*2023 Summer Biomechanics, Bioengineering,
and Biotransport Conference*

June 4th – 8th, 2023

Vail, Colorado

*Building Interfaces Across Tissues,
Disciplines, and Communities*

Funding for this conference was made possible (in part) by the National Science Foundation and the National Institutes of Health. The views expressed in written conference materials or publications and by speakers and moderators do not necessarily reflect the official policies of the Department of Health and Human Services; nor does mention of trade names, commercial practices, or organizations imply endorsement by the U.S. Government. The 2023 Summer Biomechanics, Bioengineering, and Biotransport Conference (SB³C) organizers gratefully acknowledge the support of the National Science Foundation and the National Institutes of Health.

National Institute of Biomedical Imaging and Bioengineering
Creating Biomedical Technologies to Improve Health

Congratulations to the 2022 Cover Art Contest Winner:

Kacper Ostalowski, Joseph A. Insley, and Jifu Tan, Northern Illinois University.

Title: Direct Numerical Simulation of Blood Flow with Cells in Retina Vascular Network

Description: The photo depicts the transport of red blood cells through a patient-specific retina vascular network. The velocity magnitude is indicated by the background color in the tubes. The top inset illustrates the accumulation of cells in a T-branch vessel, while the bottom inset provides an enlarged view of cells in complicated vessels with branches and loops.

Permission to download, print, and photocopy a single, individual copy of any of the works contained in this file for personal use in research and/or educational pursuit is granted by the SB³C Foundation, Inc. For other uses, contact the Board of the SB³C Foundation, Inc., 20 South Duke Street, #1, Lancaster, PA 17602.

SB³C 2023 Meeting Pitch Competition

Sunday, June 4

4:00PM – 5:30PM MT

Translational Technologies Pitch Competition Finals

Zermatt

Session Chairs: **Ethan Kung**, *Clemson University of Utah*
Lyle Hood, *University of Texas at San Antonio*

- 4:00PM** **On-Demand, Volumetric Liquid Biopsy From Solid Tumors** SB³C2023-PC01
Y. Kimura¹, MC. Sheehan², NR. Raghuraman², D. Downing², G. Srimathveeravalli²
¹Osaka University Graduate School of Medicine, ²University of Massachusetts, Amherst
- 4:20PM** **Improving Clinical CT Image Data To Develop Better Fracture Risk Algorithms And Patient Outcomes** SB³C2023-PC02
Lance L. Frazer¹, Nathan Louis^{1,2}, Kal L. Clark³, Daniel P. Nicolella¹
¹Southwest Research Institute, ²University of Michigan, ³University of Texas Health Science Center at San Antonio
- 4:40PM** **SLIC-VAD: A Wirelessly Powered LVAD With Magnetic Levitation Bearings**
SB³C2023-PC03
Shweta Karnik¹, Huang Chen¹, Simon Kiang⁴, Arun Kumar Kota², Yaxin Wang³, Joseph Cavallaro⁴, Oscar H Frazier³, Lakshmi Prasad Dasi¹
¹Georgia Institute of Technology and Emory University, ²North Carolina State University, ³Texas Heart Institute, ⁴Rice University
- 5:00PM** **I-KinCor: Revolutionizing Pediatric Duct-Dependent Surgeries** SB³C2023-PC04
Luis René Mata Quiñonez¹, Shweta Karnik¹, Srujana S. Joshi¹, Leon Cheng¹, Holly Bauser-Heaton, MD^{1,2}, Lakshmi Prasad Dasi¹
¹Georgia Institute of Technology and Emory University, ²Children's Healthcare of Atlanta

Poster Session: Translational Technologies**Cascade ABC**

- P1 Solving the Problem of Bicycle Helmet Fit** SB³C2023-PC05
William J. Makowski, Thomas L. Martin, William A. Schaudt
Virginia Tech
- P2 Faciliflow: An Implantable Device to Prevent the Onset of Breast Cancer-Related Lymphedema** SB³C2023-PC06
A. Swarup¹, A. Vella¹, K. Rowley², J. Frattolin¹, J. Moore Jr.¹
¹Imperial College, ²Lympha Motus, Ltd.
- P3 Predicting Fracture Healing by Measuring Compliance Via Direct Electromagnetic Coupling** SB³C2023-PC07
Kevin M. Labus¹, Kirk C. McGilvray¹, Branislav Notaros¹, Milan Ilic², Julie Dunn³, Christian M. Puttlitz¹
¹Colorado State University, ²University of Belgrade, ³University of Colorado Health North
- P4 Tackling Antimalarial Drug Resistance in Africa Using Novel Drug Repurposing and Nanotechnology Strategies** SB³C2023-PC08
Samuel W. Uzundu, Petra O. Nnamani, Anthony A. Attama
University of Nigeria
- P5 Tapping into Ligament Tension with Our Ligament Tensiometer to Enhance Outcomes Following Orthopedic Procedures** SB³C2023-PC09
Lesley R. Arant, Kai M. Heineman, Josh D. Roth
University of Wisconsin-Madison
- P6 Orthopedic Cast Saw** SB³C2023-PC10
Ryan A. DeJesus, Nicholas J. Graham, Evan M. Lunney, Jaedan D. Morton
The Pennsylvania State University
- P7 Artificial Multi-Organ Replacement (AMOR) System** SB³C2023-PC11
Nanye Du, Suhail Ahmad, Shaohang Hao, Ziyuan Wang, Ye Jin, Alexander Novokhodko, Dayong Gao
University of Washington
- P8 A Novel Hardware and Software Device to Non-Invasively Predict Post Thrombotic Syndrome** SB³C2023-PC12
Cyrus J. Darvish, Pete H. Gueldner, Rabih A. Chaer, David A. Vorp, and Timothy K. Chung
University of Pittsburgh
- P9 Polymeric transcatheter aortic valve replacement (TAVR) for treating aortic stenosis** SB³C2023-PC13
B. Kovarovic¹, O.M. Rotman¹, M. Slepian², D. Bluestein¹
¹Stony Brook University, ²University of Arizona
- P10 Automatically perfusable human vessel chip platform for preclinical research in hazardous containment environments and space** SB³C2023-PC14
J. Eades¹, A. Kumar¹, A. Jain^{1,2}
¹Texas A&M University, ²Houston Methodist Hospital

SB³C 2023 Meeting Scientific Podium Sessions

Monday, June 5

9:45AM – 11:15AM MT

Machine Learning in Biofluids

Cascade ABC

Session Chairs: Amir Arzani, *University of Utah*
Fanwei Kong, *University of California, Berkeley*

- 9:45AM A Deep Learning Approach For Cardiac Model Construction For Congenital Heart Disease Patients** SB³C2023-402
Fenwei Kong, Alison L. Marsden
Stanford University
- 10:00AM Enhancing Corrupt Cardiovascular Flow Data With Machine Learning** SB³C2023-026
Hunor Csala, Amirhossein Arzani
University of Utah
- 10:15AM Automatic Model Construction For Patient-Specific Aortic Flow Simulations Using Geometric Deep Learning** SB³C2023-273
Pan Du, Delin An, Chaoli Wang, Jian-Xun Wang
University of Notre Dame
- 10:30AM Physics-informed Neural Networks with Fourier-based Activation Function To Model Complex Cardiovascular Flows** SB³C2023-015
Arman Aghaee, M. Owais Khan
Toronto Metropolitan University
- 10:45AM Data-Enhanced Personalized Models For Coronary Hemodynamics And Myocardial Perfusion** SB³C2023-014
Karthik Menon¹, Zachary Sexton¹, Owais Khan², Daniele Schiavazzi³, Koen Nieman¹, Alison Marden¹
¹Stanford University of Texas Dallas, ²Toronto Metropolitan University, ³University of Notre Dame
- 11:00AM Machine Learning-Based Reduced Order Modelling For The Simulation Of Braided Stent Deployment.** SB³C2023-303
Beatrice Bisighini^{1,2,3}, Miquel Aguirre^{1,4,5}, Baptiste Pierrat¹, David Perrin², Stéphane Avril¹
¹University of Lyon, ²Predisurge, ³University Tor Vergata, ⁴Universitat Politècnica de Catalunya, ⁵Gran Capità

Monday, June 5

9:45AM – 11:15AM MT

Soft Tissue Mechanics

Cascade D

Session Chairs: *Kyoko Yoshida, Univ of Minnesota*
Colleen Witzenburg, Univ of Wisconsin

- 9:45AM A Clot Composition Dependent Hyperelastic Model In The Simulation Of Direct Aspiration Thrombectomy** SB³C2023-362
K. Bein Snee¹, R. McCarthy², P.E. McHugh¹, B. Fereidoonenezhad³, J.P. McGarry¹
¹University of Galway, ²Cerenovus, ³TU Delft
- 10:00AM Using Bayes' Optimization For Inverse Finite Element Analysis Of The Tricuspid Valve In Hypoplastic Left Heart Syndrome** SB³C2023-338
Colton J. Ross¹, Jaden Norman¹, Arshid Mir¹, Harold M. Burkhart¹, Ming-Chen Hsu², Chung-Hao Lee¹
¹University of Oklahoma, ²Iowa State University
- 10:15AM Calcified Plaque Has A Local Effect On The Dissection Behavior Of Human Aortas** SB³C2023-563
Carly L. Donahue, Raturaj Badal, Victor H. Barocas
University of Minnesota
- 10:30AM Influence Of Material Parameter Variability On The Predicted Coronary Artery Biomechanical Environment Via Uncertainty Quantification** SB³C2023-413
David Jiang, Caleb C. Berggren, Y.F. Jack Wang, Jake A. Bergquist, Lindsay C. Rupp, Zexin Liu, Rob S. MacLeod, Akil Narayan, Lucas H. Timmins
University of Utah
- 10:45AM Spatial Configurations Of 3D Extracellular Matrix Density And Anisotropy Simultaneously Guide Angiogenesis** SB³C2023-084
Steven A. LaBelle¹, Steve A. Maas¹, Adam Rauff¹, Gerard A. Ateshian², Jeffery A. Weiss¹
¹University of Utah, ²Columbia University
- 11:00AM Spatiotemporal Evolution Of Collagen Micro-Mechanics Under Breast Cancer Cell Driven Remodeling** SB³C2023-125
Adil Khan, Jacopo Ferruzzi
University of Texas at Dallas

Monday, June 5

9:45AM – 11:15AM MT

Ocular and Lower Abdomen Biomechanics

Cascade E

Session Chairs: Jake Hermann, *University of Iowa*
Katrina Knight, *University of Pittsburgh*

- 9:45AM** **Lamina Cribrosa Beam Insertions. The Humble Heroes Of The Lamina-Sclera Interplay** SB³C2023-513
Fengting Ji, Hua Yi, Ian A. Sigal
University of Pittsburgh
- 10:00AM** **Mechanical Properties of Porcine Iris Stroma Using Micro-Indentation: The Effect Of Temperature And Hydration** SB³C2023-495
F. Sebastian¹, G. Bailey¹, V. Kondiboyina¹, S. Dorairaj², R. Amini¹
¹*Northeastern University*, ²*Mayo Clinic*
- 10:15AM** **Structural And Functional Heterogeneity Of The Uterosacral Ligaments In The Rat** SB³C2023-243
Joseph G. Thomas, Kandace Donaldson, Yizheng Zhu, Clara Gimenez, Raffaella De Vita
Virginia Tech
- 10:30AM** **Biaxial Mechanics Of The Murine Vagina During Postpartum Healing Before And After Elastic Fiber Disruption** SB³C2023-272
Shelby E. White¹, Lily M. Buchanan², Niyousha Karbasion³, Matthew R. Bersi³, Maria Florian-Rodriguez⁴, Kristin S. Miller^{2,4}
¹*Tulane University*, ²*University of Texas, Dallas*, ³*Washington University in St. Louis*, ⁴*University of Texas, Southwestern*
- 10:45AM** **Passive Mechanics Of Deep And Superficial Human Female Pelvic Floor Muscles** SB³C2023-455
Megan R. Routzong^{1,3}, Justin Dubik², Raffaella De Vita², Marianna Alperin³, Pamela A. Moalli¹, Steven D. Abramowitch¹
¹*University of Pittsburgh*, ²*Virginia Tech*, ³*University of California, San Diego*
- 11:00AM** **Bladder Wall Stress Is Lower In Female Compared To Male In A Murine Model Of Ex-Vivo Filling** SB³C2023-422
Eli Broemer, Pragya Saxena, Nathan R. Tykocki, Sara Roccabianca
Michigan State University

Monday, June 5

9:45AM – 11:15AM MT

Biotransport in Therapeutic Design and Analysis

Cascade F

Session Chairs: **Chris Rylander**, *University of Texas at Austin*
R. Lyle Hood, *University of Texas at San Antonio*

- 9:45AM A Biphasic Fluid-Structure Interaction Model Of Backflow During Infusion Into Agarose Gel** SB³C2023-090
Arthur D. Ayers, Joshua H. Smith
Lafayette College
- 10:00AM Thermodynamics Of Phase Transformation Of Water: Theory And Experiments** SB³C2023-301
Raphael J. Kepecs, Gerard A. Ateshian
Columbia University
- 10:15AM Model For Heat Conduction In Vaporizable Endoskeletal Droplet In Response To X-Ray Photon Absorption** SB³C2023-578
William N. Frantz, David H. Thomas, Mark A. Borden
University of Colorado
- 10:30AM Computational Modeling Of Machine Perfusion Of The Human Liver Vasculature** SB³C2023-585
Daniel Emerson, Yoed Rabin, Levent Burak Kara
Carnegie Mellon University
- 10:45AM Conformal Ablation Of Atherosclerotic Plaque Based On Multi- Electrodes And NSGA II** SB³C2023-590
Hongying Wang, Ruizhe Hou, Shiqing Zhao, Aili Zhang
Shanghai Jiao Tong University
- 11:00AM N-Acetyl Cysteine Rescues Chondrocytes From Oxidative Stress And Increases Their Metabolic Activity** SB³C2023-275
Austin C. Jenk^{1,2}, Elisabeth A. Lemmon^{1,2}, Sarah E. Gullbrand^{1,2}, Robert L. Mauck^{1,2}
1University of Pennsylvania, 2Veterans Affairs Medical Center

Monday, June 5

9:45AM – 11:15AM MT

Engineered *In Vitro* Models

Gore AB

Session Chairs: Nathaniel Dymnt, *University of Pennsylvania*

Kristan Worthington, *University of Iowa*

- 9:45AM Modeling Cardiac Fibrosis: Understanding the Effects of Exogenous Extracellular Matrix on 3D Cardiac Tissues** SB³C2023-229
Natalie Weiss-Pachter, Kristen Allen, Tracy Hookway
Binghamton University
- 10:00AM Engineered Composite Fibrous Hydrogels that Mimic Dynamic Developmental Signals during Fibrous Tissue Development** SB³C2023-376
Karen L. Xu¹, Jason A. Burdick^{1,2}, Robert L. Mauck¹
¹*University of Pennsylvania*, ²*University of Colorado*
- 10:15AM An explant-in-a-chip perfusion model for ex vivo preservation of tissue viability and function with applications for personalised medicine in cancer** SB³C2023-419
Evangelia E. Zeringa, Foivos Chatzidimitriou, Ester Reina-Torres, Larry O'Connell, Beatrice-Cristina Bezdadea, Alexandria Mitchell, Paula Cunnea, Christina Fotopoulou, Olivier Pardo, Joseph van Batenburg-Sherwood, Iain A. McNeish, Darryl R. Overby
Imperial College London
- 10:30AM Prolonged Subculture and Progerin Expression Sensitize VSMCs to Three Dimensional Fiber Structures** SB³C2023-374
Yu-Yu Hsueh, Pen-hsiu Grace Chao
National Taiwan University
- 10:45AM The Role Of Monocyte And Macrophages In The Development Of Aortic Valve Calcification In A 3D Tri-Culture In Vitro Model** SB³C2023-121
Fatemeh Saleemizadehparizi, Peter Huang, Mei-Hsiu Chen, Gretchen J. Mahler
Binghamton University
- 11:00AM Development of a Schlemm's canal "inner wall on a chip" for high content biomechanical screening** SB³C2023-417
Seyed Mohammad Siadat¹, Jacques A. Bertrand², Babak N. Safa¹, Darryl R. Overby², W. Daniel Stamer³, C. Ross Ethier¹
¹*Georgia Institute of Technology*, ²*Imperial College of London*, ³*Duke University*

Monday, June 5

9:45AM – 11:15AM MT

Cartilage: Composition and Lubrication

Gore CD

Session Chairs: Jennifer Puetzer, *Virginia Commonwealth University*

Phoebe Szarek, *University of Connecticut*

- 9:45AM Mechanical Weakening Precedes Cartilage Loss During Osteoarthritis Progression Across the Human Tapezium** SB³C2023-196
Brendan D. Stoeckl^{1,2}, Kendall M. Masada^{1,2}, Lorielle G. Laforest¹, Michael W. Hast¹, David R. Steinberg^{1,2}, Robert L. Mauck^{1,2}
¹University of Pennsylvania, ²Corporal Michael J. Crescenz VA Medical Center
- 10:00AM Quantitative Raman Measurement Of Cartilage Composition Via Tissue Phantom Calibration** SB³C2023-461
Erik Erslund¹, Dev Mehrotra¹, Mark W. Grinstaff¹, Brian D. Snyder², Mads S. Bergholt³, Michael B. Albro¹
¹Boston University, ²Beth Israel Deaconess Medical Center, ³King's College London
- 10:15AM Decorin Maintains Cartilage Surface Integrity And Chondrocyte Mechanotransduction During Aging** SB³C2023-159
M. Fan¹, B. Kwok¹, P. Singh¹, J. Xiang¹, L. Qin², D.E. Birk³, R.V. Iozzo⁴, R.L. Mauck², L. Han¹
¹Drexel University, ²University of Pennsylvania, ³University of South Florida, ⁴Thomas Jefferson University
- 10:30AM A chemo-mechano-biological model of cartilage in FEBio: Studies of pathological loading, homeostatic adaptation and bio-chemical treatments** SB³C2023-486
Muhammed M. Rahman¹, Paul N. Watton², Corey P. Neu³, David M. Pierce¹
¹University of Connecticut, ²University of Sheffield, ³University of Colorado
- 10:45AM Synovial Fluid Provides A Protective Effect In Articular Cartilage Fatigue Failure** SB³C2023-215
C.V. Sise, C.A. Petersen, J.X. Dewing, B.K. Zimmerman, J. Yun, R.J. Kepecs, C.T. Hung, G.A. Ateshian
Columbia University
- 11:00AM The Role of Hyaluronic Acid in the Synergistic Lubrication of Articular Cartilage** SB³C2023-082
Emily P. Lambeth, David L. Burris, Christopher Price
University of Delaware

Monday, June 5

9:45AM – 11:15AM MT

Translational Bioengineering

Powell

Session Chairs: Lin Li, *Eli Lilly*

Elizabeth Shih, *University of Minnesota*

- 9:45AM** **Shifting The Endovascular Paradigm: Patient-Specific Treatment Of Intracranial Aneurysms Using Shape Memory Polymers And Additive Manufacturing** SB³C2023-124
Sergio A. Pineda-Castillo¹, Tanner Cabaniss¹, Bradley N. Bohnstedt², Chung-Hao Lee¹
¹University of Oklahoma, ²Indiana University
- 10:00AM** **Impacts Of Type V Collagen Insufficiency On Cutaneous Wound Healing And Scar Formation** SB³C2023-153
Y. Liu¹, C. Wang¹, D.C. Stewart², E.M. O'Brien¹, B.K. Brisson², D.E. Birk³, K.L. Spiller¹, S.W. Volk², L. Han¹
¹Drexel University, ²University of Pennsylvania, ³University of South Florida
- 10:15AM** **Understanding Impacts Of Collagen Organization In An Infected Diabetic Wound Model Treated With A Novel Oxygenating And Antibacterial Hydrogel** SB³C2023-168
Hannah A. Durr¹, Samuel D. Salinas², Rouzbeh Amini², Nic D. Leipzig¹
¹University of Akron, ²Northeastern University
- 10:30AM** **Development And Utilization Of A Vascularized In Vitro Physiologically Representative Skin Tissue Platform For Burn Injury Investigation** SB³C2023-257
S. Brocklehurst, N. Ghousafim, K. Zuniga, D. Stolley, M.N. Rylander
University of Texas
- 10:45AM** **Proteomic Characterization And Metabolic Labeling Of A Fibrin-Based In Vitro Wound Healing Model** SB³C2023-418
Dalton Miles¹, Tyler Tuttle¹, Julian Jimenez², Yifan Guo², Adrian Buganza-Tepole², Sarah Calve^{1,2}
¹University of Colorado, ²Purdue University
- 11:00AM** **Experimental And Computational Analysis Of The Injection- Induced Mechanical Changes In The Skin Microenvironment During Subcutaneous Injection Of Biologics** SB³C2023-518
Yingnan Shen, Sameep R. Shah, Kejie Zhao, Bumsoo Han
Purdue University

Monday, June 5

9:45AM – 11:15AM MT

Cardiovascular Mechanobiology

Zermatt

Session Chairs: Bryan Good, *University of Tennessee*

Friederike Schäfer, *Norwegian University of Science and Technology*

- 9:45AM** **Effect of aging, sex, and gene (fibulin-5) on the arterial stiffness of mouse: 20 weeks adult mice with fibulin-5 knockout are older than 100 weeks wild-type mice** SB³C2023-341
H. Dong¹, J. Ferruzzi², M. Liu¹, L. Brewster³, R. Gleason¹
¹Georgia Institute of Technology, ²University of Texas, Dallas, ³Emory University
- 10:00AM** **Functional Differences in Human Aortic Valve Interstitial Cells from Patients with Varying Calcific Aortic Valve Disease** SB³C2023-458
R. Tuscher¹, A. Khang¹, T. West¹, G. Ferrari², M. Sacks¹
¹University of Texas, Austin, ²Columbia University
- 10:15AM** **Reduced Vascular Smooth Muscle Cell Mechanoadaptation in an in vitro Model of Cerebral Amyloid Angiopathy** SB³C2023-279
Samuel F. Boland, Patrick W. Alford
University of Minnesota
- 10:30AM** **Constitutive Modeling Of Mouse Arteries Suggests Changes In Directional Coupling And Extracellular Matrix Remodeling That Depends On Artery Type, Age, Sex And Elastin Amounts** SB³C2023-300
Keshav A. Kailash, Jie Z. Hawes, Austin J. Cocciolone, Robert P. Mecham, Jessica E. Wagenseil
Washington University in St. Louis
- 10:45AM** **Determining How VEGFR-2 Inhibition Affects Phosphorylation And Function In The Presence Of Mechanical Strain** SB³C2023-320
Bronte Miller, Michael Heim, Bryan Mortimer, M.K. Sewell-Loftin
University of Alabama at Birmingham
- 11:00AM** **A Testable Mechanism for Force Generation and Maintenance in the Tonic Smooth Muscle** SB³C2023-606
Suzzane E. Stasiak, Dhanajay T. Tambe, Harikrishnan Parameswaran
Northeastern University

Monday, June 5

11:30AM – 1:00PM MT

Thrombosis and Hemolysis

Cascade ABC

Session Chairs: Debanjan Mukherjee, *University of Colorado Boulder*
Bryan Good, *University of Tennessee*

- 11:30AM Numerical Predictions Of Flow-Induced Hemolysis: Can The Accuracy Of The Power Law Model Be Improved Using Calibrated Coefficients?** SB³C2023-371
Alberto Mantegazza¹, Nicolas Tobin², Keefe B. Manning², Brent A. Craven³
¹*Polytechnic University of Bari*, ²*Pennsylvania State University*, ³*US FDA*
- 11:45AM An In Vitro Assessment of Emboli Trajectories Within a Patient Specific Model: Investigation into the Influence of Thrombus Size, Mechanical Properties, and Cerebral Blood Pressure** SB³C2023-308
A. Glynn^{1,2}, A. Consoli³, B. Murphy^{1,4}, R. McCarthy², C. Lally^{1,4}
¹*Trinity College Dublin*, ²*Cerenovus*, ³*Hôpital Foch*, ⁴*RCSI & TCD*
- 12:00PM Hematocrit Is A Potent Driver Of Platelet Adhesion At Supraphysiological Shear Rates** SB³C2023-126
C. Watson¹, K. Manning^{1,2}
¹*Pennsylvania State University*, ²*Penn State Hershey Medical Center*
- 12:15PM Computational Simulation Of Patient-Specific Blood Coagulation In Stent Thrombosis** SB³C2023-404
Janneke M.H. Cruts¹, Mohammad Rezeimoghaddam², Frans N. van de Vosse², Frank J.H. Gijsen^{1,3}
¹*Erasmus Medical Center*, ²*Eindhoven University of Technology*, ³*Delft University of Technology*
- 12:30PM Image driven simulation of hemodynamics around a dynamic clot in vivo** SB³C2023-566
Chayut Teeraratkul¹, Timothy J. Stalker², Maurizio Tomaiuolo³, Debanjan Mukherjee¹
¹*University of Colorado*, ²*Thomas Jefferson University*, ³*Wills Eye Hospital*
- 12:45AM Multiscale, Cell-Resolved Simulations of Red Blood Cells in Macroscale Flows for Hemolysis Prediction** SB³C2023-105
Grant J. Rydquist, Mahdi Esmaily
Cornell University

Vascular Pathology and Fluid Flow

Cascade D

Session Chairs: Grant Rydquist, *Cornell University*

Alejandro Roldán-Alzate, *University of Wisconsin - Madison*

- 11:30AM Computational Fluid Dynamics Study To Investigate The Impact Of Sudden Physiological Actions On Cerebrospinal Fluid Pressure And Flow** SB³C2023-311
 Sarah Vandenbulcke¹, Paul Condron^{2,3}, Haribalan Kumar^{2,3,4}, Soroush Safaei³, Samantha Holdsworth^{2,3}, Joris Degroote¹, Patrick Segers¹
¹Ghent University, ²Tairāwhiti-Gisborne, ³University of Auckland, ⁴GE Healthcare
- 11:45AM Blood Flow Energy Profiles in Coronary Arteries Predict Myocardial Infarction** SB³C2023-309
 M. Lodi Rizzini¹, A. Candreva^{1,2}, V. Mazzi¹, C. Chiastra¹, B. De Bruyne³, C. Collet³, D. Gallo¹, U. Morbiducci¹
¹Politecnico di Torino, ²Zurich University Hospital, ³OLV-Clinic
- 12:00PM Evolution Of The Hemodynamic Properties And Arterial Wall Remodeling In Pulmonary Arterial Hypertension** SB³C2023-154
 H. Mu, D. Valdez-Jasso
University of California, San Diego
- 12:15PM Hemodynamics Of Coarctation Of The Aorta - Comparison Of A Distributed Lumped Parameter Model And 4D Flow MRI** SB³C2023-128
 Labib A. Shahid¹, Matthew A. Culver¹, James P. Rice¹, Haben Berhane², Cynthia K. Rigsby³, Joshua D. Robinson³, Lindsay M. Griffin³, Michael Markl², Colleen M. Witzenburg¹, Alejandro Roldán-Alzate¹
¹University of Wisconsin-Madison, ²Northwestern University, ³Lurie Children's Hospital of Chicago
- 12:30PM Mitigating Post-TAVR Thrombogenic Risk: Design And Optimization Of Novel Trileaflet and Bicuspid Aortic Valve Devices** SB³C2023-109
 Kyle J. Baylous¹, Brandon J. Kovarovic¹, Salwa B. Anam¹, Ryan T. Helbock¹, Marvin J. Slepian², Danny Bluestein¹
¹Stony Brook University, ²University of Arizona
- 12:45AM A Computational Assessment of Stroke Predictors After Transcatheter Aortic Valve Replacement** SB³C2023-491
 B. Vogl¹, Z. Wang², A. Chavez Ponce³, A. El Shaer³, M. Alkhouli³, H. Hatoum¹
¹Michigan Technological University, ²The Ohio State University, ³Mayo Clinic

Monday, June 5

11:30AM – 1:00PM MT

Ocular and Lung Biomechanics

Cascade E

Session Chairs: Yi Hua, *University of Mississippi*

Arina Korneva, *Virginia Tech*

- 11:30AM Eye-Specific Modeling Of Effects Of Intraocular Pressure On Optic Nerve Head Oxygenation** SB³C2023-297
Yuankai Lu, Yi Hua, Bingrui Wang, Fuqiang Zhong, Andrew Theophanous, Shaharoz Tahir, Po-Yi Lee, Ian A. Sigal
University of Pittsburgh
- 11:45AM Effects of Glaucoma and Optic Nerve Crush on the Biomechanical Behavior Of Mouse Astrocytic Lamina Cribrosa** SB³C2023-510
A Korneva, E. Kimball, T.V. Johnson, S. Quillen, M.E. Pease, T.D. Nguyen, H.A. Quigley
Johns Hopkins University
- 12:00PM Quantifying the Remodeling Strain in the Lamina Cribrosa Years After Pressure Lowering Surgery** SB³C2023-208
Cameron A. Czerpak, Harry A. Quigley, Thao D. Nguyen
Johns Hopkins University
- 12:15PM The Influence Of Recruitment Maneuvers On Localized Murine Lung Strains Assessed With Digital Image Correlation** SB³C2023-123
M. Shankel, T.M. Nelson, K.A.M. Quiros, T. Biddle, G.O. Ramirez, C.A. Mariano, J. Bebawy, D.D. Lo, M. Eskandari
University of California, Riverside
- 12:30PM Quantifying Temporal Dynamics Of Alveolar Recruitment During Mechanical Ventilation** SB³C2023-236
Daniel S. Meggo, Edward A. Sander, Jacob Herrmann
University of Iowa
- 12:45AM Probing Lung Function At High Spatiotemporal Resolution Via Crystal Ribcage** SB³C2023-434
Rohin Banerji, Gabrielle N. Grifno, Linzheng Shi, Dylan Smolen, Rob LeBourdais, Johnathan Muhvich, Cate Eberman, Bradley Hiller, Jisu Lee, Kathryn Regan, Siyi Zheng, Sue S. Zhang, John Jiang, Riley Pihl, Katrina Traber, Giovanni Ligresti, Joseph P. Mizgerd, Bela Suki, Hadi T. Nia
Boston University

Monday, June 5

11:30AM – 1:00PM MT

Sex, Age, and Disease in Brain and Head Injury

Cascade F

Session Chairs: Kaveh Laksari, *University of Arizona*

Ken Monson, *University of Utah*

- 11:30AM Sex Difference In Axon Dynamic Behavior Under Axial Loading And Unloading**
SB³C2023-324
C. Zhang, S. Ji
Worcester Polytechnic Institute
- 11:45AM Evolution Of Human Cortical Thickness And Morphology Throughout Growth And Development** SB³C2023-041
Nagehan Demirci, Maria A. Holland
University of Notre Dame
- 12:00PM Age- And Sex-Based Skull Thickness Distribution For Predicting Skull Fracture Patterns** SB³C2023-428
Yousef Alsanea, Timothy Dixon, Tagrid Ruiz-Maldonado, Brittany Coats
University of Utah
- 12:15PM Spatial Gradient in Brain Mechanical Properties Changes Through Development But Is Consistent During Adulthood** SB³C2023-239
Kyra E. Twohy¹, Grace McIlvain^{1,2}, Jeffrey M. Spielberg¹, Curtis L. Johnson¹
¹*University of Delaware*, ²*Georgia Institute of Technology*
- 12:30PM High Resolution MR Elastography of the Human Brain: Technical Development and Applications in Aging and Alzheimer's Disease** SB³C2023-132
E. Triolo¹, O. Khagai², A. Alipour², T. Hedden², P. Balchandani², M. Kurt^{1,2}
¹*University of Washington*, ²*Mount Sinai*
- 12:45AM The Relationship Between Imbalance Symptom And Cardiac Pulsation Induced Mechanical Strain In The Brainstem And Cerebellum For Chiari Malformation Type I** SB³C2023-471
Mohamad Motaz F. Al Samman¹, Alaaddin Ibrahimy², Blaise Simplicie Talla Nwotchouang³, John N. Oshinski⁴, Daniel L. Barrow⁴, Philip A. Allen³, Rouzbeh Amini¹, Rafeeqe A. Bhadelia⁵, Francis Loth¹
¹*Northeastern University*, ²*Yale University*, ³*University of Akron*, ⁴*Emory University*, ⁵*Harvard*

Monday, June 5

11:30AM – 1:00PM MT

Bioprinting and Emerging Technology in TCE

Gore AB

Session Chairs: Deva Chan, *Purdue University*
Edward Sander, *University of Iowa*

- 11:30AM Particulated ECM Biomaterial Inks Enable 3D Bioprinting of Osteochondral In Vitro Models With Multi-Scale Architecture** SB³C2023-535
Juliet O. Heye, Shannon A. Blanco, Jeanne E. Barthold, Emily Y. Miller, Corey P. Neu
University of Colorado
- 11:45AM Novel Metabolic Labeling Demonstrates A Critical Role Of Decorin In The Assembly And Turnover Of Cartilage Matrix** SB³C2023-399
T. Li¹, M. Fan¹, A. Porter², B. Kwok¹, C. Wang¹, D.E. Birk³, R.V. Iozzo⁴, X.L. Lu², R.L. Mauck⁵, L. Han¹
¹Drexel University, ²University of Delaware, ³University of South Florida, ⁴Thomas Jefferson University, ⁵University of Pennsylvania
- 12:00PM Modeling Human Sex-Specific Fibrotic Activation In 3D-Bioprinted Pulmonary Artery Adventitia** SB³C2023-039
Duncan J. Davis-Hall, Chelsea M. Magin
University of Colorado
- 12:15PM A Thermodynamic Framework For The Evolution Of Sarcomeres In Cardiomyocytes Subjected To Dynamic Loading** SB³C2023-522
Ryan J. Coleman¹, Vikram S. Deshpande², Patrick McGarry¹
¹University of Galway, ²University of Cambridge
- 12:30PM Effects of Conditional SV40-T Immortalization on Human Retinal Progenitor Cell Differentiation** SB³C2023-593
Qi Wang, Jessica A. Cooke, Budd A. Tucker, Kristan S. Worthington
University of Iowa
- 12:45AM Sub-Millimeter Stiffness Gradients Within 3d Printed Composite Scaffolds For Osteochondral Tissue Engineering** SB³C2023-517
Kevin N. Eckstein, A. Camila Uzcategui, John E. Hergert, Sarah A. Schoonraad, Stephanie J. Bryant, Robert R. McLeod, Virginia L. Ferguson
University of Colorado

Monday, June 5

11:30AM – 1:00PM MT

Cartilage: Imaging and Degeneration

Gore CD

Session Chairs: Jill Middendorf, *Johns Hopkins University*
David Pierce, *University of Connecticut*

- 11:30AM Enzymatic Digestion Does Not Compromise Sliding-Mediated Cartilage Lubrication** SB³C2023-182
Meghan E. Kupratis, Atia Rahman, David L. Burris, Elise A. Corbin, Christopher Price
University of Delaware
- 11:45AM Raman Probe Predicts Cartilage Functional Mechanical Properties Better Than ORSI Score And MRI T2* Mapping** SB³C2023-547
Masumeh Kazemi¹, Chenhao Yu¹, Farida Korna¹, Dev Mehrotra¹, Erik Ersland¹, Juncheng Zhang¹, Thomas P. Schaer², Julie B. Engiles², Mark W. Grinstaff¹, Brian D. Snyder³, Mads S. Bergholt⁴, Michael B. Albro¹
¹*Boston University*, ²*University of Pennsylvania*, ³*Beth Israel Deaconess Medical Center*, ⁴*King's College London*,
- 12:00PM Cartilage Strain And T1rho MRI Mapping In Response To Load In An Initial ACL-Reconstructed Patient Cohort** SB³C2023-169
Emily Y. Miller, Hongtian Zhu, Woowon Lee, Corey P. Neu
University of Colorado
- 12:15PM Cartilage Contact Pressures During Walking are Related to T2 Relaxation Times in Patients with Knee Osteoarthritis** SB³C2023-479
Benjamin D. Bernarding, Austin J. Garcia, Adam J. Bradshaw, Johnny Huard, Scott Tashman, Lauren E. Watkins, Colin R. Smilth
Steadman Philippon Research Institute
- 12:30PM In Vivo Assessment Of Passive And Active Articular Cartilage Strain Recovery** SB³C2023-283
Shu-Jin Kust, Dana Voinier, Kyle D. Meadows, Dawn M. Elliott, Daniel K. White, Axel C. Moore
University of Delaware
- 12:45AM Sensitivity Of Finite Element Models To Relationship Between T2 Relaxation And Modulus In Articular Cartilage** SB³C2023-483
Alexander A. Donabedian, Deva D. Chan
Purdue University

Monday, June 5

11:30AM – 1:00PM MT

Bioengineering Design I

Powell

Session Chairs: *Ria Mazumder, Widener University*
Sriram Balasubramanian, Drexel University

- 11:30AM Photo-Curing Extracellular Matrix Sealant For Stopping Vascular Hemorrhage**
SB³C2023-199
Luke E. Schepers¹, Brooke L. Martindale², Alycia G. Berman², Hannah L. Cebull¹, William Van Alstine³, Sydney E. Hollingshead², Tyler Novak², Craig J. Goergen¹
¹Purdue University, ²Cook Biotech Inc., ³Cook Research Inc.
- 11:45AM Evaluating The Effects Of Coordinate System Selection on Thumb Carpometacarpal Joint Angles** SB³C2023-387
Adam J. Chrzan¹, Nicole D. Arnold¹, Kevin Chan², Tamara Reid Bush¹
¹Michigan State University, ²Spectrum Health
- 12:00PM Development and Validation of a Smart Screwdriver (SSD) for Spine Surgery**
SB³C2023-436
Allison M. Tanner, Daniel Jacobson, Alexander W. Hooke, James S. Fitzsimmons, Chunfeng Zhao, Brett A. Freedman
Mayo Clinic
- 12:15PM Development of an Artificial Temporomandibular Joint Disc Replacement and Surgical Strategy** SB³C2023-584
Jason Kuiper, Ryan Dobbs, Jeremiah Easley, Christian Puttlitz, Kevin Labus
Colorado State University
- 12:30PM Regenerative Rehabilitation Of Muscle Defect Under Mechanical Stimulation: An Organ Culture Study** SB³C2023-381
D. Jacho, E. Yildirim-Ayan
University of Toledo
- 12:45AM Optimization Of A Bioprinted Pulsatile Fontan Conduit Using A Multiphysics Simulation Framework** SB³C2023-066
Zinan Hu¹, Jessica E. Herrmann¹, Mark A. Skylar-Scott¹, Tain-Yen Hsia², Alison L. Marsden¹
¹Stanford University, ²University of Central Florida

Monday, June 5

11:30AM – 1:00PM MT

Multiscale Models, Cardiovascular System

Zermatt

Session Chairs: Arianna Forneris, *University of Calgary*

Lei Fan, *Marquette University*

- 11:30AM Multiscale Model Predictions Of Heart Growth During Hypertensive Rat Pregnancies** SB³C2023-147
Molly S. Kaissar, Kyoko Yoshida
University of Minnesota
- 11:45AM A Computational Model of Coarctation of the Aorta in Rabbits** SB³C2023-235
Ashley A. Hiebing¹, Matthew A. Culver¹, John F. LaDisa Jr.², Colleen W. Witzenburg¹
¹*University of Wisconsin*, ²*Medical College of Wisconsin*
- 12:00PM Numerical and Computational Analysis of Artery Stresses Considering Active Contractility** SB³C2023-609
N. Goulbourne, Y. Li
University of Michigan
- 12:15PM Multiscale Modeling of Baroreflex Feedback Loop in Response to Acute Myocardial Infarction** SB³C2023-092
Hossein Sharifi, Kenneth S. Campbell, Jonathan F. Wenk
University of Kentucky
- 12:30PM Toward a biomechanical model of aortic development** SB³C2023-393
Bruno V. Rego, Sae-Il Murtada, Guangxin Li, George Tellides, Jay D. Humphrey
Yale University
- 12:45AM A 1D Model Characterizing The Role Of Spatiotemporal Contraction Distributions On Lymph Transport** SB³C2023-155
Farbod Sedaghati, J. Brandon Dixon, Rudolph L. Gleason
Georgia Institute of Technology

Tuesday, June 6

9:30AM – 11:00AM MT

**PhD-Level Student Paper Competition Session I:
Multiscale Biomechanics and Fluid Dynamics/Transport**

Cascade ABC

Session Chairs: Debanjan Mukherjee, *University of Colorado*
Lucas Timmins, *University of Utah*

- 9:30AM Characterizing Headform Friction Coefficient For Helmet Testing SB³C2023-142**
Nicole E-P. Stark, Steve Rowson
Virginia Tech
- 9:45AM Tuning Of The Mechanical Boundary Conditions Parameters For A Patient-Specific Thoracic Aorta Model SB³C2023-192**
Leonardo Geronzi¹, Antonio Martinez^{1,2}, Aline Bel-Brunon³, Michel Rochette², Marco Sensale², Pier Paolo Valentini¹, Marco E. Biancolini¹
¹University of Rome Tor Vergata, ²Ansys, ³INSA Lyon
- 10:00AM Toward Generalizable Brain Deformation Estimators For Head Impacts With Unsupervised Domain Adaptation And Deep Learning SB³C2023-030**
Xianghao Zhan, Jiawei Sun, Yuzhe Liu, Nicholas Cecchi, Enora Le Flao, Olivier Gevaert, Michael Zeineh, David Camarillo
Stanford University
- 10:15AM Learning Diffeomorphic Deformations for Whole Heart Mesh Generation SB³C2023-113**
Arjun Narayanan, Fanwei Kong, Shawn C. Shadden
University of California, Berkeley
- 10:30AM Correlations Between Mass Transport, Elastic Fiber Fragmentation, And Thoracic Aortic Aneurysm Severity SB³C2023-111**
Christie L. Crandall, Carmen M. Halabi, Jessica E. Wagenseil
Washington University in St. Louis
- 10:45AM Successful transplant of cryopreserved kidneys enabled by engineering-based protocol optimization SB³C2023-110**
Zonghu Han, Joseph S. Rao, Lakshya Gangwar, Bat-Erdene Namsrai, Jacqueline Pasek-Allen, Srivasupradha Ramesh, Michael L. Etheridge, Erik B. Finger, John C. Bischof
University of Minnesota

Tuesday, June 6

9:30AM – 11:00AM MDT

**PhD-Level Student Paper Competition Session II:
Cardiovascular Mechanics and Remodeling**

Cascade D

Session Chairs: Joao Soares, *Virginia Commonwealth University*
Joseph van Batenburg-Sherwood, *Imperial College London*

- 9:30AM Contribution Of Microtubule Network To The Passive Anisotropic Viscoelasticity Of Healthy Right Ventricle** SB³C2023-050
Kristen LeBar, Kellan Roth, Wenqiang Liu, Erith Evans, Jassia Pang, Adam Chicco, Zhijie Wang
Colorado State University
- 9:45AM Suppressing Leaflet Thickening and Stiffening May Restore Tricuspid Valve Function** SB³C2023-150
Mrudang Mathur¹, Marcin Malinowski^{2,3}, Tomasz A. Timek³, Manuel K. Rausch¹
¹*University of Texas, Austin*, ²*Medical University of Silesia*, ³*Spectrum Health*
- 10:00AM Sex Differences in Right Ventricular Chamber Elastance and Stiffness in an Animal Model of Pulmonary Arterial Hypertension** SB³C2023-177
Ethan D Kwan, Tsui Min Wang, Hao Mu, Becky A Hardie, Daniela Valdez-Jasso
University of California, San Diego
- 10:15AM Multiscale Model Translates Microscale Vascular Smooth Muscle Cell Mechanics to Tissue-Scale Aortic Contraction** SB³C2023-148
Shannon M. Flanary, Seokwon Jo, Emilyn U. Alejandro, Victor H. Barocas
University of Minnesota
- 10:30AM Heterogeneity Of Red Cell Mechanical Properties Drives Pathophysiology In Sickle Cell Disease** SB³C2023-064
Dillon C. Williams, David K. Wood
University of Minnesota
- 10:45AM Restored Normal Blood Flow Plus Atorvastatin Promotes Atherosclerosis Regression** SB³C2023-108
Morgan A. Schake, Ian McCue, Samuel Harvey, Evan Curtis, Forrest Kievit, Ryan M. Pedrigi
University of Nebraska-Lincoln

Tuesday, June 6

9:30AM – 11:00AM MT

Undergraduate Design Competition

Gore AB

Session Chairs: **Antonia Zaferiou**, *Stevens Institute of Technology*

- 9:30AM The History And Goals Of The Undergraduate Design Competition**
Anita Singh
Temple University
- 9:45AM Pulse Oximeter For Simulation Mannequin SB³C2023-624**
Marina Walsh, Benjamin Aon, Hatice S. Emanet, Cheyenne M. Miller, Chiamaka G. Oduah, Ria Mazumder
Widener University
- 10:00AM 3D Printed Mouth Guard For Temporomandibular Joint Dysfunction SB³C2023-635**
Christopher N. Barnes, Jorge M. Pumachagua, Elias P. Saliba
Embry-Riddle Aeronautical University
- 10:15AM Design Of A Prophylactic Knee Brace To Prevent ACL Injuries In Female Athletes SB³C2023-637**
J. DiVanna, E. LoVerde, M. Taibi
Manhattan College
- 10:30AM Elert: A Haptic Emergency Alert System For The Auditorily Impaired SB³C2023-643**
Emily Bartling, Ruth Hammon, Deven Cobb, Jerritt Gutierrez
Rose-Hulman Institute of Technology
- 10:45AM A Digital Incentive Spirometer for Aiding Lung Recovery Post-Surgery SB³C2023-647**
Isabella T. Mirro, Yi-An Hsieh, Jackson C. Dooley, Parth K. Mody, Josh Freedman
University of Pennsylvania

Tuesday, June 6

9:30AM – 11:00AM MT

**PhD-Level Student Paper Competition Session III:
Morphogenesis, Maternal/Abdominal Health**

Zermatt

Session Chairs: Sihong Wang, *The City College of New York*
Alix Deymier, *University of Connecticut*

- 9:30AM Vascular remodeling during late-gestation pregnancy: an in-vitro assessment of the murine thoracic aorta** SB³C2023-247
Ana I. Vargas, Samar Tarraf, Chiara Bellini, Rouzbeh Amini
Northeastern University
- 9:45AM Maternal Anatomy Drives Mechanical Loading in the Proximal Cervix During Pregnancy** SB³C2023-186
Erin Louwagie, Jada Hinds, Lindsey Carlson, Timothy Hall, Helen Feltovich, Kristin Myers
Columbia University
- 10:00AM Mechanical Changes of the Pregnant Murine Uterus** SB³C2023-207
Emily A. Hoffmann, Shanmugasundaram Nallasamy, Kyoko Yoshida
University of Minnesota
- 10:15AM Towards Enhanced Non-Invasive Assessment Of Bladder Urodynamics - Validation Of Dynamic 3D MRI In A Patient-Specific In Vitro Model Of The Bladder** SB³C2023-254
Jeams Rice, Jack Gwertzman, Alejandro Roldán-Alzate
University of Wisconsin - Madison
- 10:30AM Using Microinjected Fluid Droplets To Locally Perturb Epithelial Mechanics And Branching Morphogenesis In Cultured Embryonic Organs** SB³C2023-213
Shelby R. Mohr-Allen, Victor D. Varner
University of Texas
- 10:45AM Ectopic Changes in Tissue Stiffness Disrupt Epithelial Buckling and FGF-10-Induced Budding Morphogenesis in Cultured Embryonic Lungs** SB³C2023-234
Kara E. Peak, Victor D. Varner
University of Texas

Tuesday, June 6

11:15AM – 12:45AM MT

PhD-Level Student Paper Competition Session IV: Musculoskeletal and Mechanobiology/Tissue Engineering

Cascade ABC

Session Chairs: **Jacopo Ferruzzi**, *University of Texas at Dallas*
Stephanie Cone, *University of Delaware*

- 11:15AM Stiffness Of Direct-Write, Near-Field Electrospun Gelatin Fibers Generates Differences In Tenocyte Gene Expression** SB³C2023-240
Zachary G. Davis¹, Drew W. Koch¹, Grant M. Scull¹, Ashley C. Brown¹, Lauren V. Schnabel¹, Matthew B. Fisher^{1,2}
¹North Carolina State University, ²University of North Carolina at Chapel Hill
- 11:30AM Role Of Sex And Sex Hormones In Pulmonary Artery Adventitial Fibroblast Mechanosignaling** SB³C2023-120
Yufan Lin, Daniela Valdez-Jasso
University of California, San Diego
- 11:45AM Type V Collagen Plays An Essential Role In The Development Of Knee Articular Cartilage And Meniscus** SB³C2023-152
Bryan Kwok¹, Mingyue Fan¹, Prerana Singh¹, David Birk², Robert L. Mauck³, Nathaniel A. Dymant³, Eiki Koyama⁴, Lin Han¹
¹Drexel University, ²University of South Florida, ³University of Pennsylvania, ⁴Children's Hospital of Philadelphia
- 12:00PM Focal Adhesion Kinase Regulates Mechanosensitive Gene Transcription And Tendon Maturation** SB³C2023-230
Thomas P. Leahy, Srish S. Chenna, Louis J. Soslowsky, Nathaniel A. Dymant
University of Pennsylvania
- 12:15PM Mechanical Models Of Collagen Networks For Understanding Changes In The Failure Properties Of Aging Mouse Skin** SB³C2023-259
Nathan J. Witt¹, Alan E. Woessner², Jacob Herrmann¹, Kyle P. Quinn², Edward A. Sander¹
¹University of Iowa, ²University of Arkansas
- 12:30PM Moderated TGF-Beta Delivery Via Latent TGF-Beta Conjugated Scaffolds For Improving Engineered Articular Cartilage** SB³C2023-214
Tiabai Wang¹, Zhonghao Dai¹, Celina C. Maldonado¹, Prem Nelesh¹, Junhan Liao¹, Sung Yeon Kim¹, Andrew Martin¹, Joanne E. Murphy-Ullrich², Mark W. Grinstaff¹, Michael B. Albro¹,
¹Boston University, ²University of Alabama

Tuesday, June 6

11:15AM – 12:45PM MT

**PhD-Level Student Paper Competition Session V:
Musculoskeletal Biomechanics**

Cascade D

Session Chairs: Deva Chan, *Purdue University*
Spence Lake, *Washington University at St. Louis*

- 11:15AM A Novel Laser Ablation Model For Studying Local Microdamage Repair In Live Tendon Explants** SB³C2023-067
Anthony N. Aggouras, Matthew T. Lim, Jeroen Eyckmans, Brianne K. Connizzo
Boston University
- 11:30AM Collagen Crosslinking Dramatically Impairs the Frictional Performance of Articular Cartilage** SB³C2023-037
Meghan E. Kupratis, Uriel Gonzalez, Atia Rahman, David L. Burris, Elise A. Corbin, Christopher Price
University of Delaware
- 11:45AM Overexpression Of Enhanced Yellow Fluorescent Protein Fused With Channelrhodopsin Causes Contractile Dysfunction In Skeletal Muscle** SB³C2023-065
Syeda N. Lamia¹, Carol S. Davis¹, Peter C.D. Macpherson¹, T. Bradley Willingham², Yingfan Zhang², Chengyu Liu², Susan V. Brooks¹, Brian Glancy², Megan L. Killian¹
¹*University of Michigan*, ²*National Institutes of Health*
- 12:00PM Temporal and spatial dynamics of new bone formation in cyclic treatment regimens of parathyroid hormone-related peptide (PTHrP)** SB³C2023-114
Tala Azar, Kruti Desai, Justin Leggin, Yuanhang Li, Wenzheng Wang, Arie Jones, Wei-Ju Tseng, Nathaniel Dymment, X. Sherry Liu
University of Pennsylvania
- 12:15PM Shear Strain Stiffening In Ligaments Arises From Unaligned Fibers And Is Amplified By Axial Strain** SB³C2023-095
Jonathan L. Blank, Darryl G. Thelen, Joshua D. Roth
University of Wisconsin-Madison
- 12:30PM Development Of An In Vitro Model To Explore Collagen Fiber Regeneration With Aged Human Mensical Cells** SB³C2023-231
Austin G. Gouldin, Jennifer L. Puetzer
Virginia Commonwealth University

Tuesday, June 6

11:15AM – 12:45PM MT

**PhD-Level Student Paper Competition Session VI:
Emerging Tissue Mechanobiology & Biomechanics II**

Zermatt

Session Chairs: Erin Berlew, *University of Pennsylvania*
Jill Middendorf, *Johns Hopkins University*

- 11:15AM Damkohler Number Analysis For Predicting Biomolecule Gradients In Engineered Tissues** SB³C2023-187
Sedat Dogru, Matthew Simkulet, Halide Z. Haciguzeller, Michael B. Albro
Boston University
- 11:30AM Multiaxial Loading Attenuates Fibroblast Activation In An In Vitro Model Of Fibrosis** SB³C2023-181
Ghiska Ramahdita¹, Xiangjun Peng¹, Mohammad Jafari², David Schuftan¹, Guy M. Genin¹, Farid Alisafaei², Nathaniel Huebsch¹
¹*Washington University in St. Louis*, ²*New Jersey Institute of Technology*
- 11:45AM Deep Learning Enables Accurate Estimation Of Tissue Deformation In Vivo** SB³C2023-163
Reece D. Huff¹, Frederick C. Houghton¹, Conner C. Earl², Elnaz Ghajar-Rahimi², Ishan Dogra¹, Andrew J. Darling², Frederick W. Damen², Guoyang Zhou², Denny Yu², Craig J. Goergen², Carisa Harris-Adamson^{1,3}, Grace D. O'Connell^{1,3}
¹*University of California – Berkeley*, ²*Purdue University*, ³*University of California- San Francisco*
- 12:00PM Time And Strain Dependent Properties Of The Extracellular Collagen Matrix Regulate Cellular Mechanical Memory And Activation Level Of Fibroblast Cells** SB³C2023-209
Yuan Hong¹, Xiangjun Peng¹, Haomin Yu¹, Mohammad Jafari², Delaram Shakiba¹, Jacob Sandler¹, Kenneth M. Pryse¹, Justin M. Sacks¹, Elliot L. Elson¹, Guy M. Genin¹, Farid Alisafaei^{1,2}
¹*Washington University in St. Louis*, ²*New Jersey Institute of Technology*
- 12:15PM Nuclear Export Inhibition Jumbles Epithelial-Mesenchymal States and Gives Rise to Migratory Disorder in Healthy Epithelia** SB³C2023-134
Carly M. Krull, Haiyi Li, Amit Pathak
Washington University in St. Louis
- 12:30PM Collective Autologous Chemotaxis In Cancer Cells** SB³C2023-087
Louis González, Andrew J. Mugler
University of Pittsburgh

Wednesday, June 7

1:45PM – 3:15PM MT

Patient Specific Flow and Physiology

Cascade ABC

Session Chairs: Alejandro Roldán-Alzate, *University of Wisconsin -Madison*
Lucas Timmins, *University of Utah*

- 1:45PM Association of hemodynamic forces with patterns of coronary artery disease and atherosclerotic plaque phenotypes SB³C2023-370**
Diego Gallo¹, Alessandro Candreva¹, Maurizio Lodi Rizzini¹, Valentina Mazzi¹, Daniel Munhoz², Jean Paul Aben³, Bernard De Bruyne², Claudio Chiastra¹, Carlos Collet², Umberto Morbiducci¹
¹Politecnico di Torino, ²OLV-Clinic, ³Pie Medical Imaging BV
- 2:00PM Patient-Specific Flap Motion, False Lumen Flow, and Aortic Stiffness in Acute Uncomplicated Type B Aortic Dissections Using 4D Flow MRI and 2D PC MRI: A Preliminary Study SB³C2023-391**
H. Cebull¹, S. Hashemi², K. Porte¹, J. Oshinski^{1,3}, B.G. Leshnower¹, M. Piccinelli¹
¹Emory University, ²Children's Healthcare of Atlanta, ³Georgia Institute of Technology
- 2:15PM Predicting Hemodynamic Outcomes In Patients With Borderline Left Ventricles Under Uncertainty SB³C2023-156**
Yurui Chen¹, Isao A. Anzai¹, Justin S. Tran², David M. Kalfa¹, Vijay Vedula¹
¹Columbia University, ²California State University
- 2:30PM Non-Invasive Estimation of Pressure Drop Across Aortic Coarctation SB³C2023-149**
Priya J. Nair¹, Martin R. Pfaller¹, Seraina A. Dual², Doff B. McElhinney¹, Daniel B. Ennis¹, Alison L. Marsden¹
¹Stanford University, ²KTH Royal Institute of Technology
- 2:45PM Association Between Resistance To Cerebrospinal Fluid Flow And Cardiac-Induced Brain Tissue Motion For Chiari Malformation Type1 SB³C2023-475**
Saeed Mohsenian¹, Alaaddin Ibrahimy², John N. Oshinski³, Blaise Simplicie Talla Nwotchuang⁴, Rafeeqe A. Bhadelia⁵, Daniel L. Barrow³, Rouzbeh Amini¹, Francis Loth¹
¹Northeastern University, ²Yale University, ³Emory University, ⁴University of Akron, ⁵Harvard Medical School
- 3:00PM High-Fidelity Fluid-Structure-Interaction Modelling Explains Flow-induced Bruits and Murmurs in Cerebral Aneurysms SB³C2023-205**
David A. Bruneau¹, Kristian Valen-Sendstad², David A. Steinman¹
¹University of Toronto, ²Simula Research Laboratory

Fluid Velocity Mapping and Flow Characterization

Cascade D

Session Chairs: Jessica Oakes, *Northeastern University*

Ryan Pedrigi, *University of Nebraska*

- 1:45PM** **Towards High Spatiotemporal Resolution Blood Flow Velocity Field Mapping For Mice: A Validation Study** SB³C2023-583
Mingyi Tang^{1,2}, David A. Steinman¹, Craig A. Simmons^{1,2}
¹*University of Toronto*, ²*Ted Rogers Centre for Heart Research*
- 2:00PM** **The Generation of Synthetic Geometric Datasets for Flow Characterization in the Carotid Bifurcation** SB³C2023-440
Retta El Sayed^{1,2}, Paul Klein², John N. Oshinski¹, Tiziano Passerini²
¹*Georgia Institute of Technology*, ²*Siemens Healthineers*
- 2:15PM** **Surrogate Models For Pressure Gradients In Coronary Artery Stenoses** SB³C2023-527
Elizabeth R. Livingston, Siddhartha Srivastava, Krishna Garikipati, C. Alberto Figueroa
University of Michigan
- 2:30PM** **Impact of wall distensibility on emerging features of carotid bifurcation hemodynamics** SB³C2023-130
Sara Zamboni¹, Marachiara Arminio¹, David A. Steinman², Claudio Chiastra¹, Umberto Morbiducci¹, Diego Gallo¹
¹*Politecnico di Torino*, ²*University of Toronto*
- 2:45PM** **Quantification Of Embolus Transport To The Brain From Carotid Stenosis Sites** SB³C2023-497
Ricardo Roopnarinesingh¹, Neel Jani², Michelle Leppert¹, Debanjan Mukherjee¹
¹*University of Colorado*, ²*University of Wisconsin-Madison*
- 3:00PM** **Subject-Specific One-Dimensional Fluid Dynamics Model Of Chronic Thromboembolic Pulmonary Hypertension** SB³C2023-165
Amirreza Kachabi, Mitchel J. Colebank, Naomi C. Chesler
University of California, Irvine

Wednesday, June 7

1:45PM – 3:15PM MT

Reproductive Biomechanics and Pregnancy

Cascade E

Session Chairs: Megan Routzong, *University of California, San Diego*

Callan Luetkemeyer, *University of Illinois*

- 1:45PM** **Material Parametric Analysis Of Polypropylene During A Contact Sensitive Simulation Of A Ball Burst Test Of A Prolapse Mesh** SB³C2023-476
Madeline Hackett¹, Teseo Schneider², Zachary Ferguson³, Daniele Panozzo³, Denis Zorin³, Pamela Moalli¹, Steven Abramowitch¹
¹University of Pittsburgh, ²University of Victoria, ³New York University
- 2:00PM** **Modelling Of The Uterosacral Ligament Suggests Changes In Microarchitecture During Pregnancy** SB³C2023-179
Lea M. Savard¹, Catalina S. Bastías¹, Kathleen Connell¹, Sarah Calve¹, Callan M. Luetkemeyer², Virginia L. Ferguson¹
¹University of Colorado, ²University of Illinois
- 2:15PM** **Biaxial Contractility Of The Murine Cervix With Elastic Fiber Deficiency** SB³C2023-512
Mari J.E. Domingo¹, Avery G. Franques¹, Qinhan Zhou², Kristin S. Miller²
¹Tulane University, ²University of Texas
- 2:30PM** **Time-Dependent Material Properties Of Nonhuman Primate Uterine Layers Through Gestation** SB³C2023-529
Daniella M. Fodera¹, Echo Z. Xu¹, Shuyang Fang¹, Ivan Rosado-Mendez², Timothy Hall², Helen Feltovich^{2,3}, Michelle L. Oyen⁴, Kristin M. Myers¹
¹Columbia University, ²University of Wisconsin-Madison, ³Mount Sinai, ⁴Washington University in St. Louis
- 2:45PM** **A Longitudinal Study Of The Anatomical Changes Of The Pregnant Murine Vagina Using Magnetic Resonance Imaging** SB³C2023-217
Aileen C. Suarez¹, Clara J. Gimenez¹, Jennifer M. Munson¹, Kristin S. Miller², Kristin M. Myers³, Steven D. Abramowitch⁴, Raffaella De Vita¹
¹Virginia Tech, ²University of Texas, ³Columbia University, ⁴University of Pittsburgh
- 3:00PM** **Diffusion MRI Characterizes Microstructural Changes Of The Cervix During Pregnancy** SB³C2023-592
Noel Naughton¹, Amir Ostadi Moghaddam¹, Mariana Kersh¹, Sanmi Koyejo², Amy Wagoner Johnson¹, Bruce Damon^{1,3}
¹University of Illinois, ²Stanford University, ³Carle Health

Wednesday, June 7

1:45PM – 3:15PM MT

Biotransport in Drug Delivery

Cascade F

Session Chairs: Govind Srimathveeravalli, *UMass Amherst*
Nichole Rylander, *University of Texas at Austin*

- 1:45PM Lymph Node Conduit Modelling Offers Insight Into The Role Of Fluid Flow In Antigen Deposition** SB³C2023-457
Daniel J. Watson¹, Willy V. Bonneuil¹, James Marshall¹, Peter Xie¹, Thomas Adam¹, Jennifer Frattolin¹, Matthew J. Russell², Francesca Fasanella Masci³, Angela E. Goode¹, Shafa Balaram¹, Alexandra E. Porter¹, Anil A. Bharath¹, Bindi S. Brook², Robert J.B. Nibbs³, James E. Moore Jr¹
¹Imperial College London, ²Nottingham University, ³Glasgow University
- 2:00PM CD44 Mechanosignaling May Regulate Drug Resistance In Ovarian Cancer** SB³C2023-195
Maranda E. Kramer, Allison Criswell, Mary Kathryn Sewell-Loftin
University of Alabama at Birmingham
- 2:15PM Functionalized Particulate Carriers Targeting Abdominal Aortic Aneurysms Under Flow** SB³C2023-349
Moran Levi¹, Yevgeniy Kreinin¹, Ido Rachbuch¹, Perla Namour¹, Josué Sznitman¹, Meinrad Gawaz², Netanel Korin¹
¹Technion – IIT, ²Univesrity of Tuebingen
- 2:30PM Investigation Of Bioeffects From Microbubble And Focused Ultrasound Assisted Blood Brain Barrier Disruption** SB³C2023-423
Jane J. Song, Payton J. Martinez, Kang-ho Song, Jenna Steiner, Adam Green, Natalie Serkova, Mark A. Borden
University of Colorado
- 2:45PM Development Of A TGFβ2 Eluting Tissue Engineered Vascular Graft With Tunable Delayed Release** SB³C2023-369
Katarina M. Martinet, Tracey Moyston, Stephen C. Balmert, Steven R. Little, Jonathan P. Vande Geest
University of Pittsburgh
- 3:00PM A Lattice-Boltzmann Fluid-Structure Interaction Framework For The Inertial Transport Of Bioparticles In Microfluidic Devices** SB³C2023-469
Alberto Mantegazza, Dario De Marinis, Marco D. de Tullio
Polytechnic University of Bari

Wednesday, June 7

1:45PM – 3:15PM MT

Engineering Tissue Regeneration

Gore AB

Session Chairs: Jennifer Puetzer, *Virginia Commonwealth University*
Alejandro Almarza, *University of Pittsburgh*

- 1:45PM Optimization Of Lipid Nanoparticles For Localized mRNA Delivery In Fracture Repair** SB³C2023-498
Anna Laura Nelson^{1,2}, Chiara Mancino³, Josh Choe⁴, Gianluca Fontana⁴, Johnny Huard¹, William Murphy⁴, Francesca Taraballi³, Nicole Ehrhart², Chelsea Bahney^{1,2,5}
¹Steadman Philippon Research Institute, ²Colorado State University, ³Houston Methodist, ⁴University of Wisconsin-Madison, ⁵University of California, San Francisco
- 2:00PM Acellular ECM Powder Provides Lateral Integration And Structural And Cellular Signaling In A 12-Month Goat Implant** SB³C2023-539
Jeanne E. Barthold¹, Juliet Heye¹, Kaitlin McCreery¹, Katie Bizzaza², Jeremiah Easley², Ben Gadomski², Corey P. Neu¹
¹University of Colorado, ²Colorado State University
- 2:15PM Stem Cell-Derived Exosomes Promote Cell Homing and Angiogenic Differentiation For Dental Pulp Regeneration** SB³C2023-444
Venkateswaran Ganesh, Piedad C. Gomez-Contreras, Henry L. Keen, Kyungsup Shin, James A. Martin, Dongrim Seol
University of Iowa
- 2:30PM Superficial Meniscus Cells And Highly Proliferative And Migratory And Generate Functional Tissue Despite A Lower Cellular Mechanosensitivity** SB³C2023-112
Sereen SF. Assi¹, Elizabeth Bernstein¹, Edward D. Bonnevie^{1,2}, Emily E. Sharp¹, Ryan C. Locke^{1,2}, Robert L. Mauck^{1,2}
¹University of Pennsylvania, ²Crescenz VA Medical Center
- 2:45PM Viscoelasticity and Micro-phase Separation Mediate Meniscal Cell Migration through Hyaluronic Acid Hydrogels** SB³C2023-138
Karen L. Xu¹, Hooman Fallahi², Lin Han², Robert L. Mauck¹, Jason A. Burdick^{1,3}
¹University of Pennsylvania, ²Drexel University, ³Univesrity of Colorado
- 3:00PM Sustained-release losartan from peptide nanofibers promotes chondrogenesis** SB³C2023-485
Kohei Yamaura¹, Nicholas A. Sather², Anna Metlushko², Haruki Nishimura¹, Radoslav Z. Pavlović², Sealy Hambricht¹, Sudheer K. Ravuri¹, Marc J. Philippon^{1,3}, Samuel I. Stupp², Chelsea S. Bahney^{1,4}, Johnny Huard¹
¹Steadman Philippon Research Institute, ²Northwestern University, ³Steadman Clinic, ⁴University of California, San Francisco

Wednesday, June 7

1:45PM – 3:15PM MT

Predictive Models in Cardiovascular Biomechanics

Gore CD

Session Chairs: Lucas Timmins, *University of Utah*
Jonathan Wenk, *University of Kentucky*

