal variance, to determine whether the parameters were significantly different or not. Some tests, due to the nature of the stretching, yielded parameters with very poor fit; these samples, all with a goodness of fit value below 0.8, were omitted from the statistical analysis to achieve a more representative p-value.

## RESULTS

The stress-strain curves for the longitudinal biaxial test and longitudinal uniaxial test can be seen in Figure 1. The p-value for the unpaired t-test was 0.219 and 0.193 for parameters a and b, respectively, indicating that neither of these values were statistically significant from each other.

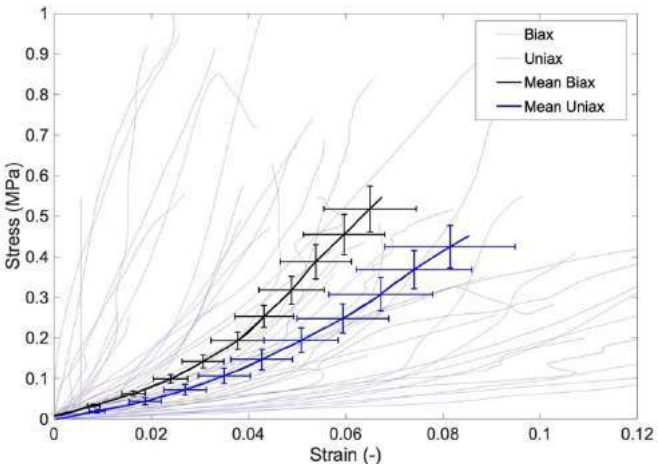

**Figure 1: Stress-strain curve of samples (n=25) under longitudinal biaxial and uniaxial stretch with stress and strain data calculated from force and displacement data, respectively.**

The stress-strain curves for the transverse biaxial test and transverse uniaxial test can be seen in Figure 2. The p-value for the unpaired t-test was 0.191 and 0.039 for parameters a and b, respectively, indicating that the former coefficients were not statistically significant while the latter coefficients were.

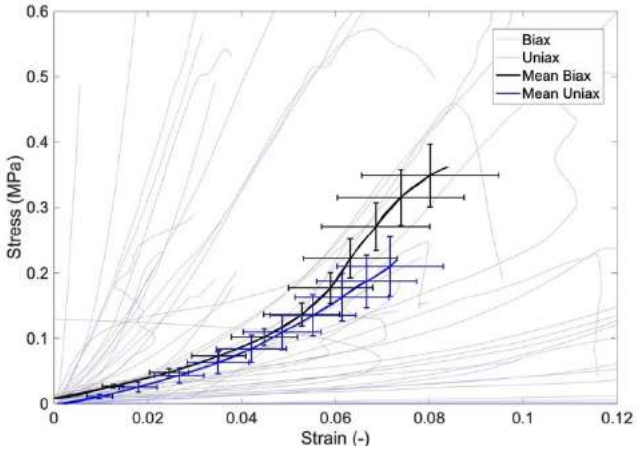

**Figure 2: Stress-strain curve of samples (n=25) under transverse biaxial and uniaxial stretch with stress and strain data calculated from force and displacement data, respectively.**

## DISCUSSION

This study presents, to the best of our knowledge, a direct comparison of uniaxially and biaxially stretched skeletal muscle for the first time. From this novel data, we conclude that there is no statistical significance in the stress-strain relationships in the longitudinal direction when fit with an exponential function (Figure 1); this indicates that there is limited functional difference in the stiffness when experiencing uniaxial versus biaxial stretch. The results of Figure 2 indicate that there was a significant difference in coefficient b, the exponent of the exponential function, which shows that the nonlinearity of the muscle varies between the two testing types in the transverse direction; judging by the two curves, the tissue experienced a marginally greater stiffness under biaxial stretch than it did in uniaxial.

Although the statistical significance can be determined via the analyses presented here, the biological significance of these results was not evaluated in this study. Biaxial stretch may be a better representation than uniaxial stretch, but our results suggest it may not cause considerable differences in observed stiffness. In order to fully see the consequences of uniaxial versus biaxial stretch, constitutive modeling should be implemented to better understand the results in the context of muscle structure and function. The exponential fit applied here, although a simple and effective method, did not capture the interaction between the longitudinal and transverse directions. The stress calculated was not an accurate simulation of the cruciform shape and the true stress experienced by the center of the muscle sample. Overall, the tests performed here are only a small representation of an attempt to characterize the deformative behaviors of skeletal muscle and can be expanded upon much farther with more advanced experimentation and computational analysis.

Our results correlate to previously published data that observed a greater stiffness in the transverse direction of passively stretched muscle; however, there have also been studies that have found the stiffness to be greater in the longitudinal direction [7,8]. The similarities in stiffness of both directions in our data indicate the variability of muscle tissue and how many factors can affect the apparent mechanical properties. In addition, there are other methods of evaluating stiffness outside what was done in this study, such as comparing tangent moduli and inverse finite element analysis that may be of interest.

The results show that biaxial stretch may be a more accurate way of characterizing the stiffness of muscle. The information gleaned from this study can be implemented into musculoskeletal models to evaluate the effect on its behaviors. One application of these models includes surgical planning for hamstring lengthening for cerebral palsy patients [9]. In this condition, the hamstring contracts into an extremely tight state that prevents full range of motion in the leg; in order to treat it, the tendons in the hamstring are either elongated or fully cut to let the muscle stretch out and prevent poor force transmission. The choice can be unclear at times, and computational tools such as musculoskeletal simulations, which could benefit from the work done here, can be used to guide such procedures by estimating hamstring lengths and forces.

Our main takeaways from this study are that skeletal muscle tissue is slightly stiffer under biaxial stretch, with more similarity in the longitudinal direction, but that the stiffness may not be functionally significant. Future work on the collection of biaxial tensile data and implementation into various models can verify these findings.

## INTRODUCTION

There are over 600 skeletal muscles in the human body, and each plays a specific role in generating and transmitting force. Skeletal muscle is considered bi-phasic, consisting of solids (such as collagen, contractile constituents, etc.) and liquids (interstitial fluid and cellular fluid). Muscle tissue is approximately 70-80% fluid, yet fluid is largely ignored when considering the mechanical function of skeletal muscle. However, recent work has shown that fluid could play a key role in force generation and transmission [1].

Intramuscular pressure (IMP) is the pressurization of skeletal interstitial fluid during active contraction and passive deformation [2]. While much work has been done to characterize the relationship between contractile force and IMP, fluid pressurization as a phenomenon is poorly understood under compressive conditions. Specifically, it is unknown how the solid and fluid phases of muscle contribute to compressive stiffness. The goal of this project is to determine the relationship between fluid pressure and compressive stress of skeletal muscle under semi-confined, passive compression conditions. We developed and employed an experimental protocol to measure fluid pressure during semi-confined compression. We hypothesized that fluid pressure and compressive stress would be correlated during compression, but that fluid pressure would remain between 50-100% of compressive stress.

## METHODS

Four porcine hind limbs were obtained from a local abattoir. No live animal handling was performed by researchers involved in this study. Following standard dissection procedures, the gracilis and semitendinosus muscles were isolated. These muscles were stored in a refrigerator at 4ºC immediately after dissection. Between 24-48 hours post-mortem, testing samples were isolated from the refrigerated muscles. The desired specimen sizes were 30x30x20 mm rectangular cuboids, cut with a custom specimen slicer. Rectangular cuboid samples had an average length and standard deviation of 30.24 ± 0.89 mm for two sides with an average height and standard deviation of 20.08 ± 0.43 mm as measured using a digital caliper.

Compression tests were conducted on a planar biaxial material testing system custom fabricated by ADMET (Norwood, MA). Force data was collected by a 50 lbf (222 N) load cell collected at 100 Hz. In semi-confinement, specimens were compressed uniaxially and confined in one direction with the third direction free from boundary conditions. All testing was completed with samples submerged in 10% phosphate buffered saline. A compression rate of 0.33 %/s was used to 30% compressive strain (0.7 stretch), followed by a 300 second relaxation period post-compression. A total of n=13 samples were used for this study. Engineering stress and engineering strain were calculated from initial sample dimensions, load cell force data, and displacement data.

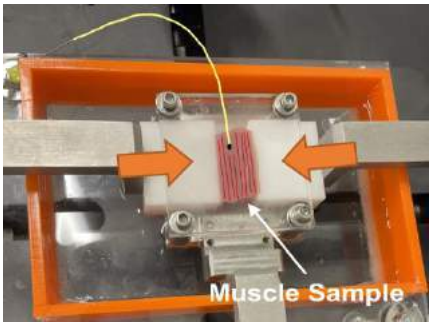

**Figure 1. Image of the experimental setup. Orange arrows denote the direction of compression. The midbelly sensor location is represented with the yellow line and black sensor tip. Muscle samples were restricted with platens in the vertical direction and free of boundary conditions in the lateral direction.**

Fluid pressure data was collected using a fiber-optic pressure microsensor (diameter 0.46 mm and ± 3 mmHg accuracy) inserted transverse to the compression direction for each sample [2] (FISO Technologies). Prior to sensor insertion, 400 µL of hyaluronic acid (HA) was placed near the needle tip, to create a stable aqueous area [3]. Muscle fibers were mounted parallel to sensor insertion and

perpendicular to the direction of compression (Figure 1). Fiber direction was established by visual inspection.

Linear regression analysis was performed for fluid pressure versus engineering stress values at 0.1, 0.2, and 0.3 compressive engineering strain levels and at 50 and 300 seconds into the relaxation period with significance set at $p<0.05$ to determine the correlation between intramuscular fluid pressure and tissue stress.

## RESULTS

Muscle tissue exhibited nonlinear stiffness in compression (Figure 2) and relaxation (Figure 3). Fluid pressure followed a similar, but inverted, pattern to engineering stress, with increases during the compression phase (Figure 2), and decreases during relaxation (Figure 3). As the skeletal muscle reaches 30% compression, fluid pressure and engineering stress exhibit a near 1:1 ratio (Figure 4). This near ratio becomes more exact in the relation period (Figure 4). Across all engineering strain and relaxation levels, fluid pressure was positively correlated with tissue engineering stress ($R^2>0.86$, $p<0.001$ for 10%, 20%, and 30% compressive engineering strain and at 50 and 300 seconds of relaxation).

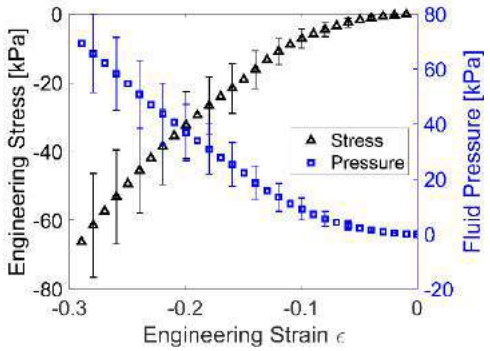

**Figure 2. Engineering stress (black triangles) and intramuscular fluid pressure (blue squares) versus compressive stretch with standard error bars).**

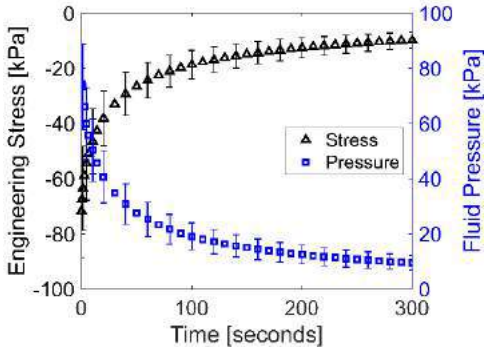

**Figure 3. Engineering stress (black triangles) and intramuscular fluid pressure (blue squares) versus time during the relaxation period. Data presented with standard error bars.**

## DISCUSSION

This work presents the first experimental study of the effect of compression on intramuscular pressure. We used a pressure microsensor and custom materials testing setup to perform semi-confined compression on porcine muscle tissue, as semi-confinement is likely to be more representative of *in vivo* conditions than fully confined or unconfined states [4]. The nonlinear stiffness and nonlinear relaxation of muscle tissue under compression agrees with previous materials testing studies of skeletal muscle [4].

Our results show that tissue engineering stress and fluid pressurization exhibit a nearly 1:1 inverse relationship, particularly under semi-confined conditions. This finding suggests that fluid pressurization plays a key role in the compressive stiffness of muscle tissue. However, further experimentation and modeling is needed to test this hypothesis more rigorously. While we hypothesized that fluid pressure would correlate to tissue stress but remain between 50-100% of stress, our data suggests slightly higher fluid pressurization during compression (Figure 4).

This work can be used to better understand how various constituents contribute to muscle stiffness in compression, and thus how the conditions such as a deep tissue injury (DTI) develop. For example, while interstitial fluid is present in all muscle, impaired or injured tissue may have altered interstitial fluid flow or pressurization. Such a case could cause mechanical damage to muscle fibers due to bearing a larger fraction of the compressive load. Future studies to investigate this potential phenomenon, particularly with computational modeling, would benefit the field.

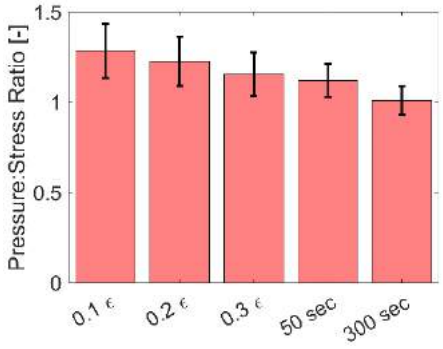

**Figure 4. Intramuscular fluid pressure:engineering stress ratio versus compressive engineering strain and relaxation points with standard error.**

## CONCLUSIONS

This study suggests that interstitial fluid may be a key contributor to muscle stiffness in compression. Previous studies have largely ignored the role of fluid pressure in muscle mechanics, with the exception of some work during elongation and contraction [1]. We employed an experimental approach to measure tissue stress and intramuscular pressure during semi-confined compression. Our results show that during compression, tissue stress and fluid pressure are highly correlated (Figures 2-4). Future work to investigate the role of interstitial fluid in various ages could be a significant contribution to the biomechanics field. Such work could be completed by performing simulations, such as a finite element modeling, to relate experimental data to tissue physiology.

## INTRODUCTION

Worldwide, about 50% of adult women are affected by pelvic organ prolapse (POP), which is characterized by the descent of any or all the pelvic floor organs: bowel, uterus, and bladder. Only 12.6% of women suffering from POP are eligible to undergo corrective surgery, which only has a ~30% success rate [1]. Multiple factors are associated with POP, such as age, body weight, pregnancy, and the number of vaginal births, which are thought to affect the mechanical integrity of pelvic floor tissues, including the uterosacral ligament (USL) [1]. USLs are critically important supportive structures for the uterus and vagina, and tether the cervix to the sacrum [2]. Pregnancy and vaginal childbirth are known to impose additional mechanical strain on the USLs, potentially causing injury and increasing the chances of developing POP [3]. Type I collagen is known to be a major tensile load-bearing protein, and therefore likely to be involved in USL failure and POP. However, mechanical thresholds (i.e., injury criteria) for collagen in the USL are unknown. Defining injury criteria for USLs before, during, and after pregnancy will inform computational models of pelvic floor injury, improve our understanding of injury risk, and guide injury prevention efforts.

In this study, we employ a murine model to investigate the effect of pregnancy on the susceptibility of USLs to mechanical injury. Murine and human anatomy are similar; USLs in both species have similar anatomical landmarks and intersection points with the uterus, cervix, and sacrum, as well as similar composition and histology [4]. Here, we develop a methodology to spatially map mechanical strain and collagen damage in the murine USL, construct multimodal injury criteria from this full-field data, and compare the injury criteria for USLs from virgin and pregnant mice. Preliminary results indicate that pregnancy-related changes may protect the USL from major collagen damage by reducing the injurious potential of strains transverse to the primary collagen fiber direction.

## METHODS

Female mice (one virgin and one pregnant at day 19 of gestation) were obtained and euthanized according to the University of Colorado Boulder's Animal Care and Use Committee. For each sample, we isolated the pelvic bone structure, a single USL, and the cervix. The cervical end of the USL was tied with a 5-0 polyglactin suture, and the uterus was cut away, leaving a section of the cervix to act as an anchor and prevent the USL from sliding out of the suture loop. The second USL was completely removed, so that only one USL was mechanically tested. The sample was then placed in a custom staining well with a solution of Ghost Dye 780 (Tonbo Biosciences) and NucBlue Reagent (ThermoFisher Scientific) in 1× PBS for 2 hours at 4 °C on a rocker.

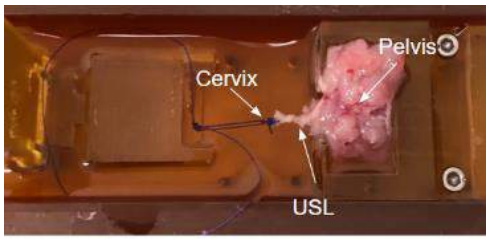

**Figure 1. Murine USLs were mechanically tested in a custom loading device.**

The sample was attached to two custom 3D printed (Objet Polyjet) grips (Fig. 1). The pelvis was secured onto a fixed grip, and the cervical attachment grip was connected to a movable Femtotools actuator. The sample was tested in a custom loading chamber with a bath of 1× PBS under a confocal microscope (Leica STELLARIS), attached to a Futek in-line 10 N load cell. The actuator was displaced until the slack in the USL was removed to determine the reference state.

Collagen hybridizing peptide (CHP) was used to determine regions with significant collagen denaturation [5]. Prior to mechanical testing, the PBS bath was replaced with a 10 µM solution of CHP for 15 minutes. This staining procedure was repeated after each deformation step to monitor changes in collagen damage. The samples were imaged at 10× magnification (2.14 µm pixel resolution) before, during, and after deformation. Deformed configurations were prescribed by actuator displacements of 1000, 2000, 3000, and 4000 µm. For each volume image, max intensity projections were created. 2D displacement fields were estimated using composite Ghost Dye and NucBlue images of reference and deformed states with MATLAB's *imregdemons* function, from which, Lagrange strain fields were derived. A moving threshold was used to determine pixels with significant collagen damage,

$$\gamma_i = \mu_i + 3\sigma_1 \quad (1)$$

Where $\gamma_i$ is the CHP image intensity threshold for the $i^{\text{th}}$ reference image, $\mu_i$ is the mean CHP intensity of the $i^{\text{th}}$ reference image, and $\sigma_1$ is the standard deviation in CHP intensity of the original reference image. This thresholding method is robust to increases in image intensity resulting from multiple stain times. Injury criteria were developed from damage maps and corresponding strain fields using logistic regression (MATLAB) to determine the strain thresholds for collagen denaturation.

## RESULTS

Ghost Dye and NucBlue composite images provided a trackable pattern for deformation mapping, and there was an increase in CHP image intensity following increased applied displacement (Fig. 2).

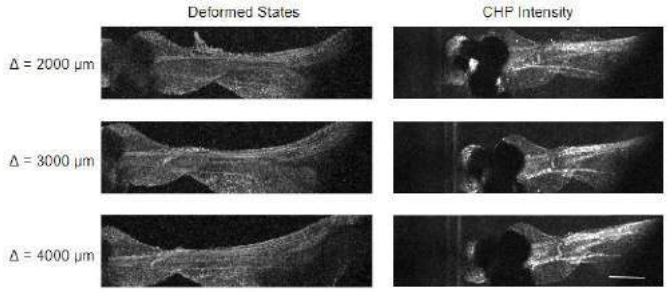

**Figure 2. Raw images of a USL from a virgin mouse at applied displacements of 2000, 3000 and 4000 µm and respective CHP images following deformation (scale bar = 500 µm).**

Computed deformation fields and collagen damage maps were inhomogeneous (Fig 3). Axial strains ($E_{11}$) increased as the applied deformation increased. This strain is along the orientation of the collagen fibers, and as predicted, damage increased with axial strain.

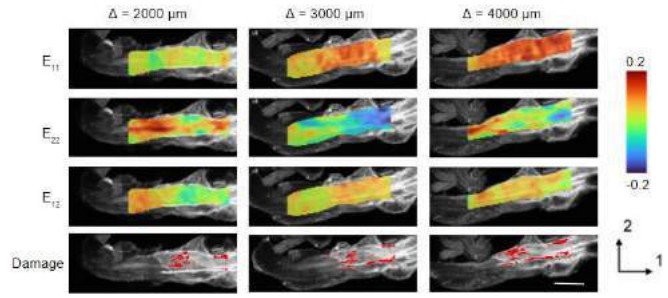

**Figure 3. Lagrange strain fields and damage maps after 2000, 3000 and 4000 µm displacements for a USL from a pregnant mouse (scale bar = 500 µm).**

Comparing collagen injury criteria for USLs from a virgin mouse and a pregnant mouse (gestation day 19), we saw a slight increase in $E_{11}$ thresholds: 0.08 vs. 0.085, respectively (Fig. 4). However, the biggest difference in injury criteria was observed in transverse strain ($E_{22}$). $E_{22}$ was a significant predictor of collagen damage for the virgin USL, but did not have a pronounced effect on collagen damage in the pregnant USL. Shear strain ($E_{12}$) did not correlate with collagen damage in either case.

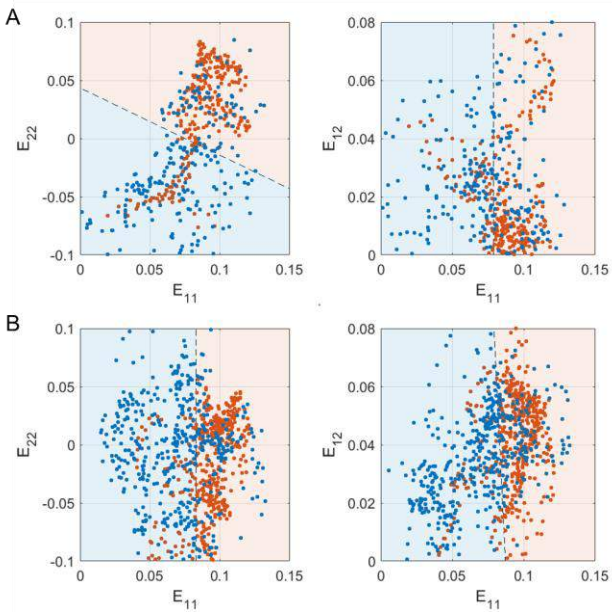

**Figure 4. Collagen injury criteria in $E_{11}$-$E_{22}$ and $E_{11}$-$E_{12}$ planes for USLs from virgin (A) and pregnant (B) mice.**

## DISCUSSION

We present a method to determine collagen injury criteria for the murine USL, accounting for spatial inhomogeneity and multi-directional strains. Our findings demonstrate that axial strain is a significant predictor of collagen damage in the USL (determined by logistic regression analysis), as has been assumed. However, transverse strain also appears to be a significant predictor of collagen damage in USLs from virgin mice. This result may indicate a decrease in collagen crosslinking in late pregnancy, which has been demonstrated in the cervix by Yoshida et al. [6].

This is the first study to model the mechanical thresholds for collagen damage in the USL. The method is limited to 2D, and more data is needed to confirm the present results. Nevertheless, the data suggest there are pregnancy-related changes in the relationship between deformation and collagen damage in the USL.

## INTRODUCTION

A pulmonary artery aneurysm (PAA) is a rare condition (~1 out of 14,000) defined by dilation of all three layers of the vessel wall (intima, medial, adventitia) and can lead to dissection or be fatal if ruptured (50-100% mortality).[1,2] Patients with a PAA have a dilated main pulmonary artery (MPA) diameter more than 1.5 times the normal value, with the normative MPA diameter estimated to be 2.89 cm in males and 2.69 cm females.[3] Although most PAAs are managed conservatively, other PAAs require surgical intervention to prevent future rupture or dissection or to alleviate symptoms (chest pain, dyspnea, palpitations, syncope).[4,5] Proximal PAAs are treated surgically by replacement of the native dilated vessel with a graft – either synthetic or biological. Synthetic dacron grafts are made of woven or knitted polyester while biological grafts may be either xenogeneic (animal origin) or allogeneic (from a human donor) and are decellularized using tissue engineering techniques to prevent immune response. However, we have a limited understanding of optimal treatment.

4D-flow magnetic resonance imaging (4DMRI) provides non-invasive comprehensive assessment of anatomic and blood velocity features in a time-resolved 3D velocity field.[6] Visualization and quantitative velocity metrics from 4DMRI has shown promise in evaluating hemodynamics in several diseases.[7] Although previous studies have analyzed pulmonary artery (PA) hemodynamics using 4DMRI, these have primarily been focused on characterizing pulmonary arterial hypertension (PAH) and not PAAs.[8]

In this case study, we evaluate the MPA hemodynamics using 4D Flow MRI in two patients with a PAA before and after surgical correction with a dacron graft and an aortic homograft from donor tissue to understand the extent to which different surgical replacement grafts aid in restoring healthy hemodynamics.

## METHODS

We obtained time-resolved 4DMR scans with 20-30 cardiac frames from two patients with a PAA from the Marie Lannelongue Hospital in France before and after they received surgical corrections. Patient 1 had a PAA located in the MPA and received a synthetic dacron graft (woven polyester) to replace the dilated PA trunk. Patient 2 had PAH with a PAA in the MPA and the right PA (RPA) and received a bilateral lung transplant attached distally to the left and right lobar branches as well as a donor aortic homograft to replace the dilated PA trunk and RPA in a valve-sparing procedure.

4DMR scans were downloaded from the medical imaging cloud platform, Arterys (Arterys Inc., San Francisco, CA, USA) where phase offsets and background corrections were applied. To isolate 4DMR velocity in the PAs, we created patient-specific 3D models of the PAs (beginning at the pulmonary valve and ending at the left and right PAs) using the open-source software SimVascular (simvascular.org). To account for movement of the PAs throughout the cardiac cycle, patient-specific models were created at two timepoints in the cardiac cycle when the PAs were minimally deformed and maximally deformed with dilation and lateral movement. The shape analysis registration algorithm from the open-source software Deformetrica was used to interpolate geometries throughout the cardiac cycle, specifically between the minimum and maximum deformed timepoints, and then back down to the minimum. These interpolated geometries were visually checked and adjusted to match the magnitude 4DMR images. 4DMR velocity was resampled onto a discretized tetrahedral element mesh for all PAs at all timepoints in the cardiac cycle.

We compared blood flow in the preoperative and postoperative state for both patients by visualizing velocity streamlines. Additionally, we computed the fractional area of reverse flow (RF) for a cross-sectional slice taken in the middle of the MPA to capture recirculating and reverse flow using **Equation 1:**

$$FractionaliAreaiRF = \frac{A_{\vec{u}\cdot\vec{n}\leq 0}}{A_{total}} \quad (1)$$

where $A_{total}$ is the total area of the slice and $A_{\vec{u}\cdot\vec{n}\leq 0}$ is the area of the slice with reverse flow as defined by the dot product of $\vec{u}$, the velocity, and $\vec{n}$, the surface normal, less than or equal to 0. We also calculated the spatially and temporally averaged velocity through a cross-sectional slice taken at the most proximal portion of the MPA, parallel to the pulmonary valve (PV).

## RESULTS

We found that both patients' preoperative hemodynamics were characterized by a large area of recirculation in the MPA, the result of the systolic jet from the PV hitting the MPA wall opposite to it. We found an initial drop in the fractional area of RF (**Equation 1**) in the MPA during early systole due to the onset of the systolic jet. Although the fractional area of RF remained high during systole preoperatively, indicating larger regions of inefficient reverse flow, it remained low during postoperative systole in both patients (**Figure 1**). This indicates a large percent of recirculation flow in the pre-op MPA as opposed to the more forward and laminar flow seen postoperatively. Furthermore, we found that the fractional area of RF during systole is greater in the patient with the aortic homograft than in the patient with the dacron graft. In the postoperative aortic homograft MPA, there were more regions of lower velocity recirculation, specifically two separate regions at the native valve annulus.

Additionally, both patients had greater MPA velocity postoperatively, but the patient with the dacron graft had higher post-op velocities than the aortic homograft patient (**Figure 2**). Further, both the Dacron and aortic homograft patients postoperatively had vortices to the right and left of the MPA bifurcation as well as near the valve annulus.

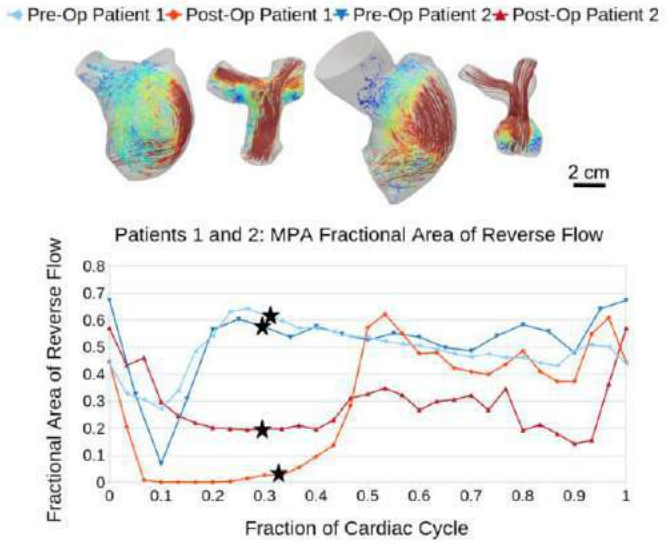

**Figure 1: Fractional Area of RF in a cross-sectional middle MPA slice. Patient 1 (Dacron) and Patient 2 (Aortic Homograft). Fractional Area of RF is low during post-op systole and high during most of pre-op systole apart from the onset of the systolic jet.**

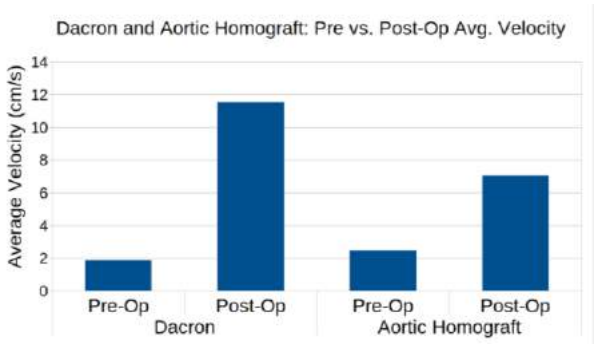

**Figure 2: Average Velocity (cm × $s^{-1}$) through a slice parallel to the pulmonary valve is low preoperatively. Dacron graft restored high velocity flow to greater extent than Aortic homograft.**

## DISCUSSION

In two PAA patients, we compared the 4DMRI-derived PA hemodynamics between a dacron graft and an aortic homograft pulmonary trunk replacement before and after surgical correction. We found both grafts recovered healthy hemodynamic phenotypes postoperatively but saw slight differences between the grafts in the laminar flow and velocity at the valve annulus and in the MPA.

Specifically, we found that preoperative MPA hemodynamics in PAA patients were characterized by a large area of recirculating flow which became more laminar after surgical replacement of the aneurysms with grafts. Because laminar blood flow is associated with more efficient transport of blood, the grafts in patients 1 and 2 improved PA hemodynamics leading to more desirable blood flow.[9]

Though both patients' grafts improved and restored a healthier flow, the aortic homograft yielded postoperative hemodynamics with lower velocity flow and more areas of recirculation near the valve annulus than the synthetic dacron graft, indicating greater inefficient flow and likely due to the native MPA geometry. However, a more direct comparison of the performance of different graft types with more patients is needed to understand the long-term PA hemodynamics and longevity across graft types.

This case study provides insights from 4DMRI into the changing PA hemodynamics before and after correction of a PAA using a dacron graft and an aortic homograft. These insights show promise in evaluating the performance of different graft types for PAA correction to aid in the surgical decision-making process.

## ACKNOWLEDGEMENTS

De-identified 4DMR data was obtained from the Marie Lannelongue Hospital. 4DMR post-processing was conducted using high-performance computing resources from Sherlock as part of the Stanford Research Computing Center.

## INTRODUCTION

The purpose of the heart's mitral valve (MV) is simple. It aims to maintain unidirectional flow from the left atrium to the ventricle while preventing the backflow of blood during ventricular contraction. Diseases can alter MV function. Most diseases render the valve unable to close and result in mitral regurgitation (MR). In MR, blood that is normally pumped to the body is reversed through the unsealed mitral leaflets, into the left atrium, and then onto the lungs, for which the extra work with time tires the heart's muscles, leading to heart failure.

Worldwide, MR is the most common heart valve dysfunction whose prevalence and severity increase with age. When left untreated this disease results in excess morbidity and mortality. Open heart surgery is the established treatment of choice. The most common type of surgery is MV repair, where a prosthetic annuloplasty ring is sutured into the tissue surrounding the MV orifice. By constraining the MV's orifice to a comparably smaller ring, the shape and size of the valve orifice is reduced to force the MV leaflets into a state of closure [1].

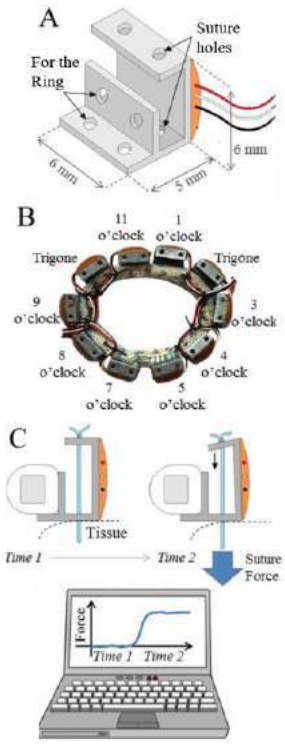
Ring annuloplasty is effective in most patients but failures can occur. The most common surgical failure is suture dehiscence where the sutures securing the ring to the MV tear out of their underlying tissue. Mechanistically, *this occurs when the forces on each suture exceed the holding strength of the underlying tissue.* In review of historical clinical findings, suture dehiscence more frequently is reported with completely rigid annuloplasty rings and occurs more frequently in one region of the mitral valve orifice (posterior region) [1-3].

To build understanding for these clinical observations and develop further insight for clinical translation, our group developed sensors to measure the forces in each suture used to secure an annuloplasty ring to the MV in the beating heart of sheep. To understand the effect of ring stiffness, two differing rings were tested (full rigid vs. fully flexible). To understand why suture dehiscence seems regionally dependent, suture pull-out force testing was completed and compared to the beating heart suture force measurements.

## METHODS

### *Force Sensors and Annuloplasty Ring Selection*

Miniature, strain-gage based force sensors were designed and fabricated (**Figure 1A**). The spring element of each sensor was rapid prototyped from 316L stainless steel. Half-bridge strain gages were adhered and protected on each spring element. Each sensor was calibrated and then attached to an annuloplasty ring (**Figure 1B**). As demonstrated in **Figure 1C**, forces applied to a suture result in the bending of the spring element's upper arm, creating a moment arm to deform the cantilever beam for which the strain gages are adhered. The strain gages deform with the measurement arm, resulting in changes to the gauge's electrical resistance. Through calibration, changes in electrical output are correlated to known forces providing the ability to measure cyclic suture forces in the beating heart of animals.



Two ring types were instrumented with force sensors. Completely rigid (Medtronic Profile 3D™) and completely flexible (fabricated to the same dimensions as the Profile 3D™ rings). Multiple sizes of each ring were instrumented and made ready for each animal experiment.

### *Animal Experiments*

A diseased large animal model was utilized for this study. This model creates MR in sheep. Fourteen healthy sheep (~90 kg) were subjected to a coronary artery occlusion which blocks blood flow to ~20% of the left ventricular wall, including the posteromedial papillary muscle. Following occlusion, the animals were recovered, and their MR allowed to develop over a 6-8 week period. At the completion of this period, an open-heart ring annuloplasty procedure was completed using the force sensor instrumented annuloplasty rings.

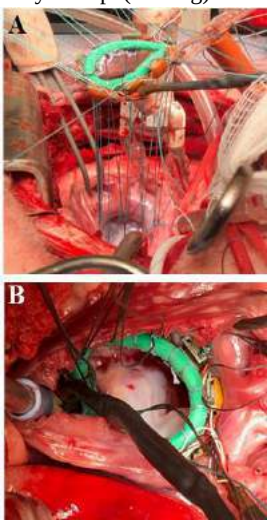


**Figure 2**

Open heart surgeries were completed (**Figure 2A-B**), implanting the instrumented rings using the same exact methods used clinically. Seven animals were implanted with the fully rigid ring and remaining animals implanted with the fully flexible ring (**Figure 2**). Following implantation, each animal was weaned from cardiopulmonary bypass, stabilized, and cyclic suture force measurements recorded for cardiac cycles reaching a peak left ventricular pressure of 125 mmHg to approximately match left ventricular pressures in humans. All suture force data was recorded using LabView and analyzed in MATLAB.

### *Suture Pull-Out Testing*

Following each animal experiment, each heart was removed, left atrium opened, and rings removed so that the sutures remained within the annular tissue. The mitral valves were then excised and secured to a fixture to conduct suture pull-out testing using an 858 MiniBionix (MTS, Eden Prairie, MN) (**Figure 3**). Each suture was pulled perpendicularly to the plate until it tore through the tissue. The maximum force was recorded for each suture position.

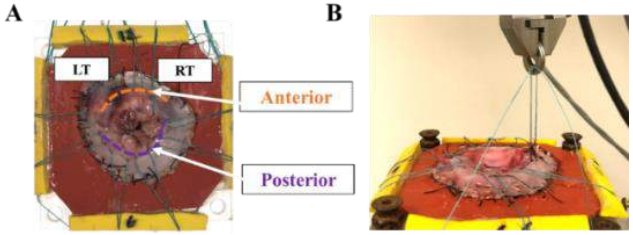

**Figure 3.**

## RESULTS

At the time of ring implantation, each animal exhibited MR and incomplete leaflet closure. Ring implantation successfully eliminated MR in all animals. The mean cyclic suture forces measured for both ring types by ring position are reported in **Figure 4**. The flexible ring experienced greater suture loading at the anterior positions, especially at 1 o'clock, compared to the posterior positions. Compared to the posterior region of the rigid rings, suture loading in the posterior region of the flexible rings were lower.

Suture pull-out testing (**Figure 5**) demonstrated differences in suture holding strength between suture positions and regions. The highest suture pull-out forces were observed along the anterior region (Left Trigone, 11'oclock, 1 o'clock, and Right Trigone). Overall, the anterior positions had greater holding strength than the posterior regions, with the lowest being in the 5 and 7 o'clock regions.

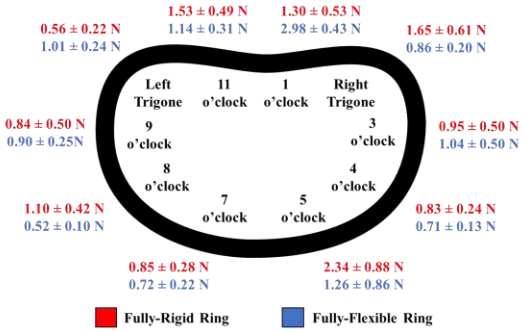

**Figure 4. Cyclic Suture Force Measurements**

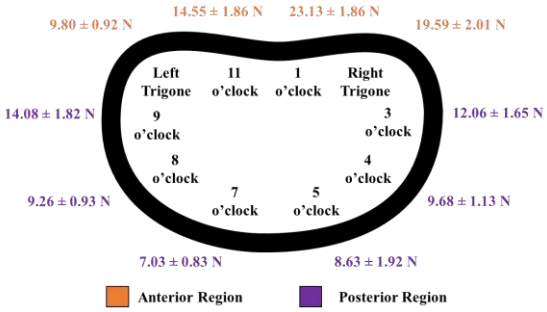

**Figure 5. Suture Pull-out Force Data**

## DISCUSSION

Preliminary results in fourteen animals with MR demonstrate regional differences in suture force loading between ring types. The flexible ring experienced lower posterior suture loading compared to the rigid ring, which suggests that reduced ring stiffness may redistribute the loads to the more robust anterior region, where suture holding strength is greater. Pull-out testing revealed suture holding strength was less in the posterior region, correlating well with clinical reports detailing suture dehiscence to occur in this region more commonly.

This data is currently limited to fourteen animals that were selected by weight. Each ring was selected to 'undersize' the mitral valve by 2 sizes, as done clinically. As part of the procedural protocol, there were no controls for the force for with which the surgeon tied the sutures into the underlying tissue. This was done to reflect real-world conditions at the cost of experimental control. The effect sizes between the ring types may have been reduced but may improve with further experiments.

Initial findings suggest rigid rings may as a whole elevate suture forces, and the posterior region of the annulus exhibits lower suture force holding capacity. These initial data, with their further expansion and study, provide possibility and promise for further serving the large MR patient population by improving knowledge for the effect of ring selection and regional holding strength, to further reduce the potential for surgical repair failures.

## INTRODUCTION

Aponeurosis is a tendinous sheath-like tissue found in many muscle-tendon units that covers the muscle belly and transitions into tendon. The sheath-like structure of aponeurosis is thinner towards the muscle belly and thicker near the tendon. Unfortunately, not much else is known about the structure-function mechanics of aponeurosis tissue, especially in comparison to other musculoskeletal tissues such as tendon and ligament. Previous work has shown that the mechanical properties of the aponeurosis tissue vary depending on whether it is a thinner portion of the tissue near the muscle or the thicker portion near the tendon [1]. Little research has been done to understand how collagen fiber microstructure contributes to aponeurosis stiffness.

The mechanical function of musculoskeletal soft tissues is often driven by collagen microstructure, such as orientation, waviness, and dispersion. While the mechanical properties of aponeurosis tissue have been studied, it remains unclear how the collagen fiber morphology – such as collagen crimping – change in response to stretch. Evaluating how the structure of the aponeurosis tissue changes in relation to its observed functional characteristics will enable a better understanding of how aponeurosis functions in the human body. These data can enable the improvement of computational models that include aponeurosis as a component of muscle-tendon units and improve our understanding of how aponeurosis tissue may accumulate damage as a result of injury. The goal of this work was to use scanning electron microscopy to characterize the microstructure of aponeurosis tissue be comparing waviness values measured in unstretched and stretched tissue. It is hypothesized that the waviness of the collagen fibers will decrease after tissue has been stretched.

## METHODS

Porcine shoulder tissue, obtained from a local abattoir, was dissected to obtain 40x10 mm specimens that include the transition from thick to thin aponeurosis tissue. Long and steady cuts using sharp dissection blades were used to ensure minimal damage to the aponeurosis (Figure 1A). As much muscle tissue as possible was removed without tearing or damaging the aponeurosis [2,3]. All samples were kept moist by applying 10% phosphate buffered saline throughout the dissection process and before testing [2,3].

Unstretched samples (n=10) were fixed in a 1:20 volume to fixative ratio of 10% formaldehyde for 24 hours at 4 C, while stretched samples (n=10) were similarly fixed in a custom fixing stretcher at five percent strain (Figure 1B).

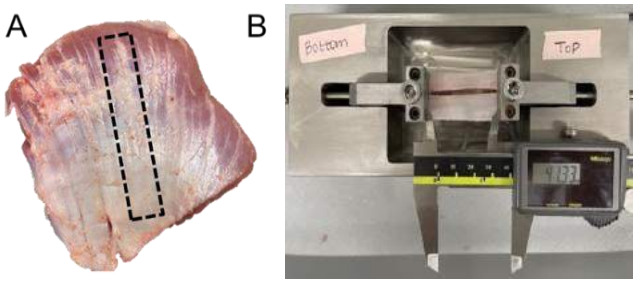

**Figure 1: (A) Sample aponeurosis tissue showing the transition from thick to thin tissue. (B) Sample of aponeurosis tissue in uniaxial material testing setup.**

Both the stretched and unstretched samples were then subject to a series of graded ethanol soakings that included 15min in 30% ethanol. 15min in 50% ethanol, 15min in 70% ethanol, 15min in 90% ethanol, 15min in 100% ethanol, and finally 30min in 100% ethanol. In preparation for dehydration, samples were placed in the fume hood and soaked in a 1:2 solution of HMDS to ethanol for 20min followed by 20min in 2:1 solution of HMDS to ethanol. Samples were then dehydrated in two 20min soakings in 100% HMDS. The final HMDS was poured off to just cover the top of the samples and left in a fume

hood to evaporate overnight. After 24 hours, all samples were fully dried and prepared for SEM.

Once all the samples were fully dehydrated 24-48hrs later they were sputter coated with gold and stored in an airtight container until they were imaged with the SEM. Images were taken at 50, 100, 1k, and 3.5k magnification at 6 equally spaced points along the entire 40mm length of the aponeurosis with the Hitachi SU5000 Field Emission Gun Microscope. Waviness was determined using the NeuronJ plugins for Fiji/ImageJ, a free image analysis tool [4]. Waviness of the stretched and unstretched aponeurosis was quantified as the ratio of the true length of the collagen fiber to the tangent of two endpoints of that same collagen fiber [5]. Approximately 3 fibers were measured for each image at 50 and 100 magnification and waviness values were calculated based on these measurements. An unpaired two-way t-test was run to determine if the waviness values of the stretched tissue was greater than the waviness values of the unstretched tissue.

## RESULTS

Scanning electron microscopy of aponeurosis tissue showed that it exhibited a hierarchical structure, similar to that of tendon or ligament, with collagen-rich fascicles (75μm to 200μm diameter), fibers (50μm to 20μm diameter), and fibrils (10-300nm) (Figure 2). Waviness in the collagen fibers was observed at lower magnifications (100 μm), while at higher magnifications the sheet-like structure of the collagen fibrils was seen (1,000 μm). At lower magnifications, the collagen fibers exhibited some degree of alignment, while at higher magnifications the fibrils appeared to be more randomly organized in the collagen sheet (Figure 2). The unstretched collagen fibers had an average waviness value of 1.174 ± 0.211 The stretched collagen fibers had waviness values ranging from 1.051 ± 0.064 (Figure 2). The p-value was 6.615e-08, which shows there is a statistically significant difference in the waviness values of stretched and unstretched tissue.

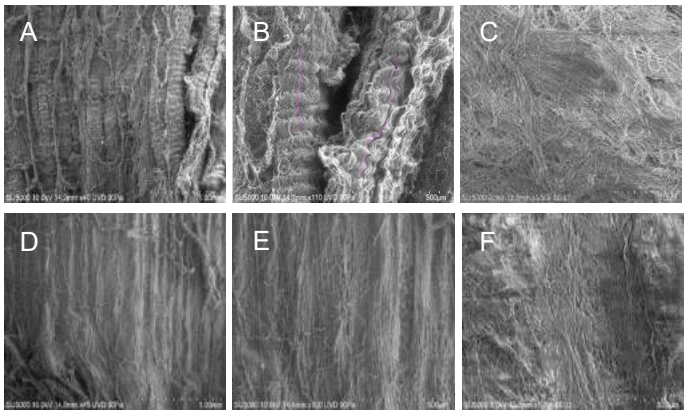

**Figure 2: Porcine triceps brachii aponeurosis SEM images at increasing magnifications. Unstretched samples at (A) 40x magnification, (B) 100x magnification, and (C) 1,000x magnification. Stretched samples at (D) 40x magnification, (E) 100x magnification, and (F) 1,000x magnification.**

## DISCUSSION

SEM imaging was used to characterize aponeurosis microstructure and determine how waviness changed in stretched and unstretched tissue. Aponeurosis tissue appeared to have a similar hierarchal structure comprised of fascicles, fibers, and fibrils similar to tendon tissue. This is unsurprising as aponeurosis tissue is largely an extension of tendon. Additionally, unstretched tissue exhibits a high degree of waviness and there is observed collagen crimp. Tissue that has been fixed under a five percent stretch appeared to have a lower degree of collagen waviness and less collagen crimp compared to the unstretched tissue. This is unsurprising because as the tissue is stretched the collagen fibers stretch out making them straighter and less wavy. This also supported by the transition out of the toe-region to the linear elastic region of the stress-strain curves for aponeurosis tissue, which occurs at approximately five percent stretch [1].

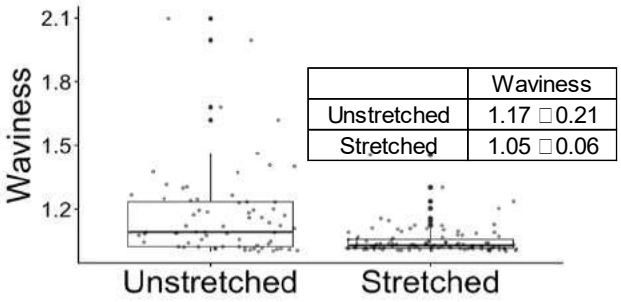

**Figure 3: Comparison of unstretched and stretched aponeurosis collagen fiber waviness values. The average waviness value of unstretched aponeurosis is greater than the average waviness value of stretched aponeurosis ($p < 0.05$).**

The hierarchical structure of aponeurosis tissue can be implemented to develop better musculoskeletal simulations and modeling efforts, which will allow for more accurate analysis of how muscle forces are transmitted to tendon. All analysis was performed on undamaged tissue, and it is unclear how damage affects aponeurosis mechanics. Improved modeling efforts can inform how collagen structures change in response to load and how the tissue becomes damaged so better protocols on how to help heal injuries more quickly can be developed. Future work will include comparing how waviness values of stretched and unstretched tissue compare depending on the location of the aponeurosis tissue, closer to the muscle belly or closer to the tendon.

## CONCLUSION

Aponeurosis exhibits a similar hierarchical structure similar to tendons that is composed of fascicles, fibers, and fibrils. Additionally, when the tissue is stretched the fibers become less wavy which is agrees with stress strain curves that show around five percent stretch the tissue becomes linearly elastic [1]. Using these data, better musculoskeletal simulations can be developed to improve clinical care of injuries and impairments that affect muscle-tendon units.

# CHARACTERIZING THE MECHANICAL HETEROGENEITY OF PORCINE CAROTID ARTERY BIFURCATIONS

**Claire L. Westman (1), Carly L. Donahue (1), Victor H. Barocas (1)**

(1) Department of Biomedical Engineering, University of Minnesota —Twin Cities, Minneapolis, Minnesota, United States

## INTRODUCTION

Arterial bifurcations serve as important regulators in the distribution of blood throughout the body. Due to their anatomy, bifurcations experience a heterogeneous distribution of stresses from the blood pressure and wall shear stress. Because arteries are known to remodel in response to mechanical load [1], we expect that bifurcations would have a heterogeneous distribution of mechanical properties.

The carotid artery (Fig. 1A) has been widely characterized using both *in vivo* and *ex vivo* techniques [2,3]. However, the local material heterogeneity that arises in healthy bifurcations has been less explored. Using a combination of uniaxial tensile testing and digital-image-correlation-based displacement tracking, this study characterized the stiffnesses in different regions of porcine carotid bifurcations.

## METHODS

**Dissection and Sample Preparation:** Strips of tissue were cut from three different regions of healthy porcine carotid arteries. Each carotid artery either yielded two samples, the outer side of the interior and exterior carotid [Fig. 1B], or one sample from the apex of the bifurcation [Fig. 1C]. In addition to samples from the three regions of interest, a control sample was also tested that was from the common carotid artery.

Each sample was cut to a width of 5.29 mm ± 1.23 mm (mean ± SD). The thickness for each sample ranged from 0.5 mm to 1 mm and was consistent along the length of the samples. Samples were tested within 48 hours of tissue harvest and were kept refrigerated and suspended in 1X Phosphate Buffered Saline before and after dissection. Testing was performed at room temperature.

**Uniaxial Tensile Testing:** The rectangular samples were loaded into the grips of a Q Series Test Resources uniaxial mechanical tester equipped with 10lbf load cells. The measured gauge length was 10.48mm ± 2.47mm (mean ± SD). Each sample was pre-conditioned to 50% engineering strain for 5 cycles at a controlled displacement rate of 3 mm/min, followed by extension to failure at the same rate. Both tests were videorecorded from above for digital image correlation (DIC).

**Strain Tracking and Analysis:** Once the testing was complete, the data from the tests and the videos were uploaded and analyzed. Quasi-static analysis of the load-cell data allowed the determination of the tissue stress throughout the test. An existing DIC and strain-tracking program [4] was used to determine the local strain on the tissue. Strain field graphics were generated using TecPlot.

Stress-strain curves were made by taking an average of the strain for three different regions within a sample for each frame. Strain data were removed on both ends of the sample to eliminate error that could occur from proximity to the grips. The stress is assumed to be uniform across the sample for each time frame.

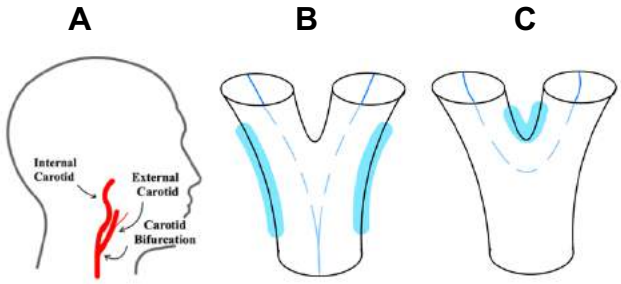

**Figure 1: A) Anatomical location of the carotid bifurcation and its internal and external daughter branches. B) Dissection diagram highlighting the regions of interest on the outer wall of the bifurcation. C) Dissection diagram highlighting the apex of the bifurcation.**

## RESULTS

The experimental results are summarized in Fig. 2-5. For the apex sample [Fig. 2], there was slightly more strain farther from the bifurcation region, especially at large strains. For the strip taken from the interior branch [Fig. 3], there was a clear gradient in strain, with the largest strains occurring in the distal segment (i.e., that which is in the internal carotid rather than the common carotid artery); no such gradient was seen in the exterior branch [Fig. 4] or the control sample [Fig. 5]. The measured stresses were much higher in the apex and interior samples than in the exterior and control samples.

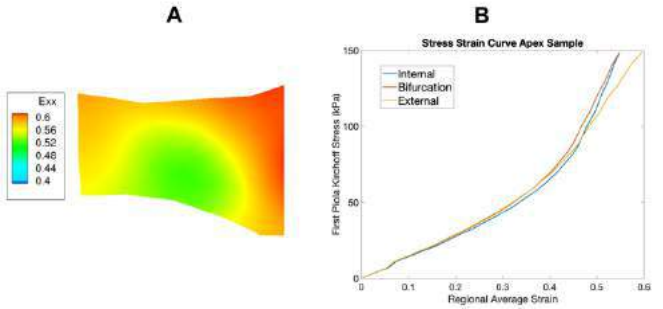

**Figure 2: A) Local strains along the bifurcation apex at 50% grip strain. B) Stress-strain curves showing material heterogeneity in different regions of the sample.**

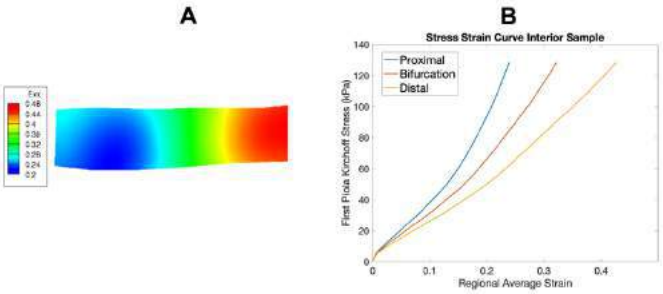

**Figure 3: A) Local strains along the wall of the bifurcation between the common carotid and the interior carotid at 50% grip strain. B) Stress-strain curves showing material heterogeneity in different regions of the sample.**

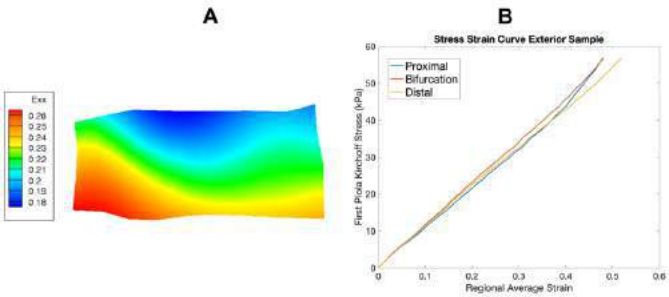

**Figure 4: A) Local strains along the wall of the bifurcation between the common carotid and the exterior carotid at 50% grip strain. B) Stress-strain curves showing material heterogeneity in different regions of the sample.**

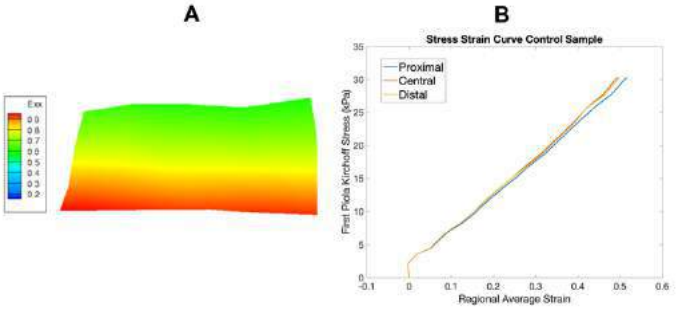

**Figure 5: A) Local strains along the common carotid artery at 50% grip strain. B) Stress-strain curves showing material heterogeneity in different regions of the sample.**

## DISCUSSION

The common carotid artery, the control, experienced the least amount of stress of any of the samples. This is expected because it has been found that the principal stresses arising in the apex and walls of the bifurcation are higher than the principal stresses of the carotid artery. [5]. A control was used to validate the tensile testing procedure.

The apex of the bifurcation exhibited greater longitudinal stiffness than the surrounding vessel wall, which may be the a result of remodeling in respoinse to the heterogeneous loading experienced by the bifurcation. From finite element studies, it has been seen that the wall thickness of the parent artery affects how much stress the apex experiences [6]. In [6], it was found that when the apex and external transition have a normalized wall thickness of 0.5, the stress of the apex is about 200% of the stress of the external transition. Those estimates are consistent with our results.

Previous studies of carotid heterogeneity are largely focused on atherosclerotic plaque lesions [7]. However, it is also important to characterize heterogeneity resulting from the arterial remodeling process in healthy tissues as well.

While this work expands on our current understanding of the material behavior of arterial bifurcations, there were some limitations that should be considered, including that the samples were only tested in the axial direction. Future work will involve testing the arteries circumferentially, expanding the number of samples tested, and studying heterogeneity in other healthy arterial bifurcations in the body. This work contributes to our understanding of the arterial remodeling process in complex anatomical structures.

# BLOOD CLOT REMOVAL PRESSURES IN AN EXPERIMENTAL MODEL OF ASPIRATION THROMBECTOMY

## INTRODUCTION

Blood clots form in many places throughout the body and often break off and lodge in downstream locations within the vasculature. One such instance is acute ischemic stroke (AIS), which results from embolic occlusion of a cerebral artery. This obstruction of normal blood flow prevents nutrients and oxygen from getting to the brain, and brain cells can begin to die within minutes [1]. Without early action to restore blood flow, major complications can occur for the patient including paralysis, loss of muscle movement, difficulty talking, and cognitive losses [2].

A common method to treat AIS is aspiration thrombectomy, which utilizes a guidewire to navigate an aspiration catheter to the proximal face of the lodged clot and remove it via suction [3]. Different factors have been shown to influence the effectiveness of aspiration thrombectomy, including the clot's length and composition [4]. The goals of this study are therefore to determine the relationships between the aspiration pressures required to remove lodged blood clots and their length and composition, specifically their hematocrit. With an improved understanding how clots of varying geometry and hematocrit respond to thrombectomy, we can establish a relationship between the removal pressures and clot properties. The knowledge gained from this study could be utilized to improve surgical recanalization techniques and devices, with the goal of achieving complete reperfusion on the first pass with decreased rates of clot fragmentation.

## METHODS

*Part I: Embolus Analog Preparation and Flow Loop Set-Up*

Bovine blood was collected in CPDA-1 anti-coagulated bags (Lampire Biologic) and separated into its components (plasma and red blood cells (RBC)) using a centrifuge before being recombined in specific hematocrit ratios. Blood was reconstituted in increments of 20% hematocrit over a range of 0-80%. Coagulation was initiated by the addition of $CaCl_2$ to a 20 mM concentration in the reconstituted blood. Roughly 7 mL of the coagulating blood was drawn into a section of 0.25" inner-diameter (ID) PVC tubing before being placed into a Chandler loop and allowed to clot dynamically for 1-2 hours under physiologically flow rates and temperatures. The resulting embolus analogs (EAs) were refrigerated and stored in PBS for 1 week after their creation to maintain their physical properties before use.

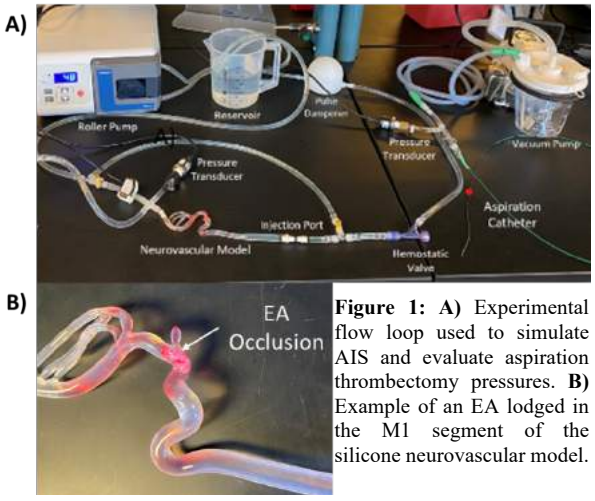

**Figure 1: A)** Experimental flow loop used to simulate AIS and evaluate aspiration thrombectomy pressures. **B)** Example of an EA lodged in the M1 segment of the silicone neurovascular model.

An experimental flow loop was built to model the physiological environment of AIS (**Fig. 1A**) and consisted of a peristaltic pump pushing fluid from a reservoir through 0.25" ID PVC tubing. A flow dampener was included downstream to minimize flow oscillations from the pump before entering a silicon middle cerebral artery (MCA) model (United Biologics). EAs were introduced into the loop through a connection upstream of the neurovascular model and subsequently lodged in the MCA model. A rotating hemostatic valve upstream of the MCA model was used to insert the aspiration catheter for each experimental test. The fluid used in the loop was a mixture of water and baby shampoo to mimic the physiological resistance of the catheters being guided through the cerebral vasculature.

*Part II: EA Lodging and Catheter Aspiration*

Cylindrical EAs of varying hematocrit created in the Chandler loop were cut to be approximately 10 mm in length but varied between 8-15 mm. Each EA was measured using digital calipers prior to its injection into the flow loop. After EA insertion, the samples would flow into the silicone cerebral model and lodge in the M1 segment of the MCA, seen in **Fig. 1B**. After allowing approximately 15 minutes for the EAs to lodge, distal pressures were measured and compared to baseline data to determine how lodging altered the system conditions. A React 68 aspiration catheter (Medtronic) was then inserted into the flow loop through the hemostatic valve and guided to the proximal end of the EA. Using a VC-701B medical aspiration pump (Cliq Medical), vacuum pressure was applied via the catheter to the EA to dislodge it from the model. Starting at 200 mmHg, the aspiration pressure was increased in increments of 50 mmHg and an aspiration thrombectomy pass was attempted the EA with the catheter, similar to standard surgical techniques. A second pressure transducer was connected to the proximal end of the catheter base and used to measure the pressures being applied by the catheter. If EA removal was unsuccessful after two passes, the pump pressure was increased by 50 mmHg and the process was repeated. The final recanalization pressure as well as the fate of the clot (i.e., ingestion into catheter, clean removal, or fragmentation) were recorded.

## RESULTS

Analysis of the experimental pressures data revealed a positive correlation between EA length and the magnitude of aspiration pressure required to dislodge it (**Fig. 2**).

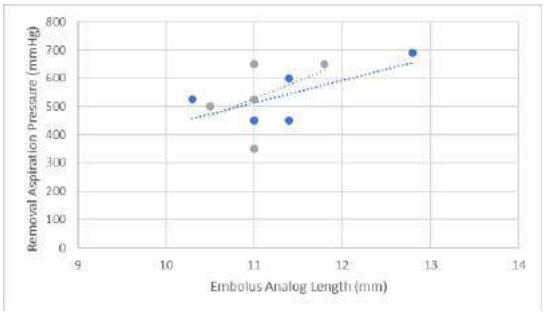

**Figure 2:** Correlations between aspiration removal pressure and EA length (0% hematocrit EAs in gray and 40% in blue).

For both 0% (gray markers) and 40% (blue markers) EAs, removal pressure increased with EA length. The smaller EAs, approximately 10 mm in length only needed 500 mmHg of pressure to remove while the longest 13 mm EAs needed nearly 700 mmHg of pressure. Similarly, a negative correlation was observed between EA hematocrit and the magnitude of removal pressure (**Fig. 3**). The platelet rich 0% hematocrit EAs were the hardest to remove and required aspiration pressures between 500-675 mmHg. As EA hematocrit increases, the amount of pressure for removal decreased with the 80% hematocrit EAs requiring only about 300 mmHg of aspiration pressure.

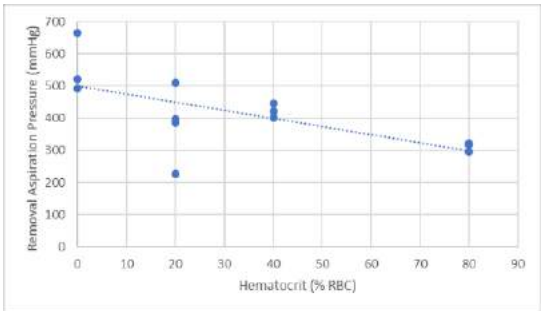

**Figure 3:** Correlation between EA hematocrit and the aspiration pressure required for their removal.

Fragmentation of the EAs occurred about 25% of the time, with little consistency in terms of length, hematocrit, or removal aspiration pressure. However, it most often occurred after multiple unsuccessfully removal attempts at lower pressures.

## DISCUSSION

A positive relationship was found between EA length and vacuum removal pressure. This is most likely due to longer EAs having increased contact area, and ultimately increased friction, between the EA and the MCA walls. It was also found that a negative relationship exists between EA hematocrit and vacuum removal pressure. It has been shown in several other experimental studies that RBC rich clots (higher hematocrit) are softer compared to platelet rich (lower hematocrit) clots and could contribute to their easier removal. Softer clots under higher pressures may also have an increased tendency to fragment and result in micro-emboli downstream of the initial clot location. If a clot's size and composition can be determined through pre-surgical imaging data, this information could be leveraged as part of surgical planning and enable clinicians to remove the clots more effectively by knowing the optimal vacuum pressures to apply. By analyzing the behavior of EAs of varying size and composition experimentally, we can potentially improve the surgical techniques used clinically to optimize recanalization.

## ACKNOWLEDGEMENTS

We thank Dr. Michael Froehler of the Vanderbilt University Medical Center for providing the catheters used in this study.

# PHYSIOCHEMICAL MECHANISMS OF BONE DISSOLUTION PLAY A SIGNIFICANT ROLE IN REGULATING BONE COMPOSITION AND FUNCTION IN ACIDOSIS

**Margaret E. Easson (1), Stephanie Wong (1), Mikayla M. Moody (1), Tannin A. Schmidt (1), Alix Deymier (1)**

## INTRODUCTION

Metabolic Acidosis (MA) is a condition characterized by reduced blood pH and bicarbonate levels and affects millions of people annually. [1]. A healthy body is able to maintain a homeostatic pH level near 7.4 by removal of carbon dioxide and excretion of hydrogen ions through the lungs and kidneys, respectively. However, the skeletal system, which is the largest ionic reservoir in the body, also helps regulate the body's pH. When pH levels decrease, bone dissolution releases buffering ions from bone mineral returning the body to pH homeostasis, but it also in turn causes bone loss and increases fracture risk [2, 3]. Previous work indicates that this process of bone dissolution during acidosis is a 2-part mechanism that involves cell-mediated resorption and physiochemical bone dissolution. Although these two mechanisms have been identified, the relative contributions of each remain unknown [4]. The current consensus points to cell-mediated dissolution as the primary cause of bone loss/modification [5]. However, the physiochemical response of bones to acid remains largely unstudied. Therefore, the goal of this study was to determine the effects of cell-free acid exposure on bone composition and mechanics in comparison to established in vivo acidosis data.

## METHODS

The shin bones, tibia and fibula, and forearm bones, radius and ulna, were excised from 4-5-month-old male CD-1 Wild Type Mice. Groups of one shin and one forearm were incubated in 1x Phosphate Buffered Saline (PBS) at an initial pH ($pH_i$) of 5.5 (as seen in cancerous environments), 7.0 (clinical acidosis), or 7.4 (physiological) for 5 days at 5°C. Controls included bones not exposed to solution and each of the PBS solutions at the varying pH's without the bones. Each condition was performed in triplicate. Over the course of the 5-day exposure, pH testing was performed at 0, 1, 3 and 6 hours followed by every successive 24 hours using a pH probe. Changes in calcium, phosphorus, potassium, and sodium of the solutions post exposure were measured by Inductively Coupled Plasma Optical Emission Spectroscopy (ICPOES). The tibia/fibula complex was mechanically tested via 3-point bend on a Biomomentum Mach-1 system. The samples were loaded at a rate of 0.1 mm/s until failure. Force-displacement curves were used to calculate structural mechanical properties. Stress-strain plots were calculated from the bone cross-sectional area and the span of the 3pt bend setup. The cross-sectional areas were determined by measuring the distance between bone facets using calipers. Raman spectroscopy was used to determine compositional changes in the exterior and interior of the tibia after solution exposure and fracture. The bone exterior was measured at 5 points along the anterior facet starting at the distal end to the point of fracture. The interior was measured using six points, one at each apex of the triangular cross section and one at the medial point of each facet. The measurements were taken using Witec alpha 300 Raman Spectrometer with a 785 nm laser at a power of ~60 mW. A 50X long range objective was used for both the interior and exterior regions of the bones with an acquisition time of 5 x 30s. Each Spectra was fit using Lorentzian curves to fit 8 peaks of interest. One-Way ANOVA, was used to measure statistical differences between controls and samples with significance set at $p<0.05$.

## RESULTS

The pH of the $pH_i$ 7.0 and 7.4 solutions remained relatively constant over the 5-day exposure. However, the $pH_i$ 5.5 solution showed a significant increase in pH at all timepoints of exposure. Furthermore, ICPOES data showed an increase in calcium and phosphate in all solutions when exposed to bones as compared to controls. The increase was much greater at pH 5.5 than at pH 7 or 7.4 for calcium. While the solution phosphate showed similar increases at $pH_i$ 5.5 and 7.0 but smaller changes at pH 7.4.

Raman spectroscopy indicated a significant decrease in mineral to matrix content in both the interior and exterior of the bone between pH 7.4 and 5.5, but not relative to the control. There was also a significant

decrease in mineral to matrix content on the exterior only between pH 7.4 and pH 7.0 (Fig 1A).

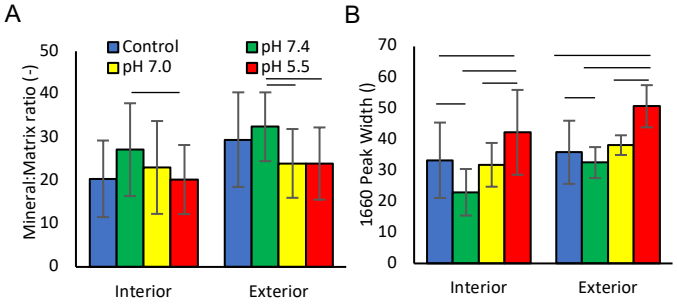

**Figure 1: A. Raman values of mineral:matrix and B. 1660 amide I peak width on the bone interior and exterior after acid exposure. Bars indicate p<0.05**

There were also significant differences in the collagen peaks after solution exposure. Specifically, the 1670/1640 peak on the exterior showed a significant increase between control and pH 5.5 and an increase between pH 7.0 and pH 5.5. This was accompanied by an increase in the width of the joint 1660 peak (Fig 1B). The width of the 1660 peak on the interior had a significant decrease between control and pH 7.4, and a significant increase between control and pH 5.5. On the exterior the width of 1660 had a significant increase between control and 5.5. In addition, the 1000/1660 ratio also showed a significant decrease between control, pH 7.4 and pH 7.0 versus 5.5.

Mechanical testing on the tibia-fibula complex after exposure showed no significant change in structural mechanical parameters. However, it showed a significant increase in material toughness of 91.6% and 91.7% for pH 7.0 and 5.5 compared to controls (Fig 2).

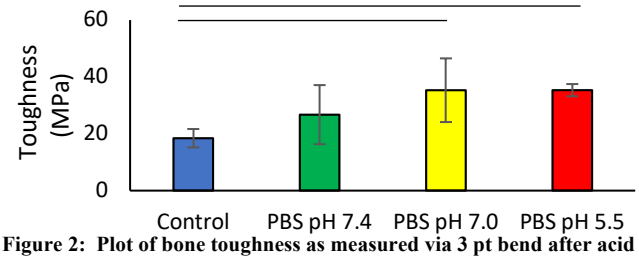

**Figure 2: Plot of bone toughness as measured via 3 pt bend after acid exposure. Bars indicate p<0.05**

## DISCUSSION

The current research suggests that bone loss during acidosis is mainly mediated by cellular responses. However, this work points to physiochemical acid exposure as a significant cause of compositional, and mechanical changes to bone. Mineral dissolution during solution exposure was indicated by a significant increase in solution pH as well as calcium and phosphate levels in all solutions. This is similar to the pH change and calcium release seen with biomimetic apatite mineral crystals in solution [6] suggesting that bone mineral, even at neutral pHs, releases buffering anions and cations into solution via dissolution or ion exchange. At pH 5.5, the solution had a significantly higher pH increase as well as calcium and phosphate levels than at the higher initial pH's suggesting greater ion release. The solutions Ca/P ratio at pH 5.5 is 1.97, indicating stoichiometric dissolution [7], while that at 7.0 and 7.4 falls around 0.7, suggesting a preferential ion exchange. This predicted dissolution is measureable in the Raman derived mineral:matrix ratio which is significantly decreased at pH 5.5 compared to pH 7.4 throughout the bone. Interestingly, mineral levels are also decreased at pH 7.0 on the bone surface compared to 7.4 suggesting that the measured ion release is causing mineral loss even at neutral pHs associated with physiological acidosis. One must note that the decreased mineral:matrix ratios are only significant relative to pH 7.4 and not control. This may be an indication of mineral accumulation or crystallization despite the ionic releases at physiological pH in conjunction with mineral loss at pH 7 and 5.5.

In addition to the changes in mineral content in the bone, there were also significant changes to the collagen structure throughout the bone as measured by Raman. Collagen has been shown to be pH sensitive with lower pH levels causing denaturation and collagen uncoiling [8]. The measured increase in the 1670/1640 ratio as well as the increased width of the combined 1660 peak both indicate an increase in collagen disorder, possibly caused by denaturation [9,10]. These results indicate that bone collagen is also significantly affected by exposure, even at acidosis associated pH's. These results are similar to those recently measured in bones exposed to in vivo acidosis [data not shown].

We expected that the combination of decreased mineral content and changes in collagen structure would likely cause significant changes to the bone's mechanical properties. 3-point bend tests showed that exposure led to a significant increase in toughness at both pH 7.0 and pH 5.5 compared to control. Toughness, defined as the amount of stress needed for failure, is controlled by many structural and compositional factors. Studies have shown that collagen denaturation causes a decrease in toughness suggesting that collagen changes are not responsible for our measured mechanical changes. Instead, we hypothesize that the reduced mineral:matrix ratio, which has been shown to increase tissue toughness [11], may be responsible for our measured changes.

## CONCLUSION

Acidosis-induced bone loss is caused by both cell-mediated resorption and physiochemical dissolution; however, the relative contributions of these mechanisms remain unknown. The data presented here shows that exposure of cell-free *ex vivo* bones to pathological pH's results in pH regulation via ion release, decreased whole bone mineral content, increased collagen denaturation, and increased toughness. This suggests that physiochemical acid exposure may play a more significant role that previously expected in structural, compositional, and mechanical changes of bone in acidosis.

## INTRODUCTION

Nearly 5.5 million people use manual wheelchairs as an integral part of their daily lives [1]. Users self-propel their wheelchairs by pushing on the wheel rims or tires and they stop by creating friction on these surfaces with their hands. Existing brakes used to lock the wheels and are not suitable for dynamic braking. When wheelchair users need to actively control the speed of their wheelchair, their hands become dirty, calloused, burned or even severely injured because they are being used as brake pads. Braking is especially difficult for individuals with low hand or wrist motor function, such as those with tetraplegia. This population has greater potential for losing control of their wheelchairs, especially on an incline. A dynamic brake device on the wheelchair could improve the safety and controllability of a manual wheelchair during daily life activities.

Currently, only a few dynamic braking systems exist on the market that partially satisfy this need. The ADI Disk Brake System [2] does not have a suitable user interface for users with low grip ability, adds significant weight, and is prohibitively expensive (> $1000 USD).

A mechanical engineering senior design team at the University of Utah has developed a dynamic braking system that is lightweight, adjustable, and inexpensive (Figure 1).

## PRODUCT DESIGN

The dynamic hand brake shown in Figure 1 is designed to be an ergonomic interface between the user's hands and the wheelchair tire. The brake provides friction to the tire without damaging the user's hands. This hand brake system will aid wheelchair users in slowing and stopping under various circumstances, including rolling downhill. This brake will serve as a mobility aide for manual wheelchair users by giving them safer control over their speed.

The brake system is comprised of four main parts: fender, sliding base, T-bracket, and collar. The fender is the portion users push down with their hand, fist, or forearm to activate the brake, as shown in Figure 2. It is ergonomically designed to reduce interference during self-propulsion.

The sliding base holds the pivot point for the lever mechanism, which is held at a neutral position with a torsion spring to keep the brake off the wheel when not being pressed. This part interfaces with the T-bracket to create anterior-posterior adjustability and the T-bracket slides into the collar's T-slot for up and down adjustability. Both lock in place with a set screw. The collar attaches the system to the wheelchair's frame using four bolts.

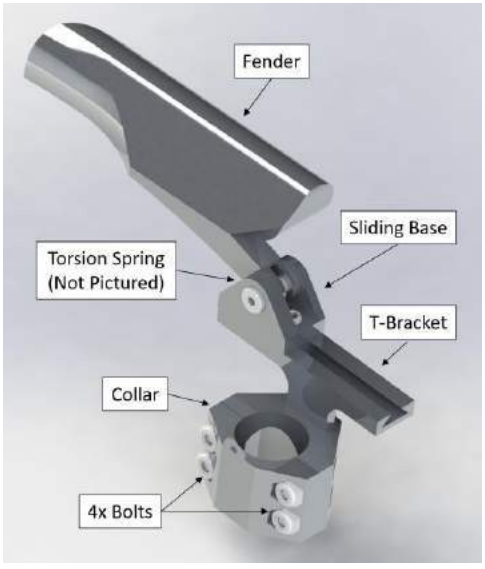

**Figure 1: Rendered aluminum model of right-side dynamic hand brake prototype. Labeled are the main parts of the prototype: Fender, Sliding Base, Torsion Spring, T-Bracket, Collar, and 4 Bolts.**

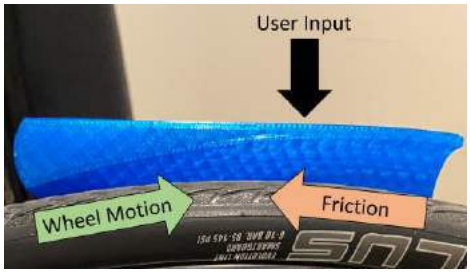

**Figure 2: Side view of right-side dynamic hand brake 3D printed prototype. Noted are the direction of user input (down), wheel motion (clockwise), and friction force (counterclockwise).**

The full assembly will be manufactured using 6061 Aluminum. It will weigh approximately 0.2 kg per side, or 0.4 kg total for a pair of hand brakes. This would add approximately 2% mass to a 18 kg wheelchair.

This design meets user needs by providing a simple, but effective dynamic hand brake system for manual wheelchairs. The system is intuitive to use, lightweight, and inexpensive.

## TESTING

Exploratory brake material testing determined 11 N input force on a plastic or metal hand brake would provide sufficient deceleration for the wheelchair. This metric meets the requirements of ISO 7176-3:2012 [3] where hand-activated wheelchair brakes require no more than 13.5N of input force.

User feedback testing indicated the current prototype, shown in Figures 2 and 3, meets user needs for form, fit, and function of the hand brake system. The fender profile is easy to push down, provides effective proportional braking, and does not impede users' natural self-propulsion motions.

**Figure 3: Front view of dynamic hand brake 3D printed prototype used for exploratory testing.**

Usability evaluations conducted with 3 individuals with a spinal cord injury indicated they would like additional adjustability for placement along the wheel and something that could replace static parking brakes. The team is currently working to implement these features.

Functional testing was performed on the 3D printed prototype (Figures 2 and 3) by able-bodied participants to show proof-of-concept when travelling downhill. The 3D-printed prototype successfully slowed down and stopped users when in use. Further testing will be performed to determine how much force is required to stop a wheelchair using this hand brake.

## BUDGET & MARKET ANALYSIS

The University of Utah Spinal Cord Injury Acute Rehabilitation Program sponsored the project with $2000 and two donated manual wheelchairs. Student fees for the University of Utah contributed an additional $600 for a total of $2600 for the project budget. The budget plan is listed in Table 1. The team expects to use $1800 of this budget on prototyping and testing through April 2022.

**Table 1: Prototyping Budget**

| | |
|---|---|
| Prototyping | $1300 |
| Test Equipment | $500 |
| **Total Expenses** | **$1800** |

The North America wheelchair market size was $940 million in 2020 and is expected to reach $ 1.7 billion by 2028. Around 60% of this market is dominated by manual wheelchairs [4]. The market share for manual wheelchairs was estimated at $564 million in 2020. As an add-on for manual wheelchairs, this hand brake system would occupy a small percentage of the market share. Table 2 demonstrates the potential profits, expenses, and ROI over 3 years.

**Table 2: 3-Year Startup Profits, Expenses, and ROI**

| | **Year 1** | **Year 2** | **Year 3** |
|---|---|---|---|
| Units Sold | 1,000 | 2,500 | 5,000 |
| Cost Per Unit | $124 | $114 | $104 |
| Projected Sales Price | $250 | $250 | $250 |
| **Sales Profit** | **$126,000** | **$340,000** | **$730,000** |
| Engineering | $100,000 | $100,000 | $100,000 |
| Tooling | $100,000 | $10,000 | $10,000 |
| Yearly Profit | ($74,000) | $230,000 | $620,000 |
| **ROI** | **($74,000)** | **$156,000** | **$776,000** |

Over three years, hand brake system could yield an estimated $776,000 return on investment. The current prototype (provisional patent pending) meets the weight, cost, and functional needs of users and further iterations will only improve these metrics. This hand brake has the potential to improve the lives of many people who use manual wheelchairs.

## ACKNOWLEDGEMENTS

We would like to acknowledge Dr. Jeffery P. Rosenbluth, MD and his team at the Spinal Cord Injury Acute Rehabilitation program at the University of Utah for funding support and expert knowledge. His team has been critical in ensuring this design meets the needs of individuals with various spinal cord injuries who use manual wheelchairs.

## INTRODUCTION

Mastery experience, vicarious experience, and verbal persuasions all play a role in self-efficacy development [1]. It has been found that women's self-efficacy is most informed by verbal persuasions and vicarious experiences, whereas men's self-efficacy is most informed by mastery experiences [2]. Investigating how these elements of self-efficacy are reflected in student writing may be revealing of impactful experiences of students in STEM, thus giving insight into how to better build student confidence in STEM environments. Additionally, how they choose to write about these experiences may be revealing of student attitudes and values, in turn providing insight on how students may portray confidence.

As part of an application, students may use personal statements to convey confidence. Previous work analyzed personal statements from before and after completion of the Biomedical Engineering in Simulations, Imaging, and Modeling (BME-SIM) Research Experiences for Undergraduates (REU) program [3]. Quantitative writing measures were compared to self-reported confidence in research abilities. The relationship between elements of writing – most notably noun variation – and self-reported confidence differed between men and women. Women's self-reported confidence was found to have a moderate positive relationship with noun variation, while men's self-reported confidence was found to have a weak negative relationship; additionally, these relationships seemed to change between pre- and post-program statement groups [3]. This raised questions on how students may choose to reflect confidence in personal statements.

This investigation aims to explore what experiences students choose to discuss, how they choose to discuss these experiences, and how these choices may relate to self-reported confidence.

## METHODS

This study was approved by the Institutional Review Board at ECU and informed consent was received by all participants. The BME-SIM program is a 10-week residential summer program providing students with research experiences, professional development, workshops on written and verbal communication, and mentoring opportunities [4]. Students are asked to submit personal statements before and after the program, detailing their goals, experiences, personality, and accomplishments. Surveys were also administered before and after program completion, assessing students' mastery of knowledge and skills on a 10-point Likert scale. This investigation utilized self-reported confidence in research abilities from survey results and personal statements from before and after program completion.

A subset of students' (n=16) personal statements from before and after program completion were coded in NVivo by two student readers and analyzed through the Linguistic Inquiry and Word Count (LIWC2015) software to explore the types of words students were using and how these word choices may relate to different social and psychological states [5]. The LIWC2015 takes specific words and sorts them into a variety of different categories, then determines what percentage of total words used in the personal statement fall into that category [5]. This study utilized the categories of positive emotion, negative emotion, tentativeness, certainty, achievement, power, and reward. Examples of words categorized by the LIWC2015 can be found in Table 1.

**Table 1: Examples of LIWC2015 Word Categorizations**

| Categorization | Examples |
|---|---|
| Positive Emotion | Determined, loved, success, graciously, etc. |
| Negative Emotion | Problem, defense, pain, traumatic, etc. |
| Tentativeness | Any, question, most, maybe, perhaps, etc. |
| Certainty | Specific, exact, true, particularly, etc. |
| Achievement | Best, lead, successful, recovery, etc. |
| Power | Mentor, honors, bigger, help, etc. |
| Reward | Got, opportunity, best, won, etc. |

NVivo will be used to analyze personal statement content through categorizing themes and topics within the personal statements, revealing common ideas throughout personal statements. A ground-up approach will be used to organize and interpret findings. Coding with NVivo is still being conducted. Once data from the LIWC2015 was collected, categorization percentages between overall, pre-, and post-program statement groups were compared among all students and between genders. Differences between groups were analyzed using a student's *t-test* to determine if students differed in LIWC2015 categorization frequencies between pre- and post-program statement groups. Correlations between self-reported confidence and categorization percentages were also investigated to gauge how frequencies of types of words may relate to self-reported confidence. Correlation coefficients of ± 0.3 and less were classified as no relationship, ± 0.31-0.49 as a weak relationship, ± 0.5-0.69 as a moderate relationship, and ± 0.7 and above as a strong relationship.

## RESULTS

No significant differences were found in the self-reported confidence in pre- or post-program evaluations between genders [3]. No significant differences were found between all students' pre- and post-program statements among any LIWC2015 categorization. No significant differences were found in any LIWC categorization between men and women's pre- nor post-program statements. When investigating how self-reported confidence related to differing LIWC2015 categorizations, multiple relationships arose.

Among all students, achievement had a moderate negative relationship to self-reported confidence in both pre- and post-program statements. Self-reported confidence was found to have moderate relationships with positive emotion, negative emotion, tentativeness, certainty, power, and reward among post-program statements. In all students' post-program statements, tentativeness and power were both moderate and positive, while positive emotion, negative emotion, certainty, and reward were all moderate and negative. All correlations between self-reported confidence and LIWC2015 categorizations can be found in Table 2.

**Table 2: Comparison of Correlations Between LIWC2015 Categorizations and Self-Reported Confidence**

| | All Students | | Women | | Men | |
|---|---|---|---|---|---|---|
| | **Pre** | **Post** | **Pre** | **Post** | **Pre** | **Post** |
| Positive Emotion | 0.06 | -0.67 | -0.38 | -0.51 | 0.34 | -0.77 |
| Negative Emotion | -0.46 | -0.62 | -0.59 | -0.49 | 0.19 | -0.75 |
| Tentativeness | 0.26 | 0.62 | -0.37 | 0.36 | 0.39 | 0.90 |
| Certainty | -0.38 | -0.68 | 0.49 | -0.67 | -0.40 | -0.69 |
| Achievement | -0.54 | -0.58 | -0.59 | -0.44 | -0.54 | -0.66 |
| Power | 0.18 | 0.67 | 0.64 | 0.42 | -0.31 | 0.81 |
| Reward | -0.29 | -0.62 | -0.51 | -0.18 | -0.32 | -0.82 |

Moderate negative relationships were found between negative emotion, achievement, and reward and self-reported confidence in women's pre-program statements. A moderate positive relationship was found between women's self-reported confidence in pre-program statements and power. Moderate negative relationships were found between women's post-program self-reported confidence in positive emotion and certainty.

A moderate negative relationship was found between achievement and self-reported confidence in men's pre-program statements. In men's post-program statements, moderate negative relationships were found between certainty and achievement. Strong negative relationships were found in men's post-program self-reported confidence and positive emotion, negative emotion, and reward. Strong positive relationships with self-reported confidence in men's post-program statements in tentativeness and power.

## DISCUSSION

Previous research has found that STEM environments tend to value agentic, assured communication styles [2]; additionally, other research has found that men tend to use more boosters, or words exemplifying power, sureness, and success [6]. This investigation found that men seemed to feel most confident while using tentative language rather than language expressing certainty, and both genders used less certainty-related words as their confidence increased. Additionally, all students' self-reported confidence had either no relationship or negative relationships with both positive and negative emotion categorizations. Given that STEM fields tend to value objectivity [2], students may feel the need to present their experiences rather than their feelings around their experiences. This may show an additional need to evaluate specific experiences discussed in these personal statements.

Additionally, research has found that genders may alter their communication styles based on the environment they are in [7]. Reward had a negative relationship with self-reported confidence among multiple groups. In women's pre-program statements, this negative relationship could be due to fear of promoting oneself in STEM environments or altering their communication styles to remain object about their experiences. In men's post-program statements, this may be due to emphasizing objectivity about their experiences. Moreover, other research has found that men tend to use more boosters, or words exemplifying power, sureness, and success [6]; however, no significant differences were found between the percentages of power-related words that men and women were using. This may fall back to male communication styles favoring dominance, while women's communication styles seem to value community [2, 6]. Men may feel most confident when they are abiding by these norms. Women's relationship between self-reported confidence and power between pre- and post-program statements may be explained by the feeling to need to 'prove' oneself in STEM environments [1, 2]. Following program completion, the need to use power-related language to prove oneself may seem unneeded as they have gained confidence in the area.

While the LIWC2015 has given some insight into the types of language students are using and how it may relate to self-reported confidence, investigating the context of these words would be more revealing of student values that may inform their confidence.

# THE ROLE OF ACTIN CORRALLING IN THE FORMATION OF CELL-CELL ADHESIONS

**Payton J. Thomas, Tamara C. Bidone**

Biomedical Engineering, University of Utah, Salt Lake City, UT, USA

## INTRODUCTION

E-cadherins are single-pass transmembrane glycoproteins that create cell-cell adhesions in epithelial tissues [1]. Dysregulation of E-cadherins may cause reduced tissue permeability, and metastatic initiation [2-3]. Understanding how E-cadherins form cell-cell adhesions is necessary for the study of tissue development and repair, as well as the for the development of new cancer therapeutics.

During cell-cell adhesions assembly, E-cadherins transit across molecular states: monomers, dimers (*trans*-associated), and *cis*-associated E-cadherins. *Trans*- associated E-cadherins embedded in the membranes of neighboring cells exist in a stable 'S-dimer' state which they enter by transiting through an unstable 'X-dimer' state (Fig. 1A). Once in the S-dimer state, E-cadherins form lateral *cis*- associations with E-cadherins in the same membrane (Fig. 1A).