- 1:45PM** **Towards Real-Time Predictive Models of Transcatheter Aortic Valve Replacement Procedures via Reduced Order Modeling** SB³C2023-328
I Shah^{1,3}, F. Ballarin², A. Veneziani³, L. Dasi¹
¹Georgia Institute of Technology, ²Università Cattolica del Sacro Cuore, ³Emory University
- 2:00PM** **Predicting Long-term Patient-Specific Outcome Of Cardiac Resynchronization Therapy Using A Fast Computational Model** SB³C2023-249
Clara E. Jones¹, Derek J. Bivona², Kenneth C. Bilchick², Pim J.A. Oomen¹
¹University of California, Irvine, ²University of Arizona
- 2:15PM** **Aortic Wall Stress Concentration As A Predictor Of Type A Aortic Dissection** SB³C2023-351
Christina Sun¹, Tongran Qin¹, Asanish Kalyanasundaram², Wei Sun¹, John Elefteriades², Liang Liang³
¹Lake Forest, ²Yale University, ³University of Miami
- 2:30PM** **A Modular Framework For Strong 3D/0D Coupling In Cardiac Mechanics Simulations** SB³C2023-032
Aaron L. Brown, Zinan Hu, Alison L. Marsden
Stanford University
- 2:45PM** **A Neural Network Finite Element Approach For High-Speed Cardiac Pressure-Volume Simulations** SB³C2023-459
Shruti Motiwale, Wenbo Zhang, Michael S. Sacks
University of Texas at Austin
- 3:00PM** **No Strings Attached: Predicting Tricuspid Valve Coaptation Without In Vivo Chordal Geometry** SB³C2023-473
Mrudang Mathur, Vijay Dubey, Manuel K. Rausch
University of Texas at Austin

Wednesday, June 7

1:45PM – 3:15PM MT

Bioengineering Design II

Powell

Session Chairs: Zhongping Huang, *West Chester University*
Anita Singh, *Temple University*

- 1:45PM** **Mixed Approaches to Noninvasive Ventilation Mask Design: Triphasic Mixture Theory Material Model Calibration and Global Finite Element Analysis** SB³C2023-290
Anne D. Zakrajsek¹, Marty O. Visscher¹, Vivek Narendran^{1,2}, Eric A. Nauman¹
¹University of Cincinnati, ²Cincinnati Children's Hospital
- 2:00PM** **Retropubic Trocar Temporal Characteristics Between Expert and Novice Surgeons** SB³C2023-438
Md A. Arif, Austin Bachar, Gregory W. King, Gary Sutkin, Antonis P. Stylianou
University of Missouri
- 2:15PM** **Continuous inter-limb gait coordination and stability in veterans and service members with transtibial limb loss: influences of prosthetic ankle-foot devices** SB³C2023-221
Alexis Sidiropoulos¹, Brad D. Hendershot², Jonathan Gladish², David Herlihy^{1,3}, Jason Maikos¹
¹New York Harbor Healthcare System, ²Extremity Trauma and Amputation Center of Excellence, ³Narrows Institute of Biomedical Research and Education
- 2:30PM** **Analysis of a New Socket Based Reference Frame for Ankle Rollover Shape for Transtibial Prostheses** SB³C2023-451
David Herlihy¹, John Chomack², Jason Maikos²
¹Narrows Institute of Biomedical Research and Education, ²New York Harbor Healthcare System
- 2:45PM** **Development Of A Novel Hand Worn Sensor For Objective Assessment Of Hand Dexterity In Neurodegenerative Conditions** SB³C2023-035
Conor D. Hayden¹, Deirdre Murray^{1,2}, Dara Meldrum¹, Dermot Geraghty¹, Orla Hardiman^{1,2}, Bruce P. Murphy¹
¹Trinity College Dublin, ²Beaumont Hospital
- 3:00PM** **The Impact Of Regulating The Plantarflexion And Dorsiflexion Resistance Of An Articulated Ankle Foot- Orthosis On Lower Limb Kinematics And Kinetics Of Stroke Survivors During Ambulation** SB³C2023-406
Oluwaseye P. Odanye¹, Emily E. Steffensen¹, Christopher J. Burcal¹, Aaron D. Likens¹, Elisa S. Arch², Brian A. Knarr¹
¹University of Nebraska, ²University of Delaware

Wednesday, June 7

1:45PM – 3:15PM MT

Cardiovascular Tissue Structure and Mechanics

Zermatt

Session Chairs: Jonathan Vande Geest, *University of Pittsburgh*

Lakshmi Dasi, *Georgia Institute of Technology*

- 1:45PM** **Right Ventricular Myocardium Remodeling in Pulmonary Arterial Hypertension is Sex Dependent** SB³C2023-265
Becky A. Hardie, Jessica Huberts, Daniela Valdez-Jasso
University of California, San Diego
- 2:00PM** **Cyclic Stretch Results in Directionally Dependent Recellularization Aligned with Cellular Stress Avoidance Reorientation** SB³C2023-267
Adam W.Y. Ley, Eric Slaughter, Victor H. Barocas, Robert T. Tranquillo
University of Minnesota
- 2:15PM** **Evaluation Of Hypertension And Intraluminal Vascular Injury On The Biomechanics Of The Murine Femoral Artery** SB³C2023-508
J. Caleb Snider¹, Zachary Tentor², Yujun Xu¹, Matthew R. Bersi¹
¹*Washington University in St. Louis*, ²*University of Virginia*
- 2:30PM** **Impact of local collagen architecture on rupture behavior of tissue-engineered atherosclerotic plaque caps** SB³C2023-012
Hanneke Crielaard¹, Tamar B. Wissing^{1,2}, Su Guvenir Torun¹, Pablo de Miguel^{1,3}, Gert-Jan Kremers¹, Frank J.H. Gijzen^{1,3}, Ali C. Akyildiz^{1,3}, Kim van der Heiden^{1,2}
¹*Erasmus Medical Center*, ²*Eindhoven University of Technology*, ³*Delft University of Technology*
- 2:45PM** **An Optimized Method For Constitutive Model Fitting Of Soft Tissues Bi-Directional Mechanical Stress-Stretch Data** SB³C2023-119
Sayed Ahmadrza Razian, Alexey Kamenskiy, Majid Jadidi
University of Nebraska at Omaha
- 3:00PM** **Mechanical Characterization of Porcine Tricuspid Valve Anterior Leaflets Over Time: Applications to Ex-vivo Studies** SB³C2023-582
Julia Clarin, Dominique Dang, Lucas Santos, Rouzbeh Amini
Northeastern University

Wednesday, June 7

3:30PM – 5:00PM MT

Heart Valve Fluid Mechanics

Cascade ABC

Session Chairs: Hoda Hatoum, *Michigan Tech*
Lucas Timmins, *University of Utah*

- 3:30PM Impact of Blood Pressure on Coronary and Sinus Flow Dynamics After Aortic Valve Replacement** SB³C2023-562
B. Vogl¹, S. Lilly², V. Thourani³, M. Alkhouli⁴, B. Lindman⁵, H. Hatoum¹
¹Michigan Technological University, ²The Ohio State University, ³Piedmont Heart Institute, ⁴Mayo Clinic, ⁵Vanderbilt University
- 3:45PM Biomechanical Analysis Of A Fetal Pulmonary Heart Valve Replacement**
SB³C2023-388
Sanchita S. Bhat, Katelynne Berland, Anna Farnan, Katherine Vietmeyer, Lakshmi Prasad Dasi
Georgia Institute of Technology
- 4:00PM On The Closure Kinematics Of Aortic Mechanical Heart Valves Versus Bioprosthetic Heart Valves** SB³C2023-044
Syed Samar Abbas, Iman Borazjani
Texas A&M University
- 4:15PM Bio-Inspired Polymeric TAVR To Improve Durability Outcomes** SB³C2023-204
Nipa Khair¹, Sanchita Bhat², Katie Vinterella², Satheesh Kumar Harikrishnan², Lakshmi Prasad Dasi², Susan James¹
¹Colorado State University, ²Georgia Institute of Technology
- 4:30PM Experimental Study of Flow-Mediated Fibrin Clot Accumulation in Prosthetic Heart Valves** SB³C2023-367
Yevgeniy Kreinin, Moran Levi, Yahel Talmon, Josué Sznitman, Netanel Korin
Technion - IIT
- 4:45PM Effect Of Sinotubular Junction Size In TAVR Leaflet Thrombosis And The Potential Of TAV-in-TAV Procedure: A Fluid Structure Interaction Based Thrombogenic Risk Assessment Analysis** SB³C2023-299
Symon Reza¹, David Oks², Brandon Kovarovic¹, Mariano Vázquez², Danny Bluestein¹
¹Stony Brook University, ²Computer Applications in Science and Engineering

Emerging Areas in Thrombosis and Vascular Modeling

Cascade D

Session Chairs: Diego Gallo, *Politecnico di Torino*

Hannah Cebull, *Emory University*

- 3:30PM Shear-Mediated Platelet Adhesion Dynamics And Multi-Platelet Aggregation: In Vitro Validated Multiscale Simulations Using Coarse-Grained Molecular Dynamics And Dissipative Particle Dynamics SB³C2023-288**
Peineng Wang, Yicong Zhu, Jawaad Sheriff, Peng Zhang, Yuefan Deng, Danny Bluestein
Stony Brook University
- 3:45PM Investigating Changes in Hematological and Hemorheological Parameters in a Mouse Stent Implantation Model SB³C2023-274**
D. Kokkinidou, E. Kaliviotis, C. Shamas, A. Anayiotos, K. Kaprnis
University of Technology
- 4:00PM Usability Of Low-cost 3D Visualization Sharing Interfaces For Cardiovascular Blood Flow Dynamics Data SB³C2023-509**
Zainab Husain¹, Noah Egnatis¹, Karol Calò², Diego Gallo², Umberto Morbiducci², Peter Coppin³, David A. Steinman¹
¹University of Toronto, ²Politecnico di Torino, ³Ontario College of Art and Design University
- 4:15PM Excessive Shear Rate, not Shear Stress, is Responsible for Cell Mechanolysis in Small Bore Needle Injections SB³C2023-368**
George Morgan, Lamis Elsayah, Alejandro Esclamado-Cadenas, Amelie Daudet, Jennifer Frattolin, Daniel Watson, Qian Xu, Nicola Negrini, Adam Celiz, James E. Moore Jr.
Imperial College London
- 4:30PM Real-Time Optimization of the Total Cavopulmonary Connection via Reduced Order Modeling SB³C2023-331**
I Shah^{1,2}, F. Ballarin³, T. Iliescu⁴, O. San⁵, L. Dasi¹, A. Wei⁶, A. Veneziani²
¹Georgia Institute of Technology, ²Emory University, ³Università Cattolica del Sacro Cuore, ⁴Virginia Tech, ⁵Oklahoma State University, ⁶University of Massachusetts
- 4:45PM Validation Of The Coupled Momentum Method Against A Compliant Aortic Phantom In A Hybrid Mock Circulatory Loop SB³C2023-358**
Francesco Bardi^{1,2,3}, Emanuele Gasparotti¹, Emanuele Vignali¹, Miquel Aguirre², Stéphane Avril², Simona Celi¹
¹BioCardioLab, ²INSERM, ³PrediSurge

Wednesday, June 7

3:30PM – 5:00PM MT

Multiscale Biomechanics

Cascade E

Session Chairs: Pim Oomen, *University of California – Irvine*
Chung-Hao Lee, *University of Oklahoma*

- 3:30PM Anisotropic Stiffness Measured Using A Toroidal Probe In Meso Level And Cell Level** SB³C2023-251
J. Li, T. Paradis, M. Vandadi, N. Rahbar, K.L. Billiar
Worcester Polytechnic Institute
- 3:45PM A Validated Data-Driven, Constitutive Model Of Type II Collagen Including Failure** SB³C2023-228
Phoebe Szarek, David M. Pierce
University of Connecticut
- 4:00PM Active Microtissue Arrays For Probing Tissue Response To Dynamic Conditioning** SB³C2023-366
William P. Cortes, Kalyn R. Younger, Thao D. Nguyen, Daniel H. Reich
Johns Hopkins University
- 4:15PM The Non-Affine Network Solver Plugin: A Generalized Fiber Network Material Model From Volume Averaging Theory** SB³C2023-287
Ryan R. Mahutga, Victor H. Barocas, Patrick W. Alford
University of Minnesota
- 4:30PM A Non-Contact Microfluidic Approach To Distinguish Large Extracellular Vesicles From Idh1-Mutated Glioblastoma Cells Based On Stiffness** SB³C2023-342
Mi Ho Jeong, Hyungsoon Im, Joanna B. Dahl
Massachusetts General Hospital
- 4:45PM Augmented Reality Visualization Of Biomechanical Wall Stresses On Abdominal Aortic Aneurysms Using Artificial Intelligence** SB³C2023-511
Timothy K. Chung, Nathan L. Liang, David A. Vorp
University of Pittsburgh

Wednesday, June 7

3:30PM – 5:00PM MT

Experimental Head and Injury Mechanics

Cascade F

Session Chairs: Brittany Coats, *University of Utah*
Mehmet Kurt, *University of Washington*

- 3:30PM Head Kinematics in Stock Car Racing: Quantifying Differences Between Tracks** SB³C2023-514
Sophia R. Zoch^{1,2}, Logan E. Miller^{1,2}, Cole M. Binder², Destiny R. Mason^{1,2}, John P. Patalak³, Matthew G. Harper³, Jillian E. Urban^{1,2}, Joel D. Stitzel^{1,2}
¹Virginia Tech-Wake Forest, ²Wake Forest School of Medicine, ³National Association for Stock Car Auto Racing
- 3:45PM Late Triggering of Tagged MRI for Measurement of In Vivo Brain Deformation during Head Rotation** SB³C2023-551
Yuan-Chiao Lu¹, Andy Knutsen¹, Ahmed Alshareef¹, Wen-Tung Wang², Joy Mojumder², Jerry L. Prince³, Philip Bayly⁴, John A. Butman², Dzung L. Pham^{2,5}
¹Henry M Jackson Foundation for the Advancement of Military Medicine, ²National Institutes of Health, ³Johns Hopkins University, ⁴Washington University at St. Louis, ⁵Uniformed Services University
- 4:00PM Non-Concussive Head Impact Kinematics And Brain Strain Distribution In Collegiate Football** SB³C2023-344
Enora Le Flao¹, Xianghao Zhan¹, Nicholas J. Cecchi¹, Yuzhe Liu¹, Ashlyn A. Callan¹, Landon P. Watson¹, Collin Pang¹, Gerald A. Grant^{1,2}, Michael M. Zeineh¹, David B. Camarillo¹
¹Stanford University, ²Duke University
- 4:15PM Behavioral Impairments In Repetitive Mild Traumatic Brain Injury** SB³C2023-262
S. Vafadar, H. Li, S. Assari, S.J. Ward, R.F. Tuma, K. Darvish
Temple University
- 4:30PM Influence of Fragment Impact Attributes in Cutaneous Injury** SB³C2023-086
O. Elsafty, R. Dauskardt
Stanford University
- 4:45PM A Methodology to Obtain Injury and Biomechanical Data from Live Swine Experimentation for Behind Armor Blunt Trauma** SB³C2023-302
Alok S. Shah¹, Narayan Yoganandan¹, Mary F. Otterson¹, Brian D. Stemper¹, Joost Op't Eynde², Cameron D. Bass², Justin McMahon³, Robert S. Salzar³, B. Joseph McEntire⁴
¹Medical College of Wisconsin, ²Duke University, ³University of Virginia, ⁴US Army Aeromedical Research Laboratory

Wednesday, June 7

3:30PM – 5:00PM MT

Biophysical Effects on Cells and Tissues

Gore AB

Session Chairs: Sarah Calve, *University of Colorado*
Victor Varner, *University of Texas at Dallas*

- 3:30PM** **Effect of the Physical Environment on Embryonic Kidney Progenitor and Explant Culture** SB³C2023-174
Aria (Zheyuan) Huang, Alex J. Hughes
University of Pennsylvania
- 3:45PM** **Elastic Fibers Confer Tensile Stiffness To The Dorsal Mesentery, Driving Buckling Morphogenesis Of The Small Intestine** SB³C2023-425
Elise A. Loffet, John F. Durel, Hyunjee Lim, Richard Kam, Nandan L. Nerurkar
Columbia University
- 4:00PM** **A Thermodynamic Framework For Sarcomere Formation In Cardiomyocytes Spread On Micro-Patterned Substrates** SB³C2023-253
Ryan J. Coleman¹, Vikram S. Deshpande², Patrick McGarry¹
¹*University of Galway*, ²*University of Cambridge*
- 4:15PM** **Cyclic Stretch Inhibits Cell Invasion And Migration In 3D Scaffolds** SB³C2023-017
Rozanne W. Mungai, Kevin Piskorowski, Grace Jolin, Ying Lei, Kristen L. Billiar
Worcester Polytechnic Institute
- 4:30PM** **Connecting Cyclic Stress To Nephron Induction In Kidney Organoids and 3D Co-Culture Models** SB³C2023-178
John M. Viola, Alex J. Hughes
University of Pennsylvania
- 4:45PM** **Delineating Effects of Substrate Stiffness, Chemistry, and Cyclical Strain on Lung Fibroblasts Gene Expression** SB³C2023-258
Qi Wang, Kristan S. Worthington, Edward A. Sander
University of Iowa

Wednesday, June 7

3:30PM – 5:00PM MT

Structure and Function in Biomechanics

Gore CD

Session Chairs: Stephanie Cone, *University of Delaware*
Kara Peak, *University of Texas - Dallas*

- 3:30PM Cell-Scale Measurements Of Tissue Viscoelasticity Using Thermoresponsive Mechanosensors In Engineered Tumor Models** SB³C2023-489
Benjamin E. Campbell, Stephanie Mok, Christina-Marie Boghdady, Nikita Kalashnikov, Luke McCaffrey, Christopher Moraes
McGill University
- 3:45PM Finite Elements Of Multiscale Mixtures (Fe2M): Theory, Numerical Implementation, And Analyses Of Size Effects** SB³C2023-389
Ashkan Almasi¹, Tim Ricken², David M. Pierce¹
¹University of Connecticut, ²University of Stuttgart
- 4:00PM Surgical Augmentation And Preservation Of Remnant ACL Tissue Best Restores Knee Function After Partial ACL Injury** SB³C2023-023
S. Cone^{1,2}, R. Salbego¹, J. Roth¹, P. Lang¹
¹University of Wisconsin, ²University of Delaware
- 4:15PM Characterizing The Biaxial Properties Of Skeletal Muscles Of The Mouse Hindlimb** SB³C2023-599
Katherine R. Knaus, Rebecca Hardie, Jessica Huberts, Daniela Valdez-Jasso
University of California, San Diego
- 4:30PM Cyclic Strain Induces Matrix Turnover To Better Maintain Tendon Composition In Explant Culture** SB³C2023-069
Anthony N. Aggouras, Brianne K. Connizzo
Boston University
- 4:45PM Microstructure-Based Estimation Of The Effective Stiffness Of Crosslinked, Embedded Fiber Networks** SB³C2023-330
Sotirios Kakaletsis¹, Emma Lejeun², Manuel Rausch¹
¹University of Texas at Austin, ²Boston University

Wednesday, June 7

3:30PM – 5:00PM MT

Growth and Remodeling I

Powell

Session Chairs: Colleen Witzenburg, *University of Wisconsin - Madison*
Jacopo Ferruzzi, *University of Texas - Dallas*

- 3:30PM Multiscale Model Predicts the Effect of Beta Blockers on Ventricular Remodeling in Dogs with Experimental Mitral Valve Regurgitation** SB³C2023-315
J. Bracamonte¹, L. Watkins², J. Saucerman², J. Holmes¹
¹University of Alabama at Birmingham, ²University of Virginia
- 3:45PM Computational Modeling Of Arterial Growth And Remodeling Including Mechanosensitive Notch Signaling** SB³C2023-420
Jordy van Asten¹, Marcos Latorre³, Cansu Karakaya¹, Frank Baaijens¹, Cecilia^{1,3}, Tommaso Ristori¹, Jay Humphrey⁴, Sandra Loerakker¹
¹Eindhoven University of Technology, ²Universitat Politècnica de València, ³Åbo Akademi, ⁴Yale University
- 4:00PM Growth And Remodeling Of The Pulmonary Arterial Tree For Evolution Of Pulmonary Arterial Hypertension** SB³C2023-546
Jason M. Szafron, Weiguang Yang, Jeffrey A. Feinstein, Marlene Rabinovitch, Alison L. Marsden
Stanford University
- 4:15PM Multiscale Computational Modeling Of TGF β 1/2 Knock-Out In Adult Mouse Aortas** SB³C2023-575
Ana C. Estrada, Linda Irons, Jay D. Humphrey
Yale University
- 4:30PM Semi-Automatic Quantification of Early Structural Remodeling Following Myocardial Infarction** SB³C2023-089
Catherine C. Eberman, Colleen M. Witzenburg
University of Wisconsin
- 4:45PM Mechanical Characterization of Sheep Lymphatic Growth and Remodeling** SB³C2023-106
Sophia M. Mavris, Zhanna V. Nepiyushchikh, J. Brandon Dixon, Rudolph L. Gleason
Georgia Institute of Technology

Wednesday, June 7

3:30PM – 5:00PM MT

Modeling in the Cardiovascular System

Zermatt

Session Chairs: Manuel Rausch, *University of Texas - Austin*
Beatrice Bisighini, *Mines Saint-Etienne*

- 3:30PM** **Classification-based super-resolution reconstruction in CMR to quantify four-dimensional myocardial strains in mice** SB³C2023-545
Tanmay Mukherjee¹, Sakthivel Sadayappan², Reza Avazmohammadi^{1,3}
¹Texas A&M, ²University of Cincinnati, ³Houston Methodist Academic Institute
- 3:45PM** **A Novel Image-based Computational Framework to Evaluate the Material Properties of Arterial Tissue from High-resolution Magnetic Resonance Image Data** SB³C2023-505
Y.F. Jack Wang, Samer S. Merchant, Edward W. Hsu, Lucas H. Timmins
University of Utah
- 4:00PM** **Novel Automated Aortic Root Echocardiography Feature Tracking Algorithm For Pediatric Aortopathy** SB³C2023-176
Elnaz Ghajar-Rahimi¹, Frederick W. Damen^{1,2}, Benjamin J. Landis², Craig J. Goergen^{1,2}
¹Prudue University, ²Indiana University
- 4:15PM** **3D Passive Strain Mapping of the Embryonic Zebrafish heart** SB³C2023-587
Alex L. Gendernalik^{1,2}, David Bark^{1,2}
¹Colorado State University, ²Washington University
- 4:30PM** **Computational modeling study of the effects of pulmonary hypertension on right heart perfusion** SB³C2023-024
Lei Fan¹, Jenny S. Choy², Ghassan S. Kassab², Lik Chuan Lee¹
¹Michigan State University, ²California Medical Innovations Institute
- 4:45PM** **Imaging And Mechanical Characterization Of Human Blood Clot Analogues With Different Compositions And Degrees Of Contraction** SB³C2023-395
Rachel Cahalane¹, Janneke M.H. Cruts¹, Ahlam Rachid², Kim van Gaalen¹, Heleen M.M. van Beusekom¹, Moniek de Maat¹, Marcel L. Kijkshoorn¹, Nikki Boodt¹, Aad van der Lugt¹, Frank Gijsen^{1,3}
¹Erasmus Medical Center, ²Eindhoven University of Technology, ³Delft University of Technology

Thursday, June 8

1:45PM – 3:15PM MT

Cardiovascular Devices and Design

Cascade ABC

Session Chairs: Zahra Keshavarz-Motamed, *McMaster University*

Ethan Kung, *Clemson University*

- 1:45PM Analyzing The Impact Of TAVR Device Orientation On Post-TAVR Paravalvular Leakage Severity And Thrombogenicity In Bicuspid Aortic Valve Patients**
SB³C2023-076
S. Anam¹, B. Kovarovic¹, A. Hamdan², R. Haj-Ali³, D. Bluestein¹
¹*Stony Brook University*, ²*Rabin Medical Center*, ³*Tel-Aviv University*
- 2:00PM In Silico Investigation on Stroke Risks from Left Ventricular Assist Device**
SB³C2023-538
Sreeparna Majee¹, Akshita Sahni¹, Erin E. McIntyre¹, Jay D. Pal², Debanjan Mukherjee¹
¹*University of Colorado*, ²*University of Washington*
- 2:15PM Hemodynamic Performance Of Dual Lumen VV ECMO Cannulas** SB³C2023-284
Louis P. Parker¹, Anders Svensson Marcial², Torkel B. Brismar², Lars Mikael Broman^{2,3}, Lisa Prohl Wittberg¹
¹*Royal Institute of Technology*, ²*Karolinska Institute*, ³*Karolinska University Hospital*
- 2:30PM A Preliminary In Silico Study On The Fluid Dynamic Changes With Central Venous Catheter Insertion** SB³C2023-414
B. Su, H. Palahnuk, T. Harbaugh, E. Rizk, S.W. Hazard, K.B. Manning
Penn State University
- 2:45PM Predicting Device Related Thrombosis After Left Atrial Appendage Occlusion Using Computational Fluid Dynamics** SB³C2023-151
B. Vogl¹, A. Chavez Ponce², A. El Shaer², A. Bavo³, M. De Buele³, M. Alkhouli², H. Hatoum¹
¹*Michigan Technological University*, ²*Mayo Clinic*, ³*FEops*
- 3:00PM Development Of A Novel Polymeric TAVR Valve: Design Optimization And Addressing TAVR Clinical Complications** SB³C2023-408
B. Kovarovic¹, R. Helbock¹, O.M. Rotman¹, K. Baylous¹, M. Slepian², D. Bluestein¹
¹*Stony Brook University*, ²*University of Arizona*

Savio Woo Session I: Joint, Ligament, and Muscle

Cascade D

Session Chairs: Daniel Cortes, *Pennsylvania State University*
Beth Winkelstein, *University of Pennsylvania*

- 1:45PM** **Strain Thresholds for Neuronal Activation During High-Rate Tensile Loading to Failure: Implications for Pain and Trauma** SB³C2023-078
Daniel Du, Sittinon Nuethong, Prabesh Ghimire, Beth A. Winkelstein
University of Pennsylvania
- 2:00PM** **Estimating Soleus Muscle Volume By Anthropometric And Ultrasound-Measurable Parameters** SB³C2023-372
Shabnam Rahimnezhad¹, Karin G. Silbernagel², Daniel H. Cortes¹
¹*Pennsylvania State University*, ²*University of Delaware*
- 2:15PM** **Quantifying The Effect Of Femoral Component Internal Rotation On Ligament Forces For Total Knee Arthroplasty With Varus Tibial Alignment** SB³C2023-448
Jonathan Glenday, Jonathan Vigdorchik, Peter Sculco, Cynthia Kahlenberg, David Mayman, Eytan Debbi, Joseph Lipman, Timothy Wright, Fernando Quevedo Gonzalez
Hospital for Special Surgery
- 2:30PM** **The Role of Posterior Cruciate Ligament on Femoral Rollback in Medial Congruent Total Knee Arthroplasty: A Computational Study** SB³C2023-525
Reza Pourmodheji, Jacob M. Hirth, Brian P. Chalmers, Cynthia A. Kahlenberg, William J. Long, Geoffrey H. Westrich, David J. Mayman, Peter K. Sculco, Timothy M. Wright, Carl W. Imhauser
Hospital for Special Surgery
- 2:45PM** **Blebbistatin As A Method To Improve Outcomes Following Joint Capsule Release Surgery In An In Vivo Rat Elbow Model** SB³C2023-083
Austin J. Scholp, Timothy P. Fowler, Emily Petersen, Douglas Fredericks, James A. Martin, Aliasger K. Salem, Edward A. Sander
University of Iowa
- 3:00PM** **Obesity Affects The Biomechanics Of The Posterior Kinetic Chain During Manual Lifting** SB³C2023-456
Sergio A. Lemus¹, Mallory Volz¹, Francisco Beron-Vera¹, Mitchell Hurtado¹, Eduard Tiozzo¹, Arlette Perry¹, Thomas M. Best^{1,2}, Francesco Travascio^{1,3}
¹*University of Miami*, ²*UHealth Sports Medicine*, ³*Mount Sinai*

Thursday, June 8

1:45PM – 3:15PM MT

Emerging Mechanobiology and Biomechanics I

Cascade E

Session Chairs: Soham Ghosh, *Colorado State University*

Ian Sigal, *University of Pittsburgh*

- 1:45PM** **Nuclear Deformation Of The Tricuspid Valve Interstitial Cells: The Effects Of Nuclear Orientation And Extracellular Matrix Structure** SB³C2023-222
Mina Pakzadmanesh, Samuel D. Salinas, Vineet S. Thomas, Rouzbeh Amini
Northeastern University
- 2:00PM** **Ultrasoft Edge-Labelled Hydrogel Sensors Reveal Internal Tissue Stress Patterns In Invasive Engineered Tumors** SB³C2023-223
C.M. Boghdady, W. Lee, V. Lelarge, R.L. Leask, L. McCaffrey, C. Moraes
McGill University
- 2:15PM** **Deep Learning Enhances Micro-Computed Tomography Image Resolution Of Murine Femurs** SB³C2023-604
Michael A. David¹, Tillman James², Douglas J. Adams¹
¹*University of Colorado*, ²*Washington University at St. Louis*
- 2:30PM** **The Role Of Skin Biomechanics In Tactile Perception Of Anti-Aging Formulations** SB³C2023-206
S. Hendrickx-Rodriguez, O. Elsafty, R. Dauskardt
Stanford University
- 2:45PM** **Constitutive Modeling Of The Airway Tree Informed By Experimental Biaxial Mechanical Behavior** SB³C2023-019
S. Sattari¹, CA. Mariano¹, T. Sigaeva², M. Eskandari¹
¹*University of California, Riverside*, ²*University of Waterloo*
- 3:00PM** **Integrated Right Ventricular-Pulmonary Artery Biomechanics In Pulmonary Hypertension** SB³C2023-197
Sunder Neelakantan¹, Peng Zhang^{2,3}, Gaurav Choudhary^{2,3}, Reza Avazmohammadi¹
¹*Texas A&M University*, ²*Providence VA Med Center*, ³*Brown University*

Thursday, June 8

1:45PM – 3:15PM MT

Biotransport in Directed Cell Migration

Cascade F

Session Chairs: Netanel Korin, *Technion*

Joanna Dahl, *University of Massachusetts*

- 1:45PM** **A Microfluidic Platform To Investigate Transport Phenomena In Chemokine Gradient Establishment** SB³C2023-380
J. Frattolin¹, D.J. Watson¹, W.V. Bonneuil¹, F. Fasanella Masci², M. Russell³, B.S. Brook³, R.J.B. Nibbs², J.E. Moore Jr¹
¹Imperial College London, ²University of Glasgow, ³University of Nottingham
- 2:00PM** **Quantitative Assessment Of The Role Of Chromatin Mechanics And Architecture In Monolayer Cell Migration** SB³C2023-397
Jack Forman, Brady Hine, Eric Havenhill, Samantha Kaonis, Soham Ghosh
Colorado State University
- 2:15PM** **The Mechanics And Morphodynamics Of 3D Migrating Cancer Cells** SB³C2023-432
Bo Sun
Oregon State University
- 2:30PM** **Interstitial Chemokine Gradients And Dendritic Cell Migration During Inflammation** SB³C2023-464
Matthew J. Russell¹, Francesca Fasanella Masci², Willy V. Bonneuil³, Daniel J. Watson⁴, Jennifer Frattolin⁴, James E. Moore Jr.⁴, Robert J.B. Nibbs², Bindi S. Brook¹
¹University of Nottingham, ²University of Glasgow, ³KTH Royal Institute of Technology, ⁴Imperial College London
- 2:45PM** **Mechanoregulation Of Cadherin Expression In A 3D Co-Culture** SB³C2023-431
Vaishali Bala, Faith Muriuki, M.K. Sewell-Loftin
University of Alabama at Birmingham
- 3:00PM** **Cellular Signal Processing Machinery During Directed Migration Of Cancer Cells** SB³C2023-359
Andrew Mugler, Bumsoo Han
¹University of Pittsburgh, ²Purdue University

Thursday, June 8

1:45PM – 3:15PM MT

Mechanobiology in Cancer, Inflammation, and Motility

Gore AB

Session Chairs: Jacopo Ferruzzi, *University of Texas at Dallas*
Alix Deymier, *University of Connecticut*

- 1:45PM** **Macrophage Signaling Alters Fibroblast Responses to Mechanical Loading**
SB³C2023-519
McKenzie E. Sup, Min Kyu M. Kim, Lee Song, Beth Ashinsky, Jieon J. Kim, Stavros Thomopoulos
Columbia University
- 2:00PM** **Stromal Cells Modulate Chemo-Mechanical Factors In The Tumor Microenvironment Required For Leader Cell Driven Collective Migration** SB³C2023-141
Jessanne Y. Lichtenberg¹, Trey P. Redman¹, Ella Ramamurthy^{1,2}, Christopher A. Lemmon¹, Priscilla Y. Hwang¹
¹*Virginia Commonwealth University*, ²*University of California, Berkeley*
- 2:15PM** **Mechanosensitivity of Naïve and Pro-inflammatory Macrophage Polarization upon Extravasation in 3D Musculoskeletal-like Tissue** SB³C2023-560
P. Babaniamansour, D. Jacho, A. Rabino, R. Garcia-Mata, E. Yildirim-Ayan
University of Toledo
- 2:30PM** **Mechanically Primed Cells Transfer Memory To Fibrous Matrices For Invasion Across Environments Of Distinct Stiffness and Dimensionality** SB³C2023-185
José Almeida, Jairaj Mathur, Ye Lim Lee, Bapi Sarker, Amit Pathak
Washington University in St. Louis
- 2:45PM** **Impact of Type V Collagen Deficiency on Fibroblast Mechanosensing Under Inflammatory Stimulation** SB³C2023-384
N. Patel¹, T. Li¹, J. Duggan¹, S.M. Kallish², K.L. Spiller¹, R.J. Petrie¹, L. Han¹
¹*Drexel University*, ²*University of Pennsylvania*
- 3:00PM** **Mechanical Stiffening of Extracellular Matrix by Neutrophil Extracellular Traps Promotes Breast Cancer Progression** SB³C2023-405
C.-M. Boghdady, N. Wong, A. Shen, E. Solymoss, M. de Meo, A. Chandrasekaran, R. Rayes, Y. Chen, A. Ghagre, A. Ehrlicher, L. McCaffrey, J. Spicer, P. Siegel, C. Moraes
McGill University

Thursday, June 8

1:45PM – 3:15PM MT

Fibrocartilage: Intervertebral Disc, Meniscus, TMJ

Gore CD

Session Chairs: Alejandro Almarza, *University of Pittsburgh*
Sonia Bansal, *University of Delaware*

- 1:45PM** **Non-enzymatic Glycation Strengthens Annulus Fibrosus Through Crosslinks Aligned With Primary Collagen Fibers** SB³C2023-031
Minhao Zhou, Erin Archibeck, Yarah Feteih, Yousuf Abubakr, Grace D. O'Connell
University of California
- 2:00PM** **Multiscale Biomechanics Across Scales: Micromechanics and Nonlinear Viscoelasticity of the Nucleus Pulposus in Inflammation** SB³C2023-573
Timothy D. Jacobson, Gerard A. Ateshian, Nadeen O. Chahine
Columbia University
- 2:15PM** **Influence of Multidirectional Loading On Meniscus Wear Behavior** SB³C2023-435
Kate J. Benfield, Katherine J. Fors, Trevor J. Lujan
Boise State University
- 2:30PM** **Identifiability of Poroelastic Model Parameters Using Uniaxial Tension Data: Role of 3D Strain and Unloading** SB³C2023-504
John M. Peloquin, Dawn M. Elliott
University of Delaware
- 2:45PM** **Comparison Of Mechanical Response of TMJ and Knee Cartilage Under Dynamic Loading** SB³C2023-143
Annie Porter¹, Michael Santare¹, Lin Han², John Peloquin¹, X. Lucas Lu¹
¹*University of Delaware*, ²*Drexel University*
- 3:00PM** **Tribological Assessment of PVA Hydrogels as Interpositional Implant Materials in the Temporomandibular Joint** SB³C2023-353
Kevin M. Labus, Jason P. Kuiper, Christian M. Puttlitz
Colorado State University

Thursday, June 8

1:45PM – 3:15PM MT

Educational Education: Challenges and Innovations

Powell

Session Chairs: Chiara Bellini, *Northeastern University*
Zhongping Huang, *West Chester University*

- 1:45PM** **Computation For Bioengineering And Mechanical Engineering Students: An Experiential Learning Opportunity In Norway** SB³C2023-318
Samuel D. Salinas¹, Ana I. Vargas¹, Turner Jennings¹, Sean Harington¹, Mohammad J. Sadeghinia², Mojgan Y. Jacobsen³, Trine Eide³, Cecilie Udberg-Helle³, Torill Andersen Eidsvaag⁴, Torjer A. Olsen⁵, Jonathan Crossen⁵, Victorien Prot², Bjørn H. Skallerud², Rouzbeh Amini¹
¹Northeastern University, ²Norwegian University of Science and Technology, ³Kinn Education and Resource Centre, ⁴Univesrity of Bergen, ⁵UiT The Arctic University of Norway
- 2:00PM** **Integration Of FEBio As An Instructional Tool For Undergraduate Biomechanics** SB³C2023-412
David Jiang, Jeffrey A. Weiss, Lucas H. Timmins
University of Utah
- 2:15PM** **ChatGPT And The Future Of Education In Biomedical And Mechanical Engineering** SB³C2023-588
Sara E. Wilson
University of Kansas
- 2:30PM** **Mega Data Analysis of Sex Distribution of Study Samples Reported in Summer Biomechanics, Bioengineering, & Biotransport Annual Meeting Abstracts** SB³C2023-093
F. Sebastian, A. Hurgoi, M. Schaenen, H. Shah, V. Rivera, K. Le, D. Ng, R. Amini
Northeastern University
- 2:45PM** **Bringing Discussions of Accessibility to Engineering Classrooms** SB³C2023-378
N. Rich¹, S. Johnson¹, C. Bellini²
¹Tatum Robotics, ²Northeastern University
- 3:00PM** **It Takes a Village: Catalyzing Clinically-driven Undergraduate Design Projects at the Nexus of Engineering, Medicine and Business** SB³C2023-337
Byron D. Erath, Laurel Kuxhaus
Clarkson University

Biomechanical Considerations in Cardio. Biomechanics

Zermatt

Session Chairs: Kyoko Yoshida, *University of Minnesota*
 Matthew R. Bersi, *Washington University in St. Louis*

- 1:45PM The Effects Of Strain History On Aortic Valve Interstitial Cell Activation In A 3D Hydrogel Environment** SB³C2023-071
 Toni M. West, Daniel P. Howsmon, Miles W. Massidda, Helen N. Vo, Athena A. Janobas, Aaron B. Baker, Michael S. Sacks
University of Texas at Austin
- 2:00PM Improving Anti-Thrombogenic Potential Of A Porohyperelastic Bilayered Vascular Graft Using Luminal Reversal Flow** SB³C2023-164
 Ali Behrangzade¹, Sang-Ho Ye^{1,2}, William R. Wagner^{1,2}, Jonathan P. Vande Geest^{1,2,3}
¹University of Pittsburgh, ²McGowan Institute for Regenerative Medicine, ³Vascular Medicine Institute
- 2:15PM Measurement of clot attachment forces to biomaterials and comparison to a hyperelastic simulation** SB³C2023-317
 Jose L. Monclova, Sara E. Almasy, Nicolas Tobin, Vikas Kannojiya, Francesco Costanzo, Scott Simon, Keefe B. Manning
Penn State
- 2:30PM Biomechanical Effects Of Annuloplasty Ring Sizing For Functional Mitral Regurgitation Repair** SB³C2023-140
 Gediminas Gaidulis, Muralidhar Padala
Emory University
- 2:45PM Investigating Elastin Fiber Kinematics In Porcine Epicardial Layer With Laser Scanning Confocal Microscopy** SB³C2023-345
 Sara R. McMahan¹, Alan Taylor¹, Duc Khang Chung¹, Jiazhu Xu¹, Matthias Peltz², Pietro Bajona^{1,2}, Yi Hong¹, Jun Liao¹
¹University of Texas, ²Drexel University
- 3:00PM Comparison of some novel 1D implementations of hyperelastic arterial models with 3D approaches for a cylindrical test case** SB³C2023-453
 Jacob Sturdy¹, Friederike Schäfer¹, Aleksander Sinek^{1,2}, Mateusz Mesek^{1,2}, Marek Rojczyk², Wojciech P. Adamczyk², Bartłomiej Melka², Ziemowit Ostrowski², Ryszard Białecki²
¹Norwegian University of Science and Technology, ²Silesian University of Technology

Thursday, June 8

3:30PM – 5:00PM MT

Emerging Areas in Biofluids

Cascade ABC

Session Chairs: Joseph van Batenburg-Sherwood, *Imperial College London*
Ellie Rahbar, *Wake Forest University*

- 3:30PM** **Effects of Wildland Fire Smoke Exposure on Airflow and Particle Deposition in the Mouse Respiratory Tract** SB³C2023-443
Matthew J. Eden, Jacqueline Matz, Chiara Bellini, Jessica M. Oakes
Northeastern University
- 3:45PM** **The Effects of Cerebrospinal Fluid and Hyperelastic Model on Aneurysm Wall Vibration Using High-fidelity Fluid-structure Interaction Simulations** SB³C2023-379
Kei Yamamoto¹, David Bruneau², David Steinman², Kristian Valen-Sendstad¹
¹*Simula Research Laboratory*, ²*University of Toronto*
- 4:00PM** **Dynamic Response Characterization Of Sheep Lymphatic Pumping During Growth And Remodeling** SB³C2023-541
Young Jae Ryu, Sophia Mavris, Zhanna Nepiyushchikh, Rudolph L. Gleason, J. Brandon Dixon
Georgia Institute of Technology
- 4:15PM** **Improved In Vivo Measurements Of Outflow Facility In Mice By Accounting For The Time-Varying Effects Of Anesthesia** SB³C2023-480
Michael Madekurozwa¹, Nicholas Tolman², Simon W. John², Darryl R. Overby², Joseph van Batenburg-Sherwood¹
¹*Imperial College London*, ²*Columbia University*
- 4:30PM** **Left Renal Vein Stenosis Alters Renal Venous Impedance During Murine Pregnancy** SB³C2023-200
Jennifer L. Anderson¹, Riley L. Holloway¹, Paula A. Torres Loza^{1,2}, David G. Reuter³, Craig J. Goergen¹
¹*Purdue University*, ²*National University of Colombia*, ³*Seattle Children's Hospital*
- 4:45PM** **Dynamics Of Shear Stress In Embryonic Chick Heart Anatomies Reconstructed From Light Sheet Fluorescence Microscopy** SB³C2023-219
K. Giesbrecht, S. Rossi, M. Bressan, B. Griffith
University of North Carolina at Chapel Hill

Thursday, June 8

3:30PM – 5:00PM MT

Savio Woo Session II: Ligament & Tendon Growth & Loading

Cascade D

Session Chairs: Jeffrey Weiss, *University of Utah*
Stephanie Cone, *University of Delaware*

- 3:30PM ACL Injury And Joint Instability Leads To Meniscal Hypertrophy In A Skeletally Immature Porcine Model** SB³C2023-536
Jacob D. Thompson, Margaret E. Easson, Danielle Howe, Lauren V. Schnabel, Jeffrey T. Spang, Brian G. Pietrosimone, Matthew B. Fisher
North Carolina State University
- 3:45PM Mechanical and Multiscale Structural Changes Due to Repetitive Fatigue Loading in an In Vivo Rat Overuse Model** SB³C2023-218
Pooja Chainani^{1,2}, Maria Buzo Mena¹, Diana Yeritsyan¹, Daniela Caro¹, Kaveh Momenzadeh¹, Joseph P. DeAngelis², Arun J. Ramappa², Ara Nazarian^{1,2}
¹*Harvard Medical School*, ²*Boston University*
- 4:00PM Changes in Viscoelastic Mechanical Properties and Gene Expression in Rat Achilles Tendon Due to Treadmill Running Depend on Exercise Intensity and Duration** SB³C2023-532
Margaret K. Tamburro, Kelsey A. Bonilla, Snehal S. Shetye, Thomas P. Leahy, Jeremy D. Eekhoff, Daniel C. Farber, Louis J. Soslowsky
University of Pennsylvania
- 4:15PM Reduced Postnatal Loading After Sciatic Nerve Resection Impairs Achilles Tendon Growth And Maturation** SB³C2023-454
Talayah A. Johnson¹, Natalie Fogarty¹, Alisia Lin¹, Tonia K. Tsinman¹, Xi Jiang¹, Eiki Koyama², Lin Han³, Josh R. Baxter¹, Robert L. Mauck¹, Nathaniel A. Dymment¹
¹*University of Pennsylvania*, ²*Children's Hospital of Pennsylvania*, ³*Drexel University*
- 4:30PM Tendon Overload Using A Rodent Model Of Synergist Ablation Leads To Mechanical Degeneration** SB³C2023-494
Lily M. Lin, Ellen T. Bloom, John M. Peloquin, Michael H. Santare, Justin Parreno, Karin G. Silbernagel, Dawn M. Elliott
University of Delaware
- 4:45PM Cellular Senescence Suppresses ECM Synthesis In Response To Mechanical Unloading in Tendon Explants** SB³C2023-047
Emma J. Stowe, Brianne K. Connizzo
Boston University

Thursday, June 8

3:30PM – 5:00PM MT

Emerging Mechanobiology and Biomechanics II

Cascade E

Session Chairs: Hannah Cebull, *Purdue University*
Chiara Bellini, *Northeastern University*

- 3:30PM Plasticity And Avalanche Failure In Computational Models Of Pulmonary Collagen-Elastin Fiber Networks** SB³C2023-598
Jacob Herrmann¹, Yuqing Deng², Béla Suki²
¹University of Iowa, ²Boston University
- 3:45PM Determining Strains From Intact Airway Inflation Tests As Compared To Isolated Uniaxial And Biaxial Tensile Tissue Testing** SB³C2023-166
Crystal A. Mariano¹, Stanislav Polzer², Mona Eskandari¹
¹University of California, Riverside, ²VSB-Technical University of Ostrava
- 4:00PM PolyFEM: Finite Element Solver For Complex Biomechanics Problems** SB³C2023-441
Pranav Jain¹, Liam Martin², Zachary Ferguson¹, Torkan Gholamalizadeh³, Faezeh Moshfeghifar⁴, Kenny Erleben⁴, Steven Abramowitch², Daniele Panozzo¹, Teseo Schneider⁵
¹New York University, ²University of Pittsburgh, ³3Shape ApS, ⁴University of Copenhagen, ⁵University of Victoria
- 4:15PM Spatial Mapping The Material And Structural Properties Of The Uterine Fibroid-Myometrium Boundary** SB³C2023-298
Daniella M. Fodera¹, Johanna L. Lund-Jackson¹, Shuyang Fang¹, Arnold Advincula¹, Michelle L. Oyen², Kristin M. Myers¹
¹Columbia University, ²Washington University in St. Louis
- 4:30PM Design And Evaluation Of A Floating Platform System For Mechanical Testing Of Mesoscale Gels And Tissues** SB³C2023-403
Tyler G. Tuttle, Sarah Calve
University of Colorado Boulder
- 4:45PM Modeling Ultrasound-Derived Acoustic Radiation Forces In Hydrogels Using 3D Force Microscopy** SB³C2023-096
Kevin P. Grassie, Fei Wang, Bryan D. Huey, Yusuf M. Khan
University of Connecticut

Thursday, June 8

3:30PM – 5:00PM MT

Innovative Brain Mechanics Characterization

Cascade F

Session Chairs: Maria Holland, *University of Notre Dame*
Reuben Kraft, *Pennsylvania State University*

- 3:30PM** **ElastUNet: Three-Dimensional Discovery of Elastic Material Parameters Using Deep Learning** SB³C2023-057
Ali Kamali, Kaveh Laksari
University of Arizona
- 3:45PM** **Inverse Finite Element Modeling Captures Wave Propagation in High-Rate Oscillatory Shear Tests on Porcine Brain Tissue** SB³C2023-172
Gregory M. Boiczyk, Noah R. Pearson, Kenneth L. Monson
University of Utah
- 4:00PM** **Identifying Commonalities of Harmonic Brain Deformation Induced by Magnetic Resonance Elastography in Vivo** SB³C2023-180
J.D. Escarcega¹, A.A. Alshareef², A.K. Knutsen², R.J. Okamoto¹, P.V. Bayly¹
¹Washington University, ²Henry M. Jackson Foundation for the Advancement of Military Medicine
- 4:15PM** **Investigating the Frequency-Dependent Skull-Brain Motion Transmissibility through MR Elastography** SB³C2023-600
F. Rezayaraghi¹, E. Triolo², C. Neher¹, M. Kurt^{1,2}
¹University of Washington, ²Mount Sinai
- 4:30PM** **Novel Magnetic Resonance Imaging Phantoms For Investigating Skull-Brain Mechanics** SB³C2023-576
Joy Mojumder¹, Suhas Vidhate², Yuan-Chiao Lu^{1,3}, Ahmed Alshareef^{3,4}, Curtis L. Johnson⁵, Dzung L. Pham^{1,6}, John A. Butman¹
¹National Institutes of Health, ²Intuitive Surgical, Inc., ³Henry M. Jackson Foundation, ⁴University of South Carolina, ⁵University of Delaware, ⁶Uniformed Services University
- 4:45PM** **Post-mortem Changes in Anisotropic Mechanical Properties of Brain Tissue Measured by MR Elastography** SB³C2023-033
Shuaihu Wang¹, Charlotte A. Guertler¹, Ruth J. Okamoto¹, Curtis L. Johnson², Matthew D.J. McGarry³, Philip V. Bayly¹
¹Washington University in St. Louis, ²Delaware University, ³Dartmouth College

Thursday, June 8

3:30PM – 5:00PM MT

Mechanobiology in Tissue and Cellular Engineering

Gore AB

Session Chairs: **Spencer Szczesny**, *Pennsylvania State University*
Virginia Ferguson, *University of Colorado*

- 3:30PM Prestress On Nascent Desmosomes Regulates Electrophysiology Of Stem Cell-Derived Heart Muscle** SB³C2023-346
Daniel W. Simmons, David R. Schuftan, Jingxuan Guo, Kasoorelope Oguntuyo, Ghiska Ramahdita, Mary Munsell, Brennan Kandalaft, Missy Pear, Nathaniel Huebsch
Washington University in St. Louis
- 3:45PM Epigenetic Treatments Restore Nuclear Architecture in Cardiomyocyte Cultures**
SB³C2023-556
Stephanie E. Schneider, Adrienne K. Scott, Corey P. Neu
University of Colorado
- 4:00PM Synaptopodin Enables Focal Adhesions To Resist Perpendicular Force** SB³C2023-224
Chengqing Qu¹, Shumeng Jiang¹, Farid Alisafaei², Jeffrey H Miner¹, Hani Y. Suleiman¹, Guy M. Genin¹
¹Washington University in St. Louis, ²New Jersey Institute of Technology
- 4:15PM Multiscale Mechanobiologically Optimized Scaffold Designs For Bone Tissue Engineering** SB³C2023-054
Timothy O. Josephson, Elise F. Morgan
Boston University
- 4:30PM In-Situ Viscoelasticity Measurement Of Cell Monolayer By Strain Sensing Of Elastohydrodynamic Force In Microfluidic Channel** SB³C2023-216
Tianzheng Guo, Xiaoyu Zou, Shalini Sundar, Xinqiao Jia, Charles Dhong
University of Delaware
- 4:45PM Development Of An Activating And Inactivating Optogenetic Toolbox For Perturbation Of Rhoa-Yap Mechanotransductive Feedback** SB³C2023-173
Erin E. Berlew, Annapurna Pranatharthi-Haran, Brian Y. Chow, Joel D. Boerckel
University of Pennsylvania

Thursday, June 8

3:30PM – 5:00PM MT

Spine and Shoulder Mechanics

Gore CD

Session Chairs: Arin Ellingson, *University of Minnesota*
Grace O'Connell, *University of California, Berkeley*

- 3:30PM Examination of the Coupled Motion of the Lumbar Functional Unit During Dynamic Motion** SB³C2023-558
Matthew R. MacEwen, Rebecca E. Abbot, Victor H. Barocas, Arin M. Ellingson
University of Minnesota-Twin Cities
- 3:45PM Risk Of Vertebral Endplate Failure During Vertebral Fracture** SB³C2023-060
Neilesh R. Frings, Elise F. Morgan
Boston University
- 4:00PM Cyclic Loading Comparison Between Standard Ultra-High Molecular Weight Polyethylene Blocks And Biofidelic Solid Rigid Polyurethane Blocks For ASTM Pedicle Screw Testing** SB³C2023-333
Jeremy G. Loss¹, Robb W. Colbrunn¹, Kevin J. Lawson²
¹*Cleveland Clinic*, ²*Ascension Medical Group*
- 4:15PM Bulk Properties of the Murine Spine are Maintained During 30-Days of Microgravity on the International Space Station** SB³C2023-088
Shiyin Lim¹, Joanna E. Veres¹, Eduardo A.C. Almeida², Grace D. O'Connell¹
¹*University of California – Berkeley*, ²*NASA Ames Research Center*
- 4:30PM Adaptive Changes In The Bat's Shoulder Anatomy Allow For Repetitive Overhead Motions** SB³C2023-528
Iden Kurtaliaj¹, Jennifer Kunes¹, K. Michael Rowley^{2,3}, Lynn Ann Forrester¹, Mikhail Golman¹, Guy M. Genin⁴, Sharon M. Swarz², Stavros Thomopoulos¹
¹*Columbia University*, ²*Brown University*, ³*California State University East Bay*, ⁴*Washington University at St. Louis*
- 4:45PM Evaluating The Effect Of Soft Tissue Forces On The Fixation Mechanics Of Reverse Shoulder Arthroplasty: A Finite Element Analysis Driven By Musculoskeletal Simulations** SB³C2023-400
Jonathan Glenday¹, Benjamin Johnston², Fernando Quevedo Gonzalez¹, Lawrence Gulotta¹, Andreas Kontaxis¹
¹*Hospital for Special Surgery*, ²*Cornell University*

Thursday, June 8

3:30PM – 5:00PM MT

Growth and Remodeling II

Powell

Session Chairs: Kyoko Yoshida, *University of Minnesota*
Adrian Buganza Tepole, *Purdue University*

- 3:30PM The mTOR Inhibitor Rapamycin Decreases Subchondral Thickness And Affects Variability In The Tibial Plateau Of Common Marmosets SB³C2023-336**
Michael D.K. Focht¹, Dennis M. Minton^{2,3}, Adam B. Salmon^{4,5}, Adam R. Konopka^{2,3}, Mariana E. Kersh¹
¹University of Illinois, ²University of Wisconsin-Madison, ³William S. Middleton Memorial Veterans Hospital, ⁴University of Texas, ⁵Audie L. Murphy Hospital
- 3:45PM Growth And Remodeling In Sparse And Semi-Sparse Tissues: Bridging The Gap Between The Constrained Mixture Model And Eshelby's Inclusion SB³C2023-446**
Ryan R. Mahutga, Elizabeth D. Shih, Patrick W. Alford
University of Minnesota
- 4:00PM Personalized Finite Element Model Of Pediatric Tissue Expansion SB³C2023-135**
Tianhong Han¹, Kaleem Ahmed², Arun Gosain², Taeksang Lee³, Adrian Buganza Tepole¹
¹Purdue University, ²Northwestern University, ³Myongji University
- 4:15PM Telocollagen Injectable Significantly Improves Supraspinatus Tendon Mechanical Strength After Full-Tendon Tear in Rats SB³C2023-553**
Alexandrea A. Silverman¹, Nicolo Rossi², Jeffrey A. Paten¹, Mark A. Randolph², Luke S. Oh^{2,3}, Jeffrey W. Ruberti¹
¹Northeastern University, ²Massachusetts General Hospital, ³Rothman Orthopaedics
- 4:30PM Computational Analysis of Heart Valve Growth and Remodeling in Pulmonary Autografts after the Ross Procedure SB³C2023-292**
Elmer Middendorp¹, Fabian Bräu^{2,3}, Frank P.T. Baaijens¹, Jay D. Humphrey⁴, Christian J. Cyron^{5,6}, Sandra Loerakker¹
¹Eindhoven University of Technology, ²Singapore National Eye Center, ³Singapore-MIT Alliance for Research and Technology, ⁴Yale University, ⁵Hamburg University of Technology, ⁶Helmholtz-Zentrum
- 4:45PM Identifying Contributors to Aneurysmal Progression in the Marfan Aorta Using a Constrained Mixture Model SB³C2023-295**
David S. Li¹, Cristina Cavinato², Marcos Latorre³, Jay D. Humphrey¹
¹Yale University, ²Univerity of Montpellier, ³Valencia Polytechnic University

Thursday, June 8

3:30PM – 5:00PM MT

Noninvasive Metrics for Cardio. Biomechanics

Zermatt

Session Chairs: Jun Liao, *University of Texas*

- 3:30PM Pre-Operative Functional Characterization Of Aortic Neck In Abdominal Aortic Aneurysms And Its Association With Type I Endoleak Following EVAR Procedure** SB³C2023-482
A Forneris^{1,2}, A. Satriano², R.A. Beddoes², R.D. Moore¹, E.S. Di Martino^{1,2}
¹University of Calgary, ²ViTAA Medical Solutions
- 3:45PM 4D Ultrasound-Based Strain Can Characterize Early Progression of Myocardial Infarction in Mice and Rats** SB³C2023-048
Conner C. Earl^{1,2}, Ana C.M. Omoto³, Karthik Annamalai¹, Alyssa Richards¹, Samuel X. Zhang¹, Adalyn M. Meeks¹, Alexandre A. de Silva³, Craig J. Goergen^{1,2}
¹Purdue University, ²Indiana University, ³University of Mississippi
- 4:00PM Comparison Between Material Properties Obtained from Ultrasound Image Based Inverse FE Method Against Ex-Vivo Inflation Test** SB³C2023-385
Hadi Wiputra¹, Sydney Q. Clark², Craig J. Goergen², Matthew R. Bersi³, Victor H. Barocas¹
¹University of Minnesota, ²Purdue University, ³Washington University in St. Louis
- 4:15PM Procedural Strategy Impact On Outcomes Of Transcatheter Aortic Valve Replacement For Bicuspid Aortic Valves** SB³C2023-131
Breandan Yeats¹, Sri Krishna Sivakumar¹, Milad Samaee¹, Pradeep Yadav², Venkateshwar Polsani², Vinod Thourani², Stephanie Sellers³, Janarthanan Sathananthan³, Lakshmi Dasi¹
¹Georgia Tech & Emory University, ²Piedmont Heart Institute, ³University of British Columbia
- 4:30PM A New Approach To Characterize Trabeculae Carneae Structures Using High-Resolution Human Heart Images** SB³C2023-567
Yasamin Seddighi¹, Keith Bartels², Hai-Chao Han¹
¹University of Texas at San Antonio, ²Southwest Research Institute
- 4:45PM Evaluating the use of Elastic Registration for Determining Atrioventricular Valve Annulus Mechanics** SB³C2023-390
Devin W. Laurence¹, Christian Herz¹, Silvani Amin¹, Ana Sulentic¹, Patricia Sabin¹, Andras Lasso², Matthew A. Jolley¹
¹Children's Hospital of Philadelphia, ²Queen's University

Poster Sessions

Posters will be presented in two sessions as listed below. Please see the “Instructions for Poster Presenters” on Page 8. The poster viewing area is located in the **Gore Pavilion** and will be open throughout the conference.