In cell-cell adhesions, the number and size of E-cadherin clusters vary [6-7]. This variance may be attributed to E-cadherin concentration, association with the actomyosin cytoskeleton through α- and β-catenin, and the spatial arrangement of the actin filaments. It has been reported that the mesh formed by cytoskeletal actin filaments regulates the movement of E-cadherins by corralling them into clusters [8-9]. However, it remains unknown whether an actin mesh either increases the fraction of E-cadherins that interact laterally (*cis*-interactions), increases the overall number of clusters, or both. This is due, in part, to the difficulty in experimentally tracking the molecular state of E-cadherins in relation with cytoskeletal arrangements. However, these properties may be probed *in silico*, where clustering can be measured in relation with actin mesh properties such as size and permeability. Here, we extended our computational model of E-cadherin clustering [10] by incorporating a mesh of actin filaments that form regular spaces in which E-cadherins can freely diffuse. We used the model to evaluate the transitions of E-cadherins between monomers, *trans*-dimers and *cis*-associated proteins at different mesh sizes and at different values of cytoskeletal force.

Our results collectively indicated that actin mesh size controls both the amount of laterally associated E-cadherins and the number of clusters. Interestingly, mesh permeability did not affect the distribution of E-cadherin molecular states.

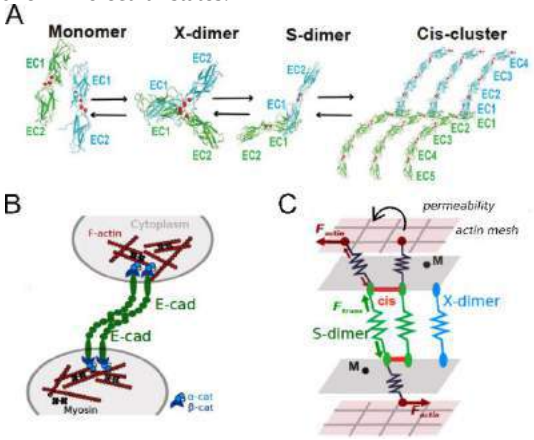

**Figure 1 E-cadherin molecular states during clustering** (A) Ribbon representation of E-cadherin molecular states. (B) Illustration of two E-cadherin *trans*-dimers that interact laterally and associate with the cytoskeleton. (C) Schematic diagram of our 3D, including E-cadherin state transitions (adapted from [10]).

## METHODS

A 3-dimensional simulation domain composed of four different layers was used: two internal layers represented the plasma membranes of neighboring cells, and two external layers mimicked the actin cytoskeleton. E-cadherins were represented as single point particles on the plasma membranes that switch between molecular states according to previously determined rate constants [10], and the actin mesh was

represented using a regular grid, in which free diffusion of E-cadherins was allowed within the grid spaces and hopping between the spaces was determined by the permeability. Simulations were performed with Euler's method on the Langevin Equation under a low-Reynold's number assumption (Eq. 1).

$$F_i - \varepsilon_i \frac{dr_i}{dt} + F^T{}_i = 0 \qquad (1)$$

Where $r_i$ is the position vector of the i-th E-cadherin, $\varepsilon_i$ is the 2-dimensional drag coefficient corresponding to the diffusion coefficient $D = 0.028\ \mu m^2/s$, and $F_i$ and $F^T{}_i$ are net deterministic and stochastic force, respectively. Deterministic force was the sum of forces due to actin association and cadherin *trans*- association, both of which were approximated to be Hookean (Eq. 2).

$$F_i = k_{actin}(l - l_{actin,0}) + k_{trans}(l - l_{trans,0}) \qquad (2)$$

Where $k_{actin} = 2$ pN/μm, $k_{trans} = 2$ pN/μm, $l_{actin,0} = 10$ nm, and $l_{trans,0} = 20$ nm [12]. Stochastic force was applied only to cadherins outside of clusters, which were assumed to be diffusive. Stochastic force was modeled according to the fluctuation-dissipation theorem (Eq. 3):

$$\langle \boldsymbol{F_i^T}(t)\boldsymbol{F_j^T}(\boldsymbol{t})\rangle = \frac{2k_B T\varepsilon_i\delta_{ij}}{dt}\boldsymbol{\delta i} \qquad (3)$$

where $k_B$ is the Boltzmann constant, $T$ is the temperature, $\delta_{ij}$ is the Kronecker delta, and $\boldsymbol{\delta}$ is a unit second-order tensor.

Mesh size was systematically varied from 0.1 μm to 1μm, a value corresponding to the side dimension of our 3-dimensional domain and indicating the absence of actin corralling. The probability of hopping between neighboring grid spaces was varied systematically between 0-1 (permeability). Force from E-cadherin interactions with actin, $F_a$, was systematically varied between 0-50 pN. As outputs, we evaluated cluster size, in terms of number of E-cadherins per cluster, proportion of E-cadherins in *cis*-interactions, and number of clusters at steady state.

## RESULTS

Analysis of our simulation results showed that the number of clusters increases with increasing mesh size up to about 22/μm$^2$ (Fig. 2A). The increase in cluster number with mesh size is due to an increase in the fraction of E-cadherins that interact laterally (Fig. 2B). Increasing force magnitude reduces the fraction of E-cadherins involved in *cis*-interactions (Fig. 2B), and thus reduces cluster numerosity (Fig. 2A).

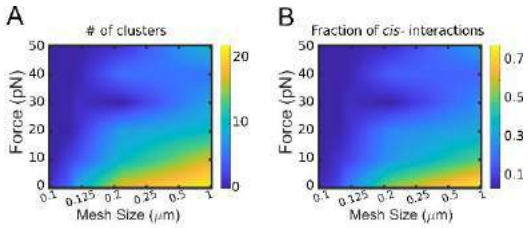

**Figure 2 Cluster numerosity and E-cadherin molecular states.** (A) Mean number of clusters as a function of actin corralling (mesh size) and $F_a$, using permeability of … (B) Mean proportion of E-cadherins in the S-state as a function of actin corralling (mesh size) and $F_a$, using permeability of 0.5. Data are extracted between 20-30 s of simulations.

Using mesh permeability of 0.4, cytoskeletal force $F_a = 30\,pN$ and mesh size 0.25 $\mu m$, about 50 % of the clusters contain between 1-5 E-cadherins and 60% of the cluster contain between 6-10 E-cadherins, without larger clusters due to the limited mesh size. In these conditions, about 20% of E-cadherins are involved in cis-interactions at steady-state and the majority of E-cadherins present as monomers (Fig. 3A). The relative fractions of E-cadherins in the different states are comparable for lower permeability, with about 20% *cis*- E-cadherins and about 80% monomers (Fig. 3C). This suggests that inhibition of E-cadherin diffusion from decreased mesh permeability does not affect the molecular state of E-cadherins.

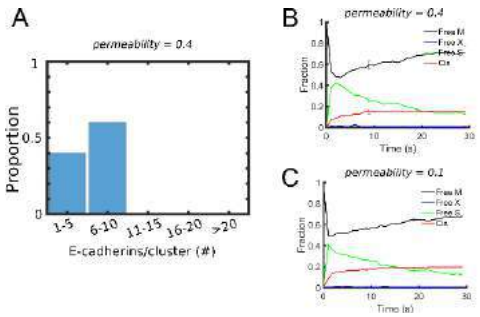

**Figure 3 Effect of mesh permeability on E-cadherin clustering and molecular states.** (A) Distribution of cadherin cluster sizes with a permeability of 0.4. mesh size of 0.25 μm, and $F_a$ = 30 pN. Data are extracted between 20-30 s of simulations. (B and C) Time evolution of proportion of E-cadherins in each state as permeability varies. Error bars indicate the standard error.

## DISCUSSION

Here, we extended our computational model of E-cadherin clustering in order to evaluate the effects actin corralling on the assembly of cell-cell adhesions with varying degrees of cytoskeletal tension. Consistent with our previous results [10], force reduces the number of clusters (Fig. 2A) by decreasing the fraction of E-cadherins that interact laterally (Fig. 2B). Actin mesh size promotes clustering to different extends, depending on cytoskeletal force, with overall less clusters at high force (Fig. 2). This is consistent with previous experiments suggesting that binding of E-cadherins to cytoskeletal filaments guide clustering [8-9]. Here, however, we provide insights that actin mesh size promotes clustering while actin force reduces it because of it changes E-cadherin molecular states. Interestingly, actin mesh permeability does not impact the molecular state of E-cadherins (Fig. 3). It will be interesting to test, in the future, if variations in permeability affects cluster size and number.

# OPEN-SOURCE SYSTEM FOR REAL-TIME FUNCTIONAL ASSESSMENT OF ENGINEERED MULTICELLULAR FILTRATION BARRIERS

**Tess K. Fallon (1,2), Alan D. Stern (2), Nanditha Anandakrishnan (3), Ilse S. Daehn (2), Evren U. Azeloglu (2,3)**

## INTRODUCTION

One goal of precision medicine is to develop patient-derived tissue analogs that enable faster and more accurate drug screening and discovery. Others[1] and we have developed various kidney organoid and organ-on-chip systems that aim to recapitulate the physiological functions of the kidney (Figure 1), most importantly selective filtration, which is an important function of the kidney. Malfunction of selective filtration is associated with acute kidney injury and chronic kidney disease (CKD), which affects 37 million people in the US alone. Recently, organ-on-chip models have been proposed to study kidney dysfunction that results in altered filtration characteristics, and use this metric as a surrogate parameter to evaluate drug candidates for treatment of kidney disease. To test applicability of such model systems, we need a quantitative assay that can evaluate the filtration status of these tissue analogs in real-time.

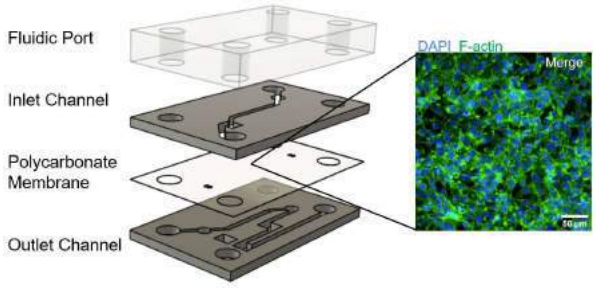

**Figure 1: Microfluidic kidney-on-chip seeded with mouse glomerular endothelial cells**

Current methods use absorbance or enzyme-linked immunosorbent assay (ELISA) to determine the presence of biomarkers.[2] Looking at absorbance is not physiologically applicable and limited since quantitative evaluation of more than one molecule at a given time is challenging. Additionally, perfused media must be removed from the microfluidic device. Repeated removal of medium can damage cells, preventing continuous monitoring of filtration status over time. Non-invasive methods use regenerating electrochemical or physical sensors within the microfluidic device to track target molecules.[3,4] Regeneration of sensors takes up to 4 hours, limiting the ability to continuously measure biomarkers within the regeneration time frame using a single chip.[5] Additionally, if there is a sudden increase in biomarker levels, sensors can immediately saturate and values above the saturation range can be missed. In the case of kidney selective filtration, detecting sudden increases is important for detecting potential cellular damage.

Here, we report a non-invasive, open-source fluorescence-based sensor system that can simultaneously track real-time filtration of human serum albumin (HSA) and inulin, two molecules used to estimate kidney function.

## METHODS

Working with a simple epifluorescent light path and a dual-bandpass filter set, we developed a 3D printable sensor that tracks the filtration status of a kidney-on-a-chip system. The model used for the purposes of this paper was a retrofitted Thermo-Fischer Countess II™ system.

For our first prototype, we used the optical path of Countess II in combination with 3D printed materials (Figure 2a). Organ-on-chip was mounted on a custom-built stage and secured using magnets (Figure 2b). The objective was a 0.1 NA 4X Olympus Plan Achromat (Part #RMS4X). The three optical components of the light cube, namely excitation, emission, and beam-splitter, were obtained from Chroma (59010x, 59010m, and 69015bs, respectively). This filter combination allowed simultaneous imaging of both fluorescein isothiocyanate (FITC) and Texas Red dye conjugates, and it was mounted on a custom filter cube (Figure 2c). An amber 595nm LED (Luxeon-C) was

used to excite Texas Red and 490nm MCPCB LED (Thor Labs) was used for FITC.

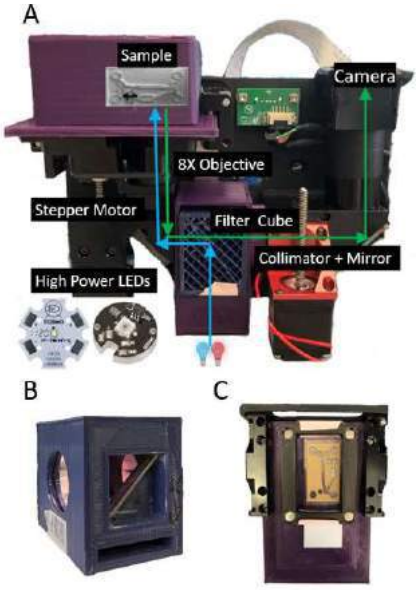

**Figure 2: Custom (A) light path, (B) filter cube, and (C) sample mount**

The sensor was automated using Raspberry Pi™ and Arduino™ UNO. Stage movement was automated with a Haydon-Kerk™ linear actuator stepper motor, allowing focus control. A circuit was designed to give user control over LED brightness and stage height (Figure 3a). A Raspberry Pi™ HQ Camera was used to acquire 8-bit-depth images at 507x380pixel resolution, binned eight times relative to the initial camera resolution. A graphical user interface (GUI) was designed for basic user controls and the live-streaming (Figure 3b).

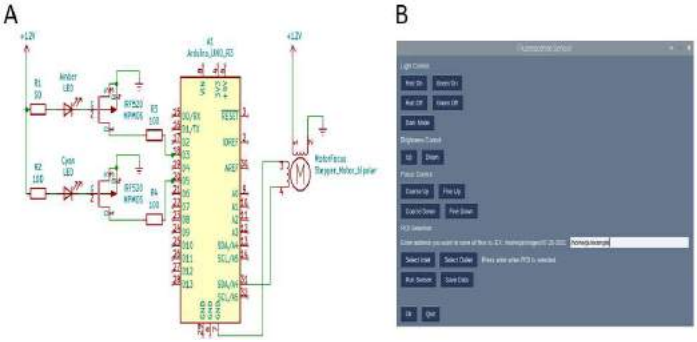

**Figure 3: (A) Electronics circuit diagram and (B) the user interface**

Media containing HSA-Texas Red and inulin-FITC was perfused into the inlet. Over a user-specified length of time, the sensor can acquire data with FITC excitation followed by Texas Red excitation. We then quantified the concentration of HSA and inulin in both the inlet and the outlet by comparing the pixel intensity values of each case. Higher intensity indicated higher concentrations of dye. In healthy kidneys, HSA is selectively retained while inulin is selectively filtered; we therefore expect equivalent concentrations of inulin at both inlet and outlet, while only low levels of HSA at the outlet. Thus, comparing pixel intensity values of the two species over time can allow continuous evaluation of the functional status of the selective filtration barrier.

## RESULTS

Several quality control assays were performed to verify the sensitivity and precision of the sensor. We confirmed that only one target molecule was excited at each time, by placing inulin-FITC in the left chamber and HSA-Texas Red on the right and selectively turning on the LEDs in different combinations (Figure 4a-d). We also ensured image consistency by placing 1 mg/mL of each solution and taking timelapse images at 15-minute intervals (Figure 4e). Finally, we found the linear sensitivity region of pixel intensities as a function of target molecule concentration (Figure 4f). The linear sensitivity region for inulin-FITC was found to be between 0.01mg/mL and 1mg/mL.

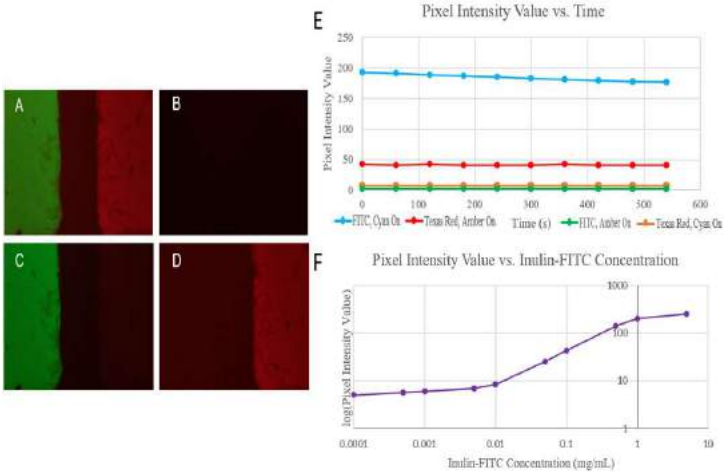

**Figure 4: Visual verification with (A) both LEDs on (B) both LEDs off (C) only cyan on (D) only amber on and quantified verification for (E) consistency over time and (F) sensor sensitivity.**

## DISCUSSION

We present an economical system for real-time, quantitative and non-invasive assessment of filtration status in engineered kidneys using off-the-shelf components. The final prototype will be available through a CC BY 4.0 open-access license. Unlike complicated electrochemical sensors, our design can be implemented by those without a technical background for their own engineered systems. We plan on using this sensor to compare filtration function of healthy and diseased kidney cells differentiated from patient-derived induced pluripotent stem cells.

# MECHANICAL IMPROVEMENT AND HAPTIC QUANTIFICATION OF DIGITAL EXTENDERS INTUBATION DEVICE

**Tristan Arias (1), R. Lyle Hood (2), Emma Treadway (1)**

(1) Engineering Science, Trinity University, San Antonio, Texas, United States
(2) Mechanical Engineering, University of Texas at San Antonio, San Antonio, Texas, United States

## INTRODUCTION

There currently exist several methods of performing endotracheal intubation on an individual. One is to use a laryngoscope to depress the patient's tongue and guide the endotracheal tube into their trachea. Another, called Digital Intubation (DI), consists of the same actions performed with the provider's own fingers. While direct laryngoscopy is considered the gold standard of airway management, DI can be more advantageous in field scenarios when the glottal opening cannot be visualized with the laryngoscope, either due to obstruction by tissues or fluids or when the patient's injuries prevent the necessary head and neck tilt tied to laryngoscopy performance [1]. In these cases, use of DI enables a haptic, tactile performance of intubation that does not require visual data nor the patient positioning necessary for laryngoscopic intubation [2]. However, DI is generally discouraged as it can be dangerous, to both the caregiver and patient, as well as unsanitary. If the patient is even partially conscious, they can reflexively bite down, damaging the medical provider's fingers, and the insertion of natural digits can introduce contaminants into the patient's system [1].

Hernandez-Hinojosa et al. [3] designed a device to extend the reach of a user's digits with two-joint robotic digits. While it was shown these Digital Extenders (DEs) could perform intubation while decreasing both the quantity of necessary applied force and duration over which this force was applied to complete the procedure, there were significant disadvantages and shortcomings associated with their use. Greater head and neck tilt were seen with the use of DEs compared to other methods, hypothesized as due to a decreased ability to visually confirm procedure performance as the platform visually obstructs the oral cavity. It was suggested that the lack of haptic feedback that might be present in standard DI may have contributed to this issue [3].

The objective of this research was to compare control of force applied with the Digital Extenders to force applied with natural digits, in order to quantify the useful haptic forces exerted on the user by the device.

## METHODS

### Prototype Fabrication and Mechanical Changes

First, a single digit of the Digital Extenders was fabricated, with minor design changes in most areas (Figure 1) relative to previous work. An Arduino microcontroller measures the deflection of the trigger (via a potentiometer) and uses that to command the rotation of the servo (ANNIMOS DS3225MG). Red, low-strength parts were made on an Ultimaker S5 FDM printer using Ultimaker Tough Red PLA ($S_{ut}$=37 MPa, E=1.8 GPa, $E_{flex}$=2.5 GPa). Blue, high-strength parts were made on a Formlabs Form 3 SLA printer using Formlabs Tough Resin V, cured with a Formlabs Form Cure for 60 minutes at 60°C ($S_{ut}$=55.7 MPa, E=2.7 GPa, $E_{flex}$=1.6 GPa).

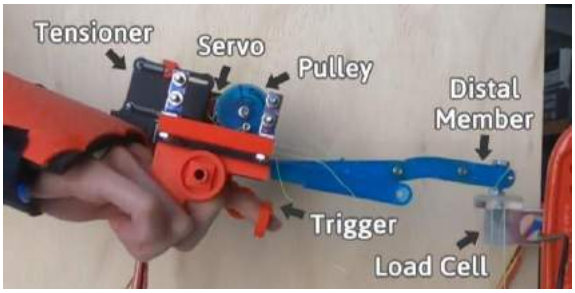

**Figure 1: Digital extenders prototype**

The major improvement upon the original design was the incorporation of an adaptive line tensioner, which employs springs to keep the lines threaded along the top and bottom of the Digital Extender digits from developing slack. This decreased the amount of time during which the servo motor delayed actuating the members while it collected slack, thus resulting in more immediate and intuitive response to user trigger movement. The dark grey tensioner components made on a Markforged Onyx One FDM printer using Onyx composite with Fiberglass reinforcement ($S_{ut}$=37 MPa, E=2.4 GPa, $E_{flex}$=3.0 GPa).

### Control and Haptic Feedback Testing

A human-participant experiment was performed to quantify forces exerted at the fingertips and on the back of a user's hand under a protocol approved by the Trinity University Institutional Review Board. During the experiment, each of two participants (21yr old F, right-handed; 20yr old F, right-handed) was asked to apply target forces to a load cell (Transducer Techniques LSP-10), either with the DE fingertip, or with their own fingertip, the finger held flat against the load cell pad in either case. The inclusion of natural digit data allowed a comparison in some manner parallel to Digital Intubation, while NoVis trials allowed a measurement of the helpfulness of non-visual feedback to control operation.

Data was taken under four conditions: DEs with visual feedback (DE/Vis), DEs with no visual feedback (DE/NoVis), natural digits with visual feedback (ND/Vis), and natural digits with no visual feedback (ND/NoVis). In each condition, three trials were performed where, during each trial, the participant was asked to apply 5 target forces to the load cell, presented in a randomized sequence for 5 seconds each. The two Vis condition trial sets were each performed before their respective NoVis condition trial sets, to allow the participant to become accustomed to whatever data might exist without visual feedback. During the Vis condition, the participant was allowed to view their proximity to the target force on a graph, while during the NoVis condition, the participant was shown the target and their

they tried to achieve it. At the end of the target, they were allowed to view how close they had gotten to the goal after the five seconds had expired to allow them to adjust their correlation of force output to any received data. Applied forces were mapped to a linear 1-5 scale for display to the user through a MATLAB Simulink scope window, with 0 being the approximate resting weight of the DEs and participant's hand on the load cell and 5 being the maximum recorded exertable force by the DEs.

In our analysis, the best three seconds of each target in terms of mean absolute percentage error (MAPE) of applied force relative to target force were averaged:

$$MAPE = \frac{100\%}{n}\sum_{i=1}^{n}\frac{|A_i - T|}{T}, \quad (1)$$

where, $n$ is the number of datums averaged, $i$ is an indexer, $T$ is the target force, and $A_i$ is the actual measured force. An average MAPE per condition was calculated.

To quantify the inherent force feedback available to the user, we mounted two resistive pressure sensors under the DE hand cover, with one located closer to the participant's knuckles and the other positioned closer to the participant's wrist. The applied force data was scaled to the approximate range of the haptic force data and plotted together to observe any potential relationship.

## RESULTS

The MAPE (represented by the shaded regions of Figure 2) was no greater than 8.6% for any given condition. Average performance for each of the four conditions is summarized in Table 1. As expected, both participants performed better in the Vis condition than in the NoVis condition for both ND and DE. In the NoVis conditions, both participants performed better with DEs than with ND.

The maximum normal force exerted by the device on the load cell during the trials was recorded as 4.97 N, compared with the median maximum force of 17.0 N recorded in Hernandez-Hinojosa et al. [3].

## DISCUSSION AND CONCLUSIONS

We found the accuracy of force-matching with the DEs surprising, especially in the NoVis condition. There was only a 0.4% difference between the average DE/Vis and ND/Vis accuracies, and only 2.6% difference between the average DE/Vis and DE/NoVis accuracies. Additionally, the DE/NoVis condition had on average 2.9% less error than the ND/NoVis condition. This could be due to the relatively lower noise in force profiles applied with the DEs as compared to ND, which can be observed in Figure 2.

These results indicate a high level of Digital Extender control relative to natural digits and suggest the existence of useful haptic feedback inherent in the device, which allowed participants to maintain some level of accuracy in the absence of visual feedback, even outperforming ND accuracy in the case of NoVis. This conclusion is supported by measurements taken with the pressure sensors under the hand cover, shown in Figure 3, which demonstrate a correlation between the forces applied to the load cell and those felt where the device is worn.

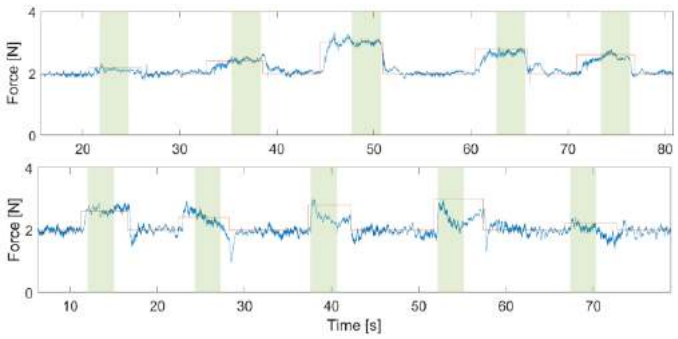

**Figure 2: Sample force accuracy trials for one participant, with target (red) and measured forces applied to the load cell (blue): NoVis/DE Trial 3 (Top), and NoVis/ND (Bottom). Green bars indicate best 3 seconds for MAPE calculation.**

**Table 1: MAPE to Target Force (Best 3s Averages)**

| | Vis | NoVis | Avg |
|---|---|---|---|
| Digital Extenders (DE) | 3.1% | 5.7% | 4.4% |
| Natural Digits (ND) | 2.7% | 8.6% | 5.6% |
| Avg | 2.9% | 7.2% | |

However, these conclusions come with some limitations worth discussing. In some cases, participants did not achieve a steady-state force-application before the 5 seconds for one target had expired, which could be addressed in future work by extending the time for each target force. Additionally, these conclusions are limited to the low range of forces exerted, namely between 2-5 N. This range is distinctly lower than expected from previous work. While the exerted forces were similar to those seen during intubation in [3], the conditions under which that force was exerted, namely the digit angles, were not replicated. Future work will investigate losses, as well as endeavor to pursue testing under conditions that conform to the higher flexion state seen in intubation to investigate the holding of these conclusions in such a condition.

The existence of haptic feedback has been confirmed, but the exact relationship between the magnitude and nature of this feedback and the accuracy of DE control has not been established. Users' reliance on haptic feedback could have been obfuscated by the availability of auditory feedback, which we plan to address in future work by employing noise-cancelling headphones.

Finally, this experiment contained a limited dataset from two participants, which future work will need to expand on in order to make more meaningful conclusions to the application of improved intubation. Neither participant in this study had any training in performing intubation, and it would be valuable to see how medical professionals trained in intubation compare in their fine motor control and use of the DEs. Future work should include expert participants and investigate the utility of haptic feedback in applied intubation settings, extending beyond simple force control.

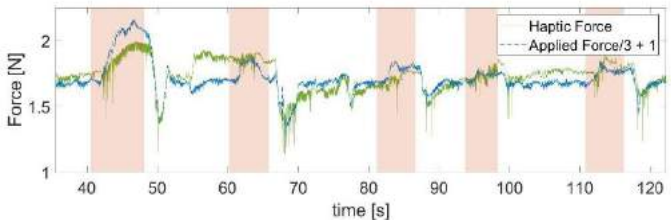

**Figure 3: Load cell force scaled to range of pressure sensor for ease of interpretation**

## ACKNOWLEDGEMENTS

The advice, expertise, and insight of Ernesto Hernandez-Hinojosa was instrumental in the production of this work.

# MODELING OF ORGAN-SPECIFIC TUMOR MICROENVIRONMENTS TO ANALYZE CELL-TO-CELL INTERACTIONS

**Morgan C. Connaughton (1), Mahsa Dabagh (2), (1,2)**

(1) Biomedical Engineering Department, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, United States
(2) Biomedical Engineering Department, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, United States

## INTRODUCTION

Cancer is one of the leading causes of deaths worldwide and in 2020 alone, it accounted for about 10 million deaths. Various organ-specific cancers have a higher chance of being properly treated and even cured if caught in the early stages, which is typically more difficult to diagnose and can even be misdiagnosed entirely.

The tumor microenvironment (TME) seen within the extracellular matrix (ECM), consists of stromal cells (fibroblasts) and is highly complex. The ECM, itself, is a type of non-cellular structure that regulates most cellular functions of tissue and organs, which overall, determines cell behavior, which includes, cell proliferation, polarity, differentiation, migration, and adhesion [1]. Mechanical properties, such as cell elasticity and stiffness, of single cells are important factors for many different biological processes, and this includes cancer. Elasticity plays a huge role in determining a cells resistance to deformation and the stiffness will determine the rigidity of a material in response to the stress imposed onto it. Cancer cells are different than the surrounding normal cells by their high elasticity and have even been shown to have a lower Young's modulus (E), which indicates a higher elasticity.

There has been a great deal of effort directed toward developing novel therapeutics for different cancer types in the laboratories that do not reach the clinic. The main reason for current limited success in cancer treatment is lack of biologically relevant *in vitro* or *in vivo* models resembling the complexity and heterogeneity of the TME. The purpose of the present study is to develop a novel computational model of tumor tissue. Our main goal is to build an investigational platform to study the crosstalk between cancer cells (CCs), stroma cells (SCs), and ECM.

## METHODS

The TME and ECM were created using COMSOL Multiphysics. The model consisted of a structure of singular cells surrounded by the ECM. The cells consisted of stromal cells (fibroblasts) and one singular cancer cell. The Young's modulus and Poisson ratio of the cells and the organ-specific ECM were obtained through a short literature review. Six different cancer cell lines were used throughout the present study, which included two breast cancer cell lines (MCF-7 and T-47D), two kidney cancer cell lines (ACHN and A-498), and two pancreas cancer cell lines (PANC-1 and MIA PaCa-2).

The cancer cell was placed either within the singular cell structure, not directly in contact with the ECM or on the outside of the singular cell structure, so directly in contact with the ECM. A boundary load was added to the model to represent both high (160 mmHg) and normal blood pressure (80 mmHg). This load acted on the ECM, therefor the surrounding TME. The data was then exported to MATLAB to evaluate and process the data computed from the model.

## RESULTS

Our results show that there is an interaction between the CC and SC from the given mechanical properties of the ECM and cells. Figure 1 depicts the CC that is directly in contact with the ECM and shows how the stress is impacting the CC and the surrounding SC on the x-axis with a boundary load of 160 mmHg (~21,332Pa), whereas Figure 2. depicts how the stress is impacting the CC and surrounding SCs on the y-axis, with a boundary load of 160 mmHg (~21,332Pa). The CC lines with a higher Young's modulus behave differently than its organ-specific counterpart. For example, on Figure 1 both pancreatic cancer cell lines, PANC-1, and MIA PaCa-2 both behave similarly, but then behave differently at 30 $\mu$m. The only mechanical property that is different between the two is the Young's modulus. The Young's modulus for PANC-1 was 2.4 kPa, which was higher than the Young's modulus of MIA PaCa-2, which was 1.7 kPa. This is also seen in the CC's with a

higher Young's modulus with the breast cancer cell lines and the kidney cancer cell lines.

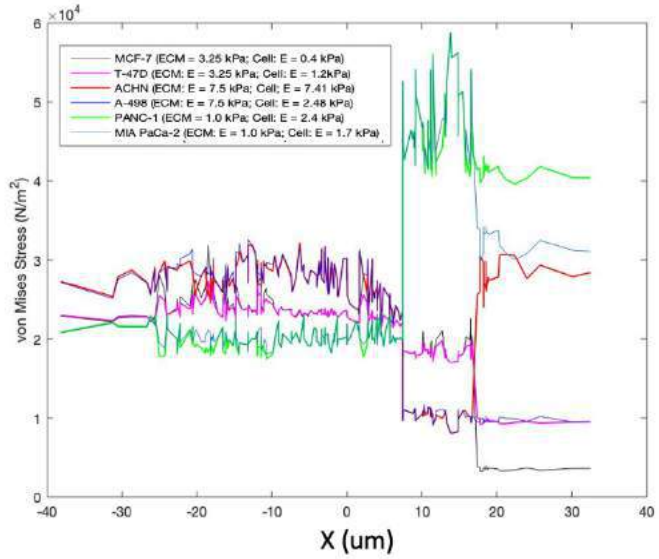

**Figure 1:** Cancer cell line that is directly in contact with the ECM on the x-axis with a boundary load of 160 mmHg (breast cancer cell lines, MCF-7 and T-47D; kidney cancer cell lines, ACHN and A-498; Pancreatic cancer cell lines, PANC-1 and MIA PaCa-2).

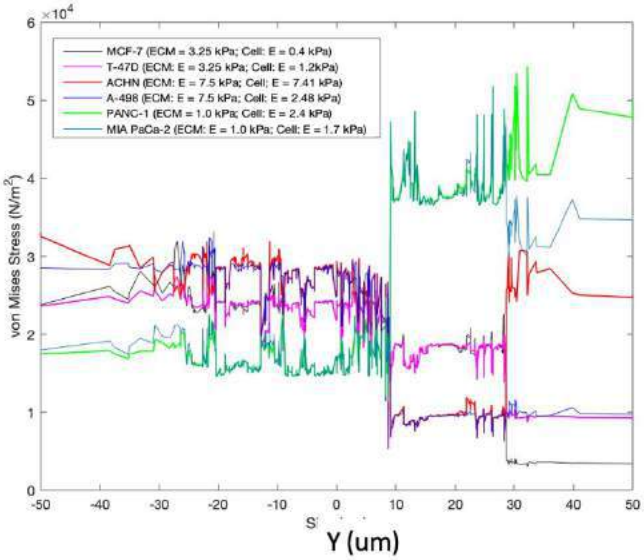

**Figure 2:** Cancer cell line that is directly in contact with the ECM on the y-axis with a boundary load of 160 mmHg (breast cancer cell lines, MCF-7 and T-47D; kidney cancer cell lines, ACHN and A-498; Pancreatic cancer cell lines, PANC-1 and MIA PaCa-2).

## DISCUSSION

Our results show that heterogeneity of CCs, SC, and ECM properties, representing different organ-specific biological condition, impact the stresses that the cells and ECM exert on each other. These CCs are leading to higher stress within the ECM and surrounding SCs, which can allow for the growth of tumors to become easier. This is because the cells are then pushing on the TME and allowing for further turmeric growth. This impacts CC competition because these cells are winning because of the structure of the ECM and SCs. Our study reveals that cell competition can be controlled by forces exposed on cancer cells by their TME. To our knowledge, this is the first study done on this type of work and it will serve as an important first step in understanding the mechanisms of cell competition, a process controlling preferential elimination of one cell by another through apoptosis.

# The Impact of Disturbed Flow Induced Arterial Stiffness on Mechanotransduction in Endothelial cells

**Andrea Alonso, Mahsa Dabagh**

Biomedical Engineering, University of Wisconsin, Milwaukee, WI, United States

## INTRODUCTION

Atherosclerosis prone regions of the vasculature are exposed to disturbed flow where low and oscillatory wall shear stress affect endothelia cell (EC) functions such as proliferation, apoptosis, migration, permeability, cell alignment and mechanical properties. ECs transduce fluid shear stress resulting from blood flow into intracellular signals whereas the response of subcellular structures to hemodynamic forces play a significant role in vascular health and disease. In this project, we are developing a multiscale, multicomponent model of endothelial cells and intra/inter-cellular organelles to explore how the mechanotransduction in subcellular structures of endothelial cells are influenced under exposure to the disturbed flow. Moreover, we take into account the impact of disturbed flow induced arterial stiffness on mechanotransduction. Our model includes adheres junction, glycocalyx, cytoskeleton, focal adhesions, nucleus, cytosol, and apical layer. In our study, we hypothesize that disturbed flow induced stiffness of the arterial wall will significantly impact the activation of mechanosensors relative to unidirectional flow applied on straight regions of the vasculature. Our results show that changes in the stiffness promotes the activation of mechanosensors in cells exposed to disturbed flow while it doesn't have same influence in ECs exposed to unidirectional flow. Our study quantifies the forces on integrins, adherence junctions, filaments and other substructures in the range that activate mechanotransduction. Our results provide insight into mechanisms underlying the progress of atherosclerosis and identifies new pathways that may lead to novel therapies to suppress the disease progression.

## METHODS

In this study, a three-dimension multi-structural model was used to interpret EC seven cells layers(figure 1): where each EC consists of the following major subcellular load-bearing structures: the apical glycocalyx layer with thickness that is in direct contact with fluid flow; the apical cortex layer with thickness; the cytosol, respectively; the nucleus at the center of each EC is located above the cell base taken as an ellipsoid with maximum radius along x-axis minimum radius along y-axis, and maximum height along z-axis ; the cytoskeleton linking the apical plasma membrane to FAs or the nucleus or intercellular junctions FAs providing the contact points with the extracellular matrix and ADJs binding ECs together across their lateral boundaries, The base of the EC is made of hexagonal cells.EC located in pro-athero-sclerosic region of the arteries/aorta. In this case the apical plasma membrane/cortical cytoskeleton layer and the glycocalyx layer with a smaller thickness are located over the cytosol. In the process of the research there is a deliberation between the in vitro and in vivo of the thickness of the denser inner layer that can have a mechanically signific. It's have shown that the thickness of the culture cells has consist firm and uniform on the cells which at the given point has not been exposes to the shear stress. It can be observed that EC cell changes within minutes of shear exposure, keeping in mind that unfortunately in this model the reflection of the biomolecular responses of the cell are not

captured in this model. The nucleus is located at the center of each EC and within them the cell base. The cytoskeleton network in this model is characteristic of a cell upon initial exposure to shear stress. The EC's do not have a preference in orientation.

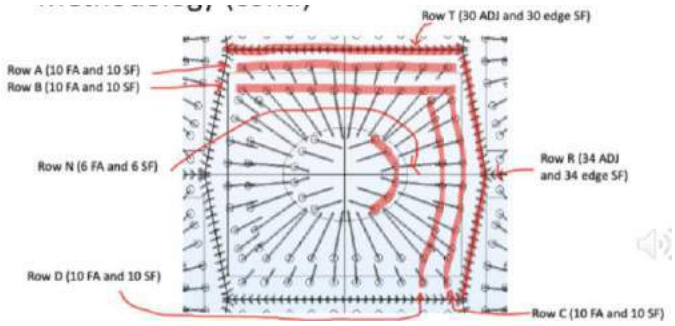

Figure1. A close- up of the model, displaying the individual rows of components through the cell to be analyzed

**Equations:**

$$U = C_{10}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3), \quad (1)$$

$$\sigma_{VM} = \left\{\tfrac{1}{2}[(\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{xx} - \sigma_{zz})^2 + (\sigma_{yy} - \sigma_{zz})^2 + 6(\sigma_{xy}^2 + \sigma_{xz}^2 + \sigma_{yz}^2)]\right\}^{\frac{1}{2}}. \quad (2)$$

$$\varepsilon = \frac{L_1 - L_0}{L_0}. \quad (3)$$

**RESULTS**

In this specify study the focused was particularly on how the EC, Focal Adhesions(FA), Stress Fibers(SF), and the Adherens junction with particular parameter. In this case there where 7 different cases that where sun to be able to compare the data obtained. The parameters where flow over the endothelium cells disturbed or unidirectional, ECM Properties young module, relaxation time in EMC and the behavior of ECM (viscoelastic). The thickness was keeping the same for all cases. In this particular the behavior of adherens junction through all cases showed that the data collected from a multidirectional flow have a similar behavior despite their difference in parameter. (figure2).

# PEDIATRIC HEART ASSIST DEVICE MONITOR

**Rachel M. Hillner (1), Luke Perry (1), Yuzhong Gong (1), Abdulaziz Khayat (1)**

**Faculty Advisor(s)**

**Dr. Venkat Keshav Chivukula (1)**

(1) Biomedical Engineering, Florida Institute of Technology, Melbourne, Florida, United States

## INTRODUCTION

Heart failure among pediatric patients remains a relevant area of concern throughout the medical field with 11,000 to 14,000 new cases occurring annually in the United States alone[1]. However, there is currently only one FDA approved device on the market for treatment: the Berlin Heart EXCOR[2]. The EXCOR is composed of two separate chambers: an air chamber and a blood chamber, which are divided by a flexible membrane. Thrombosis, or clot formation, in the blood chamber is a prevalent area of concern and is the leading cause of death associated with the EXCOR with 29% of patients experiencing a neurological injury[2]. A thrombus within the device would affect the movement of the membrane, causing it to deform in an unnatural fashion. Therefore, clinicians are required to perform a qualitative assessment of the membrane motion every four hours to ensure proper functioning[3]. Due to the rapid motion of the membrane (often greater than 120 bpm), clinicians record a video and qualitatively inspect the movement of the membrane frame by frame. The next steps for the patient are based on the clinician's judgment. This method can be time consuming for clinicians and is prone to subjectivity. Developing an accurate method to monitor the functioning of the device towards detecting a thrombus is of the utmost importance in order to reduce thrombogenic risk and improve patient outcomes. Our goal is to design a smartphone application that provides a tool for clinicians to perform a quantitative assessment of the EXCOR in a timely fashion, within 30 minutes, whilst maintaining high accuracy.

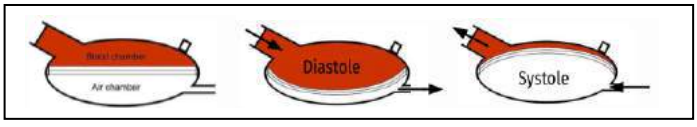

**Figure 1: The EXCOR is divided into two regions, blood and air chambers, separated by a flexible membrane. During diastole, the membrane is pulled down allowing blood to fill. During systole the membrane is pushed up and blood exits the device.**

## PRODUCT DESIGN

The PHADM (Pediatric Heart Assist Device Monitor) utilizes computer vision and machine learning to quantitatively assess the performance of the EXCOR based on the relation between membrane deformation and device functionality. The front end of PHADM will be in the form of an user-friendly smartphone application. An outline of the application can be seen in Figure 2 and 3. The first page of the mobile application will allow the clinician to determine the method of data collection: to upload a previously recorded file from files or to record a video in app. If selecting a previously recorded file, then the clinician will be asked to select a recording and ensure its quality. If recording in app, they will be directed to a camera application with directions detailing how to record a quality video. Afterword they will be asked to review the video. Lastly, after inputting patient specifications such as expected bpm and patient ID, the clinician can proceed to analysis. While the algorithm is evaluating membrane motion, a progress bar with expected completion time will appear. Once complete, a notification will be sent to the clinician from which the results can be viewed.

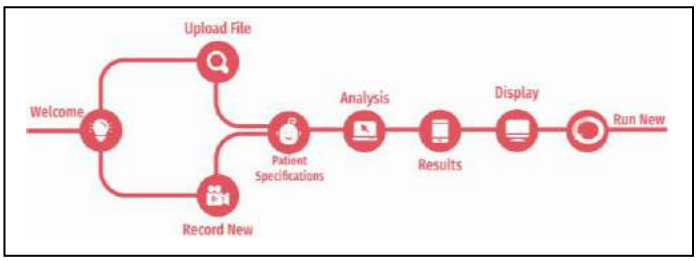

**Figure 2: Outline of Application Design**

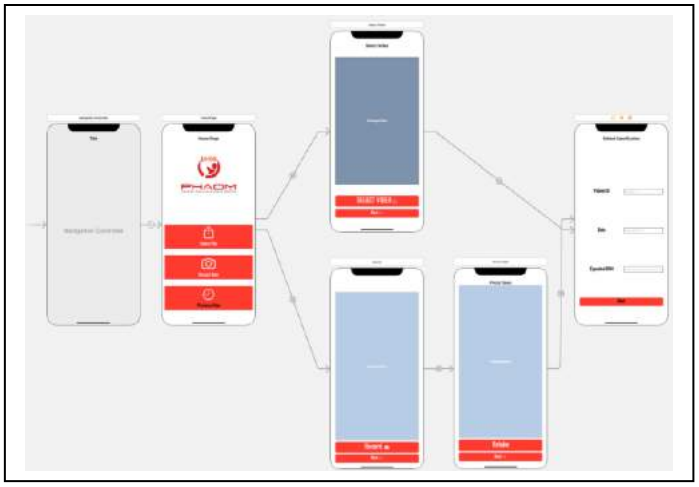

**Figure 3: Current Application Display. Application is under construction.**

Membrane movement will be quantified through the use of a computer vision algorithm, HOG (Histogram of Oriented Gradients). HOG quantifies the change in pixel intensity of neighboring pixels; large differences in pixel intensity are indicative of membrane deformation and small changes represent a smoother membrane. HOG is solely applied to the membrane region of the EXCOR through the process of background subtraction. In doing so, noise will be greatly reduced, thus amplifying the signal produced from the movement of the membrane. HOG is calculated for every pixel in a given frame and summed such that each frame can be represented by a single HOG value. The corresponding HOG values are then normalized and features are extracted from this signal. Peak prominence and time between peaks are the two features most telling of membrane performance. Peak prominence is calculated from the difference between maximum and minimum HOG values for a given time frame. Time between peaks is calculated as the difference in time from $peak_n$ and $peak_{n+1}$. The HOG of the membrane motion is capable of clearly indicating the smoothed and deformed phases of membrane movement. Small changes in membrane deformation may suggest that the membrane is not completely smoothing as it should and would be flagged. In addition, increased time between identified smooth points suggests that the membrane is not completely smoothing twice during each cardiac cycle as shown in Figure 4. Both features will be used in order to accurately assess the functioning of the EXCOR in a quantitative manner. Based on preliminary results, PHADM is able to successfully identify slight deviations in membrane movement that could easily be missed by the human eye. When analyzing an EXCOR functioning at 120 bpm, good filling would result in a smooth point occurring at a mean of every 0.25s. It was found that diastole takes longer than systole, approximately 0.31s compared to 0.19s respectively. When plotted with a playback speed 1/8 of real time, a cardiac cycle is 4s (2.5s diastole, 1.5s systole). This information is helpful when identifying at what stage the EXCOR is malfunctioning. Figure 4, point D was identified to be abnormal through the usage of peak prominence and time between peaks. The peak was minimal and the time between peaks was greatly increased, ~3.7s plotted at 1/8 real speed or 0.46s real time, and occurred during systole.