Poster Session I	Monday, June 5, 1:00PM – 2:30PM MT
Poster Session II	Tuesday, June 6, 12:45PM – 2:15PM MT

Poster Session I

Biotransport

- P1 Molecular dynamics studies of sugar solutions for controlling water rotational relaxation time** SB³C2023-098
Kang Hu, Ryo Shirakashi
University of Tokyo
- P2 Repeatability And Backlash Distances Of Microneedles Displaced Using A Novel Actuation Block** SB³C2023-241
Brianna E. Morales, Christopher G. Rylander
University of Texas at Austin
- P3 Non-Invasive Stroke Work As A Predictor Of Myocardial Contractility In Duchenne Muscular Dystrophy** SB³C2023-238
Israel O. Ajiboye¹, Navaneeth Chandran¹, Michael D. Taylor², Rupak K. Banerjee¹
¹University of Cincinnati, ²Cincinnati Children's Hospital Medical Center
- P4 MRI Guided Focused Ultrasound Drug Delivery to DIPG Tumors in a Mouse Model** SB³C2023-025
Payton J. Martinez, Genna Nault, Jenna Steiner, Natalie Serkova, Adam Green, Mark Borden
University of Colorado
- P5 A Cost Function Approach Applied to Muscle Cryopreservation** SB³C2023-013
Casey J. Kraft, Weston J. Upchurch, Michael L. Etheridge, Paul A. Iaizzo, John C. Bischof
University of Minnesota
- P6 Enabling Cryopreservation Through Vitrification And Rewarming At The Scale Of A Human Organ** SB³C2023-171
Lakshya Gangwar¹, Zonghu Han¹, Mikaela Hintz¹, Jacqueline L. Pasek-Allen¹, Robert C. Goldstein², Michael L. Etheridge¹, John C. Bischof¹
¹University of Minnesota, ²AMF Life Systems LLC
- P7 Frequency Optimization of a Novel Skin Blood Flow Transducer** SB³C2023-501
Georgia E. Robles, Christopher M. Francis, Saeed I. Latif, David A. Nelson
University of South Alabama

- P8 Characterization Of Cellular Response To Endovascular Ablative Therapies In 2D And 3D** SB³C2023-270
S. Brocklehurst, Amin Sabaghan, D. Stolley, N. Ghousifam, E. Cressman, D. Fuentes, M.N. Rylander
University of Texas at Austin

Design, Dynamics, & Rehabilitation

- P9 Joint Space Of The First Carpometacarpal Joint: Correlation Between Computed Tomographic And Simulated X-Ray Measurement** SB³C2023-063
David Jordan, C. Kent Kwok, Zong-Ming
University of Arizona
- P10 Changes In Thumb Force Due To Osteoarthritis** SB³C2023-427
Nicole D. Arnold¹, Adam J. Chrzan¹, Kevin Chan², Tamara Reid Bush¹
¹Michigan State University, ²Spectrum Health

Fluid Mechanics

- P11 Poroelastic Model Of Trabecular Structures In The Developing Heart** SB³C2023-305
Christine Miller Buffinton, James W. Bush
Bucknell University
- P12 A self-powered pump for patients with a single ventricle heart** SB³C2023-296
Mahdi Esmaily, Dongjie Jia
Cornell University
- P13 A Comparative Study on the Difference in Arteriovenous Fistula CFD Simulations Based on Geometry Length** SB³C2023-503
Kaitlin M. Southern, Fatemeh Bahmani, Veeranna Maddipati, Stephanie M. George
East Carolina University
- P14 Patient-Specific Pulmonary Hypertension Simulations in Sickle Cell Disease Patients, a Viscosity Model Study** SB³C2023-549
Fatimah Bahmani, Alex Vahdati, Veeranna Maddipati, Stephanie M. George
East Carolina University
- P15 Sensitivity of Platelet Activation in an ECMO Pump due to Different Modelling Approaches** SB³C2023-357
Francesco Fiusco¹, Lars Mikael Broman^{2,3}, Lisa Prahli Wittberg¹
¹KTH Royal Institute of Technology, ²Astrid Lindgren's Children's Hospital, ³Karolinska Institutet
- P16 Post-MitraClip Mitral Valve Gradient with MitraClip G4** SB³C2023-326
Shelley C. Gooden¹, Mani A. Vannan², Konstantinos D. Boudoulas³, Vinod H. Thourani², Pradeep K. Yadav², Lakshmi P. Dasi¹
¹Georgia Institute of Technology, ²Piedmont Heart Institute, ³Wexner Medical Center

- P17 Fluid-Structure Interaction Simulation In An Idealised Model Of The Dissected Aorta: Relation Between False Lumen Pressure And Outflow Via Side Branches** SB³C2023-383
Amith Balasubramanya¹, Lise Gheysen¹, Nele Famaey², Joris Degroote¹, Patrick Segers¹
¹Ghent University, ²KU Leuven
- P18 A Computational Model For The Roughness Of Coronary And Cerebral Artery Stenosis And Treatment For Diabetes Mellitus Disease** SB³C2023-433
S. Piskin
Istinye University
- P19 Effect of Aortic Curvature on Bioprosthetic Aortic Valve Performance** SB³C2023-490
B. Vogl¹, R. Gadhav¹, Z. Wang², A. Chavez Ponce³, A. El Shaer³, M. Alkhoul³, H. Hatoum¹
¹Michigan Technological University, ²The Ohio State, ³Mayo Clinic
- P20 Vorticity Transport In Aneurysms Of The Abdominal Aorta** SB³C2023-356
Valentina Mazzi¹, Karol Calò¹, Maurizio Lodi Rizzini¹, Ludovica Saccaro^{2,3}, Diego Gallo¹, Angelo Iollo^{2,3}, Umberto Morbiducci¹
¹Politecnico di Torino, ²Université de Bordeaux, ³Inria-Bordeaux Sud-Ouest
- P21 Investigating The Role Of Eccentric Inlet Conditions On Hemodynamic Results At Different Stages Of Aneurysm Growth** SB³C2023-601
Federica Galbiati^{1,2}, Emanuele Vignali³, Katia Capellini³, Claire Morin², Stéphane Avril², Emiliano Costa¹, Simona Celi³
¹RINA Consulting SpA, ²INSERM, ³BioCardioLab
- P22 A Fluid-Solid-Growth Framework For Simulating Patient-Specific Vascular Growth And Remodeling Using Constrained Mixture Theory** SB³C2023-268
Erica L. Schwarz¹, Martin R. Pfaller¹, Jason Szafron¹, Christopher Breuer², Jay D. Humphrey³, Alison L. Marsden¹
¹Stanford University, ²Nationwide Children's Hospital, ³Yale University
- P23 Towards Modeling Acute Ischemic Stroke: In Vitro Experiments and Simulations of Blood Flow and Mean Arterial Pressure in an Artificially Clotted Cerebrovascular Model** SB³C2023-447
Saurabh Bhardwaj¹, Brent A. Craven², Jacob E. Sever¹, Francesco Costanzo¹, Scott D. Simon¹, Keefe B. Manning¹
¹Pennsylvania State University, ²US FDA
- P24 The Influence Of Hemodiluted Blood Viscosity On Patient Hemodynamics During Cardiopulmonary Bypass** SB³C2023-162
Nafis M. Arefin, Allison R. Cripps, Bryan C. Good
University of Tennessee
- P25 Validating Multi-scale Coronary Simulation Pipeline Against Coronary Intravascular Velocity and Pressure Measurements** SB³C2023-016
Anahita A. Seresti¹, Alison L. Marsden², Andrew M. Kahn³, M. Owais Khan¹
¹Toronto Metropolitan University, ²Stanford University, ³University of California – San Diego

- P26 Multi-Omic Analysis Of Resected Thrombi Identifies Complex Traits Associated With Ischemic Stroke Etiology** SB³C2023-191
Briana A. Santo, Kerry E. Poppenberg, Andre Monteiro, Adnan H. Siddiqui
University of Buffalo
- P27 Laser Ablation: A New Leaflet Modification Strategy To Prevent Coronary Obstruction In Redo Tavr** SB³C2023-100
John T. Briansky, Masod Sadipour, Ali Azadani
University of Denver
- P28 Verification Errors In Eulerian Power-Law Hemolysis Model Predictions In Simple Flows** SB³C2023-280
Mohammad M. Faghih¹, Brent A. Craven¹, M. Keith Sharp²
¹US FDA, ²University of Louisville
- P29 Endothelial Nuclear Morphology is Incrementally Sensitive to Shear Stress Magnitude and Directionality** SB³C2023-515
Jaideep Sahni¹, Mehwish Arshad², Peter D. Weinberg², Ryan M. Pedrigi¹
¹University of Nebraska-Lincoln, ²Imperial College London
- P30 Computational Study of Role of Ultra Large Von Willebrand Factor in COVID-19 Related Thrombosis** SB³C2023-350
Nahid Rahmati, Nima Maftoon
University of Waterloo
- P31 Rotational Impact-Induced Brain Injury, a Biomimetic Study** SB³C2023-232
Q. Wang¹, J. Lang², R. Nathan³, Q. Wu¹
¹Villanova University, ²Southeast University, ³Pennsylvania State University

Solid Mechanics: Cardiovascular

- P32 High-Throughput Automated Mechanical Analysis of Human Induced Pluripotent Stem Cell Derived Cardiac Microtissue** SB³C2023-022
H. Kobeissi, E. Lejeune
Boston University
- P33 Changes In Right Ventricle Anisotropic Viscoelastic Behavior With Pulmonary Hypertension Development** SB³C2023-058
K. LeBar, K. Roth, W. Liu, B. Garcia, J. Pang, A. Chicco, Z. Wang
Colorado State University
- P34 A Three-node Rotation-free Kirchhoff-love Shell Formulation For Cardiovascular Applications** SB³C2023-570
L. Shi, Y. Chen, V. Vedula
Columbia University
- P35 Establishment Of A Validated Finite Element Framework To Predict The 3D, Patient-Specific Arterial Mechanical Environment** SB³C2023-597
Caleb C. Berggren, Y.F. Jack Wang, Lucas H. Timmins
University of Utah

- P36 Anisotropic Material Property and Local Strength Characterization of Human Carotid Plaques: A Bayesian Optimization Based Inverse Finite Element Modeling** SB³C2023-091
S. Guvenir Torun¹, B. Kaaij^{1,2}, P. de Miguel Munoz^{1,2}, H. Crielaard¹, H.J.M. Verhagen¹, G.J. Kremers¹, A.F.W. van der Steen¹, A.C. Akyildiz^{1,2}
¹Erasmus Medical Center, ²Delft University of Technology
- P37 Changes in Myocardial Deformation Induces Abnormalities in Valvular Dynamics Causing Mitral Valve Regurgitation** SB³C2023-294
Tawfik M. Hussein^{1,2}, Gediminas Gaidulis^{2,3}, Michael Silverman³, John N. Oshinski^{1,3}, Muralidhar Padala^{2,3}
¹Georgia Institute of Technology, ²Carlyle Fraser Heart Center, ³Emory University
- P38 Computational Assessment of Elastin in a Hybrid Modelling Approach of Arterial Biomechanics** SB³C2023-321
Yousof MA. Abdel-Raouf¹, Mathias Peirlinck², Nele Famaey³, Patrick Sips¹, Patrick Segers¹
¹Ghent University, ²Delft University of Technology, ³KU Leven
- P39 Pattern Of Aortic Valve Leaflet Calcification In As Patients: In-Vivo Geometric Description Of Calcific Progression** SB³C2023-006
Mohamed Abdelkhalek, Zahra Keshavarz-Motamed
McMaster University
- P40 An Inverse FE Method To Quantify The Relationship Between Mechanical Properties And Residual Stresses In The Myocardium** SB³C2023-478
Manoj Ghosh, Marissa Grobbel, Lik Chuan Lee, Sara Roccabianca
Michigan State University
- P41 Effects Of Chordae Rupture On Tricuspid Valve Septal Leaflet Strains: An Ex-Vivo Study On Porcine Hearts** SB³C2023-227
Julia Clarin¹, Keyvan Amini Khoiy², Samuel D. Salinas¹, Dipankar Biswas², Kourosh T. Asgarian³, Francis Loth¹, Rouzbeh Amini¹
¹Northeastern University, ²The University of Akron, ³Jersey Shore University
- P42 Right Ventricular Global Longitudinal Strain And Ventricular Dynamics In Patients With Pulmonary Hypertension** SB³C2023-521
Alexandra M. Janowski, Scott Visovatti, Raymond L. Benza, Rebecca R. Vanderpool
The Ohio State
- P43 Viscoelastic and Fracture Properties of Clot from Human and Bovine Blood** SB³C2023-104
Gabriella P. Sugerman, Sapun H. Parekh, Berkin Dortdivanlioglu, Manuel K. Rausch
University of Texas at Austin
- P44 Biomechanical Characterization Of Neonatal Aortic Coarctation Tissue Informs The Need To Design Bespoke Patient Therapies For Neonatal Coarctation Of The Aorta** SB³C2023-094
Niall Linnane^{1,2,3}, Robert Johnston¹, Damien P. Kenny^{2,3}, Caitriona Lally¹
¹Trinity College Dublin, ²Royal College of Surgeons, ³Children's Health Ireland

- P45 Ultrasound Imaging To Characterize Inflated Atherosclerotic Plaques** SB³C2023-327
 Yasmine Guendouz¹, Brooke Tronifoglio¹, Sherif Sultan^{2,3}, Niamh Hynes^{2,3}, Cleona Gray⁴,
 Caitriona Lally¹
*¹Trinity College Dublin, ²University Hospital Galway, ³Galway Clinic, ⁴Mater Misericordiae
 University Hospital*
- P46 Design, Computational And Experimental Evaluation, And 3D Printing Of Patient Specific
 Stents For Treatment Of Paediatric Aortic Coarctation** SB³C2023-286
 Robert D. Johnston¹, Niall Linnane^{1,2,3}, Samuel Geraghty¹, Conor O’Keeffe¹, Shirsha Bose¹,
 Damien Kenny³, Caitriona Lally¹
¹Trinity College Dublin, ²Royal College of Surgeons, ³Children’s Health Ireland at Crumlin
- P47 Using A Three-Dimensional Biventricular Mathematical Model To Help Understand Sex
 Differences In The Onset And Progression Of Pulmonary Arterial Hypertension**
 SB³C2023-211
 Kristen M. Garcia, Becky A. Hardie, Jennifer Stowe, Daniela Valdez-Jasso
University of California – San Diego
- P48 Multiscale Modeling of Myofiber Disarray In The Left Ventricle Using A Stress-Based
 Reorientation Law** SB³C2023-118
 Mohammad Mehri, Charles K. Mann, Hossein Sharifi, Kenneth S. Campbell, Jonathan F. Wenk
University of Kentucky
- P49 Method Of Applying Twist To Complex Femoropopliteal Artery Deformations In A Finite
 Element Study** SB³C2023-565
 Ali Ahmadi, Anastasia Desyatova
University of Nebraska-Omaha
- P50 Implementation Of Experimentally Acquired Tricuspid Valve Leaflet Pre-Strains To An In-
 Silico Finite Element Model** SB³C2023-137
 Colton J. Ross¹, Arshid Mir¹, Harold M. Burkhart¹, Ming-Chen Hsu², Devin W. Laurence³,
 Chung-Hao Lee¹
¹University of Oklahoma, ²Iowa State University, ³Children’s Hospital of Philadelphia
- P51 Patient-Specific Predictive Simulation of Transcatheter Edge-to-Edge Repair in Humans
 with Mitral Regurgitation** SB³C2023-452
 Natalie T. Simonian¹, Sneha Vakamudi², Mark J. Pirwitz², Alison M. Pouch³, Joseph H.
 Gormann, III³, Robert C. Gorman³, Michael S. Sacks¹
¹University of Texas at Austin, ²Ascension Texas Cardiovascular, ³University of Pennsylvania
- P52 Comparing The Elastic And Fracture Properties Between Fibrin And Whole Blood**
 SB³C2023-407
 Grace N. Bechtel¹, Gabrielle P. Sugerman¹, Sapun H. Parekh¹, Manuel K. Rausch^{1,2}
¹University of Texas at Austin, ²Oden Institute for Computational Engineering and Sciences

Solid Mechanics: Injury & Brain

- P53 Effect Of Muscle Activation on Head-Neck Response in Simulated Frontal Impact Compared To A Unique Military Data Set** SB³C2023-072
Jesse W. Gerringer^{1,2}, Karthik Somasundaram^{1,2}, Frank Pinter^{1,2}
¹Medical College of Wisconsin and Marquette University of Tennessee, ²VA Medical Center
- P54 Development of Three - Dimensional Finite Element Model of the Neonatal Brachial Plexus** SB³C2023-027
Sarah J. Wright, Michele J. Grimm
Michigan State University
- P55 Measurement Error Associated With Decoupling Of Instrumented Mouthguards** SB³C2023-245
Ryan A. Gellner, Mark T. Begonia, Matthew Wood, Lewis Rockwell, Taylor Geiman, Caitlyn Jung, Steve Rowson
Virginia Tech
- P56 Effect Of Excitation Direction And Frequency On Regional Dynamic Deformation Of The Human Brain** SB³C2023-561
Ruth J. Okamoto¹, Jordan D. Escarcega¹, Ahmed Alshareef², Curtis Johnson³, Philip V. Bayly¹
¹Washington University, ²Henry M. Jackson Foundation for the Advancement of Military Medicine, ³University of Delaware

Solid Mechanics: Musculoskeletal

- P57 Raman Spectroscopic Probe Predicts The Composition And Functional Mechanical Properties Of The Intervertebral Disc** SB³C2023-550
Chenhao Yu¹, Masumeh Kazemi¹, Farida Korna¹, Erik E. Ersland¹, Mark W. Grinstaff¹, Thomas P. Schaer², Mads S. Bergholt³, Edward J. Vresilovic⁴, Brian D. Snyder⁵, Michael B. Albro¹
¹Boston University, ²University of Pennsylvania, ³King's College London, ⁴University of Delaware, ⁵Beth Israel Deaconess Medical Center
- P58 The Effectiveness of Custom ACL Bracing in Adolescent Populations: A Finite Element Analysis** SB³C2023-009
Alexandria D. Mallinos¹, Brian L. Davis¹, Kerwyn C. Jones²
¹Cleveland State University, ²Akron Children's Hospital
- P59 Bendable Osteochondral Allografts for Improved Congruence: Comparison of Computational and Cadaveric Models** SB³C2023-194
Katherine A. Spack¹, Courtney A. Petersen¹, Peter T. Shyu¹, Edward Guo¹, James T. Cook², Melvin P. Rosenwasser¹, Clark T. Hung¹, Gerard A. Ateshian¹
¹Columbia University, ²University of Missouri
- P60 Mechanical Failure Properties Of Porcine Annulus Fibrosus: An I-PREDICT Study** SB³C2023-382
J. Seifert^{1,2}, A. Shah^{1,2}, L.L. Frazer⁴, N. Yoganandan^{1,2}, B.S. Shender³, J.B. Sheehy³, G. Paskoff³, T. Bentley⁵, D.P. Nicoletta⁴, B.D. Stemper^{1,2}

¹Medical College of Wisconsin, ²Zablocki VA Medical Center, ³Naval Air Warfare Center,
⁴Southwest Research Institute, ⁵Office of Naval Research

- P61 Calcium Signaling In In-Situ Chondrocytes Under Dynamic Compressive Loading**
SB³C2023-319
Vineel Kondiboyina, Timothy Boyer, Sandra J. Shefelbine
Northeastern University
- P62 Partial Meniscectomy Of The Meniscal Inner Part Increases The Meniscal Deformation And Extrusion** SB³C2023-343
Satoshi Yamakawa, Tomoki Ohori, Issei Ogasawara, Akira Tsujii, Shoji Konda, Seira Sato, Takashi Kanamoto, Ken Nakata
Osaka University
- P63 Effects Of External Bathing Solution Osmolarity On Tribological Rehydration And Cartilage Lubrication** SB³C2023-074
Shamimur R. Akanda, David L. Burris, Chris Price
University of Delaware
- P64 Slick Yet Stuck: Elucidating The Underlying Adhesive Mechanisms In Articular Cartilage**
SB³C2023-250
Jamie M. Benson, David L., Burris
University of Delaware
- P65 Partial Meniscus Transplant To Treat Horizontal Cleavage Tear Restores Contact Areas Similar to Partial Meniscectomy** SB³C2023-145
Farid Amirouche^{1,2}, Eric Chang¹, Asher Lichtig¹, Jason Koh²
¹University of Illinois, ²NorthShore University Health System

Solid Mechanics: Other

- P66 Multiscale Characterization of Human Tooth with Combination of SEM, AFM, and FEM**
SB³C2023-170
Y. Zhai¹, J. Wang¹, Z. Shi¹, T. Premaraj², S. Premaraj², T. Karpova¹, P. Dong¹, L. Gu¹
¹Florida Institute of Technology, ²Nova Southeastern University
- P67 Depth Map Image Based Inflation Test For Mechanical Characterization Of Soft Matter**
SB³C2023-468
Rahul L. Maurya¹, Yash K. Shrivastava², Samarth S. Raut¹
¹Indian Institute of Technology, ²Manipal University Jaipur
- P68 Micromechanical Model Of Mechanosensitive Collagen Tissues** SB³C2023-437
Kalyn G. Younger, William Cortes, Daniel H. Reich, Thao D. Nguyen
Johns Hopkins University
- P69 A Mesoscale Model Of Skin To Investigate The Role Of The Dermis-Epidermis Interface On The Tissue Biomechanics** SB³C2023-161
O. Moreno Flores¹, M. Rausch², A. Buganza Tepole¹
¹Purdue University, ²University of Texas at Austin

- P70 Deep Learning Framework For Stress Strain Analysis Over Point Cloud** SB³C2023-429
Jia Lu, Nishant Sundaravaradan
University of Iowa
- P71 An Inexpensive, Shared Biaxial Device To Study The Multiscale Mechanics Of Soft Materials** SB³C2023-332
Alberto Madariaga, Chien-Yu Lin, Mrudang Mathur, Manuel K. Rausch
University of Texas at Austin
- P72 Negative-Pressure Lung Mechanics Of Fibrotic And Emphysematous Mouse Lungs** SB³C2023-021
K.A.M. Quiros¹, T.M. Nelson¹, A. Ulu¹, E.C. Dominguez¹, T.M. Nordgren^{1,2}, M. Eskandari¹
¹University of California - Riverside, ²Colorado State University
- P73 The Material Properties of Healthy Versus Diseased Mouse Lung Parenchyma** SB³C2023-049
T.M. Nelson, K.A.M. Quiros, C.A. Mariano, S. Sattari, M. Eskandari
University of California – Riverside
- P74 Histopathology of Capsule and Cartilage Predict Elbow Biomechanics via Machine Learning** SB³C2023-605
Michael A. David¹, Spencer P. Lake²
¹University of Colorado, ²Washington University in St. Louis
- P75 Understanding mechanotransduction of the distal colon and rectum by multiscale and multimodal computational modeling** SB³C2023-516
Amirhossein Shokrani, Ashkan Almasi, Bin Feng, David M. Pierce
University of Connecticut
- P76 Effects Of GAGs On Microstructure Of Corneal Extracellular Matrix** SB³C2023-116
M.E. Emu, H. Hatami-Marbini
University of Illinois at Chicago
- P77 Effect Of GAGs On Tensile Properties Of Porcine Cornea** SB³C2023-363
H. Hatami-Marbini
University of Illinois at Chicago
- P78 Fibrous Finite Element Modeling Of Posterior Sclera** SB³C2023-278
Mohammad R. Islam, Fengting Ji, Manik Bansal, Yi Hua, Ian A. Sigal
University of Pittsburgh
- P79 Comparing Five Methods To Identify Fracture Toughness Of Soft Tissues** SB³C2023-540
Matthew J. Lohr, Manuel K. Rausch
University of Texas at Austin
- P80 Extracting Inhomogeneous Orientation Distribution Functions From 3d Image Data Of Fibrous Tissues For Finite Element Simulations** SB³C2023-242
Adam Rauff, Michael R. Herron, Steve A. Maas, Jeffrey A. Weiss
University of Utah

P81 Understanding Ciliary Waveforms Through Optimization SB³C2023-533

Louis G. Woodhams, Philip V. Bayly
Washington University in St. Louis

Tissue & Cellular Engineering

P82 Targeting the Chromatin Remodeling in Mesenchymal Stromal Cells Under Hyper Oxidative Stress for Maintaining Cell Phenotype and Viability SB³C2023-335

Lauren A. Monroe, Samantha Kaonis, Neda Kabi, Abigail Fennell, Jack Forman, Soham Ghosh
Colorado State University

P83 Mechanical Regulation of Lumen Growth SB³C2023-557

Wenhui Tang¹, Anqi Chen², Jessie Huang³, Darrell N. Kotton³, Shengqiang Cai⁴, Ming Guo¹
¹MIT, ²Harvard University, ³Boston University, ⁴University of California – San Diego

P84 Fabrication And Mechanical Characterization Of Direct Ink Write 3D Printed Methacrylated Hyaluronic Cerium Oxide Scaffolds SB³C2023-472

Aritra Chatterjee¹, Jordan Turner², Jonathan Banks², Joan Adebawale², Deva D. Chan¹, Juana Mendenhall²
¹Purdue University, ²Morehouse College

P85 Functionalized Nanowires Successfully Load And Sustain Release Of NGF SB³C2023-594

Molly E. Czachor¹, Joel A. Finbloom², Nafisa A. Elghazali², Darnell L. Cuylear², Kevin O. Rivera², Tejal A. Desai³, Chelsea S. Bahney^{1,2}
¹The Steadman Philippon Research Institute, ²University of California – Riverside, ³Brown University

P86 The Association Between Clot Presentation On Ct, Biological Composition, And Material Properties: Implications For Pre-Treatment Imaging Biomarkers SB³C2023-421

TaJania D. Jenkins^{1,2}, Briana A. Santo^{1,2}, Shiau-Sing K. Ciecierska¹, Tatsat R. Patel^{1,2}, Debanjan Mukherjee³, Adnan H. Siddiqui^{1,2}, Vincent M. Tutino^{1,2}
¹Canon Stroke and Vascular Research Center, ²University at Buffalo, ³University of Colorado

P87 A Vascularized Tissue Model To Investigate Human Synoviocyte - Endothelial Cell Crosstalk In Joint Health and Disease SB³C2023-410

Hannah M. Zlotnick¹, Abhishek P. Dhand^{1,2}, Matthew D. Davidson¹, Gabriel J. Rodriguez-Rivera¹, Christopher J. Calo¹, Hannah K. Weppner¹, Laurel E. Hind¹, Jason A. Burdick¹
¹University of Colorado, ²University of Pennsylvania

P88 Quantifying Alignment in Engineered Tissue Constructs Using Raman Spectroscopy and Computational Modeling SB³C2023-193

Maedeh Lotfi, Hui Zhou, Janny Piñeiro Llanes, Ghatu Subhash, Chelsey S. Simmons, Malisa Sarntinoranont
University of Florida

- P89 Amobarbital Prevents Intervertebral Disc Degeneration By Inhibiting Oxidative Stress** SB³C2023-146
Venkateswaran Ganesh¹, Deborah A. Vacek¹, Douglas C. Fredericks¹, Emily B. Petersen¹, Youssef W. Naguib^{1,2}, Anupam Tiwari¹, Yochana Kancharia³, Mitchell C. Coleman¹, James A. Martin¹, Aliasger K. Salem¹, Tae-Hong Lim¹, Dongrim Seol¹
¹University of Iowa, ²Deraya University, ³Des Moines University
- P90 Gelatin Hydrogel Poly-Caprolactone 3D Printed Composite Biomaterial Characterization For Meniscal Tissue Engineering** SB³C2023-531
Anthony J. El Kommos, Gabi Schwartz, Andy J. Morejon
University of Miami
- P91 Multi-physics Modeling of Neural Dendrite Growth With Electrical Polarization** SB³C2023-079
Shuolun Wang, Xincheng Wang, Maria A. Holland
University of Notre Dame
- P92 Highly Parallel Production of Designer Organoids by Mosaic Patterning of Progenitors** SB³C2023-202
Catherine M. Porter, Alex J. Hughes
University of Pennsylvania
- P93 Epithelial Monolayers Develop Density and Effective Temperature Differentials to Migrate across Confined Matrices** SB³C2023-225
W.J. Lin, A. Pathak
Washington University

Undergraduate Research and Design

- P94 3D Printed Patient-Specific Lower Extremity Model For Assessing Developmental Dysplasia Of The Hip** SB³C2023-638
E. Fontz¹, O. Burkowski¹, J. Palmer¹, E. Scott¹, C. Price^{2,3}, V. Huayamave¹
¹Embry-Riddle Aeronautical University, ²International Hip Dysplasia Institute, ³Orlando Health
- P95 Numerical Modeling For Infants With Ductal-Dependent Pulmonary Flow** SB³C2023-641
S. Mulla, M.H. Alzaeim, W.S. Basha, K.B. Kose
Istanbul Medipol University
- P96 Development of a Novel Animal Model for Osteochondritis Dissecans: A Radiofrequency Ablation Approach** SB³C2023-644
Kosisochukwu Ogbonna-ukuku, Boyuan Liu, Kristine Fischenich, Virginia L. Ferguson
University of Colorado
- P97 Significance of Vasa Vasorum Oxygen Supply in the Nourishment of the Aneurysmal Wall** SB³C2023-617
Manoela Neves, Alexis Throop, Rana Zakerzadeh
Duquesne University

- P98 Biomechanical Follow-Up And Evaluation Of Aneurysm Growth** SB³C2023-608
F.A.M. Garbou, O.O.M. Elnamla, W.A.K.A. Saber, K.B. Kose
Istanbul Medipol University
- P99 Heart Rate Impact On Plaque Deposition At The Carotid Artery Bifurcation** SB³C2023-571
Ramita Sajankila, Esha Navaneethakrishnan, Elvan Dogan, Amir K. Miri
New Jersey Institute of Technology

Bachelor's Level Research

- P100 The Effects Of Progeria On Central Vascular Tissue, Blood Flow, And Blood Pressure** SB³C2023-646
L. Roukoz¹, T. Hopper¹, S. Murtada², J. Humphrey², C.A. Figueroa¹
¹University of Michigan, ²Yale University
- P101 Computational Modeling Of Hemodynamics In Aortic Root Enlargement** SB³C2023-642
Surya Sanjay¹, Mia Bonini¹, Alexander Makkinejad¹, Maximilian Balmus², Marc Hirschvogel², Nicholas Burris¹, Bo Yang¹, David Nordsletten¹
¹University of Michigan, ²King's College London
- P102 High Aortic Diameter Variation Is Associated With Turbulent-Like Flow Conditions In Post-Norwood Patients** SB³C2023-611
Vivian Tan¹, Ankavipar Saprungruang², Brandon Peel², Christopher K. Macgowan², David J. Barron², Shi J. Yoo², M. Owais Khan¹

University of Pittsburgh
- P17 Developing and Testing a Novel Device for Detecting Peripheral Artery Disease Using Radio Frequency Energy** SB³C2023-615
J Nelson, C Cobb, J Keller, D Nelson, M Francis
University of South Alabama
- P18 Performance comparison of portable suction devices** SB³C2023-264
Saketh R. Peri, Forhad Akhter, Robert A. De Lorenzo, R. Lyle Hood
University of Texas
- P19 Testing the Validity of Various Viscosity Values for a Versatile Oxygenating Perfusion System** SB³C2023-623
A Fasci, S Salazar, J Oseghale, M Garcia, A Khalil, B Wearden, L Muenchow, J Gonzalez, C Villareal, D Portillo
University of Texas at San Antonio

- P20 Multifiber Computational Modeling of Hollow-Fiber Hemodialyzers** SB³C2023-256
Ruhit Sinha, Anne E. Staples
Virginia Tech
- P21 An Intravascular Catheter With Switchable Flexural Rigidity** SB³C2023-269
D.G. Rucker, J.W. Osbun, M.A. Zayed, G.M. Genin
Washington University
- P22 Tissue Diffusion and Two Component Computational Model to Predict Leaching from Medical Devices** SB³C2023-068
Martin L. Tanka¹, David M. Saylor², Robert M. Elder²
¹*Western Carolina University*, ²*US FDA*

Education

- P23 Building Entrepreneurial Mindset: Motivating Curiosity, Connections, and Creating Value in an Assistive-Device Design Project** SB³C2023-316
Joshua A. Gargac
Ohio Northern University
- P24 Scaffolded And Iterative Course Design In a Biomechanics Laboratory Course** SB³C2023-352
S Bansal, J Benson, S Sullivan, E Corbin
University of Delaware
- P25 Effect Of Standards-Based Grading On The Course Grade Distribution In A Biomechanics Course** SB³C2023-488
Kenneth J Fischer, Christopher J Fischer
University of Kansas

Fluid Mechanics

- P26 Investigating the impact of aortic root geometry on TAVI implantation using 3D reconstructions and FSI** SB³C2023-053
K Bates, K Lachapelle, G Martucci, RL Leask
McGill University
- P27 Advance In Hybrid Cardiovascular Modeling: Coupling Volumetrically Dynamic In-Vitro Experiments To Numerical Physiology Simulation** SB³C2023-103
Abraham E. Umo, Ethan O. Kung
Clemson University
- P28 Toward Real-Time Simulation of Cardiovascular Flows by Introducing a Stabilized Time-Spectral Finite Element Method** SB³C2023-085
Dongjie Jia, Mahdi Esmaily
Cornell University

- P29 Computational Modeling Of Coronary Venous Retroperfusion Treatments For Ischemia** SB³C2023-052
Haifeng Wang, Lei Fan, Jenny S. Choy, Ghassan S. Kassab, Lik Chuan Lee
¹Michigan State University, ²California Medical Innovation Institute
- P30 Impact of the Coronary Stent Footprint on Wall Shear Stress in Patient-Specific Arteries - Analysis from the Shear-Stent Trial** SB³C2023-322
I Shah^{1,2}, D Molony³, K. Crawford^{2,3}, A. Lefieux², A. Veneziani², H. Samady^{2,3}
¹Georgia Institute of Technology, ²Emory University, ³Northeast Georgia Medical Center
- P31 A 3D Particle Tracking Study on the Blood Residence Time in a Cerebral Aneurysm under Different Inflow Conditions** SB³C2023-552
Huang Chen, Roya Kamali, Thangam Natarajan, Satheesh Kumar Harikrishnan, Lakshmi Dasi
Georgia Institute of Technology
- P32 Biomechanical Follow-Up and Evaluation of Aneurysm Growth** SB³C2023-323
F.A.M Garbou, O.O.M. Elnamla, W.A.K.A. Saber, K.B. Kose
Istanbul Medipol University
- P33 The Impact Of Transcatheter Aortic Valve Replacement Deployment Parameters On Coronary Artery Hemodynamics** SB³C2023-007
Seyedvahid Khodaei, Zahra Keshavarz-Motamed
McMaster University
- P34 Developing a Perfusion Optimization Framework For Synthetic Vasculature In Biofabrication Applications** SB³C2023-564
Zachary A. Sexton, Karthik Menon, Lazaros Papamanolis, Alison Marsden
Stanford University
- P35 Quantitative comparison of flow parameters in rigid vs compliant aneurysm models using 4D particle image velocimetry (PIV)** SB³C2023-157
Nikhil S. Shirdade, Sandy Karam, Baha T. ElKhader, Ephraim W. Church, Guha Manogharan, Melissa C. Brindise
Penn State
- P36 Tomographic X-ray Particle Tracking Velocimetry And Possible Applications In Biological Fluid Dynamics** SB³C2023-496
Jason T. Parker, Simo A. Mäkiharju
University of California - Berkeley
- P37 Vascular Cross-Section Morphometrics Can Predict First Pass Outcome Of Mechanical Thrombectomy For Ischemic Stroke** SB³C2023-188
Briana A. Santo, S.M.M. Janbeh Sarayi, Muhammad Waqas, Andre Monteiro, Adnan H. Siddiqui, Vincent M. Tutinio
University at Buffalo
- P38 Bovine Pericardium Density Measurement And Its Implications On Leaflet Stress Distribution In Bioprosthetic Heart Valves** SB³C2023-107
Masod Sadipour, Ali Azadani
University of Denver

- P39 A Novel Electrochemical Catheter For Cardiac Output Monitoring** SB³C2023-055
Marco A. Nino, Abdulsattar H. Ghanim, Syed Mubeen, Suresh M.L. Raghavan
University of Iowa
- P40 Computational Fluid Dynamics Simulations Of Aortic Dissection Using Immersed Boundary Method** SB³C2023-117
Gokul G. Anugrah, Sam Tyagi, Mary B. Sheppard, Christoph Brehm, Jonathan F. Wenk
University of Kentucky
- P41 Peristalsis Alone Is Inconsistent With Measured Flow In The Paravascular Space** SB³C2023-281
M. Keith Sharp
University of Louisville
- P42 An Euler-Lagrange Approach For Modeling Particle-Laden Flows In Biological Applications** SB³C2023-401
Abhilash Reddy Malipeddi, Jesse Capecehatro, C. Alberto Figueroa
University of Michigan
- P43 Pulse Wave Velocity Increases With Extending The Length Of Vascular Stent-Grafts** SB³C2023-189
Ramin Shahbad, Anastasia Desyatova
University of Nebraska Omaha
- P44 Design and characterization of a silicone venous valve model** SB³C2023-306
Matthew S. Ballard, Dallin Brimhall, Sarah Dayley, Andrew Rasmussen
Utah Valley University

Solid Mechanics: Cardiovascular

- P45 Comparing Approaches to Estimate Failure Strength of Sutured Patches Used in Pediatric Cardiac Surgery** SB³C2023-580
Shannen B. Kizilski^{1,2}, Dominic P. Recco^{1,2}, Lauren E. Marshall¹, Nicholas E. Kneier¹, Patrick D. Earley¹, Peter E. Hammer^{1,2}, David M. Hoganson^{1,2}

INTRODUCTION

Analysis of the arterial pressure waveforms can offer a deep insight into the hemodynamic status of a patient and might be a promising prognostic factor of cardiovascular disease. The central aortic blood pressure, measured in the ascending aorta, has been shown to be a more accurate predictor of clinical outcomes in comparison to blood pressure measurements acquired in the periphery, such as the brachial artery [1].

METHODS

In this study, we developed and validated a deep learning method for estimating aortic systolic blood pressure (aSBP) from the brachial blood pressure waveform (brBP_{wave}) using convolutional neural networks (CNNs). We used *in vivo* invasive data collected from 38 subjects [2] and *in silico* data (3'748 virtual individuals) [3] generated from a previously validated mathematical model of the cardiovascular system [4]. Simultaneous high-fidelity, invasive central aortic and brachial pressure waveforms were recorded for 20–30 consecutive beats to cover at least two respiratory cycles. A 2F custom-made dual pressure sensor catheter (Model SSD-1059, Millar Instruments Inc. Houston, TX, USA) was advanced within a standard 6F Judkins coronary artery catheter. The first pressure sensor was placed at the ascending aorta and the second pressure sensor was positioned in the brachial artery at the level of the mid humerus. We performed two training experiments for the CNN models: 1) a CNN was trained and tested using the *in vivo* dataset (CNN_{in vivo}), and 2) a second CNN was trained using *in silico* data and tested using the *in vivo* data (CNN_{TL}). The idea behind the second experiment (transfer learning) was to assess whether the *in silico* data can simulate accurately the content of human data in the prediction of aSBP from the brBP_{wave}.

RESULTS

The CNN trained and tested using the *in vivo* data yielded the highest accuracy with an RMSE loss of 6.46 mmHg (bias = -0.4 mmHg,

limits of agreement (LoA) = [-13, 12] mmHg, $r=0.95$). The performance of the CNN trained with the *in silico* was similarly highly satisfactory, achieving an RMSE loss of 8.61 mmHg (bias = 0.2 mmHg, LoA = [-20, 21] mmHg, $r=0.87$). A slight systematic bias was reported in the Bland-Altman analysis of CNN_{TL} (aSBP was underestimated at higher BP level and overestimated at lower BP level). The comparison between the model predictions and the reference data is presented in Figure 1.

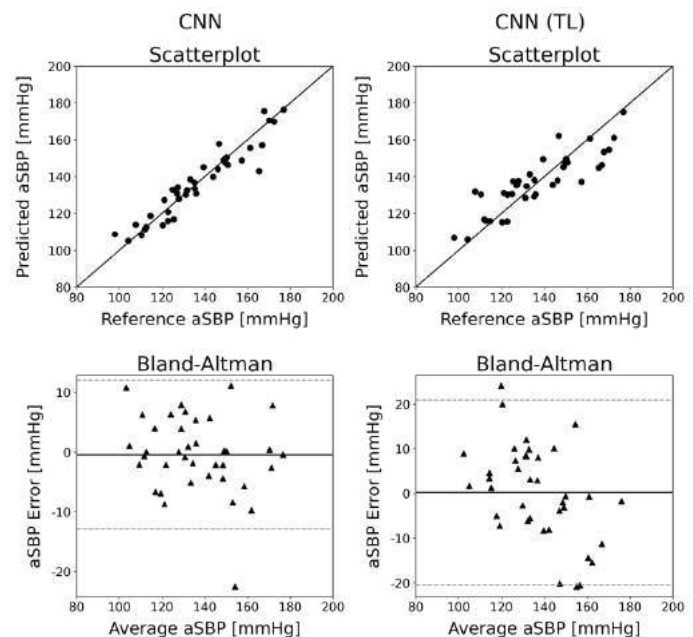

Figure 1: Scatter plots and Bland-Altman plots: Predicted versus reference data for CNN_{in vivo} (left panel) and CNN_{TL} (right panel).

DISCUSSION

The results showed that the methods used to obtain the predictions of aSBP are accurate and may facilitate the acquisition of aSPB in the clinical setting. Importantly, *in silico* data may offer a valuable alternative for training purposes when high-volume *in vivo* data are difficult to find. Future work will focus on improving the CNN architecture to correct for potential bias resulted from transfer learning. Pending validation using non-invasively measured brachial pressure waveforms, the proposed methodology provides plausible aSBP estimation from the morphology of the raw brBP_{wave}.

INTRODUCTION

Procedural planning for transcatheter aortic valve replacement (TAVR) is routinely performed using contrast computed tomography (CT) in patients with severe aortic stenosis (AS) (1). Despite its potential, little investigation has been done into the possibility of aortic valve (AV) calcification (AVC) scoring in contrast-enhanced CT (2). This is valuable because contrast-enhanced CT has better dynamic contrast and spatial resolution than non-contrast CT, allowing for better descriptors of calcific lesions in the aortic valve (3, 4). Previous calcification scoring techniques (3,4) based on luminal attenuation or fixed HU thresholds have been widely used only to predict post-TAVR complications.

We developed a new method that automatically finds a threshold to minimize the false positive rate (FPR), defined as the ratio of falsely labeled calcific pixels to the total number of calcific pixels (Fig.1A). We also introduce a scheme for describing the geometric and relative concentration of calcification via intensity as well as radial and longitudinal maps (Fig.1B). The method was evaluated on a retrospective cohort of 178 patients diagnosed with AS from a single center (Hamilton General Hospital, ON, Canada) between 2020 and 2022. Non-consecutive data collection only included patients that have undergone 2D doppler echocardiography and both gated contrast and non-contrast CT to allow for a wide variety in gender (46%/54% female/male) and AS severity (28%/72% non-severe/severe). Severity was categorized by recommended thresholds for aortic valve area, peak aortic jet velocity and mean valve pressure gradient (1, 2). The data was collected after

approval from the Hamilton integrated research ethics board (HiREB) and waiver of informed consent.

Scores produced using the proposed method were compared to the standard scores produced from non-contrast images using commercially available software (Calcium scoring application, Syngovia; Siemens Healthineers). Correlations and comparisons between continuous variables were evaluated using Spearman's rank test and Bland-Altman analysis of difference. Interobserver variability was assessed on a random sub-group of 49 patients using intraclass correlation coefficient (ICC; two-way random agreement) showing excellent reproducibility (ICC:0.95; 95%CI 0.94-0.96; raters=2).

METHODS

Calcium Detection (Global Calcium Volume Score). We developed a method that does not explicitly rely on luminal attenuation. Initial leaflet calcification regions are determined instead based on the intensity characteristics of a bounding aortic root segmentation. Using those initial conditions, an iterative region growing method adjusts the Hounsfield band for calcific detection gradually, until satisfying a minimum false positive (0.01/1%) ration between calcific and non-calcific segments in the local region of interest.

Calcium Regional Map (Local Regional Calcium Deposition). We developed an anatomical 18 region mapping scheme based on standardized measurements of height to sino-tubular-junction, annular area derived radius and angles of the inter-leaflet triangle which we used to parametrize distance thresholds (18 regions from coaptation zone to attachment) in order to quantify regional calcific volume across the cohort.

RESULTS

Calcium Detection (Global Calcium Volume Score). We compared techniques based on average luminal attenuation (LA) plus constant multiplier to standard deviation (SD) in the ascending aorta. We showed that calcification volume using the FPR method showed the best correlation against non-contrast volume and Agatston scores ($r = 0.919$; $p < .001$) ($r = 0.913$; $p < .001$) in contrast-enhanced images (Fig. 1). Visual differences between detected calcific volumes using the proposed method (FPR) and other LA methods are shown in (Fig. 1). Moreover, comparative analysis showed the FPR method had the highest correlation to ground truth non-contrast volume and Agatston scores as shown in the correlation matrix heatmap (Fig. 1).

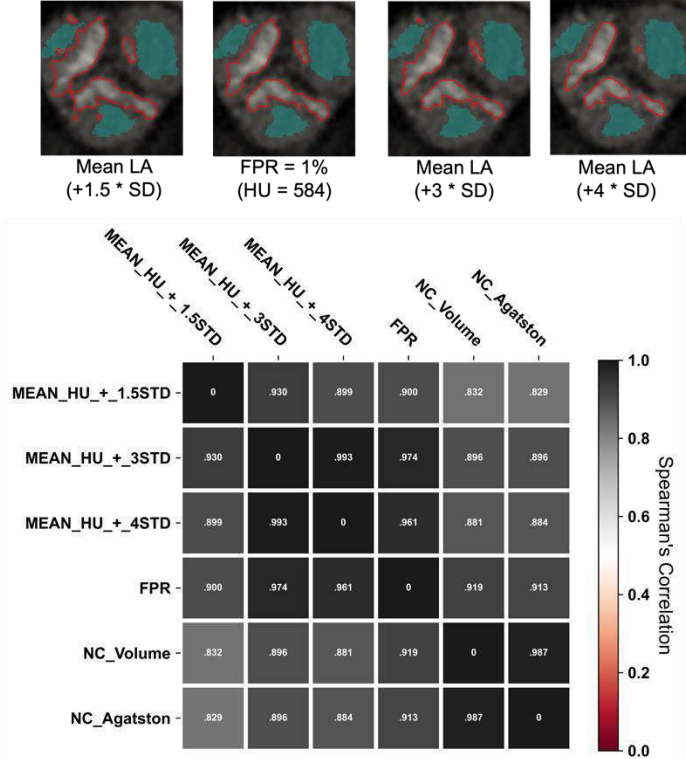

Figure 1. Top panel : The detected calcification is identified with a red outline around the region of interest in each subplot with high thresholds (+3*SD, +4*SD) missing small calcific nodules and low thresholds (+1.5*SD) merging large calcific regions between the leaflets. **Bottom panel:** Spearman’s correlation heatmap between all contrast calcific volume scores and non-contrast volume and Agatston scores.

Aortic root and coronary arteries fluid dynamics (local hemodynamics).
Calcium Regional Map (Local Regional Calcium Deposition). The high contrast and spatial resolution in contrast images combined with a precise calcific detection method provides a unique opportunity to examine the regional presentation of calcific deposition in AS. In that respect, we generated topographic distance maps for both radial and longitudinal distance relative to each patient’s aortic valve

dimensions (annular radius and STJ height) as presented in Fig. 2. These maps were then used to map calcific volume concentrations onto shape invariant 2D polar map with 18 regions organized by cusp (3 sectors), distance to center (3 levels) each radial distance level was further decomposed by angle (Distal to center – 3 angles, Mid – 2 angles and Proximal – 1 angle).

In terms of the regional presentation of calcification for each cusp, we observed four primary patterns of calcific distribution as follows:

1. Severe: Maximal calcific deposition in near the belly region of all leaflets followed by root attachment edges with significantly lower calcification near the coaptation zones. In males the amount of calcification is significantly higher across most regions. While in females a lower calcific progression rate, presents calcific arcs primarily near free edges of the leaflets, that have not yet developed in rings at the fixed edge (Fig. 2).
2. Non-severe: Maximal calcific deposition near sites of root attachment and belly, prominent near the non and left coronary cusps. At this stage calcification primarily presents as disconnected deposits. With males presenting with significantly higher calcific deposition near leaflet attachment edges between the non and right coronary leaflets than females (Fig. 2).

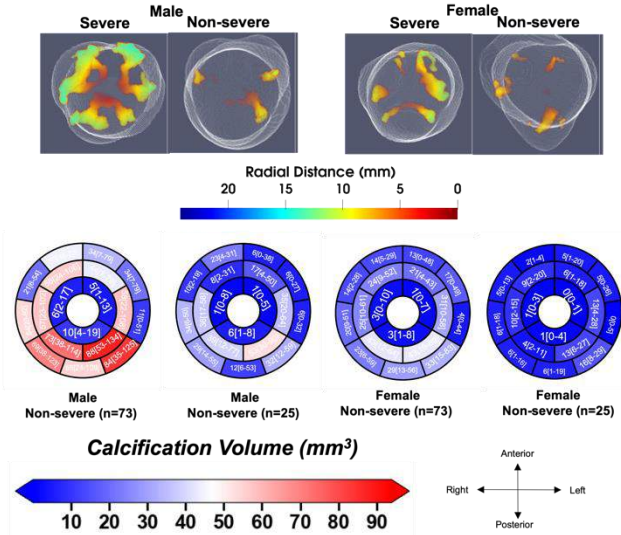

Figure 2. Top panel: Distance map of detected calcification, color mapped by a normalized radial distance range of [0-25.4 mm]. **Bottom panel:** Bullseye aortic valve plot with 18 region map localizing the radial and angular location for each cusp. Median volume values for each categorical group (sex and severity) were used to color the volume with median [IQR] values were annotated inside the borders of each region.

DISCUSSION

Calcific AS is the most common valvular disease, with high mortality rate once symptoms are presented. AVR intervention is currently the only treatment option in which aortic valve calcification in and around the valve is an important factor for procedural risk assessment and predicting complications in TAVR. The presented computational assessment tool can be

used to characterize the complex patterns of calcification at different stages of the disease. We found that calcific progression appears to follow distinctive patterns for each leaflet (5–8), with differences emerging in the stage of calcific progression between the leaflets. This difference in rate of progression is also significantly affected by sex which cannot be explained by the difference in valve sizes (3, 9, 10). In addition, we provide a new method for calcific detection that could potentially overcome the inherent variability of contrast material effect on HU attenuation (1–4), which could enable additional quantitative criteria for calcific assessment in routinely used contrast CT for TAVR planning(1). All in all, detailed quantitative description of the complex patterns of leaflet calcification, combined with accurate anatomical assessment of aortic valve morphology, could be critical for simultaneously monitoring the progression of AS, and determining the best treatment options, especially for asymptomatic patients who might eventually need an aortic valve replacement.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is becoming popular for patients who are of a high, intermediate, or low risk, indicating that it may become the superior treatment modality for aortic stenosis (AS) for the whole risk spectrum and younger populations (1,2). While coronary artery disease (CAD) is present in up to two third of the TAVR population (3), CAD severity assessment is challenging and the decision for coronary lesion revascularization is currently mainly based on invasive procedures (4). However, invasive coronary access is limited in significant proportion of patients who undergo TAVR, due to anatomical restrictions such as overlap between transcatheter heart valve and the coronary ostia (5). Consequently, this presents a dilemma among patients with post-TAVR complications, regarding the relative contribution of CAD versus the valve insufficiencies on long term symptoms and prognosis, and more studies are needed to understand how TAVR affect coronary hemodynamics (3).

Computational simulations are a powerful tool for accurate and early diagnosis of long-term hemodynamic complications that are difficult or impossible to infer in clinical practice. Some technical challenges and concerns of the effect of TAVR on both short term and long-term coronary hemodynamics can be predicted through numerical simulation (3). However, such simulations should be personalized for each patient and be able to capture the effect of global and local hemodynamics on a case-by-case basis to provide a clinically meaningful tool based on patient anatomy and valve implantation parameters (6,7).

In this study, we propose a novel strategy to quantitatively investigate the impact of TAVR on coronary artery hemodynamics. We developed a personalized lumped parameter model and computational fluid dynamics framework based on patient-specific hemodynamic and anatomical parameters to examine the effect of factors such as valve to coronary distance, aortic root diameter, coronary ostium height and commissural misalignment on coronary artery hemodynamics. We showed that coronary flow improvement depends on post-TAVR aortic root remodeling and ventricular-vascular coupling hemodynamics. We quantified the effect of TAVR on coronary flow and cardiac function and investigated the correlation of hemodynamic parameters with the metrics currently used in clinical practice.

METHODS

Global hemodynamics. We have previously developed a non-invasive diagnostic computational-mechanics framework for complex valvular, vascular, and ventricular disease (C3V-LPM), described in detail elsewhere (6). In this study, the C3V-LPM was developed to a greater extent to compute global hemodynamics in patients with mixed valvular, vascular, mini-vascular and ventricle diseases. The model uses a limited number of input parameters all of which can be reliably obtained using Doppler echocardiography and a sphygmomanometer.

Local hemodynamics. A computational fluid dynamics and lumped parameter modeling framework was developed to compute 3D blood flow dynamics in all main coronary artery branches, aortic root, ascending aorta, sinus, and neo-sinus

regions for both pre- and post-TAVR (Figure 2). This framework is based on lumped parameter modelling and 3D FSI modelling as implemented in open-source foam-extend library and validated against in-vivo DE data (7).

RESULTS

LV workload and coronary artery flow (global hemodynamics). The LV workload is an effective metric of the LV load and clinical state and represents the energy that the ventricle delivers to the blood during ejection plus the energy necessary to overcome the viscoelastic properties of the myocardium itself. Pre-TAVR, untreated AS increased the load on the LV due to the augmented flow resistance which caused a LV pressure overload. Although the flow resistance and consequently the LV pressure decreased greatly post TAVR, the LV workload did not improve (Figure 1a). Interestingly we observed a reduction in coronary flow after TAVR (figure 1b), while improvement of coronary flow is expected after AS removal. This could probably explain why TAVR might not be associated with reduced workload if the coronary flow is not improved.

Figure 1. Global hemodynamics in a sample patient between baseline and 90 days post-TAVR: (a) Left ventricular workload: LV workload did not improve after TAVR. (b) Coronary artery flow: TAVR was associated with a reduced coronary flow during both systole and diastole phases

Aortic root and coronary arteries fluid dynamics (local hemodynamics). It has been shown that after TAVR the coronary flow influences the flow patterns of aortic root and neo-sinus and favors the transfer of blood flow towards ostium during diastole (8). However, our results showed that due to the extra anatomical nature of transcatheter valve stent, the aortic root vortices might not favor the transfer of blood flow towards ostium in the aortic root and neo-sinus region (figure 2a). TAVR can also lead to a pro-inflammatory state of endothelial cells due to the reduced wall shear stress microenvironment after intervention which is linked to plaque progression. Our findings demonstrate that TAVR might exacerbate the washout mechanism for the sinus and neo-sinus regions and lead to a significantly lower shear stress at the coronary walls due to the decreased blood supply during diastole after TAVR. This makes the coronary arteries susceptible to atherosclerosis, due to the low wall shear stress-induced inflammatory activation of

endothelium mainly at the inner bend of curved arteries, ostia of branches and lateral walls of bifurcations.

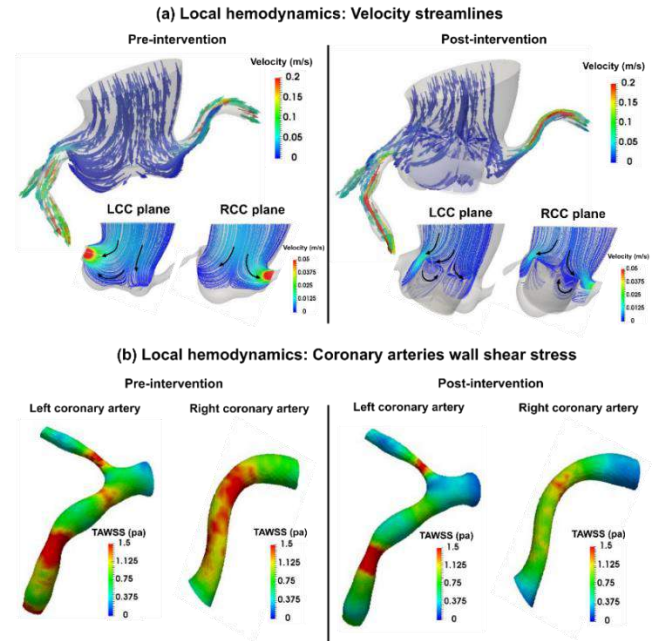

Figure 2. Flow modeling in an aortic root and coronary arteries in a sample patient. (a) Velocity vector at peak diastole. (b) Left and right coronary time averaged wall shear stress during diastole.

DISCUSSION

TAVR prosthetic and its influence on natural flow pathways in the sinus of Valsalva attributes to disturbance of the blood entering the coronary circulation which might limit the benefit of TAVR: may increase the LV load, may potentially worsen coronary perfusion, and worsens heart failure. Atherosclerosis promotion through loss of physiological flow-oriented alignment of endothelial cells and its exacerbation will likely play an important hindering role in success of TAVR. The findings of this study suggest that beyond routine clinical indices for hemodynamic evaluation of the valvular disease (e.g, Doppler pressure gradients), valvular, vascular, and ventricular hemodynamics and their interactions should be clinically quantified and considered to better conduct the aortic valve management and treatment planning.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is an emerging treatment alternative to surgical aortic valve replacement that covers a range of patients suffering from moderate to severe aortic stenosis (AS). AS is one of the most common and serious cardiovascular problems and if left untreated, often leads to death. Surgical valve replacement remains the standard treatment method for AS, however, many patients suffering from this pathology are at a high risk for surgery and may suffer death or other complications [1].

TAVR is a growing alternative for intervention of AS patients across a broad risk spectrum and has lower death rates in severe cases compared to a surgical approach. Although TAVR has critical benefits for surgical high-risk patients, there are several drawbacks that patients may experience [2]. *Given the associated risks with TAVR, it is crucial to determine: how the implant will affect the cardiac function? when is the proper timing for intervention? Will TAVR improve or worsen the outcome of the patient [3].*

The condition of the heart valves heavily relies on the geometry and material properties of the leaflets as well as the interaction between the flow and the valve [3,4,5,6]. Valvular disease, including AS, often results in, or is a result of abnormal stress and strain distributions on aortic valve leaflets for both pre- and post-interventional cases.

In this study, we developed a highly innovative non-invasive Doppler-exclusive computational-mechanics framework that can function as a diagnostic tool to assess aortic

valve dynamics in pre and post-TAVR states at no risk to the patients. The developed diagnostic tool is able to dynamically couple the local valve dynamics with the global circulatory system [4] which provides a platform for testing intervention scenarios (e.g. TAVR) and evaluating their effects.

METHODS

We developed a Doppler-based computational mechanics diagnostic framework to non-invasively investigate the dynamic behavior of the aortic valve (e.g., transient 3-D distribution of stress and displacement field, 3-D deformed shape of leaflets, geometric orifice area, angular positions of leaflets, stiffness, etc.). This framework is based on a Doppler-based patient-specific lumped parameter algorithm (LPM) [4] along with a 3-D Doppler-based nonlinear (using anisotropic hyper elastic) finite element solver CalculiX with some supplements. The developed LPM algorithm [4] consists of a parameter estimation algorithm and a lumped-parameter model that includes several sub-models allowing analysis of any combination of complex valvular, vascular and ventricular diseases. A Doppler-based parametric method was developed to construct the 3-D geometry of the asymmetric aortic valve leaflets. Calculations of this Doppler-based computational mechanics diagnostic framework were validated against clinical Doppler echocardiography data in patients with AS.

RESULTS

In patients with aortic stenosis, the healthy instantaneous LV pressure and/or volume are altered which ultimately overloads the heart. We investigated metrics of cardiac function (global hemodynamics) computed by our Doppler-based lumped parameter algorithm to determine the effects of TAVR on patient condition. The impacts of the TAVR on the aortic valve pressure gradient were not always be associated with reduction in LV function parameters, e.g., LV workload, normalized LV workload to stroke volume and maximum LV pressure. LV hemodynamics metrics worsened in some patients, and they were not significantly improved in the others (Figure 1, panel c)

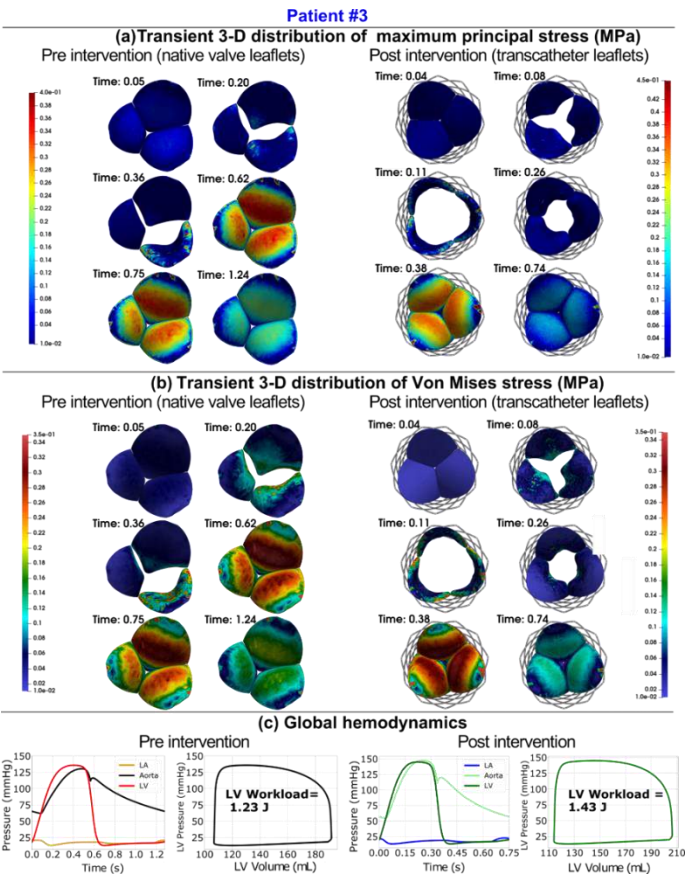

Figure 1. Changes in valve dynamics and global hemodynamics in patient #3 between baseline and 90-day post-TAVR.

Biomechanical factors resulting from hemodynamic loads are a common dominator of a variety of vascular diseases. Various mechanical metrics including 3-D Mises stress (the derivative format of principle stress), 3-D major principal stress (the maximum value of the three principal stresses), as well as displacement magnitude resulted from our Doppler-based computational framework reveled that TAVR worsened valve dynamics in some patients. Indeed, mechanical forces are the driving force behind the degeneration and failure of prosthetic heart valves and must be measured regularly to prevent the deterioration of the replacement valve.

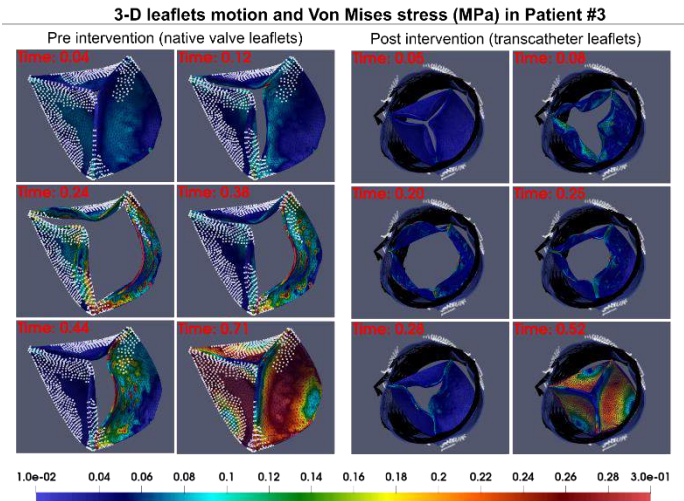

Figure 2. 3D motion and 3D distribution contours of Mises stress in patient #3 at six time points throughout the cardiac cycle in both pre- and post-intervention states

DISCUSSION

TAVR does not always improve cardiac function metrics. LV hemodynamics metrics worsened in some patients, and they were not significantly improved in the others. TAVR does not always improve valve dynamics metrics. Valve dynamics post-intervention should be quantified and monitored to ensure the improvement of patient conditions and prevent any further complications. Improper evaluation of biomechanical valve features pre-intervention as well as post-intervention may result in harmful effects post-TAVR in patients including paravalvular leaks, valve degeneration, failure of TAVR and heart failure.

INTRODUCTION

Functional Anterior Cruciate Ligament (ACL) orthoses are prescribed to patients with the goal of preventing anterior tibial translation and valgus moments at the joint [1]. However, despite the prevalence of ACL tears, there has been much debate within the medical community on the effectiveness of functional bracing after reconstructive surgery [2-4]. Part of the controversy surrounding this discussion is due to the insufficient amount of data supporting the theory that ACL functional orthoses “control joint translation and prevent re-injury” [2].

The limited and inconsistent data available on knee orthosis (KO) biomechanics make it difficult to assess the effectiveness of functional ACL bracing. Fortunately, advancements in finite element technology have opened the possibility for accurate and quantitative assessments of subject-specific knee orthoses.

The purpose of this study was to determine how effective custom functional ACL bracing is in preventing anterior tibial translation. The contact pressures of custom ACL orthoses exerted along the tibia obtained by Ghadikolaei et al. [5] were replicated in the patient-specific finite element models. Our previously developed baseline knee models that have been validated in accurately predicting anterior tibial displacement [6] were utilized to determine how effective this orthosis design is in preventing joint translation when subject to Lachman and pivot shift tests.

METHODS

A total of 22 CT images of juvenile knees were utilized (ages: 9-18, m: n=16, f: n=6). 3D Slicer was used to convert the CT images into a three-dimensional representation of the bony

anatomy. FEBio was used to construct each tibiofemoral joint and perform the finite element analyses.

Two sensor pads (C1 = 5.08 kPa; C2 = 6.75 kPa) of 400mm² area were placed along the tibial crest following the sensor placement established by Ghadikolaei et al. [5] (Figure 1).

Figure 1: Finite element model of adolescent knee. C1 and C2 depict pressure sensor placement.

To replicate the Lachman test, anteriorly directed forces of 67 N, 89 N, and 133 N were applied to the tibia [7]. To simulate the pivot shift test, an anteriorly directed force of 133 N was applied to the tibia in addition to a combined rotatory load of 4 Nm internal tibial torque and 10 Nm valgus [8].

A 95% confidence interval was used to determine statistical significance between the bracing and non-bracing groups for each loading condition.

RESULTS

As expected, the custom ACL orthosis simulation resulted in less anterior tibial translation than the non-bracing models for both loading conditions (Table 1).

Table 1: Descriptive statistics of FEBio anterior tibial translation of Lachman and pivot shift test simulations with and without bracing.

FEBio - Lachman Test (mm)				
<i>Mallinos et al. - Without Bracing</i>		<i>Ghadikolaee et al. - Custom KO</i>		
	Mean	SD	Mean	SD
67 N	5.53	0.33	4.82	0.39
89 N	6.53	0.28	5.60	0.30
133 N	7.54	0.34	6.58	0.42
FEBio - Pivot Shift Test (mm)				
<i>Mallinos et al. - Without Bracing</i>		<i>Ghadikolaee et al. - Custom KO</i>		
	Mean	SD	Mean	SD
	4.38	0.78	3.64	0.18

The 95% confidence intervals demonstrate that the custom ACL knee orthosis provides a significant ($p<0.05$) resistance to anterior tibial translation compared to the non-bracing models (Figures 2 and 3).

Figure 2: 95% confidence interval for the Lachman test anterior tibial translation between bracing and non-bracing simulations.

Figure 3: 95% confidence interval for the pivot shift test anterior tibial translation between bracing and non-bracing simulations.

DISCUSSION

The finite element simulations showed that custom knee orthosis designs statistically minimize anterior tibial translation when subject to loading conditions that can harm the healing graft. The custom knee orthosis design resulted in approximately 1 mm less anterior tibial translation than the non-bracing options.

This highlights the importance of accurately fitting a knee orthosis to a patient. If the fit of the orthosis is not sufficient, it is likely that the device will not be effective in preventing anterior tibial translation. This is especially significant if there is a gap of 1 mm between the orthosis and the tibia as this might result in minimal resistance to anterior tibial movement.

As demonstrated in the simulations, gapping between the orthosis and the patient can place the healing ACL graft at risk for reinjury by allowing less resistance to ligament translation. Incorrect orthosis fitting that allows gapping between the device and the tibia is ultimately ineffective in preventing excess stress and strain to the healing graft. This highlights the significance of having orthotic designs that are contoured to fit the patient's unique anatomy and size because the posterior directed forces along the tibial pad provide significant resistance to unwanted anterior tibial translation.

Understanding the biomechanical impact ACL knee orthoses have in protecting the healing ACL can provide clinicians with the opportunity to prescribe the best orthosis that will significantly minimize the risk of reinjury and provided further justification for insurance purposes.

Future studies will utilize this methodology to assess the biomechanical effectiveness of the different knee orthosis designs (four-point force system vs total contact; custom vs custom-fit/off-the-shelf) to determine which offers the greatest protection to an ACL-deficient knee.

In conclusion, utilizing finite element technology makes it possible to assess knee orthosis biomechanics in manner that cannot be assessed in a clinical setting. Custom functional ACL knee orthosis provide a significant resistance to anterior tibial displacement – ultimately protecting the healing graft from significant stress and strain.

INTRODUCTION

Blood clot is a natural bio-adhesive that prevents bleeding after vascular injury. It comprises three constituents: fibrin, platelets, and red blood cells. In its role as a wound sealant, blood clot is critical to our health. On the other hand, if pathologically formed within the intact vessels (i.e., giving rise to a thrombus), it can also be deadly. That is, when blood clots break (or fracture), they may shed small emboli that can travel downstream and occlude vital arteries or veins, leading to deadly sequelae such as ischemic strokes, heart attacks, and pulmonary emboli. Together, thromboembolic diseases cause one in four deaths worldwide [1].

Given this high mortality, it is imperative to understand when, why, and in whom blood clot breaks off, i.e., embolizes. This breaking-off may be interpreted as a fracture process. It is, therefore, vital to learning to describe and predict blood clot fracture. We are not the first to identify the importance of studying blood clot fracture. In fact, several experimental and numerical studies have reported on the fracture toughness of blood clot, which is a critical measure of its resistance (or lack thereof) to fracture, see for example [2-6]. Among other questions, previous studies investigated how blood clot's aforementioned constituents contribute to its fracture toughness [4,5]. Despite this important prior work, the in vivo mechanisms of blood clot fracture remain incompletely understood. In other words, we still do not know when, why, or in whom blood clot breaks off.

Among the many questions that remain unanswered about in vivo blood clot embolization is that of the driving force. That is, blood clot is exposed to wall shear stress due to blood flow in cases where clot is non-occlusive, as well as tensile and shear from wall-stretch and blood pressure. To date, it is not clear which of those mechanical loading conditions are most critical in causing blood clot fracture. Please note, this question is difficult to answer experimentally. For example, in experiments it is difficult to deconvolute different loading scenarios and identify their relative contributions to blood clot fracture. In contrast,

computational tools allow us to investigate the driving factors behind thrombus embolization by applying shear stress, wall stretch, and blood pressure in isolation and in combination. Therefore, the goal of this study is to use a computational model of an idealized blood clot geometry to investigate the driving forces behind clot embolization. To this end, we will first inform a phase-field finite element model of an idealized occlusive clot embedded within a vessel wall and then investigate its response to different loading scenarios. Specifically, we chose a deep vein thrombus as a model problem.

METHODS

This section is devoted to the phase-field modeling of blood clot fracture. To this end, let \mathcal{B} and \mathcal{S} denote the reference and deformed configurations for the body of interest. The coupled problem of fracture is described by the deformation map $\boldsymbol{\varphi}_t$ and the assisting field variable, which we call the crack phase-field d . While the deformation map transforms a point $\mathbf{X} \in \mathcal{B}$ onto its spatial counterpart $\mathbf{x} \in \mathcal{S}$, the phase-field continuously interpolates between the intact, i.e., $d = 0$, and the ruptured state of the solid, i.e., $d = 1$. Upon establishing the standard kinematical descriptions for hyperelasticity and the crack phase-field approach, see [7-8], we choose the one-term Ogden model to describe the isotropic mechanical response of the clot. Having only two parameters – one accounting for the shear modulus and the other one giving the degree of nonlinearity – the one-term Ogden model is well-suited for the numerical representation of blood clot [9].

The present study features a variational principle based on the power balance of the rate of the internal and external energy functionals and the dissipation functional. The corresponding minimization of the field variables yield the governing equations, i.e., strong forms, of the mechanical problem, namely the balance of the linear momentum,

$$\text{div}(\boldsymbol{\sigma}) + \boldsymbol{\gamma} = \mathbf{0} \quad (1)$$

and the evolution equation of the crack phase-field

$$\eta l \dot{d} = l(1 - d)\mathcal{H} - (d - l^2 \Delta d) \quad (2)$$

In Equation (1), σ and γ represent the Cauchy stress tensor and the body force vector per unit volume. In Equation (2) we introduce the artificial viscosity η stabilizing the algorithm, the length-scale l , and the crack driving source term

$$\mathcal{H} = \max_{s \in [0,1]} \left(\frac{\Psi_0}{G_c} - 1 \right), \quad (3)$$

which is irreversible and filters out positive values. Therein Ψ_0 denotes the effective free energy function of the Ogden model, whereas G_c represents the fracture toughness. \mathcal{H} can be interpreted as an isotropic failure criterion as cracking does not initiate until $\Psi_0 \rightarrow G_c$. Finally, Equations (1) and (2) are discretized in time and space via Galerkin-type weak formulations and solved for the respective primary field variables, i.e., displacement and phase-field. We implemented this framework in the nonlinear finite element solver FEAP.

RESULTS

We first used our phase-field modeling approach to inversely identify the fracture toughness G_c from Mode-I fracture experiments on in vitro blood clot, see Figure 1. Please note, details on the coagulation conditions and experimental aspects of the Mode-I fracture experiments can be found in [10]. Also, note that the hyperelastic Ogden material parameters for this numerical experiment were informed from pure shear experiments on blood clot that was coagulated from the same blood as those samples used for the Mode-I experiments ($\mu = 10.4 \times 10^{-4}$ [MPa] and $\alpha = 7.2$). After inversely identifying an optimal G_c (9.6×10^{-4} [N/mm]) the numerical, predicted Mode-I experiment and the experimental data show great agreement, see Figure 1A. Additionally, snapshots throughout simulation time show the fracture process which agrees qualitatively with our experimental observations, see Figure 1B.

Figure 1: A phase-field model of Mode-I fracture agrees well with experimental data. A) Mode-I fracture test with force-displacement results obtained from phase-field simulations (black solid line) and experiment (green circles). B) Snapshots i-iv) show the predicted evolution of the crack phase-field in the solid, which agree well with our experimental observations. Elements are blanked if $d \geq 0.95$.