Preliminary testing using pre-recorded patient data from clinical collaborators at the University of Iowa suggest that PHADM is highly accurate in quantifying membrane movement as well as identifying cardiac phase (systole vs diastole), as shown in Figure 4. More testing will be conducted using additional pre-recorded data from clinical collaborators. A mock flow loop with an EXCOR will be used to investigate clinically relevant EXCOR scenarios in a controlled manner. Finally, the smartphone application will be made available to clinicians for beta testing in the near future.

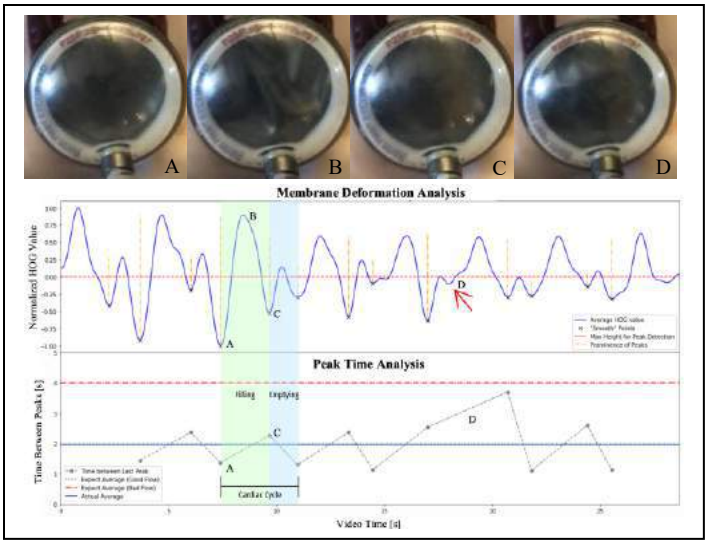

**Figure 4: Membrane Deformation & Peak Time Analysis with Respect to Cardiac Cycle where blue line represents membrane movement: (A) Minimal HOG value representative of a smooth membrane; (B) Maximum HOG value representative of increased membrane deformation; (C) Second smooth point of the cardiac cycle; (D) Point that did not completely smooth indicated by the red arrow and minimal peak prominence representative of abnormal membrane deformation.**

## BUDGET & MARKET ANALYSIS

The current budget is $99. This project is primarily a software based design from which free IDEs such as XCode and JupyterLab are utilized. The sole expense associated with the maintenance of this app is a $99/year fee to keep PHADM on the Apple App Store. Future expenses such as further app development, i.e. hiring of a software engineer, may ensue, however, such expenses won't be relevant until future years. Regardless, PHADM will be sold with a subscription plan from which a hospital will pay a base fee for the software, then an additional fee for each device added the account. Subscription plans will start at $110/year for a single device. An additional $22/year will be charged for each new device added to an account.

# INVESTIGATING THE ROLE OF ASPIRIN ON THE GEOMETRIES AND MECHANICAL PROPERTIES OF EXPERIMENTAL BLOOD CLOTS

**Nolan Corbitt (1), Bryan C. Good (1)**

(1) Mechanical, Aerospace, and Biomedical Engineering
University of Tennessee
Knoxville, TN, USA

## INTRODUCTION

An acute ischemic stroke (AIS) occurs when a blood clot occludes a vessel in the brain, causing a lack of oxygen and nutrients being delivered to downstream regions of the brain [1]. In 2016, the American Heart Association and National Institute of Health reported the stroke mortality rates in patients aged 65 or older to be 271.4 per 100,000 [2]. In many countries, stroke is the second or third largest cause of death, and one of the highest causes of adult disability [3]. One way to treat patients that are at risk for an AIS is to administer medication like aspirin to reduce or prevent clot formation. However, AIS's can still occur in these patients, and it is unclear how their clots may differ from those of untreated patients. The mechanical properties and size of AIS patient clots have also been shown to affect successful recanalization via mechanical thrombectomy. To improve patient outcomes in these procedures, the effects of medication on the geometries and mechanical properties of AIS blood clots should be further investigated to determine how they can be used in combination with thrombectomy devices.

## METHODS

To determine the effects of aspirin on embolus analog (EA) geometries and mechanical properties, two experimental protocols were utilized to create EAs. In both protocols, EAs were created *in situ* from bovine blood collected in CPDA-1 anticoagulated bags (Lampire Biologic). The blood was first centrifuged to separate the red blood cells (RBCs) and platelet rich plasma (PRP). The RBCs were then further centrifuged to separate the platelet poor plasma (PPP) from the RBCs. For all solutions, the blood was reconstituted to a hematocrit of 40%, modeling typical human blood. To add aspirin into the blood, acetylsalicylic acid powder was diluted with a HEPES buffer solution and pH adjusted to 7.4 [4]. To separately investigate the effect of the buffer solution on EA properties, three solutions were used: blood with no buffer or aspirin solution added (H=40), blood incubated with only the buffer solution (HEPES), and blood incubated with the aspirin-buffer solution (ASP).

For the first experimental protocol, the effect of aspiration incubation time was also investigated to determine its role on EAs. Following reconstitution to a 40% hematocrit, the blood was put into one of five groups: 1) H=40 blood, HEPES incubated with blood for 2) 24 and 3) 48 hours, and ASP incubated with blood for 4) 24 and 5) 48 hours. Each solution was recalcified using a 1:25 ratio of $CaCl_2$ to blood, drawn into ¼" diameter PVC tubing, and inserted into a Chandler Loop system (**Fig. 1A**). The tubing was submerged in a water bath at body temperature and was rotated to achieve velocities observed in the carotid artery. After 1-2 hours of clotting, the EAs were removed from the Chandler Loop and their length and mass measured with calipers and a balance, respectively.

**Figure 1: A)** Chandler Loop system used to create EAs and **B)** Instron mechanical tester used for measuring EA mechanical properties.

The second experimental protocol was used to determine the mechanical properties of the EAs. 6-well cell culture plates were filled with the same three blood solutions (H=40, HEPES, or ASP) and allowed to mix for 24 hours on an orbital shaker. The blood was then recalcified at a 1:25 ratio with $CaCl_2$ to blood and mixed on the orbital shaker for another 1-2 hours to coagulate. After coagulation, the EAs were removed, and uniaxial compression testing was performed with a single-column mechanical tester and 50 N load cell (Instron) (**Fig. 1B**). The EAs were cylindrical in shape with thicknesses and diameters of approximately 10 mm and 34 mm, respectively. All EAs were compressed at a rate of 10 mm/min and their stress and strain curves output for further analysis.

## RESULTS

The Chandler loop experimental system led to the formation of consistent cylindrical EAs with 1-2 hours of dynamic clotting. Examples of these EAs can be seen in **Fig. 2**.

**Figure 2:** Examples of ¼" diameter cylindrical EAs taken from Chandler Loop under varying experimental conditions.

EAs formed from whole blood, blood incubated with HEPES, and blood incubated with aspirin were all measured and weighed after their removal from the Chandler loop tubing. Decreases in EA length (**Fig. 3A**) was observed from the HEPES EAs to the ASP EAs for both the 24- and 48-hour incubation groups with average lengths decreasing by approximately 7 and 4 mm, respectively.

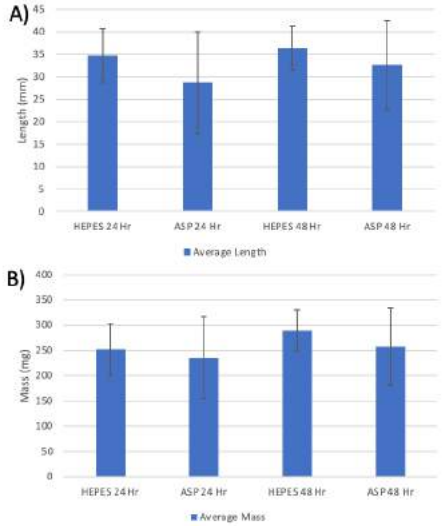

**Figure 3:** Averaged **A)** length and **B)** mass for EAs taken from Chandler loop.

The average EA masses (**Fig. 3B**) followed a similar trend, with the ASP EAs weighing less than the corresponding incubation time HEPES EAs, (decreases of approximately 10 and 30 mg, respectively). While both length and mass parameters decreased from the HEPES to ASP EAs, indicating that the addition of aspirin is playing a role in EA formation, the results were not statistically significant.

The mechanical testing results are shown in **Fig. 4**, and H=40, HEPES, and EA stress values were compared at strains of 10, 20, 30, and 40%. At all strains, there was a large decrease in resultant EA stress in both the HEPES and ASP EAs compared to the H=40 EAs. Additionally, there was a further decrease with the addition of aspirin compared to the EAs with only buffer added. Similar to the EA geometric data, the differences between the HEPES and ASP EA mechanical properties were not statistically significant but clear trends were observed that point to the role of aspirin in modifying the EAs.

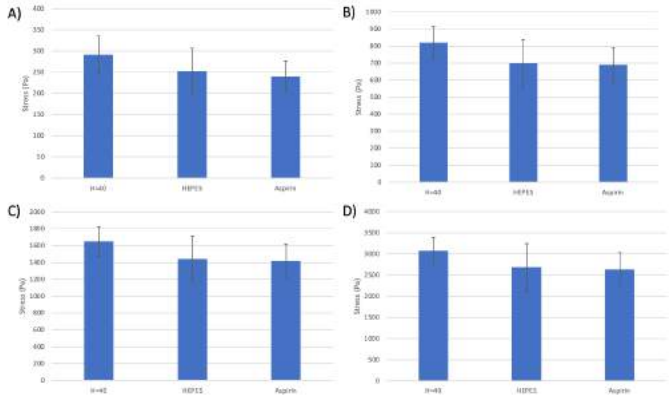

**Figure 4:** Averaged EA stresses at strains of **A)** 10%, **B)** 20%, **C)** 30%, and **D)** 40%.

## DISCUSSION

The trends of decreasing EA length, mass, and stiffness between the HEPES and ASP test groups suggest that the addition of aspirin is playing a role in clotting. This is likely due to the role aspirin plays in lowering platelet activity, causing decreased coagulation. The decrease in EA stiffness upon the addition of the HEPES buffer could be due to the buffer solution diluting the coagulation factors in blood plasma and effecting the EA structure compared to H=40 EAs. These experiment protocols will be applied in future experiments with other therapeutic drugs including blood thinners, like Warfarin, and thrombolytic drugs, like tissue plasminogen activator (tPA). Additionally, one of the risks of any drug that affects the mechanical properties of EAs is that they can soften the EAs too much and cause fragmentation during mechanical thrombectomy and distal embolization. Further experiments will focus on EA failure using a lap-shear test setup on the Instron mechanical tester to determine the role these same therapeutic drugs play.

# SILENT SPEECH INTEFACE FOR AUGMENTED REALITY DEVICES

**Tania Rivas (1), Gianna R. Distefano (2)**

**Faculty Advisor(s)**

**Victor Huayamave, PhD. (1), Cristine Dailey Walck, PhD. (2)**

(1) Mechanical Engineering, Embry Riddle Aeronautical University, Daytona Beach, FL, USA

## INTRODUCTION

Silent speech is defined as communication through biosignals when no acoustic means is outputted or received. Many applications for silent speech interfaces (SSIs) have risen over the years including aiding those with communication and/or movement disorders in multiple areas such as rehabilitation therapy, training for jobs where bulky equipment was previously required and entertainment. The beginning of this project involved using electromyography (EMG) sensors to collect subvocalization data from four neck muscles activated during the speech production process to train and test a 1-dimensional convolutional neural network (CNN) that works as a classifier to categorize the six command words in the current library. This is to eventually be integrated into an augmented reality (AR) device to be controlled solely by subvocalizations. The team explored the unique characteristics of EMG signals from various neck muscles, experimented with post-processing the data filtration and expanded the datasets. While preliminary testing accuracies show promising results, the process of applying the sensors themselves has proven to be cumbersome. Each EMG sensor requires two pieces of double-sided medical grade adhesive and separate positioning of the reference sensor and sensor head. This current method exhausts resources concerning time, finances, and energy from the user. The team posits a hardware design that can house all four sensors simultaneously and override the need for the tape to streamline the sensor application process.

## PRODUCT DESIGN

The hardware design idea is centered on the contour of the reference electrode since ensures only material that is absolutely needed is being used. Initially, a spider like design was envisioned where a main block with four extrusions to hold four flexible conduits to house the EMG sensors would be placed on the side of the neck. This idea was discarded because of the bulky design and inconvenient placement. Eventually, the team decided to house only the reference electrodes and add some type of flexible housing for the wires that would be sturdy enough to hold up the sensor heads as well. It was decided a short wall would surround the sensors as it would offer enough traction around all sides to ensure a safe and sturdy placement and provide a small face to attach the future wiring housing to hold the sensor heads. Two curves were cut through on the back side of the apparatus to maximize the flexibility to best fit the contour of the neck. It was decided the apparatus would be 3D printed out of thermoplastic polyurethane because of its low density, flexibility, affordability, and machinability. The current reference sensor housing, Figure 1, design highlights the goal of finding a balance between maximizing structural flexure by reducing the material used and maintaining structural integrity by lodging the sensors with the aid of friction.

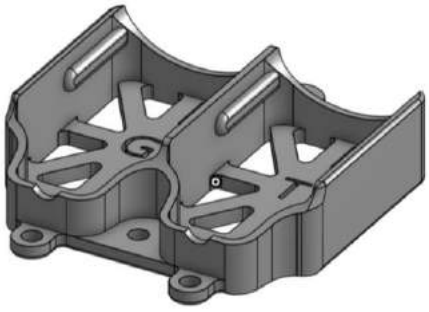

**Figure 1: Complete reference sensor housing CAD.**

The software design of the SSI began with experimenting with sensor placement. The placement selection was determined through an amplitude qualities and characteristic waveform comparison during the speech production process. Sensors with poor signal to noise ratios were excluded as they were considered low quality. A healthy 22-year-old Caucasian male, 20-year-old Hispanic female, 23-year-old Caucasian female, and 18-year-old Caucasian male with no speech impairments in a controlled lab environment were prompted to subvocalize command words from a library of six words: Up, Down, Left, Right, Yes, and No. To ensure high accuracy rates while reducing potential error from differences within individual subvocalizations, the subject was prompted to subvocalize commands forty times. Preliminary subvocalization data was collected using EMG sensors applied to the Digastric, Sternohyoid, Stylohyoid, and Cricothyroid and their respective reference muscles, as seen in Figures 2 and 3. Then, data was filtered to remove environmental noise that could potentially interfere with the recognition model. According to the sensor manufacturer, the EMG electrodes have a bandwidth of 10 – 450 Hz establishing the value of a band-pass filter to remove high and low frequency noise from the

signal at a window of 10 – 400 Hz. Applying the filter allowed the band of frequencies describing the subvocal activity to be isolated. Individual command words were parsed from the EMG signal data and placed into individual training datasets. A one dimensional, seven layered CNN was created with the Keras library in Python. Important characteristics of this model are the two dropout layers integrated to reduce overfit by randomly compensating for small training datasets and reduce the model's dependency on the current training data while simultaneously improving the accuracy of unseen data.

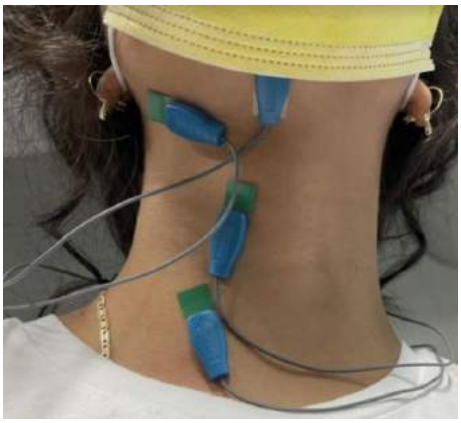

**Figure 2: The EMG sensor heads applied to neck muscles of interest.**

**Figure 3: The EMG reference sensors applied to stationary neck muscles.**

## BUDGET & MARKET ANALYSIS

The American Speech, Language and Hearing Association reports 7.5 million Americans have communication disorders and the University of Michigan's medical department reports another 40 million have movement disorders [1]. Integrating silent speech and AR, creates opportunities for those with disabilities to recover ranges of motion, expand their career choices and even immerse themselves into dynamic entertainment. By easing the process of sensor application, constraints for those opportunities minimize even further.

Potential market size initially would be kept to the 38,800 clinics in America providing physical, occupational and speech therapy. They have an average annual receipt (per clinic) of $886,000 and have a 14.6% net profit gain [2]. Included in the price of the product would be the Delsys EMG sensors themselves, the price of the 3D printed sensor housing, the soldering wire, as well as overhead costs. The design budget $4,007.73. Expected manufacturing/testing/overhead, including engineering and tooling price of the sensors, cost comes out to $1,162.73, and the product would be sold for $3,463.00 resulting in a profit of $2,208.00. Below in Figure 3 the budget breakdown, without the price of the sensors and licenses, can be seen. Since wire and 3D printing are low in price the shoelaces used to tie the apparatus together is taking up the majority of the budget.

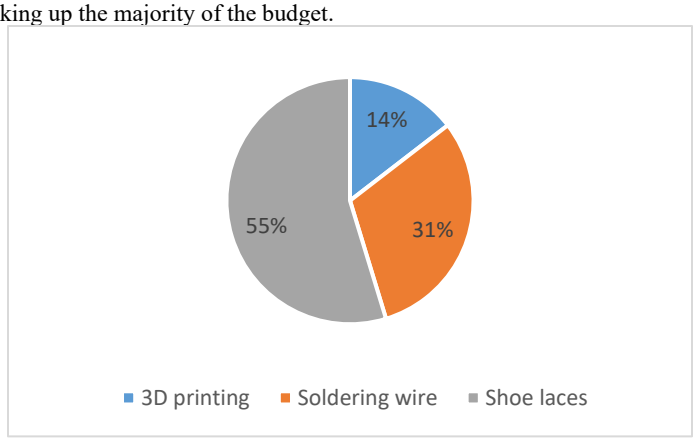

**Figure 3: Budget Breakdown by Percentages (sensor prices excluded)**

## INTRODUCTION

Lower urinary tract symptoms (LUTS) are costly and contribute to lower urinary tract dysfunction [1]. The investigation of biomechanics during voiding, with respect to the urethra, may provide some insight into the function of the LUT. Current diagnostic methodologies, such as cystoscopy, retrograde urethrography, and multichannel urodynamics with fluoroscopic imaging, are invasive and limited in the information they provide [2, 3]. In contrast, magnetic resonance imaging (MRI) can provide anatomical and functional information of the LUT as shown in previous studies [4, 5] in a non-invasive manner. Building upon those previous studies, we examine the potential for MRI to deliver a non-invasive methodology to acquire anatomical and biomechanical information of the urethra throughout the voiding process.

## METHODS

This study was HIPAA-compliant, IRB approved, and was performed after informed consent. All scans were completed on a clinical MRI 3T scanner (Premier, GE Healthcare, Waukesha, WI), with a high-density flexible surface coil array. (AIR Coil, GE Healthcare). Four healthy adult males ages 29, 55, 62, 74 were recruited for this study. The subjects were instructed to drink copious amounts of fluids before testing and to not void prior to the study. 15 minutes prior to the MRI scans, 1/3 of a single weight-based dose (0.1 mmol/kg) of gadolinium-based contrast was hand injected intravenously into each subject to enhance the visualization of urethral change during the voiding process. Subjects were equipped with a condom catheter and instructed to void whilst in the MRI scanner. A dynamic acquisition was performed using 3D Differential Subsampling with Cartesian Ordering (DISCO) Flex, with a temporal resolution of 3.7 seconds. After urination, the subjects were given the remaining 2/3 of the contrast. A static acquisition was then performed using a fast-spin echo T2-weighted axial sequence with an in-plane resolution of .625mm, to get anatomical reference images of the prostate.

The resulting images were imported into Mimics (Materialise, Leuven, Belgium). At each point of the dynamic imaging, the internal and external urethral sphincter (IUS, EUS) diameters, urethral length, prostatic urethral angles were measured, while the prostatic, membranous, and penile urethra were segmented (Figure 1a). Using these segmentations, 3D renderings of the urethra were calculated (Figure 1b) at each point of the dynamic imaging.

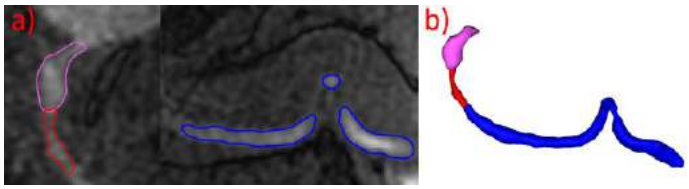

**Figure 1: a) Segmentation of the prostatic (purple), membranous (red), and penile (blue) urethras. b) 3D renderings of those segmentations**

Using the centerline tool, centerlines were created for each urethral segment at each time point during the voiding event, and the corresponding average best-fitted diameter were calculated. From the 3-D rendering, the urethral volumes were also calculated. The prostate volume was determined by creating 3D renderings using segmentations from the anatomical reference images.

From an affiliated study done by this lab, voided volume, and flow rates of urine from the bladder into the urethra were calculated and used in this study. The IUS and EUS diameters were correlated with these flow rates, and an $R^2$ were calculated.

## RESULTS

This novel MRI-based technique was successfully implemented to characterize the anatomy and biomechanics of the urethra during voiding. The anatomical dimensions of the prostate and urethra at listed in Table 1.

**Table 1: Observed dimensions of the prostate and urethra.**

| | PV (cc) | Largest Urethral length (cm) | Largest Urethral Volume (cc) | Post-void urethral residual (cc) |
|---|---|---|---|---|
| Subject 1 | 22.4 | 23.5 | 13.2 | 0.18 |
| Subject 2 | 36.2 | 22.6 | 19.1 | 12.6 |
| Subject 3 | 49.4 | 22.2 | 11.1 | 0 |
| Subject 4 | 16.6 | 23.2 | 13.2 | 4.85 |

The average IUS across the voiding process was significantly larger than the average EUS ($p < 0.05$) for all four subjects.

As displayed in Figure 2, the EUS correlated with flow rate ($R^2$ = 0.8 - 0.91), while the IUS showed no correlation ($R^2$ = 0.03 - 0.3).

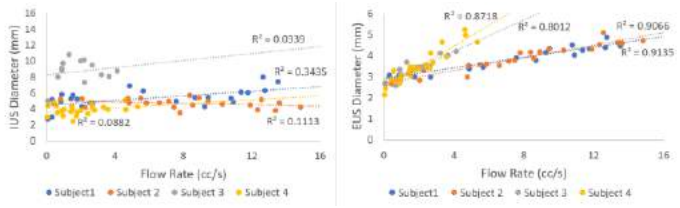

**Figure 2: IUS and EUS diameter over flow rate with each respective $R^2$ value.**

The biomechanical changes of the membranous urethra showed to be consistently smaller than both the Prostatic and Penile across the voiding cycle, as shown in Figure 3.

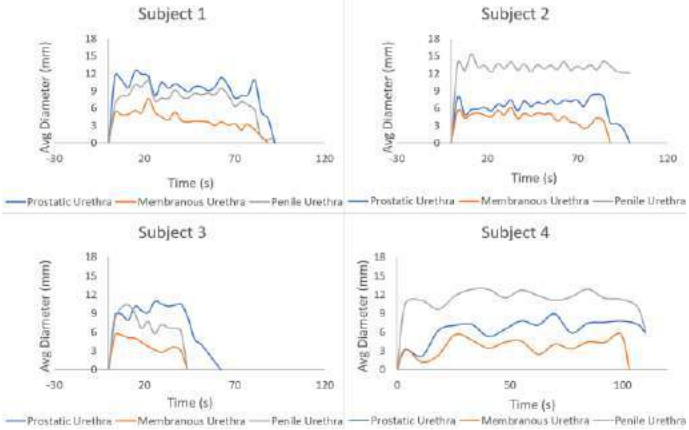

**Figure 3: Average diameter of prostatic (blue), membranous (orange), and penile (grey) urethra during the voiding process.**

During the resting phase, the subjects displayed average prostatic angle of 41.1 degrees. During voiding the prostatic urethra straightened by 19.1 degrees.

## DISCUSSION

Prior studies have signaled that the LUT and urological diseases create anatomical changes in the body [6, 7]. Current methodologies to medically examine these anatomical changes in the urethra is to invasively instill fluid into the urethra to get comprehensive imaging [8]. Such methodologies inhibited researchers from collecting information about the biomechanical function of the urethra during the voiding process. However, advancements in dynamic MRI can be used to inspect the LUT during the voiding process. In this MRI based study, we introduce a novel technique for the non-invasive quantitative and qualitative analysis of urethral anatomy and biomechanics during the voiding process.

MRI is a noninvasive imaging tool used primarily to analyze soft tissue, much like that found in the LUT. With this novel technique we can image the urethra throughout the duration of the voiding process at a variety of urethral capacities. This unique ability enables for the investigation of urethral dynamics at various stages and for those dynamics to be compared for the duration of the voiding process. Thus, providing a level of information detail, unique to this technique.

In this study, we obtain measurements of urethral length, prostatic urethral angle, IUS and EUS diameter, and region-specific diameter (Prostatic, Membranous, Penile). The EUS diameter showed a strong positive correlation with flow rate for all 4 subjects. The IUS diameter, however, showed no correlation to the flow rate. This difference in trends of the EUS indicate that the EUS plays a large active role in determining flow rate when compared to IUS**.** The prostatic urethral angles straightened during voiding suggesting a potential tactic to decrease resistance.

As observed in our study, our technique can be applied to a wide variety of subjects with diverse physiological and anatomical differences. For instance, subject 3 and 4 voided 91.23 and 186.83, respectively. Despite these, comparatively low voids we were still able to obtain an in depth quantitative and qualitative analysis of their urethral anatomy and biomechanical function during the voiding process. Such analysis could be used to investigate voiding disfunction and signs for urological diseases. Furthermore, it is also clear that the data obtained yields varied information from subject to subject. This suggests that the technique can discern between anatomical and physiological diversity and reflect this diversity in the data produced. The technique's ability to differentiate between diverse voiding processes, introduces a significant amount of specificity in the observed results, which can be utilized to quickly gage the extent to which a subjects anatomical and biomechanical characteristics deviate from the norm.

In summary, the new methodology presented here, which uses MR imaging to obtain quantitative and qualitive data about the LUT can give specific and varied informational about anatomy and biomechanics during the voiding process in a safe, accurate and reproducible way. Further investigations into this technique will focus on establishing a healthy baseline for the biomechanics of LUT. This information can then be compared with patients with conditions involving LUTS and lead to earlier diagnosis and more specific treatment which is informed directly by their anatomical and biomechanical characteristics.

# OPTIMIZATION OF ECM/GELATIN SOLUTION IN A NEAR FIELD ELECTROSPINNING SYSTEM FOR ENGINEERING TENDON

**Aasim F. Hussain (1), Zachary G. Davis (1,3), Matthew B. Fisher (1,2,3)**

(1) Department of Biomedical Engineering, University of North Carolina-Chapel Hill and North Carolina State University, Raleigh, NC, USA

## INTRODUCTION

Tendon injuries are one of the most pervasive injuries and a leading cause of mobility issues with tendons involved in ~50% of musculoskeletal injuries [1]. Yet, the full complexity of the injury and subsequent healing is not well understood, including cell-matrix interactions in these processes. To understand such interactions, three-dimensional (3D) *in vitro* models such as fibrous scaffolds have grown in use, as an alternative to animal models. More recently, electrospinning has grown as a technique for creating fibrous scaffolds that mimic the structural nature of the extracellular matrix (ECM) [2]. Electrospinning, through the manipulation of an electric field and a fine nozzle, actively converts polymer solutions into a random sheet of nanofibers, however, individual fiber control is limited [2]. The overall orientation and alignment are essential in creating a scaffold as it greatly influences the efficacy of cells on the scaffold in terms of function and growth [1,2]. 3D additive manufacturing methods, such as fused deposition modeling can be used to create singular fibers, however, the size of the fibers range in the 100-400 µm range whereas collagen fibers are in the range of 1-20 µm. Direct-write, near-field electrospinning (DWNFE) is a computer-guided, single fiber deposition method for creating 3-D structures on a collagen fiber scale. DWNFE, though more widely known for its use within synthetic polymers, more recently has shown promise with natural polymers such as collagen and gelatin [2]. DWFNE can produce fibers that can match natural collagen size and allow for fine fiber orientation, allowing control of specific aspects of tendon behavior within engineered tissues in vitro [2].

Gelatin is a natural, biodegradable, and biocompatible polymer that is obtained from the partial hydrolysis of collagen [3,4]. Gelatin is known to be a more cost-effective alternative to collagen. Compared to synthetic polymers, gelatin can provide a better environment for cell attachment, growth, and proliferation. Previous work in the lab showed success with the use of a gelatin-acetic acid solution within a DWNFE system whilst being able to control fiber morphology and fiber diameter [2]. Further incorporation of ECMs into this system will allow for more tissue-specific bioactivity and specific proteins that can impact cell behavior. Currently, the use of ECM in DWNFE systems is limited, though its use within bioinks illustrates the feasibility of ECM-based solutions in fabricating constructs with the beneficial, bioactive nature needed to elicit a more innate response. Objective**:** To demonstrate the feasibility of using gelatin-acetic acid solution as a carrier for decellularized tendon extracellular matrix (dECM) within the DWNFE process.

## METHODS

Equine superficial digital flexor tendon was obtained from 3 specimens and decellularized, digested, neutralized, and powdered following *Wolf et al* (Figure 1) [5]. To determine the optimal ratio of dECM to gelatin, 625 mg/mL dECM/gelatin solute concentration solutions in 70 v/v% acetic acid were mixed at 0%, 10%, 15%, and 25% dECM. Solutions were mixed for 2 days at 40°C. Afterward, the solutions were stored at 4°C. As viscosity has a direct impact on fiber diameter and fiber morphology for electrospinning, solution viscosities, and shear stress were measured with a rheometer over a two-ramp sweep across a shear rate of 0.1 to 1000 (1/s). Each of the groups was printed using a custom DWNFE system following the protocol established in Davis et al [2]. The fibers were then printed in crosshatches with a length of 10 mm and a width of 30 mm. The pressure was set to 0.1 psi, stage speed of 75 mm/s, spacing of 0.5 mm for both horizontal and vertical fibers, a working distance of 1.0 mm, and an accelerating voltage was set at 3 kV with an ambient humidity of 50-55%. The values for the DWNFE were designated by a custom MATLAB script and were converted to GCODE for printer recognition following previous work in the lab [2]. Fibers were printed onto a noncharged glass microscope slide with a blunt 22 G metal needle. An n=3 solution was made for each concentration, and n=10 scaffolds were fabricated for each solution. To qualify the presence of collagen and glycosaminoglycans (GAGs) for the 25% dECM solution, picrosirius red and alcian blue stains were used to determine the presence of collagen and GAGs respectively, after crosslinking with 10:1 1-ethyl-3-

(3-dimethyl aminopropyl) carbodiimide (EDC)/N-hydroxysuccinimide (NHS) for 24 hours.

Brightfield imaging was used to measure fiber diameter and an inverted microscope was used to visualize staining. Fiber diameters were derived with ImageJ. Outliers were removed for scaffolds with the ROUT method and a Q=1%. A Mann-Whitney t-test was used to compare each dECM to the 0% dECM control (α=0.05).

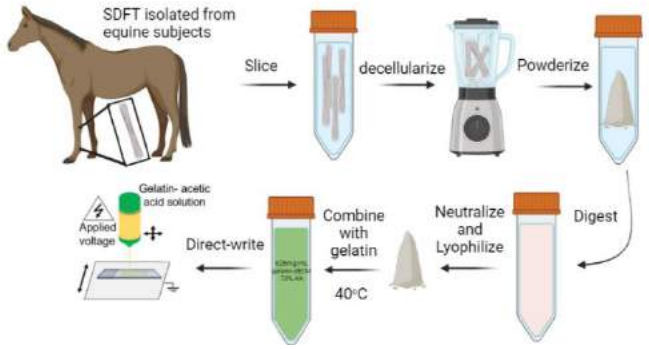

**Figure 1: Schematic for DWNFE dECM/gelatin solution preparation**

## RESULTS

The dECM/gelatin hybrid solutions were successfully produced with a total concentration of 625 mg/mL and varied dECM concentrations from 0 to 25 w/w%. The mean viscosity for the 0, 10, 15, and 25% dECM was 13.8, 17.7, 8.0, and 22.8 Pa*s respectively (Figure 2).

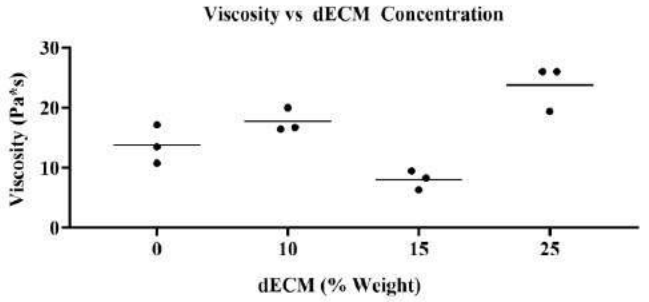

**Figure 2: Average viscosity of the 0, 10, 15, and 25 percent dECM over linear region for shear rates 0.1-100 [1/s]. Dots represent individual solution viscosity. Bars represent mean viscosity with dots representing solution viscosities**

The median fiber diameters for 0, 10, 15, and 25% were 3.0, 3.9, 3.1, and 6.0 µm with an interquartile range (IQR) of 2.5-3.5, 2.4-7.4, 2.5-3.9, and 4.0-10.4 µm respectively (Figure 3B). The Mann-Whitney t-tests showed statistically significant differences from each group to the 0% dECM (Figure 3B). However, the lowest difference was seen by the 15% dECM in comparison to the 0% with a mean difference of 0.3±1.1 µm whilst the 10% and 25% showed a mean difference of 2.2±3.4 and 4.9±4.9 µm respectively (Figure 3C). Picrosirius red and Alcian blue stains showed the presence of collagen and GAGs in the ECM fibers (Figure 4).

## DISCUSSION

We successfully produced tendon ECM that can be incorporated with gelatin and successfully direct-written with fibers similar to gelatin only fibers in diameter and morphology. Davis et al found median fiber diameter for gelatin only fibers to be 2.3 µm with an IQR of 1.7-3.0 µm [2]. The fibers presented here are slightly larger, even for the similar 0%

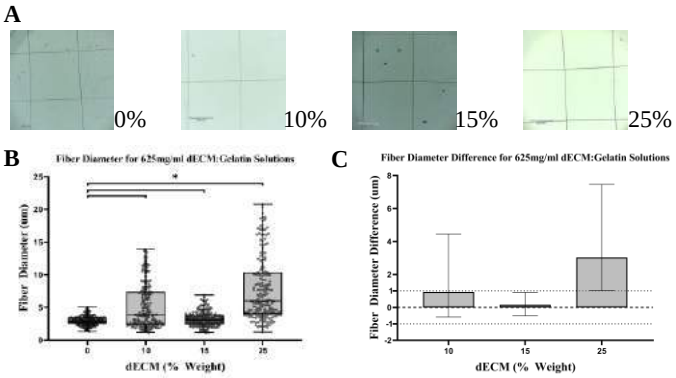

**Figure 3: Impact of dECM on DWNFE fibers. (A) Representative scaffold images for the dECM groups [Scale bar: 220 um]. (B) DWNFE fiber diameters with 20 fibers from 10 scaffolds for each concentration of dECM. (C) Fiber diameter difference to 0% dECM. Bar graph represents normalized median with interquartile range.**

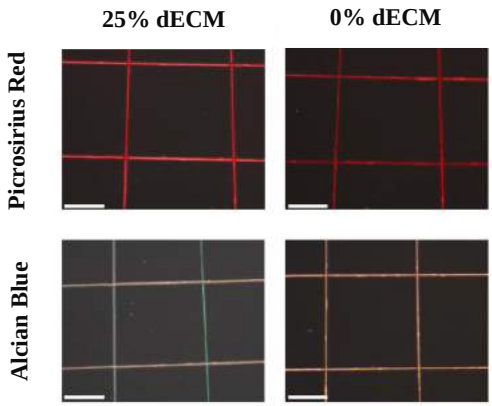

**Figure 4: DWNFE fibers written with 25 and 0% dECM with picrosirious red or alcian blue stain [Scale bar: 110 µm]**

dECM fibers with a median fiber diameter of 3.0 µm. This difference could be due to slightly altered ambient humidity [2]. Fiber diameter for the 0% and 15% dECM showed the highest similarity with a mean difference of 0.3±1.1 µm, though statistically different. Picrosirius red illustrated collagen networks being retained in both scaffolds. Alcian blue illustrated GAGs in the 25% dECM, showing retention of dECM content. Additional concentrations of dECM needs to be examined across multiple scaffolds to establish the repeatability of the approach. We also need to further analyze the protein content of the dECM/gelatin fibers to better understand what components of the ECM are retained, and a cell study is needed to investigate how the addition of the dECM impacts cell behavior. This process shows the validity of a new technique for fabricating scaffolds for applications like tissue-on-a-chip models.

# SIXTH SENSE – A HANDS FREE AND HAPTIC FEEDBACK NAVIGATION TOOL FOR THE VISUALLY IMPAIRED

**Alyssa N. Taylor (1), Joseph H. Lahmann (1)**

**Faculty Advisor(s)**

**J. Miles Canino (1)**

(1) Department of Mechanical Engineering, Rose-Hulman Institute of Technology, Terre Haute, IN, USA

## INTRODUCTION

According to the Center for Disease Control and Prevention (CDC) approximately 12 million people 40 years and older in the United States suffer from visual impairment [1]. A 2018 survey conducted by the National Health Interview Survey (NHIS) found that 994,000 people above the age of 18 admitted being legally blind. Legal blindness is defined as corrected eyesight no better than 20/200 for either eye or a restricted field of vision of less than 20 degrees wide [5]. Only 2 to 8% of the visually impaired population utilize the common white cane, with the majority relying on guide dogs or sighted guides [3].

While white cane and guide dogs are the most common visual impairment aids, Electronic Travel Aides (ETAs) have been adopted by very few visually impaired individuals. ETAs are largely avoided due to impracticality of use, specifically the need for the user to repetitively scan the environment manually [2], low reliability, and little feedback [4]. We believe our design addresses these drawbacks and creates a compelling ETA that intuitively addresses the needs of the visually impaired population.

## PRODUCT DESIGN

The Sixth Sense device is a hands-free haptic-feedback device that has two main components: a sensor module designed to be clipped to pants at the waist and a haptic feedback belt that is worn in direct-skin contact of the torso. The current prototype consists of a 3rd housing for the motor control unit, though this will be consolidated in subsequent designs. Figure 1 depicts all 3 modules of the current prototype.

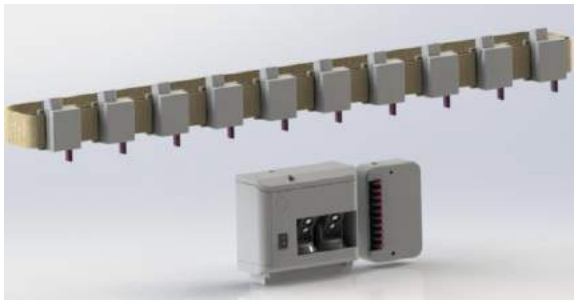

**Figure 1: Complete scanning housing and secondary housing for motor driver with haptic feedback belt.**

The main sensor module consists of two LIDAR sensors that continually scan the environment in front of the user. They are geared together on rotating spindles, driven by a servo. This housing also features a power switch, internal battery bank, and removable top panel, allowing access to the internal components. Figure 2 shows the internals of the main sensor module.

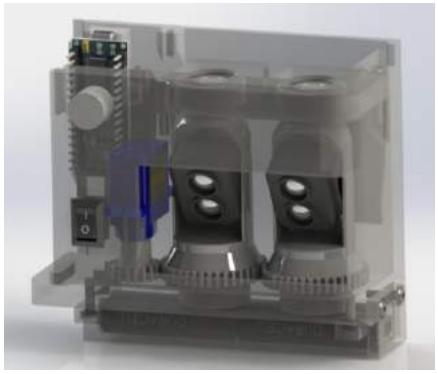

**Figure 2: Main housing for the lidar scanners and microcontroller.**

The haptic feedback belt consists of an array of 10 micro high torque DC motors. Each of these motors has a small, ribbed rubberized end effector that contacts the skin, as shown in Figure 3.

**Figure 3: Sensory feedback belt units with rubberized end effectors.**

This motor-skin interfacing imparts a gentle shear force on the skin, allowing for enhanced perception compared to traditional vibratory feedback. The magnitude and location of this skin-shear effect can be directly correlated to the proximity of adjacent objects, allowing for an intuitive and immersive perception of an individual's surroundings. The belt holding the motors is built with easy donning, doffing, and adjustment in mind. The belt features a robust parachute-buckle clasping mechanism and easily adjustable strap lengths for holding the belt, and motors, firmly against the user's torso. The main sensor module and motor control unit can be easily clipped onto the user's pants or affixed to a lanyard system if pants are not worn.

At startup, the device calibrates to the height of the user. The LIDAR sensors continually scan the environment in a sweeping motion, translating the surroundings to the motors in the belt. The initial prototype refreshes at an average frequency of ~2.5 Hz.

## BUDGET & MARKET ANALYSIS

Our team has prototyped this project as a self-funded endeavor. Table 1 details the major costs associated with this prototype and anticipated costs of a final production model.

**Table 1: The cost of primary components of our current prototype.**

| Component | Qt | USD/ Unit | Total | Production USD/Unit | Production Total |
|---|---|---|---|---|---|
| Elegoo Nano | 1 | 6.60 | 6.60 | 0.25 | 0.25 |
| Tf-Luna Lidar Sensor | 2 | 24.50 | 49.00 | 16.50 | 33.00 |
| PCA9685 16 Channel PWM/Servo Driver | 1 | 14.95 | 14.95 | 3.60 | 3.60 |
| 608RS Bearing | 4 | 0.66 | 2.64 | 0.03 | 0.12 |
| 9161C Micro Planetary Reducer DC Motor | 10 | 1.78 | 17.80 | 0.75 | 7.50 |
| IRLZ34N MOSFET | 10 | 0.50 | 5.00 | 0.15 | 1.50 |
| 5V DC Buzzer | 1 | 0.95 | 0.95 | 0.12 | 0.12 |
| 9g Micro Servo | 1 | 2.50 | 2.50 | 1.00 | 1.00 |
| Diodes x10 | 1 | 2.10 | 2.10 | 0.07 | 0.07 |
| Resistors x10 | 1 | 0.60 | 0.60 | 0.04 | 0.04 |
| Misc* | - | - | 20.00 | - | 20.00 |
| **TOTAL** | **-** | **-** | **$122** | **-** | **$67.20** |

* Includes plastics for housing, wires, heat shrink wrap.

As seen in Table 1, it is anticipated that the production model will cost less than 50% of the prototype. Components purchased in bulk, coupled with mass-manufacturing techniques, would reduce the manufacturing cost to around 60 USD. With a conservative profit in mind, we anticipate an MSRP of around $140 before any regulatory costs. Section 201(h) of the Food, Drug and Cosmetic Act appears to indicate that our product could be considered a medical device [6], and as such could be subject to regulatory costs that increase the price. The only item of note that could be a safety concern are the LIDAR modules, which are classified as Class 1 lasers. However, this classification is considered non-hazardous and does not require even a warning label [7]. Because our device is low risk, promotes mobility and reduces the impact of a chronic condition, we believe our device would constitute a General Wellness Product and thus not be actively regulated by the FDA [8].

Table 2 details the cost of other mobility aides in comparison to the projected cost of our proposed device.

**Table 2: The cost of other assistive solutions and products for the visually impaired.**

| Assistive Solution | Description/Notes | Cost (USD) |
|---|---|---|
| White Cane | - | $20-$60 |
| Buzzclip | A small ultrasonic sensor and buzzer that alerts the user to nearby obstacles. | $250 |
| Mini Guide | A hand-held ultrasonic sensor that correlates vibratory feedback to distance. | $500 |
| Guide Dogs | Training costs are $40,000-$60,000 and require a huge number of volunteers and donations. | Free |
| Sixth Sense | Projected costs | ~$140 |

Our device provides numerous advantages at a projected widely affordable price point. It is unique and competitive against traditional mobility solutions in its hands-free application, quality of feedback provided and discretion. It will also outperform other market ETAs due to its usage of LIDAR sensors which boast a higher resolution and reliability when compared to widely used ultrasonic sensors. Ultimately we believe our device is potentially a feasible and valuable mobility tool for the visually impaired to live with minimal impact from their disability.

Hershey, PA, USA

## INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death for men and women in the United States. The significant number of individuals suffering from CVD has created a clinical need for mechanical blood pumps that have provided numerous benefits and life-saving solutions to patients. Despite these advantages, however, their function is burdened by thromboembolic complications due to the non-physiologic blood flow induced by the device geometry. The design of the device can create instability and stagnation in blood flow, leading to mechanical activation of platelets and thrombus formation [1]. Anticoagulation therapies can reduce the occurrence of clotting; however, such treatment can be complex and increase hemorrhagic risk [2]. The prevalence of blood clotting has driven research focused on blood damage and chronic platelet activation occurring in devices. Platelet activation is an important step in coagulation and thrombus formation and can therefore be measured and used to study device-induced thrombosis [2].

This study modeled platelet activation in blood pumping devices with the use of a rotating cylinder system. The purpose of this study was to investigate platelet activation upon exposure to high and low shear stress conditions induced by a rotating cylinder system. The findings from this study provide insight into platelet activation upon exposure to shear stress, independent of plasma protein activation agonists for the optimization of device design to minimize mechanical platelet activation and reduce the occurrence of thrombosis.

## METHODS

Investigation of the specific effects of flow-induced stress on platelet activity was studied using human blood obtained from healthy volunteers at the Pennsylvania State University Noll Laboratories in accordance with the Penn State Institutional Review Board. The developed protocol involved centrifugation of whole blood to obtain platelet-rich plasma (PRP). The PRP was then filtered on a Sepharose-2B gel column to purify the platelets from plasma proteins. Gel-filtered platelets (GFP) eluted from the column and were collected into Tyrode's buffer. Filtration of the platelets allowed for the study of platelet activation specific to flow-induced stress and independent from plasma proteins in the coagulation cascade. Platelet counts were recorded in this study using a hemocytometer, and the GFP samples were fixed to a standard concentration of 10,000 platelets/µl.

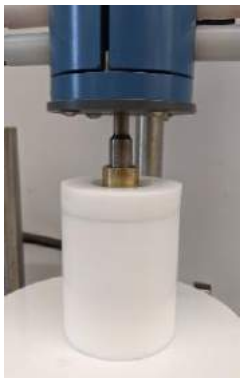

Figure 1. Cylindrical rheometer used to stress GFP.

A cylindrical rheometer consisting of a 2.4-cm diameter titanium cylinder submerged in a cylindrical vessel (depicted in Figure 1) was used to simulate the dynamic flow conditions platelets are exposed to in blood pumping devices. The GFP were subjected to constant low and high shear stress conditions at 60 rpm with a Reynolds number of 900, and 4000 rpm with a Reynolds number of 5000, respectively. The average shear stress across the gap in the 60-rpm case was 0.06 dyne/cm$^2$, while the 4000-rpm case had an average shear stress of 50 dyne/cm$^2$. The GFP were contained in a vessel for the duration of cylindrical rotation. A vessel with a 1.2 cm gap was used to stress the GFP at 60 rpm, and a vessel with a 1 mm gap was used to stress the GFP at 4000 rpm.

Experiments were run for 30 minutes, and a GFP sample was collected from the vessel every five minutes during rotation to measure platelet activation. Platelet activation was measured using a BD LSR-Fortessa Flow Cytometer. The activation of the whole blood samples, PRP, and GFP were measured throughout the protocol to ensure the protocol was conducted with low levels of platelet activation at each step. Initial low levels of activation were necessary to accurately

simulate physiological blood conditions and measure the impact of shear stress on platelet activation. Each of the samples were stained to measure expression of CD62P (for activation) and CD61 (to identify platelets) to be analyzed for activation using flow cytometry. Adenosine diphosphate (ADP) was used as an activation positive control for the whole blood and GFP samples.

Platelet aggregation was also measured using flow cytometry to determine the level of aggregation in the GFP exposed to high shear stress conditions. Half of the GFP sample was stained with CD61 antigen conjugated with PE and the remaining half was stained with CD61 antigen conjugated with APC. Platelet aggregates were then quantified as flow cytometer events that expressed both PE and APC.

## RESULTS

Samples of the whole blood, PRP obtained from centrifugation of the whole blood, and GFP after elution from the gel column were collected, stained, and measured for activation during the protocol. Activation of samples from a total of 13 experiments was measured and analyzed, and the average activation and standard error of the mean (SEM) for the samples are summarized in Table 1. Both whole blood and ADP are also reported with positive controls. The activation levels in the GFP are depicted for both the low-stress and high-stress conditions over time in Figure 2.

**Table 1. Average platelet activation of collected samples**

| Sample | Average Activation (%) ± SEM |
|---|---|
| Whole blood | 2.54 ± 1.43 |
| Whole blood + ADP | 37.86 ± 6.03 |
| PRP | 1.40 ± 0.31 |
| GFP | 2.53 ± 1.00 |
| GFP + ADP | 39.69 ± 6.30 |

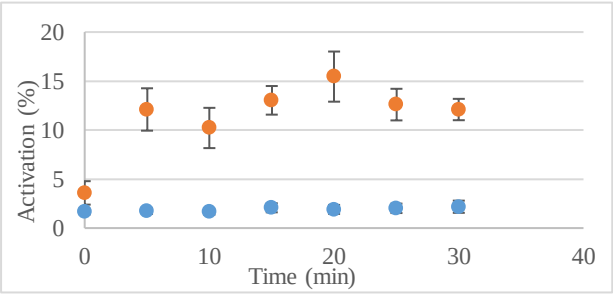

**Figure 2**. Average gel-filtered platelet activation at high (4000 rpm) and low (60 rpm) shear stress conditions. The error bars represent standard error of the mean.

Aggregation was measured for the GFP samples exposed to 4000 rpm in the rotating cylinder system. Aggregation was also measured in the GFP and ADP-stimulated GFP samples. Aggregation levels are reported in Table 2.

**Table 2. Average platelet aggregation at 4000 rpm.**

| | Sample | Average aggregation (%) |
|---|---|---|
| | GFP | 23.79 |
| | GFP + ADP | 24.90 |
| **4000 rpm** | t=0 | 16.58 |
| | t=5 | 18.53 |
| | t=10 | 18.54 |
| | t=15 | 18.03 |
| | t=20 | 17.27 |
| | t=25 | 14.03 |
| | t=30 | 12.54 |

## DISCUSSION

Low levels of activation in the whole blood and PRP were successfully maintained throughout the protocol, with an average percent activation of 2.54% and 1.40%, respectively. Recording platelet activation at various steps throughout the protocol ensured the gel-filtered platelets could be tested in the rotating cylinder without any previous activation or stress exposure. The average GFP activation at 4000 rpm at zero minutes (t=0) was 3.59%. After five minutes of rotation (t=5), platelet activation significantly increased to 12.10%. Significance was determined between t=0 and t=5 using a two-tailed t-test with a 95% confidence interval and an alpha value of 0.05. The initial exposure to flow stress modified the motion, collision, and contact of the platelets, resulting in a statistically significant increase in activation [3]. There was no significant increase in activation from t=5 through t=30. The flow conditions simulated at 4000 rpm exposed the GFP to turbulence similar to conditions induced by recirculating devices.

Data at 60 rpm showed no significant increase in activation throughout the 30 minutes of stress exposure, which suggests the platelets were not exposed to a high enough level of stress to induce activation [3].

The results of this experiment are in line with those of *Soares et al.* [4]. Researchers used a hemodynamic shearing device (HSD), a cone-and-plate rheometer, to induce platelet activation. Platelets were exposed to varying levels of constant shear stress ranging from 1 to 70 dyn/cm$^2$ for two minutes, followed by an extended period of low shear stress. The results showed that levels of shear stress similar to those in the 4000 rpm case (50 dyn/cm$^2$) were associated with increased levels of platelet activation within the first two minutes, while low stress levels showed little to no activation over time. Although a different geometry was used in this study, the results of *Soares et al.* [4] show similar trends to those depicted in Figure 2 with an increase in activation occurring upon initial exposure to high shear stress.

Supported by the results in Figure 2, exposure to high levels of shear stress can lead to mechanical activation of platelets. Upon activation, platelets form aggregates as part of the coagulation cascade leading to thrombus formation. Aggregation was measured for the GFP samples exposed to 4000 rpm in the rotating cylinder system and no significant increase in levels of aggregation were found, as reported in Table 2. Previous studies have found that platelet aggregation occurrs in response to stress exposure and activation only with platelet counts of approximately 200,000 platelets/µl, much higher than the levels in the current study [5].

The findings from this study provide insight into platelet activation upon exposure to shear stress, independent of plasma protein activation agonists. The results from this study can be incorporated into a computational model to optimize the geometry and flow patterns induced by blood recirculating devices with the goal of decreasing thrombogenic events.

## INTRODUCTION

Of the 6.2 million Americans currently living with Alzheimer's disease (AD), an estimated 37% have type 2 diabetes mellitus (T2DM) [1]. The increased AD incidence in patients with T2DM may relate to hyperglycemia, a common pathological feature of T2DM [2]. Human studies have shown acute hyperglycemia leads to increased brain glucose uptake [3], while long-term hyperglycemia leads to decreased brain glucose uptake. Hyperglycemic nonobese diabetic mice also decreased expression of the predominant glucose transporter in the brain, GLUT1 [4]. Thus, chronic hyperglycemia may result in downstream brain glucose hypometabolism [5]. A decrease in glucose metabolism in the brain leads to cognitive impairment and is a marker of AD [6]. Brain microvascular endothelial cells (BMEC) line blood vessels in the brain and form the blood-brain barrier (BBB), which tightly regulates glucose influx into the brain. However, little is known about BMEC glucose transport in hyperglycemia, and its specific contribution to AD development and progression.

BMECs derived from induced pluripotent stem cells (iPSCs) provide a powerful tool to study neurodegenerative diseases such as AD *in vitro* [7]. In this study, we investigated glucose and lactate metabolism using a BMEC Transwell model in normal and high glucose conditions. We hypothesized that acute hyperglycemia will increase iPSC-derived BMEC glucose uptake and transport, while chronic hyperglycemia will decrease iPSC-derived BMEC glucose uptake and transport. These data could contribute to our understanding of how hyperglycemia in T2DM increases the risk of AD.

## METHODS

**Cell culture:** Human IMR90 iPSCs were differentiated into BMECs (hiBMECs) following previously established protocols [7]. Briefly, iPSCs were cultured in TeSR-E6 basal medium for 4 days, with a daily medium change. On day 4, the medium was changed to human endothelial serum free medium (heSFM) with 0.1% retinoic acid (RA), 0.01% basic fibroblast growth factor (bFGF), 0.25% GlutaMAX, and 2% B27 supplement. On day 6, hiBMECs were subcultured onto Transwell filters (0.4 µm pore) coated with collagen IV and fibronectin for metabolite concentration quantification, or hiBMECs were subcultured onto a 96-well Agilent Seahorse XF Cell Culture Microplate coated with collagen IV and fibronectin for the Seahorse XF Cell Mito Stress Test. hiBMECs were compared to primary human BMECs (hpBMECs), which were cultured in microvascular endothelial cell growth medium until confluent and then subcultured onto Transwell filters (0.4 µm pore) coated with collagen IV and fibronectin.

**Metabolic Analysis:** 24 hours after subculture onto Transwells, BMECs were washed with PBS and given Dulbecco's Modified Eagle Medium containing 4.5 mM glutamine, 2% B27 supplement, and either 5.5 mM glucose (NG) in both the top and bottom Tranwell compartments or 25 mM glucose (HG) in the top compartment and 5.5 mM glucose with 19.5 mM mannitol (osmotic control) in the bottom compartment. 200 µl media samples were then taken from the top and bottom Transwell compartments at 0- and 24- hours. Medium glucose and lactate concentrations were measured using a YSI 2950 Bioanalyzer. A Seahorse XF Cell Mito Stress Test was conducted through the addition of oligomycin (1.5 µM), carbonyl cyanide-4 (trifluoromethoxy) phenylhydrazone (FCCP; 0.5 µM), and rotenone/antimycin A (0.5 µM). Oligomycin inhibits ATP synthetase, FCCP ends the inhibition of electron flow in the electron transport chain to maximize oxygen consumption, and rotenone/antimycin A shuts down mitochondrial respiration. Extracellular acidification rate (ECAR), which relates to glycolysis, was measured. Cells in the Seahorse assay were treated in DMEM containing 4.5 mM glutamine, 1 mM pyruvate, and either 5 mM glucose or 25 mM glucose.

**Statistical Analysis:** Data were analyzed using a Mann-Whitney Test in GraphPad Prism. $p<0.05$ was considered significant. For the Seahorse XF Cell Mito Stress Test, the third time point of the basal glycolytic rate was analyzed.

## RESULTS

hiBMECs preferentially localized glucose basolaterally and lactate apically (Fig 1A-B). Basolateral media contained more glucose than apical media. In contrast, apical media contained more lactate than basolateral media. This same trend was observed in hpBMECs (Fig 1C-D), as basolateral hpBMEC media contained more glucose than apical media, and apical hpBMEC media contained more lactate than basolateral media.

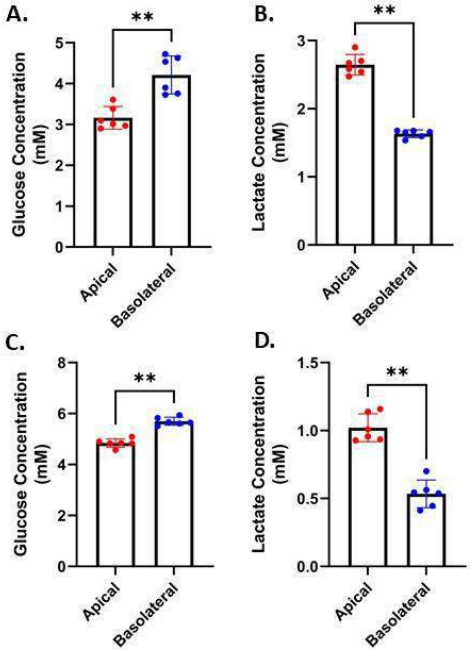

**Figure 1: hiBMECs and hpBMECs localize extracellular glucose basolaterally and lactate apically. A-B) Glucose and lactate concentrations of hiBMECs in the apical and basolateral media. C-D) Glucose and lactate concentrations of hpBMECs in the apical and basolateral media. Measured by YSI Bioanalyzer. **p<0.01**

Basal glycolytic metabolic rate trends toward being higher in hiBMECs cultured in high glucose for 24 hours as compared to cells cultured in normal glucose (p=0.0517; Fig 1A). Apical glucose uptake was higher in hiBMECs cultured in high glucose compared to cells cultured in normal glucose for 24 hours (Fig 2B). In contrast, basolateral glucose concentration was higher in high glucose hiBMECs than normal glucose hiBMECs, indicating increased glucose transport from the apical side of the hiBMECs to their basolateral side (Fig 2C). Lastly, lactate concentration was higher in both the apical and basolateral media in high glucose hiBMECs, supporting the Seahorse data suggesting higher glycolytic rate in cells cultured in high glucose (Fig 2D-E).

## DISCUSSION

Since hiBMEC and hpBMEC glucose distributions were similar, hiBMECs can act as a model of glucose and lactate localization across the brain endothelium. We originally thought that the 24-hour time point would show decreased glucose transport, as observed in long-term hyperglycemia; however, increased glucose transport was observed instead. Thus 24 hours may represent acute rather than chronic hyperglycemia. The increase in basolateral glucose in hyperglycemia is greater than the increase in glycolytic rate in hyperglycemia. Excess glucose transport across BMECs in hyperglycemia may lead to harmful effects on the brain.

We will continue to investigate glucose transport and metabolism in hiBMECs in hyperglycemic culture. We will quantify metabolite concentrations at shorter and longer times. We will also co-culture hiBMECs with astrocytes to determine how additional BBB cells affect BMEC glucose metabolism and transport. To identify the transport mechanism, we plan to label high and normal glucose hiBMECs for the glucose transporter GLUT1 and tight junction-associated protein ZO1.

Here we illustrate that hiBMECs on Transwell inserts can be used as a model of glucose and lactate polarization in the BBB. These studies improve our understanding of how T2DM induced hyperglycemia increases a patient's risk of developing AD. Eventually, hiBMECs could be used in a patient-specific manner.

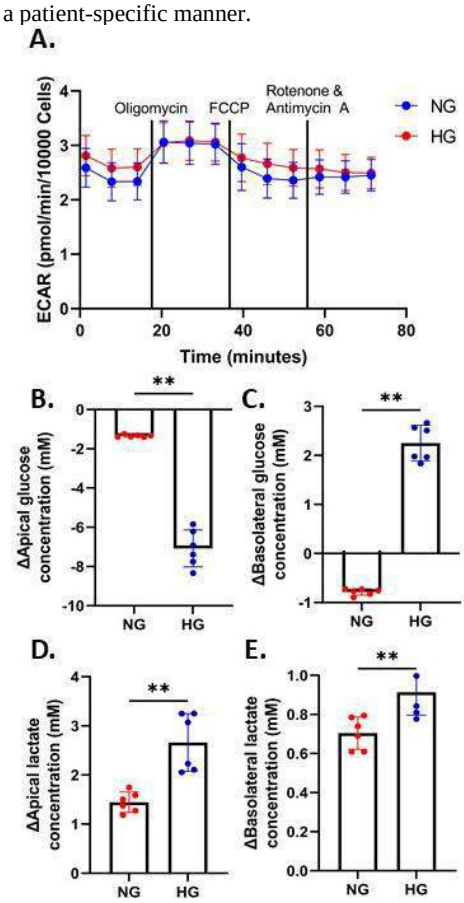

**Figure 2: In high glucose, hiBMECs increase glucose transport to their basolateral side and increase glycolytic rate. A) Glycolytic rates in hiBMECs after 24 hours of normal or high glucose culture, as measured by a Seahorse XF Cell Mito Stress Test. B-C) Apical and basolateral media glucose and D-E) lactate after 24 hours of normal or high glucose culture. Measured by YSI Bioanalyzer. **p<0.01**

## INTRODUCTION

Over 37 million Americans suffer from chronic kidney disease (CKD), which is a gradual loss of kidney function over time [1]. If not treated properly, CKD can eventually progress to end stage renal disease (ESRD), which is a life-threatening and progressive condition characterized by severely impaired renal function, anemia, and the development of various cardiovascular diseases [2]. Treatments for ESRD include replacement therapy by hemodialysis, with the creation of an arteriovenous fistula (AVF), peritoneal dialysis, and kidney transplant [2].

The brachiocephalic AVF is the most clinically used, due to its ease of creation, high flow rates, and high rate of maturation. Even though this form of treatment is effective for blood filtration and treating ESRD, recent studies have suggested connections between fistula creation (size and shape) and the development of pulmonary hypertension (PH) in this patient population [3]. ESRD patients, who develop PH, are automatically removed from the kidney transplant list.

The objective of this research is to develop a protocol for creating subject-specific computational fluid dynamics (CFD) models of fistulas in patients with PH. A better understanding of the trends between fistula creation and pulmonary hypertension will lead to more improved risk monitoring and offer physicians evidence for earlier intervention.

## METHODS

The first step of the project was to obtain approval from the East Carolina University Internal Review Board (UMCIRB19-000708). Inclusion criteria for this study are as follows: patients must be over the age of 18, have an arteriovenous fistula actively being used for dialysis, have been diagnosed with PH by right heart catheterization (RHC), have no contraindications for MRI, have not been diagnosed with connective tissue disease, and do not have advanced left heart disease.

Magnetic resonance (MR) imaging was performed, with a Siemens Aera 1.5 Tesla MR machine. Scans were completed of the fistula to obtain geometry and velocities in the proximal arterial and venous segments. A total of 22 images, with a slice thickness of 8 mm and pixel spacing of 1.61 mm, were captured. Time varying velocity data, captured through the midplane (Figure 1) of the AVF while the patient was in supine position, was gathered using phase-contrast (PC) scans at 30 time points along the cardiac cycle. During the same imaging session, similar data were acquired for the pulmonary artery, as well as clinically standard cardiac measures. Patient identifiers were removed from image files prior to processing.

MR images were imported into Mimics 20.0 (Materialise, Belgium) for model creation. A thresholding technique was used to segment the anatomical geometry captured in each MR slice and the "Calculate 3D" function was used to create a three-dimensional model of the highlighted region. The smooth, three dimensional AVF created in Mimics is shown in Figure 1.

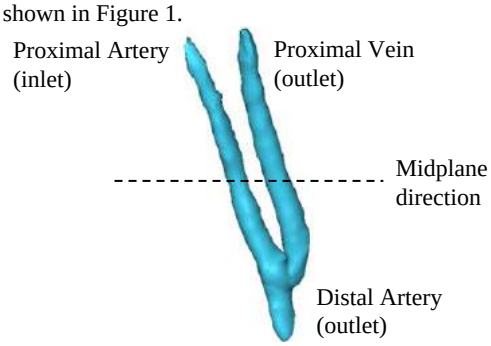

Figure 1: A smoothed, three-dimensional AV fistula model created in Mimics 20.0.

The model was then exported to 3-matic 12.0 where models were trimmed to define inlets and outlets, with perpendicular cross-sectional cuts. The 3-matic files were uploaded into ANSYS Workbench 19.1 (ANSYS Inc., USA), where they were discretized. Metrics such as

orthogonal quality and skewness were used to assess mesh quality and any necessary improvements were made accordingly [4].

Blood was characterized as an incompressible, non-Newtonian fluid with viscosity, 3.2 cP, and density, 1060 kg/m$^3$. The distal artery and proximal vein were assigned pressure-based outlets. The inlet, or the proximal artery, boundary condition was defined by the patients-specific flowrate waveform from the MR data. The MRI waveform was created using in house MATLAB file to crop and isolate cross sections of the AVF from the MRI, to segment the AVF cross sections across 30 timesteps in the cardiac cycle, and lastly to multiply the segmented AVF cross section images with the phase part of the images to calculate fluid velocity. Output parameters included fluid flowrate, mass flowrate, artery diameter, and artery diameter across all 30 points.

A double precision, second order, transient flow pressure-based solver was used during CFD analysis. A total number of 624 timesteps was used, with a single time step durations of 0.0038221 s. Times steps for each subject were calculated by multiply the RR interval, which is the times elapsed between two consecutive R waves of a QRS signal from an ECG, by three to achieve three full cardiac cycles. Residual values were set to default, $1 \times 10^{-4}$.

Post-processing included velocity streamline plots, velocity volume rendering, wall shear stress (WSS) contours, all visualized using CFD Post. These measurements were compared using maximum and minimum velocities, maximum and minimum WSS values.

## RESULTS

The results to date only include one patient. The maximum WSS was 903 Pa, and the minimum WSS was found to be 0.935 Pa. These can be shown in Figure 2.

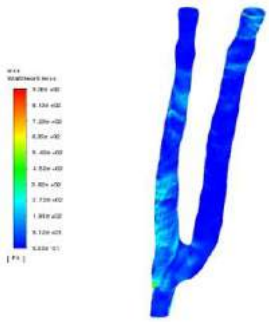

Figure 2: Wall shear stress contour for the AV fistula CFD model.

The maximum velocity of the transient CFD model was 6.58 m/s, which occurs at the distal artery. The peak velocity is significantly greater than the maximum inlet velocity in the velocity waveform utilized for the transient model (approximately 0.298 m/s). Velocity measurements are seen to be greater at the proximal vein and distal artery outlets than the proximal artery inlet.

## DISCUSSION

Over 15% of adults in the United States are affected by chronic kidney disease, which can overtime progress to end stage renal disease if not treated properly. While hemodialysis, with the surgical creation of an arteriovenous fistula provides patients with effective kidney filtration, there has been recent evidence suggesting a correlation between hemodialysis, increased pulmonary artery pressures, and the development of pulmonary hypertension [5]. The development of PH for ESRD patients removes them from the kidney transplant list, leaving them with hemodialysis and disease management treatments.

The patient analyzed in the present study had a mean AVF flow rate, mean pulmonary arterial pressure (mPAP), and pulmonary capillary wedge pressure (PCWP) of 1.97 L/min, 46.5 mmHg, and 19 mmHg, respectively. This flow rate is higher than the hypothesized limit for an AVF flow rate that is both effective for dialysis and does not overload the heart, which is currently believed to be approximately 1.5 L/min. A recent study by Tudoran et al. found significantly higher average AVF flow rates in PH patients when compared to normotensive patients [6]. This study also found a strong correlation between sPAP and the amount of time spent on dialysis as well as AVF flow rates. The areas of low wall shear stress, seen in the model may indicate disturbed flow within the AVF, which is supported by the elevated CFD resulted velocity at the distal artery and the confirmed diagnosis of PH for the retrospective patient.

There are many limitations to this study. The most apparent is the patient sample size. Due to the COVID-19 pandemic, patient recruitment was more difficult. The results presented include data from only one patient which limits interpretation of results. Furthermore, the computational approach relies on several assumptions including a rigid vessel wall. The inlet arterial velocity was modeled as a blunt profile which is not physiologically accurate. Future work could examine the impact of the shape of the velocity profile on simulation results. Despite these limitations, an in silico approach may reduce the need for in vivo or in vitro experiments and enable subject-specific predictions.

Overall, the creation of an AVF is seen to exacerbate pre-existing pulmonary arterial pressure conditions by elevating cardiac output. With the inclusion of additional patients, metrics from this study may offer insight to physicians about AVF monitoring which may lead to early surgical interventions to prevent the development of pulmonary hypertension. This improvement would cause fewer incidences of pulmonary hypertension and overall enhance the quality of life for those suffering with this condition.

# THE INFLUENCE OF EMBOLI SIZE AND DENSITY ON THEIR TRANSPORT IN A CARIOPULMONARY BYPASS FLOW LOOP

**Amy E. Chandler (1), Bryan C. Good (1)**

(1) Mechanical, Aerospace, and Biomedical Engineering
University of Tennessee
Knoxville, TN, USA

## INTRODUCTION

Cardiopulmonary bypass (CPB) is essential for a variety of open-heart surgeries in order to create a bloodless and motionless field for the surgeon to work. Roller pumps are commonly used for CPB and are composed of two rollers on opposite sides of a rotating arm which compress a section of tubing, pushing blood flow forward [1]. Consequently, roller pumps are a major attributing factor to blood clotting as their compressive function can induce damage to blood components and provoke an inflammatory response while a patient is on CPB [2]. These emboli can cause a range of issues including stroke and it is critical to understand their delivery to the cerebral arteries to help minimize postoperative complications. Previous experimental transport studies in the aorta have shown that embolus trajectory paths are proportional to the flow rate split within aortic branches during normal flow conditions [3]. However, no studies have looked into the role CPB plays in emboli distribution. To minimize the risk of embolism and potential stroke while on CPB, a better understanding of emboli delivery to the cerebral arteries must be understood.

## METHODS

To study the flow trajectories of emboli through the branches of an aortic arch under CPB conditions, a flow loop was constructed as displayed in **Fig. 1**. The flow loop consisted of a Sorin Stockert Roller Pump (10-10-00 CAPS Module 10H) with plasticized polyvinyl chloride (PVC) tubing used throughout the loop. A generalized aortic arch model was 3D printed out of polylactic acid (PLA) tubing connectors and included the four primary branches: the brachiocephalic artery (BCA), the left common carotid artery (LCCA), the left subclavian artery (LSCA), and the descending aorta (DA). Benim *et. al*. previously determined that the percentage distribution of aortic blood flow through each branch is as follows: 15.80% in the BCA, 7.89% in each the LCCA and LSCA, and 68.42% in the DA [4]. To achieve these flow splits experimentally in each branch, downstream metal tubing clamps were used to change their resistance, and a flow meter (Transonic) was used to measure the resultant flow rates in liters per minute in each branch. Water served as a substitute for blood as the densities are nearly equivalent at 1 g/cm$^3$ [5].

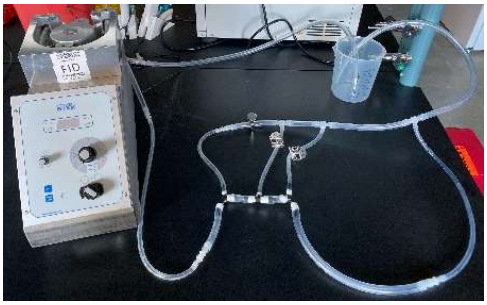

**Figure 1:** Experimental setup of model CPB flow loop on roller pump.

To represent emboli generated in the CPB system, 1/16” and 3/32” diameter Nylon and Delrin beads were individually sent through the flow loop. For the Delrin beads, a range of CPB pump flow rates (1-5 LPM) were prescribed and the aortic branch flow rates adjusted accordingly. A second set of studies were performed with the Nylon beads at a single flow rate of 3 LPM to compare between emboli of different density.

The calculated densities of the large and small Nylon beads were found to be 1.12 g/cm$^3$ and 1.17 g/cm$^3$ respectively. These densities were less than the Delrin beads which were calculated to be 1.27 g/cm$^3$ for the larger size and 1.36 g/cm$^3$ for the smaller size. After the introduction of each bead into the flow loop, their paths through the chosen aortic branch were recorded. For each bead size and type, the total number of beads through each branch was divided by the total number of beads to calculate the percentage of distribution to each branch. This resulted in separate percentages for each trial in terms of small and large Delrin beads and small and large Nylon beads.

## RESULTS

The emboli distribution of Delrin beads at various flow rates was observed and compared as displayed in **Fig. 2**. The percent distributions between each bead size (1/16" and 3/32") and flow rate followed closely to the percent flow distributions within each aortic branch regardless of the pump flow rate.

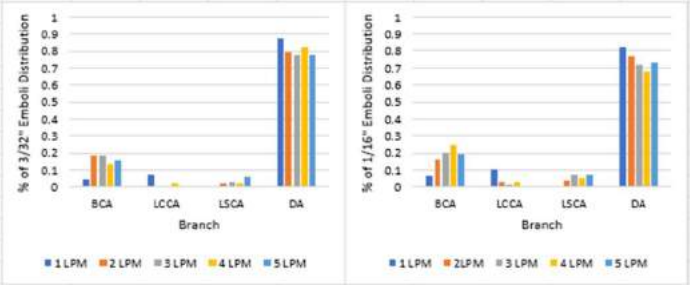

**Figure 2:** Distribution of 3/32" and 1/16" Delrin Beads Through the Aortic Arch Branches at 1, 2, 3, 4, and 5 LPM.

When flow rate was set to 3 LPM, Delrin and Nylon beads followed a similar trend in branch trajectory that aligned with the flow distribution within the CPB flow loop (**Table 1**).

**Table 1: Bead distribution from each experimental trial at 3 LPM**

| | Branch | BCA | LCCA | LSCA | DA |
|---|---|---|---|---|---|
| 3/32" Nylon | Number of beads | 9 | 0 | 2 | 95 |
| | Sum of all beads | | | | 106 |
| | Percentages | 0.0849 | 0 | 0.0189 | 0.8962 |
| 1/16" Nylon | Number of beads | 18 | 2 | 2 | 84 |
| | Sum of all beads | | | | 106 |
| | Percentages | 0.1698 | 0.0189 | 0.0189 | 0.7925 |
| 3/32" Delrin | Number of beads | 20 | 1 | 3 | 84 |
| | Sum of all beads | | | | 108 |
| | Percentages | 0.1852 | 0.0093 | 0.0278 | 0.7778 |
| 1/16" Delrin | Number of beads | 14 | 1 | 5 | 50 |
| | Sum of all beads | | | | 70 |
| | Percentages | 0.2 | 0.0143 | 0.0712 | 0.7143 |

As seen in **Fig. 3**, a majority of Delrin beads (77.78% of 3/32" and 71.43% of 1/16") flowed through the DA. The next most common pathway was the BCA for both sized beads while the least likely for any Delrin beads were the LCCA or LSCA. Similarly, in **Fig. 4**, the largest percentage of Nylon beads flowed to the DA. While the Nylon and Delrin beads followed the same trends their distributions in the other aortic branches, the higher density Delrin beads more commonly traveled through the BCA compared to the lower density Nylon beads. For the BCA, 8.49% of the 3/32" and 16.98% of the 1/16" Nylon beads entered while 18.52% of the 3/32" and 20% of the 1/16" Delrin beads entered. For all bead types and sizes, it was rare for the beads to flow through the LCCA and LSCA branches.

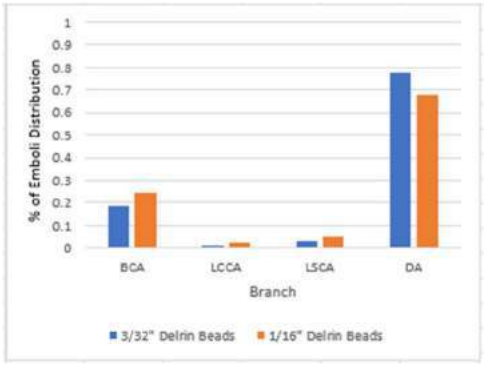

**Figure 3:** Distribution of 3/32" and 1/16" Delrin Beads Through the Aortic Arch Branches at 3 LPM.

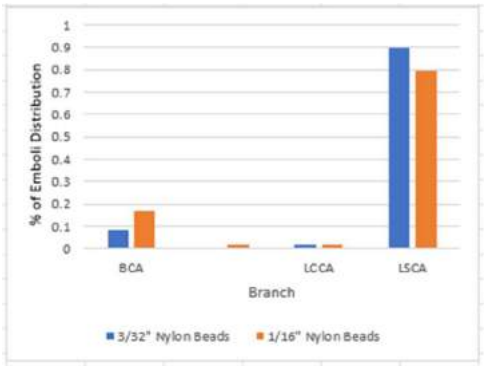

**Figure 4:** Distribution of 3/32" and 1/16" Nylon Beads Through the Aortic Arch Branches at 3 LPM.

## DISCUSSION

The results of these experimental studies indicate that emboli generated in CPB roller pumps with densities like blood (Nylon beads) are most likely to travel through the DA leading to the abdomen and lower body. This is due to the majority of blood flow leaving through the DA. The similar density allows the emboli to follow the flow of blood without deviating from the fluid. Inversely, emboli with densities greater than blood (Delrin beads) have a greater possibility of traveling through the BCA which delivers blood to the right arm and right side of the brain. Emboli traveling through this branch increases a patient's risk of stroke which can be life threatening or severely impair the patient due to lack of oxygen supply to the brain. Further experiments in this field are necessary to understand how emboli travel to the brain during CPB and what can be done to minimize this. Factors such as intraoperative hypothermia to decrease metabolism and heparin to increase activated clotting time affect blood viscosity from a range of 1.5 to 3.5 cP. To further study these results as blood's viscosity is adjusted throughout CPB, emboli traveling in this flow loop with fluids of varying viscosities and densities will be investigated.

(2) International Hip Dysplasia Institute, Orlando, Florida, USA

## INTRODUCTION

Developmental dysplasia of the hip (DDH) or hip instability is a serious medical condition occurring in 14% of infants and is the most common abnormality in neonates [1]. This congenital malformation is characterized by a ball and socket hip joint that is not fully formed and/or a hip joint that exhibits excessive laxity, resulting in instability or dislocation. Early diagnosis via physical examination or a hip ultrasound and prompt treatment of DDH is critical to ensure the best possible outcomes and avoid chronic disability. If left undiagnosed or improperly treated, DDH can result in abnormal gait and function, low strength, and early degeneration of the hip and knee, including early-onset osteoarthritis [2]. In a registry study in Norway, neonatal hip instability doubled the risk of early onset osteoarthritis and hip arthroplasty before age 40 [3]. Nearly 50% of total hip arthroplasty surgeries for patients under 50 are attributed to hip dysplasia [4].

Physical screening for DDH in infants relies on two manipulative tests developed by Thomas Barlow [5] and Marino Ortolani [6]. The Barlow and Ortolani maneuvers, have become the "gold standard" techniques to assess hip stability on 3 months old infants or younger. The Ortolani procedure is performed by gently abducting the leg with the hips flexed at 90° and applying an upward force through the greater trochanter. An Ortolani positive test will feature a palpable "clunk" sensation representing the reduction of the dislocated hip. In general, a positive Ortolani test indicates a reducible dislocation while a negative Ortolani test indicates an irreducible dislocation. On the other hand, the Barlow procedure is performed by adducting the leg with the hips flexed at 90° and gently pushing the knee. A Barlow positive test will feature a palpable "clunk" sensation and will force the femoral head out of the acetabulum confirming hip dislocation.

Unfortunately, these physical tests are highly subjective and depends greatly on the competence and experience of the examiner [7]. The actual technique with which the manipulation of the joint is carried out is poorly standardized, and the mechanical features of a successful test are not understood in detail. Current training models that closely simulate a range of different hip pathologies cost between $700-$1,200. The existing models are not intuitive for new examiners to use and do not allow visual assessment of the pathological hip as seen in Figure 1

*Figure 1: Laerdal Model*

Figure 1 shows a model known as the "Hippy Baby" created by Laerdal Medical. The model was designed to train residents in the Barlow and Ortolani techniques with each hip designed with a generic setup for residents to dislocate and reduce the hip. Unfortunately, despite a unique design it has numerous flaws that have resulted in it not being effective at mimicking the Barlow and Ortolani maneuvers.
Hippy Baby's downsides include a high cost between $700-$1,200, opaque surface preventing residents from being able to visualize what the maneuvers are doing beneath the skin to the bones, ligaments. The model is composed of a rubber-like material, resulting in more force being needed to dislocate and reduce the hips. This increased force could be disastrous if a resident attempts to apply the same amount of force to an infant during an examination as it could severely damage the infant's skeletal system.

## PRODUCT DESIGN

Figure 2 shows new DDH models using various 3D printed pelvis.

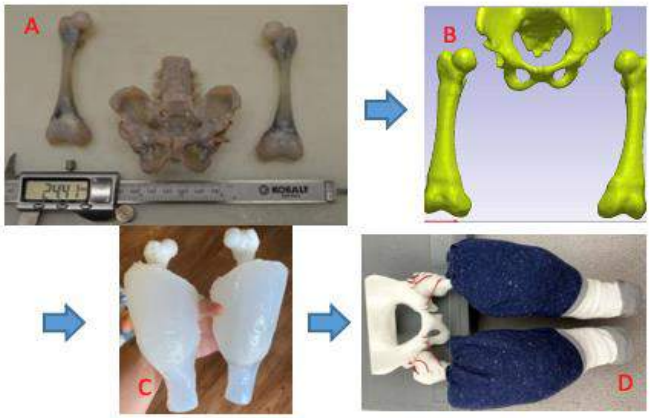

*Figure 2: Development of Hip Models*

The goal of the team while developing the new trainer was to address the major issues with the existing Laerdal model. Develop a model that allows the examiner to apply the Barlow and Ortolani techniques, and simultaneously visualize the effects of those techniques. The new model would also need to better represent the infant's softness to prevent excessive force while training residents.

The first step to developing the new model was to create a 3D model of a DDH afflicted pelvis and femora. The CT scans used were provided by the University of Padua from Dr. Marino Ortolani's collection (see Figure 2-A). The model used was that of a healthy infant that was heavily post-processed and altered which allowed for the most realistic form of the Barlow and Ortolani techniques. The model was developed and augmented in Synopsys's SimpleWare ScanIP before being exported to Dassault Systèmes Solidworks (see Figure 2-B).

The bones were initially printed on a modified Creality Ender 3 using the slicing software of Ultimaker Cura. The ligaments were also 3D printed after dissecting one of the Hippy Baby models and observing its design. The team used a combination of SimpleWare and Solidworks to create Thermoplastic Polyurethane (TPU) ligaments as well as anchor points in the form of pegs on the surface of the femur and pelvis. The team finally cast the legs of the model to simulate an infant's weight (see Figure 2-C for legs and Figure 2-D for full model).

The team then chose to use a combination of a transparent silicone skin and foam to hold the skeletal geometry in place instead of ligaments. They also acquired an Ultimaker S5 and FlashForge Creator Max 2 3D printers to improve the print quality and reduce production time of the bones The first prototype was created using a dissected Laerdal Model to create an initial prototype and gain a better understanding of the end goal.

Next steps for the project will be to create a mold of the Laerdal model and using that mold along with the custom pelvis and femora to create a similar model with different materials. The goal would then be to refine the model and prepare it for market.

## BUDGET & MARKET ANALYSIS & BUDGET

The projected price for the 3D printed hippy baby will be around $300 to $400 and it will be developed in collaboration with the International Hip Dysplasia Institute in Orlando, FL. At this price point and with the additional features that make it more useful, there are many opportunities for this product in the medical training market. Target customers are primarily medical educators while end-users are students.

The market for medical trainers as of 2021 is approximately 1.7 billion dollars. There are 210 pediatric residency programs in the USA and 27 in Canada. The potential market for that group is 2 per program every three years. Additional opportunities for sales include orthopedic residencies, osteopathic and nursing programs, educational workshops at medical conferences, and European or South American medical education programs. Projected sales of an affordable, effective model would be likely to approach 200 per year for the first three years.

Additionally, some pediatricians or pediatric orthopedic surgeons may use models in their offices for patient education. Patient education may add to the market size an additional 100 per year.

The team applied for an Ignite grant via the ERAU Office of Undergraduate Research and received a grant of $4300. Figure 3 shows the largest expenses are the 3D printer and design of a production ready prototype through a third-party 3D printing company.

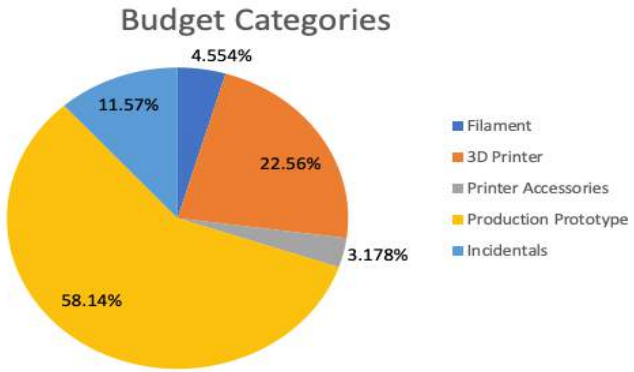

*Figure 3: Project Budget*

This group proposes licensing to a large well-established producer/seller of orthopedic training models (Pacific Research Labs in the USA and its subsidiary Sawbones Europe). The model can also be manufactured by us and then distributed through Pacific Research Labs. They currently do not have a hip dysplasia teaching model for diagnosis although they have bone models for surgical practice

The global impact has enormous potential. Newborn examination is the best way to detect infant hip dislocations that occur in approximately 1/500 infants globally [9]. Exams currently fail to detect 20% of cases in North America [10]. Far greater numbers are undetected in less developed countries. Early detection allows simple non-surgical correction with bulky diapers, harnesses, or splints, but late detection leads to surgery or disability. Improved education for diagnosis by examination has proven to dramatically decrease the incidence of late detection. A better teaching model is essential to decreasing the burden of this common infant condition. Furthermore, the design and concept of the team's models can be adapted to model other pediatric pathologies, vastly expanding the market.

# VASCULAR SMOOTH MUSCLE CELLS ALIGNMENT ON MICROPATTERNS ALTERS GLUCOSE METABOLISM

**Yusuf M. Mastoor (1), Pattie S. Mathieu (1), Alisa M. Clyne (1)**

(1) Fischell Department of Bioengineering, University of Maryland, College Park, MD, USA

## INTRODUCTION

In healthy conditions, vascular smooth muscle cells (vSMCs) circumferentially align around the blood vessel lumen. This alignment is integral for modulating vascular tone, as it allows vSMCs to efficiently contract and dilate to alter blood vessel diameter in response to mechanical and biochemical stimuli[1]. vSMCs aligned on micropatterned substrates also have reduced proliferation and migration, mimicking healthy vSMC phenotype[2,3]. In diseased states, such as atherosclerosis, vSMCs rapidly proliferate and migrate. These synthetic vSMCs also metabolize more glucose through glycolysis[4]. However, the effect of vSMC alignment on glucose metabolism has not been measured.

Micropatterns can be used to align vSMCs on a variety of substrates including polydimethylsiloxane (PDMS) and hydrogels. We previously showed that the inherent ridges created during fused deposition modeling (FDM) can be used to topographically pattern substrates and align vSMCs[5]. In the current study, we hypothesized that vSMCs aligned along micropatterned ridges will exhibit decreased proliferation and glucose metabolism.

## METHODS

**Cell Culture:** Human coronary artery smooth muscle cells between were cultured in SmGM-2 (Lonza) supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 2mM l-glutamine.

**PDMS Patterning and Mold Fabrication:** 150μm ridges were patterned in polydimethylsiloxane (PDMS) using 3D printed stamps as previously described[5]. PDMS elastomer base and curing agent were mixed in a 10:1 ratio and added to each well in a six-well plate. 3D printed molds were placed on top of uncured PDMS and cured at 80°C overnight. After the mold was removed, imprinted PDMS was plasma treated for 1 minute and coated with 50 μg/mL collagen overnight at 37°C. $10^5$ cells were added to each well in 2mL of SmGM-2.

**Immunofluorescent Imaging and Quantification:** Cells were washed with cold PBS, fixed with 4% paraformaldehyde for 20 minutes, and permeabilized with 0.2% Triton X-100 for 40 minutes. Non-specific binding was blocked with 5% bovine serum albumin (BSA). Cells were labelled with a Ki-67 primary antibody (1:200, Abcam, ab15580) overnight at 4°C. After washing with PBS, cells were labelled an Alexa Fluor 488 conjugated secondary antibody (1:1000), rhodamine phalloidin (1:80), and Hoechst (1:2000). Actin fiber alignment was quantified using MatFiber software[6].

**Glycolytic Rate:** Glucose and lactate concentrations were measured in vSMC conditioned media using a YSI biochemical analyzer 2950. The differences in glucose or lactate concentration at 48 hours were then normalized to cell number, which was determined by labelling nuclei Hoechst and counting nuclei using ImageJ.

**Western Blotting:** Cells on patterned and unpatterned PDMS were scraped and lysed in ice-cold RIPA buffer. Samples were normalized to total protein content, separated using SDS-PAGE on a 4-12% Bis-Tris gel, and transferred to a nitrocellulose membrane. Non-specific binding was blocked using 5% BSA. Membranes were treated with primary antibodies for hexokinase I (HXK1), phosphofructokinase-1 (PFK1), lactate dehydrogenase (LDH; all 1:1000) overnight at 4°C, followed by horseradish peroxidase conjugated secondary antibodies (1:2000) for two hours at room temperature. Protein bands were imaged using an Enhanced Chemiluminescence Substrate in a Fluorchem digital imager.