Next, we used our calibrated phase-field approach to investigate likely drivers for venous blood clot embolization. As a first example, we modeled an occlusive blood clot. To this end, we modeled an octant of the entire solid domain with the fully occlusive clot sitting on the inner surface of the venous wall. We tested two different scenarios: Scenario I) wall-stretch as a driver of clot fracture (wall stretch of $\lambda = 2$) and Scenario II) blood pressure as a driver of clot fracture (10 mmHg). For both scenarios the hyperelastic material parameters of the blood clot were the same as above, similarly the fracture toughness was based on the identification in Figure 1. The venous wall was modeled as a neo-Hookean material [11]. In Scenario I, we subjected the venous wall to cyclic extension in the longitudinal z -direction. Figure 2 depicts the results of this first simulation. Snapshots A (inner surface view) and B (outer surface view) at the end of the simulation show the severely

damaged zones (iso-surfaces) where $d \geq 0.8$. From the complete evolution of the fracture field along the venous wall, it is clear that the clot separated from the venous wall at their interface. Clinically, this would lead to embolization and traveling of the embolus downstream. Additionally, the crack also branched into the center of the clot, likely leading to multiple emboli.

Figure 2: Blood clot delaminates from the venous wall due to wall stretch. Snapshots A and B illustrate the inner and outer surface view of the crack growth within the thrombus. Areas (iso-surfaces) subjected to severe damage, i.e., $d \geq 0.8$ are shown.

On the other hand, Scenario II, where we applied only blood pressure without wall stretch, did not lead to any fracture development and thus embolization (results not shown). Interestingly, even when applying super-physiological pressures of 50 and 100 mmHg no significant crack propagation was observed.

DISCUSSION

In our current work, we accomplished two goals. First, we used an inverse finite element approach to inform a phase-field model of blood clot fracture. Second, we used our calibrated phase-field model to investigate the likely driving force of blood clot embolization. To this end, we studied venous blood clot as a model problem. Interestingly, we found that blood pressure alone, even when as high as 100 mmHg, does not lead to clot fracture and embolization. On the other hand, we found that wall stretch can lead to mismatched stress between the venous wall and the clot and the subsequent development of a delamination-type fracture process. Our goal is to extend our model through sensitivity analyses and by also including non-occlusive clots. Overall, we expect that our work will shed light on venous thromboembolism in particular and other thromboembolic diseases in general.

INTRODUCTION

Stroke is commonly initiated by rupture of the atherosclerotic plaque fibrous cap in a carotid artery. However, cap rupture mechanisms are not well understood yet. Understanding the impact of the structural components of the cap on its local mechanics may provide critical insights into plaque rupture. Various limitations within studying plaques *in vivo* and *ex vivo* highlight the need for additional methods to investigate rupture mechanics. Therefore, we created collagenous tissue-engineered plaque cap analogs [1]. In the current study, we obtain local collagen structural parameters, local mechanical properties, and rupture characteristics of these analogs to analyze the relationship between the local collagen architecture and local rupture mechanics of cap analogs.

METHODS

Development of fibrous cap analogs

Nine cap analogs were created by seeding human vena saphena cells (HVSCs) in 1 x 1.5 cm-sized fibrin gels (Fig 1A). After seeding, the samples were cultured statically (no loading) for 7 days, whereafter a 2 mm \varnothing soft inclusion (SI) was created by punching a hole in the center of each analog and filling this hole with fibrin (Fig 1B). This fibrin inclusion mimics the soft lipid core of atherosclerotic plaques. The analogs were statically cultured for 7 more days, after which they were

exposed to 7 days of dynamic loading (Fig 1C) using the Flexcell FX-4000T (Flexcell Int, 196 McKeesport, PA).

Collagen imaging

On day 21, samples were imaged with multiphoton microscopy (MPM) with second harmonic generation (SHG) to visualize the collagen architecture. First, an overview scan splitting the sample into tiles (728x728 μm) was made (Fig 2A). From the tile scan, two horizontal lines of adjacent tiles were selected for further analysis. One line of the selected tiles overlaid the shoulder region of the sample while the other overlaid the mid-cap, including the soft inclusion (Fig 2B). For each selected tile, z-stack imaging in the depth direction was performed (pixel size of $\sim 1.4 \mu\text{m} \times 1.4 \mu\text{m}$, 3- μm steps).

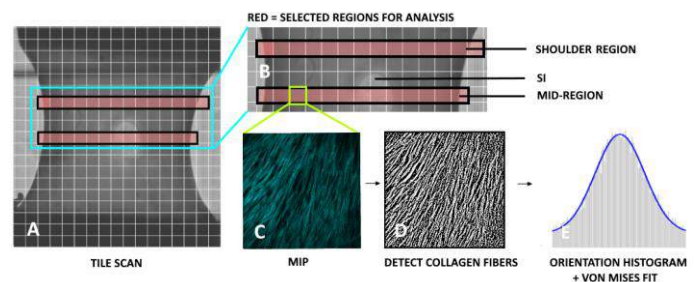

Figure 2: Collagen imaging and fiber orientation analysis pipeline.

Maximum intensity projection (MIP) image of each tile (Fig 2C) was analyzed with a MATLAB-based fiber orientation analysis tool (FOAtool [2]) to calculate the orientation of individual collagen fibers (Fig 2D). A von Mises distribution was fit to the histogram of all detected collagen fiber orientations (Fig 2E). From this distribution, the predominant fiber orientation (θ in degrees) and kappa value (κ), an

Figure 1: Protocol for developing fibrous cap analogs.

indicator of the degree of fiber anisotropy, were determined for each tile.

Uniaxial tensile tests and DIC

After imaging, the samples were mechanically tested. A speckle pattern for digital image correlation (DIC) was applied to the top surface of each sample using an airbrush and a tissue dye. After pre-stretch (15 mN) and preconditioning (10 cycles of 10% strain), the samples were uniaxially strained until complete failure at a speed of 100%/min in the y-direction, which biologically corresponds to circumferential strain (Fig 1D). Tissue deformation, rupture initiation location, and rupture propagation path were recorded with a high-speed camera (PL-D725, Pixelink). To obtain local strains (Green-Lagrange), DIC analysis was performed in MATLAB using the open-source software Ncorr [3].

RESULTS

Local collagen architecture

The predominant direction, θ (90° if y-direction), and the dispersion, κ (range=0-0.33), of the fibers for the tiles scanned are shown in Fig 3 for a representative sample. For all 9 cap analogs, the fibers were mainly oriented in the y-direction, and more so if they are located close to the sample's edges (16° vs central region: 37°). Moreover, the fibers at the sample edges showed slightly less dispersion than the ones in the central region (κ , 0.27 vs. 0.24).

Figure 3: Predominant fiber orientation (black line) and dispersion, κ , (background color) in mid-cap and shoulder regions of a plaque cap analog. A larger κ indicates greater fiber dispersion.

Rupture initiation

In three samples, the rupture initiated at a clamping site whereas in the other six samples, rupture initiated in the SI or at the SI-fibrous tissue interface. The DIC-derived local tensile strain (E_{yy}) analysis at the timepoint of rupture initiation (Fig 4A) showed statistically significantly higher strain levels at the rupture initiation locations (Fig 4B). This finding also indicates that the average tissue strain commonly used for plaque tissue rupture characterization underestimates the real, local rupture strain.

Figure 4: A) DIC-derived local tensile strains (E_{yy}). The blue oval shape indicates the soft inclusion and the green rectangle marks the location of rupture initiation. B) DIC-derived average tensile strains in the ROI are significantly lower than those in the rupture initiation region.

Rupture propagation

Qualitative analysis of rupture propagation paths showed inter-sample variation. In some samples, multiple ruptures were found, which were connected by the rupture propagation (Fig. 5A). Moreover, the shape of the rupture propagation path differed between samples. The local predominant fiber angles and the rupture propagation path in a cap

analog are shown in Fig 5A. The figure demonstrates that at most locations within the analog, the rupture propagated parallel to the local

Figure 5: A) Rupture path (red line) in a representative cap analog. B) Fiber orientation vs rupture path direction, linear regression curve in red

predominant fiber angle. Similar results were found in the other samples. Fig. 5B shows the rupture path versus the local predominant fiber orientation. The linear regression curve in figure 5B ($R=0.60$, $\beta_1=1.04$, $p < 0.001$) shows that the rupture path angle approximates the fiber angle, again supporting the hypothesis that rupture in the analogs propagated parallel to the local fiber angle.

DISCUSSION

We successfully visualized the collagen orientation and obtained local mechanical (strain) fingerprints in tissue-engineered cap analogs to study atherosclerotic plaque rupture. The results demonstrated that the created cap analogs correctly replicate the predominant circumferential collagen orientation in real plaque caps [4]. Yet, there is local variation in the fiber architecture in the analogs. In the central region, larger deviations of the predominant fiber orientation from the circumferential direction and a more dispersed fiber architecture were observed compared to the edges. Local strain measurements showed that rupture in the analogs initiated at the elevated tensile strain regions. The strains found in the analog are similar to the local rupture strain found in a previous DIC-analysis of ex vivo human plaque tissue [5]. Despite the inter-sample variation in the rupture propagation path, it was found that the ruptures usually propagated parallel to the local predominant fiber angle.

As a next step, we will investigate the rupture surfaces with scanning electron microscopy (SEM) to test our new hypothesis proposing that rupture propagation in the cap analogs is mostly parallel to the local predominant fiber direction. We will also use these SEM images to determine if fibers at the rupture location are still intact. This information will help us to gain better understanding of the underlying failure mechanisms of plaque tissue.

A COST FUNCTION APPROACH APPLIED TO MUSCLE CRYOPRESERVATION

INTRODUCTION

Tissue samples are valuable *in vitro* models for basic and preclinical research. A key research objective is to develop a cryopreservation protocol that preserves tissue viability for extended periods of time. Such a protocol may be especially beneficial in cases where the experiment or the sample is extremely valuable, such as muscle biopsies from a patient with muscular dystrophy.

To cryopreserve tissue without ice formation, a technique known as vitrification, high concentrations of cryoprotective agents (CPAs) must be used. These high concentrations of CPAs may reach a toxicity threshold, depending on factors such as tissue type and the protocol by which the CPAs are delivered.

The focus of this work is on the protocol of CPA delivery. The CPA toxicity for a given CPA cocktail and sample type is generally considered to be a function of concentration, exposure time, and temperature. The research objective, therefore, is determining the optimal “CPA exposure profile”—CPA concentration as a function of time and temperature. This profile needs to achieve the goal of sufficient CPA transport while at the same time minimizing toxicity: an optimization problem. Here, we present our solution to this optimization problem for muscle tissue, which has not been successfully cryopreserved.

METHODS

Computational

Toxicity cost function

As formulated by Davidson et al., the CPA toxicity cost function is as follows:

$$J = \int_0^{t_f} k_{\infty} \exp(-E_a/RT) C^{\alpha} dt \quad (1)$$

Where toxicity J is exponentially related to temperature T (K) and intracellular CPA concentration $C(t)$ for a given exposure time t_f . The temperature relation follows an Arrhenius-type model, with gas constant R (kJ/mol/K) and parameters k_{∞} (1/min) and E_a (kJ/mol),

which give the toxicity rate at infinite temperature and the activation energy, respectively.¹ The concentration relation is determined by the parameter α (typically $\alpha > 1$).

The goal is to minimize J while satisfying constraints of sufficient CPA loading (Eq. 2) and minimal osmotic damage (Eq. 3).

$$C \geq C_{desired} \quad (2)$$

$$V \geq V_{low} \quad (3)$$

Here, $C_{desired}$ gives the desired intracellular [CPA] at the center of the tissue and V_{low} gives the minimal fraction of initial cell volume.²

To achieve this optimization, various CPA exposure profiles— $c=f(t,T)$ —were generated in Mathematica. The profiles which failed either constraint (Eqs2-3) were removed from consideration. For each remaining profile, the CPA toxicity (Eq1) was calculated at various penetration depths within the 1.4 mm-thick tissue. The code then outputs the profile with the lowest total toxicity along the thickness of the tissue as the optimum.

Diffusion simulation

The system was modeled as two-sided one-dimensional diffusion through a rectangular slab of 1.4 mm in thickness. To calculate extracellular CPA concentration as a function of penetration depth, the finite medium solution (Eq4) was used:

$$\theta = \int_0^1 1 - 2 \sum_{i=1}^{\infty} \frac{(-1)^{i-1}}{(i+.5)\pi} \cos((i+.5)\pi\eta) \exp(-(i+.5)^2\pi^2 \frac{tD}{L^2}) d\eta \quad (4)$$

Here, the key parameter is effective diffusivity, D , which was modeled as a function of temperature via parameters given by Jomha et al.³

Shrink-swell simulation

To calculate the intracellular CPA concentration, C (Eqs1-2), and the cell volume, V (Eq3), the 2 parameter formalism for water and CPA transport was used:

$$\frac{dV_w}{dt} = -L_p A R T (c + c_n - C - C_n) \quad (5)$$

$$\frac{dN}{dt} = P_s A (c - C) \quad (6)$$

In which the two parameters are L_p , which gives the hydraulic conductivity, and P_s , which gives the CPA permeability. These two parameters were modeled as a function of temperature in accordance with parameters given by Fry et al.⁴

Experimental

To date, values for the above toxicity parameters (k_{ω} , E_a , and α in Eq1) have only been determined for glycerol exposure in endothelial cells¹. Here, we determine these parameter values for a vitrification-relevant CPA cocktail (VS55 in Celsior) in muscle tissue.

Tissue preparation and muscle bath protocol

Porcine diaphragm muscle was cut into strips of approximately 40 mm in length and 2.5 mm in diameter.

To assess CPA toxicity, the twitch force before and after CPA treatment was recorded. The muscle bath apparatus functions to electrically stimulate the muscle every 10 s, while also providing oxygenation and temperature control. In the initial stage, the temperature was 37°C and the solution was Krebs-Henseleit Buffer. In the treatment stages, the temperature was adjusted (if necessary) and a step-loading procedure (20 min, 2 M CPA steps) was used to reach the treatment CPA concentration whilst avoiding osmotic damage. In the 150 min assessment stage, the temperature was set back to 37°C and the solution was changed back to Krebs. The median initial force divided by the median assessment force was defined as the force recovery.

Extracting toxicity parameters from experimental data

This force recovery (% of initial) was used to calculate the toxicity parameters (k_{ω} , E_a , and α in Eq1). Multiple CPA concentrations and temperatures were tested (Fig. 1). For each concentration and temperature, multiple exposure times were tested (data not shown). The decline in force recovery as a function of exposure time, t , was fit to the equation $100e^{-kt}$, and the value of k was calculated and plotted in Figure 1. This k is defined as the toxicity constant, and is related to CPA toxicity, J , by the following equation:²

$$J = \int_0^t k dt \quad (7)$$

RESULTS

As expected, we found that CPA toxicity (Eq. 7) was higher at higher concentrations and higher temperatures (Fig. 1).

Figure 1: Toxicity of porcine diaphragm muscle exposed to different temperatures and concentrations of VS55 over time. Curves were generated using nonlinear regression ($R^2 = 0.89$)

One key finding was the relatively high parameter values for k_{ω} and α (Fig. 1, top left), which indicate that our system is quite sensitive to CPA toxicity, especially at high temperatures (k_{ω}) and high concentrations (α). For comparison, Davidson et al. report $k_{\omega} = 1E7 \text{ min}^{-1}$ and $E_a = 56 \text{ kJ/mol}$ ¹, and Benson et al.² report $\alpha = 1.6$. This discrepancy may simply be a result of procedural differences in CPA type and toxicity metric, though the idea that muscle tissue is more sensitive to CPA would explain the lack of successful muscle cryopreservation protocols.

These parameter values were used as inputs in the mathematical simulation, which outputs the profile (Fig. 2A) that has the least toxicity

(Eq. 1) of all the profiles which passed both the osmotic and loading constraints (Equations 2-3 with $V_{low} = 0.5$ and $C_{desired} = 3.5 \text{ M}$). As expected, the optimal profile is at the edge of these constraints (Fig. 1B).

Figure 2: Simulation results for CPA loading in 1.4 mm-thick tissue. A: Toxicity-optimal CPA step-loading profile. B: Intracellular CPA concentration at the midline, with the dashed line giving the desired CPA concentration.

One key finding is the non-monotonic increase in CPA concentration (Fig. 1A, black). This is consistent with the simulation results of Benson et al., in which they argue that a higher penultimate step results in a more uniform concentration throughout the length of the tissue, and therefore less toxicity⁵.

Another key finding is the high temperature (Fig. 1A, red). This is inconsistent with conventional wisdom, which advises to use a low temperature to minimize toxicity. The explanation for our conflicting result is that, for this simulated system, the benefit of using a high temperature (faster mass transport and therefore shorter exposure time and therefore reduced toxicity) outweighs the downside of using a high temperature (increased metabolism and therefore increased toxicity). This finding has implications for CPA protocol development generally: a low temperature may not always be best.

There is some precedent for this result. In the simulation from Davidson et al., they identify an E_a threshold for the first CPA loading step in their system. At $E_a < 89 \text{ kJ/mol}$, they found that it was better to load CPA in a manner that was fast and hot instead of slow and cold.¹

DISCUSSION

In 2018, Benson et al. proposed a cost function approach for developing a toxicity-optimal CPA exposure profile in tissue systems. In their work, they determined the optimal time for each CPA loading step.⁵ In our simulation, we also determined the optimal temperature for each CPA loading step, in addition to the optimal time. By exploiting the fact that mass transport parameters are higher at higher temperatures, it may be possible to develop a successful cryopreservation protocol for sensitive systems such as muscle tissue.

In the development of CPA loading protocols, many researchers start with a historical protocol from the literature. The approach described here offers a better experimental starting point. Experimental development may still be necessary, but in this case the experimenter will be iterating from the theoretical optimum, likely saving time and resources. The vision is for every cryobiologist to employ a computational approach such as this for developing CPA loading and unloading profiles.

INTRODUCTION

Coronary artery disease (CAD) is the leading cause of death globally. Current treatment to restore flow in occluded coronary arteries is often guided by anatomy-based risk assessment, which has poor outcomes compared to treatment based on hemodynamic metrics [1]. To address this, personalized computational fluid dynamics (CFD) simulations are an emerging way to improve CAD treatment outcomes via non-invasive hemodynamic risk assessment and virtual treatment planning.

The accuracy of patient-specific CFD, which uses anatomical models constructed from non-invasive clinical imaging, depends on the quality of imaging on which it is based. A major source of error in current CFD models is the exclusion of arteries in the anatomical model that are under-resolved by clinical imaging. This causes erroneous flow distributions amongst coronary arteries in the model. Moreover, the flow distribution amongst arteries in CFD models is also affected by the boundary conditions specified at the outlet of each artery. The widely-used Murray's law [2], which empirically splits flow amongst arteries based on diameter, does not account for occluded and collateral arteries, metabolic regulation or anatomical uncertainty.

To address these issues, this work demonstrates a framework for more accurate and personalized coronary hemodynamics models that are enhanced by clinical and morphometric data. To create more anatomically realistic models, we combine conventional image-based models with synthetic vascular trees to represent arteries that are under-resolved in clinical imaging. Furthermore, these models are informed by novel non-invasive CT myocardial perfusion imaging (MPI_{CT}) [3] and clinical measurements of cardiac function, to estimate more accurate and personalized model parameters and boundary conditions. We also couple the coronary hemodynamics to patient-specific simulations of myocardial blood flow, which

allows quantitative estimates of hemodynamic CAD severity as well as myocardial ischemic risk.

METHODS

We use patient-specific coronary anatomical models based on CT angiography (CTA). The models are created using the segmentation and model building tools available in the open-source *SimVascular* software. We augment these image-based models with synthetic vascular trees generated using Constrained Constructive Optimization (CCO) [4] to represent vessels that are under-resolved in CTA. CCO can generate multiple non-intersecting trees in concave ventricle-like volumes that are constrained by hemodynamics and vascular scaling laws while minimizing vascular volume.

The hemodynamics is simulated using multi-scale 3D and reduced order models. The 3D flow in large arteries is simulated using the finite element solver, *svSolver*, included with *SimVascular*. The flow in synthetic and distal vasculature is simulated using 0D lumped-parameter models of flow (electric circuit analogy).

We enforce patient-specific flow distributions in the coronary tree based on clinical dynamic CT myocardial perfusion imaging (MPI_{CT}) [3]. MPI_{CT} is a non-invasive contrast-based imaging modality that quantifies the spatial distribution of blood flow/volume perfusing the left ventricle myocardial tissue. From clinically-acquired MPI_{CT}, we extract patient-specific left ventricle (LV) volumes and myocardial blood flow (MBF) distributions. Using co-registered 3D models of each patient's coronary vascular tree obtained from CTA and the MBF distribution in the LV obtained from MPI_{CT}, we estimate the LV perfusion regions and MBF volumes corresponding to each coronary artery. These are incorporated into the out-flow boundary conditions for the simulated hemodynamics. We compare

this novel method to specify flow splits with the conventionally used modified Murray's law [2] with an exponent of 2.6.

We use closed-loop lumped parameter network (LPN) boundary conditions at inlets and outlets of the aorta and coronary arteries in the 3D simulations [5] to capture the coupling with downstream systemic circulation. This includes blocks to model the resistance and capacitance of distal vasculature, each heart chamber, and the intramyocardial pressure in coronary arteries that causes out-of-phase flow with respect to the cardiac cycle. This model also incorporates the distribution of flow amongst coronary arteries, described above. Parameters are tuned using an automated surrogate-based optimization framework so that the resulting simulations reproduce clinically measured flow splits, heart rate, aortic pressure, cardiac output and ejection fraction for each patient within a specified error tolerance.

Finally, the coronary hemodynamics models are coupled to finite element simulations of myocardial blood flow based on Darcy flow through porous materials. A single compartment Darcy model is used to simulate myocardial blood flow, which is coupled to the coronary hemodynamics via pressure sources in the myocardium that are driven by coronary flow [6].

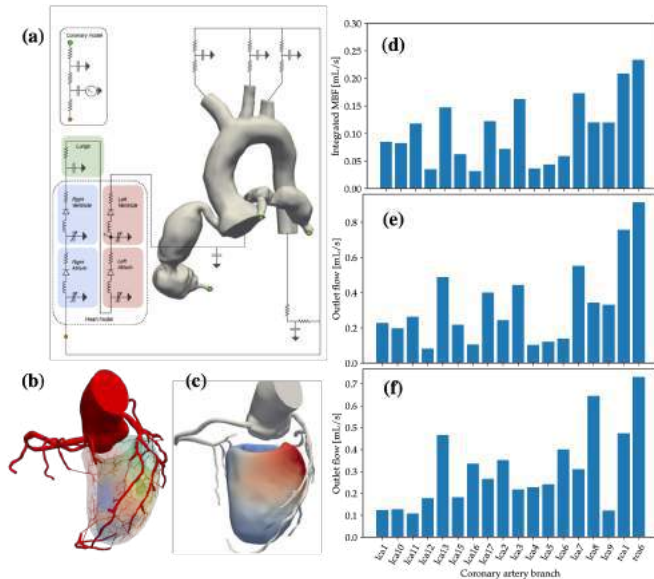

Figure 1: (a) Schematic of the simulation setup. (b) Sample case with synthetic vascular trees. (c) Myocardial perfusion simulation showing capillary pressure. (d) Flow in each coronary artery evaluated from MPI_{CT}. (e) Simulated flow in each coronary artery when using perfusion-informed boundary conditions. (f) Simulated flow in each coronary artery when using Murray's law boundary conditions.

RESULTS

Figure 1(a) shows a schematic of the image-based coronary hemodynamics model used in this study (shown without synthetic vascular trees for clarity) which is coupled with reduced-order models for systemic circulation and the four heart chambers. Figure 1(b) shows a sample case of an image-based anatomical model augmented with synthetic vascular trees that are constrained to grow in the patient-specific LV volume. This example shows 15 vascular trees perfusing the LV volume with 30 outlets in each tree. A sample myocardial perfusion simulation result is shown in figure 1(c), where the colors on the myocardium represent capillary pressure.

Preliminary results indicate that our automated framework to personalize and tune coronary hemodynamics models accurately recapitulates patient-specific clinical measurements. Figure 1(d) shows the clinically measured flow in each branch of the coronary tree, estimated from vessel-specific MPI_{CT} perfusion territories. This is compared with the simulated

flow using boundary conditions based on the novel imaging-informed technique and conventional Murray's law. The flow splits tuned based on perfusion imaging, shown in figure 1(e), qualitatively reproduce the measured distribution of flow (from MPI_{CT}) amongst the coronary arteries. However, the flow distribution obtained from using Murray's law, shown in figure 1(f), does not show good agreement with the clinically measured flow splits in figure 1(d). We note that the absolute volume of flow differs between the clinical measurement and both simulation cases because MPI_{CT} is known to underestimate flow volumes. We therefore focus on relative flow distributions in this study. Although not shown here, the automated parameter estimation framework used to tune the coronary hemodynamics simulations also produces good agreement between simulations and clinically measured metrics of cardiac function such as cardiac output, stroke volume and ejection fraction.

DISCUSSION

This work presents a novel framework for simulations of patient-specific coronary hemodynamics and myocardial perfusion that are enhanced by non-invasive myocardial perfusion imaging and morphometric synthetic vascular trees. We seek to address two significant sources of error in current coronary hemodynamics CFD models; (1) the exclusion of anatomical features of the coronary tree that cannot be resolved from clinical imaging; and (2) the use of empirical flow splits amongst arteries that are not patient-specific. Preliminary results indicate good success with the automated framework for tuning simulation parameters to reproduce patient-specific clinical measurements of coronary flow distributions as well as cardiac function.

Previous studies have highlighted the inaccuracies introduced in coronary hemodynamics simulations due to inaccurate branching in the model anatomy [7] as well as uncertainty in outflow boundary conditions [8]. We expect that the inclusion of synthetic vascular trees in place of under-resolved arteries will aid in producing more physiological flow distributions and, in the future, will also allow more rigorous studies of the effect of branching. Moreover, the incorporation of non-invasive perfusion imaging into the tuning of coronary flow boundary conditions is a novel method to obtain personalized flow distributions in the coronary tree, which in turn leads to more accurate estimates of clinically relevant hemodynamic metrics such as fractional flow reserve.

PHYSICS-INFORMED NEURAL NETWORKS WITH FOURIER-BASED ACTIVATION FUNCTION TO MODEL COMPLEX CARDIOVASCULAR FLOWS.

Arman Aghaee(1), M. Owais Khan (1)

(1) Electrical, Computer and Biomedical Engineering, Toronto Metropolitan University, Toronto, ON, Canada

INTRODUCTION

Physics-Informed Neural Networks (PINNs) has emerged as a powerful approach to encode governing partial differential equations (PDEs) and training data to solve complex engineering problems. In cardiovascular applications, PINNs can be designed to encode Navier-Stokes equations and clinically-acquired hemodynamic data (e.g., from 4D Flow MRI) into the loss function to improve predictions. However, minimizing the loss function during the training process is challenging.

One key strategy to improve the training operation is to use more robust activation functions that maintain nonlinearity, differentiability, with minimal vanishing gradients. However, majority of the popular activation functions, such as Swish or Tanh, lack some of these properties, which can consequently make the training process tedious. Additionally, these functions cannot capture high-frequency signals, for example, those observed in quasi-turbulent cardiovascular flows, such as in aorta, aneurysms, and ventricles.

We propose to use a recently-introduced Fourier-based activation function that utilizes a periodic *sine* function [1]. The derivative of a *sine* function is a cosine, a phase-shifted *sine*, and thus, inherit the properties of the original function. *Sine* activation functions have shown to outperform others in computer vision problems, but their applicability in cardiovascular fluid applications is not known [1].

METHODS

PINNs Model: The solution $u(\mathbf{x}, t)$ was approximated with a deep learning network $f(\mathbf{x}, t; \theta)$, where θ represents the trainable parameters of the neural network. The loss function is defined as:

$$\mathcal{L}_{\text{total}}(\theta) = \mathcal{L}_{PDE} + \lambda_{BC}\mathcal{L}_{BC} + \lambda_{data}\mathcal{L}_{data} \quad (1)$$

where \mathcal{L}_{PDE} , \mathcal{L}_{BC} and \mathcal{L}_{data} correspond to the loss term for the Navier-Stokes equation, boundary conditions, and known sensor data, respectively. The parameters λ_{BC} and λ_{data} aim to balance the interplay of the different terms in the loss function. The training parameter θ is

optimized by minimizing the total training loss, $\mathcal{L}_{\text{total}}(\theta)$ via a standard gradient descent optimization (i.e., ADAM).

The weighting coefficients in the loss function, λ_{BC} and λ_{data} , are problem-specific and tedious to choose for complex flow cases. Hence, we applied the strategy of dynamic weights that adaptively update the coefficients by utilizing the back-propagated gradient statistics during training. The iterative formulation for the adaptive weight can be expressed as [2]:

$$\theta^{k+1} = \theta^k - \eta \nabla_{\theta} \mathcal{L}_{PDE} - \eta \lambda_{BC} \nabla_{\theta} \mathcal{L}_{BC} - \eta \lambda_{data} \nabla_{\theta} \mathcal{L}_{data} \quad (2)$$

where k is the iteration step, and η is the learning rate. The coefficients λ_{BC} and λ_{data} can be estimated using the following relation [2]:

$$\lambda_{BC} = \frac{\max_{\theta} (|\nabla_{\theta} \mathcal{L}_{PDE}(\theta_n)|)}{(|\nabla_{\theta} \mathcal{L}_{BC}(\theta_n)|)}, \lambda_{data} = \frac{\max_{\theta} (|\nabla_{\theta} \mathcal{L}_{PDE}(\theta_n)|)}{(|\nabla_{\theta} \mathcal{L}_{data}(\theta_n)|)} \quad (3)$$

Activation Functions: We compared two standard activation functions, SWISH and Tanh against a Fourier-based, periodic *sine* function (i.e., SIREN[1]). Compared to other activation functions, *sine* function has shown better convergence and differentiability for high-frequency signals. The formulation of the three activations functions is

$$\text{SWISH: } f(x) = x \cdot \text{sigmoid}(x) \quad (4)$$

$$\text{Tanh: } f(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \quad (5)$$

$$\text{Sinus: } f(x) = \sin(\omega_0 x) \quad (6)$$

Sine requires special initialization for the first layer and normalization of the input components from -1 to 1. We applied the strategy proposed by Pan et al. in our work [3].

Test Case A – 1D Advection Diffusion Equation: We tested the three activation functions on a 1D steady advection-diffusion equation:

$$\alpha \frac{\partial u}{\partial x} = v \frac{\partial^2 u}{\partial x^2} \quad (7)$$

where $\alpha = 1$ and $v = 0.001$ were chosen for advection and diffusion coefficients, respectively. The neural network consisted of 2-10 layers with 100 neurons per layer. Three sensor points were chosen along x .

Test Case B – 2D Eccentric Stenosis: A 2D eccentric stenosis geometry was created based on Varghese et al [4]. An asymmetry of 5% was introduced at the stenosis throat that served as a geometric perturbation to the flow field.

CFD simulations were performed using a higher-order finite-element solver, *Oasis* [5], that is designed to minimize numerical dissipation and dispersion errors. The geometry was meshed into 60k second-order tetrahedra, which corresponds to 480k linear tetrahedra. CFD simulations were run for 25000 timesteps for $t^* = tu_i/D = 125$.

The PINNs architecture consisted of 4 layers with 128 neurons/layer. The boundary conditions and velocity field at the mesh nodes were treated as unknown quantities. Sensitivity to sensor data (obtained from CFD) were tested by increasing sensor points from 25 to 400. The sensor points were equally distributed along the domain.

RESULTS

1D Advection Diffusion Equation: Figure 1 shows that even with 2 layers, *sine*-based PINNs is able to reconstruct the analytical solution with an order of magnitude lower errors compared to other activation functions. In addition, *sine* activation function shows a monotonic decrease in error while other activation functions require 10 layers to produce any notable reduction in error.

Figure 2: PINNs solution with different activation functions using 2 neural network layers. The inset shows error with increasing neural network layers. The green asterisk marks the location of sensor (known) data.

2D Eccentric Stenosis at Re=5000: While PINNs model with *sine* and *swish* activation functions converged, the *tanh* solution diverged due to its gradient diminishing properties.

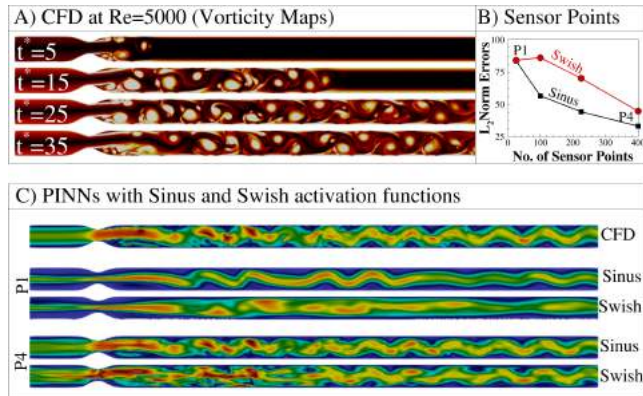

Figure 1: A) Temporal evolution of vortical structures over non-dimensional time, t^* . B) Decrease in error with increasing sensor data, and C) PINNs-predicted velocity for *sine* and *Swish* activation functions at $t^* = 35$.

The results for *sine* and *swish* functions are summarized in Figure 2:

- **CFD Flow Field:** Figure 2A shows that at $Re=5000$, the velocity field is unsteady and dynamic. The geometric asymmetry leads to formation of periodic vortical structures that shed at a constant frequency. Initial transients wash out by $t^* = tu_i/D = 35$.
- **Sensitivity to # of Sensor Points:** Figure 2B shows a monotonic decrease in L_2 errors as the number of sensor data increases from 25 to 400. There is a rapid decrease in error norm from 25 to 100 points for *sine* function compared to *swish* function.
- **PINNs-predicted Velocity Field:** Figure 2C shows the velocity field estimated by PINNs for 25 and 400 sensor points, marked with P1 and P4 respectively. We note that even with 25 sensor points, the *sine*-predicted velocity field shows the oscillatory behavior that is not captured by *Swish* activation function. At 400 sensor points *swish* and *sine* show similar L_2 norms; however, the qualitative velocity maps demonstrate that *sine*-based predictions closely match the CFD ground-truth data.

DISCUSSION

We have demonstrated that *sine* activation function provides a notable improvement in velocity field predictions compared to conventional activation functions. Although *sine* function requires specialized treatment (i.e., initialization and normalization), they provide a notable improvement in velocity predictions.

Another observation is that *sine* activation function was able to reconstruct the gross velocity field even with 25 sensor points. The reduced requirements on sensor data are beneficial since clinically-acquired hemodynamic data is often scarce and sparse, for example, in 4D Flow MRI or dynamic perfusion CT imaging.

Lastly, we note that due to the vanishing gradient problems pervasive in some of the activation functions (e.g., Tanh), these functions are unsuitable for more dynamic and complex flow problems.

Relationship to Previous Literature: We note that our study is the first to use a *sine*-based activation function for cardiovascular flow application. Previous study by Arzani et al. [6] have demonstrated that PINNs could predict wall shear stresses using sparse measurements away from the wall. Those authors used a *Swish* activation function and demonstrated excellent agreement with CFD data; however, the flow field used in their study was steady, uniform and thus, had low spatial gradients. As seen in our study, if the flow complexity and spatial gradients are increased, training with conventional activation function can produce inaccurate results, especially when sensor data is sparse.

We have demonstrated that *sine*-based activation function can better capture complex flow fields compared to conventional activation functions. Further work is needed to demonstrate the applicability of the proposed approach for patient-specific three-dimensional models.

INTRODUCTION

Ischemic heart disease is caused by restricted coronary blood flow. Thus, the availability of coronary blood flow would be helpful to guide clinical interventions or evaluate biomechanical stresses (e.g., wall shear stresses) as a proxy of plaque remodeling. However, coronary flow is challenging to measure non-invasively and routinely in clinic.

One non-invasive approach to obtain coronary pressure and velocity is to use CTA-based computational fluid dynamics (CFD) simulations, commercially popularized by HeartFlow's FFR-CT technology. A key disadvantage of CTA-based CFD simulation is related to the assumptions of inflow and outflow boundary conditions.

Boundary conditions are typically estimated using empirically-derived flow-diameter relations; however, there is no clear evidence whether these assumptions produce patient-specific results when used for CTA-based CFD simulations.

The goal of this study was to utilize a fully non-invasive approach to coronary CFD and evaluate the impact of inflow and outflow boundary conditions against intravascular velocities and pressures.

METHODS

Patient Data: Imaging and hemodynamic data were acquired for N=13 patients at the University of California San Diego, including coronary CTA, echocardiography, intravascular Doppler velocity, and pressure. Intravascular measurements were made using ComboWire XT Pressure and Flow Wire (Volcano, San Diego California) at rest and stress for multiple cardiac cycles (see Figure 1A). Only rest values were used in our analyses. For each patient, intravascular recordings were obtained for 120 ± 55 cardiac cycles. These flow waveforms were assessed for quality (e.g., peak in diastolic phase, gradual decline, noise) using an automated in-house tool. Only waveforms that had an acceptance rate of $>70\%$ were included in the study.

Computational Fluid Dynamics Simulations: All 13 coronary CTA images were segmented and meshed in the SimVascular software

package (simvascular.github.io). Fluid-structure interaction (FSI) simulations were coupled to a lumped parameter network (LPN) to model heart and closed-loop circulation (Figure 1B). An automated approach was used to tune the input variables of LPN to match clinical targets, such as heart rate, blood pressures, ejection fraction, cardiac output [1]. Briefly, $\sim 4.6\%$ of the cardiac output fed the coronary arteries, with a 70-30% flow split between left and right coronary tree. Within each coronary tree, the flow was split based on modified Murray's Law using the following relationship [2]:

$$\frac{Q_i}{\sum Q_i} = \frac{D_i^{2.6}}{\sum D_i^{2.6}} \quad (1)$$

Figure 1: A) Doppler velocity (black) and pressure (red) tracings in three representative patients. B) Multi-scale CFD pipeline, combining FSI with closed-loop LPN.

Coronary Flow Rate Estimation: Cardiac cycle-averaged intravascular Doppler flow rate was estimated assuming a parabolic velocity profile, according to the following formula:

$$Q_{Doppler} = Area \cdot \frac{AVP}{2} \quad (2)$$

where Area is obtained from coronary CTA at the location where intravascular data was recorded. AVP is the averaged peak velocity and was taken by averaging multiple cardiac waveforms. The intravascular

probe location was recorded by the interventional radiologist during the procedure and marked onto the 3D reconstructed coronary model by an experienced cardiologist (A.M.K).

CFD Post-processing: Cross-sectional slices were made at locations where intravascular data was measured. CFD flow rates were estimated using equation (2) and pressures were averaged across the cross-section.

Statistical Analysis: A Shapiro-Wilks test was performed to check for normality. Since all anatomic and hemodynamic variables were found to be non-normally distributed, a two-sided paired Wilcoxon signed rank-sum test was used to compare CFD vs. intravascular data.

RESULTS

A total of 19 vessel were analyzed from 13 patients, including left anterior descending artery (N=11), right coronary artery (N=5), left main coronary artery (N=2) and septal artery (N=1). Table 1 compares cohort-averaged intravascular vs. CFD hemodynamics.

Table 1: Hemodynamic measurements in N=19 vessels.

	Intravascular	CFD	p-value
Pressure (mmHg)	89 ± 18	63 ± 11	<0.01
Velocity (cm/s)	8.76 ± 2.80	11.7 ± 5.9	0.16
Q, Flow rate (mL/min)	38.5 ± 26.2	55 ± 48	0.16

Pressure Analysis: Figure 2 (top panel) shows that there was a statistically significant correlation between CFD derived pressures and intravascular pressures ($p < 0.01$). Bland-Altman plot showed a positive bias of 26.5 [49 – 3.4] mmHg, indicating that CFD simulations tended to underestimate the intravascular pressures. This underestimation can be attributed to differences between cuff pressures, used to compute resistances in CFD simulations, and intravascular pressures.

Velocity and Flow Rate Analysis: Figure 2 (bottom panel) shows that there was no statistically significant correlation between CFD-derived velocity vs. intravascular Doppler velocity. The same was true for flow rates. Bland-Altman plot showed a negative bias of -3 [-16.3 – 10.4] cm/s for velocity (Figure 2, bottom panel), and a negative bias of -16.5 [-86 – 53] mL/min for flow rate, with a wide 95% limits of agreement.

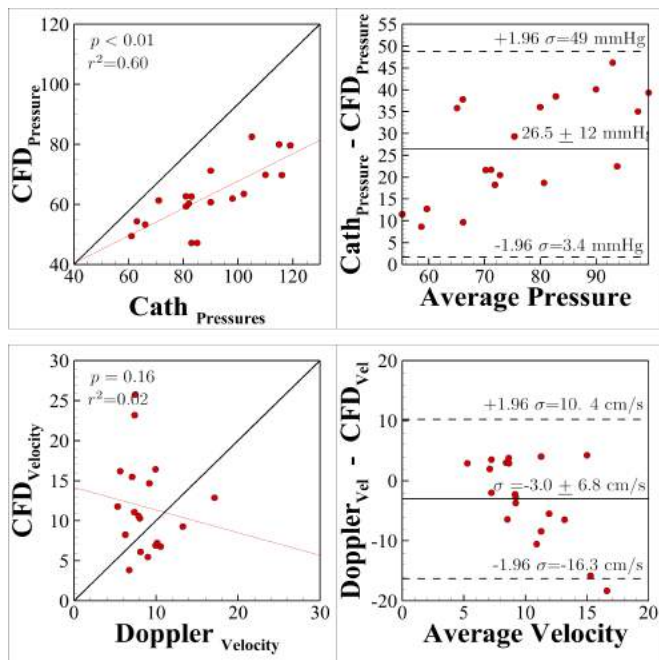

Figure 2: Correlation and Bland-Altman plots comparing CFD vs. intravascular pressure and velocity data.

DISCUSSION

CTA-based CFD simulations of coronary arteries are used widely in research and, more recently, in commercial applications; however, based on our findings, there is no clear evidence of how accurately these simulations predict in-vivo hemodynamics, particularly absolute pressures and velocities. Although we found that CFD-predicted pressures correlated well with intravascular pressures, there was a lack of correlation with intravascular Doppler velocity. These findings have important implication for coronary CFD-based technologies.

Implications for Coronary CFD-based applications: There is a strong clinical and research interest in estimating absolute coronary flow, for example to predict coronary wall shear stresses as a proxy of plaque vulnerability [3]. Additionally, recent efforts have focused on using CFD to assess coronary physiology in heart bypass surgeries for pre-planning [4], or to computationally predict myocardial blood flow perfusion [5]; all of which depends on accurate estimation of coronary hemodynamics. Our findings demonstrate that even when using highly detailed patient-tailored CFD simulations, there are still significant errors in coronary velocities and flow rate, which would naturally lead to errors in other velocity-derived quantities, such as wall shear stresses.

Interestingly, our findings demonstrate that CFD-derived pressures correlated well with those measured invasively. This good correlation can be attributed to the use of patients' cuff pressures to estimate coronary vascular resistances in our CFD strategy. Additionally, there is recent interest in simulating myocardial blood flow perfusion by coupling coronary and myocardial perfusion physiology [5]. These dynamics are dependent on accurate prediction of coronary pressures, and thus, would benefit from our coronary CFD strategy.

Relationship to Previous Literature: Previous studies have compared Doppler- vs. scaling-law approach for coronary inflow estimation [6,7], but most of these studies are limited to coronary models that have been reconstructed from 2D angiography, and consequently, permit only 2-5 outlets. In contrast, since we used CTA, we were able to reconstruct ~20 branches per model, and without the need for invasive imaging.

A recent study by Lodi Rizzini et al. investigated the impact of different inflow estimation methods (e.g., thermodilution, Doppler, and scaling law) on coronary hemodynamics [7]. Those authors reported a cohort-averaged $Q_{Doppler}$ of 44 mL/min, which is in close agreement with $Q_{Doppler}$ of 38.5 mL/min reported in our study. Similar to our findings, those authors found significant differences between their baseline approach (i.e., thermodilution) and scaling-law based flow rates.

In conclusion, our findings indicate that while CFD-derived predictions correlate well with intravascular pressures, there is no statistical correlation with intravascular velocity or flow rates. These findings highlight the need to improve inflow boundary condition estimation if absolute coronary flow rate or velocities are needed.

CYCLIC STRETCH INHIBITS CELL INVASION AND MIGRATION IN 3D SCAFFOLDS

Rozanne W. Mungai (1), Kevin Piskorowski (1), Grace Jolin (1), Ying Lei (1) and Kristen L. Billiar (1)

(1) Department of Biomedical Engineering, Worcester Polytechnic Institute, Worcester, MA, USA

INTRODUCTION

Cell invasion and migration are driving factors for various biological events such as development, wound healing, tumor invasion and host cell infiltration of implanted scaffolds. These events involve cells invading and/or migrating in response to chemical or mechanical cues [1]. Extracellular features such as matrix porosity, substrate topography, matrix stiffness and density are among a few static mechanical cues that influence cell invasion and migration [2, 3]. Dynamic mechanical stimuli such as fluid shear and stretch may also play a role [4]. Many organs experience dynamic loading (e.g., cardiovascular tissues, skin, tendons) which induces changes in cell alignment and forces [5]. It is possible that dynamic stretch also alters cell invasion and migration.

Studies utilizing 2D substrates have demonstrated reduction of cell migration in response to cyclic stretch [6-8]. Most cell types reorient away from stretch in these 2D systems. In contrast, in 3D biopolymer gels, cells and extracellular matrix (ECM) fibers generally align in the direction of uniaxial stretch [9, 10]. This cell and fiber alignment could promote contact guidance and subsequent increased directional migration, yet migration and invasion have not been studied in these 3D biopolymer systems.

We hypothesize that uniaxial cyclic strain inhibits cell invasion and migration in 3D scaffolds. Herein we describe a system for testing this hypothesis consisting of applying 10% cyclic strain at 1Hz to a collagen hydrogel containing cell spheroids and quantification of the extent and directionality of cell invasion using a custom MATLAB program and present representative data.

METHODS

Cell-spheroids were generated from male porcine aortic valvular interstitial cells (VIC) and male human neonatal dermal fibroblasts (HDF) using non-adherent microwells (Microtissues®) and combined

with collagen solution (2.0mg/mL rat tail type I). The hydrogel-spheroid mixture was plated into 8mm x 8mm square wells in a stretchable silicone well plate (CellScale) and mounted on a uniaxial stretching device (MechanoCulture FX™, CellScale). Fresh medium was added over the samples, and they were cultured at 37°C in a humidified 10% CO₂-containing incubator for two days at either a static or stretched condition (10% uniaxial stretch at 1Hz frequency).

Fluorescent z-stack images were captured using a Keyence BZ-X800 fluorescence microscope to assess the extent of cell invasion by visualizing cell nuclei. The cells were stained with Hoechst 33342 before spheroid formation and imaged at Day 0 prior to stretching. They were fixed in 4% paraformaldehyde at Day 2, permeabilized using 0.25% Triton-X 100 and further stained with Hoechst and Alexa Fluor® 488 phalloidin for nuclei and F-actin visualization. The images in each z-stack were processed to create maximum z-projection images (Figure 1A). 3D reconstruction images were processed from Z-stack images captured using a Leica SP5 point scanning confocal microscope.

Image quantification was carried out using a custom MATLAB program using the image processing package. The images were thresholded and the boundaries of the Day 0 images were traced to determine the boundary of cell invasion. The spheroid centroids were identified as well as the locations of the pixels of the Day 2 images that lay outside of the boundary of invasion. The distances (d) (Equation 1) of each of these pixels from the boundary and the centroid was calculated as well as their angles of invasion (θ) (Equation 2, Figure 1B-D).

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \quad (1)$$

$$\theta = \tan^{-1} \frac{y_2 - y_1}{x_2 - x_1} \quad (2)$$

Figure 1: Z-stack image processing and quantification. Day 2 images were processed to create maximum z-projection images from each z-stack (A). The distances and angles of the migrated pixels were calculated with reference to the spheroid boundary and center (B-D). Scale: 200µm.

These data were used to calculate the invasion area (sum of number of pixels), persistence speed (boundary distances (d_b) divided by the culture time (t)) and area moment of inertia (where $dA = 1 \mu m^2$) in the stretch (x) and cross(x)-stretch (y) directions as weighted measures of invasion (Equation 3)

$$I_{stretch} = \sum_{i=0}^n y^2 dA ; I_{x-stretch} = \sum_{i=0}^n x^2 dA \quad (3)$$

RESULTS

At Day 2, we observed reduced invasion in VICs as shown by a decreased number of migrated nuclei while HDF invasion appeared similar for both static and dynamic conditions (Figure 2).

Figure 2: Dynamic stretch reduces cell invasion area. Representative images of invasion Day 0 vs Day 2, VICs (A) and HDFs (B). Scale: 200µm.

Similarly, the invasion persistence speed for VICs was significantly slower ($p < 0.05$) in the dynamic spheroids compared to the static spheroids as assessed by a paired t-test ($p = 0.0076$) (Figure 3A). This trend further indicates that dynamic stretch reduces cell invasion in VICs. In addition, differences in the directional area moment of inertia ($I_{stretch}$ and $I_{x-stretch}$) (Figure 3B) were not significant different ($p = 0.707$) under dynamic stretch for VICs revealing that invasion was not dependent on the direction of stretch.

Figure 3: Representative persistence speed and directional area moment of inertia at Day 2 for representative VIC spheroids of one experiment. Quantified mean persistence speed, * $p = 0.0076$ from paired t-test (A). Directional area moment of inertia ($I_{stretch}$, $I_{x-stretch}$) (B). Error bars are standard error of the mean.

DISCUSSION

In this work, we developed a spheroid-based *in vitro* model utilizing collagen hydrogels to study the effects of cyclic stretch on cell invasion. We designed a custom MATLAB program to analyze captured images to robustly discern directional and speed trends. We observe that VIC invasion into a collagen hydrogel is strongly affected by stretch, whereas HDF invasion is less sensitive. These results indicate that in the 3D microenvironment, the effects of cyclic stretch on cell invasion and migration may be cell-type dependent. It is unclear why there is not a directional dependence of stretch on the VICs.

This study can be expanded by exploring the roles that different ECM proteins and growth factors play in the cell response to cyclic stretch. Although collagen is the major protein constituent of the ECM, other proteins such as fibronectin, glycosaminoglycans and elastin are also known to influence cell invasion and migration [11]. In addition, the mechanism by which cyclic stretch inhibits cell invasion in VICs but not HDFs could be further explored. This work has the potential to inform how tissues exposed to cyclic stretch can be more or less susceptible to cell invasion with possible applications in wound healing, cancer metastasis and the repopulation of scaffolds such as tissue engineered heart valves.

INTRODUCTION

Shock wave-induced deformations (e.g., from local detonations) of smaller lung tissue (lung parenchyma) are responsible for larger-scale injuries, such as hemorrhage, long term diseases, such as pneumonia, and in many cases, immediate death [1, 2]. The progression of “damage”, the biological processes that govern pathology and eventual tissue healing, and mitigation of damage through personal protective equipment (PPE) to reduce the likelihood of Behind-Armor Blunt Trauma (BABT) is an active area of research. The goal of the research is to advance our understanding of the physiology through numerical modeling given that experimental data is limited for high-strain rate loadings on lung tissue, human or otherwise.

A large deformation, coupled finite-element (FE) model is developed to simulate the multiphase response of soft porous materials subjected to high-strain rate loading. For the soft porous material of particular interest here, the lung parenchyma, conventional computational fluid dynamics (CFD) fluid-structure interaction (FSI) models are prohibitively expensive for the length scales of interest. Our approach is based on the theory of porous media (TPM) at large deformations [3–5]. Prior computational modeling of lung parenchyma treats the soft porous network (solid skeleton) of lung tissue and enclosed pore fluid (e.g., air) as a single constituent [6, 7]; TPM treats them as separate constituents to describe more physically realistic FSI. Herein, our aim is to address differences in the kinematics, with future work focusing on the assessment of differences in the quantification of damage of the soft porous material.

METHODS

We assume that the lung parenchyma continuum body constitutes a control space \mathcal{B} (current configuration of the solid skeleton) and that only liquids or gases in the pores can leave this pore space. Rather than modeling the exact microstructure of the lung parenchyma, we assume that the pores are modeled in a statistical sense such that their specific locations are arbitrary. This concept of volume fraction is illustrated in Figure 1(a).

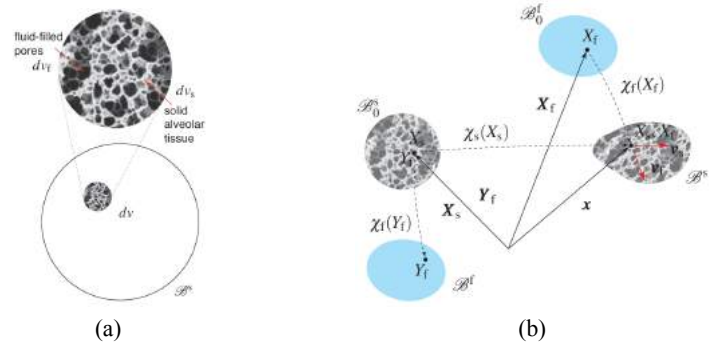

Figure 1: (a) Concept of volume fraction for biphasic (solid(s)-fluid(f)) mixture theory, showing solid skeleton composed of alveolar tissue. Note that in the theory of porous media, it is assumed that the control space is that of the solid phase $\mathcal{B} := \mathcal{B}^s$, also known as “solid skeleton.” (b) Kinematics of a biphasic (solid-fluid) mixture theory.

Detailed derivations for constituent and mixture balance of: mass, linear momentum, energy and entropy are provided in [5]. To describe the kinematics, we solve the following equations for balance of mass of the mixture, balance of momenta (mixture and fluid) in the reference configuration \mathcal{B}_0 of the solid skeleton (assuming immiscible constituents, negligible mass supplies and a nearly-inviscid pore fluid):

$$\frac{J_s n^f}{K_f} D_t^s p_f + D_t^s J_s + \frac{J_s}{K_f} \text{GRAD}_s p_f \cdot \mathbf{F}_s^{-1} \cdot (n^f \tilde{\mathbf{v}}_f) + J_s \text{GRAD}_s (n^f \tilde{\mathbf{v}}_f) : \mathbf{F}_s^{-T} = 0 \quad (1)$$

$$\text{DIV}_s \mathbf{P}_s + \rho_{0(s)} \mathbf{g} = \rho_{0(s)}^s \mathbf{a}_s + \rho_{0(s)}^f \mathbf{a}_f \quad (2a)$$

$$\mathbf{P}_s = \mathbf{P}_E - J_s p_f \mathbf{F}_s^{-T} \quad (2b)$$

$$\rho_{0(s)}^f \mathbf{a}_f + J_s n^f \text{GRAD}_s p_f \cdot \mathbf{F}_s^{-1} + \frac{J_s (n^f)^2}{\hat{k}} (\mathbf{v}_f - \mathbf{v}_s) - \rho_{0(s)}^f \mathbf{g} = \mathbf{0} \quad (3)$$

All constitutive assumptions follow from thermodynamic conjugacy laid out in [5]. For the solid skeleton stress response, we assume a neo-Hookean hyperelastic material, and for the pore fluid pressure response, an exponential relationship between pore fluid real mass density and pore fluid pressure (see [8]). Mixed constituent temperatures are also assumed (sans thermo-mechanical coupling), and Darcy's law with inertia terms is used to describe the seepage velocity $n^f \tilde{\mathbf{v}}_f$. Thereafter, simplifications to the one-dimensional uniaxial strain regime are made for the numerical implementation. To stabilize numerical noise arising from shock-like pressure loadings, the canonical shock viscosity Q is added to the solid skeleton stress response [9], and pressure stabilization is added to the balance of mass of the mixture [10]. The balance equations are discretized in space via FE method and discretized in time via implicit or explicit numerical time integration methods; a fifth-order accurate adaptive time-stepping Runge-Kutta scheme [11] provides greatest computational cost-to-accuracy ratio for shock-like loading and is thus preferred.

RESULTS

We impose a Friedlander wave overpressure boundary condition to the top of the lung parenchyma column mesh, represented here as a traction on the biphasic mixture (refer to Figure 2). Peak overpressure was chosen to be 25 kPa, which is above the injury threshold for exposed rabbit lung [12]. The base and sides of the column are held fixed; an impermeable, no-slip boundary condition for the motion of the pore air is imposed at the top of the column to be able to provide a comparison to [7] wherein the pore air is assumed to be trapped in the pores. However, in contrast to that model, pore air in the multiphase model is allowed to move freely within the lung parenchyma column.

DISCUSSION

The stress response of the single-phase and multiphase models is shown in Figure 3. We observe good agreement between both models for the total (tissue + air) axial stress, but the advantage to our multiphase model is that we can directly compute the axial stress of the solid skeleton, i.e., the lung parenchyma, which goes into tension sooner than the aggregate response of the single-phase model. Fung has suggested that excessive tensile forces in the walls of the lung aveoli can lead to rupturing of the alveoli and local injury [13]. These findings have implications for predicting injury sooner by accounting for relative motion of the air to the lung parenchyma in the multiphase model. Further work is needed to quantify damage and local injury in the multiphase solid skeleton constitutive model to say for certain.

INTRODUCTION

Understanding the mathematical relationship between applied forces and tissue deformations through constitutive modeling can improve our understanding of lung function and remodeling due to pathological conditions [1]. This is particularly key for airway mechanics, the site of occlusion in lungs diseases such as asthma and chronic obstructive pulmonary disease. Despite its importance, few studies have constructed constitutive models for the airways which have tend to opt for oversimplifying assumptions (e.g., linear, isotropic) due to the scarcity of experimental data [2]. These previous models were also limited to extrapolating trachea properties for use in whole bronchial tree modeling analyses due to challenges associated with characterizing the distal airway network [3]. Contrary to these modeling limitations, recent experimental studies of the airway tree concluded these oversimplifications to be invalid given the tissue demonstrates non-linear, anisotropic, and heterogenous behavior [4,5].

To address this knowledge gap, we analyze the performance of a purely phenomenological model (Fung) and two structurally motivated constitutive models (Four Fiber Family and Holzapfel) in simultaneously fitting experimental data from multiple biaxial loading conditions collected from the proximal and distal airways. These constitutive models capture the nonlinear, anisotropic, and heterogenous behavior of the airways and ultimately improve our understanding of lung structure by establishing a much needed foundation for generating predictive computational models for future pulmonary disease characterization as well as airway stent design.

METHODS

Four fresh porcine lungs were acquired from a local abattoir and the whole airway tree was extracted and divided into three distinct regions, including the trachea, large and small bronchi, based on their inner diameters of 18.6 ± 2.6 , 8.4 ± 1.5 , and 4.9 ± 1 mm, respectively [4]. Square soft tissue specimens (5-5.2 mm) were prepared by peeling

away the cartilage layer while noting the circumferential and axial directions of the airway. Graphite powder was used to enable tracking of the tissue surface deformation via digital image correlation (DIC) [6]. Six samples were collected from each airway region, and specimens with poor speckling or tearing were excluded, resulting in a total of 60 samples. Specimens were loaded in a commercial planar biaxial machine (CellScale Biomaterials Testing) while hydrated with 1X phosphate-buffered saline bath at 37°C. Samples were preconditioned five times. A strain rate of 1%/s was used with a maximum strain value of 60% to implement various displacement ratio protocols of 1:1 (circumferential:axial), 1:0.75, 1:0.5, 0.5:1, and 0.75:1. The first Piola-Kirchhoff engineering stress was calculated, and DIC informed the actual tissue strain using commercial software (CellScale Biomaterials Testing).

The experimental data for all five protocols were simultaneously fit to three constitutive models [1]. Four-parameter phenomenological Fung strain energy density function was used in the form of

$$\psi = \frac{C}{2} e^Q; \text{ with } Q = b_1 E_\theta^2 + b_2 E_z^2 + 2b_3 E_\theta E_z \quad (1)$$

where C , b_1 , b_2 , and b_3 are material constants obtained from experimental data and E_θ and E_z are the circumferential and axial components of the Green strain tensor, respectively [7].

Additionally, the four fiber family (4FF) model with perfectly aligned fiber families in the circumferential and axial directions along with two symmetric diagonal directions [8] was used in the form of:

$$\psi = \psi_{iso} + \psi_{aniso} = \frac{C}{2} (I_C - 3) + \sum_{i=1}^4 \frac{C_{1i}}{2C_{2i}} (e^{C_{2i}(I_{4i}-1)^2} - 1) \quad (2)$$

where C , C_{1i} , and C_{2i} are material parameters (i denotes a fiber family), I_C is the first invariant of the right Cauchy-Green tensor and $I_{4i} = \mathbf{C} : \mathbf{M}_i \otimes \mathbf{M}_i$ is the square of the stretch of i^{th} fiber family. The direction of each fiber family is denoted as $\mathbf{M}_1 = (0,1,0)^T$, $\mathbf{M}_2 = (1,0,0)^T$, $\mathbf{M}_{3,4} = (\pm \cos \varphi, \sin \varphi, 1)^T$, where φ is the angle between each diagonal fiber family and the circumferential direction [1,8,9].

The third utilized model was proposed by Holzapfel et al. (2015)

[10] to account for in-plane and out-of-plane fiber dispersions in two diagonal fiber families with the form of

$$\psi = \frac{c}{2}(I_C - 3) + \sum_{i=4,6} \frac{C_i}{2C_2} (e^{C_1(I_i-1)^2} - 1); \quad (3)$$

$$I_i^* = AI_C + BI_i + (1 - 3A - B)I_n; \quad (4)$$

$$A = 2\kappa_{op}\kappa_{ip}; \quad B = 2\kappa_{op}(1 - 2\kappa_{ip}); \quad (5)$$

$$I_i = C: \mathbf{M}_i \otimes \mathbf{M}_i; \quad I_n = C: \mathbf{M}_n \otimes \mathbf{M}_n; \quad \mathbf{M}_{4,6} = (\cos \varphi, \pm \sin \varphi, 1)^T \quad (6)$$

Here $\mathbf{M}_{4,6}$ are mean fiber family directions composing angle φ with the circumferential direction, and \mathbf{M}_n is an out-of-plane vector. Parameters of κ_{ip} and κ_{op} are related to in-plane/out-of-plane fiber dispersions [10].

Hyperfit was used to facilitate fitting the data by regression, maximizing the coefficient determination of R^2 [1]. One way ANOVA and Bonferroni correction were performed to further evaluate all model performances and assess the success of each model in capturing airway heterogeneity with significances set at * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$, and **** $p < 0.0001$ [GraphPad Prism].

RESULTS

A representative specimen's experimental response fit to each model is shown in Figure 1. 4FF outperformed capturing the non-linear shape of stress-strain curve, while Fung and Holzapfel models' curve convexity underestimates/overestimates the experimental behavior.

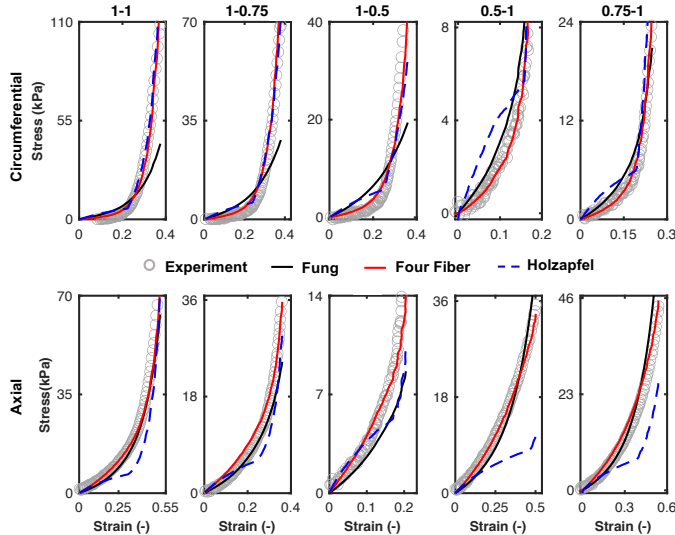

Figure 1: Representative specimen's experimental data fitted to three models. Scales vary for visualization.

The performance of these three models in simultaneously fitting all five experimental biaxial loading profiles were evaluated for each specimen as shown in Figure 2; box plots inform fit performances for all airway regions. Among the three models tested in this study, 4FF fit the region-specific data significantly better with the highest overall average R^2 and the least variability of $R^2 = 0.94 \pm 0.05$, while Fung and Holzapfel models were $R^2 = 0.89 \pm 0.07$ and 0.80 ± 0.15 , respectively.

The material parameters and R^2 values of 4FF were further analyzed to explore any notable differences between airway regions and are reported in Table 1. Parameters of C_{11} , C_{234} , and φ were found to be significantly different between the trachea and other regions.

DISCUSSION

This study is the first attempt to explore the capability of various constitutive models in describing simultaneous biaxial experimental protocols for the proximal and distal airway tree. The 4FF model, with perfectly aligned fiber families, exhibited superior performance in

Figure 2: Box plots demonstrating Four Fiber, Fung, and Holzapfel model performances to biaxial tensile tests.

Table 1: Averages \pm standard deviations of the Four Fiber model parameters fitted to experimental data from each airway region.

Four Fiber	Trachea	Large Bronchi	Small Bronchi
C (kPa)	2.05 ± 2.41	1.15 ± 3.46	0.29 ± 0.75
C_{11} (kPa)	14.3 ± 8.13	5.56 ± 8.05 (**)	5.71 ± 5.59 (**)
C_{21}	0.06 ± 0.08	5.43 ± 24.06	0.24 ± 0.77
C_{12} (kPa)	1.53 ± 1.89	2.4 ± 1.74	1.25 ± 1.18
C_{22}	2.38 ± 1.59	1.35 ± 2.69	1.28 ± 1.65
C_{134} (kPa)	3.82 ± 3.55	6.06 ± 4.81	5.66 ± 3.57
C_{234}	2.26 ± 1.8	0.26 ± 0.34 (**)	0.97 ± 2.77
φ ($^\circ$)	40.1 ± 12.95	56.9 ± 0.04 (**)	53.6 ± 14.06 (*)
R^2	0.94 ± 0.05	0.93 ± 0.04	0.93 ± 0.05

capturing the experimental biaxial mechanical behavior of all five loading protocols compared to the Fung and Holzapfel models. These results are in agreement with cardiovascular studies reporting better performance of 4FF in modeling of human abdominal aorta, porcine thoracic aorta, as well as rabbit and mouse arteries [1,8,9].

The 4FF also well represents heterogeneity within the airway tree, with significant differences in diagonal fiber families' directions between proximal and distal airways: fiber families are found to be aligned closer to the circumferential direction in tracheal specimens (40°), while they are closer to the axial direction in distal airways (57° and 54°). These results align with regional heterogeneities observed from our previous histological analyses, in which the fiber architecture of proximal and distal airways differ [3].

Despite simultaneously utilizing multiple experimental data sets to constrain the solution, constitutive models are often affected by non-unique fits [11] and pose a limit to this study. Similarly, noted regional differences in C_{11} and C_{234} parameters are not necessarily independent due to the exponential functional form in the strain energy density (Eq. 2). Nonetheless, the model parameters provided in this study yield essential information central to the development of predictive pulmonary tools and help to inform the design of airways' replacements.

INTRODUCTION

Mice are a widely used model system in engineering and life sciences as mice are inexpensive, easy to handle, and genetically highly malleable. Interestingly, much remains to be understood about the suitability of mouse skin as a model system for human skin. This is especially true for skin mechanics. For example, we have recently published a study showing only minor differences between the mechanics of young and mature mouse skin. Thus, whether mechanical changes due to skin aging are well-represented in mouse skin is unclear. Similarly, there is a sparsity of data on sex differences in mouse skin mechanics as compared to those in human skin mechanics. Therefore, the goal of our work is to answer some of these questions. Specifically, we set out to systematically study the histo-mechanical properties of young and old mouse skin of both sexes and to compare our observed differences to what is known about human skin.