**Statistics:** Statistical significance was analyzed using a two-way Student's t-test.

## RESULTS

vSMCs seeded on patterned PDMS aligned in the ridge direction, while vSMCs on unpatterned PDMS did not align in any direction (Fig. 1A-D). Furthermore, cells on the patterned substrates trended towards less proliferation as compared to those on the unpatterned substrates, as quantified by the percentage of Ki-67 positive nuclei (Fig. 1E-F).

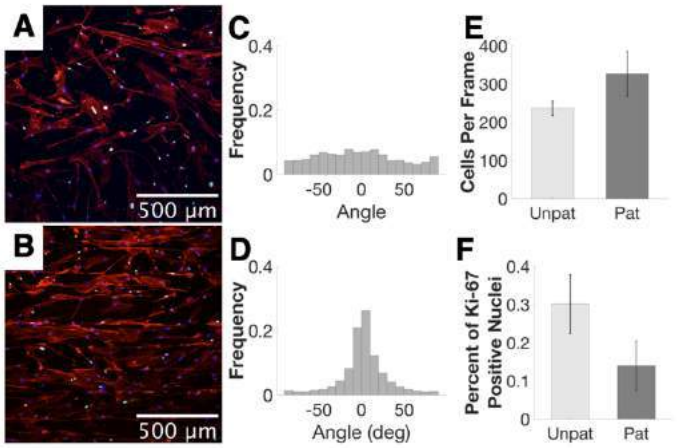

**Figure 1: vSMCs aligned on 3D patterned PDMS. Representative images of vSMCs labelled for nuclei (Hoechst, blue), actin (phalloidin, red), and Ki-67 (green) on (A) unpatterned PDMS and (B) patterned PDMS. Alignment of actin fibers on (C) unpatterned and (D) patterned PDMS. (E) Average number of cells per frame and (F) percentage of Ki-67+ cells.**

Cells on patterned PDMS consumed significantly less glucose and produced less lactate compared to cells on unpatterned PDMS (Fig. 2A-B). For every one molecule of glucose metabolized, vSMC produced three lactate molecules (Fig. 2C). To determine if decreased glycolysis was related to glycolytic enzymes, the relatives amounts of HXK1, PFK1, and LDH were compared in cells on patterned versus unpatterned PDMS. There were no significant differences in the amounts of these key glycolytic proteins in cells on patterned versus unpatterned PDMS (Fig. 3)

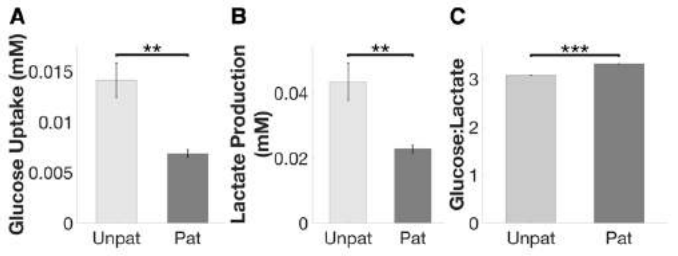

**Figure 2: vSMCs on patterned PDMS have decreased glucose uptake and lactate production. (A) Glucose uptake and (B) lactate production normalized to average cell number. (C) Glucose to lactate ratio. ** p < 0.01, ***p < 0.001.**

## DISCUSSION

In this study, we investigated how vSMCs aligned along micropatterned PDMS ridges changed proliferation and glucose metabolism. Similar to previous studies, we found that aligned vSMCs had lower proliferation[2,3]. We further found decreased glucose uptake for vSMCs on patterned PDMS. Thus aligned vSMC are more similar to contractile healthy vSMCs, whereas non-aligned vSMC are more similar to unhealthy synthetic vSMC[7].

After glucose is taken up by the cell, it can be processed into two molecules of lactate via glycolysis. We found that vSMCs on both patterned and unpatterned PDMS produced three lactate molecules per one glucose molecule, indicating that the cell is generating lactate from a non-glucose source. Since glycolytic enzyme quantity did not change in vSMC on patterned and unpatterned PDMS, the functional changes in glucose metabolism may related to regulatory glycolytic proteins such as 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 (PFKFB3) or to glycolytic reaction inhibition by metabolites. We will elucidate the mechanism behind the decreased glucose metabolism in aligned vSMCs via metabolic mass spectrometry.

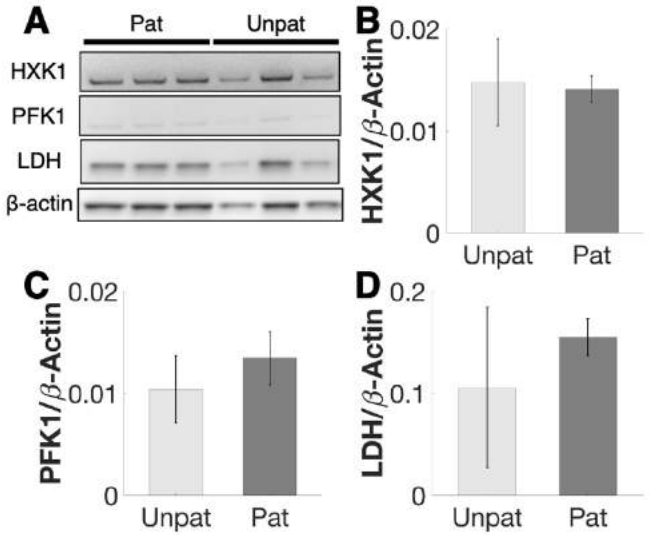

**Figure 3: vSMC glycolytic protein expression did not change in cells on patterned and unpatterned PDMS**

In conclusion, we showed that micropatterns created by 3D printed molds can be used to align vSMCs decreasing their proliferation and glucose metabolism. Understanding the mechanism by which vSMCs alter their glucose metabolism on patterned PDMS will help us develop tissue engineered blood vessels which both look like and act like healthy human blood vessels.

# DYNAMIC ANKLE BRACE FOR ANKLE SPRAIN RECOVERY

**Amulya Bajracharya (1), Caitlin Brumley (1)**

**Faculty Advisor(s)**

**Dr. Victor Huayamave**

(1) Mechanical Engineering Department, Embry Riddle Aeronautical University, Daytona Beach, FL, USA

## INTRODUCTION

Ankle injuries are a common problem one will experience in their lifetime. Whether it is simply stepping incorrectly on your feet or through excessive strain on the ligaments through sports or other activities, these types of injuries are an unfortunate part of life. 65.6% of all injuries that occur in men's soccer happen to the lower limbs with 25.3% being ligament sprains [1]. Of those ligament sprains, 12.2% occur in the ankle representing a large amount of injury to this location [1]. The most common sprains of this nature are lateral sprains where there is an over-inversion of the ankle joint on the lateral collateral ligaments. These sprains are categorized into mild, moderate and severe sprains and can increase the chances of reinjury tremendously depending on the severity of injury. To help prevent injury and reinjury, external ankle supports are key with ankle braces proving better than taping or casts [2]. Athletic taping is common for injury prevention and stability though they tend to be one time use items and require professionals to properly taping up individuals. Ankle braces are reusable and can typically be put on by the injured person. Common types of braces on the market are straps, lace ups, stirrups, or some combination of the 3. Straps are adjustable and comfortable though only provide mild support, lace ups provide more support though they are bulkier and are difficult to place in shoes, and provide great support due to their rigidity, but greatly reduce a person's inversion and eversion motions. The ankle brace designed by the team seeks to be a combination of the different types of braces to provide maximum support while still being able to fit comfortably inside a shoe. The end goal is to allow this brace to be used during competitions to help prevent ankle injury while allowing users full range of motion. Specifically, this product was originally designed for soccer players and hopes to tap into the professional market to allow ankle braces to become as commonplace as athletic taping.

### PRODUCT DESIGN

**Figure 1: First and third design prototypes stitched onto compression socks**

The current brace model is constructed using an ultimaker S5 3D printer. The brace is made of TPU and currently there are five different types of ankle brace designs. Each print is sewn onto a compression sock and has holes for laces to ensure a conformed fit to the user. Elastic straps are attached to the bottom of the foot and behind the lower calf and heel.

The first design consists of a triangular geometric pattern with a solid outline for sewing on to a compression sock. The lacing holes are grouped towards the top of the brace.

The second design is a solid print with a thin solid outline for easier sewing. The lacing holes are also grouped towards the top of the brace.

The third design is a solid print with no thin outline. The lacing holes are the same number but spread evenly across the arc of the brace.

The fourth design is a combination of solid and mesh. There are three thin layers. The base layer is solid, the middle is triangular geometry, and the top layer is solid. The lacing holes are again, evenly spread out along the arc of the brace.

The fifth design combines the two prints into one print, making a rainbow shape. The goal is to eliminate the need for silicone straps and ensure the brace stitching will stay intact after each use.

The main benefit to these TPU braces is that they are thin, easy to put on, fit comfortably inside shoes, flexible enough to allow range of motion and yet supportive enough to help prevent injury. In addition, these braces are machine washable meaning they can be reused unlike taping.

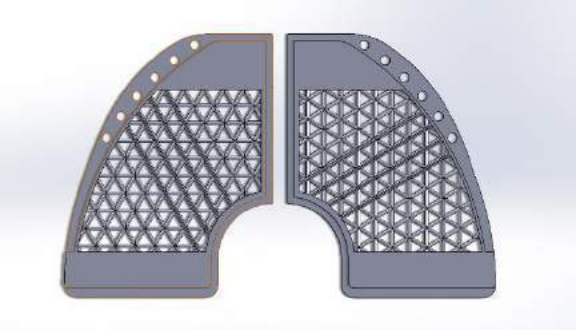

**Figure 2: Triangular geometry design**

## BUDGET & MARKET ANALYSIS

The budget for developing, printing and using these ankle braces is a projected 5,000 USD. This cost includes the purchase of the ultimaker 3D used, TPU filament, compression fabric, and lacing used for the braces. The ultimaker is an investment cost as it is an industry grade printer that should last for years and provide accurate prints. It uses TPU ranging from 50 to 70 USD for a 750 g roll with printing time of about 8 hours. The average cost to produce one ankle brace is 10 USD predicted to retail for 60 USD. The most popular ankle braces sell between 20 to 100 USD so these braces are within normal price ranges. With the resurgence of the sport industry after initial shutdowns due to the pandemic, the demand for support devices is increasing. The braces are intended to be sold to sports departments through online ordering. Initial prototypes for a brace are one size fit all though research and development is being made to create different sizing options for customers. This way, the brace is not only a preventative and rehabilitative device, but also highly customizable to suit the needs of each wearer.

## INTRODUCTION

A pneumonectomy is a surgical procedure during which one entire lung is removed from a patient and the connective vessels are sealed off [1]. Postpneumonectomy pulmonary edema is one of the most prevalent fatal complications resulting from the procedure, affecting nearly 2.5-5% of patients that undergo this procedure with an 80-100% mortality rate [2]. Our study aims to explore the effect of changes in blood flow after pneumonectomy. This is modeled by controlled flow through a macrofluidic cell chamber modeling the geometry of the pulmonary arteries to depict vascular changes after pneumonectomy.

The glycocalyx is a cell coating composed of proteoglycans, glycosaminoglycans, and plasma proteins. The endothelial glycocalyx forms an interface between blood vessels walls and circulating blood [3]. The glycocalyx protects the endothelial cells and in doing so helps maintain cellular homeostasis [4]. The glycocalyx is regulated by the shear stress blood flow creates, and changes in flow can impair its ability to function. The disruption of this layer can lead to cardiovascular disease which can be fatal in many cases. [5]. Our study will examine how this component might be affected in a pneumonectomy by measuring how components of this layer such as heparan sulfate are affected by increases in shear stress after a pneumonectomy.

## METHODS

To mimic the conditions that endothelial cells and the glycocalyx experience after a pneumonectomy a flow chamber was developed as seen in Figure 1. There are four main components that make up the 2D flow chamber. The bottom plate has cut outs for culture media to flow through. This flow path was created to accurately mimic the anatomical features of the pulmonary arteries as the diameters and angels of the pulmonary arteries are accurately displayed here [3]. A Teflon gasket sits along the edges of the flow path to prevent leaking and give the required height needed for shear stress. Seven glass slides sit in the flow path at data collection points so cells can be seeded to them. Finally, a top plate screws into the bottom plate and has an opening that introduces the flow into the system. This model allows different shear stresses to be applied on the cultured endothelial cells through fluid flow changes through the system. Using Solidworks, the flow chamber was created to include the main pulmonary artery, the left pulmonary artery, and the right pulmonary artery.

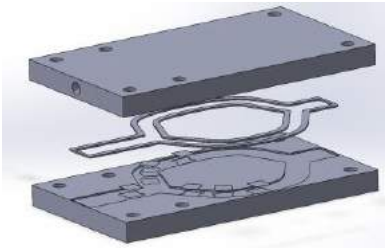

**Figure 1: Solidwork model of the 2D flow chamber. Parts include a bottom plate, glass slides, a gasket, and a top plate.**

Using Solidworks, flow simulations were run to confirm the increased shear stress that would be experienced on the cells by introducing an input volume flow rate of 5 L/min similar to the rate that the heart pumps blood through the pulmonary arteries to the lungs [3].

## RESULTS

Fluid flow simulations were performed on the 2D CAD model to compare the shear stress produced along the pulmonary artery with or without a pneumonectomy. These simulations revealed that the shear stress produced by the single pulmonary artery remaining after a pneumonectomy was significantly higher than the regular shear stress experienced by the pulmonary artery without undergoing a pneumonectomy.

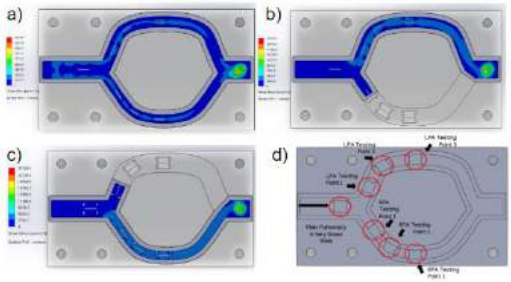

**Figure 2: Flow simulations of shear stress completed on solidworks. a) no pneumonectomy model b) right pneumonectomy model c) left pneumonectomy model d) shows the seven testing points where shear stress is being measured**

Shear stress was measured in seven different locations which is where the glass slides were placed. Figure 2 displays the shear stress overly throughout the model due to the flow for the three different models.

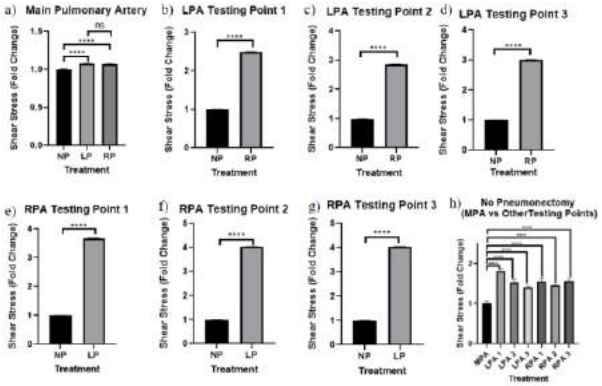

**Figure 3: Statistical analysis of difference in shear stress for the seven different testing points in the three different models (no pneumonectomy (NP), left pneumonectomy (LP), and right pneumonectomy (RP). a) Anova analysis comparison between the three models at the main pulmonary artery testing point. b) T-test analysis between the NP and RP models at LPA testing point 1. c) T-test analysis between the NP and RP models at LPA testing point 2. d) T-test analysis between the NP and RP models at LPA testing point 3. e) T-test analysis between the NP and LP models at RPA testing point 1. f) T-test analysis between the NP and LP models at RPA testing point 2. g) T-test analysis between the NP and LP models at RPA testing point 3. h) Anova analysis for the NP model comparing the MPA testing point against all other testing points. For all statistical testing there was strong significance found.**

Statistical analysis (including Anova analysis & t-tests) were used to determine if there was statistical significance in the shear stress between the no pneumonectomy model and the two pneumonectomy models. As seen in figure 3, the shear stress observed at all 7 testing points during either type of pneumonectomy, when compared to the no pneumonectomy model, had very high significance.

## DISCUSSION

With the flow simulations showing an almost 300% increase in shear stress after a pneumonectomy, the amount of shear stress on the endothelial glycocalyx is nearly triple what it would normally be. This data and information can be critical in helping reduce the mortality rate of patients with complications post-pneumonectomy. Furthermore, the results show a significant increase in shear stress depending on which lung is removed. Using the data from the flow simulations, a left pneumonectomy had a higher shear stress result than the right pneumonectomy.

The future direction of this project is to test the model with Human Lung Microvascular Endothelial Cells and measure the effect of exposure to shear stress for longer periods of time in each condition. By increasing the flow by sectioning off one side of the arteries represented in the chamber, the shear stress will increase. Imaging and staining analysis tools will further allow us to examine how increased shear stress affects these cells, modeling how the endothelial glycocalyx is affected after a pneumonectomy.

Other future work for this project includes designing a 3D model that will hopefully confirm what was found in the 2D model for shear stress on the cells. The 3D model will be more anatomically correct, including the diameters, lengths, and angles of the pulmonary arteries, following the actual shape of the pulmonary arteries. This will allow for a more accurate representation of the pulmonary arteries and how the cellular components of the endothelial glycocalyx are affected by increased shear stress resulting from a pneumonectomy or increased blood flow.

## ACKOWLEDGEMENTS

The authors would like to Dr. Aaron Waxman and Dr. Solomon Mensah for the valuable support, direction, and discussions, and the Biomedical Engineering Department at Worcester Polytechnic Institute, and by the WPI Provost Startup funds awarded to Solomon A. Mensah for funding.

## INTRODUCTION

More than 80% of medical schools and 87% of nursing schools have integrated high-fidelity human simulation mannequin-based training into their curriculum [1]. Simulation mannequins provide an immersive learning environment by mimicking real-life clinical scenarios that healthcare workers will potentially encounter in the field. These realistic education opportunities allow students to enhance their skills and competencies in a controlled and risk-free environment.

While today's high-fidelity human simulation mannequins are equipped with multiple intricate features, there is still a lack in the ability to replicate several essential, clinically relevant attributes that improves the realism of simulations. One attribute is the ability to realistically assess body temperature from the mannequin. Human body temperature can serve as an early warning sign of infection, illness, and injury. As a result, it is one of the first vital measurements taken during a clinical assessment to determine a treatment plan. During the COVID-19 pandemic, the importance of proper temperature assessment escalated as part of the effort to identify potential carriers of the virus. Temperature measurements were taken in more locations than ever before, including, but not limited to, hospitals, schools, workplaces, and airports.

Given the reliance on temperature, it has become essential that medical professionals, such as nurses, should have temperature assessment integrated into their simulation regimes, so they can practice taking human body temperature and evaluating the potential causes of a patient's elevated temperature. Therefore, there is a need to incorporate a temperature assessment component into existing simulation mannequins that can accurately portray the qualitative and quantitative components of human body temperature.

The prototype proposed by our team will have two components; (i) a qualitative component that will allow tactile assessment of the mannequin's temperature and (ii) a quantitative component that will allow the user to directly measure temperature from the mannequin's surface. As in all simulation set-ups, the instructor will predetermine the simulation mannequin's temperature based on the clinical scenario, and then configure both the qualitative and quantitative components prior to the simulation lab experience. Overall, this project will result in a prototype that will enhance the realism of simulation-based education and better prepare medical professionals for real-world clinical experiences.

## PRODUCT DESIGN

After careful consideration of the input from the expected users and discussion to identify constraints and need, several design criteria were considered for this project. The most significant criteria of those criteria are safety, ease of use, interchangeable between mannequins, low cost, minimal maintenance, temperature-controlled, and realistic, in terms of temperature assessment and appearance. Additionally, it is important to keep manufacturing standards in mind for the eventual production and sale of this device.

Based on the design criteria to address the quantitative objective of this project we are building a radio frequency identification (RFID) temperature measurement system which focuses on high precision and realistic measurements of temperature. As shown in Figure 1, the system features an RFID chip containing stickers with unique IDs and a device that mimics the role of the thermometer (scanner). The scanner's main components are an RFID scanning element, microprocessor, LCD display, and various buttons for operation. These components of the scanner will be housed in an in-house 3D printed case that will resemble a typical thermometer present in a mobile stand for vital signs measurement.

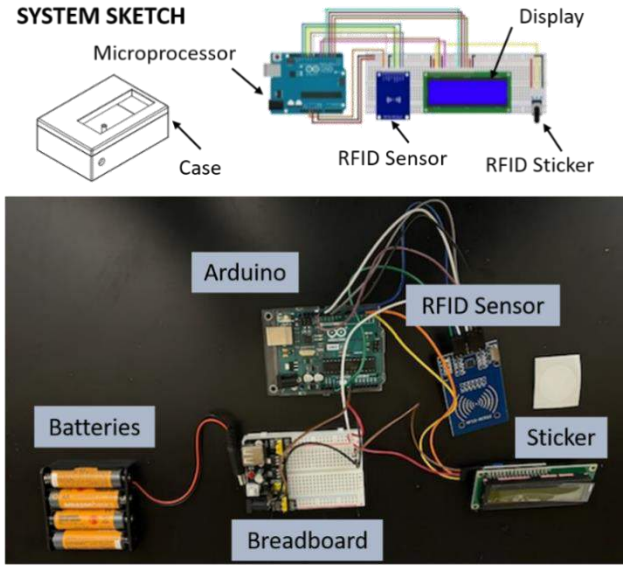

**Figure 1: Current layout of the quantitative component**

Prior to simulation, an instructor will be required to place the RFID stickers on the mannequin in reasonable locations for measurement sites, for example the oral cavity. The instructor will then preset the

output value that resembles the desired temperature for the simulation scenario. For student use, they simply need to operate the scanner like a contact tip thermometer, placing the probe element near the stickers and the device registers the ID causing the LCD screen to display the corresponding temperature. The provision for students to measure temperature in the aforesaid manner is an important aspect of realism that has been integrated into this prototype.

The major benefits to the users of this device are the precise, controllable temperature read-out and the realistic motion needed to operate it. Additionally, different cases can be programmed to fit the needs of the simulation: such as an increase in temperature in order to simulate hyperthermia or a drop in temperature in order to simulate hypothermia. The device is easy to operate and transferable between mannequins making it a robust standalone design. The major drawback to this design is that it lacks a tactile assessment component, I.e., it does not produce heat. We sought to mitigate this issue by incorporating a second component that meets the qualitative objective of the project since tactile assessment was determined to be equally as beneficial to the simulation as the quantitative assessment.

The qualitative component (shown in Figure 2), that addresses surface heat sensation, consists of a band heater that sits on top of a resistive base, with a layer of skin colored material on top of the band heater. A piece of Velcro allows the device to be strapped onto the forehead/forearm. The resistive base prevents heat conduction to the underlying mannequin and the skin-colored material on top resembles human skin. An attached controller allows the instructor to set the desired temperature output based on the simulated scenario requirements. The temperature is maintained using a thermocouple. This controller and the band heater are powered by rechargeable batteries. These electrical components are designed to be tucked away below the simulation bed so that it is not in the way during the simulation.

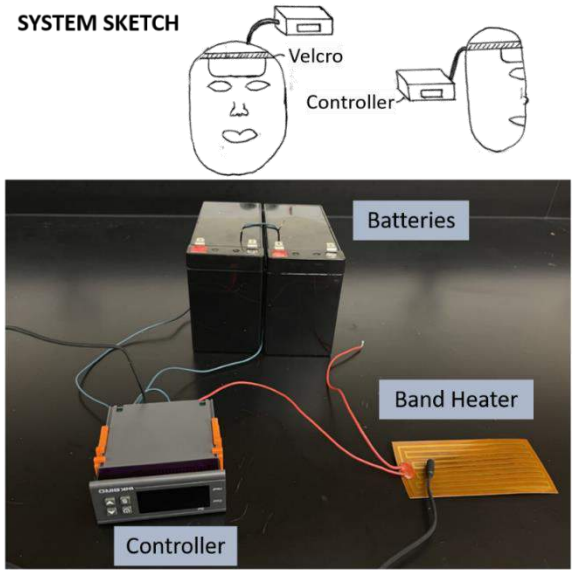

**Figure 2: Current layout of qualitative component**

The main benefit of this design is that it is mobile and reusable. This design can easily be moved between mannequins and, since it is battery powered, the simulation mannequin can be moved from one location to another without having to disconnect the device. The batteries also prevent extra wires from being present in the simulation and avoid the need for a nearby outlet power source. Constructing the device is simple because it can be easily assembled from a series of preexisting electronic components.

The proposed final design is a combination of the two described components, envisioned to be housed in one organized tower. This tower will contain the electrical components of the qualitative design, the controller, batteries, and wiring, with a storage location for the heated portion when not on the mannequin's forehead. It will also have a system to hold the quantitative mock thermometer realistic to true hospital probe placement techniques. This tower will condense the two components and be reasonably sized to fit next to the mannequin's bed without interfering with the simulation.

## BUDGET & MARKET ANALYSIS

The budget for this project is $550. This budget includes building and testing the prototype, and a contingency. So far, $247.45 has been spent to develop both the quantitative and qualitative components of the design. The next steps are to test the qualitative component that has been built, program the quantitative component, and purchase casing materials for both components. Given the forecasted work and remaining materials that need to be purchased, it is predicted that the proposed final design will cost, at most, $450 to develop.

Based on the "Mannequin-Based Simulation - Global Market Trajectory & Analytics" report [2], the global market for mannequin-based simulation estimated at US$1.2 Billion in the year 2020, is projected to reach a revised size of US$5 Billion by 2027, growing at a CAGR of 22% over the period 2020-2027. Given that our product is a standalone system, it not only has potential in the newly manufactured mannequin market, but could also be integrated into the existing mannequins, resulting in a very large market for the product. Additionally, since the product is easily interchangeable between different mannequins (irrespective of size, functionality, manufacturer), individual institutions do not need to acquire independent products for all their mannequins. This cost-effective option makes the product a lucrative investment for institutions. As mentioned earlier, the potential market size for this device branches to schools that utilize human simulation mannequins in their clinical simulations which includes 87% of nursing schools and 80% of medical schools [1].

Based on this need and the current growing market for human simulation-based mannequins, we could be considering selling about 150,000 temperature assessment units a year (100K for existing mannequins and 50K for newly manufactured mannequins). After developing the initial prototype, the forecasted price to build a single device is $345.65 and the projected sell price is $1000 per unit the net gain on one unit at this price would be $654.35. This gain would be used in for marketing the product, renting lab space, employing engineers for mass production and in other relevant expenses related to manufacturing. After all the expenditures we still envision to make an approximate profit of 25% on the selling price of each device.

## ACKNOWLEDGEMENTS

We would like to extend our thanks to Widener University's School of Nursing for allowing us access to their simulation lab and providing us with feedback. We would also like to thank David Leuter, Tyler Hoikins, Dr. Syed Ali Hamza, and Dr. Piotr Hryniewicz for their assistance in the development of our prototype.

## INTRODUCTION

There are currently over 100,000 people on the national transplant waiting list [1]. In 2020, only 39,000 people were able to receive the life-saving procedure [1]. Lack of efficient preservation methods is one of the leading reasons as to why only 30% of the people on the transplant list are able to receive the transplant procedure. The current gold-standard method of preservation is known as static cold storage (SCS), although hypothermic machine perfusion (HMP) has been discovered to provide better perfusion pressures and oxygenation rates [2]. There are six major competitors within the organ preservation market: Paragonix Tecnhologies, Inc; 21st Century Medicine, Inc; Essential Pharmaceuticals LLC, Organ Recovery Systems, Inc; and Preservation Systems, Inc; and Transmedics, Inc. [3]. Unfortunately, the systems produced by these companies are all organ specific, electrically powered, and either only provide static cold storage or provide perfusion but are prohibitively expensive to purchase and operate. Due to these issues, hospitals are required to have a variety of organ preservation devices on hand. Many of them are non-portable, which eliminates them from use when the donor and recipient are not at the same hospital.

The proposed device to sufficiently versatile to preserve a variety of organs and tissues, is pneumatically powered, and has a streamlined design with fewer moving parts which is intended to lead to a substantially reduced price point. We have named this device the multi-organ preservation system (MOPSY) [4]. The MOPSY device was designed to be portable and easy to use while providing the necessary components to effectively transport a variety of organs that range from hypothermic to normothermic temperature ranges making it more versatile than various organ preservation devices because that can only manage hypothermic machine perfusion or normothermic machine perfusion. In addition to that, other devices do not supply oxygen to the organ but it has been shown that oxygenation of the perfusion solution increases the quality of preservation which the MOPSY device does. For battlefield usage, the device being small and lightweight are key benefits due to space constraints in field hospitals, as well as the need to transport between the donor and recipient. The device being nonelectric allows it to be in settings out on the field where power may not be as easily accessible.

## PRODUCT DESIGN

The MOPSY device is composed of two main chambers: the pump chamber and organ storage chamber. Figure 1 shows the 6 total components: the top cap, the silicone tubing, the fastening lid, the tube casting, the organ chamber, and the base cap. The top chamber consists of the top cap, the silicone tubing, and the fastening lid. The silicone tubing is positioned in helical coils for optimal effectiveness and can be bought to fit the specification of the device. The organ storage chamber is the lower half of the device; it contains the base cap and the organ chamber which is made out of acrylic and has the capacity needed to store a human sized kidney, liver, heart, pancreas, or forelimb. The chamber has threads machined on the out end which allows other components, specifically the pump cover and the base cap, to be easily fastened to it. The top cap, pump chamber, fastening lid, and base cap are machined out of 6061 aluminum. Both chambers of the device are filled with a perfusion solution.

Compressed oxygen inflates and deflates the silicone tubing causing circulation of the perfusion solution to occur through two separate one way valves. In the organ chamber, a catheter could be directly connected from the pump chamber to the organ through a perfusion point allowing the perfusion to circulate through the organ. After circulating, the

perfusion solution exits the organ and mixes with the perfusion solution that organ is immersed in. In turn, this forces the perfusion solution from the organ chamber back into the pump chamber through the perfusion return port.

Currently, the device is set up to conduct tests regarding various viscosities and silicone tubing lengths. Aspects that make the device novel include it ability to preserve multiple organs entirely free of electronics, while being lightweight and easily transportable. The addition of a pneumatic circuit allows the device to be free of electronics, and it operates by having two valves that work synchronously. Within each of the valves, there is a piston that has two positions that gets turned on and off through the compressed oxygen that is provided. When one valve is open, the other valve is in the closed position, and their outputs feed into each other's inputs, ultimately providing pulsatile flow. The device so far has proved to be technically feasible from the approximate 200 hours of total data collected.

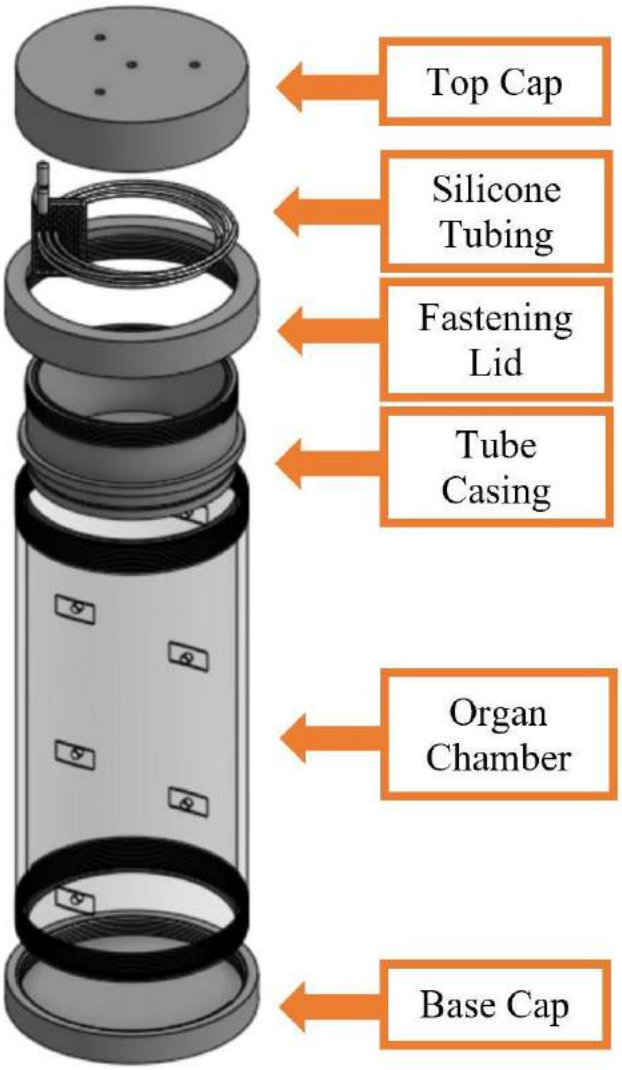

**Figure 1: MOPSY Device**

## BUDGET & MARKET ANALYSIS

The organ preservation market it forecasted to grow nearly 6.3% within the time period of 2018-2026 [3]. This initial investment of engineering and tooling is a one-time purchase for design purposes. According to the U.S. Bureau of Labor and Statistics, the average labor cost of designing a device is roughly $35 per hour (U.S. Bureau of Labor Statistics, 2020), and $22-26 per hour for testing and machining (U.S. Bureau of Labor Statistics, 2020). Within the research department there has been over 140 hours of design, machining, and testing the device, if valuating the volunteer hours towards the average labor cost would translate to $27.6 per hour at 140 hours equating to $3,850 labor. The material cost for a singular device is approximately $650 using acrylic, silicone tubing, aluminum, and the pneumatic circuit. Thus, the initial prototype development is approximately $4,500, which includes the labor and material costs ($3,850 and $650, respectively). Those costs could change depending on different manufacturing processes and specifications to optimize material and machining cost, but will not be addressed in this discussion.

There are approximately 36,000 transplants per year, including kidneys, livers, hearts, and pancreases. Since the MOPSY device has been shown to achieve perfusion parameters for all of those organs, there is a large market pool. Pricing the device at $5,000 for consumers covers the initial costs for the device as well as $1,150 in profit per device sold. That market price would be extremely competitive, as competitors' disposable packages cost roughly $10,000 (not including the device itself). The profit margin could be further increased with possible alternatives due to manufacturing costs and materials used. In addition to the reduced cost, this device offers the versatility to be utilized for a non-specified organ preservation method. In the event that 36,000 units are sold per year at a price point of $5,000 each, the yearly gross income would be $180,000,000. That estimation does not account for the potential to increase the donor pool and number of organ donations, as this technology presents the opportunity to be used for various organs, rather than buying multiple different devices.

## ACKNOWLEDGEMENTS

# THE IMPACT OF HYPERGLYCEMIA AND OVARIECTOMY ON HOST RESPONSE TO VAGINAL PROLAPSE MESH IMPLANTS

**A. Fisk (1), G. King (2), K. Weber (2), R. Liang (2),**

(1) Department of Bioengineering, University of Pittsburgh, Pittsburgh, Pennsylvania, United States of America

## INTRODUCTION

Pelvic organ prolapse (POP), a common pelvic floor disorder in menopausal women, is often treated with surgical repairs. Compared to native tissue repair which has high failure rate (~70% at 6 years), mesh augmented surgeries are related to better outcomes. However, the use of mesh is associated with several mesh related complications such as mesh erosion through the vaginal cavity and chronic pain [1]. These complications hamper the use of mesh in urogynecologic surgeries.

Diabetes, which affects 1 in 10 women in the US, has been associated with higher rates of mesh related complications and has been identified as an independent risk factor by previous literature [2]. Mechanisms which increase the risk of mesh complications in diabetic patients are unknown. The hypothesis is that impaired wound healing caused by hyperglycemia dysregulates the mesh associated inflammation (MAI) and therefore causes higher rates of mesh complications within this group of patients.

In addition, previous literature has shown that the significant decrease in estrogen following menopause has adverse effects on cell functioning and tissue [3]. Recently site-specific hormonal treatments have been popularized for the management of mesh complications. As many women with diabetes undergoing mesh augmentation surgeries are also postmenopausal, the objective of this study is to compare the mesh associated inflammatory response under hyperglycemic and normoglycemic conditions with/without ovariectomy. As both conditions have potential impact on the vaginal tissue integrity, this study also examines the effects of both factors on vaginal muscularis in the context of mesh implantation.

## METHODS

Diabetes was induced in 18 rats with 19 nondiabetic rats being used as controls. Two weeks following the development of hyperglycemia, a polypropylene mesh was implanted on the anterior and posterior vagina via sacrocolpopexy after a supracervical hysterectomy with or without a bilateral ovariectomy (OVX). Nondiabetic rats underwent the same procedures. At 42 days (OVX diabetic n = 9 & nondiabetic n=10 and non-OVX groups, diabetic n = 9 & nondiabetic n =9) post-surgery, mesh-grafted vaginal tissues were collected for gross morphology and histology analysis**.**

Harvested tissue was cryosectioned and stained using a Hematoxylin & Eosin (H&E) and Masson's Trichrome staining protocol. Three indexes of inflammation were quantified. The overall area of MAI (fibrosis capsule + granuloma area) and foreign body giant cell (FBGC) formation was quantified in H&E-stained samples. In Trichrome stained samples the area of the granuloma was also quantified (figure1).

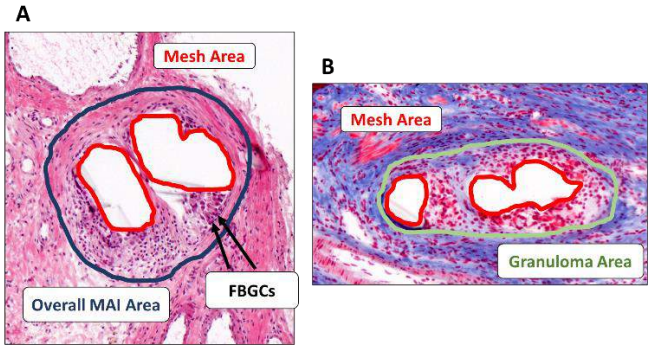

**Figure 1. Shows quantified gross morphology of the three indexes of inflammation in H&E samples (A) and Trichrome samples (B).**

In Trichrome stained samples the SM wall thickness was measured at intervals of approximately 100 μm. SM wall measurements were spilt into two groups: SM wall without mesh impact, and SM wall impacted by mesh. SM wall impacted by mesh was defined as the SM wall

adjacent to the mesh fibers and areas within a 100 μm ratio horizontally from the mesh fibers (figure 2).

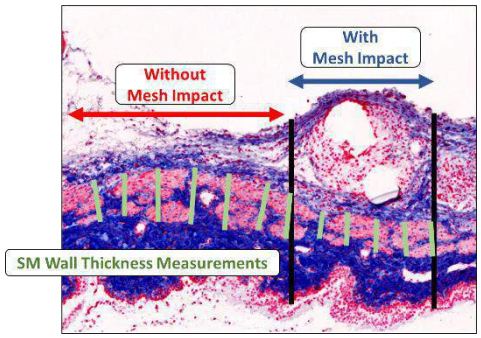

**Figure 2. Shows SM wall thickness quantification method in areas with mesh impact and areas without mesh impact.**

JMP pro was used to preform comparative analysis between the diabetic & nondiabetic groups and the OVX & non-OVX groups. All comparisons were made using Kruskal-Wallis tests. Significance for all analysis was set at $\alpha = 0.05$.

## RESULTS

Positive correlations were found between mesh fiber area and each index of inflammation, overall MAI, granuloma area, and FBGC formation, under normoglycemic conditions ($p < .01$ for all groups). Similar trends were observed under hyperglycemic conditions.

Without OVX, overall MAI, granuloma area, and FBGC formation were all significantly increased in diabetic rats ($p = 0.0031$, $p = 0.0274$, $p = 0.0022$). With OVX, granuloma area and FBGC formation significantly increased under hyperglycemic conditions compared to normoglycemic conditions ($p = 0.0014$, $p = 0.0086$) while overall MAI was not found to be significantly changed despite an increase by 60 % in diabetic rats (figure 3). OVX was not found to significantly affect inflammatory response when comparing rats with OVX and without OVX under both glycemic conditions.

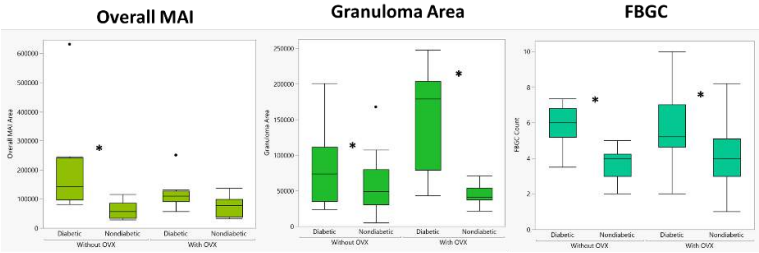

**Figure 3. Shows comparisons of diabetic and nondiabetic rats relating to the three indexes of inflammation.**

Smooth muscle wall thickness was significantly decreased in areas impacted by mesh fibers when compared to areas not impacted by mesh fibers in both diabetic and nondiabetic rats without OVX ($p = 0.0469$, $p = 0.0284$) (figure 4).

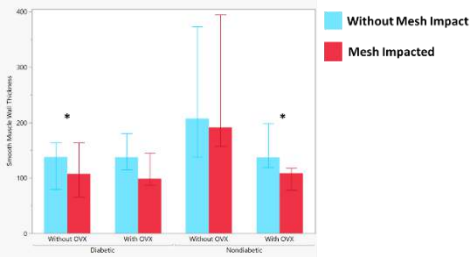

**Figure 4. Median SM wall thickness in areas both impacted by mesh and areas without mesh impact.**

OVX was found to significantly decrease smooth muscle wall thickness in areas adjacent to mesh fibers under normoglycemic conditions ($p = 0.0014$). However, no significant difference was found between the smooth muscle wall thickness in OVX and non OVX samples under hyperglycemic conditions.

Further, SM wall thickness was significantly decreased in diabetic rats when compared to nondiabetic rats without OVX in areas impacted by mesh fibers ($p = 0.0274$) (figure 5).

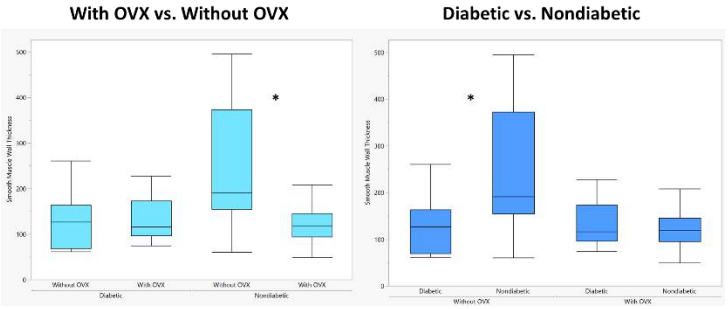

**Figure 5. Shows comparisons of SM wall thickness in OVX vs. non-OVX groups and diabetic vs. nondiabetic groups**

## DISCUSSION

Quantification of the mesh associated inflammatory response shows that inflammation is dysregulated under hyperglycemic conditions at a long-term time frame, which may contribute to the increased risk of mesh complication. The dysregulation of inflammation in diabetic samples occurs independent of estrogen levels.

While estrogen does not seem to have a significant effect on inflammation the presence of surgical menopause significantly decreases the smooth muscle wall thickness in areas impacted by mesh fibers. Hyperglycemia also has a significant effect on the SM wall thickness but only without postmenopausal conditions. This could indicate that the effect of hyperglycemia on SM wall thickness is increased without estrogen withdrawal. Another possibility is that under postmenopausal conditions smooth muscle wall thickness is too dysregulated to show any significant differences between diabetic and nondiabetic samples. While this could be hypothesized further research on SM wall dysregulation is needed to confirm the observations made in this study.

Data from this study also suggests that as mesh fiber area increases inflammation increases. This supports previous literature which supports the use of stable mesh configurations which decrease the risk of shrinking and buckling.

This study highlights several components of a dysregulated host response under hyperglycemic conditions. The exact molecular mechanisms causing dysregulation should be examined in future work. Targeting both MAI and SM wall formation could have the potential to develop effective therapeutic strategies for the management of mesh complications in patients with diabetes.

## INTRODUCTION

Cardiovascular disease remains as the leading cause of death worldwide, with mortality strongly correlated with coronary artery disease and commonly observed as stenosis or occlusion of blood vessels leading to myocardial infarction. Engineered tissue vascular grafts (ETVGs) promise an attractive alternative option to autologous grafts typically employed in coronary artery bypass grafting surgery.[1] In theory, ETVGs hold many advantages such as relieving supply limitations, the ability to grow and repair in vivo, and lacking the need of either using the internal mammary artery or harvesting the saphenous vein. However, more research is necessary before this technology can reach clinical application. The main hurdles lie in achieving similar mechanical properties of native vessels as compliance mismatch is a strong factor correlating with grafting success. It is known that mechanical conditioning of engineered tissues during incubation improves their properties and physiological function; specifically, biaxial loading of ETVGs has been shown to improve vascular mechanics.[2] However, there is a lack in systematic understanding of the parameters driving ETVG growth and remodeling during in vitro incubation and the resulting patency of the ETVG once deployed in vivo. Therefore, more research is necessary in determining the ideal protocols of mechanical stimulation to produce viable ETVGs. Unfortunately, access to bioreactors capable of providing this stimulation is a limiting factor in the field due to complexity and cost.[3] A low-cost, automated, robust, and reproducible method for experimenting with in vitro culture of ETVGs is needed to progress the field through systematic collection of data for model generation. Here, we propose and validate a custom designed dynamic biaxial bioreactor to meet these criteria.