METHODS

Towards this objective, we used 12-week (young) and 80-week (old) C57BL/6 mice, both male and female. After sacrificing the mice, we applied a 6 mm x 6 mm square ink stamp to dorsal and ventral skin regions of the mice and excised the tissue as 10 mm x 10 mm square samples. Subsequently, we photographed the excised tissue while floating on 1x PBS to compare the stamp size before and after the excision. Thereby, we determined the prestrain between the *in vivo* (pre-excision) and floating (post-excision, stress-free) configurations (Figure 1). Prior to mounting the samples for biaxial testing, we measured their average thicknesses with a digital thickness gauge and speckled the epidermal side with graphite powder for digital image correlation (DIC). We then mounted, preconditioned, and tested each sample in equibiaxial tension. In the following analysis, we isolated and analyzed the final downstroke of the equibiaxial tests. Next, we transformed the force-displacement data into Cauchy stress-stretch data via the samples' cross-sectional areas and the acquired true strains via DIC. To

quantitatively compare biaxial data from different groups, we next computed three metrics for each sample: toe stiffness (i.e., stiffness at small strains), calf stiffness (i.e., stiffness at large strains), and transition stretch (i.e., the stretch at which data showed clear strain-stiffening), in the lateral and cranial-caudal directions.

Figure 1: We stamped skin regions *in vivo* before excision and photographed them while floating on 1x PBS.

We also determined the thicknesses of different skin layers of each group from Masson's Trichrome histological images. Moreover, we performed hydroxyproline and BCA assays to acquire the normalized collagen content of the skin samples from each group. Lastly, to analyze the *in vitro* collagen fiber orientation, we used second harmonic generation (SHG) with a two-photon microscope. We used the orientation distribution analysis with a Gaussian gradient method in ImageJ-FIJI OrientationJ, and subsequently fit a symmetric von Mises distributions to the raw data to estimate the distribution's location parameter $\tilde{\mu}$ and concentration parameter $\tilde{\kappa}$ as a function of imaging depth. Please note, we only showed representative results for each experiment given the constraints of the abstract format.

RESULTS

In Figure 2, we showed that skin samples shrank upon excision as quantified by Green-Lagrange strain. This strain differed significantly between the lateral and cranial-caudal directions ($p < 0.001$) in all

groups. Additionally, we observed differences due to sex in some groups, but not due to age.

Figure 2: Green-Lagrange strain between *in vivo* configurations and floating configurations.

Figure 3: Biaxial mechanics showed that mouse skin is more compliant in lateral direction on the ventral side.

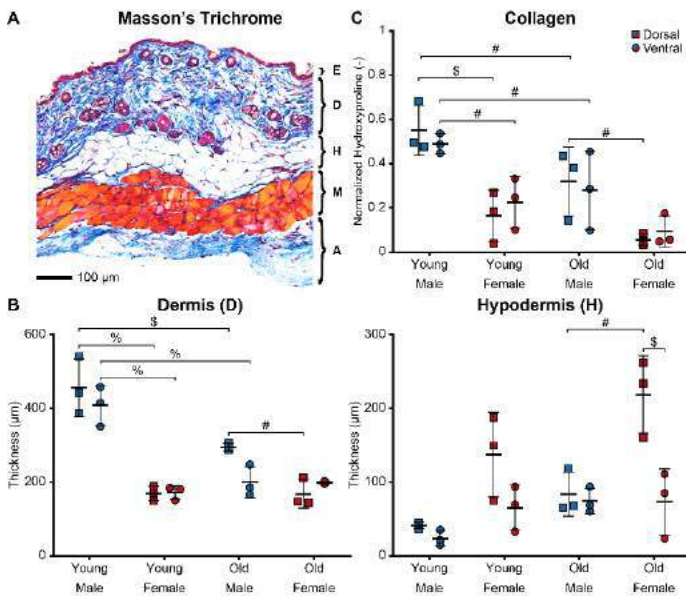

Figure 4: (A) Representative image of mouse skin layers stained with Masson's Trichrome. (B) Thickness measurements of dermis and hypodermis layers of mouse skin from each group. (C) Normalized collagen content of mouse skin from each group.

We observed a classic J-shaped stress-stretch curve for all samples in the biaxial data. In Figure 3, we reported skin stiffness as the tangent moduli (i.e., the slopes of the equibiaxial data) in the “calf region” at 0.15 MPa. We found some differences with age, but none with sex. The calf stiffness significantly varied between the lateral and cranial-caudal directions ($p < 0.05$) in all groups on the ventral side.

Figure 4A depicted a histological image of mouse skin: epidermis (E), dermis (D), hypodermis (H), muscle (M) and adventitia (A). We found significant differences with both sex and age in dermal thickness (Figure 3B) and also found that the differences among the groups were consistent with the normalized collagen content shown in Figure 4C. That is, the collagen content of mouse skin decreased with age in both male and female mice. Moreover, hypodermis layers of old and female skin appeared to be thicker (Figure 4B). However, these differences were only significant in two comparisons.

Figure 5A illustrated the representative von Mises probability density function of collagen fiber orientation from three young male mouse skin samples by depth, with the averaged orientation distribution projected underneath. Qualitatively, these data suggested that collagen fibers are widely dispersed with a mean orientation in the lateral direction (Figure 5B). Statistically comparing the distribution's location parameter $\tilde{\mu}$ and concentration parameter $\tilde{\kappa}$ of the collagen orientation distributions for sample sex, age, location, and depth only revealed differences due to depth ($p < 0.01$).

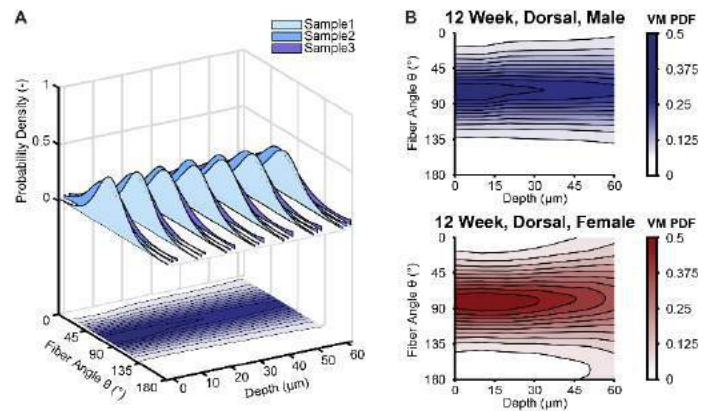

Figure 5: (A) Representative plot of von Mises collagen orientation histograms by depth and the projected orientation distribution. (B) Collagen orientation distributions of dorsal skin samples from young male and female mice ($n = 3$).

DISCUSSION

We investigated sex and age-dependent histo-mechanical properties of mouse skin using young/old, male/female, dorsal/ventral mouse skin samples (a total of 152 individual skin samples). Of note in our findings was that the calf stiffness dropped significantly during normal aging in male mice, yet there were almost no significant differences between young and old female mice. This contrasts with findings in human skin, where the mechanical properties of male and female skin have both been found to decline with age [1]. In contrast, we found that mouse skin thinned with age, independent of sex, which is congruent with findings in humans [2]. Specifically, mouse skin thinned with age, and collagen concentration – the principal component of the dermis – also decreased with age (mostly in old mice). In summary, we found good agreement between aging skin from male and female mice with aging skin in humans.

INTRODUCTION

Chronic pulmonary diseases are devastating, lifelong conditions, affecting an estimated 545 million people worldwide, with annual per-patient costs of over \$200,000¹⁻³. Despite the egregious effects of conditions such as pulmonary fibrosis and chronic obstructive pulmonary disease (COPD), diagnostics and treatment tools are lacking^{1,2,4}. In recent years, research into early detection of chronic conditions has received more attention⁵, as current diagnostic strategies consisting of expensive imaging and invasive biopsies limit clinicians' disease detection capabilities to only advanced stages². Improved inexpensive and noninvasive screening processes are necessary to facilitate the potential for early medical intervention.

Lung mechanics, determined from pressure-volume (PV) curves, are altered in diseased states, and may serve as an effective diagnostic tool^{6,7}. However, explorations of changes to the PV curve in diseased states as conducted in the laboratory on animal models are principally limited to artificial positive pressure ventilation as opposed to negative pressure ventilation, which more closely mimics physiological breathing⁸. To fully evaluate the diagnostic potential of PV curves, it is crucial to determine whether pulmonary mechanics are also measurably altered in curves collected under physiologically representative negative pressure breathing. As such, here we investigate the comparability and potential dissimilarity of PV curves collected from healthy, emphysemic, and fibrotic lungs under negative-pressure ventilation compared to previously published positive-pressure ventilation studies.

METHODS

Twenty mouse lungs (29.4 ± 2.9 g, 8-12 weeks old) were collected from male C57BL/6J mice purchased through Jackson Laboratory (Bar Harbor, ME, USA) and separated into four treatment groups following published protocols^{9,10}. The treatment groups are as follows: (1) Mice (n=5) were subjected to a single intranasal instillation of elastase and housed for 4 weeks to simulate emphysema. (2) Mice (n=5) were given

a single instillation of phosphate buffered saline (PBS) and aged for 4 weeks to provide an aged-matched control for group 1. (3) To induce fibrosis, mice (n=5) were subjected to chronic dust exposure via intranasal agricultural dust thrice weekly for 21 weeks. (4) Mice (n=5) intranasally received PBS thrice weekly to serve as the aged-matched control group to the fibrosis treatment group 3¹⁰. Lungs were dissected as previously outlined¹¹ and negative pressure cyclic inflation was imposed, utilizing our validated electromechanical testing apparatus⁸. A 5 cmH₂O preload was applied followed by four inflation-deflation cycles. The first three cycles served to precondition the lungs and the fourth cycle was analyzed. Two breathing frequencies (10 and 20 breaths per minute, BPM) and two inflation volumes (0.7 and 0.9 ml) were tested¹². The emphysema and fibrotic groups were most sensitive to 10 BPM and 20 BPM, respectively; as such, these results are reported.

Four pulmonary measures (e.g., compliance, peak pressure, inflation compliance C_{inf} , and deflation compliance C_{def}) were analyzed for each treatment group (control and exposed represented by grey and orange, respectively in Figure 1). C_{def} and C_{inf} were calculated as the PV curve tangent via linear regression ($R^2 > 0.99$) using MATLAB, according to previously described methods^{8,12} (Figures 1A, 1F). Mean \pm standard deviation (SD) of calculated measures for emphysema and fibrosis groups are represented by Figures 1B-F and 1G-J respectively. Statistical analysis of mean \pm SD of all samples was investigated by Wilcoxon signed-rank test (GraphPad Prism 9).

RESULTS

Representative specimens PV curves, generated from the pressure and volume data collected during cyclic inflation testing, demonstrate disparate healthy (grey) and diseased (orange) PV curve shapes and contrasting slopes (Figures 1A, F).

For three of the four mechanical measures considered (static compliance, peak pressure, and inflation compliance), alterations between control and exposed groups were significant. Specifically, in

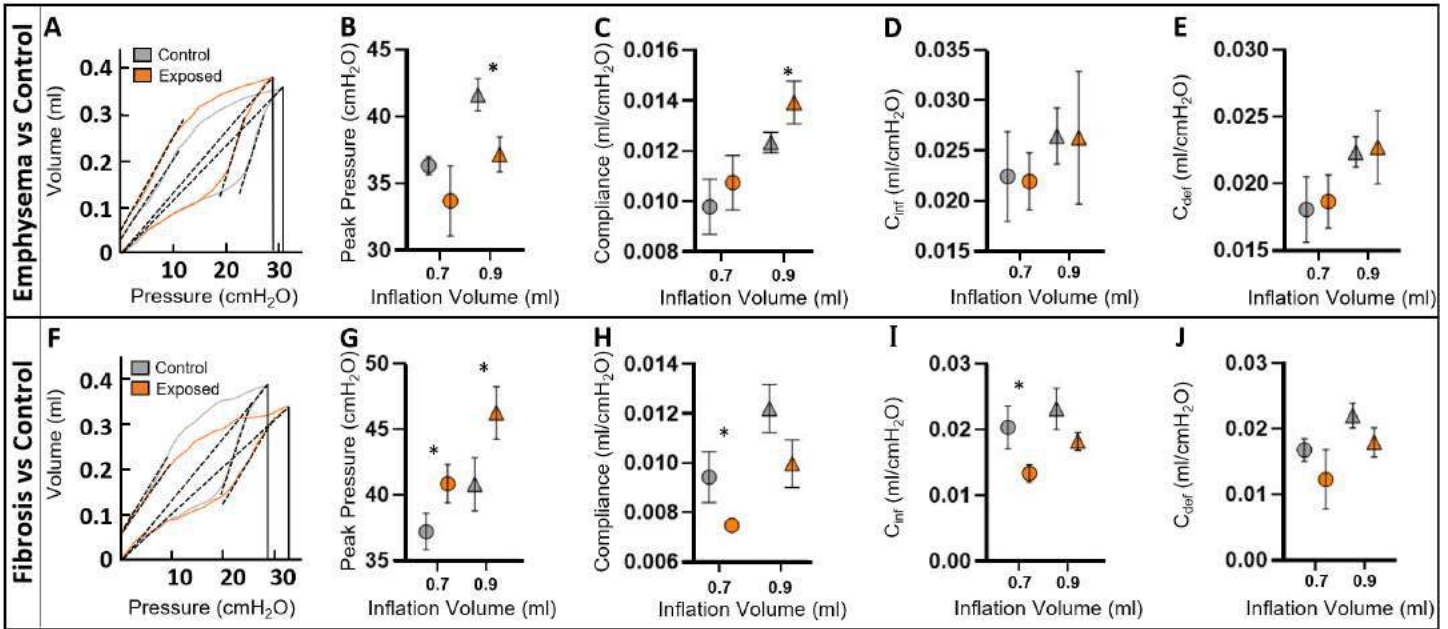

Figure 1: (A & F) PV curves and analyzed features demonstrating healthy controls (grey) compared to exposed diseased (orange) subjects. Resulting lung mechanics reported as mean \pm SD comparing control (grey) and exposed (orange) groups: (B & G) peak pressure, (C & H) static compliance, (D & I) inflation compliance, (E & J) deflation compliance. (Top) Results from emphysema treatment group at 10 BPM for inflation volumes 0.7 (circle) and 0.9 ml (triangle). (Bottom) Results from fibrosis treatment group at 20 BPM for inflation volumes 0.7 (circle) and 0.9 ml (triangle).

the emphysema treatment group, significancies occurred solely at 0.9 ml for static compliance and peak pressure (Figure 1B and 1C). In the fibrosis treatment group, static compliance, peak pressure, and inflation compliance were significantly altered at 0.7 ml (Figure 1G-1I). Peak pressure was also significantly varied between the control and exposed group at the larger volume of 0.9 ml.

DISCUSSION

We find that under negative pressure loading, static compliance and peak pressure are significantly altered in both emphysema and fibrosis with reverse trends between the two exposure groups (i.e., in comparison to healthy counterparts, peak pressure increases in fibrotic lungs but decreases in emphysemic lungs and the compliance increases in emphysema but decreases in fibrosis). Characteristic bulk lung inflation and deflation compliances measured from the PV curves are not significantly altered in emphysematous lungs, indicating comparable behavior despite alveolar damage. Conversely, the inflation compliance of fibrotic lungs is shown to significantly decrease compared to healthy counterparts; similarly, the deflation compliance exhibits a decreasing trend.

The static compliance trends seen in this negative-pressure study agree with reports from clinical studies^{6,13}. Altered compliance in fibrotic states is thought to result from the modified structure of the extracellular matrix, where increased levels of collagen result in stiffening of the entire structure, thereby limiting distensibility^{10,14,15}. Similarly, in emphysema, marked alveolar damage lowers the concentration of elastin, modifying lung compliance and shifting the PV curve upward and leftward^{16,17}. These respective trends are in agreement with both disease groups presented here.

Another potential biomarker of disease is deflation compliance⁷. In contradiction with our findings, prior investigation of positive-pressure PV curves from emphysema and fibrosis treatment groups indicates C_{def} is altered in both disease treatment groups⁷; C_{def} significancies are not observed in this study. The lack of C_{def} dependencies under negative

pressure ventilation is unexpected, suggesting differences between the two ventilation modes. This prompts further study to investigate differences between lung mechanics under the two modes specific to behaviors manifesting in diseased states^{8,17}.

While C_{def} significancies are not present in this negative-pressure ventilation study, the use of tangential slopes as diseased markers is still promising. We find that when ventilating with negative pressure, C_{inf} is lower in fibrosis compared to control groups. Due to the connection between C_{inf} and alveolar recruitment, this suggests recruitment may differ in fibrotic lungs^{12,18}. The contrasting lack of C_{inf} dependencies in emphysematous tissue is unexpected given the known manifestation of alveolar damage. In conclusion, we find in this study that biomarkers traditionally present under positive pressure loading are not consistently translatable to negative pressure physiological loading.

HIGH-THROUGHPUT AUTOMATED MECHANICAL ANALYSIS OF HUMAN INDUCED PLURIPOTENT STEM CELL DERIVED CARDIAC MICROTISSUE

H. Kobeissi (1), E. Lejeune (1)

(1) Department of Mechanical Engineering, Boston University, Boston, MA, USA

INTRODUCTION

Despite recent advances in cardiovascular disease prevention and diagnosis [1,2], heart disease remains the most common cause of death among adults globally [3]. To be able to alleviate this immense health burden, the disease mechanisms must be understood. Furthermore, human cardiac tissue has poor regenerative ability, and any damage to the heart muscle is irreversible [4]. More than a decade since their development in Yamanaka's lab [5], human induced pluripotent stem cells (hiPSCs) differentiated into cardiomyocytes (CMs) offer promising in-vitro platforms for different applications including disease modeling, drug discovery, and regenerative tissue engineering [6,7,8]. Yet, with the attractive opportunities that hiPSCs offer for advancing cardiac research comes a key limitation: they are physiologically immature. They resemble fetal CMs that are not only morphologically distinct from adult CMs, but also function differently [8].

One method to promote physical maturity of hiPSC-CMs involves employing different culture platform designs that allow for mechanical, electrical, or magnetic actuation. Each of these two-dimensional or three-dimensional constructs has its own advantages and challenges [9,10,11,12] (Fig. 1). With the variability of implemented setups and preparation methods arises a need to develop protocols to collect and compare testing data on these different constructs and assess cardiac microtissue characteristics and functional maturity. Available image-based data extraction and analysis software at the microtissue scale measure contractile kinetics such as contraction/relaxation velocities and contraction frequency in 2D cultures where the contractile direction is preferably organized in the uniaxial direction [13]. Despite this prior work, the research community is still lacking software tools to reliably assess the mechanical function of these tissue constructs. Here, we present our ongoing work in: (1) developing methods and metrics for analyzing the mechanical function of beating hiPSC derived microtissue

constructs, and (2) deploying these methods as automated analysis tools released under open-source software licenses.

METHODS

In this Section, we present our open-source computational framework, "Microbundle Compute", that tracks the contractile action of beating microtissue across bright-field frames and computes full-field displacement and subdomain-averaged strain results. In brief, our software builds on OpenCV's implementation of the Lucas-Kanade sparse optical flow algorithm [14]. In our implementation, the tracking points are Shi-Tomasi corner points (points at which a slight shift in location leads to "large" changes in intensity along both main horizontal and vertical axes) [15] computed on the first frame of the movie (Fig. 1). Notably, our approach relies solely on the natural contrast of bright-field microtissue images and the resulting intensity gradients which makes it straightforward to implement in the experimental setting. From tracking these points across consecutive frames, we are able to compute full-field displacement, strain, and strain derived metrics to quantitatively capture mechanical function.

Figure 1: Examples of different cardiac microtissue culture platform designs with detected track points in a segmented mask region of the microtissue domain.

Figure 2: Pipeline for generating synthetic data. The main steps include segmenting a real movie frame to extract both the tissue contour coordinates and the tissue texture. FEA simulation results are used to warp the tissue texture following a realistic deformation pattern.

To validate our approach and ensure that experimental images have sufficient spatial and temporal resolution for the chosen algorithms, we implemented a pipeline for generating synthetic data with a known ground truth. Specifically, we extracted the microtissue component of a microbundle movie frame and generated, from its contour coordinates, a microtissue mesh. We ran Finite Element simulations and extracted displacement results. Finally, we estimated projective transformations based on the deformed microtissue model and warped the image texture accordingly (see Fig. 2). Notably, this pipeline combined with our diverse set of sample experimental datasets, led to many improvements in our software such as image drift correction and smoothing. In addition, this synthetic data pipeline made it possible to design metrics (e.g., synchrony metrics derived from Green-Lagrange subdomain strain timeseries) that would be robust to confounding factors such as image corruption with realistic experimental noise.

RESULTS

In this Section, we briefly present example results from applying our computational framework to the multiple cardiac microtissue platform designs shown in Figure 1. In Figure 3, we show results for full-field absolute displacement (top left), full-field displacement in x-direction (top right), and average subdomain strain in x-direction (E_{xx}) (bottom left) and its time series plot (bottom right) at the automatically identified peak of the first beat of the movie. These plots show the heterogeneous behavior of the cardiac tissue and highlight regions where the microtissue experiences tensile versus compressive strains.

Figure 3: Example results of “Microbundle Compute” software.

Notably, all software functionality is implemented in a test-driven development framework with 100% code coverage and automatic testing on ubuntu, windows, and macOS platforms implemented through GitHub Actions. To date, the lite version of our software (with

the more robustly tested functions) is available under an open-source MIT License on GitHub (<https://github.com/elejeune11/MicroBundleCompute-Lite>). In addition, the code to implement our synthetic data pipeline and the entire synthetic dataset are available on GitHub (<https://github.com/HibaKob/SyntheticMicroBundle>) under MIT license.

DISCUSSION

Here, we briefly presented a summary of the main capabilities of our software in analyzing movies of beating cardiac microtissue. The results clearly show the feasibility and significance for developing computational tools to automatically extract meaningful mechanical metrics from this type of imaging data. Without such tools, the anticipated heterogeneous contractile behavior of the microtissue would be very challenging to quantify. Furthermore, being able to implement the same pipeline and extract quantitatively related results on different testing platforms allows us to meaningfully assess microtissue behavior across multiple in-vitro culture conditions. Ongoing work includes: (1) adding functionality to automatically assess additional experimental platforms, (2) integrating with calcium imaging, (3) integrating with microstructural imaging, (4) using machine learning based data analysis techniques to identify patterns in these datasets, and (5) using these results to directly inform computational models. By making our software open-source and disseminating it from this early stage, we aim to collect feedback from potential users to further improve the software interface, computed output, and result visualization to maximally benefit the research community.

SURGICAL AUGEMENTATION AND PRESERVATION OF REMNANT ACL TISSUE BEST RESTORES KNEE FUNCTION AFTER PARTIAL ACL INJURY

INTRODUCTION

Partial anterior cruciate ligament (pACL) injuries pose a treatment dilemma in skeletally immature athletes. Particularly in cases where the pACL injury is local to the posterolateral bundle (PLB), pACL injuries are associated with recurrent instability and high risk of reinjury with return to sports [1]. Standard surgical treatments for these pACL injuries require removal of any remaining intact ACL tissue for adequate visualization in the ACL reconstruction (ACLR) procedure. However, physeal sparing ACLR using an iliotibial band (ITB) graft instead supplements any remaining ACL tissue with two stages of the reconstruction procedure: a lateral extra-articular tenodesis (LET) and the ITB ACLR fixation [2]. LET procedures independently have gained popularity as a secondary procedure during standard ACLR surgeries in patients with hyperlaxity or a high risk of reinjury. The purpose of this study was to evaluate the biomechanical responses at both the joint and tissue level of the knee to pACL injuries in the PLB, and to assess LET and ITB ACLR procedures both with and without maintenance of the remnant ACL tissue. We hypothesized that tissue-retaining surgical procedures will result in the closest kinematics to the native knee, and that graft tissue and remnant ACL tissue will share loads in cases where both are present, limiting the risk of secondary failure for either.

METHODS

Five cadaveric human knees (2F/3M) were collected and prepared for robotic testing [3]. Mechanical testing was performed on a 6 degree-of-freedom (6DOF) universal force-sensing robotic testing system (Figure 1) [3] to assess knee joint kinetics and kinematics under three common clinical testing modalities: the Lachman, Slocum, and Pivot-Shift exams. The Lachman exam consisted of kinematically fixing the knee in 30° of flexion, applying a ramped anterior tibial load from 0N-100N-0N, maintaining a compression load of 50N, and minimizing loads in all other directions. The Slocum exam involved kinematically fixing the knee in 80° of flexion, applying a ramped anterior tibial load

from 0N-100N-0N, maintaining kinetic internal and valgus moments of 3N*m, and maintaining 50N of compression. The Pivot-Shift exam was designed to maintain 5N*m of internal and valgus moments and 50N of compression loads, and vary the flexion angle of the knee from 10°-50°-10° during the test.

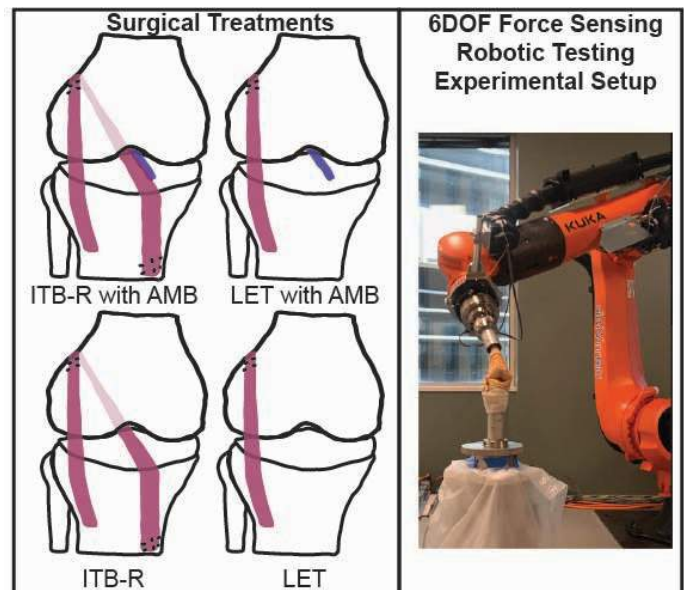

Figure 1: Surgical treatments consisted of lateral extra-articular tenodesis (LET) and all-outside iliotibial band (ITB-R) anterior cruciate ligament reconstructions (ACLR) with or without the anteromedial bundle (AMB) or the ACL intact. Testing was performed on a multiaxial robotic system.

Each test was performed with hybrid kinetic and kinematic controls in the following states: intact ACL, partial injury (PL bundle injury), AM bundle + LET, AM bundle + ITB ACLR, LET, and ITB ACLR (Figure 1). Kinematics were repeated after serial dissections of the tissues of interest: the AM bundle, PL bundle, LET graft, and the ITB ACLR graft. Knee joint kinematics were collected directly from the robotic software (simVITRO, Cleveland Clinic), and calculations were performed using the principle of superposition to assess the 6DOF and resultant loads carried in each tissue [4]. Statistical comparisons consisted of ANOVA testing with kinematic path and knee state as main effects, while individual knees were treated as repeated measures.

RESULTS

Partial and complete ACL injuries both resulted in kinematic destabilization of the knee joints, with respective increases in anterior translation of 0.1 mm and 4.6 mm for the Lachman exam, 0.1 mm and 3.4 mm for the Slocum exam, and 0.03 mm and 0.03 mm for the Pivot-Shift exam. These effects were compounded by destabilization in the other DOFs, with the average resultant translations for each exam shown in Figure 2. Knee joint kinematics were best restored to the intact state in cases where the ITB ACLR was performed with the anteromedial (AM) bundle of the ACL remaining intact. However, in the Pivot-Shift exam, this approach resulted in a slight over-constraint of the knee in the immediate outcome. Across tests, maintenance of the AM bundle resulted in significantly lower laxity measurements compared to LET or ITB ACLR procedures without the AM bundle.

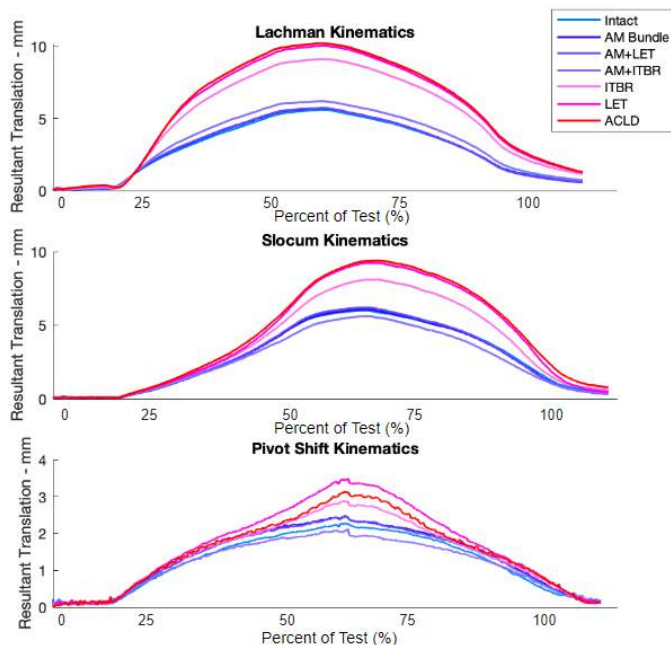

Figure 2: Resultant translations of the tibia during Lachman, Slocum, and Pivot-Shift testing across all joint states of interest.

With applied anterior loads of 100N (Lachman and Slocum) and valgus and internal moments of 3N*m (Slocum) or 5N*m (Pivot-Shift), resultant forces in the knee reached peaks at or slightly above 100N during robotic testing. In the intact knee, these loads were carried primarily by the ACL, with forces split between AM and PL bundles. Specific splits varied between testing modalities, with the AM bundle carrying 70% of the peak ACL load in the Lachman exam, 38% in the Slocum exam, and 74% in the Pivot-Shift exam (Table 1).

Table 1: Peak resultant loads carried in anteromedial (AM) and posterolateral (PL) bundles of the anterior cruciate ligament (ACL) and graft tissues in each surgical case.

Peak Resultant Loads in Tissues Across Clinical Exams			
Test Kinematics	Lachman	Slocum	Pivot-Shift
Intact Case			
ACL	106.5 N	71.3 N	67.7 N
AM Bundle	74.6 N	27.0 N	49.8 N
PL Bundle	24.9 N	32.2 N	81.8 N
Augmented LET Surgical Treatment			
AM Bundle	110.6 N	38.4 N	52.9 N
LET Graft	13.7 N	18.1 N	20.7 N
Augmented ITB ACLR Surgical Treatment			
AM Bundle	87.7 N	28.9 N	44.6 N
ITB Graft	22.8 N	24.4 N	29.5 N
LET Surgical Treatment			
LET Graft	21.9 N	21.6 N	25.8 N
ITB ACLR Surgical Treatment			
ITB Graft	64.8 N	32.5 N	44.8 N

Surgical treatments resulted in significant changes to the loading in the knee joint tissues, with both the grafts and the remnant AM bundle carrying substantial loads (Table 1). When the AM bundle remained in the knee, it carried at least 28.9N of resultant load at peak translation, relieving the forces experienced in the surgical graft tissue. In all cases, removal of the AM bundle resulted in significant increases in the load carried by the graft tissue for both LET and ITB ACLR procedures, with remaining loads accounted for by secondary restraining tissues.

DISCUSSION

The AM bundle-retaining ITB ACLR procedure resulted in the greatest stability, best replicating intact knee kinematics after a partial ACL injury, especially in Lachman and Slocum tests. Interestingly, the AM bundle retaining ITB ACLR procedure overconstrained the knee in the Pivot-Shift test. All surgical interventions restored some stability to the joint compared to partial and complete ACL injury cases, and both techniques were improved when maintaining the AM bundle. The AM bundle relieved loads in both the LET and ITB ACLR graft tissues, suggesting that in cases where the remnant ACL is left intact, load-sharing across tissues should decrease the likelihood of future graft rupture. This study was limited to analysis of partial injury to the PL bundle, with the entire AM bundle remaining intact. In the clinic, partial ACL injuries may affect any percentage of each bundle, potentially limiting the translation of this study to clinical cases with varied injury characteristics. Additionally, this study was limited to assessing the acute functional impacts of these treatments, while clinical outcomes may be affected by graft lengthening or other known long-term effects. Overall, this study suggests that in partial ACL injury cases, LET and ITB ACLR treatments preserving the remnant ACL tissue may be ideal solutions for restoring knee function, especially in young populations where all-outside treatments are desirable.

COMPUTATIONAL MODELING STUDY OF THE EFFECTS OF PULMONARY HYPERTENSION ON RIGHT HEART PERFUSION

Lei Fan (1), Jenny S. Choy (2), Ghassan S. Kassab (2), Lik Chuan Lee (1)

INTRODUCTION

Right heart failure is the leading cause of death in patients with pulmonary hypertension (PH), which is associated with an elevated mean pulmonary artery pressure (mPAP) greater than 25 mmHg. The underlying mechanisms of how PH affects right heart perfusion (that may in turn cause right heart failure) are not well-understood. While several computational models have been developed to investigate PH, they do not consider right heart perfusion. To address this limitation, a novel computational model coupling a biventricular finite element (FE) model with the main coronary branches and their corresponding microvascular networks, including those in the right ventricle (RV) is developed. The model is applied to quantify the effects of acute and chronic PH on biventricular mechanics and perfusion on both the left ventricle (LV) and RV.

METHODS

The computational framework that couples a biventricular FE model with blood flow in the microvascular networks associated with right coronary artery (RCA), left anterior descending (LAD) and left circumflex (LCx) arteries is developed. Besides the coronary circulation, the framework also considers the systemic and pulmonary circulations in a closed-loop system (**Fig. 1**). The framework consists of four cardiovascular components associated with the ventricle, atrium, arteries and veins, each in the systemic and pulmonary circulations. Conservation of total mass of blood in the circulatory model requires the change of inflow and out flow rates of each compartment be related to the rate of change of the volume. The functional relationship between the LV and RV pressures and volumes is obtained by minimizing a Lagrangian function consisting of myocardial tissue strain energy function and terms associated with the enforcement of constraints on 1) myocardial tissue incompressibility, 2) zero-mean rigid body translation and rotation, and 3) cavity volume [1]. Mechanical behavior of the biventricular unit is modeled using an active stress formulation, in

which the passive and active mechanical behaviors are described, respectively, by a Fung-type strain energy function and a modified time-varying elastance model [2-3]. The left atrium and right atrium are described by time-varying elastance models. There are a total of 12 microvascular 400-vessel networks [4] located at the endocardium, mid-wall and epicardium regions associated with the perfusion territories of RCA, LAD, LCx and posterior descending artery (PDA).

Fig. 1: Schematic of the closed-loop lumped parameter framework that couples the FE biventricular model with coronary networks at endocardium, mid-wall and epicardium regions of the RCA, LAD and LCx.

Intramyocardial pressure (IMP), which varies across regions in the biventricular unit, is imposed on each vessel. Invoking mass conservation across different vessels in each network results in a system of ODEs in terms of the unknown pressures in each vessel. The ODEs are solved using the backward differentiation formula in the freely available library CVODE.

The model was first calibrated to predict cavity pressure and volume waveforms of the LV and RV, as well as the PAP waveform associated with a health human (baseline). The calibrated model was then applied to simulate **1)** different degree of acute PH (without remodeling) by increasing the PA resistance, R_{pa} , and reducing the preload, V_{sv0} to keep the ratio of end-diastolic volume (EDV) of RV/LV below 1.5; **2)** chronic PH (with remodeling) by increasing the RV free wall (FW) thickness from 3 mm to 9 mm. For each simulation, we also considered the case when the PDA was supplied by RCA or LCx in right- and left-dominant heart, respectively.

RESULTS

Peak RV pressure and mPAP are increased from 23 to 60 mmHg and from 14 to 49 mmHg, respectively, from baseline (base) to acute PH at different degree (PH+ and PH++) (Fig. 2a). LVEDV is reduced by 5 ml but RVEDV is increased from 96 to 111 ml (Fig. 2b). Intramyocardial pressures at different transmural locations are increased in the RVFW and septum but is unchanged in the LVFW in acute PH compared to baseline (Fig. 2c). As a result, transmural distribution of total coronary flow is reduced in the RCA and the RV in acute PH. This reduction is more significant in right-dominant heart than left-dominant heart (Fig. 2d). Transmural distribution of total coronary flow is relatively unchanged in the LCx of the right-dominant heart as both perfusion pressure and IMP in the LVFW do not change with in acute PH. Flow in the LCx of left-dominant heart, however, is reduced because the increased IMP at the septum impedes more flow in the PDA (Fig. 2e). Flow rate waveform of the RCA is also different in the left- and right-dominant heart (Fig. 2f). In the right-dominant heart, flow rate in the RCA is reduced during systole due to effects of higher IMP at septum on PDA whereas in the left-dominant heart, RCA flow rate waveform follows the perfusion pressure waveform. In chronic PH where RV wall thickness is increased, the model predicts that blood flow is reduced more in the RCA, LAD and LCx microvascular networks at the endocardium than acute PH (Fig. 2g-i). This reduction is more than that found at the epicardium.

DISCUSSION

We developed a novel computational modeling framework coupling a biventricular FE model with coronary perfusion at different transmural locations in the RVFW, septum and LVFW. We apply the model to investigate the effects of PH on heart perfusion. The key findings are **1)** IMPs at different transmural locations of the RVFW and epicardium of the septum are increased in PH, which reduce coronary flow in the RVFW and septum, as well as in the LCx network in the chronic PH; **2)** the coronary flow in RVFW is reduced more at the endocardium than epicardium in PH, suggesting that endocardium is more vulnerable to ischemia with PH; **3)** the coronary flow in LCx is reduced more in the left-dominant heart than the right-dominant heart in PH, suggesting left-dominant LCx is more vulnerable to ischemia with PH. These findings suggest that right heart perfusion is affected by PH and may contribute to the development of right heart failure in PH.

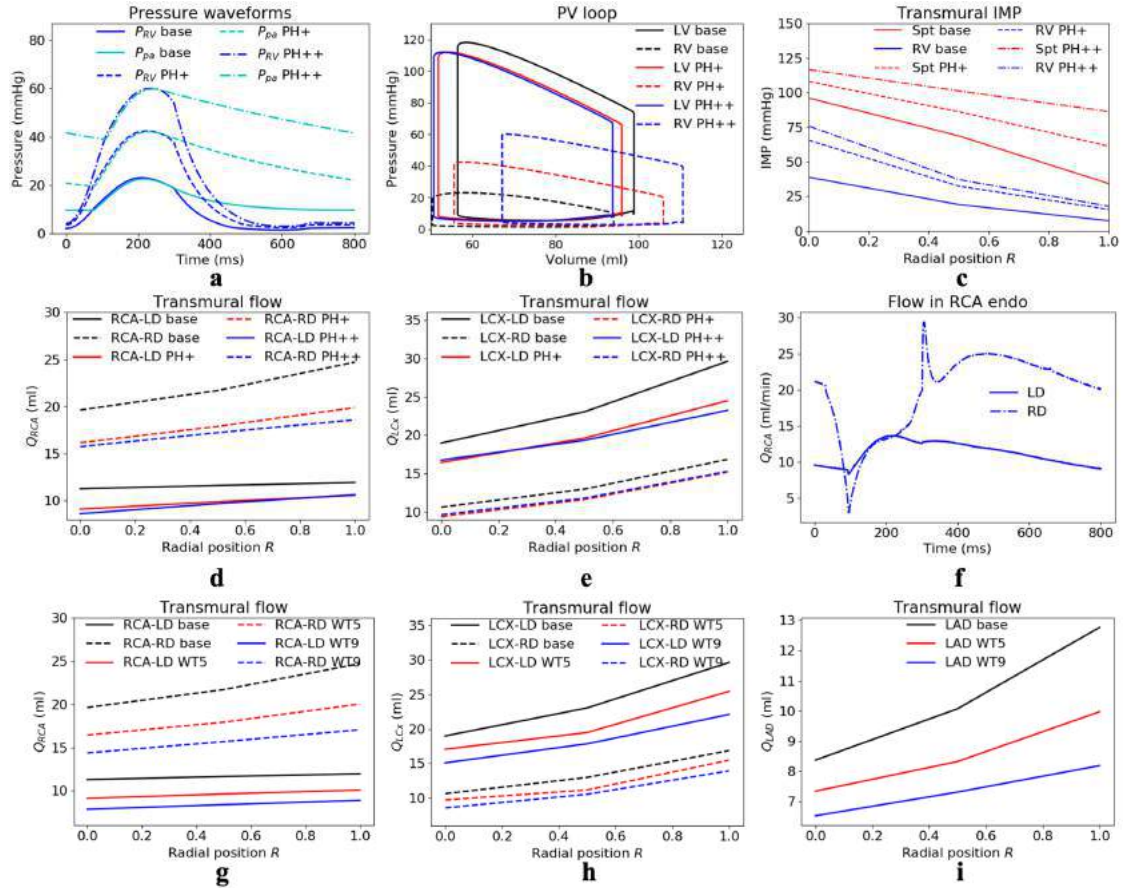

Fig. 2: Comparison of **a.** RV and PA pressures; **b.** LV and RV PV loops; transmural distribution of **c.** IMP in the LVFW, septum and RVFW; **d.** RCA total flow; **e.** LCx total flow, in baseline and acute PH. **f.** representative RCA flow rate waveforms at endocardium in the left- and right-dominant heart. Comparison of total flow in **g.** RCA; **h.** LCx; **i.** LAD, in baseline and chronic PH.

INTRODUCTION

Diffuse midline glioma, specifically pontine and H3 K27M-altered, is the most common and unfortunately the deadliest brainstem tumor in children [1]. Current clinical treatment methods only involve palliative radiotherapy. These do not significantly improve survival beyond its poor mean survival of 9 months [2]. These tumors remain difficult to treat with chemotherapy as they maintain an intact blood brain barrier (BBB). Although, a technique using focused ultrasound (FUS) and microbubbles (MBs) has been shown to disrupt the blood brain barrier (BBBD) allowing larger chemotherapeutics to enter the parenchyma [3]. Panobinostat is one of the chemotherapeutics that has difficulty crossing the BBB however it has promising effects in vitro [4]. Therefore, in this study we hypothesized that using FUS, we could disrupt the BBB allowing a higher concentration of Panobinostat to enter the tumor region and provide a therapeutic effect.

METHODS

Mice were injected with BT-245 (DIPG tumor cell line) orthotopically into the pons, 1 mm laterally to the right hemisphere. Initial set of mice (n=12) had two weeks of growth. Magnetic Resonance (MR) images were then taken and used to guide FUS targeting to the center of the tumor location. In house microbubbles were size isolated to $3 \mu\text{m} \pm 0.5 \mu\text{m}$ and half of the mice (n=6) were injected via tail vein at 25 $\mu\text{l/kg}$ right before (10-20 seconds) sonication. Sonication parameters were as follows: center frequency: 1.515 MHz, peak negative pressure: 0.77 MPa, pulse length: 1 ms, pulse repetition frequency: 1 Hz. Sonication lasted for 3 minutes and passive cavitation data was collected and analyzed as previously described [5]. Directly after FUS Panobinostat (LBH-589) was given (10 mg/kg) intraperitoneally (IP) and MR images were taken to determine extent of BBBD. After 1.5 hours, mouse serum and brains were extracted and split at the midbrain and cerebellum. All three samples were sent in for liquid chromatography and mass spectrometry to determine concentration of

Panobinostat at each location.

The second set of mice (n=20) were treated weekly for three weeks. Half of which were treated with both FUS and Panobinostat with the same parameters to the first set, the other half was only given Panobinostat. After 3 weeks no treatment was done on either set. MR images were taken and body weight was examined weekly prior to treatment and after treatment period ended to evaluate extent of BBBD and tumor progression.

RESULTS

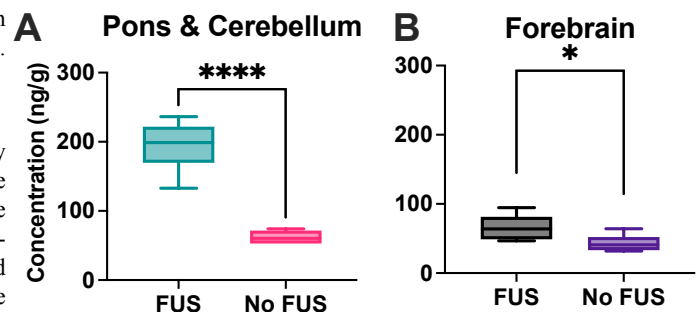

Figure 1: Concentration of Panobinostat found in the pons and cerebellum (A) and forebrain (B) 1.5 hours after FUS-mediated BBBD occurred (if applicable) and Panobinostat was injected IP. Analysis was done using mass spectrometry. Wiskers illustrate 10-90 percentile. Significance testing was done using student's t test (n=6). *, ** indicates $P < 0.05$ and $P < 0.0001$ respectively.**

We have demonstrated that FUS-mediated BBBD can successfully deliver Panobinostat (LBH-589) to the pons and cerebellum region with DMG tumors over 3-fold (Fig.1a) while only slightly increasing the concentration of the forebrain 51 percent (Fig. 1b).

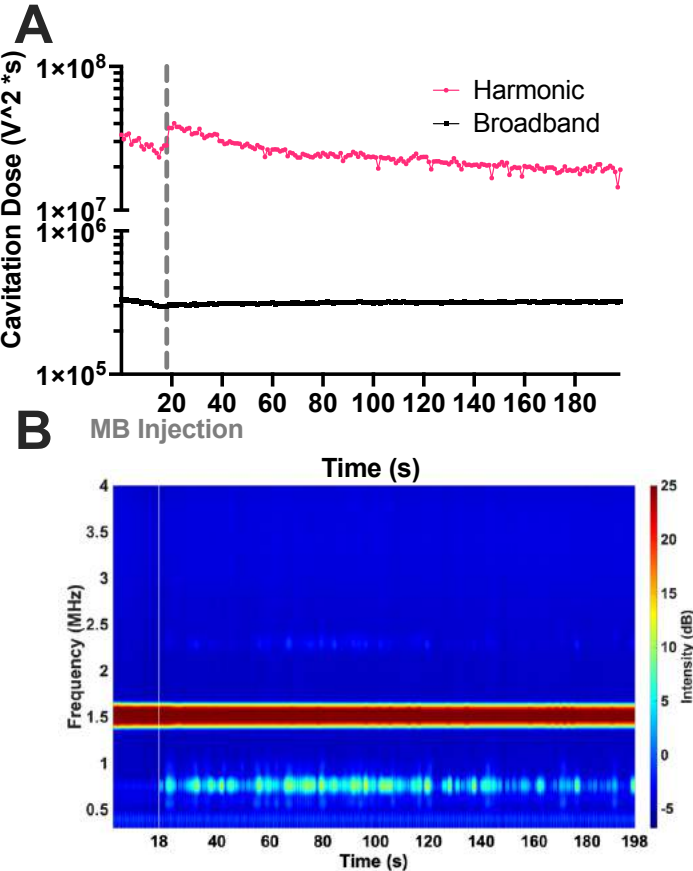

Figure 2: Passive cavitation detection during 3 minute treatments. A) Illustrates the harmonic and broadband cavitation dose (HCD and BCD respectively) found during each 10 ms pulse. Gray dotted line at 18 seconds represents the point where all microbubbles were injected. **B)** Spectrogram of total treatment. Non-sonication time between pulses were removed. White line at 18 seconds represent the time at which microbubbles were injected.

Passive cavitation detection (PCD) during treatments showed ideal harmonic cavitation throughout the 3 minutes while not having any significant broadband cavitation (Fig. 2a). Harmonic cavitation doses showed a spike right after injection of microbubbles and decay that matches the pharmacokinetics found for similar doses and compositions of microbubbles. PCD illustrates the presence of microbubbles in focal region with the introduction of sub- and ultra-harmonic responses only when microbubbles were injected (Fig. 2b).

Figure 3: Longitudinal analysis of tumor volume using MR images obtained weekly (A) and survival (B). Dotted gray lines on both plots represent the treatment days. Significance testing was done using student's t test for A, and Mantel-Cox test (n=10) for B, where *, **, *** indicates P <0.05, 0.01, and 0.001 respectively.

The combination of both Panobinostat and FUS showed major decreases in tumor growth by 71 percent by the end of the treatment weeks when compared to Panobinostat without FUS (Fig. 3a). A significant survival benefit was also demonstrated when treated with both Panobinostat and FUS improving the mean survival from 21 to 31.5 days (Fig. 3b).

DISCUSSION

Our study demonstrates that FUS-mediated BBBD can increase the delivery of Panobinostat (LBH-589) to an orthotopic DMG tumor (BT-245). The increased concentration exclusively at the tumor site was shown to significantly decrease tumor growth (71 percent) and significantly increase survival (50 percent). Therefore, we see a strong indication that this methodology can be used to improve the treatment of DMGs in patients.

ENHANCING CORRUPT CARDIOVASCULAR FLOW DATA WITH MACHINE LEARNING

Hunor Csala (1,2), Amirhossein Arzani (1,2)

(2) Scientific Computing and Imaging Institute, University of Utah, Salt Lake City, UT, USA

INTRODUCTION

Obtaining clean, high resolution velocity measurements of blood flow inside small arteries such as cerebral vasculature is challenging, as the existing experimental techniques have several limitations. Time-resolved three-dimensional phase contrast magnetic resonance imaging (4D flow MRI) is a popular approach in research settings, however it is constrained by low spatio-temporal resolution, noise, and other artifacts [1]. Particle image velocimetry (PIV) often considered the gold-standard in experimental fluid dynamics also suffers from some limitations. Therefore, handling corrupt blood flow data is key challenge towards developing more accurate and robust cardiovascular flow models. There are well developed algorithms in the machine learning community that can tackle similar issues, such as data imputation, denoising or outlier detection. Existing methods have been less frequently used and leveraged for complex real-world fluid flow problems [2], such as cardiovascular flows [3]. Specifically, we do not understand which one of these approaches commonly used in the machine learning community perform better for hemodynamics data. This study investigates and compares several techniques for filling in missing values and denoising unsteady blood flow data in an image-based 3D intracranial aneurysm model.

METHODS

Voxel-based data mimicking some of 4D flow MRI data features was created from computational fluid dynamics (CFD) simulation results. Pulsatile blood flow inside an internal carotid artery (ICA) aneurysm was simulated using SimVascular, a finite element numerical solver. The Reynolds number was 555, based on the maximum systolic inlet velocity and inlet diameter. A population averaged inlet waveform was used, 1000 snapshots were saved through one cardiac cycle. The unstructured mesh consisted of 6.6M elements, which was resampled to a voxelized grid with a uniform spatial resolution of 0.5 mm, resulting in 27000 voxels. Two types of data corruption were investigated here, missing data and Gaussian noise. These were artificially added to the voxelized data. Voxels were randomly removed in space and time for the missing data case and Gaussian noise was added for the noisy case. The process of creating corrupt synthetic voxel-

based data is illustrated in Figure 1. For the missing data case, the fraction of missing data was varied between 10% and 90%. For the denoising case, the fraction of noisy data was varied between 10% and 70%. The standard deviation of the added noise was 10% of the maximum velocity value.

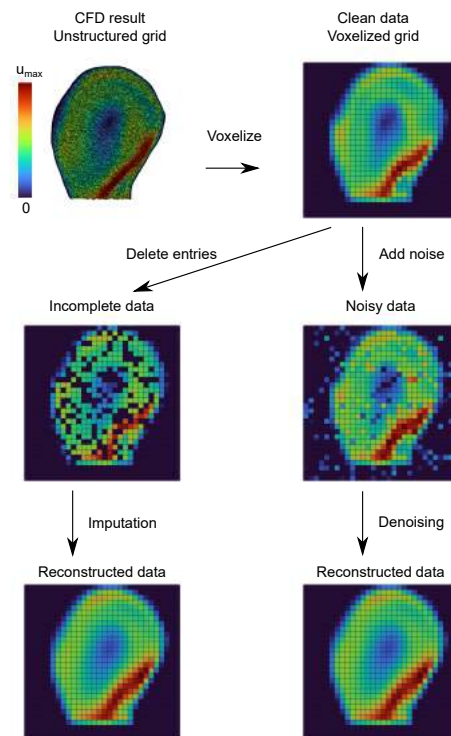

Figure 1: Process of creating corrupt voxel-based data from CFD results.

Imputation is the process of filling in missing data based on some statis-
SB³C2023-026

tics of the observable dataset. Four methods were used for data imputation: probabilistic principal component analysis (PPCA), iterative singular value decomposition (itSVD), softImpute, and an autoencoder. PPCA is a probabilistic version of PCA using the expectation-maximization (EM) algorithm. itSVD and softImpute are two techniques based on iterative low-rank SVD decompositions and soft-thresholding. The autoencoder approach is a fully-connected deep neural network that has a bottle-neck layer in the middle, whose dimensionality is much smaller than the input and output, therefore the network learns a low-dimensional embedding of the data.

Three algorithms were used for denoising: robust principal component analysis (RPCA), Noise2Noise autoencoder (N2N), and a conventional denoising autoencoder (DAE). RPCA tries to separate the data into a low-rank matrix containing the noise-free data and a sparse noise matrix. N2N is a neural network based denoising algorithm that does not require clean training data. That is, the input and the target data are both noisy data representing two samples from the same noise distribution. The DAE approach does denoising in a supervised fashion. It was trained with 7 simulations with different mean inlet velocities (Reynolds number ranging between 380 and 650, based on the systolic maximum inlet velocity) on the same geometry, then tested on unseen velocity data ($Re_{max} = 555$). The noise and missing data characteristics (fraction of data missing or noisy and noise standard deviation) were the same during training and testing. It is important to note that the matrix completion (itSVD, softImpute) and PCA-based methods (PPCA, RPCA) do not require training data.

RESULTS

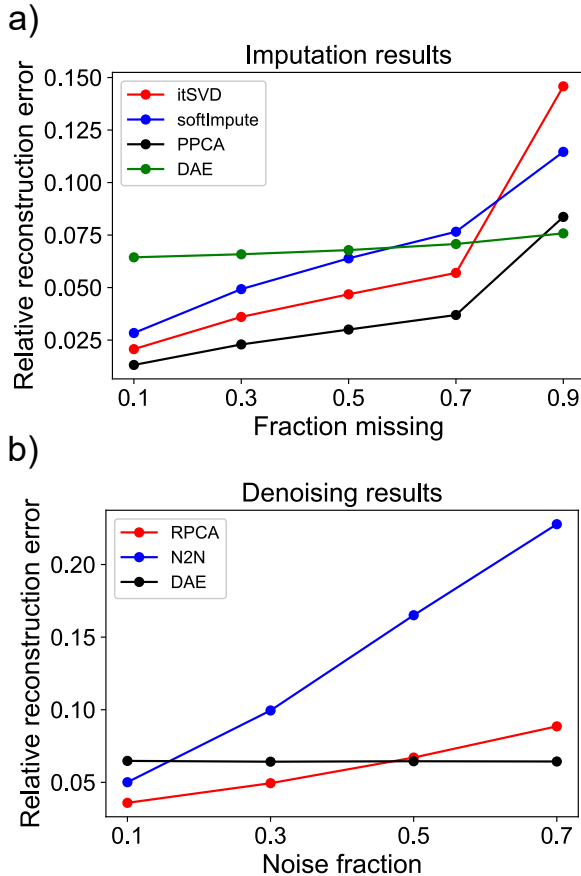

Figure 2: a) Imputation relative reconstruction error with different percentage of data missing. b) Denoising relative reconstruction error with different percentage of data being noisy.

Imputation and denoising results are shown in Figure 2, top and bottom panel, respectively. The relative reconstruction error ϵ is defined as

$$\epsilon = \frac{\|\mathbf{X} - \mathbf{X}_{rec}\|}{\|\mathbf{X}\|}, \quad (1)$$

where \mathbf{X} is the clean ground-truth data, \mathbf{X}_{rec} is the filled in or denoised data, and the Frobenius norm is used. In case of imputation, the two matrix completion methods (itSVD and softImpute) have similar results. PPCA has the lowest error in almost all cases. As the percentage of missing data grows the error increases, and a sharp rise can be seen at 90% missing data for these three methods. The autoencoder is much less sensitive to the amount of data missing, probably due to the nature of supervised learning, and its error is only slightly increasing as the fraction of missing data increases. Overall, all methods perform well and can fill in the missing entries in the aneurysm velocity data, as the relative reconstruction error is below 10% for most cases, and even for the highest missing fraction of 0.9 the error is less than 15% for all four techniques. This suggests that blood flow inside an aneurysm can be described well by an intrinsic low-dimensional model that can be inferred from a few data points.

For denoising, N2N has clearly inferior performance to the other methods. RPCA achieves good performance in the low-noise setting, while the DAE outperforms RPCA in the high-noise scenario. Again, the autoencoder errors does not seem to be depending too much on the fraction of noisy data. RPCA and DAE achieve an error smaller than 10% for all noise fractions, while for N2N the error exceeds 20% at 70% of noisy data.

DISCUSSION

We investigated several machine learning algorithms for handling corrupt blood flow data inside an ICA aneurysm. Matrix completion, PCA-based, and neural network-based techniques proved to be able to enhance blood flow data corrupted with randomly missing voxel entries and added Gaussian noise. Matrix factorization methods seem to be more useful in the low-corruption case, while for highly corrupted datasets neural networks perform better. Overall, these machine learning algorithms have the potential to significantly improve hemodynamic data quality and enable the creation of robust cardiovascular models.

Our findings suggest that neural networks are more valuable when dealing with highly corrupted datasets with available data for training. On the other hand, matrix completion and PCA-based methods can achieve excellent results with mildly corrupted data, without the need for clean training data. However, there is a serious limitation to the matrix completion and PCA methods. These methods assume that the missing data is random in space and time, and the noise is Gaussian noise. Without these assumptions, these methods could fail. On the other hand, if there is enough training data available, the autoencoder based methods can achieve good results, no matter the pattern of missing data or the characteristic of the noise. Obviously it is desired that the training and testing data have the same type of corruption. Creating models that can handle multiple noise or missing data characteristics is a future challenge that needs to be investigated.

Our future work includes extending this setup to real experimental data. Additionally, we are working on other types of data corruptions such as aliasing in 4D flow MRI, which could be treated using outlier detection algorithms.

DEVELOPMENT OF THREE – DIMENSIONAL FINITE ELEMENT MODEL OF THE NEONATAL BRACHIAL PLEXUS

INTRODUCTION

The brachial plexus is a complex system of nerves that connect to the cervical (C5-C8) and thoracic spinal cord (T1). This system of nerves is responsible for motor and sensory functions of the upper extremities. During the birthing process, vaginal or cesarian, these nerves are susceptible to an injury known as Neonatal Brachial Plexus Palsy (NBPP). NBPP occurs approximately 1-4/1,000 total births [1]. It has been documented clinically and through research that, for cephalic presentations with the fetal arm adducted against or across the body, the injury is initiated at C5 and progresses down to sequentially include the lower nerve roots.

Conducting research into the mechanism of NBPP is a challenge due to the vulnerable populations that it involves. Computational modeling is an ethically sound and scientifically valid method to explore this injury, as it allows parameters to be precisely controlled and varied within a known range of values – including nerve diameter and nerve root angle.

Key to obtaining precise estimates of localized stress and strain in the brachial plexus is having accurate anatomy, which has been a challenge to obtain. Medical images of the infant brachial plexus may be used; however, they have limitations due to obscured visuals that result from other anatomical structures (e.g., clavicle). Exploratory surgery is unlikely to occur as it is not ethically sound to experiment on this age of subjects.

The main objective of this study was to develop a 3D model of the brachial plexus and then conduct a simulation study to determine how injury to the upper nerve roots, through complete rupture or avulsion, affects the stress along the remainder of the brachial plexus.

METHODS

A computational neonatal brachial plexus model was created and analyzed using Solidworks software. The initial dimensions to create this model – diameters and lengths of the nerve roots and trunks – were

collected by the University of Michigan Neurosurgery Department during primary reconstructive surgery of infants [2]. The dimensions for the divisions, cords, and branches were determined based on their calculated ratios to the root and trunk dimensions, as estimated from images of adult brachial plexus using ImageJ. Figure 1 demonstrates the entire model that was created, including the anterior and posterior portions of the divisions.

Due to the lack of research done on human neonatal nerves, the material properties are unavailable. For this reason, properties determined from neonatal piglet brachial plexus nerves in an *in vivo* tensile stress analysis were used [2].

Figure 1: Three – Dimensional Brachial Plexus Model

The material properties, boundary conditions and external loads were added to the model within Solidworks. The entire spinal cord was subjected to an encasté boundary condition, in which all active structural degrees of freedom are constrained. No boundary conditions were used to constrain the anterior and posterior surfaces of the nerves. A tensile force was applied at the distal end of each nerve branch, as would occur with the depression of the shoulder while the head and neck remained aligned with the axis of the spine. The force was applied as a

surface stress perpendicular to the face of the nerve, and the tensile stress was calculated based on the maximum load (1.08N) [2] normalized by the estimated cross-sectional area of each nerve branch. The stress in each nerve root was determined for the complete, intact brachial plexus. The simulation was repeated with a complete discontinuity between C5 and the spinal cord, representing an avulsion or rupture, and then a discontinuity at C5 and C6 (Figure 2).

Figure 2: (A) C5 avulsion and (B) C5 and C6 avulsion

RESULTS

When a complete avulsion or rupture occurs only at C5, a significant increase in stress ($> 16x$) occurs to the C6 nerve root, as seen in Figure 5. The stress in C7 also increased, but to a lesser extent ($3x$). When an avulsion occurs to the entire upper plexus (C5 and C6), the predicted increase in the stress at C7 nerve root was about 8 times higher than in the intact brachial plexus (Figure 5). Figure 3 illustrates the stress on a non-injured brachial plexus. Within this model, the stress is distributed along the entire brachial plexus beginning from the nerve roots and continuing down to the five branches. A higher stress occurred at the anterior and posterior portions of the divisions than at the nerve roots.

Figure 3: Control - Von Mises Stress (MPa)

Figure 4: C5 and C6 Avulsion - Von Mises Stress (MPa)
** Displacement is not shown

Figure 4 illustrates the impact of a C5 and C6 discontinuity, in which the nerve roots separate from the spinal cord. When this injury occurs, it is shown that less stress occurs in the upper plexus. The roots and trunks of the upper plexus are essentially unstressed. This

displaces the stress within the nerve root to the nerve root levels below the avulsion. In this case, a large increase of stress occurs within the C7 nerve root.

Figure 5: Von Mises (MPa) stress comparison for different injuries

DISCUSSION

In some children, there may be more than one level of nerve root in the brachial plexus that is injured. An anatomically accurate model of the complex, 3D plexus allows for more detailed assessment of the stresses and injury progression to be evaluated. It also allows for the effect of full or partial disruption of the nerve roots to be investigated.

Clinical patterns of brachial plexus injury and some experimental work demonstrate that C5 and C6 experience higher stress under initial loading of the brachial plexus than do the lower roots and that these levels are damaged first [3]. This simulation confirms this outcome. While this may be an obvious result to biomechanical engineers, it is not obvious to neurosurgeons or obstetricians.

While two three-dimensional models of the adult brachial plexus have been published [4, 5], they are anatomically accurate only through the level of trunks. This is the first 3D model of the complete brachial plexus, for either neonates or adults, that extends through the distal branches. This complete computational model will allow in-depth analysis of NBPP injuries by providing a better understanding of the stress distribution within the nerves that occurs during the birthing process.

INTRODUCTION

Cardiomyocytes (CMs) are the primary contractile cells of the native heart, responsible for executing coordinated contractions sufficient to maintain cardiac function. While not mechanically active, cardiac fibroblasts (CFs) are prevalent in cardiac tissue, necessary for maintenance and remodeling the extracellular matrix (ECM), direct cell-to-cell communication, and paracrine signaling factor secretion [1], [2]. CFs play a role in cardiac development, homeostasis, and repair in response to myocardial injury or disease [3], [4], though their effects on CM mechanical function and maturation remain unclear.

Despite recent advances, potential applications and cell therapies involving iPSC-CMs are hindered by relative immaturity of these myocytes in comparison to primary adult CMs [5]. iPSC-CMs display electrophysiological, morphological, and mechanical characteristics of embryonic CMs [6]-[8]. Methods to influence iPSC-CMs towards a more mature phenotype *in vitro* have been developed, such as chronic mechanical and electrical stimulation [9],[10], metabolic cues [11], and coculture with alternative cell types [12], [13]. CM-CF coculture increases the amplitude of force generation by CMs [14], as well as the spontaneous rate of contraction [15]. We have previously shown that CFs improve calcium kinetics and increase contractile strain when in coculture with CMs [16]. Such findings demonstrate the importance of developing models of myocyte-fibroblast-ECM interactions to understand the bidirectional communication between cell types, and their role in mechanical function.

This work explores the differential effects of CM-CF coculture and CF conditioned media on iPSC-CM mechanical function on an engineered 2D platform. We seek to determine to what extent coculture and conditioned media enhance mechanical function of CMs and to elucidate if the observed improvements are the result of ECM remodeling and direct cell contact through the concurrent presence of CFs, the result of CF-mediated paracrine signaling not requiring direct cell contact, or a more complex interplay of the two.

METHODS

Human induced pluripotent stem cell-derived cardiomyocytes (iPSC-CMs) were differentiated using a modified version of the small molecule GiWi method and purified using lactate medium [17], [18]. iPSC-CFs were differentiated as described previously [19]. Microcontact printing and soft lithography was used to generate compliant substrates with patterned ECM proteins in defined geometries as previously described [20]. Decellularized ECM substrates were produced by Matrigel patterning as described and seeding iPSC-CFs at a density of 253 CFs/mm². CFs were cultured and allowed to remodel the deposited ECM for 14 days before decellularizing [21].

CM only and CF conditioned samples were seeded with purified iPSC-CMs at a density of 2,528 CMs/mm². CM-CF coculture samples were seeded at an equivalent CM density, as well as a density of iPSC-CFs of 253 CFs/mm². CM only and CM-CF coculture samples were maintained with EB2 medium: DMEM/F12, 2% FBS, 1% NEAA, 0.5% GlutaMax, and 0.07% 2-Mercaptoethanol. For CF conditioned samples, EB2 media was conditioned by a CF monoculture before being transferred to the samples unaltered or at a 1:1 dilution with fresh EB2.

Mechanical analysis was performed using digital image correlation (DIC) to quantify maximum contractile strain and spontaneous contraction rate [22], [23]. Statistical analysis of two groups was performed using an unpaired two sample t-test. Analysis of more than two conditions used a one-way ANOVA test followed by multiple comparison test to perform pairwise comparisons using Tukey's honestly significant difference criterion.

RESULTS

iPSC-CMs were seeded either alone or in coculture with iPSC-CFs on platforms of micropatterned ECM or ECM remodeled by CFs and decellularized. CMs cultured alone remained within the boundaries of the defined ECM pattern through 18 days and demonstrated a similar arrangement to CMs conditioned by CF media. CM-CF coculture

demonstrated progressive remodeling of the patterned ECM and migration to previously unoccupied regions of the substrate, resulting in an appearance similar to a confluent monolayer under brightfield microscopy although stained images reveal that the underlying CMs retain their organization [16].

Videos of coordinated cell contractions were captured using brightfield microscopy, and the contractile strains were calculated using digital image correlation (DIC). At each time point, there was a significant difference in the maximum strain generated in the CM-CF coculture condition and the CM Only condition (Fig. 1). However, a significant difference between the CF conditioned media condition and CM only condition was only present at the Day 12 and Day 18 timepoints, and the magnitude of the difference was less pronounced.