## METHODS

Axial Stimulation. The bioreactor is designed to accept four electrospun PCL scaffolds of 2mm diameter, 3cm length, and 200μm thickness suitable for deployment as an aortic interposition graft in rats. A novel scaffold mounting system and associated fixturing procedures were developed to grip the scaffolds. The scaffolds are attached to stainless steel cannulas at both ends, and these cannulas are gripped by collets that hold the scaffold and stretch it between two spaced brackets made of stainless steel. The system ensures consistent mounting results while minimizing leakage and scaffold damage at mounting points. Axial stretch on the scaffolds is achieved through the use of a linear actuator acting on one of the brackets through a linear bearing system with minimal resistance. The use of a single linear actuator simplifies the bioreactor design, yet it retains the capability of providing uniform axial displacement to four scaffolds simultaneously.

Circumferential Stimulation. A closed bioreactor flow system was developed to provide cell media circulation through the scaffolds as well as control over the pressure and velocity of the fluid, and it serves as an analogic fluid level sensor on the culture chambers. The system utilizes a single multi-channel pump and a four-channel pinch valve placed downstream to regulate the pressure in the loop. Circumferential strain is controlled by coordinating the controls of the pump and pinch valve via software to achieve predetermined pressure levels in the scaffolds. To prevent cross-talk and possible cross-contamination, each scaffold has an independent flow loop with an isolated bioreactor chamber and cell media reservoir.

Bioreactor Design and Construction. The bioreactor was designed in Solidworks. The main body with 4 separate ETVG chambers was developed with 3D printing constraints in mind, specifically for FDM manufacturing with ABS thermoplastic. The remaining pieces of the bioreactor system are primarily off-the-shelf parts and electronics. While some of the brackets are custom, they were designed for reproducibility and ease of manufacture. Overall, the design is not technologically demanding, and the construction can be easily and quickly performed with basic tools. Sterility during seeding and incubation is another integral design feature. A custom room-

temperature-vulcanizing silicone gasket was developed, which was formed and cured in a 3D printed mold; this method is simple to recreate and could be easily scaled. The gasket provides an air-tight seal for the lid of the incubator to avoid contamination in culture. The linear bearing system and the inlets and outlets of the flow system were also designed to prevent exposure of the inner chamber of the bioreactor to the incubator environment.

Software Control. A custom user interface was developed to control the bioreactor system in LabView. The user can adjust all inputs to control the pump velocity, axial stretch magnitudes and frequencies, max pressure, time to hold pressure, number and duration of cycles, etc. The fine control over these parameters allows for future experimentation with different mechanical stimulation procedures on the scaffolds. Additionally, a single Texas Instruments data acquisition board controls all the electronic components of the bioreactor. The entire assembly can easily be transported in a single tray and placed on an incubator shelf with the possibility being able to run 2 bioreactors simultaneously in a standard 160L incubator.

Validation of Mechanical Stimulation. A computer vision program was implemented for tracking the circumferential and axial strain response of the scaffolds. Grayscale-based edge tracking of the scaffold reports changes in the diameter. For the axial component, three dots are drawn on the scaffolds and the distances between them are used to compute axial stretch. Additionally, a pressure sensor was added to the flow system to measure luminal pressure inside the ETVG. Test scaffolds were produced by casting silicone around a brass rod of 2mm diameter to match the desired scaffold dimensions. After curing, the thin silicone tubes were pulled off the rod and cut to length for use in validation of the axial and circumferential strain feedback in the bioreactor flow loop. Impermeable silicone model scaffolds were a useful tool for prototyping the pressure system and the actuation for axial stretch by providing repeatable strain values from the various inputs.

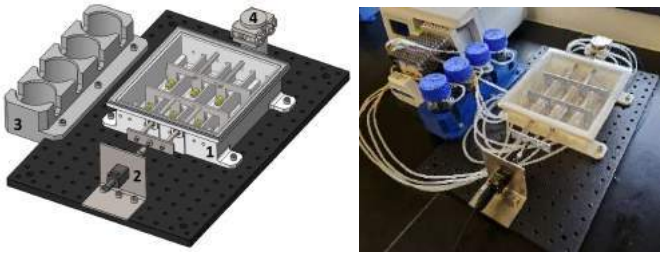

**Figure 1: Final 3d-CAD assembly (left) and constructed bioreactor (right). Legend: 1) Bioreactor Chambers, 2) Linear Actuator, 3) Reservoir Fixture, 4) Pinch Valve.**

## RESULTS

The custom-designed ETVG bioreactor (Figure 1), was demonstrated to be effective in producing axial and circumferential stretch on small-diameter tubular scaffolds. The control programs and hardware effectively delivered the desired inputs to the bioreactor, and outputs could be measured with sufficient accuracy. The computer vision measurement system was capable of recording deformations less than 0.1mm in the scaffolds. We were able to prescribe any type of combination of axial and circumferential stretches. Circumferential stretch is achieved with a three-phase cycle (Figure 2) that involves a sequential activation of pump driving flow with pinch valve closing downstream to build luminal pressure. We found a linear correlation between time and pressure/diameters achieved, which could then be held for any duration until valve opens and initial diameter is recovered. Axial strain implementation was also validated; we found that displacement of the linear actuator applied strain directly and uniformly to the scaffolds as expected. We were able to reproducibly impart axial strains of ~10% and circumferential strains of ~4%, which are typical values of physiological strains observed in vivo due to pulsatility.[2] These results were met while maintaining a low cost for the bioreactor. In total, the system costs about $450 in hardware and $5,800 in electrical components, most of which are standard laboratory equipment that may already be available.

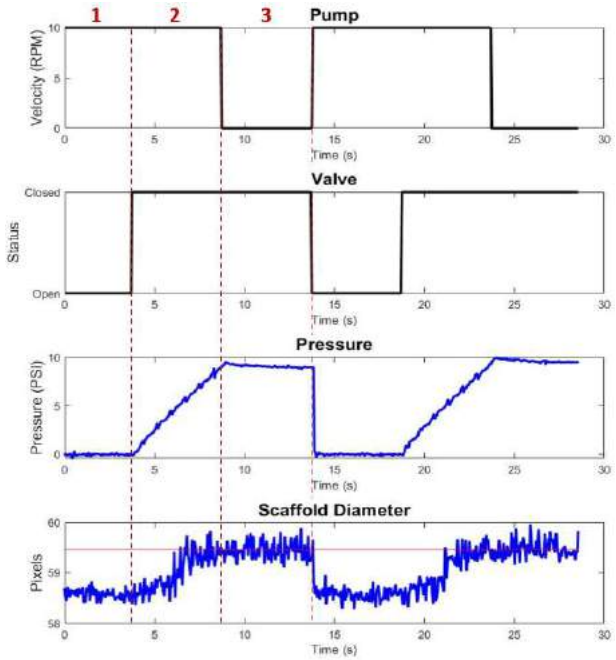

**Figure 2: Cyclic circumferential strain data from bioreactor operation. Inputs are shown in black and outputs in blue. Vertical red dashed lines show different phases of the pressure cycle.**

## DISCUSSION

3D printing holds many advantages as a manufacturing process in this application.[4] First, it allows the bioreactor to remain low-cost relative to commercial alternatives. Additionally, 3D printing allows for rapid prototyping of the bioreactor, making it simple to perform future design iterations if desired. The technology is also easily accessible, which contributes to the reproducibility of the design. Increased availability of bioreactor technology for dynamic mechanical stimulation of engineered tissues during their incubation will enable systematic experimentation of ETVG development and determination of ideal mechanical stimulation protocols. Additionally, the bioreactor is easily scaled; a sample size of n=8 can be achieved with two bioreactors in one standard-size incubator. Due to its low cost, reliable results, and ease of manufacture and assembly, the proposed dynamic biaxial bioreactor holds potential for broader impact in the field of small-diameter vascular graft tissue engineering.

# ESTIMATION OF FLOW DATA FROM ANGIOGRAPHIC TIME SERIES

## INTRODUCTION

Coronary artery disease (CAD) is one of the most widespread causes of heart disease, accounting for over 20% of adult mortality in the US [1]. CAD is characterized by a buildup of plaque in the coronary arteries known as stenosis. The condition is diagnosed using X-ray angiography, in which dye is injected into the patient's bloodstream to estimate diameter reduction of the arteries. While diameter reduction is useful for informing clinical management of the disease, functional metrics such as Fractional Flow Reserve (FFR) lead to better patient outcomes [2]. FFR, defined as the ratio of distal and proximal coronary pressures, provides a quantitative measure of stenosis severity. Traditionally, FFR is measured via an invasive pressure guidewire which is pulled through the stenosed artery to record pressures proximal and distal to the stenosis. However, this technique presents several risks to CAD patients and has great inter-operator variability [3].

To eliminate these drawbacks, patient specific computational fluid dynamics (CFD) simulations of coronary blood flow can be used to derive FFR. A major challenge of these simulations is determining patient-specific boundary conditions, particularly since the flow and pressure in each vessel are not typically measured clinically. In this work, we developed an algorithm to extract patient-specific flow information from an angiographic time series. Previous work on angiographic velocity extraction has preliminarily explored comparison of extracted flow to simulation results or doppler measurements using techniques such as spline fitting [4, 5]. However, this is the first implementation of a flow estimation algorithm that tracks changes in 2-D planar vessel area in an angiographic time series compared against simulation results, ultimately with the goal of creating patient-specific flow boundary conditions.

## METHODS

We generated synthetic angiography data based on patient-specific blood flow simulations performed using CRIMSON [6] to evaluate the accuracy of our flow-extraction algorithm in controlled conditions (no cardiorespiratory motion, steady flow, known ground truth flow in each branch of the coronary tree. We extracted flow in each branch of two models: one healthy right coronary tree and one containing a stenosis (Fig. 1A).

The 3D geometry of the right coronary artery (RCA) was reconstructed from computed tomography angiography (CTA) images. Boundary conditions were assigned to the model as follows: a steady flow of 0.1 L/min was assigned at the inlet, resistances were assigned to the outlets, and no slip was applied at the walls. Resistances were tuned until the flow in each branch matched literature values [7]. A scalar species—angiography dye—was introduced at the inlet with a constant concentration of 200 mol/mm$^3$, and the position of the dye was tracked over time. The results of 3D scalar transport were converted into a binary angiographic time series (Fig. 1B) by projecting the dye onto manually chosen image planes at several time steps. We chose viewing angles where the distal branches were most clearly visible to minimize error due to foreshortening (Fig. 1C). The procedure was repeated in the same model, but with a 92% stenosis added to the medial RCA.

Once the angiographic time series was generated, an algorithm based on that of Khanmohammadi *et al.* [5] was used to automatically extract velocity. For each frame, a Euclidean distance transform was used to compute the radius along the centerline in the vessel of interest; the area was approximated as the vessel diameters summed along the centerline. The difference in area per branch between consecutive frames was plotted as a function of time. The flow in each branch was calculated using the area as a function of time and vessel radius as

$$\mathrm{Q(t)} = \frac{\frac{\mathrm{d}}{\mathrm{dt}}(A(t))}{2R} \cdot \pi R^2 \qquad (1)$$

where $Q(t)$ is the flow [mm$^3$/s], $A(t)$ is the area of the vessel as a function of time [mm$^2$], and $R$ is the mean radius of vessel [mm].

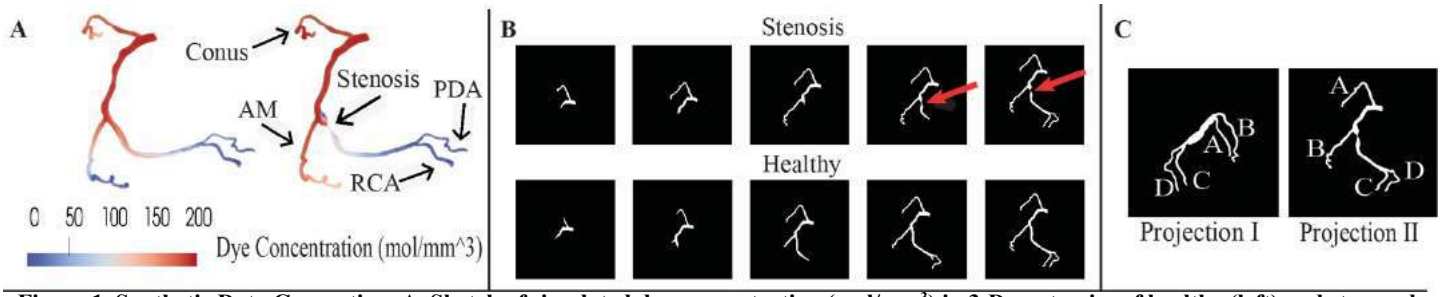

**Figure 1. Synthetic Data Generation. A. Sketch of simulated dye concentration (mol/mm$^3$) in 3-D anatomies of healthy (left) and stenosed (right) coronary trees. B. Simulated angiographic time series for the stenosed (top) and healthy (bottom) trees, used to extract flow data. C. Two projections depicting the PDA (D), the RCA (C), the AM (B), and the conus (A).**

Percent flow in each branch was calculated by dividing its flow by the flow at the inlet of the right coronary tree.

Flow was calculated for each of the four branches of interest—the posterior descending artery (PDA), the right acute marginal (AM), the conus, and the distal main RCA. The relative flow in each branch was averaged between two projection angles to mitigate the error due to foreshortening or magnification from projecting a 3-D structure onto a 2-D plane.

## RESULTS

Figure 2 compares the ground truth flow in healthy and stenosed coronary trees with the estimated flows from our flow extraction algorithm. The mean percent error between the simulation values and the algorithm values is 21.5±6.29% in the healthy coronaries and 15.2±5.69% in the stenosed coronaries. Plots of the estimated flow vs time in each branch for both the healthy and stenosed model are presented in Figure 3.

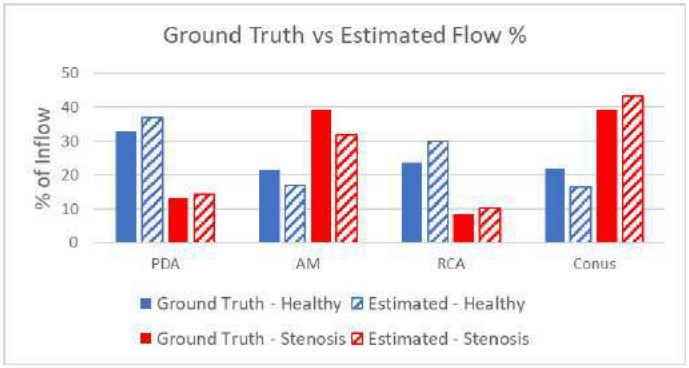

**Figure 2 - Percent flow values of healthy and stenosed coronaries, including both simulation and algorithm flow values.**

## DISCUSSION

The flow estimation algorithm successfully distinguished the change in relative flow values in each branch between the healthy and stenotic models. According to the ground truth simulations, the addition of the medial RCA stenosis leads to decreased flow in the branches distal to the stenosis (PDA, distal RCA), while the proximal branches (AM and conus) would have an increased flow compared to the non-stenotic geometry. This is depicted in our measured values, as the PDA changed from 36.8% flow to 14.4% flow with the stenosis. Similarly, the RCA changed from 29.9% without the stenosis to 10.3%. with the stenosis. Both the AM and conus flow percentages increased as well, going from 16.9% and 16.5% to 31.8% and 43.4% respectively.

Relative to the ground truth data, the estimated values of percent flow were similar in most branches. The largest error was a 26.7% percent error between the estimated and ground truth distal RCA flow in the healthy model. Discrepancies in relative flow (in both the healthy and stenosed models) could be due to the choice of projection angles. Projection angle I is oriented such that the PDA and RCA are in closer proximity to the viewer, while the AM and conus branches are more distant. Not only will the radius of the AM and conus branches appear smaller, but the dye will also appear to move at a slower rate due to being angled out of the image plane. These artifacts of the projections directly contribute to the error in flow computation. In the future, we can minimize these errors by incorporating the true distance and radius values from the 3-D geometry of the vessel tree.

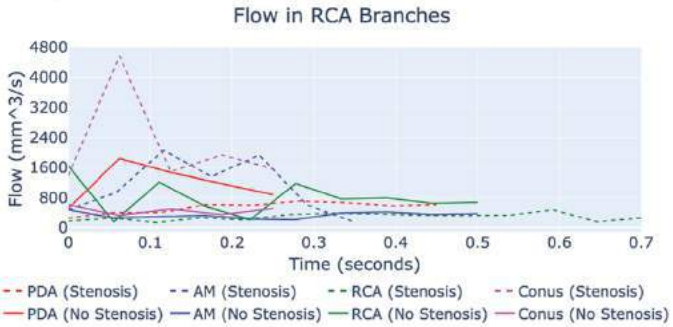

**Figure 3 - Flow in coronary branches as a function of time in healthy (solid) and stenotic (dashed) models using Projection I data.**

# THE EFFECT OF DEVELOPMENT SLOW ELONGATION IN DRIVING HEIRARCHICAL COLLAGEN FIBER FORMATION IN ENGINEERED TISSUES

**Kelly R. Ott (1), Jennifer L. Puetzer (1,2)**

## INTRODUCTION

Hierarchical collagen fibers are the primary source of strength and function in tendons, ligaments, and menisci. Injuries to these tissues disrupt collagen organization, resulting in loss of function, and over 1.6 million surgeries in the US each year [1,2]. Current treatment strategies fail to restore the structure or function of native tissue. It remains a challenge to form the hierarchical collagen fibers essential for long term mechanical success in engineered replacements or *in vivo* after injury [2]. Previously, we developed a novel culture system that guides anterior cruciate ligament (ACL) fibroblasts to produce aligned collagen fibrils at 2 weeks, which mature into native-sized fibers and fascicles by 4 and 6 weeks (Fig 1A)[2]. These are some of the largest hierarchical collagen fibers produced to data, however, further maturation is needed to be clinically relevant. Mechanical cues, such as slow growth and rapid cyclic muscle loading, are critical for fiber development *in vivo* and if not present tissues fail to mature [3,4]. However, this environment is complex and it is unknown how each type of load effects fiber formation. In particular, growth rates of the ACL can vary more than 10 fold between embryonic to early postnatal stages [5]. The objective of this study was to investigate whether slow stretch at rates similar to neonatal and postnatal ACL growth rates differentially drive hierarchical collagen fiber development in our system and whether the effect of load varies at different levels of collagen organization.

## METHODS

Engineered constructs were created by mixing immature bovine ACL fibroblasts with rat tail type I collagen to form 20 mg/mL sheet gets at $5x10^6$ cells/mL [2]. Rectangular constructs (30x8 mm) were cut from the sheet gels and cultured in our static clamping device (Fig 1A) or in a modified CellScale tensile bioreactor. Two experiments were performed to evaluate the effect of prolonged and temporal slow stretch. To evaluate the effect of prolonged slow stretch (Fig 1B), constructs were continuously stretched for up to 3 weeks at 0.1 mm/day to mirror ACL postnatal growth rates[5] or at 1 mm/day to mirror neonatal growth rates[3] (Fig 1B). To determine the temporal effect of load and whether the effects of stretch vary for different levels of collagen organization, constructs were clamped for 0, 2 or 4 weeks and then loaded at 0.1 mm/day or 1 mm/day for 1 week to evaluate load applied to unorganized collagen and at the fibril or fiber level (Fig 1C). Post culture, constructs were weighed and sectioned for analysis of organization, composition, and mechanics. Confocal reflectance was performed to analyze collagen organization. DNA, glycosaminoglycans (GAGs), and collagen content were measured via Picogreen, DMMB, and hydroxyproline (hypro) assays. All data were normalized to wet weight and multiplied by construct weight to determine composition per construct to account for differences in size from stretch. Mechanical properties were analyzed by tensile tests at 0.75% strain/sec to failure. Statistical analysis was performed by two-way ANOVA with Tukey's post-hoc ($p$<0.05).

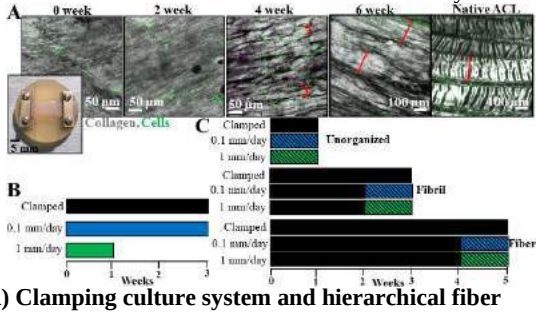

**Figure 1: A) Clamping culture system and hierarchical fiber development over 6 weeks (brackets denote fibers and fascicles). Slow stretch B) duration and C) temporal experimental set up.**

## RESULTS

In the first experiment we evaluated the effect of prolonged slow stretch on cell driven hierarchical fiber development. While constructs exposed to 0.1 mm/day stretch could be cultured for up to 3 weeks, constructs cultured at 1 mm/day began to rupture by 1 week. One week of stretch at 1 mm/day resulted in increased collagen and cell alignment

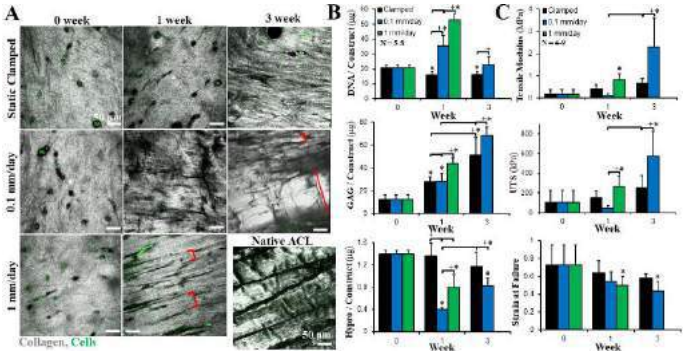

**Figure 2: Effect of slow stretch over extended culture on A) collagen organization, B) matrix composition, & C) mechanics. Significance compared to *0 week & +bracket**

(Fig 2A), significantly increased DNA and GAG content (Fig 2B), and significantly increased tensile modulus, ultimate tensile strength (UTS), and decreased strain at failure (Fig 2C). Interestingly, cell free constructs loaded at 1 mm/day did not have increased mechanics at 1 week (data not shown), suggesting changes in matrix mechanics are cell driven. Constructs cultured with 0.1 mm/day stretch had more aligned fibrils by 1 week in comparison to clamped controls, and developed larger fibers and fascicles by 3 weeks (Fig 2A). Similar to 1 mm/day constructs, 0.1 mm/day constructs had significantly improved DNA and GAG content, and significantly increased tensile modulus, UTS, and decreased strain at failure, however these changes primarily occurred at 3 weeks, rather than 1 week (Fig 2B-C). Both 0.1 and 1 mm/day constructs had decreased collagen (hypro) content compared to static clamped constructs after one week of loading, however collagen content did later increase after 3 weeks of 0.1 mm/day stretch (Fig 2B).

In the second experiment we evaluated whether the two stretch rates had differential effects when applied for 1 week in unorganized collagen (0 weeks) or after collagen had organized into aligned fibrils (2 weeks) or fibers (4 weeks). Regardless of timing or stretch rate, loading increased degree of collagen organization resulting in larger collagen fibers compared to clamped controls (Fig 3A). It appeared 1 mm/day constructs had larger, more organized collagen fibers than 0.1 mm/day constructs at each timepoint, and both rates of stretch resulted in more wavy or crimped collagen fibers when load was applied at 4 weeks once fibers had formed (5 week timepoint, Fig 3A). Regardless of timing of load, both stretch rates resulted in significantly increased DNA, in a dose dependent fashion, compared to clamped constructs (Fig 3B). While 1 mm/day load applied to unorganized collagen resulted in significantly increased GAG content at 1 week, this effect was lost at the fibril and fiber level, with both stretch rates accumulating similar

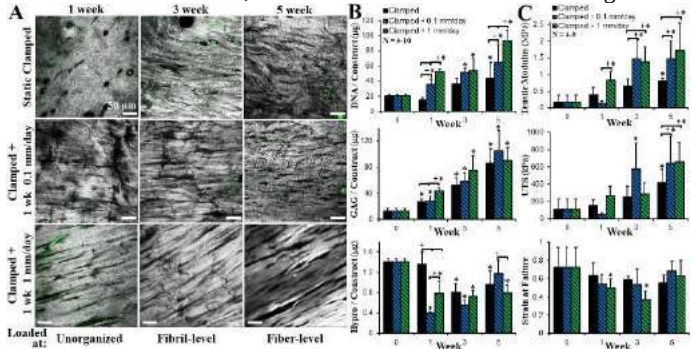

**Figure 3: Temporal effect of load applied to unorganized collagen or at the fibril or fiber level on A) collagen organization (collagen = grey, cells = green), B) matrix composition, & C) mechanical properties. Significance compared to *0 week and +bracket.**

GAG as clamped constructs at 3 and 5 weeks. Further, while both rates of stretch in unorganized collagen resulted in significantly decreased collagen (represented by hydroxyproline content) compared to clamped constructs at 1 week, this effect was lost at higher levels of organization (Fig 3B). Particularly, both rates of stretch at the fibril level resulted in similar collagen content as clamped constructs at 3 weeks, and at the fiber level 0.1 mm/day constructs had significantly more collagen in comparison to 1 mm/day constructs by 5 weeks (Fig 3B). Finally, both rates of stretch resulted in significantly increased tensile moduli when applied at the fibril and fiber level and UTS when applied at the fiber level (Fig 3C). Interestingly, while 1 mm/day stretch reduced the tissue failure strain at 1 and 3 weeks, this effect was lost by 5 weeks when load was applied at the fiber level.

## DISCUSSION

Collectively, in this study we found that slow stretch that mirrors neonatal and early postnatal growth rates increases collagen organization, DNA and GAG accumulation, and tissue mechanics in a dose and duration dependent manner. Further, these stretch rates have differential effects when applied at different levels of collagen organization. Specifically, we found that slow stretch increased cell proliferation regardless of collagen organization, as evident by the increase in DNA with load. Further, 1 mm/day stretch increased GAG content in unorganized collagen, however this effect was lost at later timepoints. Interestingly, by 5 weeks, all constructs had reached GAG concentrations that match native immature ACL tissue [2](data not shown), thus cells may differentially regulate GAG synthesis in response to stretch depending on tissue organization or tissue GAG concentration. Additionally, both rates of stretch appeared to differentially affect cellular collagen synthesis depending on the degree of collagen organization. Previously, we have found the largest turnover of collagen in our device is in the first two weeks when cells reorganize the collagen from unorganized to aligned fibrils [2]. During this period, it appears slow stretch may increase the rate of collagen turnover, resulting in significantly lower collagen concentrations and more organized aligned fibrils by 1 week. However, once cells are on aligned collagen, with altered tissue mechanics, they will most likely sense these stretch rates differently, possibly account for altered GAG and collagen production at 3 and 5 weeks.

Both rates of stretch resulted in increased collagen fiber organization, and increased tensile moduli and ultimate strength, regardless of the timing of load. However, both rates of stretch resulted in increased waviness or crimp-like formation and increased strain properties when applied at 4 weeks. Collagen crimp plays an important role in force transduction, absorbing initial load and reducing the load applied directly to fibers [6]. While it is not completely understood how crimps form, it is believed to be due to a mechanobiological response [6], thus slow stretch applied once fibers form may drive cells to start to form crimp. Overall, this study provides new insight into how different rates of growth during development effect hierarchical fiber formation and cellular response. A better understanding of how mechanical cues regular collagen fiber formation could help to develop better rehabilitation protocols to drive repair and help engineer replacements.

## INTRODUCTION

The population ratio of elders who are 65 years or older is growing at approximately 860,000 people per month (Henry). The main objectives to consider for the assistive devices such as walker frames are the guaranteed safety and comfortability of use from the user. The most basic walking frame is the Zimmer walking frame. The Zimmer frame assists its users with walking at the cost of long-term back strain, pain, and compromising support. Using static FEA analysis to identify stresses and strains present in the erector spinae muscles, we determined that conventional walkers tend to induce poor posture. An introduction to a modern and effective assistive walking device is pivotal step towards the solution of this problem. After our market research, we determined that there is a need for a high-end upper walker that has all the features that are present in its competitors while incorporating a modern lens. To achieve this optimization, we used our engineering discipline to redesign the most popular walker that is out in the market and create our walker named “The-Franny”.

## PRODUCT DESIGN

The-Franny is a modernized mobility aid that will be used to assist the senior citizen population with walking while ensuring user safety, comfortability, and ease of transportation. The overall height, width, and length of the device, as shown in Figure 2, is 41.7, 42, and 21, inches respectively. The-Franny is a walker that takes the safety and comfortability of a bulky and expensive upper walker and brings it to the conventional Zimmer Frame while maintaining a lightweight and compactable frame through aluminum tubing and a linked bar folding mechanism. Designed with the intention of reducing lower back strain while promoting an upright posture, this device features elbow rests, vertical handle/brake bars, and a set of 5-inch casters. In addition, it provides storage and a retractable seat for when the user needs to rest. Finally, a heart rate sensor as shown in Figure 1 is to be located at the handles of the walker, recording orthostatic vital signs to be accessible by the user and healthcare professionals.

This device will be designed and manufactured using CAD, 3D Printing, and laser cutting software. Using the engineering department and university resources, all necessary materials will be ordered while meeting budgetary restraints. The equipment and machinery necessary for tube bending, welding, fabrication, and assembly will be provided.

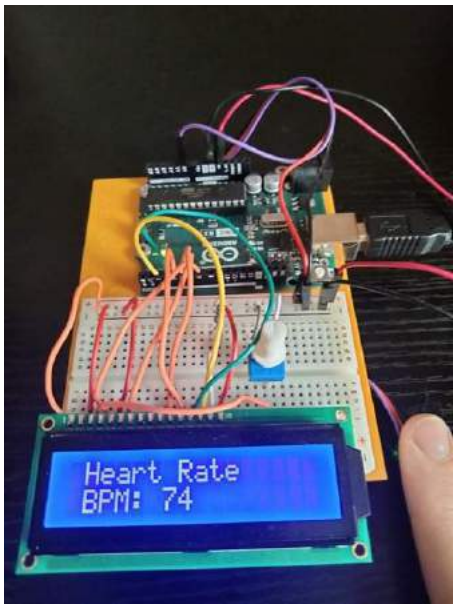

**Figure 1: Built Heartbeat Sensor (With Current Finger Reading) to be Incorporated Towards Final Build of The-Franny**

**Figure 2: Isometric View of The-Franny on SOLIDWORKS**

## BUDGET & MARKET ANALYSIS

The total design utilized a budget of $500. The total cost is dependent primarily on the build of The-Franny for the prototype. A lot of components for the walker were 3D-printed making effective use of the budget and resources available.

Walkers are used by nearly 5 million people in the United States alone. The expected manufacturing cost, when meeting this demand of walkers is dependent on the type of contracts made on bulk order basis, but the general high-end walker is sold for $700. If The-Franny is sold for $600 per walker, the end user would save 14% compared to what is available on the market, and the product would have a 20% profit margin. An important aspect of the cost to consider is that the user will not usually be paying for the full price of the walker, but a portion after insurance. When designing The-Franny, the design team never intended to create the device for profit. Everyone who needs a walker should have access to an affordable walker fitting for the 21st century. Therefore, the 20% profit margin is a figure that is a variable that can go lower when considering the greater mission of the design team.

## ACKNOWLEDGEMENTS

The project has received funding from the Grove School of Engineering at the City College of New York.

# GADOLINIUM-INFUSED SILICONE: A NEW MATERIAL FOR CYCLICALLY DEFORMING MRI PHANTOMS

## INTRODUCTION

Rigorous assessment and verification of biomechanical measurements obtained from existing magnetic resonance imaging (MRI) techniques are clinically important. In particular, the development of diagnostic tools for conditions characterized by subtle pulsatile motion and deformation, such as Chiari malformation, could benefit from such validated clinical approaches. Our group has recently developed a method to examine the accuracy of displacement encoding with stimulated echoes (DENSE) MRI technique for measurements of rigid body displacement that is within the range of brain motion in vivo [1]. However, unlike the brain, the phantom used in the abovementioned study does not undergo any deformation. To better understand the behavior of biological tissues experiencing small-scale deformations (<5% strain) a proprietary imaging phantom that can be deformed cyclically is necessary. The purpose of this study was to develop such a phantom that (a) can be easily detected in MRI scans, and (b) deforms in a controlled manner to produce physiologically relevant strains. In this study, for the first time, we examined gadolinium (a typical contrast agent for MR imaging)-infused silicone as a potential candidate for the MRI strain phantom. We hypothesized that gadolinium-infused silicone is detectable in MRI and the addition of gadolinium to silicone does not alter its mechanical properties.

## METHODS

Three different Smooth-On Sorta Clear$^{TM}$ molding silicones were acquired with Shore A 12, 18, and 37 hardness values. Consequently, three different concentrations of gadolinium were chosen – 100μg/mL silicone, 200μg/mL silicone, and 300μg/mL silicone – so that nine different gadolinium infused silicone samples were examined in total. The samples were made by dissolving the appropriate amount of gadolinium in one milliliter of water and then mixing the solution with a small sample of the corresponding silicone. These samples were then cured in a vacuum chamber to reduce bubble concentration. Each sample was "biopsied" wherein a piece was removed and pared down to a small piece for later mechanical testing. The samples were cured with a segment of toothpick in it to act as a fiducial marker. The number of toothpick segments corresponded to the sample number (one toothpick in sample 1, two toothpicks in sample 2, and so forth). These markers appeared as black dots along the edge of the sample (Figure 1).

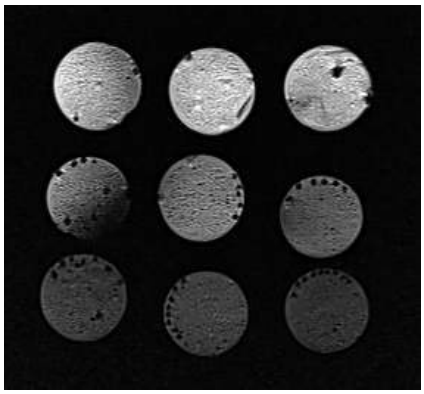

**Figure 1: Sample materials viewed with phase-sequence MRI. Each row has a different material hardness, each column has a different gadolinium concentration as described above.**

Biaxial mechanical testing was subsequently performed on the gadolinium-infused silicone. The setup involved applying load in X- and Y-dimensions to cause deformation. The samples for testing were manually shaped with a scalpel to approximately 11mm by 11mm by 1mm. From there, black markers were attached to the face of the sample in a square pattern and cables with hooks were embedded in the edges

of the sample. The sample was then pulled by means of a linear actuator attached to a series of pullies and hooks. A camera was used to track the markers and an internally developed software was used for calculation of stresses and strains, as described previously [2].

## RESULTS

The results of MRI scans are shown in Figure 1. The quality of the signal for these samples greatly exceeded expectation when compared to materials currently being used. It was determined that the relationship between the concentration of gadolinium in silicone samples and the subsequent MR visibility was non-linear. More surprisingly, it was observed that there was an optimal gadolinium density in a material sample after which increasing the gadolinium concentration led to a decline in MR visibility. Because sample 2 provided the greatest quality of signal, it was selected for the final prototype.

The results of biaxial mechanical testing of a representative sample are shown in Figure 2. The material behaved in a linear manner with little difference between the responses of the two axes, indicating an isotropic response. Based on the biaxial mechanical testing, and with the assumption of a linear elastic model, the elastic modulus of the gadolinium-infused silicone medium was determined to be 554kPa (Figure 2).

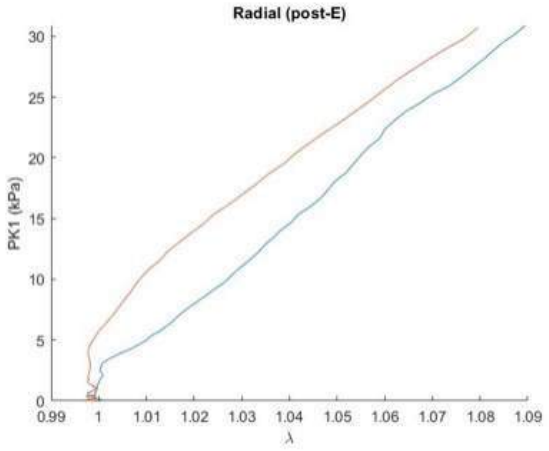

**Figure 2: Stress-stretch curve from biaxial testing showing a largely linear and isotropic relationship. The blue line and red line represent two different directions of the deformation.**

A finite element model of a phantom was subsequently developed in ANSYS Workbench with the assumption of linear elastic properties on the silicone encasement and embedded balloon with an internal pressure of 1960 Pa. There were fixed boundary conditions on all walls of the medium encasement as well as the two spherical ends of the balloon. The other boundary conditions were defined from the pressure and displacement relationship along the balloon boundary. The model confirmed that the phantom can produce small strain values comparable to those produced in the brain due to in-vivo pulsatile motions (Figure 3). The MRI displacement values from DENSE will ultimately be compared directly to the FEA results to verify the MRI outputs and to validate intracranial strains.

## DISCUSSION

Based on the results obtained, the most important takeaway was the ability to visualize silicone with MRI by way of infusing dissolved gadolinium into the material. Without gadolinium, silicone is an invisible medium in standard MRI practices, which may explain why it has yet to be used in phantom studies. The signal obtained from the samples tested, on the other hand, proved that gadolinium-infused silicone was a viable option for MRI phantoms. The clear relationships between silicone hardness and gadolinium volume for optimal signals are yet to be determined.

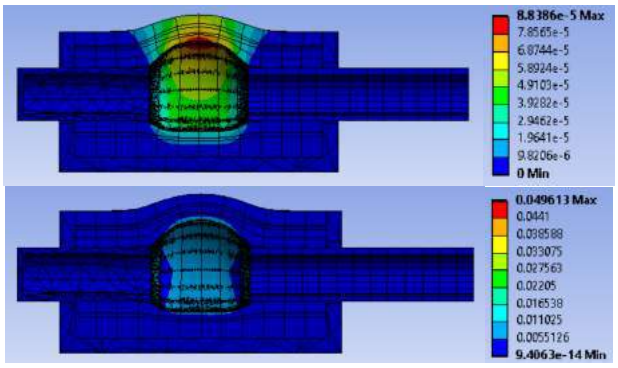

**Figure 3: Finite element simulations produced in ANSYS of pulsations occurring due to a balloon embedded within a volume of silicone. This simulation maps strain (top) and stress (bottom) of the balloon assuming rigid sides and bottom, and exposed top surface.**

The preliminary mechanical testing of the gadolinium-infused silicone proved that the dissolved gadolinium produced less than 0.1% change in the measured material properties of the silicone rubber, which falls well within the typical range for silicone rubber [3]. This finding is key to predicting behavior of potential future silicone samples, as it demonstrates the known mechanical properties of silicone are preserved. Such a finding is extremely valuable for the small-scale deformations that are associated with Chiari malformation and the ongoing research to properly diagnose diseases with DENSE MRI.

Our design was not without limitations. For one thing, the processing of the material needs to be improved to ensure repeatability and complete and even diffusion of gadolinium. In addition, the relationships between the volume of gadolinium and signal strength remains unclear.

In summary, we determined that that gadolinium-infused silicone provided excellent signal in MRI. Additionally, we observed that the infusion of gadolinium does not demonstrably influence the mechanical properties of silicone.

## ACKNOWLEDGEMENTS

## INTRODUCTION

Microtubules are cytoskeletal filaments responsible for many vital cellular processes. They align to form the spindle during cell division, making them an important target for cancer therapeutics. They maintain intracellular organelle organization and enable the movement of intracellular components throughout the cell. These diverse functions are made possible by the ability of microtubules to rapidly grow and shrink—an activity termed "dynamic instability."[1] Dynamic instability also enables microtubules to respond to mechanical signals. Positive tensile forces in the form of positive strain result in increased microtubule mass, while compression forces in the form of negative strain result in decreased microtubule mass[2]. However, it's currently unknown how microtubules respond to vibration forces. Because low-intensity vibrations (LIV) are known to cause an increase in the actin cytoskeleton[3] and microtubules are known to respond to other mechanical signals, we hypothesize that the polymerization dynamics of microtubules will be affected by LIV. In this study, we apply LIV to mouse mesenchymal stem cells (MSCs) and use centrifugal separation and Western blot analysis to determine its effect on the amount of polymerized microtubules.

## METHODS

**Experimental Design** Mouse MSCs were plated, then starved in adipogenic media before applying LIV. Lysates were collected at 0 hours, 1 hour, and 3 hours after LIV. They were immediately centrifuged at low speed to pellet out large microtubules—this pellet is referred to as the "low-speed pellet" (LSP). The supernatant was centrifuged at ultra-high speed to pellet out small microtubules—this pellet is referred to as the "high-speed pellet" (HSP). The resulting supernatant contains the free tubulin protein—this sample is referred to as the "high-speed supernatant" (HSS). Western blot analysis was used to determine the relative abundance of tubulin in the LSP, HSP, and HSS.

For each treatment, the absorbance of each sample (e.g. LSP) was divided by the sum of the absorbances of all the tubulin samples in the treatment and multiplied by 100 to obtain the % sample (see Equation 1) to determine the fraction of cellular tubulin present in the form of large microtubules, small microtubules, and free tubulin. The LIV and control treatments were compared by calculating the difference between their respective percentages of each sample for each timepoint. An ANOVA test was used to determine if differences between control and LIV treatments were significant.

**Equation 1: Calculating % LSP**

$$\%\, LSP = \frac{LSP}{(LSP+HSP+HSS)} \times 100 \qquad (1)$$

The experiment was repeated multiple times with an increasing number of vibrations until 6 rounds of LIV became the standard. 6 rounds of LIV were used because it yielded samples with the greatest difference between control and LIV (compared with fewer rounds) and performing more rounds was logistically difficult.

**Mesenchymal Stem Cell Culture** MSCs were plated at 100K/well in 6-well plates and cultured using 10% FCS, 1% P/S Iscove's Modified Dulbecco's Medium (IMDM). After ~30 hours, the medium was changed to IMDM with 2% serum, 1% P/S, 5 ug/mL Insulin, 0.1 uM Dexamethasone, 50 uM Indomethacin. Cells remained in this media for ~12 hours before the start of vibration.

**Application of LIV** LIV was applied 6 times. For each round, plates were placed on a machine at room temperature that vibrated them at 90 Hz, 0.7 xg for 20 minutes (see Figure 1). Control plates were not vibrated, but they were also kept at room temperature during vibrations. Plates were incubated for 60 minutes at 37 ℃ between each dose. Samples were taken down at the following time points: immediately after LIV (0H), 1 hour after (1H), and 3 hours after (3H).

**Figure 1: Apparatus with subwoofers underlying 4 platforms fitted for 6-well plates used for LIV application.**

**Collection of Cell Lysates** The "Microtubules/Tubulin In Vivo Assay Kit" from Cytoskeleton.com (Cat. # BK038) was utilized to take down cell lysates, separate large microtubules from small microtubules from free tubulin, and quantify their abundance with Western blot. Protocol was done as per the manufacturer's instructions. Briefly, lysates were taken down into a microtubule stabilizing buffer. The lysates were homogenized and centrifuged at 1000 xg for 5 minutes at 37 ℃ to obtain the LSP. 100 uL of the supernatant from each sample was centrifuged at 100,000 xg for 60 minutes at 37 ℃ to obtain the HSP and HSS (see Figure 2). To ensure band visibility on the Western blot, lysates from at least two wells were combined for each treatment before the first centrifugation. Samples were run on Western blots.

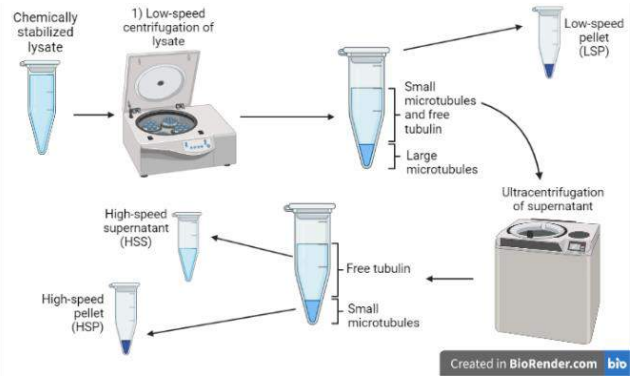

**Figure 2: Centrifugal separation of the LSP, HSP, and HSS.**

## RESULTS

The experiment was repeated 3 times using 6 rounds of LIV. Western blots revealed a trend: 3 hours after LIV. LIV treatments diminished the LSP was by 9.8 percentage points (p=0.16) and the HSS was increased by 12.4 percentage points (p=0.26), signifying a lower amount of large microtubules and larger amount of free tubulin (see Figure 3). One-way ANOVA tests were used to determine p values.

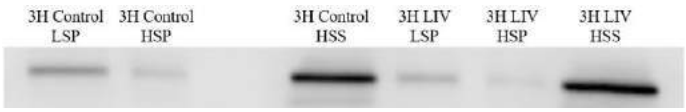

**Figure 3: Western blot showing LSP, HSP, and HSS for 3H control and LIV treatments. The LSP is diminished and the HSS is increased in the LIV treatment.**

## DISCUSSION

LIV results in a trend of depolymerization of large microtubules and thus increasing the number of smaller microtubules. The trend is not statistically significant, so we are performing more experiments to increase the sample size. Based on our inter-group variations, power calculations indicate that a sample size of 5/group will be sufficient to

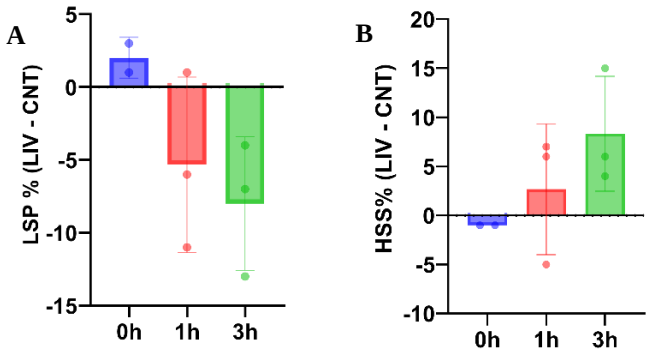

**Figure 4: A) Difference between % LSP between the LIV and control samples. At 3 hours, LSP is diminished in the LIV treatment by 9.8 percentage points (p=0.16). B) Difference between % HSS between the LIV and control samples. At 3 hours, HSS is increased in the LIV treatment by 12.4 percentage points (p=0.26).**

detect significant differences at the 3-hour timepoint. Past studies examining microtubule response to large mechanical signals (±10% strain) showed that tensile strain increases microtubule growth while compression decreases it.[2] Additionally, microtubule response is known to dominate over actin response in higher magnitude strain[4]. Thus, since vibration exerts a dynamic and oscillating force with relatively small magnitude, if we find that LIV does not affect microtubule dynamics, it may indicate that that the tension-compression environment may not be a suitable regulator of microtubule growth or LIV-induced forces may not be sufficient in magnitude to drive microtubule dynamics.