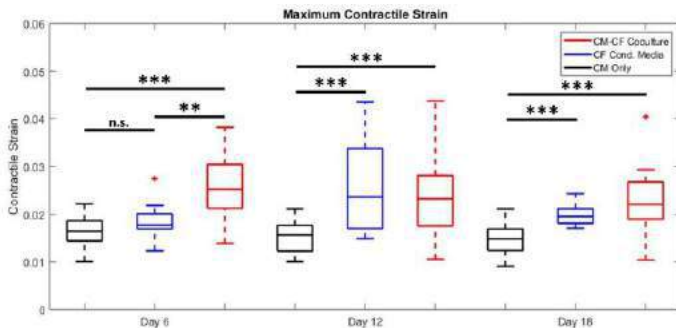

Figure 1: Matrigel strain analysis; The maximum contractile strain is significantly higher in the CM-CF coculture condition than the CM Only condition at Days 6, 12, and 18. Strain is significantly higher in the CF conditioned media condition than the CM Only condition at only Days 12, and 18. ** $p < 0.01$, *** $p < 0.001$.

To understand other features of contractile behavior, the spontaneous contraction rate was evaluated. Only videos collected at Day 6 were included as not all samples at later timepoints captured greater than one contraction. CM-CF coculture resulted in increased rates of contraction on both ECM conditions (Fig. 2A), while CF conditioned media had no effect on rate on either ECM condition. A similar trend was observed at later experimental timepoints for samples capturing multiple contractions. The contraction rate was significantly decreased on decellularized ECM in comparison to Matrigel (Fig. 2B). No correlation was observed between the amplitude of contractile strain and the spontaneous rate of contraction (data not shown).

Figure 2: (A) Spontaneous contraction rate is significantly higher in the CM-CF coculture condition compared to the CM only and CF conditioned media condition on both Matrigel and decellularized ECM. (B) Spontaneous contraction rate is increased on Matrigel in comparison to decellularized ECM. (***) $p < 0.001$

DISCUSSION

While CMs are the contractile cells of the heart, CFs contribute to the structural, biochemical, mechanical, and electrical properties of the myocardium. In this work, we sought to characterize the effects of CF coculture and CF conditioned media on the mechanical function of CMs. We demonstrated that CM-CF coculture increases the maximum contractile strain achieved by CMs, matching the literature and our previous findings. We also found that media that has been conditioned by CFs, with no direct coculture, results in an increase in maximum strain, albeit at a lower magnitude. Interestingly, direct CM-CF coculture resulted in an increase in the spontaneous rate of contraction for both ECM conditions, while CF conditioned media had no effect on the rate of contraction for either ECM condition.

Taken together, these results suggest that CFs may influence CM activity and functional maturity through a mechanism that requires both paracrine signaling and direct cell-to-cell interactions. These findings may have implications in enhancing iPSC-CM maturity *in vitro*, an increasingly important goal in cardiac tissue engineering, as well as in potential future cell-free therapies *in vivo*. Future work will explore the mechanisms of the differential enhancement through characterization of the CF conditioned media and the CM-CF coculture microenvironment.

INTRODUCTION

Traumatic brain injury (TBI) has become a global health threat. In 2016, over 27 million cases of TBI were reported globally [1]. The fast diagnosis and early warning approaches of TBI are significant to helping prevent repetitive sport-related TBI [2]. Physiologically, the brain is damaged because of the brain deformation resulted from the inertial movement of the brain after the head sustains an impact or suffers rapid acceleration and deceleration. Therefore, metrics of brain deformation are effective predictors of TBI. Brain strain, particularly the maximum principal strain (MPS) and MPS rate (MPSR), has been shown to correlate with TBI pathologies [3-5]. To calculate MPS and MPSR, the state-of-the-art approach, finite element modeling (FEM), can take hours to model one impact. Recently developed machine learning head models (MLHMs) trained on large quantities of simulated impacts or lab-reconstructed impacts, in contrast, can substantially reduce the computational cost [6-8].

Despite their superiority in the computational time, MLHMs are often biased towards data similar to the distribution of their training data, which can vary with the type of the impact (i.e., football impacts, car crash impacts) [9]. The dependence on training data distribution raises the issue of generalizability across datasets. For example, in our previous study, a promising prediction accuracy was found using a simulation dataset of 2,130 impacts, and the accuracy decreased when the model was applied to the combined datasets of simulation impacts and the on-field impacts (college football (CF, size of 302) or mixed martial arts (MMA, size of 457)) [9]. The reason for the decreasing accuracy was the remarkably different data distribution in different contact sports [10]. To address this problem, transfer learning has been applied and successfully reduced the MPS and MPSR estimation errors. However, transfer learning requires labeled data (FEM-computed reference MPS and MPSR for the kinematics are required to fine-tune the deep learning models) of a particular type of head impacts, which are typically not available to the user [11]. In this study, to improve the

brain strain estimation across types of head impacts without labeled data, we perform unsupervised domain adaptation by establishing mapping between domains represented by different datasets, including the simulation dataset and two different on-field datasets, or from these domains to a unified regularized domain, followed by brain deformation modeling with an MLHM. We compare the approach of deep-learning unsupervised domain adaptation based on the cycle-generative adversarial network (cycle-GAN) architecture with a non-deep-learning approach, domain regularized component analysis (DRCA), and attempted the approach of combining both DRCA and cycle-GAN.

METHODS

We collected a total of 13,539 samples of head impact data from diverse but representative impact types, including: 1) 12,780 laboratory head impacts simulated from a validated FEM of the Hybrid III anthropomorphic test device headform (labeled as HM for head model); 2) 302 college football head impacts recorded by the Stanford instrumented mouthguard (labeled as CF); 3) 457 MMA head impacts recorded by the Stanford instrumented mouthguard (labeled as MMA)[10]. From each sample, we extracted 510 temporal and spectral features according to four physical quantities describing the head translation and rotation: linear acceleration at the brain's center of gravity, angular velocity, angular acceleration and angular jerk. Four channels are associated with each quantity: the three anatomical axes (x: posterior-to-anterior, y: left-to-right, z: superior-to-inferior) and the magnitude. Feature extraction details are shown in [11]. The reference MPS and MPSR are computed with a validated finite element head model: the KTH finite element model (Stockholm, Sweden) [12], which modeled the human brain with 4,124 brain elements. We firstly developed the baseline deep neural networks to estimate MPS and MPSR based on dataset HM, as in our previous studies [10,11].

Then, to compensate for the data distribution drift (also known as domain drift in machine learning), we applied two types of unsupervised domain adaptation approach: the DRCA and cycle-GAN. The convex-

optimization-based DRCA looks for a projection hyper-plane (i.e., the domain-invariant feature subspace) on which the difference between the projected source domain (the dataset HM) and target domain (the dataset CF/MMA) is minimized while the within-domain variance is maximized [13]. The linear projection matrix was found by the optimization of constrained Rayleigh Quotient [13]. Upon projecting the data onto the hyper-plane, deep-learning MLHMs are developed on the features along the projection hyper-plane.

Alternatively, we used the deep-learning approach for domain adaptation: mapping on-field data to the domain of the HM dataset before prediction of brain deformation via cycle-GAN [14]. To further address the potential domain drift from the real data and the cycle-GAN-generated data, we performed the Kernel Means Matching (KMM, also referred as shift-GAN) or the DRCA on the top of the cycle-GAN, which are compared against the cycle-GAN alone, the DRCA method, and the baseline without any domain adaptation. The model development and evaluation processes are visualized in Fig. 1.

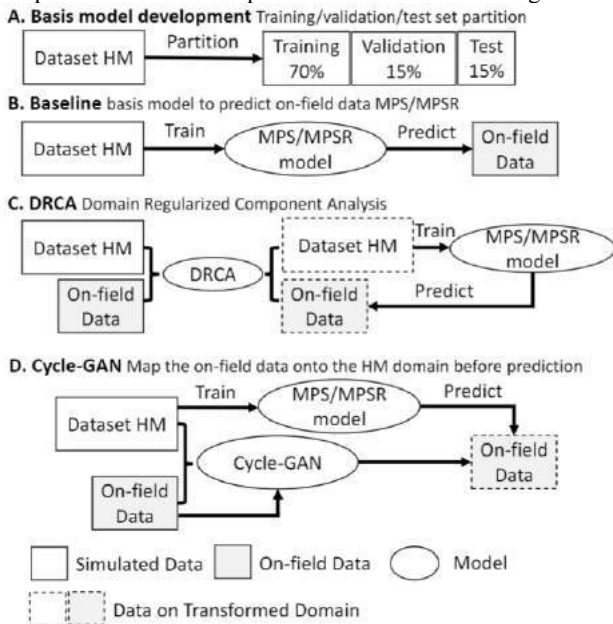

Figure 1: The pipeline of the model development and evaluation. The pipeline consists of a deformation prediction model and domain adaptation models with DRCA or cycle-GAN. On-field data: CF or MMA.

RESULTS

To evaluate the model performance, the brain-element-wise prediction error in MPS and MPSR were calculated and shown in Fig. 2. The DRCA method outperformed all the competing methods with the smallest prediction errors in both the MPS prediction and MPSR prediction, on both dataset CF and dataset MMA. The DRCA method significantly reduced the MPS/MPSR prediction error when compared with the baseline approach without any domain adaptation ($p < 0.001$, Wilcoxon signed-rank test). Furthermore, the DRCA method enables significantly more accurate predictions when compared with three cycle-GAN-based methods ($p < 0.001$, Wilcoxon signed-rank test). To quantify the overall accuracy of the prediction and compare with the previous study which reported model accuracy on simulated head impacts [11], we computed the mean absolute error (MAE) of MPS over all brain elements and then calculated the mean over all test impacts. For the MPS prediction, the DRCA method reduces the mean MAE from 0.036 to 0.017 (MPS, dataset CF), from 0.103 to 0.020 (MPS,

dataset MMA). The MAE was in the same order as that reported in our previous studies when the model (trained on the dataset HM) predicts the test impact from dataset HM (MAE: 0.015), on which the models were trained with the same kinematics features [11].

Figure 2: Absolute values of the MPS/MPSR prediction error over all the brain elements and test impacts. The prediction error of MPS on dataset CF (A) and MMA (B). The prediction error of MPSR on dataset CF (C) and (D). (*: $p < 0.001$)**

DISCUSSION

The lack of generalizability in MLHMs hinders their application in TBI detection due to the data distribution drifts in different impact datasets. In this work, we are the first to propose a generalizable brain deformation estimator that integrates domain adaptation with a deep-learning brain deformation prediction network. To perform domain adaptation, we apply either a cycle-GAN-based architecture or a non-deep-learning method, DRCA, and find that although both methods reduce the prediction error, DRCA achieves a substantially higher accuracy as quantified by the mean absolute error of the brain deformation field estimation. Our results indicate that domain adaptation can improve the accuracy of brain deformation estimation for different types of on-field head impact data to be in the same order of accuracy on the simulated head impacts, and therefore, this study address the generalizability problem of MLHMs without labeled data. As a derivative of MLHM, this study significantly enables fast and accurate brain deformation estimation for TBI detection in potential clinical applications and for better protection of soldiers, contact-sports players and motorists who are frequently at risk of sustaining TBIs.

INTRODUCTION: The annulus fibrosus (AF) in the intervertebral disc is a fiber-reinforced tissue consisting of collagen fibers embedded in a proteoglycan-rich extracellular matrix, resulting in great load-bearing and energy absorption capacities. However, due to the disc's avascularity, the AF is susceptible to catabolic remodeling with disease and degeneration, causing debilitating back pain and disability.¹⁻² Diabetes mellitus, a prevalent metabolic disorder that has been shown to cause or aggravate irreversible disc tissue damage, is a significant risk factor low back pain.³⁻⁶ A well-documented diabetes-induced AF structural change is the accumulation of advanced glycation end-products (AGEs), which can form irreversible covalent crosslinks with AF collagens due to their slow biological turnover and long half-life.⁷⁻⁸ Understanding AF structure-function relationships with diabetes-induced non-enzymatic glycation (i.e., AGEs) can provide insight into tissue failure mechanisms, which is pivotal for developing injury prevention measures and effective therapeutic interventions.

Previous studies reported an increased AF stiffness and toughness with non-enzymatic glycation.⁹⁻¹⁰ Our recent work examined AF uniaxial tensile mechanics at physiologically relevant AGEs levels and observed significantly increased tensile modulus and failure stress in circumferential-axial (circ-ax) samples (Fig. 1A).¹¹ Thus, how diabetes increases or accelerates AF tissue mechanical failure remains unclear.

Crosslinking schematics with AGEs are still unclear due to experimental limitations.¹² Finite element models (FEMs) are a valuable tool for predicting stress-strain distributions in complex tissue structures. We recently developed and validated a robust multiscale structure-based FEM framework for the disc. Tissue-level FEMs were able to accurately predict multiscale AF mechanics under different loading configurations (e.g., uniaxial and biaxial tension, simple shear) and specimen geometries.¹³⁻¹⁴ Thus, the objectives of this study were to: (1) examine the effect of AGEs on AF uniaxial tensile mechanics in loading directions with less fiber engagement, and (2) to expand our FEM framework to describe AF mechanics with non-enzymatic glycation.

METHODS: *Experimental:* Bovine caudal discs were dissected from mature coccygeal spines. Circumferential-radial (circ-rad) and radial samples were prepared using a freezing stage microtome to obtain 2 mm-thick rectangular specimens. The lengths of circ-rad and radial specimens were ~10 and ~5 mm; specimen widths were ~5 mm for both orientations. For repeatable midlength failure, a 1-mm full-width notch was created using a custom-made cutting jig in the thickness direction for circ-rad specimens.¹⁵ Radial specimens exhibited limited grip failure during preliminary testing and were thus unnotched (Fig. 1A).

Fig. 1: (A) Specimen orientation, loading direction, and notch geometry. **(B)** Model schematics demonstrating possible crosslinking mechanisms.

AF specimens were prepared at three physiologically relevant glycation levels (18 hr soak). Control samples were soaked at 25 °C in a SPEG5 solution to minimize excessive swelling (CTRL, $n_{\text{circ-rad}} = 15$, $n_{\text{radial}} = 7$).¹⁶ Glycated samples were soaked in 0.3 M methylglyoxal pH-balanced to 7.4 at 25 °C (GLY25, $n_{\text{circ-rad}} = 15$) or 50 °C (GLY50, $n_{\text{circ-rad}} = 15$, $n_{\text{radial}} = 7$). Samples were gripped with custom-made clamps and tested in SPEG5 to maintain hydration. Quasi-static monotonic uniaxial tension was applied at 0.1 mm/min until failure. Linear-region modulus, failure stress, and failure strain were evaluated for specimens that failed at midlength post-testing. AGE content was also measured.

Computational: The multiscale structure-based FEM framework previously developed and validated for the AF was adapted to describe crosslinks within the extrafibrillar matrix with model geometries determined using experimental samples.¹¹ Non-enzymatic crosslinks, whose orientations are still unknown, were described in three possible directions, including crosslinks parallel to collagen fibers (in-plane shear crosslinks, ISCs), crosslinks perpendicular to collagen fibers (in-plane normal crosslinks, INCs), and out-of-plane radial crosslinks (ORCs, Fig. 1B). All crosslink components were modeled as directional homogeneous interfibrillar reinforcements with identical mechanical properties. A higher AGE content was assumed to generate denser AGEs compounds per unit volume, leading to a larger overall crosslink stiffness. Crosslink modulus was calibrated by comparing model-predicted bulk AF tensile modulus to experimental data; other model parameters were directly linked to reported AF physical or biochemical properties.¹³ Simulated boundary and loading conditions replicated those of experiments. Multivariate linear regression was conducted based on a parametric group of FEMs with varying crosslink modulus to estimate the relative contribution of crosslink modulus to the increase in bulk AF tensile modulus with non-enzymatic glycation.

Fig. 3: (A) AGE content, (B) modulus, and (C) failure stress at each glycation level. *: $p < 0.05$ vs CTRL; ^: $p < 0.05$ vs GLY25.

RESULTS: Experimental: 51/59 specimens experienced midlength failure and exhibited a nonlinear stress-strain response. AGEs content normalized by dry weight increased by 95% in GLY25 and 206% in GLY50 samples ($p < 0.001$ vs CTRL; Fig. 3A). For circ-rad specimens, non-enzymatic glycation increased linear-region modulus and failure stress by 62% (18.13 vs 11.22 MPa; $p < 0.001$) and 60% (4.09 vs 2.55 MPa; $p < 0.01$) in GLY50 samples. For radial specimens, AGEs did not increase tissue modulus but increased failure stress by 42% (0.54 vs 0.38 MPa; $p = 0.04$; Fig. 3B-C). Failure strain was not affected by the non-enzymatic glycation treatment in both directions.

Computational: Preliminary FEMs predicted that ORCs could result in a 10 to 100× increase in AF radial tensile modulus. However, experimental work showed that AF radial modulus did not increase with glycation (Fig. 3B). Thus, ORCs were excluded from the model.

Model predictions agreed well with experiments when the crosslink modulus was 12.5% and 25% of collagen fibers in GLY25 and GLY50 specimens, respectively (7.5 and 15 vs 60 MPa). For circ-ax specimens, model-predicted linear-region modulus were 25.2, 38.4, and 48.7 MPa for CTRL, GLY25, and GLY50 samples, respectively ($< 0.35\times$ standard deviation (std) from experimental means; Fig. 4A).¹¹ Model-predicted linear-region modulus were 8.7, 13.0, and 17.3 MPa for CTRL, GLY25, and GLY50 circ-rad samples, respectively. Model predictions were within $0.8\times$ std from experimental means except for Werbner et al. (8.7 vs 11.3 ± 1.8 MPa; Fig. 4A).¹⁷ Model-predicted tensile modulus was 0.38 MPa for both CTRL and GLY50 radial specimens ($< 0.23\times$ std from the experimental means; Fig. 4A).

Models with only ISCs or INCs greatly underestimated AF linear-region modulus for circ-ax and circ-rad GLY50 specimens (Fig. 4B). Thus, ISCs and INCs were both required to accurately describe the effect of non-enzymatic glycation. Multivariate linear regression suggested that the increase in AF circumferential tensile modulus with glycation was more sensitive to ISC modulus than INC modulus.

Particularly, ISC and INC modulus contributed $\sim 90\%$ and $\sim 10\%$ to the increase in tensile modulus for both circ-ax and circ-rad specimens.

Fig. 4: Model-predicted (A) tensile modulus in three specimen orientations and (B) GLY50 sample tensile modulus with different crosslinking schematics vs experimental data (mean \pm std).^{11, 15, 17}

DISCUSSION: Non-enzymatic glycation modifies AF collagen structure via crosslinking. The current study found that glycation increased AF tensile modulus and failure stress without affecting failure strain. These findings agreed with previous studies for circ-ax samples,⁹⁻¹¹ indicating that AGEs accumulation is unlikely to cause premature tissue failure by adversely affecting AF quasi-static monotonic uniaxial tensile mechanical properties. However, tendon studies have reported a significantly reduced tissue viscoelasticity (i.e., energy dissipation capabilities) with AGEs,¹⁸⁻¹⁹ suggesting that non-enzymatic glycation with diabetes could cause premature disc failure by compromising tissue performance under dynamic, especially fatigue loading.

Observations from the current study indicated that non-enzymatic crosslinks had a larger effect along the primary collagen fiber direction. Particularly, glycation did not stiffen the AF in the radial direction. Model predictions also showed that including out-of-plane radial crosslinks led to unrealistically high radial tensile modulus, suggesting that interlamellar crosslinks, most likely through elastic fibers,²⁰ were not probable. Furthermore, glycation had a greater effect in directions with more fiber engagement. With GLY50 treatment, AF tensile modulus increased by $\sim 100\%$ in circ-ax specimens but by only $\sim 60\%$ in circ-rad samples ($p < 0.001$ for both orientations).¹¹ Multivariate linear regression suggested that the increase in bulk AF tensile modulus was more sensitive to the mechanics of in-plane shear crosslinks aligned with collagen fibers. These findings agreed with previous tendon studies, where AGEs treatment increased tendon uniaxial tensile modulus along the fiber direction by $\sim 100\text{--}400\%$.^{12, 21} Our findings also agreed with a previous quantitative imaging study, which showed that collagens were more responsive to AGEs formation than interlamellar elastic fibers, which are mainly oriented in the radial direction.^{20, 22}

FEMs in the current study accurately and robustly predicted AF uniaxial tensile mechanics with AGEs. Since collagen mechanics were not altered in the glycated FEMs, model predictions indicated that glycation could strengthen bulk AF without stiffening individual collagen fibers or fibrils, which remains a debate in the field.¹²

Determining the effect of non-enzymatic glycation on AF mechanics plays a pivotal role in understanding diabetes as a risk factor for tissue injury, which is essential for developing preventive measures and therapeutic interventions for low back pain. Adding to previous literature, the current study showed that AGEs did not compromise AF monotonic quasi-static uniaxial tensile mechanical properties. The proposed FEM framework also provided a powerful tool for examining multiscale AF mechanics with disease and degeneration. Future work aims to examine the effect of glycation on AF damage accumulation.

A MODULAR FRAMEWORK FOR STRONG 3D/0D COUPLING IN CARDIAC MECHANICS SIMULATIONS

INTRODUCTION

In numerical simulations of cardiac mechanics, the circulatory system, which is typically represented with a 0D lumped-parameter model, is important for capturing the physiological behavior of the heart. Due to the strong *physical* coupling between the heart and the circulation, accurate and efficient *numerical* coupling methods remain an active area of research [1,2,3]. In this work, we present a modular, strong coupling framework for coupling a 3D mechanical (fluid or structural) simulation of the heart to a 0D fluid model of the circulation. “Modular” denotes that we take advantage of separate, preexisting 3D and 0D solver codes, which operate independently except for communication of select information during the iterative solution. We demonstrate that fluid models (e.g., blood flow in the aorta) and structural models (e.g., contracting left ventricular myocardium) can be coupled to a 0D circulation model in a uniform manner. The present coupling is a generalization of the 3D fluid – 0D fluid coupling of [4] to a 3D structure – 0D fluid coupling. Interestingly, that coupling, as well as the present work, was found to be an application of the Approximate Newton Method (ANM) [5]. This connection provides a rigorous mathematical basis and proven convergence results for our coupling algorithm, both of which were lacking in [4].

METHODS

The 3D fluid or structure equations are discretized in space with the finite element method and discretized in time with the generalized-alpha method. This results in a system of nonlinear equations to be solved at the unknown time step $n + 1$

$$\mathbf{R}^{3D}(\Phi_{n+1}) = \mathbf{0}, \quad (1)$$

Figure 1: Schematic showing an idealized left ventricle (3D structure) coupled to an open-loop lumped-parameter model of circulation (0D fluid). The 3D state vector is Φ while the 0D state vector is χ . The 0D imposes a pressure (Neumann) boundary condition on the 3D coupled surface, while the 3D imposes a flow (Dirichlet) boundary condition on the 0D coupled node.

where \mathbf{R}^{3D} is called the 3D residual and is a function of the 3D state vector Φ at the unknown time step $n + 1$. Φ in general, contains the nodal degrees of freedom of the finite element model.

Blood flow in the circulatory system (not including the heart) is modeled using a lumped-parameter network (LPN), following common practice in the field. This amounts to a 0D model of blood flow, described only by pressure and flowrate. This model yields a system of nonlinear ODEs, which upon application of a suitable time-stepping scheme yields a system of nonlinear equations,

$$\mathbf{R}^{0D}(\chi_{n+1}) = \mathbf{0}, \quad (2)$$

where \mathbf{R}^{0D} is the 0D residual and is a function of the 0D state vector χ at the unknown time step $n + 1$. χ in general, contains the pressure and flowrate at and into each node, respectively.

The 3D and 0D models are coupled in that they impose boundary conditions on each other, as follows. The pressure imposed on a coupled surface of the 3D model is taken as the pressure at the corresponding coupled node of the 0D model (see Figure 1). Analogously, the flow rate imposed on a coupled node of the 0D model is taken as the flow rate through the corresponding coupled surface of the 3D model. Mathematically, this means that the 3D residual \mathbf{R}^{3D} is also a function of the 0D variables χ through the coupling pressure \mathbf{P} . Likewise, the 0D residual \mathbf{R}^{0D} is also a function of the 3D variables Φ through the coupling flow rate \mathbf{Q} . Thus, in the time-discrete setting, the coupling problem reduces to a coupled system of nonlinear algebraic equations

$$\begin{cases} \mathbf{R}^{0D}(\chi_{n+1}, \mathbf{Q}_{n+1}(\Phi_{n+1})) = \mathbf{0} \\ \mathbf{R}^{3D}(\Phi_{n+1}, \mathbf{P}_{n+1}(\chi_{n+1})) = \mathbf{0} \end{cases} \quad (3)$$

Solving these two nonlinear equations simultaneously via Newton's method yields the monolithic system

$$\begin{bmatrix} \frac{\partial \mathbf{R}^{0D}}{\partial \chi} & \frac{\partial \mathbf{R}^{0D}}{\partial \Phi} \\ \frac{\partial \mathbf{R}^{3D}}{\partial \chi} & \frac{\partial \mathbf{R}^{3D}}{\partial \Phi} \end{bmatrix}_{n+1} \begin{bmatrix} \Delta \chi \\ \Delta \Phi \end{bmatrix} = - \begin{bmatrix} \mathbf{R}^{0D} \\ \mathbf{R}^{3D} \end{bmatrix}_{n+1}^{(k)} \quad (4)$$

Performing Schur Complement Reduction yields an equivalent system

$$\begin{bmatrix} \frac{\partial \mathbf{R}^{0D}}{\partial \chi} & \frac{\partial \mathbf{R}^{0D}}{\partial \Phi} \\ \mathbf{0} & \frac{\partial \mathbf{R}^{3D}}{\partial \Phi} - \frac{\partial \mathbf{R}^{3D}}{\partial \chi} \left(\frac{\partial \mathbf{R}^{0D}}{\partial \chi} \right)^{-1} \frac{\partial \mathbf{R}^{0D}}{\partial \Phi} \end{bmatrix}_{n+1} \begin{bmatrix} \Delta \chi \\ \Delta \Phi \end{bmatrix} = - \begin{bmatrix} \mathbf{R}^{0D} \\ \mathbf{R}^{3D} - \frac{\partial \mathbf{R}^{3D}}{\partial \chi} \left(\frac{\partial \mathbf{R}^{0D}}{\partial \chi} \right)^{-1} \mathbf{R}^{0D} \end{bmatrix}_{n+1}^{(k)} \quad (5)$$

We point out that the effect of the 0D model is to modify the 3D equation with particular tangent and residual contributions. In this work, borrowing ideas from [5, 6], Eq. 5 is solved in an approximate and modular manner using separate 0D and 3D solvers, with proper communication of pressure \mathbf{P} and flow rate \mathbf{Q} between the two. This involves approximating the 0D contributions in a finite difference manner. Communication between 0D and 3D solvers is required each Newton iteration, as shown in Figure 2.

Figure 2: Communication scheme between 3D and 0D solvers [4]. Pressure and flow rate are communicated every Newton iteration.

RESULTS

Figure 3 shows a pressure-volume (PV) loop obtained by coupling an idealized left ventricle (LV) structural model to a 0D circulation model (Figure 1). We model the contracting myocardium using an active stress approach with a prescribed temporal profile. As seen in the figure, we obtain a realistic pressure-volume loop. In particular, the four cardiac phases – isovolumic contraction, ejection, isovolumic relaxation, filling – are easily identified.

Figure 3: PV loop obtained by coupling a structure simulation of an idealized left ventricle with active stress to a 0D circulation model (as shown in Figure 1).

DISCUSSION

Compared to an uncoupled 3D simulation, our coupling additionally requires evaluating the 0D solver each Newton iteration. In our application, the 0D solver is far cheaper to evaluate than the 3D solver, so this presents a minimal extra cost. In addition, the present coupling method retains the quadratic convergence of Newton's method, as proven by [5]. We do not require the additional volume constraint (for structure solver) nor the ad hoc stabilization found in the partitioned coupling strategies of [1,2,3]. Finally, we reiterate that the coupling uniformly treats a 3D fluid – 0D fluid coupled system and a 3D structure – 0D fluid coupled system. To our knowledge, none have previously pointed out the equivalence between fluid and structure in the context of this cardiovascular coupling problem.

INTRODUCTION

Computational models of brain biomechanics are emerging as important tools to simulate traumatic brain injury (TBI) and improve methods for injury prevention, diagnosis, and treatment. These models require accurate material properties of brain tissue [1], but the mechanical behavior of the intact, living brain remains incompletely characterized, due to its complexity and inaccessibility. Most mechanical testing of brain tissue has been performed using animal tissue post-mortem (either *in vitro* or *in situ*) [2, 3], which may not necessarily reflect *in vivo* mechanical behavior [4]. Thus, understanding how brain mechanical properties change after death is important in order to correctly interpret post-mortem measurements.

Magnetic resonance elastography (MRE) provides estimates of mechanical properties non-invasively in soft tissue by imaging harmonic wave motion and inverting the full-field displacement data [5]. White matter (WM) brain tissue is structurally anisotropic, consisting of aligned neural fibers, and exhibits strongly anisotropic diffusion, so is expected to be mechanically anisotropic as well. MRE inversion has typically assumed material isotropy [5] to estimate only shear modulus and damping, but recently we have developed anisotropic (transverse isotropic) inversion [6] to also estimate shear and tensile anisotropy. The objective of this research is thus to measure anisotropic mechanical properties in the porcine brain before and after death and use MRE to characterize changes that occur post-mortem.

METHODS

Three female Yucatan minipigs (age 7-8 months, weight 21-32 kg) were scanned using a Siemens Prisma® 3T scanner. Each animal was scanned *in vivo* and immediately after death. The anesthetized minipig was positioned supine on the scanner table with head placed in the bottom half of the Siemens Head/Neck 20 coil. Shear waves in the brain were induced at a frequency of 100 Hz using a pneumatic driver (Resoundant™) and custom jaw actuator in three different

configurations, exciting both, left or right sides of the jaw. MRE imaging was performed with a 2D multishot spiral sequence with OSCILLATE acceleration [7]. Phase contrast images proportional to displacement (1.497 microns/rad) were acquired with 8 samples per period of harmonic motion; TR/TE = 4800/60 ms; FOV = 180×180×72 mm³ with 1.5 mm isotropic spatial resolution. The displacement field data were fitted to a model of rigid-body displacement to estimate rigid-body motion. Wave motion was isolated by subtracting the rigid-body motion from the total displacement field. T1- and T2-weighted anatomical MR images were also acquired at 0.8 mm isotropic resolution. Diffusion tensor imaging (DTI) was performed to estimate WM fiber direction and diffusion fractional anisotropy (FA). DTI parameters included: single-shot echo-planar imaging acquisition; 30 diffusion-weighted directions with two averages; and FOV = 192×192×72 mm³ with 1.5 mm isotropic resolution. After *in vivo* scanning was completed, the minipig was euthanized by intravenous (IV) injection of sodium pentobarbital; extension lines were used to allow IV injection while the animal is in the scanner without inducing motion between *in vivo* and *in situ* scanning. *In situ* scanning was initiated 5 minutes after heartbeat cessation was determined by pulse oximeter. Identical imaging procedures were used *in situ*. The interval between *in vivo* and *in situ* MRE scanning was ~35 min, corresponding to the time needed for euthanasia and anatomical imaging.

A transversely isotropic (TI) material model was recently incorporated into a non-linear inversion (NLI) framework [6]. TI-NLI inversion was performed using MRE displacement data from all three actuator configurations and DTI-derived fiber directions to estimate anisotropic mechanical properties of the minipig brain. The medulla, pons, and olfactory bulbs were removed from the mask prior to the estimation of material parameters since the size of these regions are relatively small compared to both the wavelengths of shear waves and the subzone size. Four parameters (baseline shear stiffness, μ_1 , damping ratio, ξ , shear anisotropy $\phi = \mu_{\parallel}/\mu_1 - 1$, and tensile

anisotropy, $\zeta = E_{\parallel}/E_{\perp} - 1$) as well as diffusion anisotropy (FA), were analyzed using a repeated-measures two-way ANOVA.

RESULTS

Figure 1 shows examples of anatomical structure, fiber direction, and wave displacement fields. The three configurations of the MRE jaw actuator imparted different types of wave motion to the brain, providing four combinations of input data for the TI-NLI algorithm. The dorsal-ventral ('V') component of wave motion is the dominant component, and the maximum displacement amplitude is about $2 \mu\text{m}$. Figure 2 displays representative TI-NLI-estimated material properties for both *in vivo* and *in situ*. The difference of baseline shear stiffness refers to ratio difference, $(\mu_{iv} - \mu_{is})/\mu_{iv}$, and difference for other three parameter, for example, $\xi_{iv} - \xi_{is}$. For baseline shear stiffness, μ_{\perp} , estimated values are generally higher after death, which is consistent with longer wavelength after death in Figure 1C, but for the damping ratio, ξ , shear anisotropy, ϕ , tensile anisotropy, ζ , estimated values appear generally lower after death.

Figure 1: Example images. (A) T2-weighted image slices in sagittal and axial planes. (B) Directionally encoded DTI color map where colors (red = RL, green = RC, blue = DV) indicate direction of maximum diffusivity and brightness indicates diffusion anisotropy (FA). (C) MRE data: U, V and W wave displacement components corresponding to RL, DV, RC motion, respectively. DV: dorsal-ventral; RC: rostral-caudal; RL: right-left.

Figure 2: Mechanical properties before and after death estimated by TI-NLI and their difference for an axial slice of minipig brain in animal MP2. (A) Baseline shear stiffness (μ_{\perp}). (B) Damping ratio (ξ). (C) Shear anisotropy (ϕ). (D) Tensile anisotropy (ζ).

The means and standard deviations of the parameters in WM and GM sub-volumes for both before and after death are plotted in Figure 3. For all these four parameters, the differences between *in vivo* and *in situ* were statistically significant. The shear stiffness and diffusion anisotropy increase obviously right after death, but other parameters decrease after death. The difference between WM and GM decrease after death.

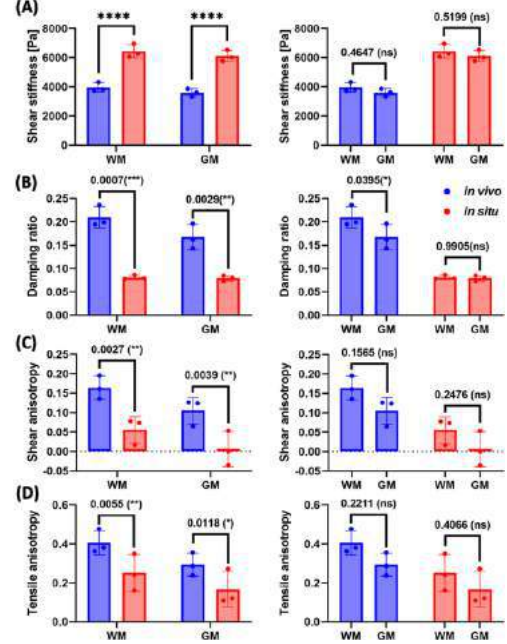

Figure 3: Mean NLI-estimated mechanical properties of WM and GM for all 3 minipigs. Each marker represents the mean value for an individual minipig at a specific age. Bars denote standard deviations. (A) Baseline shear stiffness (μ_{\perp}). (B) Damping ratio (ξ). (C) Shear anisotropy (ϕ). (D) Tensile anisotropy (ζ).

DISCUSSION

MRE measurements reveal significant mechanical anisotropy in brain tissue, both *in vivo* and post-mortem. Mechanical anisotropy arises from tissue microstructure, which is also reflected in diffusion anisotropy measured by DTI. All parameters of the anisotropic material model of brain tissue change post-mortem, some by a large fraction of their mean value *in vivo*. Baseline shear stiffness increases, damping decreases, and anisotropy (particularly tensile anisotropy) decreases post-mortem. These changes all represent important differences between the behavior of the intact, living brain and brain tissue *ex vivo*. Computer models of brain mechanics that are parameterized or evaluated using experimental data from *ex vivo* brain tissue should account for the differences in brain properties post-mortem.

SIMULATION OF UTERUS ACTIVE CONTRACTION AND FETUS DELIVERY IN LS-DYNA

R. Tao (1), M. Grimm (2)

INTRODUCTION

Childbirth, also known as delivery or labor, is the final phase of pregnancy when one or more fetuses pass through the birth canal from the uterus and is a biomechanical process [1]. However, approximately twenty percent of labors are difficult or dysfunctional, which leads to a high risk of injuries to both the infant and the mother resulting from the stress, strain and stretch of the biological tissues or anatomical structures of the fetus and the mother during the delivery process [2].

Normal biomechanical function and regulation of the uterus is vital for childbirth. Poor quality uterine contractions contribute to many labor problems, including labor dystocia (a delay in labor progression), which has proven to be a significant reason for the rising Caesarean section rate [1]. In addition, the interaction of the uterus, the fetus, the maternal pelvis, and the vagina results in both the normal cardinal movements of labor and abnormalities of descent. Therefore, it is important to understand the mechanical process of labor and delivery so that mechanisms of injury can be more realistically investigated.

In this study, we developed an FEM model in LS-DYNA to simulate uterine active contraction, which was driven by the contractile fibers inside the uterine wall, and the fetus delivery through the birth canal.

METHODS

The geometry of the uterus was designed in NX software with a length of 35 cm, a maximum width of 15.6 cm, a thickness of 1 cm, and diameter of 10 cm at the cervix, as shown in Figure 1a. The fetus model included head, neck and body (Figure 1a). Meshing was done in Hypermesh software using hexahedral elements (Figure 1b), which was then exported to LS-DYNA. Each element was bonded with truss beam elements. These beams were assigned to seven regions in LS-DYNA (Figure 1c). These beams were used to provide the contraction force based on the Hill material model [3] (MAT_156 in LS-DYNA). The activation curves for the seven beam regions were assumed as shown in

Figure 1d, based on uterine physiologic behavior [4]. The solid portion of the uterus, representing the non-contractile portions of the tissue, was modeled as a hyperelastic material with a Neo Hookean model ($c1 = 0.07$ MPa) [5].

The bony pelvis and fetus were modeled as rigid bodies. The pelvic muscle floor, rectum, and vagina were modeled as hyperelastic materials with a Mooney Rivlin model ($c1 = 0.026$ MPa, and $c2 = 0.014$ MPa) [6]. For the boundary conditions, the cervix and the bony pelvis were fixed in x, y, and z translation directions in space. The nodes connecting the pelvic soft tissues and the bony pelvis as well as the nodes on the top edge of the vagina were also fixed in all translation directions. No external loads were applied.

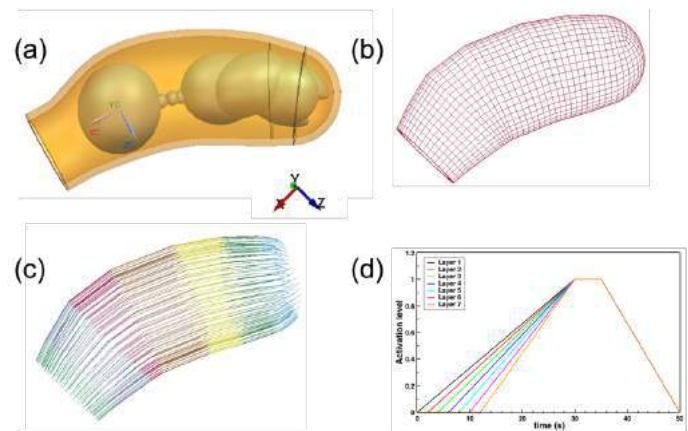

Figure 1: Modeling details: (a) uterus and fetus geometry; (b) meshwork; (c) seven regions of contractile beams; and (d) activation level curves.

RESULTS

The simulation results showing contraction of the uterus are shown in Figure 2. At $t = 0$ s, there was no deformation (Figure 2a). After that, the uterus started to contract from the fundus region and the contraction wave started to propagate to the lower part. By $t = 5$ s, the first three regions had started to contract, and the largest effective strain was 32.0% at the top of the fundus area (Figure 2b). By $t = 10$ s, the contraction wave had propagated to the first five regions. The largest strain was 51.4% (Figure 2c). By $t = 15$ s, all of the regions had started to contract, and the largest strain was 68.4% (Figure 2d). The entire uterus continued to contract until 22 s, when the largest strain was 94.5%.

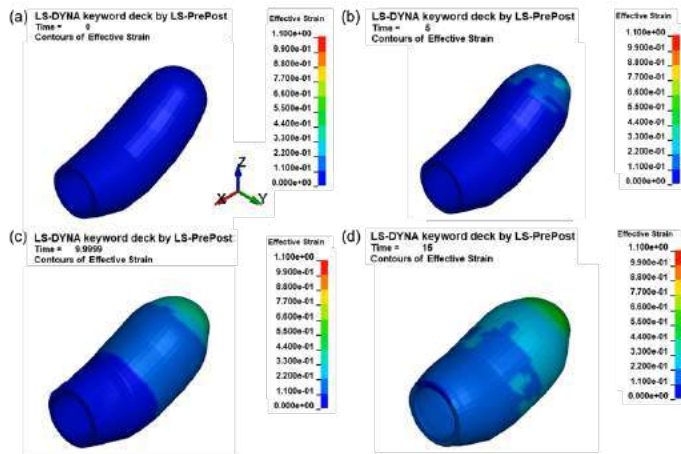

Figure 2: Representation of the deformation for the uterus at times of (a) 0 s, (b) 5 s, (c) 10 s, and (d) 15 s.

The simulation results for the pelvic soft tissue structures are shown in Figure 3. The pelvic muscle floor had no deformation until the fetus contacted with the structure (Fig 3a). At time = 10 s, the largest strain of the pelvic muscle floor was 23.6% (Fig 3b). As the fetus continued to move forward, the strain of the pelvic muscle floor and vagina became much larger. At time = 15 s, the largest strain was 77.9% (Fig 3c). At time = 20 s, the fetal head filled the vagina, and the largest strain was 213.8%, occurring in the contact surface (Fig 3d) between the fetus head and the vagina. At time = 22 s, the fetal head was out of the vagina. The strain started to drop, with a maximum value of 52.6%.

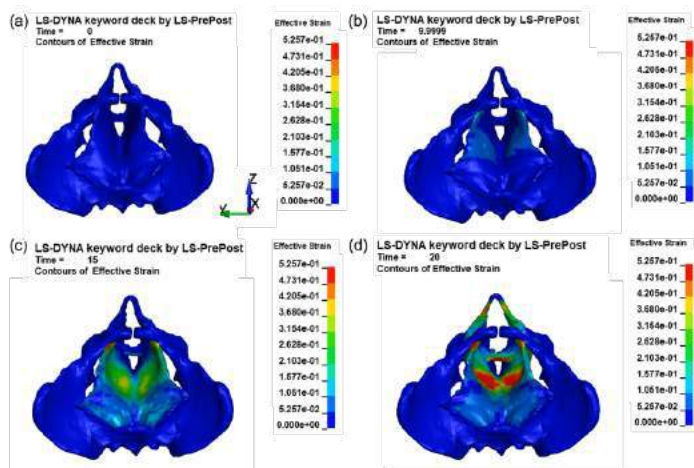

Figure 3: Representation of the deformation for the uterus at times of (a) 0 s, (b) 5 s, (c) 10 s, and (d) 15 s.

The simulation result of the fetal displacement with time is shown in Figure 4. The fetus started to move at time = 2 s, when the uterus' fundal region contracted and contacted with the fetus. The contraction of the uterus pushed the fetus to move forward through the pelvic structures and the vagina. Since this fetus was modeled as a rigid body, no deformation occurred to the fetus during the delivery process. The fetus rotated clockwise as it moved through the birth canal. The velocity of the movement was almost a constant from the beginning of the fetus' motion to time = 21 s. After that, there was a sudden acceleration of the fetus' movement, and the fetal head was delivered at 22 s. The overall displacement of the fetus during the delivery process was about 320 mm.

Figure 4: Representation of the deformation for the uterus at times of (a) 0 s, (b) 5 s, (c) 10 s, and (d) 15 s.

DISCUSSION

In this study, we developed a FEM model to simulate the uterine active contraction and fetus delivery. The fetus in our current model was modeled as a rigid body. However, in order to investigate the mechanisms of injuries to the fetus during the labor, especially brachial plexus injury, the fetus has to be modeled as a deformable structure, and the nerves inside the neck of the fetus will also need to be modeled. This work is currently being conducted within our group.

We recognize that we are currently modeling a single contraction to deliver the fetus. We are currently working to simulate the second stage of labor more accurately, so that multiple contractions bring the fetus through the pelvis and birth canal.

In addition, this uterus model is not linked to the cellular level models to study how cell-level electrical, chemical, and mechanical behaviors influence tissue and organ-level behaviors. However, such cellular-level models could be incorporated into the Hill muscle model to develop a new multi-scale constitutive model in the future.

INTRODUCTION

Upper limb and hand dexterity impairment is common in neurological conditions such as Parkinson's Disease, Stroke or Amyotrophic Lateral Sclerosis. The most widely used measurement methods for these conditions are multi-item ordinal performance rating scales that are either condition specific or generic in application [1]. These scales have inherent subjective biases and lack sensitivity to small but meaningful changes. To address this, performance-based tests such as the nine-hole peg test (NHPT) or grip strength dynamometry have been utilized but these tests are limited by floor and ceiling effects, reliability or accessibility in the clinical setting. This may contribute to failed clinical trials, as the lack of sensitive objective endpoints hamper the ability to assess the impact of novel treatments.

We hypothesized that the development of a new measurement tool for hand dexterity could provide an enhanced outcome measure that would be able to detect small but meaningful changes in patient function.

METHODS

The new tool was designed to satisfy predefined user needs and design requirements. It digitises the Finger Tapping Test (FTT), a widely used clinical test in neurological practice [2]. This involves tapping the index finger against the thumb rapidly, while the clinician visually evaluates the size, speed and accuracy of the movement. This approach is subjective, insensitive and yields a bivariate result of normal or abnormal. The novel device (Figure 1) is comprised of two sections, a mechanical system attached to a participant's thumb and index finger and an electronic system which captures and transmits the data to an app on an Android phone for instant evaluation. The two primary outputs of the device are distance travelled and the associated time in milliseconds. Testing was carried out to validate the mechanical reliability and accuracy of the device.

This study evaluated the device in a healthy population and in people with a neurodegenerative condition that affects hand function (pwNDC). It was approved by the School of Medicine Research Ethics Committee, Trinity College Dublin for healthy people (REC 20190209) and the Beaumont Hospital Medical Ethics Research committee (REC 18/25) for pwNDC. Potential participants were invited to participate, provided with an information leaflet and written consent obtained.

Participants were tested using the novel dexterity device and using three traditional tests; grip strength dynamometry, pinch gauge and the NHPT. A hand function questionnaire, the Disability of Arm, Shoulder and Hand (DASH) was completed by pwNDC. Participants who were unable to complete the NHPT were given a score of 200 seconds. The testing method for the dexterity device was as follows: participants rested their hand in a custom hand support to standardise orientation and were instructed to place the tip of their index finger on the distal crease of their thumb and to extend their finger as high and as fast as they could, returning to the starting point of the distal crease between each tap, for eleven taps, with ten taps used in the analysis. Participants completed three FTTs for both hands with a 'best test' chosen. The maximal passive height of the index finger was also recorded once for each hand, where the tester passively extended the participant's index finger to the maximum potential height. **180** healthy participants (90 Males, mean age \pm SD = 49.7 \pm 17.3). **58** pwNDC (36 Males, mean age \pm SD = 62.6 \pm 11.3) participated.

RESULTS

The accuracy of the dexterity device (four prototypes were manufactured) was confirmed by plotting the known displacements against the calculated displacements; this test was conducted using a static testing machine (Zwick Instron, UK) (Fig. 2A). The R^2 values were high (R^2 greater than 0.99 for every device). The maximum forces recorded were 0.51N, 0.39N, 0.51N and 0.44N for Devices 1-4 respectively (Fig.2B).

Figure 1: Photographs of the system in place on a person's hand.

Despite significant hand impairment only four pwNDC (6.9%) were unable to complete the FTT using the device using their dominant hand with two (3.4%) unable using the non-dominant hand. In comparison, ten (17.2%), were unable to complete both the NHPT or grip strength test using their dominant hand and 13 (22.4%) were unable to complete the NHPT and ten (17.2%) the grip strength using their non-dominant hand (Figure 3).

Figure 2: (A) calculated displacement for four devices when the associated calibration factors were used, plotted against known measurement points. (B) average force for the four devices over five tests using the force recorded at a displacement of 200 mm.

15 features were extracted from a participant's raw data graph (time, accuracy, speed etc.). All features (along with age and gender) were used as inputs to a logistic regression which was carried out on a combined healthy and patient dataset. The linear predictor of the logistic regression output was used to determine the objective 0-1 (0 = maximum impairment) score for a participant's hand function.

The objective score accounts for the effects of age and gender on the features. Figure 4A shows the objective score plotted against age for healthy controls with lower scores seen in older participants. The score was plotted against the traditional measures (Figure 4B and 4C). The score was negatively correlated with the NHPT ($r = -0.69$ D/ -0.73 ND) and positively with the grip strength test ($r = 0.50$ D/ 0.50 ND). A negative correlation was observed between the score and the DASH questionnaire ($r = -0.55$ D/ -0.44 ND).

Figure 3: Data collected from participants with a neurodegenerative condition affecting hand function (pwNDC) dominant and non-dominant hands using the traditional measures and the novel dexterity device.

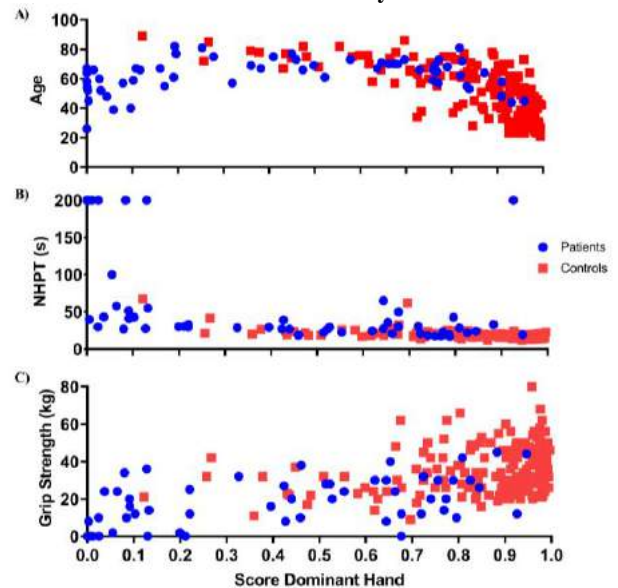

Figure 4: Objective score for participant's dominant hands plotted against ages (A) and corresponding traditional measures; NHPT (B) and Grip Strength Test (C).

DISCUSSION

Our novel hand dexterity measurement device is more sensitive than standard measurement techniques, with a low floor effect despite patients demonstrating significant hand impairment. It accurately records the finger tapping movement with a high degree of sensitivity and has potential as a small and simple to use device for remote monitoring. Our new calculated score is an objective measure of hand dexterity that is sensitive and correlates with the traditional measures. It has the potential to record changes in hand function and enables longitudinal data collection - vital for clinical trials. No previous technology-based solutions for hand dexterity assessment have been adopted in clinical practice, due to limitations in usability, cost and clinical meaningfulness, this new system overcomes these limitations.

INTRODUCTION

Despite continued progress in fracture treatment, non-unions, which can lead to additional surgeries and significant morbidity, are still prevalent and the best-practices to avoid them remain under debate. Specifically, questions regarding the optimal surgical fixation method for distal femoral fractures have been investigated through conventional clinical trials and bench-top tests. However, most remain unanswered due to the constraints of *in vivo* and *in vitro* trials, such as limited patient and surgeon recruitment capacity [1] and limitations of *in vitro* callus development. *In silico* trials have successfully addressed questions left unanswered by clinical trials and *in vitro* testing [2].

Fracture healing algorithms, such as the Ulm Fracture Healing Model [3], simulate the progression of fracture healing and can be used to compare fixation methods and configurations. The algorithms model callus chondrogenesis and ossification based on the mechanical strain environment at each location in the callus. A finite-element (FE) model of fracture and fixator calculates the strains due to expected external loading. The healing algorithm calculates updated material properties for each callus finite element, representing the progression of healing; the simulation is repeated in an iterative process. Despite the progress of fracture healing algorithms, they are not fully validated. Specifically, they have not been validated across different fracture geometries, healing metrics, and applied strains [4].

This study presents a qualitatively validated fracture healing model of an ovine metatarsal fracture stabilized with a custom external fixator. We compared it against corresponding experimental data from literature [5] across 3 different initial interfragmentary gap sizes and 2 different initial interfragmentary strains. These experimental data were chosen for comparison against the simulations due to the controlled mechanical properties of the external fixator used and the variety of fracture geometries and loads analyzed. Bending stiffness is used as the primary comparison metric since interfragmentary movement has been shown to be a poor indicator of successful union [5].

METHODS

An FE model was developed in MSC.Marc (v2021, MSC Software) of a simple transverse mid-diaphyseal metatarsal ovine osteotomy secured with an external fixator with a pre-defined callus domain. A 40 mm long section of the fracture region was modelled with the metatarsus represented as a hollow cylinder, with outer diameter and thickness of 16 mm and 2 mm, respectively. The external fixator was represented as an axial spring according to the specified design criteria of the original experiment [5]. The bone fragments were meshed using quadratic tetrahedral elements with an average element size of 1 mm. The callus domain was meshed using quadratic tetrahedral elements with an element size of 0.7 mm at the fracture gap and an average element size of 1.2 mm. A diagram of the FE model is shown in Figure 1. An axial compressive load of 500 N was applied.

Figure 1: Diagram showing the longitudinal section of the 3D FE model of the healing simulation, with bone fragments shown in grey and the callus domain shown in blue, with the external fixator represented as an axial spring.

The fracture healing algorithm was developed based on a modified version of the Ulm Fracture Healing Algorithm [3] which assumes unconstrained callus perfusion [4]. 6 different initial conditions were simulated, representing the experimental conditions of Claes et. al. [5] (Table 1). Gap sizes of 1, 2, and 6 mm, and allowable interfragmentary

strains of 7 and 31%, were used (Table 1). The simulations were run for 56 iterations, representing 56 days.

Table 1: Model set up: fracture gap width and interfragmentary strain allowed in each of the developed models, recreating the experimental conditions of Claes et. al. [5].

Group	Gap Size (mm)	Strain (%)
A	1	7
B	1	31
C	2	7
D	2	31
E	6	7
F	6	31

A mesh convergence study and a callus domain-size independence study were performed on the Group C (Table 1) simulation. The converged callus domain size was 26 mm long and 32 mm in diameter.

Bending stiffness of the simulated fracture region at the final iteration was assessed using virtual mechanical testing [4]. The bone fragments were extended in length for an overall limb length of 200 mm, matching the experimental conditions [5]. An *in silico* four-point bending rig was developed and the bending stiffness of the metatarsus was assessed.

RESULTS

Simulations which yielded successful union displayed an initial bony outgrowth from the periosteum followed by initial bony bridging at the external callus, followed by cartilage ossification in the interfragmentary region, thus demonstrating the qualitative physiological secondary fracture healing stages [6].

The simulated bending stiffness of the ovine metatarsus at 8 weeks for groups A-F were 19.8, 19.7, 19.8, 1.8, 18.5, and 0.3 N mm⁻¹, respectively, and are shown against the experimental results of Claes et. al. [5] in Figure 2.

Figure 2: Bending stiffness of the simulated callus region of each case at 8 weeks post-fixation as measured by a four-point bending simulation compared against bending stiffnesses of corresponding cases reported in experimental results by Claes et. al. [5].

The simulated daily progression of interfragmentary movement (IFM) for Group C is shown in Figure 3 against the weekly measured IFM of Group C in the experimental results reported by Claes et. al. [5].

Figure 3: Simulated interfragmentary movement (IFM) compared against the experimental results by Claes et. al. for Group C [5].

DISCUSSION

Simulations of successful fracture healing groups (A, B, C, E) displayed physiologically accurate qualitative ossification patterns as demonstrated by callus healing radiography studies [6]. This contrasts the healing patterns displayed by previous fracture healing algorithms which frequently suffered from spontaneous ossification at the extremities of the callus domain due to strain artefacts [3].

The simulated callus bending stiffness at 8 weeks post-fixation (Figure 2) agrees with the data of Claes et. al. [5] for Groups A, B, C, and F. However, the detrimental effect of high strain is over-stated (Group D) and the detrimental effect of a large initial gap size is understated (Group E). The dependence of the algorithm to these input parameters could be addressed with a broad sensitivity study to quantify their effect on the algorithm outcomes.

The simulated IFM values at week 8 fall outside of the published experimental values, however, IFM has been shown to be a poor indicator of fracture healing [5]. Instead, the time period during which the largest reductions in IFM occur, likely related to initial bony bridging of the callus, are considered a better indicator. Specifically in Group C, this occurs during weeks 2-3 (Figure 3).

This study demonstrates the qualitative physiological validation of a fracture healing algorithm and an initial quantitative validation for four of the six simulated fracture fixation conditions. The discrepancies between the presented model and experimental data will be addressed with a further sensitivity study of the model. The model will then be applied to an *in silico* clinical trial to investigate the optimal fracture fixation treatment for distal femoral fractures for a variety of loading conditions and fracture types.

COLLAGEN CROSSLINKING DRAMATICALLY IMPAIRS THE FRICTIONAL PERFORMANCE OF ARTICULAR CARTILAGE

INTRODUCTION

In osteoarthritis (OA), loss of tissue stiffness is thought to expose cartilage to elevated compressive and shear strains, leading to chondrocyte dysfunction and degeneration [1-3]. As a result, reversing cartilage softening has been suggested as a means to slow or halt OA progression. For example, collagen crosslinking (CXL) can reinforce native and tissue engineered cartilage [4-7], and thus has seen interest as a method for stabilizing cartilage and preventing degeneration.

Classical stationary contact area (SCA) tribology studies support cartilage softening as a driver of elevated cartilage friction. In depressurized and slowly slid (~1mm/s) SCA contacts, equilibrium friction coefficients of 'OA' cartilage ($\mu_{eq}=0.2-0.3$) are ~2X higher than healthy tissue [2-4]. Paradoxically, though, similarly elevated SCA frictions have been reported following CXL [6]. However, the clinical relevance of such SCA-based findings are unclear given that articular cartilage operates at higher average sliding speeds (30-80mm/s) and sustains markedly lower frictions ($\mu_{eq}<0.005$) *in vivo* [8].

Alternatively, our team has pioneered the use of the convergent SCA (cSCA) to investigate cartilage function under biofidelic sliding conditions. In the cSCA, modest sliding speeds (>30mm/s) i) facilitate interstitial fluid recovery and ii) sustain near-physiological friction coefficients ($\mu_{eq}\leq 0.01$) via tribological rehydration [8-10]. Critically, cSCA tribomechanical outcomes are largely insensitive to tissue mechanical properties in both healthy [8-9] and OA-like cartilage [10]. Thus, while CXL can increase cartilage tensile and compressive moduli [6-7], whether the restoration of tissue stiffness alters articular cartilage lubrication under biofidelic articulation conditions (such as those replicated in the cSCA) remains unknown. Here, our objective was to determine if reinforcement of cartilage via CXL alters its lubricity under sliding conditions that better represent those of the intact joint.

METHODS

Osteochondral explants ($\varnothing 19$ mm) were extracted from mature bovine femoral condyles. Specimens underwent sequential

microindentation and cSCA-based tribomechanical testing in their naïve state and after treatment with crosslinking agents (**Fig. 1**).

A $\varnothing 4$ mm glass probe was used to indent each specimen in creep-relaxation (at 50 μ m/s to a 150mN load), and the time-dependent normal force and indentation depth were fit to Hertz biphasic theory (HBT) to determine tensile modulus (E_{y+}), compressive modulus (E_{y-}), and permeability (k_0) [10]. Tribological testing consisted of ramp loading to 7N ("force-matched") or 4N ("stress-matched"), followed by 30min static compression and 15min reciprocal sliding. Explants were crosslinked with 0.6% glutaraldehyde (GTA) for 1h or 10mM genipin (GP) for 24h (n=5/treatment). Differences in mechanical properties and tribomechanics following CXL were assessed via paired *t*-tests and two-way ANOVA with Tukey's post-hoc test, respectively.

Fig. 1: Experimental overview. Pairwise assessment of indentation-based mechanical properties and cSCA tribology of naïve cartilage and following reinforcement with collagen crosslinking agents (naïve and 1hr of 0.6% GTA shown).

RESULTS

Collagen crosslinking significantly increased both cartilage tensile and compressive moduli. Tensile moduli increased from 2.65 ± 0.80 to 6.31 ± 0.22 and from 3.72 ± 1.18 to 5.10 ± 1.37 MPa following GTA and GP treatment, respectively ($p<0.001$, **Fig. 2A**). Similarly, compressive moduli increased from 0.51 ± 0.08 to 1.35 ± 0.17 MPa in the GTA group

and from 0.54 ± 0.09 to 0.80 ± 0.09 MPa in the GP group ($p < 0.001$, Fig. 2B). Consistent with prior findings [6-7], these crosslinkers had no significant effect on permeability ($p > 0.2$). Dilatation under 7N loading (“force-matched” tests) was reduced by CXL, resulting in 66% higher contact stresses compared to the naïve state (Fig. 2C). Thus, “stress-matched” tests, wherein CXL cartilage was loaded to 4N, were performed, resulting in contact stresses of 0.26 ± 0.03 MPa (Fig. 2C).

Fig. 2: Cartilage tensile (A) and compressive moduli (B) increased significantly following CXL. (C) cSCA contact stresses for naïve, and “force”- and “stress”-matched CXL tribomechanical tests. Data shown as mean \pm SD ($p < 0.001$ vs. naïve).**

CXL significantly decreased elastic strain during ramp loading relative to naïve tissue ($p < 0.001$). In force-matched tests, exudative strain decreased following GTA ($p = 0.02$), but not GP treatment ($p = 0.28$, Fig. 3A). However, both treatments decreased exudative strain in stress-matched tests ($p < 0.001$, Fig. 3A). Tribological rehydration drove average strain recovery of $4.7 \pm 1.7\%$ in naïve cartilage (Fig. 3B). Following GTA treatment, strain recovery decreased to $1.2 \pm 1.0\%$ and $2.8 \pm 0.6\%$ in force- and stress-matched tests, respectively ($p < 0.05$, Fig. 3B). GP had no significant effect on strain recovery ($p > 0.35$, Fig. 3B).

In naïve cartilage, transient friction coefficients of 0.08-0.22 were observed at start-of-sliding, which then rapidly dropped to near-physiological values (median $\mu = 0.005$, Fig. 3C). In contrast, start-of-sliding friction coefficients increased after CXL (to 0.19-0.58) and remained elevated through the end-of-sliding. For GTA-treated explants median end-of-sliding friction coefficients were 0.31 and 0.23 for force- and stress-matched tests, respectively (Fig. 3C). For GP-treated explants end-of-sliding friction coefficients were significantly elevated for force-, but not stress-matched tests (Fig. 3C).

DISCUSSION

Here, we introduce the first biofidelic assessment of articular cartilage lubrication following tissue CXL with agents proposed for ‘preserving’ native cartilage or ‘strengthening’ graft materials [4-7]. Following GTA treatment, elastic and exudative strain were significantly reduced, indicating enhanced tissue resistance to compressive loads. However, GTA compromised tribological rehydration-mediated strain recovery under equivalent applied forces. At 7N, only 11% of the exudative strain was recovered in GTA-treated explants vs. 35% in their naïve condition, indicating significant reduction in the rehydration capacity of crosslinked cartilage at equivalent loads. CXL also decreased cartilage contact area expansion under load. Consequently, contact stresses at 7N nearly doubled after crosslinking (from 0.25 to 0.46 MPa). The concomitant reduction in strain recovery observed here under equivalent forces is consistent with recent findings that modestly elevated contact stresses suppress tribological rehydration [11].

To disentangle the effects of elevated contact stress on tribological rehydration from those of CXL alone, cSCA tests were repeated at 4N (0.26 ± 0.03 MPa). As expected, exudative strains were lower in these “stress-matched” tests. However, ~40% of exudative strains were recovered by tribological rehydration, suggesting that elevated contact stresses indeed impaired fluid recovery in the “force-matched” tests.

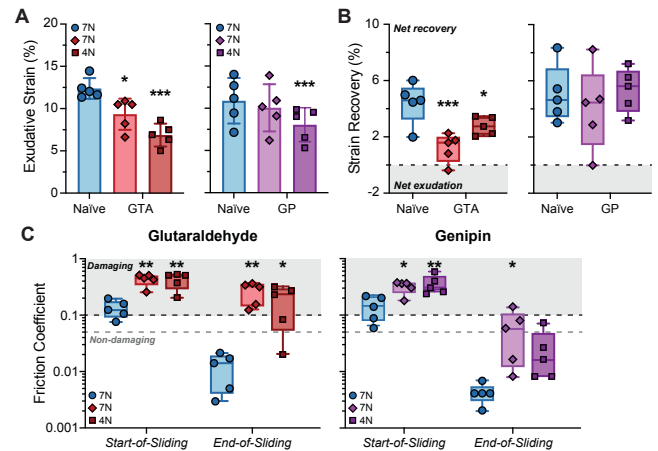

Fig. 3: (A) Exudative strain and (B) strain recovery of naïve and CXL cartilage. (C) Friction coefficients were elevated following CXL. Data shown as (A) mean \pm SD and (B-C) median \pm IQR (* $p < 0.05$, ** $p < 0.01$, * $p < 0.001$ vs. naïve).**

Most importantly, our friction outcomes revealed incontrovertible detrimental impacts of CXL on cartilage lubrication, despite the persistence of strain recovery (*i.e.*, tribological rehydration). In PBS-bathed cSCA contacts, naïve cartilage sustained near-physiological equilibrium friction coefficients (average $\mu_{eq} = 0.005$), whereas average μ_{eq} of 0.26 and 0.06 were observed among force-matched tests of GTA- and GP-crosslinked samples, respectively. Furthermore, reducing the applied contact stress failed to restore friction coefficients of CXL cartilage to those in the naïve state. Exposure to such elevated friction coefficients is likely detrimental to chondrocytes, as multiple studies report marked cell death after just 30-60min of sliding at $\mu \geq 0.10$ [1,12].

In summary, this study demonstrates that increased cartilage stiffness does not automatically equate to improved, or even adequate, tribomechanical function under biofidelic sliding conditions (*i.e.*, high sliding speeds, incomplete interstitial fluid depressurization). Marked reduction in the frictional performance of crosslinked cartilage despite their “improved” stiffness and load-bearing capacity indicates that CXL is ill-suited for cartilage preservation and/or joint resurfacing. Even if CXL were to improve the tribomechanical properties of ‘compromised’ cartilage, its effect on healthy tissue within the joint would likely preclude CXL-based OA mitigation approaches. Ongoing work will investigate if the presence of natural cartilage lubricants (*i.e.*, synovial fluid) can mitigate the deleterious effects of CXL on cartilage lubrication, or if alternative tissue reinforcement strategies (GAG-replacement) might be more suitable for rescuing articular cartilage’s tribomechanical function.

EFFECTIVE STRAIN SHARPLY CAPTURES THE RUPTURE POINT OF ANEURYSM TISSUES

INTRODUCTION

Strain- or stress-based rupture criteria have been gradually introduced into aneurysm risk assessment. However, values of ultimate strain or stress in the literature exhibit significant intra- and inter-subject heterogeneities. This brings in a certain level of uncertainties in patient-specific application if one is to rely on literature values, and eventually hinders the application of mechanics-based risk analysis. We submit that the total strain is not a suitable failure metric because it does not reflect the true strain level in the collagen network. In recent works [1,2], we introduced an effective strain to measure the net strain in the collagen after excluding the part of strain spent to straighten the fibers. In light of this new metric, we examined the effective strain of 156 sets of uniaxial tension data and 13 sets of bulge inflation test data of ascending thoracic aortic aneurysm (ATAA) tissues [3,4]. The waviness properties, which were required for evaluating the effective strain, were obtained from constitutive regression. The study found that all samples ruptured sharply around 10% of effective strain.