If the trend towards lower polymerization levels in the LIV treatment proves to be significant with a larger sample size, this finding would be more in agreement with the literature. We have reported that LIV increase F-actin contractility[3]. In this case, the cell might be responding to mechanical signals by shifting towards less polymerized microtubules in response to changes in F-actin forces.

Regardless, the assay used in this study is a global indicator of microtubule polymerization. To further characterize the results, we will use immunohistochemistry and confocal imaging to determine spatial changes in the microtubule cytoskeleton. whether there are microtubule changes localized to a particular region of the cell.

Ultimately this study will help understand whether microtubule dynamics can be regulated by low intensity high frequency vibrations.

## INTRODUCTION

Concussion and repeated head impacts are frequent in contact sports, particularly in American football [1]. This head trauma can lead to both acute and long-term deterioration of brain health and function [2]. To address safety concerns related to brain injury, protective helmets were introduced in American football over a century ago and have since evolved significantly in their appearance, materials, and efficacy in attenuating impact energy.

One recent advance in helmet technology includes the addition of a layer of padding material fashioned to fit over the exterior of a helmet shell [3,4,5]. A variety of these padded helmet shell covers have been designed and tested, with some becoming commercially available to athletes and rapidly gaining popularity. While previous evaluations of these technologies have been conducted, they have been limited to either laboratory test methods that cannot assess both linear and angular head kinematics [3] or evaluations of prototypes [4] or products that are not readily available to the general public [5]. Further, no peer-reviewed data exists that describes the on-field efficacy of these products.

The objective of this study was to evaluate the efficacy of a commercially available padded helmet shell cover in attenuating linear and angular head kinematics both in the lab and on the field.

## METHODS

Laboratory Testing: A linear impactor (Biokinetics and Associates Ltd.; Ottawa, Ontario, Canada) was used to impact a 50$^{th}$ percentile male Hybrid III headform mounted on a sliding table. The headform was equipped with three helmets individually: the Riddell Speedflex Diamond, Xenith X2E+, and Schutt Vengeance Pro LTD. These helmets represented a range of high-, middle-, and low-performing helmets according to the National Football League (NFL) helmet rankings. Each helmet was impacted at four helmet shell locations described in the NFL Helmet Test Protocol (Side, Oblique Rear, Side Upper, Oblique Front) and three velocities (3.5, 5.5, 7.4 m/s). Each helmet-location-velocity combination was repeated three times. Then, both the face of the linear impactor and a new helmet of the same model was equipped with a commercially available padded helmet shell cover (Guardian Cap, Guardian Sports; Peachtree Corners, GA) and subjected to the identical test procedure (Fig. 1).

To explore if the efficacy of the padded helmet shell cover deteriorated after repeated impact exposure, we ran a second set of laboratory tests in which we impacted a Riddell Speedflex Diamond helmet 100 times, with both the helmet and impactor equipped with a padded helmet shell cover. All impacts were performed at the oblique front location at 3.5 m/s, the average closing velocity for a professional football head impact. Approximately 80 seconds separated each impact while the test equipment was reset.

The headform was equipped with a six-degree-of-freedom sensor package including three DTS A64C accelerometers and three DTS ARS PRO-8k gyroscopes (Diversified Technical Systems; Seal Beach, CA). For each impact, linear acceleration and angular velocity in the X, Y, and Z directions was captured and used to calculate the Head Acceleration Response Metric (HARM) [5].

On-field Testing: Using the Stanford Instrumented Mouthguard (MiG2.0) [1], we captured athlete head kinematics during official practices of the Stanford University football team. Seven linebackers were equipped with MiG2.0 mouthguards that recorded a 200 ms time window of angular velocity and linear acceleration in the X, Y, and Z directions when linear acceleration in any of the X, Y, or Z directions exceeded a threshold of 10 g. Peak linear and angular accelerations were saved from this data for each impact. Data was collected in the 2019 season, when all instrumented athletes wore bare helmets, and the 2021 season, when instrumented athletes wore helmets fitted with Guardian Caps. Video footage of all team practices was captured and two of the authors reviewed and verified each impact.

We focused specifically on linebackers in practices only and only examined helmet-to-helmet impacts. Helmet-to-helmet impacts were

SB³C2022-528

classified as any impact where the helmet of one player contacted the helmet of another player. All impacts which did not feature a bare helmet striking another bare helmet, or a helmet with a Guardian Cap striking another helmet with a Guardian Cap, were discarded.

Data Analysis: Three separate two-way ANOVAs were used to test for differences in HARM between bare helmet impacts and padded helmet shell cover impacts for the three helmets in the lab experiments. Mann-Whitney tests were used to test for differences in peak linear acceleration and peak angular acceleration between bare and padded helmet impacts in the on-field dataset.

## RESULTS

In the lab, the use of a padded helmet shell cover was found to reduce HARM compared to the bare helmet impacts at all impact locations in all helmets at 3.5 m/s (Fig. 2). The same was true at 5.5 m/s, with the exception of the Schutt Vengeance Pro LTD at the Side Upper location. HARM was not decreased in any helmet equipped with the padded helmet shell cover at the Side Upper 7.4 m/s velocity impact condition. HARM reduction decreased with increasing impact velocity, a trend that was common among all three helmet models tested. The association between the number of repeated impacts and magnitudes of peak linear acceleration and peak angular acceleration met statistical significance (p=0.04), but the increase in magnitude with increasing impact count was very small (Fig. 3).

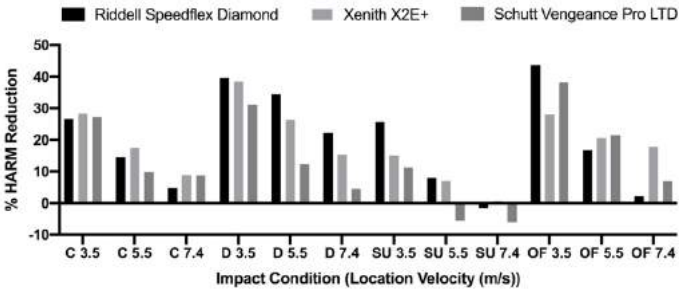

**Fig. 2 Laboratory efficacy of the padded helmet shell cover stratified by impact condition. Results shown in percentage of HARM reduced when comparing to bare helmet control (averaged across three repeat trials for each condition).**

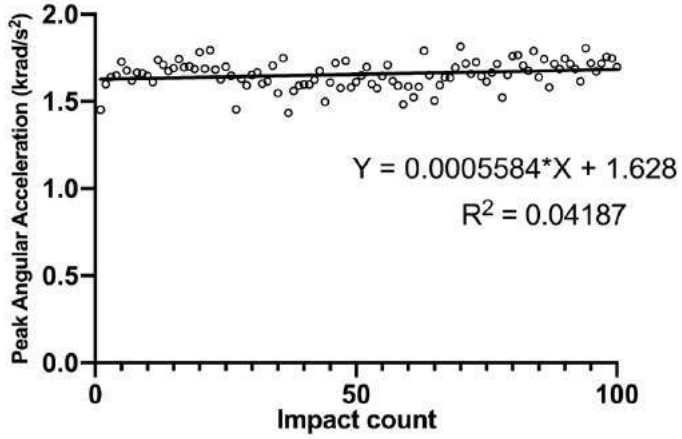

**Figure 3: Peak angular acceleration for repeated, consecutive impacts delivered to a Riddell Speedflex Diamond helmet equipped with a padded helmet shell cover. Impacts were performed at the Oblique Front location at 3.5 m/s.**

On the field, there was no significant difference between the peak head kinematics of the bare helmet impacts and padded helmet shell cover impacts (Fig. 4).

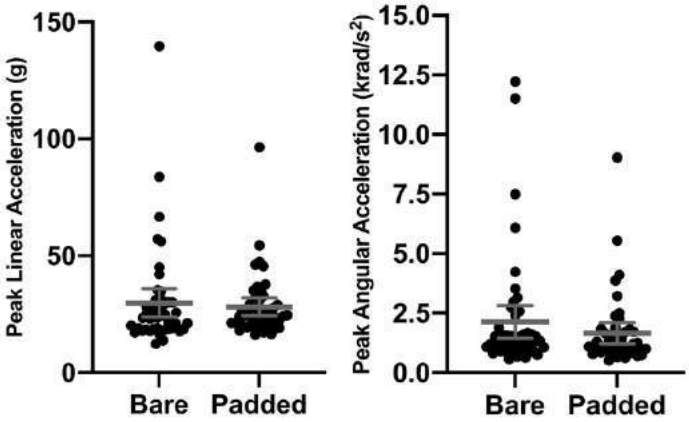

**Figure 4: Comparison of peak head accelerations of on-field helmet-to-helmet impacts with bare helmets and helmets equipped with a padded helmet shell cover. Solid gray lines and error bars represent mean values and 95% confidence intervals, respectively.**

## DISCUSSION

The present study is the first to assess the ability of the standard, commercially available Guardian Cap for reduction of brain injury metrics based on both linear and angular head kinematics and the first study to evaluate the attenuation capabilities of a padded helmet shell cover both in the lab and on the field. Several previous studies have utilized laboratory testing experiments to evaluate the efficacy of padded helmet shell coverings, with some finding effectiveness of these technologies in linear impactor tests [4,5], and others finding limited efficacy in standardized drop tests. We found the padded helmet shell cover to effectively attenuate values of HARM, a brain injury metric derived from both linear and angular head kinematics, at most impact conditions in the lab. We also observed minimal changes in peak head kinematics after repeated impact testing, suggesting the padded helmet shell cover can endure extended use without reduced performance.

Despite the ability of the Guardian Cap to reduce head kinematics in the lab, on-field reductions in peak head accelerations did not reach statistical significance. Two possible explanations for this include the small sample of on-field impacts and the inclusion of facemask impacts in our on-field dataset. As these technologies only cover the shell of a helmet, it is likely that facemask-to-facemask impacts would not be attenuated by their use. However, other studies have similarly found no difference in on-field head kinematics between helmets that significantly differed in performance in the lab [1], suggesting that more helmet testing methodology can still be improved to accurately replicate on-field football head impacts.

# ASSESSMENT OF PRESSURE GRADIENT AND RECOVERY FOLLOWING TRANSCATHETER AORTIC VALVE REPLACEMENT IN BICUSPID AORTIC VALVES

**Aniket Venkatesh (1), Breandan Yeats (1), Atefeh Razavi (1), Pradeep Yadav (2), Venkateshwar Polsani (2), Vinod Thourani (2), and Lakshmi Dasi (1)**

## INTRODUCTION

Calcific aortic stenosis (AS) is the thickening, due to calcium buildup, of the aortic valve leaflets in the heart, which control blood flow from the left ventricle into the aorta to be distributed to the rest of the body [1]. Most common risk factors that lead to AS include old age, congenital defects such as bicuspid aortic valve (BAV), and several others. Currently, the most common treatment option is transcatheter aortic valve replacement (TAVR), with more than 100,000 procedures performed annually in the US compared to 50,000 open-heart surgeries [2]. TAVR is a minimally invasive interventional procedure where bioprosthetic leaflets are attached to a stent, which is delivered through a catheter delivery system to the site of AS and deployed to expand the diseased valve, allowing the prosthetic valve to "replace" it [3].

The primary method of assessing TAVR's efficacy in treating AS is to examine the transvalvular pressure gradient (PG) post-TAVR. Current techniques to measure PG include the noninvasive Doppler echocardiography and invasive percutaneous cardiac catheterization [4]. However, studies have shown that both techniques report discordant PG measurements due to the phenomenon of pressure recovery (PR), or reconversion of kinetic energy from blood flow velocity past the vena contracta (VC) into potential energy (pressure) [5]. Neither PG nor PR have been thoroughly studied in BAV patients. Additionally, prosthetic valvular orientation during initial deployment, including implantation depth and rotational configuration, have shown to affect eventual clinical outcomes [6], but its effect on pressure recovery has not been thoroughly explored. Therefore, the main objective of this study is to quantitatively assess PG and PR following TAVR on BAV patient-specific aortic geometry, with the capability of assessing different deployment orientations. It also aims to assess the feasibility of computational methods such as Finite Element Analysis (FEA) and Computational Fluid Dynamics (CFD) in determining PG and PR post-TAVR.

## METHODS

**Valve Selection and Deployment:** A 79-year-old male with severe AS and BAV received a 29 mm Edwards Lifesciences SAPIEN 3 balloon-expandable TAV to replace the stenosed native valve. Computed Tomography (CT) images prior to and following the TAV deployment were obtained under IRB approved protocols. The patient's three-dimensional aortic root geometry was segmented and meshed using pre-TAVR CT images in Materialise Mimics (Leuven, Belgium) (**Figure 1A**).

**Finite Element Analysis:** Using the post-TAVR CT images, the stent was oriented appropriately, and its expansion was simulated using FEA in Abaqus CAE (Johnston, RI, USA). A meshed 29 mm SAPIEN 3 prosthetic leaflets model was displaced to fit the deformed post-FEA stent model in Abaqus CAE (**Figure 1B**) by tracking the displacement of contacting nodes on the meshed stent. The prosthetic leaflets were configured to simulate the motion of an aortic valve throughout a cardiac cycle by applying a time-varying pressure load to the internal surface of each leaflet. The values for the pressure load were obtained by extracting data points from an aortic and ventricular pressure vs time curve [7] using WebPlotDigitizer (Notre Dame, IN, USA), then calculating the pressure difference across the valve. To simulate peak systolic flow, the fully open prosthetic leaflets were exported along with the post-FEA stent, aortic root, and calcium nodules to Materialise Mimics to create a meshed internal fluid domain (**Figure 1C**). 300 mm extensions were added on the inlet and outlet faces to ensure fully developed flow through the aortic root.

SB³C2022-529

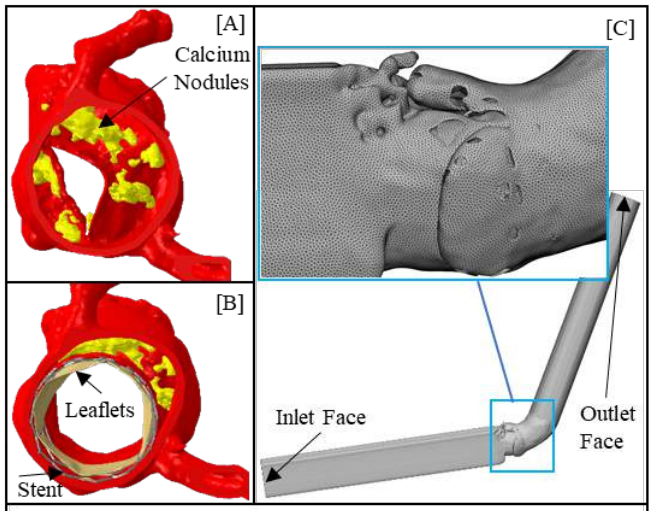

**Figure 1:** Pre-FEA segmented aortic valve with calcium nodules highlighted (A), post-FEA stent and prosthetic leaflets deployment during peak systole (B), and meshed internal fluid domain with extensions created from post-FEA geometry for CFD simulations (with inlet and outlet faces used for boundary conditions highlighted) (C).

**Computational Fluid Dynamics:** The fluid domain geometry was imported to ANSYS Fluent (Canonsburg, PA, USA) to simulate blood flow using CFD. The continuity equation and Reynolds averaged Navier–Stokes equations with a shear stress transport transitional (SST-Trans) model were used to describe 3D incompressible flow [8]. A 120-mmHg peak systolic aortic pressure was applied at the inlet face and a target peak systolic volumetric flow rate of 25 L/min was applied at the outlet for computational calculation of outlet pressures. The CFD simulation was executed under steady conditions and the pressure and velocity contours, and velocity streamlines were plotted. Planes were created on the aortic orifice and the aortic root end, and the average pressures at the inlet face, aortic root orifice, and the aortic root end were determined for calculation of mean PG and PR.

## RESULTS

Velocity streamlines and velocity and pressure contours of peak systolic blood flow through the post-TAVR aortic geometry are shown (**Figure 2**).

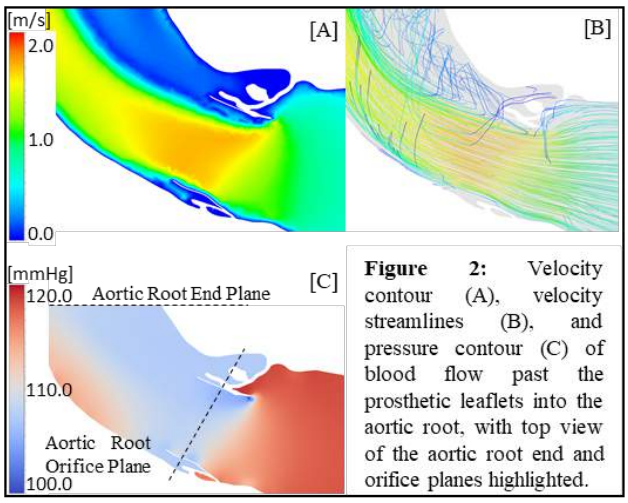

**Figure 2:** Velocity contour (A), velocity streamlines (B), and pressure contour (C) of blood flow past the prosthetic leaflets into the aortic root, with top view of the aortic root end and orifice planes highlighted.

The average pressure on the inlet face, aortic root orifice plane, and aortic root end plane were found to be 118.4 mmHg, 107.7 mmHg, and 110.0 mmHg, respectively. From the measurements above, the mean PG through the prosthetic leaflets was calculated to be 10.7 mmHg and the recovered pressure was calculated to be 2.3 mmHg, hence giving a net PG throughout the aorta of 8.4 mmHg and a PR of 21.5%. The average velocity of blood flow across the inlet face, aortic root orifice plane, and aortic root end plane were found to be 0.63 m/s, 0.74 m/s, and0.70 m/s, respectively. Low velocity recirculation zone is observed in the stenosed sinus with large calcium deposits.

## DISCUSSION

The goal of this study was to visualize changes in blood flow pressure and velocity through a BAV patient specific post-TAVR anatomy, and quantitatively assess mean PG and PR. The calculated mean PG through the aortic orifice falls within the 5-25 mmHg aortic valve mean gradient range [9], indicating the effectiveness of TAVR in reducing AS-induced high gradients. However, this calculation does not consider the recovered 2.3 mmHg of pressure downstream of the aortic orifice, which gives a mean PG closer to the normal aortic valve mean gradient range of under 5 mmHg [9]. This study therefore demonstrated the discrepancy between the mean PG readings that would be obtained if this patient underwent Doppler echocardiography and percutaneous cardiac catheterization. Since Doppler estimates the maximum pressure drop through the aortic valve using the maximum flow velocity recorded [5], it will overestimate the net gradient across the entire aorta measured through catheterization.

This study indicated the capability of patient specific CFD analysis in determining hemodynamic characteristics post-TAVR. The findings, once validated and tested in a larger cohort, can be used to assess the device hemodynamic performance. For the future study, we plan to include the impact of the stent orientation, deployment height and the degree of alignment of the prosthetic leaflets with respect to native commissure on PG, PR, as well as the sinus washout.

# EXERCISE THERAPY DOES NOT ALTER KINEMATIC REPEATABILITY IN INDIVIDUALS WITH ROTATOR CUFF TEARS WHEN REACHING BEHIND THE BACK

**Rachel P. McLoughlin (1), Luke T. Mattar (1), Adam J. Popchak (3), William J. Anderst (2), Volker Musahl (1,2), James J. Irrgang (2,3), Richard E. Debski (1,2)**

(3) Department of Physical Therapy, University of Pittsburgh, Pittsburgh, PA, USA

## INTRODUCTION

Rotator cuff tears affect over 20% of the general population, where prevalence increases with age[1]. Exercise therapy is typically prescribed as the initial treatment for individuals with rotator cuff tears who present with pain and inability to complete activities of daily living. Numerous studies have found a correlation between abnormal glenohumeral kinematics and shoulder pain[2,3]. It has also been shown that individuals with shoulder pain employ movement adaptations related to kinematics, which suggests that individuals experiencing shoulder pain may not complete provocative motions in a consistent manner[4].

One particularly painful movement commonly utilized during personal hygiene tasks such as bathing and dressing is reaching behind the back. Prior research attributes the problematic nature of this movement to a large required range of motion, sizeable shoulder moments, and maximum supraspinatus stretching[5,6]. Further, reaching behind the back is a complex movement involving motion at the scapulothoracic, glenohumeral, and elbow joints. Consequently, individuals with rotator cuff tears may vary techniques used to reach behind the back in an effort to mitigate pain.

Exercise therapy has been shown to improve patient reported outcome scores and glenohumeral kinematics[7]. Patient reported outcome score forms often include questions designed to quantify pain, indicating that exercise therapy improves pain levels for individuals with rotator cuff tears. Therefore, following exercise therapy, individuals may complete the behind the back movement in a more consistent manner with respect to glenohumeral kinematics. Thus, the objective of this study was to assess changes in kinematic repeatability during a reaching behind the back movement following a 12-week structured and individualized exercise therapy program.

## METHODS

Seventy-two individuals (59.9 ± 9.2 years of age, 28.1 ± 5.0 BMI) with a symptomatic rotator cuff tear isolated to the supraspinatus tendon were recruited after providing IRB-approved written informed consent prior to performance of any research procedure. All individuals participated in a 12-week structured and individualized exercise therapy program focused on restoring range of motion and strengthening the rotator cuff and scapular muscles. The individuals were asked to perform a behind the back task three times to assess glenohumeral joint function. To complete this task, each individual began seated with their affected-side hand placed on their thigh and reached as far as they could behind their back. No specific instructions were given, so each individual completed the task in their own manner.

Glenohumeral kinematics were measured using a previously described and validated model-based tracking technique with images acquired from a synchronized biplane radiography system at fifty images/second[8]. Individuals underwent a computed tomography scan of the involved shoulder, and images were segmented to create individual specific bone models of the humerus and scapula. Digitally reconstructed radiographs of the bone models were created from the known geometry of the biplane radiography system. The bone models were then manipulated to match the digitally reconstructed radiographs to the corresponding bones in the biplane radiographic images in all six degrees of freedom for each pair of synchronized images throughout the movement. The local coordinate system for each humerus was constructed based on the International Society of Biomechanics recommendations with the origin located at the center of the humeral head. The scapula coordinate system was modified to create a glenoid based system to describe humeral motion with respect to the center of the glenoid. An X-Z-Y Euler angle rotation sequence was used to quantify translation and rotations with accuracy of ± 0.4 mm and ± 0.5° for dynamic motion[8]. In this sequence, X rotations represented glenohumeral elevation, Y rotations represented glenohumeral flexion-extension, and Z rotations represented glenohumeral internal-external rotation.

Kinematic outcome parameters included glenohumeral elevation, glenohumeral flexion-extension, and glenohumeral internal-external rotation. To begin calculating kinematic repeatability, each rotational degree of freedom was plotted for all three movement trials on a given test day (Figures 1,2,3). As a means of standardization, the same number of points were used for analysis of each curve. Because prior biomechanical movement studies have validated the root mean square error as a measure of repeatability, the root mean square error was then calculated between curves for trials one and two, trials two and three, and trials one and three[9]. The average of these values was taken as the final root mean square error for the given test day. This process was performed both pre-therapy and post-therapy. Because all data was non-normally distributed, Wilcoxon Signed Rank tests were used to compare root mean square errors for the three pre-therapy degrees of freedom to those for the three post-therapy degrees of freedom. Significance was set at $p < 0.05$.

## RESULTS

All individuals completed the 12-week structured and individualized exercise therapy program. No statistically significant differences were found between pre- and post- exercise therapy average root mean square error values ($p > 0.05$, Table 1). Glenohumeral elevation root mean square error values ranged from 1.4° to 13.2° pre-therapy and from 1.4° to 7.8° post-therapy (Table 1). Glenohumeral flexion-extension root mean square error values ranged from 1.1° to 17.8° pre-therapy and from 1.1° to 13.6° post-therapy (Table 1). Glenohumeral internal-external rotation root mean square error values ranged from 1.8° to 32.7° pre-therapy and from 1.4° to 22.8° post-therapy (Table 1).

**Table 1: Kinematic repeatability measured as root mean square error before and after a 12-week exercise therapy program.**

| | | Elevation (°) | Flexion-Extension (°) | Internal-External Rotation (°) |
|---|---|---|---|---|
| Before | Minimum | 1.4 | 1.1 | 1.8 |
| | Mean ± SD | 4.5 ± 2.5 | 5.2 ± 3.5 | 7.9 ± 5.9 |
| | Maximum | 13.2 | 17.8 | 32.7 |
| After | Minimum | 1.4 | 1.1 | 1.4 |
| | Mean ± SD | 3.8 ± 1.5 | 4.7 ± 2.5 | 7.5 ± 4.7 |
| | Maximum | 7.8 | 13.6 | 22.8 |
| p | | 0.08 | 0.90 | 0.75 |

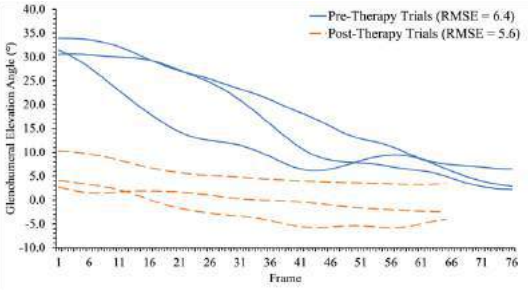

**Figure 1. Representative glenohumeral elevation angle curves before and after a 12-week exercise therapy program.**

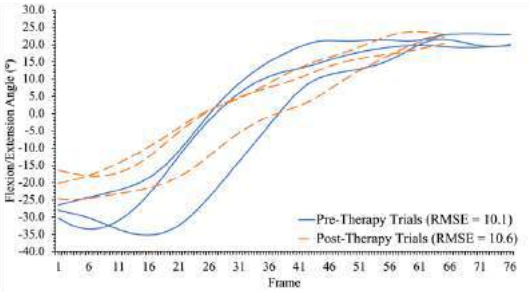

**Figure 2. Representative glenohumeral flexion/extension angle curves before and after a 12-week exercise therapy program.**

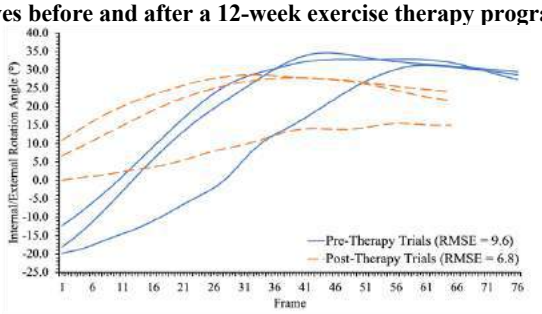

**Figure 3. Representative glenohumeral internal/external rotation angle curves before and after a 12-week exercise therapy program.**

## DISCUSSION

The primary finding of the study was that a 12-week structured and individualized exercise therapy program did not lead to changes in kinematic repeatability related to glenohumeral elevation, glenohumeral flexion-extension, or glenohumeral internal-external rotation when reaching behind the back. This suggests that glenohumeral joint motion repeatability was not affected by exercise therapy.

One potential explanation for this finding is that all individuals included in the study had isolated supraspinatus tears, which may allow for some conservation of normal joint function. This result is further supported by the fact that education has been shown to improve development of standardized clinical examination techniques[10]. Individuals in our study were not educated on the behind the back movement, which may explain why uniform motion techniques were not observed following exercise therapy.

During our protocol, overall changes in glenohumeral kinematics that may hint at adaptive motion strategies were not studied—only repeatability related to these parameters was analyzed. Future studies will aim to determine the effects of exercise therapy on glenohumeral kinematics and the relationship between patient reported outcomes and kinematic repeatability during the behind the back movement.

## INTRODUCTION

As cycling gains popularity as a sport, exercise modality, and rehabilitative tool, there is growing interest in optimizing the bicycle to meet health and performance demands. One method of optimization is the adjustment of bicycle crank length (CL). Commercial CLs are between 170-175 mm in length. However, CLs are often adjusted according to cyclist preference. These adjustments may have health and performance implications. Little research has looked at the effects of CL on lower leg muscle activation [1, 2]. Of this research, there has been no analysis on the activation of both the vastus lateralis (VL) and vastus medialis (VM) muscles. The relationship between the relative activation of these muscles is important in preventing patellofemoral joint pain (PFP). In cycling, it is common for long term overcompensation of the VL to pull the patella laterally. Lateral malalignment of the patella is a major cause of PFP [3]. It is possible that CL alters the relative activation of VL and VM, potentially increasing the risk of lateral malalignment of the patella and further PFP.

The purpose of this study is to examine the effects of two different CLs (155 and 185 mm) at a constant pedal rate (70 rpm) and constant pedal speed (1.47 m/s) and the resulting muscular activation of the vastus lateralis (VL) and vastus medialis (VM). Hypotheses were (H1) VL and VM muscle activation would not change with CL, and (H2) muscle activation would increase with an increase in pedal speed.

## METHODS

Twenty-six non-cyclists (12M, 14F, aged 18-55) participated in a single blind randomized cross-over experiment with four CL (155, 165, 175, and 185 mm). CLs 155 mm and 185 mm were analyzed for comparison. Fifteen participants were excluded from statistical analysis due to EMG signal error and sensor inaccuracy. Participant characteristics are shown in Table 1.

**Table 1. Participant Characteristics, Mean ± SD shown.**

| Participants | N = 11 |
|---|---|
| Age (years) | 28.0 ± 11.9 |
| Height (cm) | 170.7 ± 8.5 |
| Weight (kg) | 64.6 ± 11.8 |
| BMI (kg/m$^2$) | 22.0 ± 2.6 |
| Weekly Training (hrs/week) | 6.4 ± 3.4 |

A 12-camera 3D motion analysis system with Cortex software (Motion Analysis Corp., CA, USA) was used to capture crank angle. A stationary bike (SRM IndoorTrainer, Germany) with adjustable cranks was used for trials. Delsys Trigno EMG sensors were placed on target muscles of the right leg to collect electromyographic data. Electrodes for VL were placed 2/3 from the ASIS to the lateral side of the patella. Electrodes for VM were placed 4/5 between the ASIS and the joint space in front of the medial ligament. Participants performed a 3-minute warm-up for each CL at 1.5 W/kg and 70 rpm. 4x1 minute experimental trials were conducted at 2 W/kg. The first two trials were conducted at a constant cadence of 70 rpm. The second two trials were conducted at a constant pedal speed of 1.47 m/s (rpm = 90, 85, 80, 76 rpm with respect to CL). Adjusted rpm values were determined by Equation (1). There were 10 seconds of rest between trials and 5 minutes of recovery between each condition. Saddle and handle height was adjusted for each condition to maintain the same height for corresponding crank length.

**Equations:** $$\text{rpm} = (1.47 \text{ m/s} \times 60)\,(2\pi \times \text{CL})^{-1} \quad (1)$$

EMG data for each one minute trial was trimmed to 30 seconds, then averaged into one 360 degree crank cycle in MATLAB. Averaged EMG signals were rectified and filtered with a 4th order Butterworth low-pass filter, with a 20 Hz cut off frequency. A threshold value of 20% of the maximum voltage was applied to determine periods of muscular activation for each trial. Using the threshold value, total activation time (TON) and total deactivation time (TOFF) were

recorded to measure the duration of muscle activation in a 360 degree crank cycle. Average voltage (AV) and maximum voltage (MV) of the EMG signals were recorded to quantify muscle excitation. Area under the curve (AUC) was recorded to estimate total muscular activity [2]. Two-sample t-tests at 95% confidence were used to compare measures across CLs (155 and 185 mm) and cadences (70 rpm and 1.47 m/s).

## RESULTS

The five measures of muscles activation (AV, MV, AUC, TON, TOFF) for VL and VM are outlined in Figure 1. The means and SDs of each measure for each condition are shown in Table 2 and Table 3. For VL and VM, there were no significant differences between CLs at 70 rpm or between CLs at 1.47 m/s ($p>0.05$ for all measures). This supports H1. For VL and VM, there were no significant differences between the 70 rpm and 1.4 m/s trials for 155 mm or 185 mm ($p>0.05$ for all measures). This does not support H2.

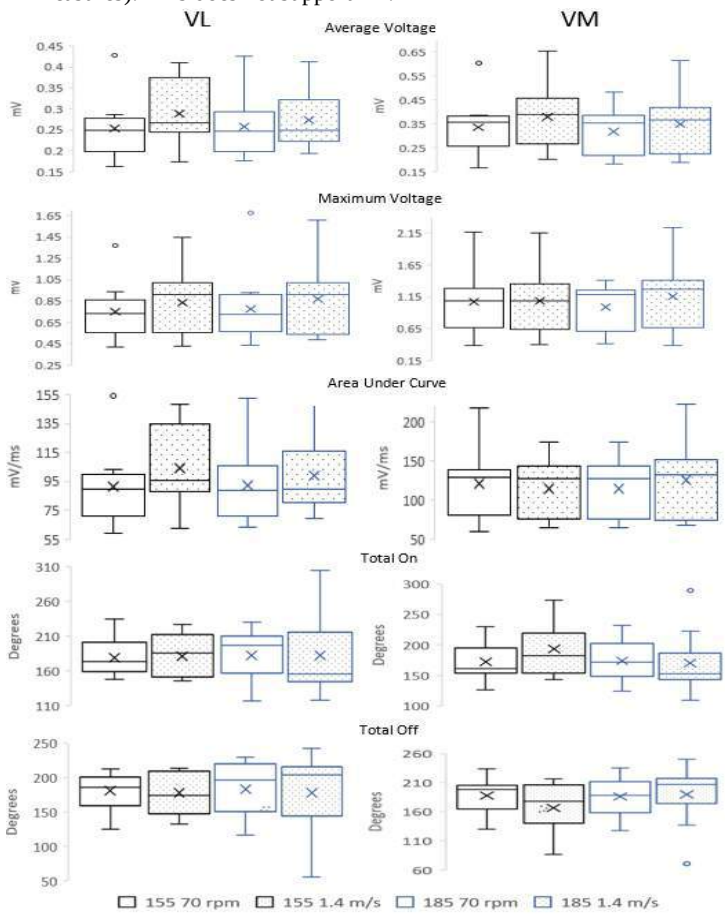

**Figure 1: Measures of muscular activation (AV, MV, AUC, TON, TOFF) of VL and VM at 70 rpm and 1.47 m/s for 155 and 185 mm CL. No significant differences in these measures.**

**Table 2: Vastus Lateralis Measures, Mean ± SD shown.**

| Trial | AV (mV) | MV (mV) | AUC (mV/ms) | TON (degrees) | TOFF (degrees) |
|---|---|---|---|---|---|
| 155 70 | 0.2529 ± 0.0708 | 0.750 ± 0.273 | 91.0 ± 25.6 | 179.0 ± 26.5 | 181.0 ± 26.6 |
| 155 1.47 | 0.2894 ± 0.0745 | 0.835 ± 0. 317 | 104.1 ± 26.8 | 181.8 ± 29.8 | 178.2 ± 29.8 |
| 185 70 | 0.2575 ± 0.0704 | 0.775 ± 0.342 | 92.6 ± 25.9 | 182.8 ± 36.6 | 182.8 ± 36.5 |
| 185 1.47 | 0.2745 ± 0.072 | 0.869 ± 0.347 | 98.8 ± 25.4 | 182.3 ± 60.7 | 177.7 ± 60.7 |

**Table 3: Vastus Medialis Measures, Mean ± SD shown.**

| Trial | AV (mV) | MV (mV) | AUC (mV/ms) | TON (degrees) | TOFF (degrees) |
|---|---|---|---|---|---|
| 155 70 | 0.336 ± 0.127 | 1.072 ± 0.536 | 120.8 ± 45.5 | 172.4 ± 32.6 | 187.6 ± 32.6 |
| 155 1.47 | 0.379 ± 0.139 | 1.085 ± 0.531 | 114.6 ± 37.6 | 193.4 ± 47.9 | 166.6 ± 47.9 |
| 185 70 | 0.319 ± 0.104 | 0.987 ± 0.384 | 114.6 ± 37.6 | 173.9 ± 37.6 | 186.1 ± 37.6 |
| 185 1.47 | 0.348 ± 0.134 | 1.161 ± 0.567 | 125.4 ± 48.3 | 170.2 ± 53.1 | 189.8 ± 53.1 |

## DISCUSSION

There were no significant differences between any of the measures at different CLs and pedal speed/rate. These results suggest that CL may not have a significant of an effect on muscle activation. Therefore, cyclists focused on performance, general knee health, or rehabilitation should not be overly concerned by the CL they use. There is no perfect formula for determining optimal CL for an individual. There is some evidence to show that optimal CL depends on leg length [4]. However, due to the amount of variability between individual people, a holistic approach that considers an individual's anthropometric dimensions, limb dynamics, health history, personal preference, and other factors will likely lead to a best suited CL.

These results may also be useful in rehabilitative contexts with stationary bicycles. While CL showed no effect on muscle activity, smaller CLs reduce range of motion (ROM) in the hip and knee joints. In addition, constant pedal speed trials at 1.47 m/s produce lower peak knee compressive forces across CLs compared to 70 rpm trials [5]. Therefore, the purpose of adjusting CL and cadence in a rehabilitation setting should be to restore ROM and reduce compressive forces. CL should not be considered as a tool for altering muscular activation in rehabilitation.

This study has several limitations. First, the number of participants used was low. Fifteen participants were excluded from statistical analysis due to EMG signal error and sensor inaccuracy. Poor EMG data was likely a result of signal noise caused by sweating and clothing. Software complications further limited the data pool for analysis. Second, although collected, onset and offset times were not analyzed in this research. While there was no significant difference in total activation time, it is possible that there were shifts in activation periods that were not accounted for.

Future research with this data will analyze a larger sample of participants across all four CLs. The research will include analysis of tibialis anterior, gastrocnemius (lateral head), and biceps femoris, as well as onset and offset times for all five muscles.

# COMMODE FOR NEUROGENIC BOWEL: A MECHANISM FOR ACHIEVING THE SQUATTING POSITION

**John D. Bates (1), Chastity C. Chavez (1), Madison L. Lang (1), Alexander J. Rivera (1), Camila Ruiz Vega (1)**

## INTRODUCTION

For individuals with neurogenic bowel (NB), performing a bowel movement can be a tedious and time-consuming process. NB is the neurological loss of normal bowel function and affects many individuals with acute spinal cord injuries and other neurological conditions such as multiple sclerosis, spina bifida, and others.

There are existing posture modification devices (PMD) that facilitate the bowel movement process such as the 'Squatty Potty,' a footstool that the user rests their feet on during defecation to produce a desired hip-flexion angle of 22.5°-35° [1]. These PMDs bring the legs up, which replicates a squatting position and straightens the colon to allow for easier passage of the bowel movement [2]. Studies have shown the effectiveness of PMD-facilitated hip flexion in reducing the time and strain involved with performing a bowel movement [1]. However, these current defecation PMDs target individuals with a full range of motion and are not suited for achieving and sustaining hip flexion for individuals with NB.

Achieving a bowel movement may take several hours for an individual with NB, putting them at risk of developing pressure ulcers. Therefore, our goal is to create a posture modification device that allows an individual with NB to safely achieve a squatting position for the duration of their bowel care program.

Our approach to creating a device capable of sustaining the squatting position is by means of an accessory item for the shower/commode chair rather than redesigning the commode chair itself. We are currently developing our device specifically for the HOMCOM Commode Shower Transport Wheelchair [3]. Nonetheless, our design process involves considerations for adjustable dimensions to cater to a range of commode chairs in the medical device industry.

## PRODUCT DESIGN

The design of our device takes a novel leaning forward approach to assist in posture modification during bowel care as depicted in Figure 1. Our design will support the user's torso to achieve the desired hip flexion angle and sustain it for the duration of their bowel care procedure. A key aspect to this novel leaning forward design is the pressure relief from the ischial tuberosities. Current PMD's achieve hip flexion by raising the knees from behind the knee, which concentrates pressure to the ischium, increasing the risk for developing pressure ulcers.

**Figure 1: General concept of the torso-lean mechanism to achieve the hip flexion angle.**

Early in our design process, we conducted a thorough literature review and met with a variety of voice of customers (VoC) to create a list of customer needs as the basis for our device. Listed in Table 1 are the goal metrics for the most crucial needs.

**Table 1: Summary analysis of customer needs**

| Needs | Goal Metrics |
|---|---|
| Support Hip Flexion Angle | 22.5º-35º [1] |
| Sustain Desired Hip Flexion Angle | 2-3 hours [3] |
| Support User Weight | 300-400 lbs |
| Provide Low User Contact Pressure | 0 to 33 mmHg per 15 to 20 minutes [4] |

The support user weight capacity was determined by HOMCOM's commode chair weight capacity and factor of safety listed by specifications of components (locking mechanism) for our device available online.

The device serves as an accessible attachment to current shower/commode chairs on the market. The interface location provides users easy access to the perianal region from the front and sides during bowel care. Our design is composed of a noncorrosive aluminum frame with adjustable dimensions to accommodate variable user demographics as shown in Figure 1. The device to commode interface consists of compatible constriction clamps to secure the device in place and adjust to variations in commode sizes

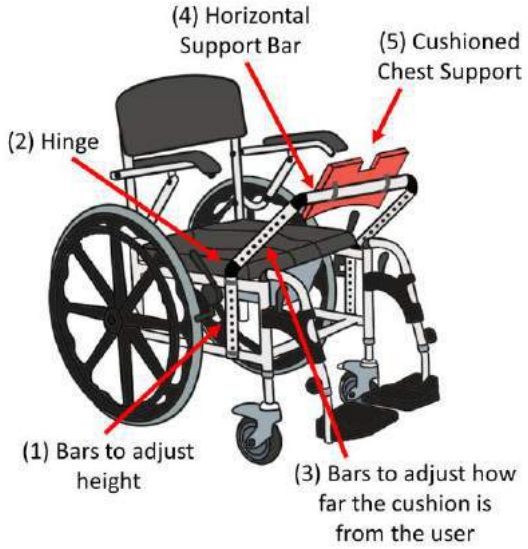

**Figure 2: Labeled schematic of the torso-lean attachment piece to the HOMCOM shower/commode chair.**

At the start of bowel care the user will need to transfer into their commode. Our design facilitates this process by incorporating a swivel mechanism to rotate the torso rest away from the user's intended path. The user can securely lock the torso rest back into place while preparing for positioning. The device can easily be adjusted and locked via a release button into the user's desired hip flexion angle through a heavy-duty aluminum hinge system. The user can then lean forward onto the torso support to sustain their hip flexion positioning throughout their bowel care procedure.

The torso support rest consists of a vinyl covered high density foam with a high-density polyethylene base for comforted support. After the user is finished with bowel care they can go right into a shower to get cleaned up and can continue to keep the device on their commode for extra support. These materials along with the lightweight aluminum frame are similar to current commode/shower chair materials providing for sufficient bathroom environmental compatibility as well as feasible manufacturability.

## BUDGET & MARKET ANALYSIS

Based on data from 1993-2012, the estimated incidence for acute spinal cord injury (SCI) was 54 cases per 1 million population, which would result in ~6 million Americans in 2022 [6]. Of those, 75% experience some degree of constipation and fecal incontinence [7]. This results in ~4.5 million Americans with NB. Commode chairs are a necessity for an individual with an SCI, and our device is designed to be used in conjunction with an existing commode rather than be a replacement. Therefore, this provides us with our rough market size and relevant demographic. As per our caregiver VoC, commodes and related devices are typically replaced in the 4–6-year range, however the material selection and nature of our device may lend itself to a slightly longer lifespan.

Below is the list of components we may need for any additional prototyping as we build towards our final device. Each category represents the overall anticipated cost for the device's subsystems. Additionally, prototyping may be necessary to test the viability of the device and help us get a preliminary sense of whether our hinge mechanism will support the load of the person's upper body and whether our device can be successfully clamped to the commode chair. Most of the materials for prototyping are found in our engineering department's design lab. We expect any additional prototyping would take 2-3 hours of our time to complete.

**Table 2: Overview of budget for prototyping.**

| Category | Cost |
|---|---|
| Torso support cushion: materials and fabrication | $72.68 |
| Locking components | $298.75 |
| Structural/stability framework | $92.44 |
| Miscellaneous (machining, screws, delivery, etc.) | $50.00 |

Therefore, the final monetary cost for our device is estimated to be approximately $514 for our device. The hinges make up a large fraction of these costs ($204/$514), so we are looking into cheaper alternatives that provide the same structural support. Our current plan is to discuss with a mechanical fabrication specialist to potentially fabricate our own hinges. The prices may also vary slightly depending on whether we choose the swivel ball joints or the split collar telescoping tube lock. Upcoming efforts will be dedicated towards deciding which mechanism to pursue and fabricating our final product.

## ACKNOWLEDGEMENTS

We would like to thank the nurse manager and the occupational therapists at The University of Rochester Medical Center Department of Physical Medicine and Rehabilitation, the specialists at Numotion, and members of Rochester Spinal Association for their continuous support and feedback, and for sharing their knowledge/experiences with us. We would also like to thank our customer, Dr. Sara Salim at The University of Rochester Medical Center Department of Physical Medicine and Rehabilitation, for providing us with our engineering design project, and our supervising TA, Lucas Lassinger, for providing detailed feedback throughout our design progress.