METHODS

Effective Strain. The effective strain was introduced in [1]. It is a tissue-scale strain measure derived in a multi-scale context. At the fiber-scale, the true stretch of a fiber is defined as the ratio of the deformed length over the undeformed arclength. If the deformation is insufficient to straighten the fiber, the true stretch is set to be unit. The effect stretch is the ensemble average of the fiber true stretch over the probability distribution of fiber waviness. In the seminal work, Rezakhanlou et al [5] showed that the waviness of arterial collagen was best described by beta distribution. Using the beta distribution, the effective stretch was derived as

$$\bar{\lambda} = F(\lambda^{-1}; \alpha, \beta) + \frac{\lambda\alpha}{\alpha+\beta} F(\lambda^{-1}; \alpha+1, \beta, upper) \quad (1)$$

Here, λ is the kinematic stretch, (α, β) are the shape parameters of the beta distribution, $F(x; \alpha, \beta)$ is the incomplete beta function, and $F(x; \alpha, \beta, upper) := 1 - F(x; \alpha, \beta)$ is its tail. The effective stretch $\bar{\lambda}$

is a monotonically increasing function of λ and is bounded above by $\lambda \cdot E(p)$ where $E(p)$ is the mean waviness. Note that $\bar{\lambda}$ is a directional stretch measure; the directional dependence enters through λ . The corresponding effective strain is

$$\bar{E} = 0.5(\bar{\lambda}^2 - 1) \quad (2)$$

Determination of waviness parameters. The effective stretch depends on the beta distribution parameters (α, β) . These parameters were identified from constitutive regression; the stress-strain response data were fitted to constitutive models that employed the effective strain as a deformation measure. For uniaxial extension, the strain energy function assumed the form

$$W = \mu_1(\lambda^2 + 2\lambda^{-1} - 3) + \mu_2\bar{E}^2 \quad (3)$$

The first term represents the strain energy of the ground substances. It is reduced from a neo-Hookean function after imposing the incompressibility condition and the assumption of isotropic transverse contraction. The second term is the contribution from the collagen network, formulated as a quadratic function of the effective strain. The model contains four constitutive parameters: $(\mu_1, \mu_2, \alpha, \beta)$.

For bi-axial response, the following constitutive model was used:

$$W = \mu_1(I_1 - \log I_2 - 2) + \mu_{21}\bar{E}_1^2 + \mu_{22}\bar{E}_2^2 \quad (4)$$

Again, the first term represents the ground substance contribution, now a function of the principal invariants (I_1, I_2) of the in-plane deformation tensor. The strain energy of the collagen network is described by quadratic functions of effective strain in two sampling directions. The angles of these two directions were also determined by regression. This model contains seven parameters: $(\mu_1, \mu_{21}, \mu_{22}, \alpha, \beta, \theta_1, \theta_2)$.

Experimental data. The uniaxial extension data were collected in Professor Ferdinando Auricchio's laboratory. Approximately 180 sets of data were obtained from ATAA tissues samples from 52 patients who underwent surgery, and 156 sets were used in this study. Some scattered data points were removed. This was accomplished by fitting the raw data to a NURBS curve, and then

computing the stress and stretch at uniformly spaced knots. Third order NURBS with 7 knot intervals was found to accurately replicate the curves.

The biaxial response data were extracted from bulge-inflation tests conducted in Professor Stephane Avril's laboratory. Briefly, ATAA tissue samples of ~3cm radius where subjected to incremental transverse pressure till rupture. At each pressure pause, the surface geometry was recorded by Digital Image Correlation. A NURBS mesh that corresponded through all deformed configurations was extracted, and the strain fields were computed from the deforming mesh. Stress field in each configuration was computed individually using an inverse analysis method [6]. In this manner, stress-strain curves were obtained at multiple material points, approximately 2300 in each specimen.

RESULTS

Constitutive regression. The optimal parameters were obtained by minimizing the squared difference of the experimental and modeled stresses. The 1D quadratic model (3) fitted the uniaxial data very well. The R^2 values were above 0.95 for 148 specimens (94.8% of the total). The 2D model (4) also described the planar response well. Sample-wise median R^2 were over 0.95 for all 13 samples. Forward finite element analyses were conducted to simulate the inflation motion. The displacement, strain and stress fields in all deformed states were replicated to high fidelity.

Rupture Strain. Figure 1 presents histograms of the effective strain at rupture, denoted by $\bar{\epsilon}_f$, from the uniaxial tests. Evidently, the ultimate effective stretches are closely packed, with nearly 70% of them cluster around 0.1. In contrast, the values of total stretch are wide-spread. The statistics are summarized in Table 1.

Table 1. Statistics of ultimate strains.
 $\bar{\epsilon}_f$: effective strain; ϵ_f : total strain

Variable	Mean \pm SD	Median ([interquartile])
$\bar{\epsilon}_f$	0.113 ± 0.049	0.109 ([0.079, 0.146])
ϵ_f	0.365 ± 0.207	0.326([0.240, 0.432])

For the planar response we define the effective strain norm as

$$\bar{\epsilon} = \sqrt{\bar{E}_{major}^2 + \bar{E}_{minor}^2} \quad (5)$$

where $(\bar{E}_{major}, \bar{E}_{minor})$ are the effective strains in the two principal strain directions. The norm of the total strain, ϵ , is defined in the same way. Note that $\bar{\epsilon}$ applies to the uniaxial extension as well because $\bar{E}_{minor} = 0$ in this case. Distributions of $\bar{\epsilon}$ and ϵ at rupture are presented in Figure 2. Again, the effective failure strains are closely clustered around 0.1 while the other spread over a wider range.

DISCUSSION

The present study underscores the importance of considering collagen waviness in assessing the ultimate strain that the tissue can sustain. The result implies that failure is dictated by the level of true strain in the collagen network, not the total strain that measures the bulk deformation of the continuum. This is reasonable, because near failure the mechanical load is sustained primarily by the collage fibers and hence, the mechanical condition of the collagen network is likely the leading factor that determines rupture. The finding suggests that the effective failure strain could be much more homogeneous than the total strain. The heterogeneity seen in the total strain could be attributed to the difference in collagen waviness (more generally, the collagen microstructure). It should be cautioned, however, that the waviness

properties were obtained from constitutive regression, not direct measurement. Lack of direct experimental measurement, or validation, of the waviness properties is a major limitation of the present work. Nonetheless, the study points to a new direction for establishing failure metrics which are hopefully more applicable, and more reliable in patient-specific studies.

MODELING HUMAN SEX-SPECIFIC FIBROTIC ACTIVATION IN 3D-BIOPRINTED PULMONARY ARTERY ADVENTITIA

INTRODUCTION

Interactions between cells and the extracellular matrix (ECM) are critical drivers of fibrotic diseases like pulmonary arterial hypertension (PAH), a progressive and incurable pathology characterized by aberrant cell proliferation and ECM remodeling. This pathology narrows blood vessels, increases blood pressure in the arteries of the lungs, and ultimately leading to right heart failure. Female patients are diagnosed with idiopathic PAH (IPAH) as much as four times more frequently than male patients, but there is no clear reason for this discrepancy [1].

Synthetic tissue culture platforms made from 3D hydrogel biomaterials are a powerful tool for studying cell-ECM interactions. Poly(ethylene glycol)-alpha methacrylate (PEG- α MA) is the backbone of a dynamic hydrogel system that undergoes an initial base-catalyzed Michael addition and can be stiffened *in situ* by photoinitiated homopolymerization. These two polymerization reactions allow the formation of an initially soft hydrogel with an elastic modulus (E) of 1-5 kPa that can be stiffened up to an E > 10 kPa. These E values recapitulate healthy and fibrotic pulmonary arterial adventitia mechanical properties [2], which allows PEG- α MA to be used as a culture platform to study human pulmonary artery adventitia fibroblast (HPAAF) behavior in a reproducible synthetic microenvironment.

Here, we use 3D bioprinting techniques to create vascular constructs with PEG- α MA hydrogels and male or female HPAAFs. These constructs are used to probe sex-specific fibrotic activation associated with PAH pathology, including cell proliferation, production of the myofibroblast marker alpha-smooth muscle actin (α SMA).

METHODS

PEG- α MA Synthesis and Hydrogel Characterization: PEG- α MA was synthesized as previously described and functionality was verified by ¹H NMR [3]. Hydrogels were fabricated by combining 17.2 wt% PEG- α MA off-stoichiometry ([thiol]:[ene] = 0.375) with dithiothreitol and MMP2-degradable peptide crosslinkers (70:30

peptide ratio). Hydrogels contained 2 mM of the adhesive peptide CGRGDS and 2.5 wt% poly(ethylene oxide) to facilitate cell attachment and suspension. Hydrogel discs were allowed to swell overnight with 2.2 mM lithium phenyl-2,4,6-trimethylbenzoylphosphine (LAP) photoinitiator. Then, storage modulus was measured on a Discovery HR-2 rheometer [4].

Cell Culture: HPAAFs from male and female IPAH patients and control donors were cultured according to supplier instructions (Pulmonary Hypertension Breakthrough Initiative). Following bioprinting, constructs were cultured with complete media supplemented with 1% sex-matched human serum (Innovative Research, Inc.). Sera from three donors between the ages of 20 and 50 years old were pooled for each sex.

3D Bioprinting: Constructs were 3D bioprinted using the Freeform Reversible Embedding of Suspended Hydrogels method [5]. Hydrogel components were dissolved in pH 9 growth media. LifeSupport gelatin microparticles were dissolved in pH 7 growth media. HPAAFs were suspended in hydrogel precursor solution, then printed in 48-well plates containing LifeSupport and allowed to polymerize for one hour. Then, the plates were placed in a tissue culture incubator for two hours. Melted support slurry was aspirated off and replaced with growth media containing 1% sex-matched human serum. On day 6, 2.2 mM LAP was added. On day 7, half of the constructs were stiffened by exposure to 10 mW/cm² 365-nm light for 5 minutes.

Immunofluorescent Staining: Control male samples were 3D bioprinted and immunostained as part of previous work [4]. Constructs were incubated with EdU overnight on day 8, then fixed, quenched, and flash-frozen on day 9. Constructs were cryosectioned and then stained with α SMA antibody, EdU staining solution, and Hoechst dye. Slices were imaged at 10x on an Olympus BX63 microscope.

Statistical Methods: Sample means were compared using ordinary two-way ANOVA with α = 0.05 and Tukey tests for multiple

comparisons. Data are presented as mean \pm standard error of the mean (SEM) for three technical replicates of each condition.

RESULTS

EdU positivity was used to assess fibroblast proliferation, and this metric was greater in stiffened bioprinted constructs compared to soft (**Fig 1A**). Control male cells in soft and stiffened bioprinted constructs were $39 \pm 6\%$ and $66 \pm 6\%$ proliferative, respectively ($p < 0.05$). Control female cells in soft and stiffened constructs were $48 \pm 4\%$ and $64 \pm 4\%$ proliferative, respectively. IPAHA male cells were $47 \pm 4\%$ proliferative in soft constructs and $66 \pm 6\%$ proliferative in stiffened constructs. IPAHA female cells in soft constructs were $63 \pm 3\%$ proliferative and $83 \pm 4\%$ proliferative in stiffened constructs ($p < 0.05$). All fibroblast conditions saw statistically significant increased activation in stiffened constructs compared to soft constructs ($p < 0.05$; **Fig 1B**). Control male cells in soft and stiffened constructs were $65 \pm 4\%$ and $88 \pm 2\%$ α SMA-positive, respectively. Control female cells were $64 \pm 5\%$ activated in soft constructs and $83 \pm 3\%$ activated in stiffened constructs. IPAHA male cells were $66 \pm 3\%$ activated in soft constructs and $81 \pm 3\%$ activated in stiffened constructs. Finally, IPAHA female cells in soft and stiffened constructs were $71 \pm 4\%$ and $90 \pm 2\%$ activated, respectively. These differences can be seen in representative images (**Fig 1C**).

DISCUSSION

Matrix stiffness is a well-established modulator of myofibroblast activation, with stiffer substrates producing more activated fibroblasts [6]. The significant increases in α SMA positivity seen in stiffened constructs lines up with the body of research done on 2D hydrogels and builds upon 3D culture studies by using an MMP2-degradable crosslinker that allows activation in 3D as well [7]. The greater percentage of activation observed in IPAHA female HPAAFs compared to other conditions was expected due to prevalence of PAH in female patients and prior research that saw increased α SMA positivity in fibroblasts treated with female serum compared to male serum [8]. Estrogen has been shown to increase cell proliferation in clinical studies, which supports our findings of increased EdU positivity in IPAHA female cells [9]. The increased proliferation we observed in male control HPAAFs is indicative of those cells' susceptibility to stiffening and may be related to the worse outcomes generally seen in male PAH patients [1]. Results shown here are preliminary, and further studies are underway to measure fibrotic gene expression through qRT-PCR, as well as characterize the effect of estrogens on activation. This platform can be used to study sex-specific fibrotic behavior in the context of pulmonary vascular disease with a reproducible 3D microenvironment.

INTRODUCTION

Reducing the damage caused to the remaining bone during a tooth extraction is an important consideration to improve patient recovery times and can influence the success of subsequent implantation at the extraction site [1,2]. Atraumatic extraction applies different forms of extraction load compared to conventional forceps extraction to minimize this damage and improve outcomes. One example, the Benex extraction system [3], uses a cable and threaded insert to apply a purely vertical extraction force to the tooth as demonstrated in Figure 1.

Figure 1: a) Cross-section of a tooth prepared for Benex extraction; b) vertical extraction force via Benex device.

Finite element (FE) models of the dental complex are important tools for the development of dental appliances and procedures, but to date there are few models suitable for studying tooth extraction. These models either offer a limited representation of the tooth geometry [4] or are computationally-expensive subject specific models with custom material models for the periodontal ligament (PDL; the soft tissue which attaches the tooth to the surrounding bone) [5]. The focus of this study is the development of an axisymmetric FE model of the dental complex with PDL properties determined via an inverse FE problem.

METHODS

Experimental Data Collection and Preparation: Force-time data was collected from partial swine incisors in an ex-vivo experiment. Incisors were extracted in three displacement-controlled schemes: 0.2mm/min, 2mm/min, and intermittent periods of 2mm/min displacement followed by 10s of relaxation. Experimental data from after 50N to the peak extraction force were parsed from full data sets.

50N was the minimum force found across all tests to align the custom-built testing apparatus, beyond which the measured crosshead displacement acts on the dental complex solely and not alignment of components. The time at which each curve passed the 50N threshold was averaged to obtain the mean transition time to which all force-time curves were shifted.

Model Boundary Conditions and Mesh: The model is composed of simplified planar bodies representing bone, PDL, dentin, and a threaded insert from a Benex extraction kit. These bodies were meshed as a revolution of planar geometry in SALOME. Symmetry boundary conditions were used to enforce axisymmetric behaviour as demonstrated in Figure 2.

Figure 2: Mesh bodies and boundary conditions; Benex insert (screw), dentin (yellow), PDL (purple) and bone (blue).

Nodal fixation was applied to the bone far from the screw. Isotropic Hookean material properties were assigned to the steel, dentin, and bone with a principal-strain based damage model for the dentin and bone using FEBio[6]. The Arruda-Boyce model [7] was selected as the hyperelastic base for the PDL:

$$W = \mu \sum_{i=1}^N \frac{C_i}{N^{i-1}} (I_1^i - 3^i) + \frac{1}{2} k (\ln(J))^2 \dots (1)$$

where μ is the initial material modulus, N the number of modelled chains, k the bulk modulus, and C_i pre-determined constants. Viscoelasticity was modelled with a single-branch quasi-linear model:

$$S_v(t) = \int_{-\infty}^t G(t-s) \left(\frac{dS_e}{ds} \right) ds \dots (2a)$$

$$G(t) = 1 + g_1 \exp\left(-\frac{t}{t_1}\right) \dots (2b)$$

where g_1 is the relaxation constant and t_1 the relaxation time, Damage was applied with a quintic polynomial and a maximum principal stress criterion:

$$\sigma = (1 - D) * dev(\sigma_v) + pI \dots (3a)$$

$$D(\epsilon) = x^3(10 - 15x + 6x^2) \dots (3b)$$

$$x = \frac{\epsilon - \epsilon_{min}}{\epsilon_{max} - \epsilon_{min}} \text{ when } \epsilon \in (\epsilon_{min}, \epsilon_{max}) \dots (3c)$$

where ϵ_{min} and ϵ_{max} are the damage-limiting strains.

Formulation of the Inverse FE Problem: Simulation loading was initiated with a linear force-controlled ramp to the 50N transition force determined by the experimental data. After the 50N transition, displacement-controlled loading was applied to match the experimental crosshead loading scheme. Only data beyond the 50N transition is used to determine the PDL properties using an optimization error function as given in Equation 4.

$$Err = \sum_{i=1}^n [(SSE_i/10^5) \Delta t_{rupture,i}^2 \Delta F_{rupture,i}^2] \dots (4)$$

where n is the number of experimental curves in the data set and Δ terms are the differences in rupture time and force between each experimental curve and the FE model response. The error function was minimized in MATLAB using the `fminsearchbnd()` function [8] with the GIBBON toolbox [9]. Seven PDL parameters were passed into the search algorithm: g_1 , t_1 , μ , N , k , ϵ_{min} , and ϵ_{max} . Limits were only applied for numerical stability. Each optimization was performed using a random initial guess, bounded only for physically permissible values (e.g. relaxation times and coefficients forced greater than zero).

RESULTS

The force-time response of each inverse result is compared to the adjusted experimental data in Figure 3. Curve shapes and peak forces and times appear to match the experimental data. The determined material parameters are presented in Table 1.

Table 1: PDL material parameters from multi-curve fits

	0.2mm/min	2mm/min	Intermittent
g_1 [n.u.]	0.997	0.929	0.695
t_1 [s]	10.3	10.29	19.6
μ [MPa]	0.464	0.545	0.506
N [n.u.]	9.94	10.9	11.7
k [MPa]	9.97	9.62	7.55
ϵ_{min} [m/m]	4.95	5.00	5.00
ϵ_{max} [m/m]	13.2	12.6	18.8

DISCUSSION

The PDL hyperelasticity and damage parameters found in this study are similar among load cases despite being fit independently. This trend indicates systematic (rather than random) relationships between the dental complex response captured in the experimental data and the FE model. This finding indicates that the model is suitable for testing extraction loading schemes similar in rate to the cases tested here.

The viscoelastic parameters obtained from the continuous displacement cases require further investigation, as they exceed 0.90, indicating an even greater load-rate dependency than the intermittent-fit model ($g = 0.695$) which clearly demonstrated relaxation behaviour. However, the initial guess for g in these fits was 1 and the magnitudes have changed very little. It may be that the effect of PDL viscoelasticity in these cases is being masked by the sensitivity to other parameters and an agreeing inverse FE result can still be obtained if viscoelasticity is not included. Future work will investigate the sensitivity of the inverse FE outcomes to the initial guess for viscoelasticity and its inclusion in the material model.

The intermittent FE model demonstrates relaxation behaviour that approximates the initial relaxation periods present in the data

immediately after the 50N transition. At later times, the reductions in force in the FE model response are not as great as those seen in the experimental data. The optimization may not be as sensitive to the difference in relaxation shape because two of the experimental curves end earlier than the FE curve where the agreement is better. Additionally, the viscoelasticity model assumes a quasi-linear response which may not capture nonlinear viscoelastic effects. Further work will investigate these possibilities and their influence on the predictive capability of the FE model.

The findings of this study indicate that the axisymmetric FE model is appropriate for modelling the case of vertical tooth extraction, although further validation of the results are required. Future work will focus on validating the material parameters and testing the model response against load schemes other than those used in the inverse FE problem to demonstrate its suitability as a predictive tool for improving tooth extraction procedures.

EVOLUTION OF HUMAN CORTICAL THICKNESS AND MORPHOLOGY THROUGHOUT GROWTH AND DEVELOPMENT

Nagehan Demirci (2), Maria A. Holland (1,2)

INTRODUCTION

The brain is one of the most intricate structures of the mammalian body. Its outermost layer, i.e., the cerebral cortex, is folded with outer gyral ridges and inner sulcal valleys. The degree of foldedness (i.e., gyrification) varies across species, such that smaller species tend to have less folded cortices, and gyrification increases gradually with an increase in size [1]. A similar picture is observed throughout the growth and development of individual species. For example, fetal cortices are relatively smooth for humans until the later stages of gestation, in which cortical folds begin to emerge and the cortex is highly folded at full-term birth (Figure 1).

Figure 1: Human brain development from gestation week 25 to 43

The folding patterns are unique to each individual, similar to fingerprints, but one common feature is that gyri are thicker than sulci [2,3]. In our previous work, we developed an open-source computational pipeline that explores patterns of cortical thickness, incorporating outer and inner folds at each depth [4]. Utilizing public imaging resources, we investigated the consistent patterns of cortical thickness for multiple primate species [1,3]. Our previous results indicate that cortical thickness patterns are consistent for primate cortices with varying shapes, sizes, and degrees of foldedness – outer folds are consistently thicker than inner folds. However, not much is known about how these patterns emerge throughout development.

MRI of the human fetal brain has been a clinical tool for many years. Advances in MRI acquisition techniques enable high-resolution, complete 3D imaging of the brain *in utero*. This allows emerging cortical folding patterns to be characterized accurately. Successful quantification of the folding patterns of the cortex *in utero* is indispensable for understanding changes in folding, which are linked to

atypical brain development, as well as early and objective diagnosis of neurological deficits and disorders via reliable and accurate biomarkers.

In this study, we are interested in understanding the evolution of cortical thickness and folding patterns throughout human brain growth and development. By this, we aim to link structural changes spatially and temporally to ontogenetic (e.g., proliferation and myelination) and biomechanical determinants (e.g., differential growth).

METHODS

Here, we investigated the ontogeny of the human cortex from gestation week (GW) 25 to 43 using publicly available fetal and neonatal structural magnetic resonance images (MRIs).

Figure 2: Fetal human brain at GW25. Left: MRIs (axial, coronal, and sagittal views) depicting manual, three-tissue class segmentation labels (red: gray matter, green: white matter, blue: subcortical structures). Middle: Reconstructed white surface. Right: Reconstructed pial surface.

To achieve this, we obtained N=7 (N=3 at GW23, N=1 at GW25, and N=3 at GW27) T2-weighted fetal brain MRIs from the FeTA (Fetal Tissue Annotation and Segmentation Challenge) public data set [5]. The images were manually segmented into seven tissue classes (external cerebrospinal fluid, gray matter, white matter, ventricles, cerebellum, brainstem, and deep gray matter). We carefully reviewed the manual annotations at each slice from each direction (axial, sagittal, coronal) and refined them further using openly available medical image visualization and editing tools MRICroGL and ITK-SNAP. Next, we

converted the gray and white matter segmentations into 3D surfaces using AFNI and Freesurfer to create triangulated surfaces with spherical topology (Figure 2).

Additionally, we accessed N=76 (N=2 at GW29 and 31, N=11 at GW33, N=21 at GW35, N=5 at GW37, N=8 at GW39, N=6 at GW41, and N=2 at GW43) neonatal human brain MRIs from the ‘Developing Human Connectome Project Neonatal Data Release’ [6]. The data set includes labels of 3 tissue classes, subcortical structures, and reconstructed pial and white surfaces.

To analyze the local and global variations of cortical thickness and morphology during the growth and development of the human brain, we used our open-source computational pipeline [4] and calculated cortical thickness, cortical thickness ratio, curvature, shape index, sulcal depth, surface area, volume, and gyrification index (GI) at each growth stage. This extensive data allows us to track the evolution of each measure and the correlations between the measures.

RESULTS

First, we observed the evolution of each morphometry measure individually. For example, we observed the gradual emergence of sulci by plotting the distribution of shape index, which reveals the maturation of cortical folds. At GW27, we observe few concave and saddle-shaped points; however, at GW37, the frequency of concave shapes increases with the formation of distinct sulci and gyri (Figure 3A).

Figure 3: Evolution of shape index (A) and cortical thickness (B) before (GW 27) and after (GW 37) cortical folding

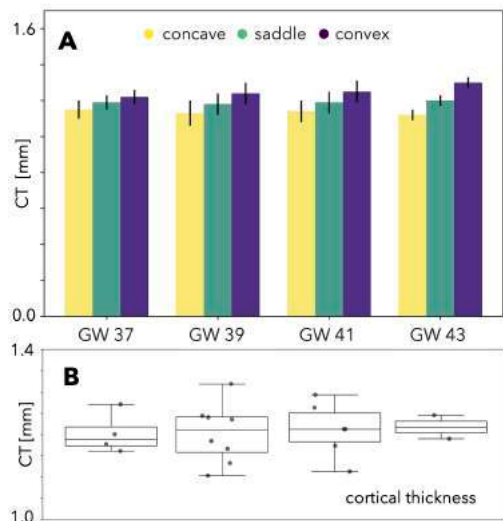

Figure 4: Cortical thickness (CT) is strongly correlated with shape (A), thickness is stable between GW 37 and 43 (B)

Second, we investigated the evolution of cortical thickness. Surprisingly, we found a thicker cortical plate at early stages of

gestation, when the cortex is still smooth. Then, the cortex thins significantly with the maturation of folds (Figure 3B).

Figure 5: Evolution of gyrification index (GI) (A). Correlation between GI and sulcal depth (SD) (B)

Third, we investigated the correlation between cortical thickness and shape. Our preliminary data for the neonatal brains reveals a similar patterning between shape and cortical thickness: the convex shape is consistently thicker than the concave shape, which is thinner than saddle shape between GW37 to 43 (Figure 4A). We also found that sulci thin and gyri thicken. As a result, the gap between gyri and sulci widens, but the average cortical thickness remains stable (Figure 4B).

Finally, we tracked the evolution of GI (measure of foldedness). We observed that GI increases immediately with the emergence of folds but then reaches a plateau towards the end of maturation of folds (Figure 5A). We also found a strong correlation between GI and average sulcal depth (Figure 5B).

DISCUSSION

Human brain growth and development are distinct before and after birth. Gyrification mainly occurs during prenatal growth, evolutionarily and genetically dissociated from postnatal growth. Primary folds, which are more consistent across species, form first, right before the emergence of secondary folds, around the second trimester of pregnancy. On the other hand, the tertiary folds continue to form after birth throughout the first years of life.

We captured the dynamic growth of cortex and gyral-sulcal patterns from GW23 to 43 using the shape index, which yields better results than sulcal depth. In this study, following our prior approach, we investigated the correlation between cortical thickness and shape and detected that at GW37, the correlation between cortical thickness and shape becomes significant and consistent. GW37 coincides with the emergence of tertiary folding patterns. This finding will help us also determine the emergence of abnormal cortical folding patterns, which might be associated with neurological diseases and disorders. In addition, we showed that cortical folding strongly affects global cortical thickness. The bending and folding of the cortex at GW25 lead to the gradual thinning of the cortical plate. As a result, the variation of the morphological measures with gestational age would give us more insight into understanding typical and atypical cortical growth rates and patterns.

CHARACTERIZATION OF LUNG LOBAR SLIDING KINEMATICS USING FINITE ELEMENT MODELLING AND HELMHOLTZ-HODGE DECOMPOSITION

Adam E. Galloy (1), Joseph M. Reinhardt (1), Suresh M. L. Raghavan (1)

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, Iowa, United States of America

INTRODUCTION

Delineating the differences in motion between healthy and diseased lungs during breathing can improve clinical diagnoses. Treatment strategies such as radiation therapy and mechanical ventilation can potentially reduce the amount of harm delivered to healthy tissue by being delivered in conjunction with the lung's natural motion. One often-overlooked aspect of lung motion is the sliding between the different lobes of the lung along the lobar fissures. Little research exists identifying the anatomical features and mechanical forces that drive lobar sliding. This knowledge gap limits our understanding of the role of lobar sliding in lung mechanics and consequently our ability to distinguish normal from diseased lung motion.

One way to improve our understanding of lobar sliding is to decompose this complex motion into simpler components. For example, Hubmayr et al. described lobar sliding in dog lungs by quantifying differences in rotations between lung lobes [1]. However, the lung lobes undergo significant nonuniform parenchymal deformation which cannot be described by a single set of rotations [2]. Helmholtz-Hodge decomposition (HHD) is promising for the characterization of sliding kinematics because it can decompose a highly nonuniform vector field into three comprehensive components associated with stretching, rotation, and translation. The goal of this study was to use finite element models (FEM) to simulate lobar sliding in the left lung and demonstrate the use of HHD to characterize sliding kinematics with physically meaningful components that still capture the full nonuniformity and complexity of sliding motion.

METHODS

Six healthy subjects (ages 22-37) underwent CT scans following a procedure approved by our institutional review board. Scans were obtained with the subjects in the supine position during breath holds at total lung capacity (TLC) and functional residual capacity (FRC). The

two left lung lobes (upper and lower) and thoracic cavity were segmented from the images. From the segmentations at TLC, solid meshes representing the lung lobes were generated along with a surface mesh of the thoracic cavity.

Exhalation was simulated by prescribing displacements to the thoracic cavity surface to drive deformation of the lobar tissue with contact constraints. Thoracic cavity displacements were derived by registering the thoracic cavity mask at FRC to the mask at TLC. Contact was assumed to be frictionless between each of the lung lobes and between the lobes and thoracic cavity. Thoracic cavity displacements were applied incrementally (minimum of 20 increments) to allow the trajectories of points throughout the deformation to be tracked. Simulations were quasi-static and assumed no viscoelasticity in the lung tissue. This contact mechanics model of lobar sliding has been described in detail in Galloy et al. [3].

After the simulations, at each node of the lower lobe along the lobar fissure, a sliding displacement vector at time increment n was computed as follows:

$$\Delta \mathbf{s}_n = \boldsymbol{\pi}^U(\mathbf{u}_{n+1}^L - \mathbf{u}_n^L - \mathbf{u}_{n+1}^U + \mathbf{u}_n^U) \quad (1)$$

Where a superscript U and L signify the upper and lower lobe respectively and $\boldsymbol{\pi}^U$ is the projection operator onto the tangent plane of the upper lobe.

For each of the six subjects, HHD was performed on the sliding displacement vector field at the 10th time increment. HHD identifies three orthogonal components for a vector field on a surface homeomorphic to an open disc: the exact component, the coexact component, and the harmonic component [4]. The exact component is rotation-free and describes sliding motion arising from one lobe stretching differently than the other. The coexact component is divergence-free and describes the sliding motion arising from one lobe rotating about the other. The harmonic component is both rotation and

divergence-free and describes translational sliding motion. An example HHD of a sliding displacement field is shown in figure 1. The square magnitude of each HHD component was normalized to the square magnitude of the whole vector field to determine the relative contribution of each component.

Figure 1: 3D model of the left lung showing the lobar fissure (a) with the streamlines of the sliding displacement vector field (b). The vector field was decomposed into three HHD components: a stretch induced exact component (c), a rotational coexact component (d), and a translational harmonic component (e).

RESULTS

The relative contributions of the three HHD components to the overall sliding displacement vector field are displayed for each subject in figure 2. On average, 88% of the sliding displacement vector field was captured by the harmonic component, 7.5% by the coexact component, and 4.2% by the exact component. The dominating harmonic component suggests that lobar sliding primarily conforms to the curvature of the fissure in a motion similar to translation that has little relative stretching or rotation between lobes.

Figure 2: Relative contributions of HHD components in the study subjects shows that lobar sliding is predominantly translational (harmonic) with lesser contributions from rotational (coexact) and stretch induced (exact) motions.

The exact and coexact components had varied contributions to the overall sliding motion ranging from 2.0% to 7.4% and 0.5% to 21.6% respectively. Figure 3 compares the sliding displacement field streamlines of subject 4 who had the largest exact and coexact contributions to subject 6 whose motion was almost entirely harmonic. Subject 4 exhibits an inward spiral towards the top right (corresponding anatomically to an apical lateral location) indicating both rotation and compression of the lower lobe relative to the upper lobe at that location. On the other hand, subject 6’s streamlines form a nearly parallel field.

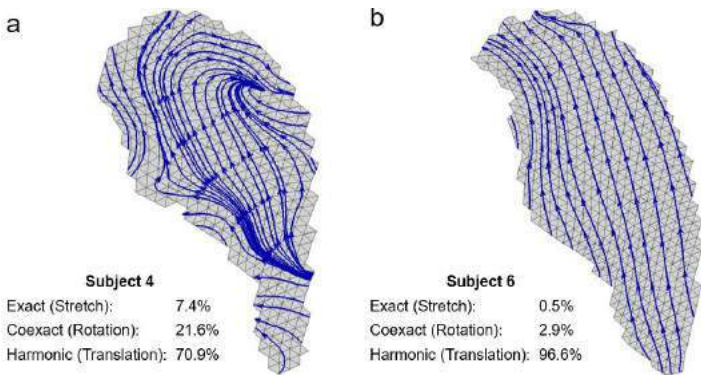

Figure 3: Subject 4’s streamlines (a) exhibit an inward spiral that is reflected by larger exact and coexact components. In contrast, subject 6 (b) exhibits nearly parallel streamlines and has small exact and coexact components.

DISCUSSION

In this study we sought to better understand lobar sliding by decomposing the sliding motion into physically meaningful components. Interestingly, we found that a large portion of the sliding motion could be described by translational motion. On the other hand, rotational motion between lobes played a smaller, sometimes negligible, role. This finding is consistent with the fact that the primary force driving lobar sliding during exhalation is the upward motion of the diaphragm which slides the lower lobe upward against the upper lobe (figure 3b). Rotation still plays a significant role in some subjects (figure 3a) but will not be an adequate descriptor of sliding motion on its own as in Hubmayr et al. [1] even when the non-uniformity of the rotation is accounted for.

A limitation to this study is that the FEM neglects three aspects of lung motion: deflection from the lung’s self-weight, the viscoelasticity of the lung tissue, and nonlinear thoracic cavity shape changes (we linearly interpolated between the TLC and FRC thoracic cavity shape for each displacement increment). Additionally, boundary effects on the HHD can potentially cause parts of the exact and coexact components to “bleed in” to the harmonic component and inflate its value. However, these limitations are unlikely to affect our finding that translation predominates lobar sliding in the left lung. Future work will examine the impact of these limitations.

VASCULAR SMOOTH MUSCLE CELLS RETAIN THEIR MATERIAL PROPERTIES IN MECHANICALLY VARIANT MICROENVIRONMENTS

Elizabeth D. Shih (1), Ryan R. Mahutga (1), Katriel S. Ng (1), Patrick W. Alford (1)

INTRODUCTION

Arterial mechanical properties are often changed in diseased tissues, such as in aneurysms and atherosclerosis.¹ Many cell functions are influenced by changing extracellular properties, guiding tissue rehabilitation or disease progression.² Vascular smooth muscle cells (VSMCs) are the mechanically dominant cells in arteries and actively respond to mechanical signals via contraction, dilation, or phenotypic switching.³ To date, it is not known whether VSMCs' nonlinear mechanical properties themselves depend on extracellular mechanics.

Here, we used cellular micro-biaxial stretching (CμBS) to examine how VSMC mechanics are influenced by extracellular mechanics.⁴ To do so, we first determined how traction force microscopy (TFM) analysis assumptions are influenced by substrate mechanics.⁵ Next, we measured mechanical properties of individual VSMCs micropatterned on substrates of varying mechanical properties. We found that VSMC mechanical properties are relatively unchanged over a physiological range of extracellular moduli. This finding has important implications for understanding the cellular mechanics of arterial disease, how they are influenced by tissue-scale properties, and how they subsequently respond to and remodel their local environments.

METHODS

Substrate Fabrication and Cell Culture. Polyacrylamide (PA) gels doped with fluorescent microspheres were synthesized onto elastomer membranes using previously described methods.⁴ PA gel modulus was varied from 14.0 kPa to 240 kPa by increasing ratios of 2% bis-acrylamide to 40% acrylamide. A layer of patterned 32 x 128 μm² fibronectin islands was stamped onto the top of the PA gel to facilitate cell adhesion onto the substrates. Human umbilical artery VSMCs (Lonza) in between passages 5-7 were micropatterned onto the gels. The VSMCs were cultured overnight in supplemented Medium 199 (Gibco), incubated at 37 °C and 5% CO₂. 24 hours before stretching, a contractile state was induced in the cells by exchanging the media with supplemented serum-free media.

Biaxial Stretching. The elastomer constructs were mounted in a custom designed CμBS apparatus on an inverted microscope (**Fig. 1A**). The CμBS device equibiaxially stretched the constructs in increments of 5% up to 20%, with brightfield and fluorescent images taken at each stretch increment of the cells and the underlying beads in the gel. The cells were then lysed and the bead layer was imaged again at the same location at each stretch increment. The fluorescent images of the gel layers with the adhered cells were paired with respective images of the gels without the cells to perform traction calculations (**Fig. 1B**).

Traction Calculation. Displacement of the beads due to cellular contraction was tracked and measured using a particle image velocimetry (PIV) ImageJ plugin between the paired images with and without the adhered VSMCs.⁶ Taking the displacement data and the known material properties of the substrate, an unconstrained Fourier

Figure 1. A. CμBS apparatus.⁴ B. Brightfield images of undeformed and stretched cell with corresponding traction maps. C. Calculation of axial and transverse PK1 stresses in a single cell.⁷

transform traction cytometry (FTTC) ImageJ plugin calculated traction stress vectors throughout the area occupied by the cell.⁶ During FTTC, a regularization factor λ is used to improve resolution and account for noise in the displacement data such that⁵

$$\iint [\tilde{G}_{ii}G_{ij}T_j - G_{ji}u_j]dr''dr' + \lambda^2 \int H_{ij}T_j dr' = 0 \quad (1)$$

λ drives the solution towards a default solution described by $\int H_{ij}T_j dr'$. G_{ij} is the Green function that maps the displacement vector u_j to the traction vector T_j . r is the absolute value of the displacement of surface point r to r' . For 0th order regularization, H_{ij} is the identity tensor.

Surface tractions were used with confocal imaging of the actin cytoskeleton to calculate the midplane first Piola-Kirchoff (PK1) stress P_i of the cell as previously described (Fig. 1C).⁴ For biaxial stretching, P_i was calculated for each stretch increment from 0% to 20% to obtain stress-stretch data. The stress-stretch curves were fit to a Holzapfel-Gasser-Ogden (HGO) strain energy density function given by

$$W = \frac{\mu_m}{2} (F_{mi}F_{mi} - 3) + \frac{C_f}{4} (K_{ij}(A_{ki}^{-1}(F_{mk}F_{mi})A_{lj}^{-1})) - 1)^2 \quad (2)$$

where F_{ij} is the deformation gradient and K_{ij} describes the actin fiber distribution.⁸ In its principal axes, A_{ij} may be described as $\lambda_a \delta_{ij}$. Eq. 2 was fit to obtain values for parameters μ_m , C_f , and λ_a , reflective of the shear modulus, actin stiffness, and activation stretch, respectively.

Finite Element Model. A finite element (FE) model was developed to simulate deformation of the gel by VSMCs during biaxial stretching in COMSOL Multiphysics. The model was comprised of the elastomer substrate, PA gel, and a micropatterned VSMC. Quarter symmetry conditions were imposed to simplify the model (Fig. 2A). The elastomer membrane and the gel were both modeled as nearly incompressible Neo-Hookean materials, and the cell was modeled as an HGO material. FTTC regularization levels were optimized using error minimization between the experimental displacement and the displacement calculated by the simulated forward problem.

RESULTS

Determining an optimal level of regularization. Prior studies in unstretched cells showed that regularization factor value (λ in Eq. 1) affects the calculated traction magnitude in TFM experiments.⁹ To determine the effect of regularization on our experiment, we first performed $C\mu$ BS studies using varying regularization, then the fitted HGO parameters from the experimental data were assigned to a finite element model of the VSMC and an that replicated the experimental protocol. The resulting simulated displacement of the gel by VSMC contraction was compared to the PIV data, and a regularization factor was calculated that minimized error between the simulation and the experiment (Fig. 2B). In cellular biaxial stretching assays, we found that as substrate Young's modulus increases, VSMCs deform the substrate less. Thus, as substrate modulus increases, the simulations using the parameters with lower regularization levels, or less filtering, are in better agreement with the experimental data (Fig. 2C).

Figure 2. Identification of an optimal regularization factor for each substrate group. A. FE model geometry and boundary conditions. B. Average experimental displacement for one group. C. Model results at different regularization factors compared against experimental data. D. Optimal regularizations plotted.

Effect of extracellular stiffness on VSMC properties. We calculated traction forces with the optimized regularization factors. PK1 stresses were calculated and average stress-strain curves were generated for VSMCs on substrates of different moduli. From the stress-strain data, we calculated basal tones as the initial axial stress (Fig. 3A), apparent axial moduli, or the fitted linear slope of the axial stress-strain curve (Fig. 3B), actin activation stretches (λ_a) (Fig. 3C), and actin stiffnesses (C_f) (Fig. 3D). On the lowest modulus substrates, VSMCs had higher basal tones, apparent moduli, and actin stiffnesses than on all other substrates. However, the VSMCs seeded on all other substrates showed little difference in the four investigated properties.

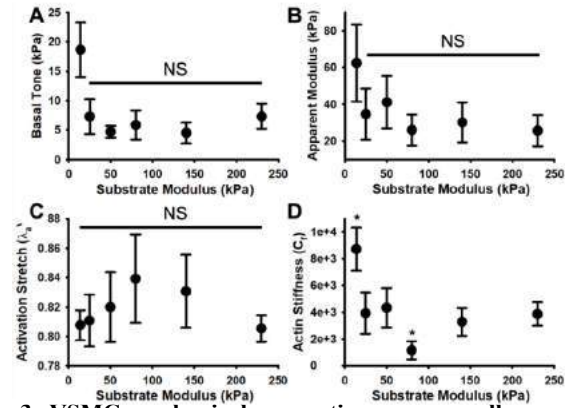

Figure 3. VSMC mechanical properties are generally consistent across substrate groups. A. Basal tones. B. Apparent moduli. C. HGO-fitted actin stiffnesses. D. HGO-fitted actin activation stretches. * denotes that that condition is statistically different ($p < 0.05$) from all other conditions and NS stands for Not Significant.

DISCUSSION

Using $C\mu$ BS with a varied regularization approach, we find that VSMC mechanical properties for cells seeded on substrates of moduli from 25 kPa up to 240 kPa are generally consistent. Prior studies have shown arterial moduli at small inflations lie in the range of 72-134 kPa.¹⁰ Taken with our data, this suggests that VSMC properties change very little in healthy arteries. Diseased tissues like cerebral aneurysms can be much softer than healthy tissue.¹¹ Here we find that in very soft environments, VSMC mechanics are altered, suggesting that in these very soft tissues, changes in extracellular mechanics might influence VSMC mechanics and potentially influence disease progression.

This work has important implications for understanding how VSMCs respond to a range of microenvironmental conditions like those observed in aneurysms. VSMC response might be a key determinant in whether an artery is able to successfully adapt to hazardous conditions or maladapt into dysfunction, such as the formation of an aneurysm susceptible to rupture or a plaque that inhibits tissue elasticity. Our results allow us to model VSMC mechanical responses as generally consistent in response to changing microenvironments, simplifying the mathematical complexity while retaining physiological accuracy.

ON THE CLOSURE KINEMATICS OF AORTIC MECHANICAL HEART VALVES VERSUS BIOPROSTHETIC HEART VALVES

Syed Samar Abbas (1), Iman Borazjani (1)

(1) J. Mike Walker '66 Department of Mechanical Engineering, Texas A&M University, College
Station, Texas, USA

INTRODUCTION

Only in the United States each year, over 100,000 patients undergo the replacement of malfunctioning aortic heart valves with prosthetic/Artificial Heart Valves (AHVs) [1]. AHVs could be mainly classified into two types: (i) Bioprosthetic Heart Valves (BHV), composed of material from live tissues [2] or (ii) Mechanical Heart Valves (MHVs), generally made up of Pyrolytic Carbon [3]. The BHVs offer an excellent hemodynamic performance, however, their constituent tissues degenerate over time, gradually resulting in their invincible deterioration. The MHVs are although durable, they have been reported to cause platelet activation that leads to thrombotic events [4]. The closure kinematics of typical MHVs bear critical importance, as they have been strongly related to their non-physiological hemodynamics, for instance, a higher regurgitation volume in comparison to the natural valves/BHVs [5] and promotion of platelet activation [6]. New designs of MHVs are therefore required to emulate the closing behavior and hemodynamics of natural valves/BHVs, such that a less thrombogenic and simultaneously durable AHV could be attained. This research, for the first time, numerically investigates the closure kinematics and hemodynamics of a newly designed Trileaflet MHV (TMHV) and compare them with a conventional Bileaflet MHV (BMHV) and a BHV under similar conditions.

METHODS

For the TMHV and the BMHV, the designs of the TRIFLO Valve (Novostia SA, Switzerland) and the On-X Valve (CryoLife Inc., USA), respectively, were selected. The BHV leaflets are modelled as non-linear, membrane-like, thin shell structures composed of anisotropic material undergoing deformations to replicate the experimentally observed stress-strain behavior of a heart valve tissue [7].

Numerical Fluid-Structure Interaction (FSI) simulations were carried out by employing the Curvilinear Immersed Boundary

(CURVIB) method as a flow solver, strongly coupled with a robust FSI algorithm for calculating the leaflet kinematics of the three AHVs [8].

Owing to the elastic deformation of the BHV leaflets, it is not possible to graphically plot the FSI angles they cover in response to the cardiac flow against time and compare them with the two MHVs. Thus, to enable the graphical visualization and facilitate a comparison of the AHVs' leaflet kinematics, the projected area of each AHV on a plane perpendicular to the streamwise direction (the z-plane) was calculated by using Equation 1 and plotted against time.

$$PA_V = \frac{IOA_V - \sum_{i=1}^n PAL_i}{IOA_{BHV}} \quad (1)$$

where, PA_V is the projected area of the AHV on the z-plane, IOA_V is its inner orifice area, PAL_i is the projected area of the '*i*th' leaflet, *n* is the number of leaflets in the AHV, being 3 for the TMHV and the BHV, whereas 2 for the BMHV, while IOA_{BHV} is the inner orifice area of the BHV, being the largest and therefore used for normalization.

RESULTS

Figure 1 illustrates the projected area on the z-plane for the three AHVs under consideration, showing that the BHV has the largest projected area during the peak systolic phase of the cardiac cycle in comparison to the TMHV and the BMHV. The BMHV has a slightly larger projected area during the peak systole in comparison to the TMHV, owing to the BMHV's non-circular housing geometry. During the forward deceleration phase of the cardiac cycle, the projected area starts to decrease for the TMHV and the BHV, indicating the commencement of the closure kinematics of their leaflets, while remains constant at the maximum for the BMHV, indicating fully opened leaflets. The projected area of the TMHV and the BHV reduces to its near minimum by the early regurgitation phase of the cardiac cycle. In contrast, the BMHV has a relatively higher projected area during early regurgitation, which reduces to its minimum by the mid-diastolic phase of the cardiac cycle. These results imply that the leaflets

of the TMHV and BHV begin to close while there still exists forward flow during the systolic deceleration phase of the cardiac cycle and complete the major fraction of their closing excursion by early regurgitation in comparison to the BMHV, for which the two leaflets start undergoing closure due to the onset of regurgitation.

Figure 1: Projected Area for the three AHVs

To understand the closing behavior of the three AHVs, the Transvalvular Pressure Gradient (TPG), calculated as shown by Equation 2, has been plotted against time in Figure 2.

$$\frac{\Delta P}{\rho U^2} = TPG = P_u - P_d \quad (2)$$

where, ΔP is the net pressure, P_u is the pressure on the upstream ventricular side of the AHV, while P_d is that on the downstream aortic side. A continuous decrease in the TPG could be observed during the systolic deceleration phase for all AHVs, with high oscillations occurring at the instant of the valve closure.

Figure 2: TPG for the three AHVs

Augmented with a decreasing TPG for the TMHV, it is observed that the sinus-sides of its leaflets develop a higher pressure in comparison to their central flow-sides during the systolic deceleration, as shown for various instants by Figure 3. Consequently, a pressure force is created which is directed towards the closure of each leaflet.

Figure 3: Pressure variation in TMHV during deceleration

In contrast, since the leaflets of the BMHV are oriented within the central flow region, the pressure on the sinus-sides of its leaflets remains nearly the same as that on their central flow-sides as shown in Figure 4 for various instants of the systolic deceleration phase. The BMHV leaflets therefore wait for the regurgitation to begin closing.

Figure 4: Pressure variation in BMHV during deceleration

The elastic deformation of the BHV leaflets as they move towards their fully closed positions causes high spatial variations in the pressure on the sinus- and central flow-sides of its leaflets. For this reason, the net fluid pressure (*Pressure Difference*) on the BHV leaflets was calculated as shown in Equation 3 and has been illustrated for one of the three BHV leaflets during the systolic deceleration, granted the three leaflets respond similarly to the pressure variations across them.

$$Pressure\ Difference = P_s - P_c \quad (3)$$

Where, P_s is the pressure on the sinus-side of the BHV leaflets, while P_c is that on their central flow-side.

Figure 5: Pressure variation on a BHV leaflet during deceleration

From Figure 5a, it could be observed that the *Pressure Difference* is positive for the belly region and the other major portion of the leaflet's surface excluding the fixed edge for early systolic deceleration, indicating a higher P_s in comparison to P_c , thereby creating a pressure force directed towards the closing position. As the cardiac cycle advances in time, the *Pressure Difference* decreases, however, remains positive and the leaflet continues its closing excursion.

DISCUSSION

This numerical study compares the closing kinematics, and the associated hemodynamics of two designs of MHVs, the TMHV and the BMHV, against a BHV under similar conditions for the first time. The leaflets of the TMHV and the BHV start to close during the systolic deceleration phase, and complete most of their closing excursion by the early regurgitation, with similar and smooth closing pattern towards the center as earlier observed in experiments [9]. Congruous to the native aortic valves which have been reported to begin their closure during the systolic deceleration [5], the leaflets of the TMHV and BHV also start to close as the flow decelerates in response to a higher pressure developed on the sinus-sides of their leaflets compared to their central flow-sides. The BMHV leaflets, however, begin their closing excursion by the onset of regurgitation as previously observed by several studies [5, 6], with high oscillations occurring in TPG at the valve closure, as earlier experimentally observed [10]. The early closure of the TMHV and the BHV is a physiologically desired feature, whereas the delayed closure of BMHV might generate a high regurgitant volume and consequently cause an additional workload on the heart [5].

INTRODUCTION

Tumor metastasis is one of the leading causes of death in cancer patients. Intravasation and extravasation are critical processes in tumor metastasis. The process of cancer cells crossing the endothelium of a blood vessel or lymphatic vessel into the circulatory system is called intravasation, and the process of cancer cells penetrating the vessel and entering the tissue parenchyma from the blood vessel is called extravasation[1]. Most studies on intravasation and extravasation had been focused on the influence of biochemical factors, such as transforming growth factor- β (TGF β) or vascular endothelial growth factor (VEGF), which increase the number of cancer cells entering into blood vessels, increasing metastasis[2, 3]. However, the underlying mechanisms of how cancer cells invade across the vascular endothelium and the biomechanical interactions between cancer cells, vascular endothelium, and extracellular matrix are poorly understood.

In this study, we focus on the biomechanics of cancer cells invading across the vascular endothelium to reveal biomechanical properties and biomechanical interactions of cancer cells, vascular endothelial cells, and extracellular matrix (ECM).

METHODS

Human umbilical vein endothelial cells (HUVEC) were seeded on a confocal dish to form a cell monolayer. Colorectal cancer cells LoVo cells were seeded on the HUVECs monolayer for invasion, forming a model for the process of tumor cell invasion of the vascular endothelium (Figure 1). After being seeded with LoVo cells, the dish with experimental samples was placed in a live cell workstation for time-series photography. In order to make living cells fluorescent, we use lentiviral transfection and actin tracking staining. To explore the role of actin polymerization and cell contraction, we used several kinds of inhibitors to inhibit actin polymerization and cell contraction. To visualize the expression of focal adhesions, we used immunofluorescence. In the measurement of cell traction, we used the

micropattern printing technique, and we measured the cell traction force by analyzing the displacement of the substrate fluorescent microbeads. The image data were processed and analyzed in ZEN BLUE 3.1, Imaris9.0.1, and ImageJ. GraphPad Prism 8 software was used for statistical analysis and graphing. The cell layer is modeled as a two-dimensional, continuous elastomer with pre-strain for considering the active contraction of cytoskeleton. The stresses in the cell layer under various conditions are obtained by solving the equation of elasticity using the numerical method in COMSOL.

Figure 1: LoVo cells were seeded on the HUVECs monolayer.

RESULTS

Our results suggest that cancer cells invade across the vascular endothelial cell layer through protruding pseudopodia, establishing adhesions and cancer cell extrusion (Figure 2). These three processes

are continuous, interrelated, and intertwined. Among these three processes, the polymerization of cancer cell actin and cell contraction plays crucial roles. With cancer cells invading and the adhesion becoming stronger, the traction force was developed.

We observed two important approaches in which the vascular endothelial cell layer acts as a barrier to the invasion of cancer cells. The first one is the density of vascular endothelial cells. A higher cell density leads to a stronger barrier and, thus, a lower invasion rate of cancer cells (Figure 3). The second one is the formation of actin rings among vascular endothelial cells, in which case the actin ring could block the nucleus of the cancer cell and prevent its passage. We further found that the stiffness of the cancer cell nucleus is critical in determining whether the actin ring between vascular endothelial cells could block the invasion of cancer cell.

The mechanical properties of the extracellular matrix also play a vital role. We found that substrate stiffness can affect cancer cells' invasion and crossover efficiency.

Figure 2: The invasion of cancer cell into the vascular endothelial monolayer.

Figure 3: The invasion rates of LoVo cells under different levels of HUVECs density.

DISCUSSION

Our research revealed the process of tumor cell invasion across the vascular endothelium. We found that substrate stiffness affects the

barrier capacity of the cell layer. And the actin ring structure formed a physical blockade to the invasion of the cancer cell. The ring-shaped actin structure of actin has been described in cell division, wound healing, epithelial cell extrusion, and *Drosophila* dorsal closure[4]. But the role of actin-ring in the cancer invasion has not been reported before. In addition, we found that the softening of the nuclei significantly reduced the chances of cancer cell nuclei being blocked by actin rings among vascular endothelial cells. Our results revealed the relationship between the stiffness of the nucleus and invasion ability. This finding differs from the previous researches on the endothelial barrier, which were mostly focused on the intercellular connection.

This study gives useful insights into the mechanics of cancer cell invasion and may provide clues for searching for potential targets and developing novel cancer therapies.

USING AN INVESTIGATIVE MICROSCALE MODEL TO STUDY MECHANICAL WHITE MATTER PROPERTIES IN DEMYELINATING DISEASES

Xuesong Zhang (1), Johannes Weickenmeier (1)

(1) Department of Mechanical Engineering,
Stevens Institute of Technology
Hoboken, NJ, United States

INTRODUCTION

Myelin plays a significant role during early brain development and strongly influences the mechanical environment of brain white matter [1]. Weickenmeier et al. studied white and gray matter of fresh bovine brain and found a proportional relation between myelin density and tissue stiffness [2]. Some other methods have been used to reveal the relationship between myelin and stiffness. Among these methods, indentation is considered as a promising approach to study mechanical white matter properties. However, the exact correlation between indentation tested stiffness and microstructure of white matter remains unclear.

Here, we present a computational approach that uses an investigative microscale model (IMM) to rationalize the microstructural origin of mechanical white matter properties. Our study will allow us to systematically explore mechanical white matter tissue behavior in diseases such as multiple sclerosis and aging.

METHODS

Model Creation. We reconstruct a representative white matter model from a transmission electron microscopy (TEM) image of an axon bundle and obtain myelin sheath properties from literature (inner diameter (0.75-2.5μm), g-ratio (0.5-0.74), and sheath length (5-35μm)) [3,4]. Specifically, as shown in Figure 1, the TEM image (1A) was binarized (1B), and subsequently imported into Simpleware to create the IMM (1C-G). First, each axon was segmented individually (1C). Next, up to four concentric layers were created around each axon to represent myelin sheaths (1D). The remaining space was filled to represent extracellular matrix (ECM). This approach allows us to model demyelination by changing material properties for each distinct ring around axons. The final 3D model included additional details such as variable sheath length and inter-sheath distance (1E). The axon, myelin, and ECM were meshed with linear tetrahedral elements (1F-G).

Figure 1: The creation of IMM, (A) TEM microstructure image of white matter, (B) the created axon (black) and ECM (white) image, (C) the created masks for axons and myelin sheaths, (D) the illustration of a single axon with four layers of myelin sheath, (E) 3D view of the IMM model with axons and myelin sheaths, (F) the axons and myelin sheaths with meshed elements, (G) the meshed model with axons, myelin sheaths, and ECM.

Material Properties and Boundary Conditions. Our model differentiates between axon, myelin, and ECM. All are posed to be well characterized by the Neo-Hookean model given by

$$U = C_{10}(\bar{I}_1 - 3) + \frac{1}{D_1}(J - 1)^2, \quad (1)$$

where U is the strain energy function, C_{10} is a material constant and equals half of the shear modulus, \bar{I}_1 is the first invariant of the isochoric part of the right Cauchy–Green deformation tensor, D_1 is the material's incompressibility parameter and is related to bulk modulus κ_0 by $\kappa_0 = 2/D_1$, and J is the determinant of the deformation gradient tensor.

We assume that the Young's modulus of myelin is twice as high as of axons and ten times higher than of ECM. Based on previous work, we assume E_{axon} to be 1.02 kPa and the Poisson's ratio to be 0.495 due to the nearly incompressible behavior of white matter [5]. Here, we study the anisotropic behavior of our IMM by simulating uniaxial tension, compression, and shear with respect to directions that align with axons (AA) and are transverse to axons (TT). We explore the mechanical response of these models for up to 30% strain, respectively.

Homogenized Stiffness Acquisition and Myelin Area Fraction Calculation. To determine the IMM's homogenized stiffness value, a simple cubic model with homogeneous material was created and meshed with linear hexahedral elements. The simple cubic model was subjected to the same boundary conditions as the IMM. An inverse method was used to determine the material property C_{10} of the simple cube by minimizing the root-mean-square error of the resulting stress and strain data between simple cubic model and IMM. The optimized C_{10} was obtained and converted to Young's modulus.

To calculate the myelin area fraction, we sliced each IMM model along the TT direction into 279 slices. In each slice, the area fraction of myelin was calculated by dividing the number of myelinated pixels by the total number of pixels.

RESULTS

The Heterogeneous and Anisotropic Response of IMM. The simulation results are summarized in Figure 2. We show von Mises stress and consistently observe that stress is highest in the myelin sheaths (2A). Loading in axon direction (AA) results in a higher stress-strain response than TT simulations under all three conditions (2B). The resulting homogenized stiffness values of AA simulations are higher than the TT simulations (2C). Specifically, the mean and standard deviation of stiffness is 0.86 ± 0.04 kPa for AA simulations and 0.76 ± 0.01 kPa for TT simulations.

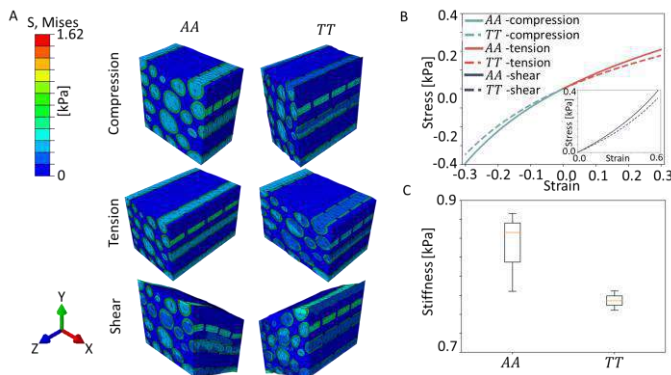

Figure 2: The simulation result of 4-layer IMM on different directions under compression, tension, and shear, (A) deformed configuration and contour plots of stress distributions, (B) the resulted stress-strain curves, (C) the boxplot of the resulted homogenized stiffness values on AA and TT direction.

The Myelin Area Fraction Changes in the IMM. Figure 3A shows the myelin content, calculated as the myelin area fraction, for each model. Myelin area fraction is proportional to the number of layers and decreases from 0.58 ± 0.14 in the 4-layer model to 0.51 ± 0.14 in the 3-layer model, 0.46 ± 0.14 in the 2-layer model, 0.40 ± 0.14 in the 1-layer model, and 0.34 ± 0.14 in the 0-layer model. This trend agrees well with decreasing myelin scores in the demyelinating cuprizone mouse model most frequently used to study white matter disease. Specifically, Gudi et al. presented myelin scores that decreased from 3 ± 0.05 at baseline to

2.30 ± 0.1 at week 3, 2.0 ± 0.1 at week 4, 1.0 ± 0.37 at week 4.5, and 0.49 ± 0.5 at week 5 [6].

Stiffness Changes with the Changing Number of Myelin Layer.

Figure 3B shows how the homogenized stiffness value increases with the number of myelin layers. For example, for TT-compression, the homogenized stiffness decreased from 780.78 Pa in the model with 4 layers to 627.19 Pa with 3 layers, 537.59 Pa with 2 layers, 447.99 Pa with 1 layer, and 391.1 Pa for the model without any myelin. Similar trends can also be found in TT-tension, TT-shear, AA-compression, AA-tension, and AA-shear.

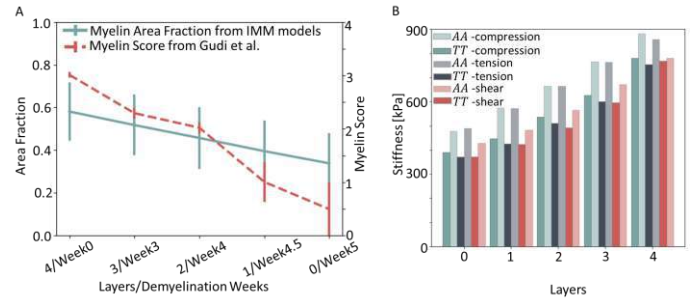

Figure 3: The area fraction of the IMM models with different myelin layers and the resulted homogenized stiffness of total 30 simulations, (A) the myelin area fraction (solid blue)) changes with the number of myelin layers in our models, and the myelin score (dash red) changes with cuprizone-induced demyelination weeks on literature [6], (B) the homogenized stiffness results of the IMM models with different myelin layers (0-4) under compression, tension, and shear on both AA and TT.

DISCUSSION

We created an investigative microstructural finite element model of white matter to systematically study the mechanical response as a result of varying anatomy. Our results suggest a highly heterogeneous and anisotropic white matter behavior. Our model reproduces previously reported softening behavior during progressive demyelination [7].

This model has great significance in the fundamental understanding of mechanical white matter behavior in some white matter diseases, such as multiple sclerosis. Going forward, this model will be used to investigate the mechanical response of white matter in acute and chronic demyelination and remyelination, which will help to predict the macroscale tissue response in white matter disease.

CELLULAR SENESENCE SUPPRESSES ECM SYNTHESIS IN RESPONSE TO MECHANICAL UNLOADING IN TENDON EXPLANTS

Emma J. Stowe (1), Brianne K. Connizzo (1)

(1) Department of Biomedical Engineering, Boston University, Boston, MA, USA

INTRODUCTION

Musculoskeletal injuries, including tendinopathies, present a large clinical burden for aging and elderly populations. Aged tendons are at increased risk for tendon injuries, exhibit poor healing outcomes, and show a loss in regenerative capacity [1]. While the biological drivers of this age-related degeneration are poorly understood, it is well accepted that deregulation of balanced matrix turnover plays a role in tendon injury. Remodeling of tendon extracellular matrix (ECM), through matrix synthesis, organization, and breakdown, is essential in the ability of the resident cells to respond and adapt to altered mechanical environments.

The accumulation of senescent cells is documented to play a role in the phenotype of aging tissues, including tendon [2]. Senescent cells are anti-apoptotic and secrete a highly pro-inflammatory senescence-associated secretory phenotype (SASP) that has potential to promote ECM breakdown. However, the role of senescent cells in the dysregulation of tendon ECM homeostasis is unknown. Our group has recently developed *in vitro* models of cellular senescence in live tendon explants using the chemotherapy drug, doxorubicin, and irradiation [3]. Using these models, we aim to investigate how ECM remodeling and homeostasis are altered with natural aging and cellular senescence.

The objective of this study is to compare the remodeling response of native young, native aged, and senescent tendons to an altered mechanical stimulus. We hypothesize that both aged and senescent tendons will exhibit altered ECM remodeling following a mechanical unloading injury, with a shift to processes that promote ECM degradation over synthesis.

METHODS

Flexor digitorum longus (FDL) tendon explants were harvested from young (4m) and aged (24m) male C57BL/6J mice [4]. Tendon explants were cultured under stress-deprived conditions (mechanical unloading) in standard culture medium for up to 14 days. Cellular

senescence was induced *in vitro* in young explants following tissue harvest with irradiation (RAD) and doxorubicin (DOX) [3]. Live/dead confocal imaging was performed to quantify cell viability and total cell density. A resazurin reduction assay was used to evaluate metabolism. To measure matrix composition, tendons were digested, and biochemical assays were performed for DNA content (PicoGreen), GAG content (DMMB), and total collagen content (OHP) [4]. Matrix biosynthesis was assessed using 24-hr incorporation of radiolabels ³H-proline and ³⁵S-sulfate to measure synthesis of total protein and sulfated GAGs, respectively [4]. Assays were normalized to tendon dry weight to account for tendon size. Changes in gene expression were evaluated using qPCR for genes encoding matrix proteins and matrix metalloproteinases (MMPs) [4]. qPCR data is presented as a change in relative expression, normalized to both a housekeeping gene, β -Actin, and day 0 expression. Generic MMP activity was assessed using fluorometric detection kit (AnaSpec). Statistical evaluation was performed using two-way ANOVAs with appropriate post-hoc t-tests, significance at $p < 0.05$ (solid lines) and trends at $p < 0.1$ (dashed lines). All data is presented as mean \pm 95% confidence interval.

RESULTS

All groups were viable for the duration of the experiment, with RAD tendons exhibiting a higher percentage of live cells than young tendons at both time points (Fig. 1a). Cell density was the same in all groups at day 7 but was reduced in senescent groups by day 14 (Fig. 1b). Similarly, while no differences in DNA content were seen at day 7, significant reductions of DNA content in aged, RAD, and DOX tendons were found at day 14 (Fig. 1c). Explant metabolism was significantly reduced in the aged, RAD, and DOX groups when compared to the young tendons at days 7 and 14 (Fig. 1d). After 7 days, no significant differences were seen in hydration, collagen content, or GAG content between groups. However, by day 14 water content and GAG content were significantly reduced in aged and senescent groups (Fig. 2).

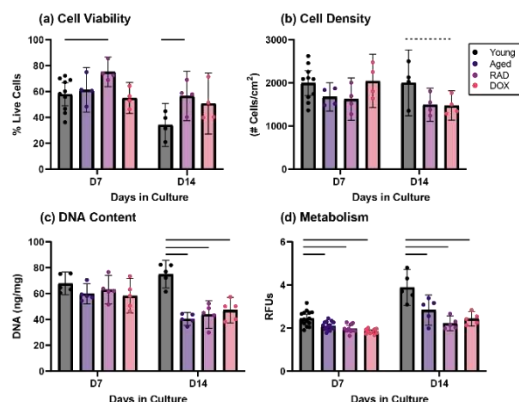

Figure 1: Explant Health. (a) Viability, (b) cell density, (c) DNA content, and (d) metabolism.

Figure 2: Matrix Composition. (a) Water content, (b) GAG content, and (c) collagen content.

Total protein and sGAG synthesis were diminished in aged and senescent cultures at both time points (Fig. 3a,b). Gene expression data at day 14, showed significant reduction in expression of matrix proteins collagen 1 (Col1α1), fibromodulin (FMOD), and decorin (DCN) in DOX and RAD tendons (Fig 3c,d,e). MMP activity increased in young FDLs over time in culture, peaking at 10 days of stress deprivation. Although non-significant, MMP activity was slightly elevated in senescent cultures compared to young at days 4 and 14 (Fig. 4a). Day 14 MMP gene expression showed downregulation of MMP-1, upregulation of MMP-3, and no changes in MMP-13 in senescent groups compared to young (Fig. 4b,c,d).

DISCUSSION

Excitingly, supporting our original hypothesis, we found that senescent tendons exhibit altered responses to changes in mechanical unloading compared to young tendons. Decreases in protein and sGAG synthesis, as well as downregulation in gene expression of key ECM components, signifies a compromised ability of cells to synthesize ECM. Despite a reduction in total number of cells, which is typically seen in natural aging, the remaining cells also appeared to be functionally different than young cells, exhibiting both reduced metabolism and capacity to synthesize matrix. In addition, while young tissues undergo swelling and GAG accumulation between 7-14 days of stress deprivation, senescent tendons lack a similar adaptation.

Interestingly, changes in ECM remodeling found here were similar between the naturally aged and senescent-induced tendons, suggesting that senescence likely contributes to divergent remodeling outcomes in aged tissues. In some cases, the response appears graded, with more severe changes in the senescent groups than in aged tissues. Since aged tissues are documented to contain a low number of senescent cells (5-10%) [5], this is expected. Future work aims to quantify numbers of senescent cells in aged and senescent-induced tendons to determine thresholds at which bulk tissue response are altered.

Contrary to expectations, MMP expression and activity, signifying matrix breakdown, were not strikingly elevated with senescence. However, stress deprivation injury itself initiates a high degradative response in young FDLs, shown by increasing MMP activity following

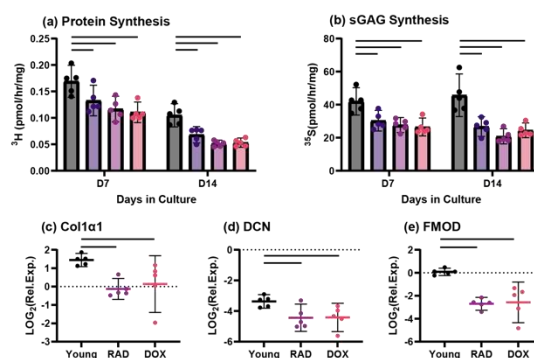

Figure 3: Matrix Production. (a) Protein and (b) sGAG synthesis. Day 14 gene expression of (c) Col1α1, (d) DCN, and (e) FMOD.

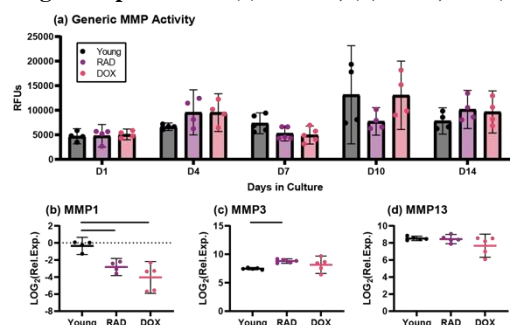

Figure 4: Matrix Degradation. (a) Generic MMP activity and day 14 expression of (b) MMP-1, (c) MMP-3, and (d) MMP-13.

injury. Thus, the senescent response is on-par with that of a mechanical injury and appears to be elevated for a sustained period. Gene expression data shows divergent trends with different MMPs. It's likely that senescence affects functionally different MMPs in distinct ways, potentially muddling the generic activity results. Elevated expression of MMP-3, responsible for breakdown of proteoglycans, could explain the lack of GAG accumulation later in culture in senescent groups.

Overall, this study is the first to investigate the response of senescent cells to altered mechanical stimuli within the native matrix environment. Compared to young tendons under identical mechanical stimuli, senescent tendons exhibit reduced matrix synthesis with similar or increased MMP activity, thus shifting the remodeling balance towards degradation over production. This lack of adaptation in aged and senescent tendons shows a reduced capacity to respond to altered mechanical environments and likely contributes to increased tendon injury and poor healing outcomes. This suggests senescence-targeting therapies may be a promising strategy for preventing age-related tendon degeneration. Ongoing work aims to investigate the ability of senescent explants to respond and adapt to physiological and injurious levels of mechanical loading, as well as explore the potential of senescence therapies to recover homeostatic ECM remodeling.

INTRODUCTION

Coronary heart disease is the number one cause of mortality worldwide, contributing to nearly 15% of all deaths [1]. Early characterization of myocardial ischemia (MI) is essential for improving surgical and medical outcomes. While two-dimensional ultrasound is often used to evaluate left ventricular function and monitor disease progression, it is insufficient to completely characterize the complex myocardial biomechanics involved in pathologic remodeling leading to heart failure, a common outcome of coronary ischemic injury. Many interventions for preventing heart failure development following ischemic injury are time dependent and rely on implementation within at least 7 days of the index MI for therapeutic benefit [2], however traditional image-base wall-thinning or histological metrics in rodents can only estimate infarct size 7-14 days following ischemic injury [3].

Here we present a method for quantifying myocardial mechanics in an ischemia reperfusion (I/R) and permanent ligation (PL) model of myocardial infarction for both mice and rats using four-dimensional ultrasound imaging (4DUS). We also describe the use of a custom MATLAB graphical user interface to leverage the value of 4D imaging (3D plus time) while streamlining analysis and processing.

While many studies examine the longer-term effects of myocardial infarction, the objective of this study is to examine the early/acute phase of cardiac remodeling following myocardial infarction during the first 7 days following the procedure. We hypothesize that 4DUS strain-based infarct size estimations within one day following myocardial infarction will be similar to estimations after one week for both rats and mice. Identifying the extent of myocardial injury at early time points could be a powerful asset for guiding surgical and medical intervention.

To our knowledge, this is the first study to describe the use of 4DUS-based mechanical characterization for I/R and PL in both mice and rats. Characterizing the progression of myocardial infarct injury during this early stage of remodeling has far-reaching implications for studying and understanding the complex mechanical response of the heart to ischemic injury.

METHODS

Mouse surgeries: We performed coronary artery ligation surgeries on 10 male, wild-type, C57BL/6J mice (age 13-15 weeks). For surgery, each mouse was anesthetized with 1–3% isoflurane and endotracheally intubated using a small-animal ventilator (SomnoSuite, Kent Scientific, Torrington, CT). A small incision was made in the third intercostal space of the left thorax and the ribs were retracted to expose the left ventricle. The pericardium was removed to visualize the left coronary artery (LCA). In the I/R group (n=5), we used PE-10 tubing in combination with a suture to temporarily ligate the LCA for 30 min before restoring blood flow to the ischemic myocardium (reperfusion) as described previously [4,5]. In the PL group (n=5), the LCA was permanently ligated to induce an infarct [4,5].

Rat surgeries: For rat surgeries, male Sprague-Dawley rats (n=10, age 12-14 weeks) were anesthetized with 1–3% isoflurane, followed by endotracheal intubation and mechanical ventilation (Harvard Apparatus, USA). The chest was opened at the fourth left intercostal space, the pericardium was removed, and the LCA was identified. In the I/R group (n=5), the LCA was temporarily ligated using 4-0 prolene suture (Ethicon, USA) for 60 minutes followed by reperfusion. For the PL group (n=5), the LCA was permanently ligated. Following each procedure, the chest retractor was removed, the ribs were drawn together, thoracic pressure was reestablished, and the skin was closed.

Imaging: 4D ultrasound images were obtained prior to surgery, 24 hours post-surgery, and 7 days post-surgery using the Vevo3100 or Vevo2100 ultrasound system (FUJIFILM, VisualSonics). We analyzed the 4DUS data using a custom-built graphical user interface in MATLAB (MathWorks, Natick, MA) to manually segment the left ventricle by tracking 48 points on the endo- and epicardial surfaces over a representative cardiac cycle. The 4D mesh generated through these tracked points was sampled uniformly at 60 interpolated time points across one cardiac cycle, with 60 rotations around the longitudinal axis, and 60 slices from base to apex for a total of 3,600 nodes at each timepoint [6]. We then estimated surface area strain (E_a) calculated as:

$$E_a(z, \theta, t) = \left[\frac{A(z, \theta, t) - A_D(z, \theta)}{A_D(z, \theta)} \right] \times 100\% \quad (1)$$

Where A represents the surface area on the endocardial surface between two sequential slice locations along the longitudinal axis z and rotational location θ over time t . We estimated infarct size by identifying nodes with low E_a magnitude ($>-20\%$) as previously described [2].

RESULTS

We found that regions with surface area strain values greater than -20% at day 1 were similar to those found at day 7 for the rat PL and I/R groups (Figure 1) and for the mouse PL groups. Mild infarct for some mice in the I/R groups was not detected at day 1 (Figure 2).

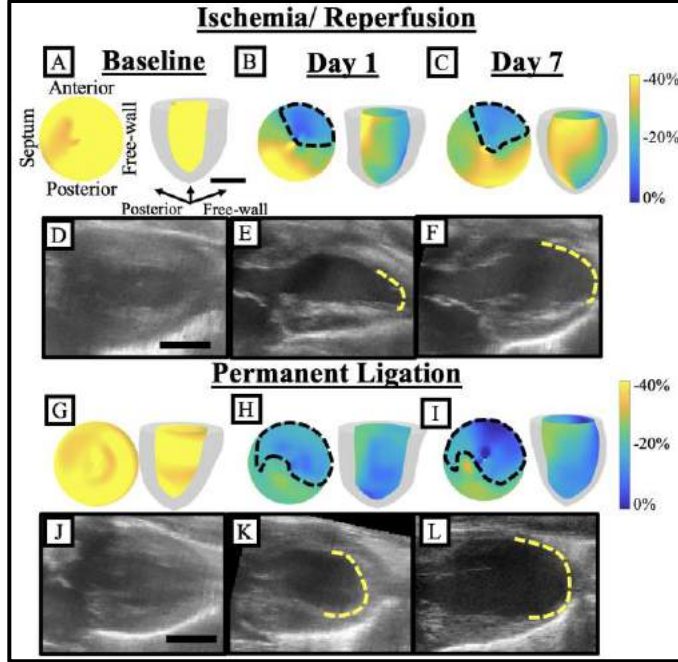

Figure 1: 4D ultrasound strain-based infarct size estimation. Example rat left ventricular surface area strain colorized polar plot (left) and 3D model (right) at baseline (A,G), day 1 (B,H), and day 7 (C,I) following ischemia reperfusion (I/R; A,B,C) or permanent ligation (PL; G,H,I). Dotted black lines represent estimated infarct. Representative 2D long axis slices identified from the rat 4D image volume at peak systole at baseline (D,J), day 1 (E,K), and day 7 (F,L) following I/R (D,E,F) or PL (J,K,L). (Yellow lines represent areas of akinesis; black scalebar=5mm).

We also found that strain estimated infarct was significantly different ($p<0.0001$) between I/R and PL groups at day 1 and day 7 for both mice and rats (Figure 2). For rats we found that left ventricular ejection fraction (LVEF) dropped from $57.4 \pm 5.9\%$, $53.7 \pm 4.8\%$ (mean \pm SD); I/R and PL respectively) at baseline to $38.2 \pm 3.6\%$, $29.7 \pm 3.7\%$ at day 1 and $36.2 \pm 3.1\%$, $27.1 \pm 3.7\%$ at day 7 post-infarction. For mice we found a similar drop from baseline $73.6 \pm 6.1\%$, $66.7 \pm 11.4\%$ (I/R and PL respectively) to $54.1 \pm 6.1\%$, $42.2 \pm 10.4\%$ at day 1 and $59.3 \pm 5.8\%$, $37.3 \pm 8.4\%$ at day 7 post-infarction.

DISCUSSION

In this study, we used a mechanics-based approach to identify infarct size in both mice and rats with varying levels of ischemic injury. Our results showed that infarct size measured using E_a estimated from 4DUS at 24 hours following the ischemic event is predictive of infarct size at day 7 for both mice and rats. This is highly impactful to the field

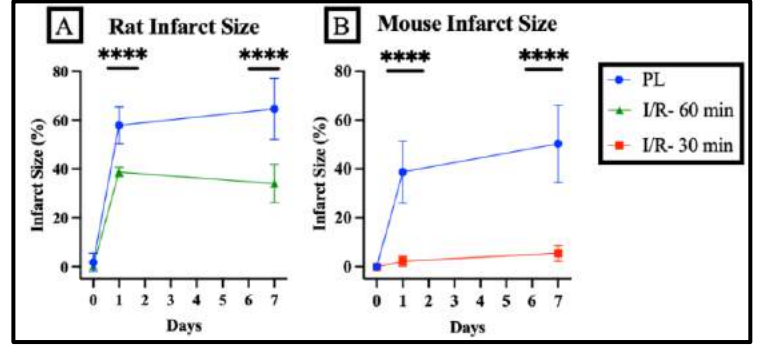

Figure 2: Rat and mouse infarct size over time. (A) Rat and (B) mouse infarct size over time for permanent ligation (PL; n=5) and ischemia reperfusion (I/R; n=5). ****PL vs I/R, $p<0.0001$, error bars: mean \pm SD.

because traditional wall-thinning or histological metrics in rodents can only assess this infarct size after 7-14 days [2]. This method is also non-invasive and can be used to track infarct progression longitudinally-limiting the need to use large numbers of animals to achieve statistical significance. Additionally, unlike traditional 2D assessment, 4D analysis can account for infarct asymmetry and heterogeneity.

Another advantage of this study is the scope of our methodology. We showed how our strain estimation method can be applied to both I/R and PL models in mice and rats. This is powerful as I/R models more closely recapitulate percutaneous coronary intervention [7], while PL models produce more severe infarcts and may represent better the response of untreated myocardial infarction more common in low-resource settings without ready access to percutaneous interventions.

It should be noted that our strain estimation technique relies on gross akinesis of myocardium to estimate infarct size. This technique has the potential to overestimate large infarcts by including the “at-risk” border zone. This may be partially reflected in the slight (but not significant) decrease we see in the moderate infarction size produced by the I/R model in rats from day 1 to day 7. We also may underestimate mild infarcts that do not induce damage throughout the entire thickness of the myocardium, which may partially explain the small infarcts we calculated in the I/R mouse group.

In summary, we demonstrated that 4DUS is an effective and useful tool for examining myocardial mechanics following experimentally induced ischemia in both mice and rats and can be used for early assessment of infarct size. Similar clinical techniques could be implemented in future preclinical research to comprehensively characterize the myocardial response to help guide interventions and decrease the burden of heart failure after MI.

INTRODUCTION

Pulmonary diseases are progressive, often incurable, and shorten life-expectancies [1]. Despite the critical role of the lungs in oxygen delivery throughout the body, rudimentary lung mechanical function is not well understood, neither in healthy nor diseased states; moreover, mechanical characterization of lung tissue is fundamental for developing predictive models and advancing disease treatment and mitigation but remains scarce [2]. Parenchymal tissue is understudied, despite being the site of injury and disease manifestation [1, 3]. Existing parenchymal studies often use precision cut lung slices (PCLS), which can alter properties due to agarose injection [4, 5]. In addition, such small-scale studies only examine uniaxial rather than more physiologically representative multi-directional loading [6]. These limitations often present challenges for evaluating physiologically relevant lung tissue behavior [7, 8, 9].

In this timely COVID-19-era pulmonary mechanics study, we characterize and compare unaltered healthy mouse lung mechanics to diseased counterparts using biaxial tensile testing for the first time. We analyze the tissue stress-strain response and viscoelastic behaviors to formulate a better local-scale understanding of the changes in diseased lungs that are witnessed at the global, pressure-volume level of the whole lung [10, 11]. Ultimately, this study quantifies lung biaxial material properties, which have been thus far absent in the field, and provides measures for future use in computational models and for comparisons to other pulmonary diseases.

METHODS

Ten male C57BL/6J mice were obtained from Jackson Laboratory (Bar Harbor, ME, USA) at 8-12 weeks old as part of a larger ventilation study [11, 12]. Half the specimens were intranasally exposed to agricultural dust, while the other half were exposed to 1X phosphate-buffered saline (PBS) three times weekly for 21 weeks, modeling fibrosis or healthy states, respectively [13]. In accordance with

Institutional Animal Care and Use Committee protocols, left lungs were extracted noting the cranial-caudal (CC) and medial-lateral (ML) directions. Uniform lung parenchymal sample dimensions were obtained using a custom-designed cutter (Figure 1A). The 1.9 \pm 0.5 mm thickness samples were loaded onto four planar rakes [8], producing a 3x3 mm testing area, and submerged in 1X PBS at 37°C. The experimental setup is shown in Figure 1A. Equibiaxial tests were executed with a BioTester 5000 and 1.5N load cells (CellScale Waterloo, ON, Canada). Tissue was stretched to 40% at 2.5%/s, selecting testing parameters mirroring whole-organ strain inflation tests [3, 10]. A 0.5mN tare was applied similar to previous studies [4]; the tissue was then preconditioned with three loading-unloading cycles followed by an analyzed fourth stress-strain load and a 300s hold for viscoelastic considerations [9].

First Piola-Kirchoff stress-strain loading curves were averaged across samples (Figures 1B and C) [2, 9], and the tangent at strain values of 15, 25, and 35% were found using the least-squares method with $R^2 > 0.9$, (MATLAB, MathWorks Inc.) [14]. Maximum stress values at 40% strain were also measured. Stress versus time plots were used to characterize percent relaxation, determined as the difference between maximum stress at the beginning of the hold and asymptotic stress, normalized by maximum stress (Figures 1D and E) [9, 15]. Statistical differences between healthy versus diseased tissue comparisons and directional differences were assessed for calculated slopes, maximum stress values, and percent relaxation values, using the Mann-Whitney and Wilcoxon nonparametric tests [GraphPad Prism, San Diego, CA, USA]. Statistical significance was designated with $p < 0.05$.

RESULTS

Parenchymal tissue stress-strain curve slopes trended greater for diseased compared to healthy tissue for the average slope measured at 35% strain (Figure 1B and C). This slope was notably steeper for diseased tissue, particularly for the CC direction, with values of 25.7

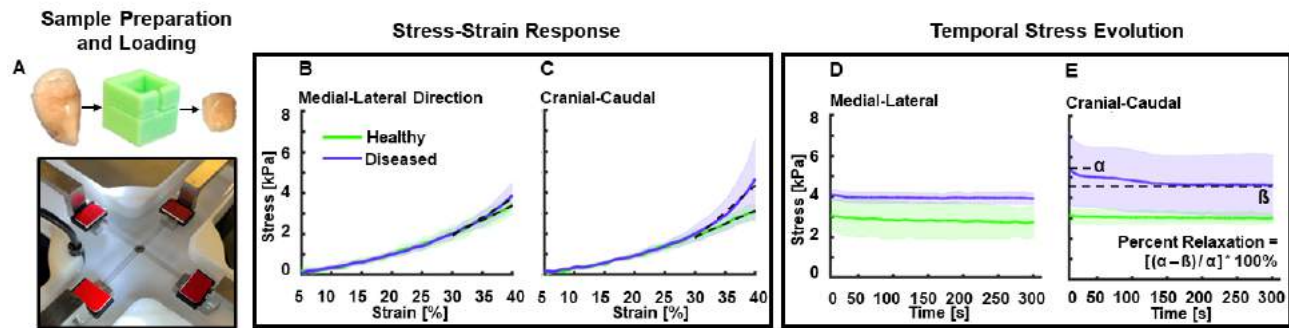

Figure 1. Murine lung parenchyma was diced into slices using a custom-designed cutter and biaxially loaded (A). Average \pm standard deviation (SD) of healthy and diseased tissue stress-strain curves, shown in the medial-lateral (B) and cranial-caudal (C) loading directions, respectively (with shown slopes fitted at 35% strain). Averaged \pm SD stress-time viscoelastic relaxation plots are similarly illustrated in the medial-lateral (D) and cranial-caudal (E) orientations (with percent relaxation calculation shown).

and 12.8 kPa/% for healthy and diseased samples, respectively. Slopes measured at 15 and 25% did not reveal measurable differences between healthy and diseased states. Comparisons of ML and CC slopes did not show significant differences; however, directional slope differences were most discernable for diseased tissue at 35% which, on average, was less steep for the ML compared to CC direction (18.4 and 25.7 kPa/%, respectively).

Maximum stress values measured from stress-strain curves did not significantly differ between healthy and diseased states (Figures 1B and C). However, diseased tissue tended to yield greater stress values at maximum loading, with 3.9 kPa in disease compared to 3.4 kPa in healthy tissue for the ML direction, and 4.7 (diseased) compared to 3.0 kPa (healthy) for the CL direction. Differences between the two directions' maximum stress values were not significant.

Stress-time plots demonstrated healthy versus diseased tissue percent relaxation trended greater for healthy (12.8%) compared to diseased (5.8%) tissue in the ML direction (Figure 1D), but greater for diseased (16.0%) compared to healthy (5.0%) tissue in the CC direction (Figure 1E). ML and CL directional comparisons were not significant.

DISCUSSION

In this study, we characterize murine lung parenchymal biaxial material properties between healthy and diseased states for the first time, broadening our understanding of how tissue mechanics are altered due to chronic lung disease. The steepened stress-strain slopes and greater maximum stress values observed in diseased tissue (Figures 1B and C) are indicative of the increased parenchymal stiffness that is a hallmark of fibrosis and ultimately restricts breathing [1, 11, 16, 17]; it is widely understood that collagen deposition in the extracellular matrix (ECM) governs this pathological remodeling. Additionally, local stiffening may result in augmented forces within the ECM which exacerbate disease progression [1, 16], further underscoring the need for characterizing diseased tissue mechanics.

Given the absence of previous murine studies and biaxial tests, we compare the stress values obtained here to those of rat parenchymal uniaxial studies [4]; we find that biaxially loaded healthy mouse tissue exhibits a near order of magnitude higher stress values when compared to the same deformation values of uniaxial loading. This agrees with the nature of uniaxial versus biaxial loading, where the Poisson's ratio raises the effective stiffness of the tissue, as also observed in studies of soft airway tissue [18].

In contrast to uniaxial methods, biaxial testing allows for simultaneous comparisons between orthogonal loading orientations. Tissue anisotropic behavior is important for understanding disease effects, as the spatial orientation of collagen is a key factor in fibrotic

tissue mechanics [1]. We observe that the CC direction consistently reveals the most evident fibrosis-induced mechanical alterations: this direction shows the greatest degree of stiffening (stress-strain slopes at 35%, Figure 1C), and the greatest amount of relaxation (Figure 1E), indicating changes in viscoelasticity. Such alterations suggest the organization of deposited collagen fibers in fibrosis may influence the CC direction more drastically, and warrants further analyses regarding the role of pulmonary collagen fiber properties and architecture [1].

We note that use of planar loading may overlook physiologically relevant tissue responses (e.g., shear stresses), and future aims include testing parenchymal cubes in three dimensions to address this limitation [7]. In addition, individual pulmonary constituents would ideally be fully isolated to elucidate their distinct roles; this challenge posed by mouse lung size, will be further explored in future work. Nevertheless, the fundamental healthy versus diseased murine lung mechanics established in this study are essential, as mice are regarded for their pragmatism and potential to advance human pulmonary research, due to shared physiology, ease in procurement, and manipulability for therapy models [15]. To the best of our knowledge, we provide the first mechanical characterization of tissue-level mouse parenchymal biaxial material properties in a diseased state, enabling future material modeling and laying the foundation for comparisons to other manifestations of pulmonary disease.

INTRODUCTION

The myocardium is viscoelastic, which means that there exist both viscous and elastic resistive forces over the cardiac cycle. Prior studies on cardiac muscles have demonstrated significant viscoelastic behavior of the myofibers and its impact on the contractile function [1-3]. However, the tissue-level investigation of the anisotropic viscoelasticity of ventricular free wall is much less compared to that of the elastic behavior of the tissue.

The right ventricle free wall (RVFW) is a complex tissue composed of myofibers, collagen, vasculature, and other extracellular matrix (ECM) components, all of which exhibit viscoelastic behavior and contribute to the anisotropic mechanical behavior of the tissue. It is thought that myofibers are the main determinant of mechanical properties of the RV at low strains and the myofiber elasticity is associated with the RV diastolic function [4]. Microtubules (MT) are key intracellular elements contributing to the myofiber viscoelasticity. The enhancement or reduction of the MT network has been shown to increase or decrease cardiomyocyte viscoelasticity, respectively [1,2,5]. However, these findings are based on 1D cell mechanics. The realignment and reassembly of MT network can lead to significant changes in anisotropy and viscoelastic properties of the entire tissue, but the exact impact remains unknown. Thus, the **aim of this study** is to investigate the effect of the MT network on the healthy RVFW anisotropic viscoelasticity. We **hypothesize** that MT hyper- and de-polymerization differentially alter RVFW viscoelastic properties and lead to the opposite changes in the ratio of viscosity to elasticity.

METHODS

All procedures and methods were approved by the Colorado State University IACUC. Healthy adult male Sprague-Dawley rats (n=6) were euthanized, and the heart was excised and placed in phosphate buffer solution (PBS) on ice. The RVFW was then dissected in cardioplegic solution (CPS) and placed in 30mM 2,3-butanedione

monoxime (BDM) solution at body temperature (37C) for 30 minutes to remove the contractility of the myocardium. The outflow tract direction was defined as the longitudinal (L) direction. RV tissue then underwent equibiaxial stress relaxation to obtain the passive, biaxial viscoelastic behavior. Preconditioning was performed before data collection. Then, the RV was stretched to a maximum strain of 6% and at a ramp speed of 0.95 mm/s using an in-house biaxial tester. After the intact tissue was tested at baseline condition (base), the RV was treated with colchicine (COL) (0.3mM) for 30 minutes to de-polymerize the MT, and the same mechanical testing was performed. The RV was then rinsed with PBS and let rest in CPS solution to remove the effect of colchicine, treated with 50% of deuterium oxide (D₂O) for up to one hour to hyper-polymerize the MT, and the same mechanical tests were repeated. Relaxation modulus [6], stored energy (elasticity), dissipated energy (viscosity) (**Fig. 1**), and the ratio of dissipated to stored energy (V/E ratio) were examined. Paired student t-test was performed and p<0.05 was considered significant.

Figure 1: Calculation of the stored (W_s ; blue shaded area) and dissipated (W_d ; red shaded area) energy at any fixed time point.

RESULTS

MT de-polymerization reduces RV circumferential elasticity but does not affect viscosity. Colchicine treatment led to a significant reduction in relaxation modulus from the baseline in the circumferential (C) direction only (**Fig. 2**), indicating a reduction in RV elasticity.

Moreover, there was a trend of decrease in stored energy ($p=0.09$) (Fig. 3A) after MT de-polymerization in the C direction. However, we observed no change in dissipated energy (Fig. 3B) in either direction, indicating that the viscosity was not changed. Lastly, a trend of decreased V/E ratio was observed in the L direction only (Fig. 3C).

MT hyper-polymerization enhances RV longitudinal elasticity and viscosity in both directions. D₂O treatment led to a significant increase in relaxation modulus in the L direction only (Fig. 2), suggesting an enhanced RV elasticity. We also observed increases in both stored and dissipated energies, although the increase in stored energy was only observed in the L direction (Fig. 3A&B). As a result, the V/E ratio remained unchanged in the L direction but was greater in the C direction with the enhanced MT network (Fig. 3C).

Figure 2: Relaxation modulus measured at equilibrium (100s) of relaxation in different conditions. * $p<0.05$ vs. baseline in the same direction. # $p<0.05$ vs. longitudinal direction in the same condition.

Figure 3: Stored energy (W_s) (A), dissipated energy (W_d) (B), and the V/E ratio (W_d/W_s) (C) measured at equilibrium (100s) of relaxation in different conditions. * $p<0.05$ vs. baseline in the same direction. # $p<0.05$ vs L in the same condition.

Enhanced RV anisotropy with MT hyper- and de-polymerization.

At the baseline state, we observed no significant anisotropy in RV relaxation modulus. However, after MT hyper- or de-polymerization, the relaxation modulus in the C direction was significantly lower than that of the L direction (Fig. 2), leading to marked tissue anisotropy. A similar behavior was seen in the stored energy (Fig. 3A). But the anisotropic behavior in RV dissipated energy (viscosity) was differently altered by the two treatments. At the baseline state, the RV exhibited marked anisotropy in dissipated energy and MT de-polymerization did not affect such behavior. However, MT hyper-polymerization caused a weakening of the anisotropy in dissipated energy (Fig. 3B).

DISCUSSION

To the best of our knowledge, this is the first investigation of the effect of MT network on healthy RVFW anisotropic viscoelasticity. A key condition of our test is applying a strain level of 6% to the RV tissue. In myocardial mechanics, the main microstructural components at play are myofibers and collagen. At lower strain levels (5%-7%), myofibers are the main determinant of the tissue mechanical properties. As the strain increases to late diastole (9%-20%), collagen is recruited and begins to dominate the RV mechanical behavior [4]. Therefore, by examining the tissue viscoelasticity at a lower strain level, we can better delineate the contribution of MT to RVFW viscoelasticity.

We firstly observed that **MT de- or hyper-polymerization did not necessarily result in equivalent changes in elasticity and viscosity in each direction.** For instance, after COL treatment, the circumferential elasticity (relaxation modulus, W_s) was reduced but the viscosity (W_d) was not changed in either direction. Similarly, MT hyper-polymerization increased viscosity (W_d) but did not alter the elasticity (W_s) in the C direction. In prior length-tension studies using cyclic test and/or stress relaxation, both cardiomyocyte elasticity and viscosity were reduced by COL [1,2,5]. Our results suggest that **the cell-level findings cannot be directly translated into tissue-level mechanical behavior, and an impaired MT network may result in the recruitment of other intracellular or ECM proteins to compensate and strengthen the tissue's overall mechanical behavior.** These data also imply that the RV elastic and viscous properties are decoupled within the myofiber domain range. More work should be performed to confirm this finding and investigate the potentially different sources to confer MT elasticity and viscosity.

Interestingly, both de- and hyper-polymerization of MT led to enhanced RV anisotropy with a larger elasticity in the L than C direction. **The anisotropic changes in RVFW viscoelasticity indicate that the MT network not only affects the viscoelastic parameter values (stronger or weaker viscoelasticity), but also impacts the structural organization and, consequently, tissue anisotropy.**

Second, we observed that **MT de- and hyper-polymerization led to opposite changes in RVFW viscoelasticity.** 1) As shown in Fig. 2 and Fig. 3A, MT de-polymerization reduced RV relaxation modulus (in C direction) and hyper-polymerization increased RV relaxation modulus (in the L direction), suggesting that an enhanced MT network is associated with stiffer myocardium. 2) The de-polymerization of MT did not affect tissue viscosity in either direction, whereas the MT hyper-polymerization leads to greater viscosity in both directions (Fig. 3B). 3) MT de-polymerization tended to decrease the V/E ratio in the L direction, whereas MT hyper-polymerization significantly increased V/E ratio in the C direction (Fig. 3C). The last two findings suggest that different sources may be responsible for the tissue viscosity and the V/E ratio with high and low content of MT, and these changes may be associated with the reorganization of MT network and recruitment of other load bearing components (e.g., titin).

Finally, our data may provide some insights on the role of MT in myocardial remodeling in heart diseases. Increases in elasticity and viscosity result in more resistance of the tissue during the passive stretch or active shortening. Therefore, an enhanced myocardial viscoelasticity is overall considered harmful to cardiomyocytes as the 'resistance' to muscle shortening is elevated. However, there may be another side of the story as some *in vitro* studies have shown a beneficial role of matrix viscosity in cell behavior (e.g., migration and proliferation) [7,8]. The viscous property to 'damp' mechanical energy may prevent wall stress elevation and cell damage in diseased conditions, and thus the MT proliferation in hypertrophied myocardium may be an adaptive response of the tissue. Future study should further investigate the roles of substrate's viscosity and the V/E ratio in cardiomyocyte function.

MODAL ANALYSIS OF NATURAL VIBRATION FREQUENCIES OF THE BRAIN AND HEAD

Turner Jennings (1), Rouzbeh Amini (1,2), Sinan Müftü (1)

(1) Department of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, USA

(2) Department of Bioengineering, Northeastern University, Boston, MA, USA

INTRODUCTION

Physical structures in the absence of outside forces tend to passively vibrate at specific natural frequencies. If an outside vibration is applied with a frequency equal to one of the natural frequencies of that structure, it induces potentially harmful resonance, leading to a larger vibration amplitude than the input force. Quantifying the natural frequencies of a structure, whether it is manmade or not, is critical in identifying potentially harmful vibration sources. Individuals experience exposure to vibrations in both low intensity long duration, such as riding in a car or operating machinery, and high intensity short duration, such as sports collisions or car accidents. As such, categorizing the natural frequencies of critical parts of the body, such as the brain, can help identify dangerous sources of vibration and improve protective technologies through attunement of dangerous frequencies.

The natural frequencies of the brain have been studied both experimentally [1,2] and numerically [3,4] in the past. Experimental measurement of natural frequencies is limited due to ethical limitations with testing with live subjects. Tests with cadavers have shown that vibrations are difficult to detect due to the soft layers of skin and muscle that inhibit amplitude measurement. The accuracy of previous finite element (FE) studies to calculate the natural frequencies have been limited by the simplicity of the models used, which frequently omit organs or sections of the head to reduce computational cost. The purpose of this study was to validate the use of a more complete and detailed FE model to calculate the natural frequencies of the head and the brain.

METHODS

We calculated the natural frequencies of the head and brain using the Total Human Model for Safety (THUMS) [5]. The THUMS model is a full-body FE model developed using the LS-DYNA (Ansys, Inc., Canonsburg, PA) FE solver for crash test safety applications. For this investigation only the head model, segmented at the base of the skull, was used. The addition of the neck was found to have no effect on the

natural frequencies (data not provided). The model features a highly detailed head (Fig. 1), including a brain fully modeled with separate white and gray matter, meninges, and cerebrospinal fluid (CSF). The geometry of the model is based on a 50th percentile male. It includes components of the head frequently omitted in previous studies, such as the eyes, facial musculature, and skin.

The head model is comprised of 257 parts made of 256,935 elements, with the brain model making up 195,783 of those elements. Different parts of the head are all modeled using linear material modeling approaches; linear piecewise plasticity (MAT_024) for the skull, viscoelasticity (MAT_006 and MAT_061) for the brain and meninges, and simple elasticity (MAT_001) for the skin, muscles, and other tissues. The linearized material models reduce computation time and enable modal analysis of the natural frequencies of the model.

Modal analysis was performed using LS-DYNA implicit analysis. The first 10 natural frequencies were calculated for six different subsections of the head: the brain matter alone, brain with falx and tentorium, brain with falx, tentorium, CSF, and meningeal layers, skull alone, skull with all contents, and the full head model. Vibration modes associated with rigid body motion of the full head, as well as nonphysical vibration modes calculated in the CSF, were rejected.

Figure 1: Layers of the THUMS head model

RESULTS

The range of the first ten natural frequencies for each sub-section of the head tested are summarized in Table 1. The vibration modes associated with the natural frequencies of the full head model are shown in Fig. 2. The type of deformation observed for each of the vibration modes shown in Fig. 2, and their associated natural frequencies are listed in Table 2.

As expected, the stiffer parts of the head, such as the skull and meningeal layers, had much higher natural frequencies than the softer brain matter. The natural frequencies of the skull alone were two to three orders of magnitude larger than the other sections tested. The brain alone had the lowest natural frequency, but the addition of the CSF and meningeal layers as supporting structures around the brain increased the natural frequency response. The natural frequencies of the full head model fell between those of the skull and the brain. The frequency range was closer to the response of the brain, consistent with the corresponding vibration modes showing deformation primarily in the cerebral brain matter.

Table 1: Range of the first 10 natural frequencies for different sub-sections of the head model

Section	1 st Natural Frequency [Hz]	10 th Natural Frequency [Hz]
Brain matter	1.1	6.1
Brain matter, falx, tentorium	1.1	5.0
Brain, falx, tentorium, CSF, meningeal layers	12.6	16.0
Skull	1026.2	2301.3
Skull with cranial cavity contents	11.2	16.2
Full head	11.1	16.2

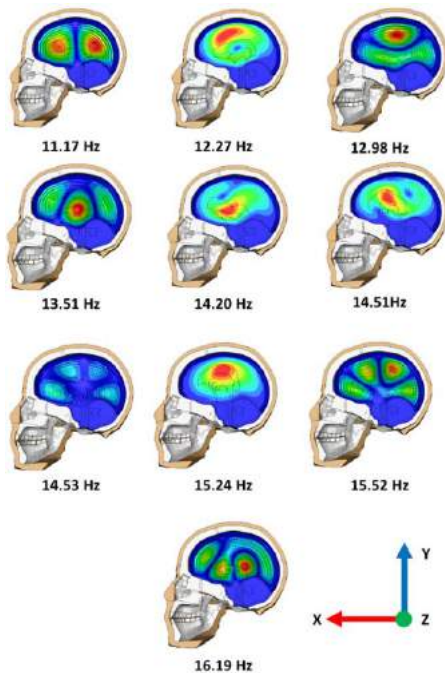

Figure 2: Vibration modes for the first ten natural frequencies of the full head model. The color plot represents the relative magnitude of displacement, with blue indicating zero displacement and red indicating maximum relative displacement.

Table 2: Description of vibration modes for the full head model

Frequency [Hz]	Vibration mode
11.17	Flexural rotation around y-direction
12.27	Flexural rotation around z-direction
12.98	Flexural rotation around x-direction
13.51	Flexion normal to x-y plane
14.20	Flexural rotation in the z-direction
14.51	Flexural rotation in the z-direction
14.53	Flexion normal to x-y plane
15.24	Flexural translation in the y-direction
15.52	Flexion normal to x-y plane
16.19	Flexion normal to x-y plane

DISCUSSION

The results of the head section analysis are consistent with expectations and prior research. The natural frequencies calculated for the skull align closely with previous experimental results measured on dry skulls [6,7]. The vibration modes observed in the full head model are similar to those observed in Tse et al [4]; however, the natural frequencies calculated in this study are an order of magnitude smaller. This discrepancy may be due to differences in the modelling techniques used. Another reason could be that the dynamic behavior of the model in Tse et al.'s work was not validated against previous experimental results.

The natural frequencies of any object are dependent on the geometry and material properties. The frequency ranges calculated in this study are estimates based on 50th percentile adult male dimensions, and average material properties. Future simulations using geometry representative of different head sizes, as well as varying the material properties according to uncertainty observed in the literature, could clarify the sensitivity of the natural frequencies to natural variations in size, shape, and material stiffness of the head. The natural frequency ranges calculated coincide with the frequency range of other physiological functions, such as heart rate (1-3 Hz) and brain waves (0.1-40 Hz). It is unknown whether the brain's mechanical preference toward these frequencies is related in any way.

The objective of this study was to validate the modal analysis results of this model against existing literature on the topic. The natural frequency response of the model is close to previous experimental and numerical results, which lays the foundation for using this model to test the effects of variation in tissue properties or subject-to-subject geometric variation on natural frequencies, as well as further investigation into cellular-level response to these vibration frequencies.

COMPUTATIONAL MODELING OF CORONARY VENOUS RETROPERFUSION TREATMENTS FOR ISCHEMIA

Haifeng Wang (1), Lei Fan (1), Jenny S. Choy (2), Ghassan S. Kassab (2), Lik Chuan Lee (1)

INTRODUCTION

Coronary venous retroperfusion, such as coronary sinus occlusion (CSO) and selective auto-retroperfusion (SARP) [1], is proposed as a treatment for coronary artery diseases. Unlike existing treatments of coronary artery diseases such as coronary artery bypass grafting, coronary venous retroperfusion seeks to deliver blood through the coronary venous system (i.e., “back door”) to the ischemic region either by occluding the coronary sinus in CSO or shunting arterial blood to the coronary veins in SARP. Their mechanisms and effects on the coronary microvasculature are, however, not well understood largely because it is especially extremely difficult, if not impossible, to measure all the relevant hemodynamic quantities in the microcirculation *in vivo*. To address this limitation, we developed a novel computational framework that couples the coronary arterial-capillary-venous microcirculation with cardiac mechanics in a closed-loop to investigate coronary venous retroperfusion treatments.

METHODS

The computational framework consists of the coronary arterial, venous and capillary networks (with cross-connections) as well as the Thebesian vessels that are not considered in most existing computational models (Figure 1). The entire network consists of 1996 vessels and each vessel is represented by a 0D nonlinear lumped model consisting of the 2 vascular resistances and compliance (as indicated in the square inset in Figure 1). Geometry (radius and length) and mechanical properties of the vessels are prescribed based on measurements. To account for the branching ratios measured in experiments [2], the equivalent resistance, R_{eq} , and capacitance, C_{eq} , for the vessel of order n are determined by

$$R_{eq}^n = \frac{128\mu L}{\pi D^4} \frac{N_{num}^n}{N_{exp}^n}, \quad C_{eq}^n = \frac{\partial V}{\partial P} \frac{N_{exp}^n}{N_{num}^n} \quad (1)$$

where N_{num}^n and N_{exp}^n are the total number of vessels of order n in the present numerical model and experimentally measured in pigs,

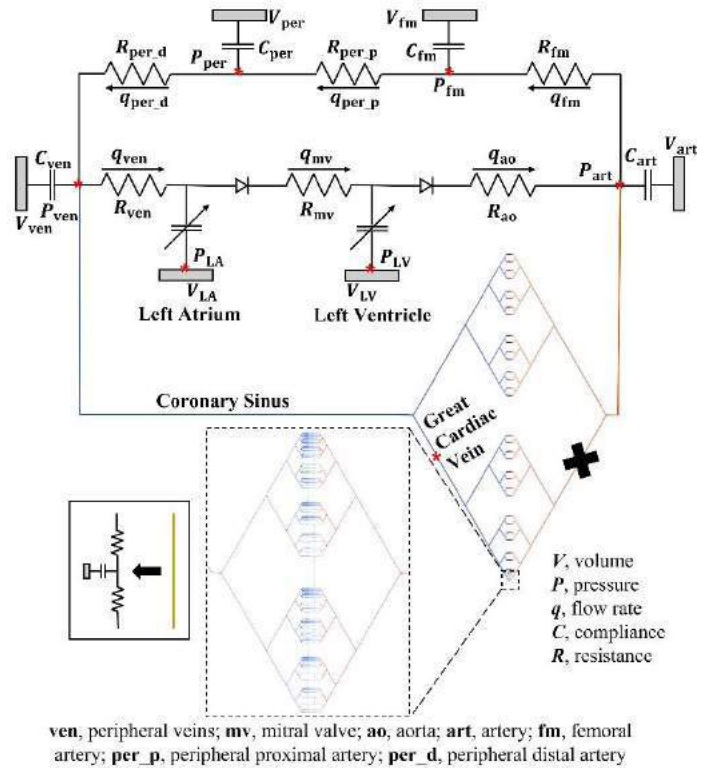

Figure 1: Schematic of the computational framework modeling coronary venous retroperfusion treatments. Dashed lines represent the microvascular network containing coronary arteries, capillaries and veins. The black cross indicates the occluded arterial vessel.

respectively. In Eq. (1), L , D , V and P are the length, diameter, volume, and transmural pressure of an individual vessel, respectively; μ denotes the blood viscosity. The function of left ventricle (LV) and left atrium (LA) are each described using a time-varying elastance model [3]. Ischemia due to the occlusion of a coronary artery (as indicated by the black cross symbol in **Figure 1**) is simulated by setting the artery resistance to infinitely large. CSO and SARP are simulated, respectively, by occluding the coronary sinus and connecting the great cardiac vein (GCV) to the femoral artery via a catheter, respectively (**Figure 1**).

RESULTS

The predicted blood pressure and flow rate distribution across different vessel order of the entire coronary network (without ischemia) are consistent with that in the arteries in previous measurements (**Figure 2**). The model predicts both SARP and CSO lead to higher intravascular pressure (**Figure 3A**), larger vessel diameter (**Figure 3B**) and slower flow (**Figure 3C**) in capillaries compared the ischemic case. The capillary transit time (CTT), which is calculated by dividing capillary blood volume by flow rate, is increased as a result (**Figure 3D**). Between the two coronary venous retroperfusion treatments, SARP produces a lower intravascular pressure (55 mmHg vs. 80 mmHg) and smaller capillary diameter (7.25 μm vs. 7.38 μm) but higher capillary transit time than CSO (25 s vs. 20 s).

Figure 2: Model predictions of the pressure-vessel order relationship (left) and pressure-flow relationship (right) without ischemia. Reference data is taken from [2] and [4], respectively. Pressure and diameter are averaged over one cardiac cycle for arterial (Art), capillary (Cap) and venous (Ven) vessels.

DISCUSSION

Capillary transit time is closely associated with tissue oxygenation. High capillary transit time, in principle, allows more oxygen and nutrients to be transported to the tissue in the ischemic region, which in turn, improves coronary microvascular function and reduces infarct size. Our results show that both CSO and SARP increase the capillary transit time substantially, which can help in increasing tissue oxygenation. The increase in capillary transit time is larger in SARP, which shunt blood from the femoral artery to the coronary veins. An interesting finding here is that while CSO produces higher GCV pressure, it does not translate to a higher capillary transit time compared to SARP. This framework can be further extended to account for myocardial contractility and oxygen transport, and eventually for optimizing coronary venous retroperfusion treatments.

INTRODUCTION

Transcatheter aortic valve implantation (TAVI) has emerged as an alternative method to treat heart valve disease, especially in those patients with a high surgical risk. Severe aortic stenosis in tricuspid aortic valves (TAV) is now routinely treated with this minimally invasive procedure. As TAVI devices have become safer and longer lasting [1], the procedure is becoming an option for populations at a lower surgical risk and with different valve phenotypes. Recently TAVI has been approved for aortic stenosis for moderate surgical risk populations by the FDA [2].

Lower surgical risk patient populations, however, tend have different valvular and surrounding structural anatomies. In particular, bileaflet aortic valves (BAV) have unique anatomical characteristics that have led to BAV patients being excluded from official clinical trials for TAVI devices [3]. As a result, a BAV is typically a counterindication for TAVI. However, BAV patients have with varying degrees of frequency been chosen as candidates for TAVI, but this is not yet the standard of care. With the approval of TAVI devices for lower risk populations, there is a need to investigate new ways of assessing patients for TAVI and the impact on BAV patients.

This study seeks to investigate the hemodynamic effects of a variety of geometrical parameters on native and TAVI device function. Parametrized 3D models are used as the basis for fluid-structure interaction (FSI) numerical modeling of flow across the aortic valve. This paper presents preliminary work to create a TAVI simulator for evaluating the impact of root geometry, hemodynamics and future implantation training. Mechanical properties of the aorta are investigated using a large-scale tensile testing study and a patient-specific parametrized 3D model of the aorta and aortic valve is developed. Initial FSI studies are also presented.

METHODS

The aortic valve and surrounding anatomy are complex structures that are often simplified to save computational power. FSI models often reduce the geometry to a symmetrical aortic valve and a straight channel [4]. Other models reconstruct fully patient-specific aortic roots with idealized leaflets to maximize fidelity [5], [6]. In this study, to better understand which parts of the anatomy affect the flow dynamics through the aortic valve, a highly parametrizable model of the aortic root, valve and ascending aorta was build using SolidWorks (Dassault Systèmes, SolidWorksCorp., Waltham MA). The parameters used allow for a patient-specific idealized model to be generated and are shown in Table 1. A retrospective study of patients having undergone TAVI were reconstructed to begin validation of the FSI simulations.

Table 1: List of geometrical parameters in 3D model

Parameter	Description
LVOT_D	Left ventricular outflow tract diameter
STJ_D	Sinotubular junction diameter
Sinus_D	Sinus diameter (one for each region)
STJ_H	Height from base of LVOT to sternotubular junction
Sinus_H	Height from base of LVOT to the maximal sinus diameter
α	LVOT-aorta angle
Commisure H	Height of each commissure (one per commissure)
Coaptation_H	Height of the central coaptation
Geometric_H	Geometric height, or total length, of the aortic valve profile
Fusion type	If case is a BAV or not
Ellipticity	Ellipticity index of the LVOT Diameter

Material properties of the aortic tissue were determined from samples obtained from aortic aneurysm resection surgeries. Biaxial tensile testing was done using a TA Electroforce (TA Instrument, New Castle, DE) planar biaxial tensile tester. Testing samples are prepared by punching four 15x15mm samples from the collected tissue. Samples are then placed in a heated saline bath using suture holders to connect the samples to the load cells. The test consists of 8 pre-conditioning cycles of loading to 60% strain at 0.4 mm/s, followed by identical loading at 0.1 mm/s. Modulus of elasticity was calculated as the slope of the stress-strain relationship at 50% strain.

Numerical simulations are performed in COMSOL Multiphysics 6.1® (COMSOL AB, Stockholm, Sweden, 2022) using a fully-coupled arbitrary Lagrangian-Eulerian method (ALE) for the FSI components. Mechanical properties of the aortic valve were taken from the literature, and blood was assumed to be a Newtonian fluid with a viscosity of 3.5 cP and density of 1060 kg/m³. Pressure boundary conditions were applied at the ventricular inlet and aortic outlet. Transvalvular gradient, effective orifice area (EOA) and maximum jet velocity were used as validation measures to compare numerical modeling results with patient data.

RESULTS

Accurate mechanical properties are key to having a robust numerical model. The aortic tissue tensile testing study allows for a large cohort of patients to be used to get an average value of aortic stiffness of patients with diseased aortas, who also often present with valvular disease. The modulus of elasticity at 50% strain was on average 0.18 MPa ± 0.07 MPa.

The parametric 3D models were built using CAD software, with an example shown in Figure 1. The parameters encompass a wide variety of parameters and capture the asymmetry of the aortic root and valve. Based on clinician evaluation, these models visually resemble the native aortic root and valve.

Figure 1: Cross-section view of the parametric 3D model

Simulations were run using these patient-specific models to start preliminary quantitative validation. The results show that the valve leaflets deform similarly to the native leaflets. The transvalvular pressure gradients, EOA and velocity profiles were comparable to the preprocedural evaluations. Figure 2 shows a visualization of the FSI results for a patient with an LVOT-aorta angle (α) of 10° at a mean

gradient of 3 mmHg (mid opening). Note the asymmetrical opening due to the higher value of α .

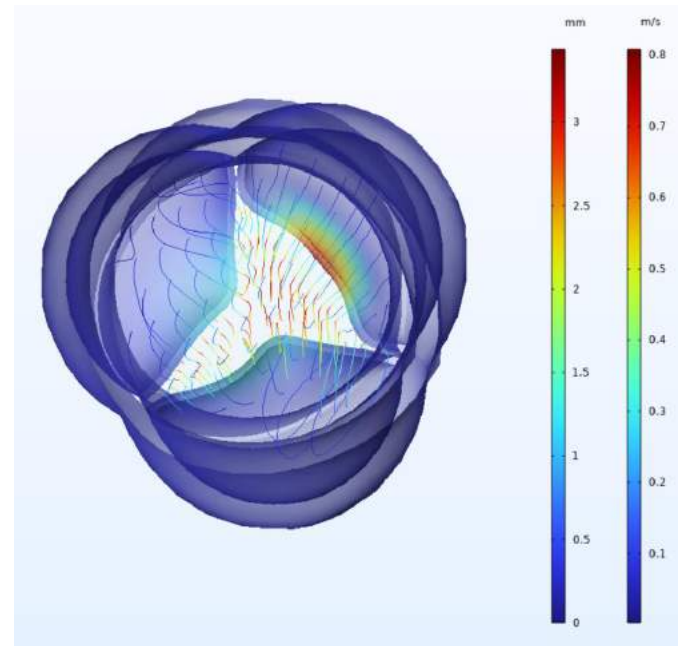

Figure 2: Top view of a FSI simulation with $\alpha = 10^\circ$

DISCUSSION

This preliminary work shows that an idealized 3D geometry that utilizes a multitude of input parameters can be used as the basis for patient-specific simulations without the need for a complete 3D reconstruction. Future studies plan for the investigation of these geometrical parameters. Geometry is one of the main aspects where BAV patients are different from TAV patients. They more often have an asymmetrical LVOT, increased LVOT-aorta angle, and larger ascending aortic diameters. Virtual deployment of a TAVI device in the 3D models coupled with a parametric analysis will allow for the determination of which of these parameters are responsible for the greatest disruption to flow, and how these could impact TAVI success.

Future work will also involve the investigation of implantation issues, different flow profiles, as well as coronary flow and how these affect TAV and BAV patients differently. Physical models can be 3D-printed to create catheterized models for procedural training.

MULTISCALE MECHANOBIOLOGICALLY OPTIMIZED SCAFFOLD DESIGNS FOR BONE TISSUE ENGINEERING

INTRODUCTION

Scaffolds for bone tissue engineering aim to treat large bone defects, such as those that occur from severe skeletal trauma. Yet, how to design a scaffold for optimal bone formation remains an open question. A variety of physical stimuli, including substrate curvature and strain, can promote osteogenic differentiation of skeletal progenitor cells. The design of scaffold architectures can thus be used to regulate the mechanical stimuli to which cells are exposed, and for the purpose of testing mechanobiological hypotheses and promoting bone repair.

Mechanically informed scaffold designs can be lumped broadly into two categories: macro-mechanical and micro-mechanical. Macro-mechanically informed designs use the concept of “mechanical homeostasis,” matching the apparent modulus of the scaffold to that of the bone the scaffold is intended to replace [1,2,3]. On the other hand, micro-mechanically informed designs rely on the concept of the cellular microenvironment [4,5] to generate designs that possess large shares of osteogenically favorable microenvironments [6,7]. However, these designs are typically only based on a single stimulus and/or are limited in the variety of designs that they consider.

Various studies have examined the role of curvature and strain in the cellular microenvironment. For this work, curvature will be represented using curvedness (C) and the shape index (SI) [8]. Swanson et al. [9], found that smaller values ($C \in [4.7, 8] \text{ mm}^{-1}$) of curvedness promoted osteogenesis while larger values ($C \in [16, 33.3] \text{ mm}^{-1}$) maintained stemness. Werner et al. [10] found that convex curvatures ($SI > 0$) led to increased osteogenic gene expression in osteoprogenitor cells. Some studies have noted that saddles ($SI = 0$) may be preferable for osteogenesis [11,12]. Triply periodic minimal surfaces (TPMSs) have thus grown in popularity as a basis for scaffold designs, because TPMSs are saddles at all points.

In addition to substrate curvature, the scaffold architecture also determines the local strains that develop throughout the scaffold when subjected to loading. Results of numerous studies support the

mechanobiological hypothesis of Prendergast and colleagues [13,14,15] which proposes that octahedral shear strain (ϵ) and fluid velocity are the predominant stimuli regulating differentiation of osteoprogenitor cells. Under that paradigm in the absence of fluid flow, strains from 0.04% to 1% and from 1% to 3.75% promote formation of mature and immature bone, respectively [15].

This study develops a “mixed-topology TPMS” optimization scheme to generate both macro- and micro-mechanically informed scaffold designs and proposes several ways to evaluate the osteogenic fitness of a scaffold architecture.

METHODS

Scaffold surfaces were defined implicitly as a weighted sum of equations defining three different TPMSs (Fig. 1): primitive ($p(x, y, z)$), gyroid ($g(x, y, z)$), and diamond ($d(x, y, z)$). The mixed topology surface is a function of three parameters, α , β , and γ :

$$s(\alpha, \beta, \gamma) = \alpha p(x, y, z) + \beta g(x, y, z) + \gamma d(x, y, z) \quad (1)$$

and corresponds to where $s(\alpha, \beta, \gamma) = \pm \frac{1}{2}$. This scheme gives α , β , and γ control over both the architecture and wall thickness of the scaffold.

Figure 1: Scaffold unit cells for (a) primitive, (b) gyroid, (c) diamond, and (d) the starting design for the optimizations. The parameters (α, β, γ) that define each architecture are given above.

Meshes of the implicit surfaces were constructed through a process involving the marching cubes algorithm [16], a dynamic mesh optimization procedure for implicit surfaces [17], a constructive solid geometry technique [18], and finally the fTetWild [19] tetrahedral mesh

generator to produce 1mm cubic unit cells. Scaffolds were simulated in Ansys (Ansys Inc., PA, USA) with a linear-elastic material model ($E=13$ GPa, $\nu=0.3$), the bottom surface fixed, and the top surface compressed with a strain of $2500 \mu\epsilon$. Equations for C and SI of the scaffolds were derived analytically [8,20] and then evaluated at each node in the surface.

For each stimulus (SI, C, and ϵ), values were first calculated at all surface nodes and then averaged over each triangular surface facet in the mesh. Linear piecewise scoring functions were used to assign a score in the range [0,1] to each triangle. For the curvedness score f_c , a maximum score was assigned to 6 mm^{-1} , decreasing outward to 0 at $C=3$ and 9 mm^{-1} . For the SI score f_{si} , the score was maximal for the interval $SI=[0.25,0.5]$ and decreased outwards to 0 at $SI=-0.25$ and 0.5 at $SI=1$, thus targeting a saddle-like-convex surface. For the shear strain score f_ϵ , the maximal score was at 0.52% and decreased outwards to 0 at 0.04% and 3.75% , targeting the midpoint of the “mature bone” range of shear strains (according to [15]). Scores for multiple stimuli were multiplied together to obtain a curvature score (eq. 2) and a total score considering curvature and strain (eq. 3):

$$f_{\text{curv}} = f_c f_{si}, \quad (2)$$

$$f_{\text{total}} = f_c f_{si} f_\epsilon. \quad (3)$$

Each of the scoring functions was used to generate a single scalar score quantifying the overall fitness F of a given scaffold design:

$$F_{\text{stimuli}} = \sum_t^n \text{Triangles} A_t f_{\text{stimuli},t}, \quad (4)$$

where A_t is the area of a triangular facet and $f_{\text{stimuli},t}$ is the facet's score for a particular stimulus or combination of stimuli.

Five optimal scaffolds were determined, each corresponding to a different objective (Fig. 2), using the gradient-free COBYLA optimizer [21], as implemented in the SciPy library [22], with α , β , and γ each constrained between 0 and 1. The starting point for each case was $\alpha, \beta, \gamma = 0.5$ (Fig. 1.d). In two of the five optimization runs (cases 4 and 5), the apparent modulus was constrained to be within the interval $[0.475, 0.525]$ GPa, an example target modulus representative of trabecular bone in the human proximal tibia and greater trochanter [23]. This constraint required the optimizer to explore micro-mechanically informed designs while simultaneously achieving a macro-mechanically informed structure.

RESULTS

For each of the first three cases, the optimized design had a fitness score greater than those of the original TPMSs, the starting design, and the results of all other cases, though the optimal design for F_ϵ converged to a diamond-like scaffold (Fig. 2). Adding the modulus constraint slightly reduced fitness in regards to the curvature score (case 4), and more than halved the fitness in regards to the total curvature & strain score (case 5). All cases converged to designs that were heavily weighted towards the diamond TPMS (large γ) and only lightly weighted towards the gyroid TPMS (small β), while the weight for the primitive TPMS (α) varied among cases.

DISCUSSION

These results demonstrate the potential of mixed-topology TPMS designs to achieve optimal architectures for various macro- and micro-mechanical objectives. The mixed-topology TPMS strategy provides a larger design space than has been considered in studies using only traditional TPMS designs, and the design space could be further expanded to four or more TPMS base structures, simply by adding more parameters. The flexibility of the scoring functions could allow for additional stimuli, such as fluid shear stress or hydrostatic pressure, to be considered within the same framework—a notable advantage over other approaches that only consider a single stimulus.

These results also emphasize that considering different stimuli leads to different “optimal” designs and thus highlight the need for

experiments that explore what combinations of stimuli (e.g. curvedness, shape index, and strain) are most favorable for osteogenesis. At present, knowledge of which stimuli, at what magnitudes, and in what combinations is insufficient to establish that the designs obtained here are truly optimal. Our approach can be used to generate designs for these future experiments, to compare scoring functions and accelerate development of scaffolds that provide requisite stimuli for bone repair.

Figure 2: Normalized scaffold fitness scores and apparent moduli for the 3 TPMS designs and the final design of each optimization. Scores are presented as the score for that design normalized by the score F of the starting point design ($\alpha, \beta, \gamma = 0.5$). For each case, the score that was optimized is outlined in black, constraints are indicated by striped bars. The final parameters (α, β, γ) are listed for each case.

Figure 3: Iteration progress for the case 5 optimization, showing the f_{total} score on each surface facet. The normalized scaffold fitness scores are reported below each design. (a) Initial design (iteration 1), (b) iteration 15, (c) iteration 25, (d) final design (iteration 49).

A NOVEL ELECTROCHEMICAL CATHETER FOR CARDIAC OUTPUT MONITORING

Marco A. Nino (1), Abdulsattar H. Ghanim (2), Syed Mubeen (2), Suresh M.L. Raghavan (1)

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, IA, USA
(2) Department of Chemical and Biochemical Engineering, University of Iowa, Iowa City, IA, USA

INTRODUCTION

Cardiac output (CO) monitoring is important in critically ill patients and for those undergoing cardiac procedures to check for adequate tissue oxygenation and effectiveness of cardiac repair. The current standard for CO monitoring is the use of the specialized pulmonary artery catheter (PAC) that works on the thermodilution principle. In thermodilution, a clinician will make controlled injections of cooler-than-blood saline into the flowing blood to induce a small drop in temperature of the blood. The transient change in local blood temperature – generally less than 0.5°C – is monitored and used to estimate blood flow rate (greater the blood flow, quicker recovery to normal temperature). Thermodilution-based CO measurement can be highly operator dependent and affected by uncontrolled confounding factors. As a result, measurements are known to have poor repeatability resulting in about 20% window of error. Overall, thermodilution is notoriously error-prone and may lead to wrong interpretations. Nishikawa et al. states that, “Knowledge of the errors inherent in thermodilution measurement is essential for the anaesthetists and other clinicians engaged in the management of critically ill patients. The erroneous estimation of CO may lead to inappropriate management and adverse outcomes”^[1].

Principle of electrodilution

We proposed the novel electrodilution method, which is operationally similar to thermodilution, but uses a distinctly different physiochemical principle allowing us to circumvent many of its known challenges^[2]. The electrodilution method for measuring flow rate leverages transient electrochemical behavior of a redox-active tracer molecule that is injected or released directly into the blood stream. The principle is that when a voltage applied to electrodes in contact with specific tracers released in blood, a measurable current is observed due to charge redistribution or electron transfer processes. Similar to thermodilution, the current response will also dissipate as a function of

CO and thus help recover it through calibration. This method avoids the use of temperature and its associated sources of error and hence holds the potential to be more reliable. Our initial findings showed that electrodilution metrics are correlated to flow rate. However, that proof-of-concept study did have some limitations – electrochemical cell design and flow conditions tested were not representative of physiological conditions. The study used steady flow conditions, but CO is pulsatile. In addition, the study used a flow-through electrochemical cell instead of a catheter and as a result it limited the flow rates tested to those that constitute neonate/pediatric regimes.

In this study, the electrochemical cell was miniaturized and an electrodilution catheter prototype was developed. A flow loop apparatus was designed to test the novel catheter using a broad range of flow rates under pulsatile flow conditions for bovine blood with hypertonic saline injections.

METHODS

Saline electrodilution experiments

To test electrodilution under conditions that more closely mimic a clinical setting, *in vitro* high-fidelity flow injection analysis experiments were conducted under physiologically representative pulsatile flow conditions. Anticoagulated bovine blood solution was prepared to have a 9:1 ratio of bovine blood to 3.2 wt% sodium citrate. Bovine blood samples were acquired from a local abattoir as needed. Hypertonic saline solution (7 wt%) was prepared as the analyte solution. Hypertonic saline was selected as it allows for greater current response in blood compared to isotonic saline. A 2.5 Fr quad-lumen PAC intended for thermodilution (131F7, Edwards Lifesciences Corp., Irvine, CA United States) was adapted to fabricate an electrodilution catheter, equipped with an electrochemical cell as a sensor, for physiological fluid flow characterization. This was achieved by threading copper wire with electrode material in two of the individually insulated catheter lumens and the catheter tip was

sealed using silicone. Only 1.5 mm of the electrode material wire was exposed at the catheter tip and the electrode spacing was 2 mm. The PAC is equipped to have analyte released from the catheter itself – operationally similar to thermodilution. The analyte release port is located 15 cm proximal to the sensing cell at the catheter tip.

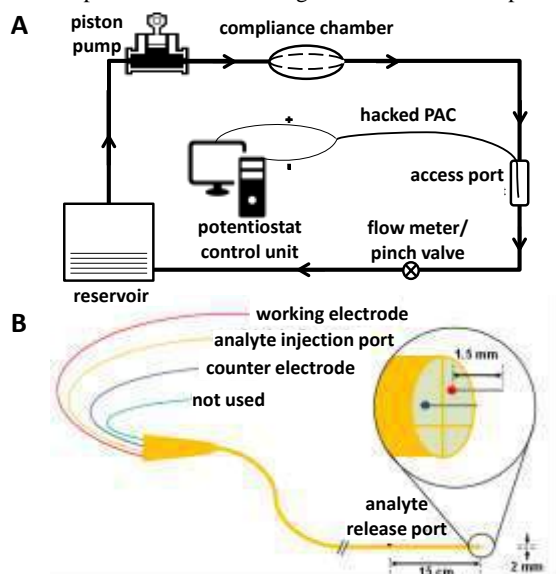

Figure 1: (A) Schematic of the flow loop apparatus. (B) Schematic of the fabricated electrodilution catheter prototype.

Experiments were conducted at various flow rates to characterize how the electrodilution curves are influenced by the flow rate of the medium. A programmable piston pump (SuperPump pulsatile pump, ViVitro Labs Inc., Victoria, BC Canada) was used to drive flow using a physiologically representative velocity waveform of large-artery blood flow. A tunable compliance chamber and pinch valve were used to target physiologically representative pressure waveforms (see Figure 1A). The electrodilution catheter was introduced into the flow loop via a catheter access port and the catheter was advanced so that 30 cm of the catheter was exposed to the flowing media. The catheter described above was connected to a potentiostat control unit (VSP-300, BioLogic Science Instruments, Seyssinet-Pariset, France). Using large-amplitude sinusoidal voltammetry (LASV), a potential waveform with AC parameters of $4 V_{pk}$ and 10 Hz was applied to the working electrode and the resulting current signal was continuously recorded at a sampling rate of 1 kHz. The pump was set to a predetermined flow rate, and the medium was allowed to flow until the measured current of the cell reached equilibrium. Next, multiple manual injections of 5 mL analyte was delivered over 1 sec into the flowing medium proximal to the sensing electrodes. The resulting current response and recovery were recorded. The process was repeated for various flow rates ranging from 0.5 to 4 L/min which constitute the ranges of blood flow for pediatric and adult patients. Experiments were repeated to test for reliability and reproducibility.

RESULTS

The current response to the analyte bolus follows a typical dilution curve – a steep rise and gradual fall back to the baseline. To characterize the temporal current response, data was post-processed using a semi-automated algorithm to identify the metrics that best correlate to flow rate of the media. The electrodilution curve is represented as the positive envelope of the current response (see Figure 2A). To quantitatively assess the relationship between flow rate

and the electrodilution curve in the time domain, an electrodilution metric was calculated for each curve: $\Delta Total Charge$ is defined as the charge observed during the duration of the rise from the baseline and fall back to baseline of current (area under the dilution curve). A description of how the metric is calculated can be found in our previous study^[2]. A schematic illustration of the prototype electrodilution catheter developed is shown in Figure 1B.

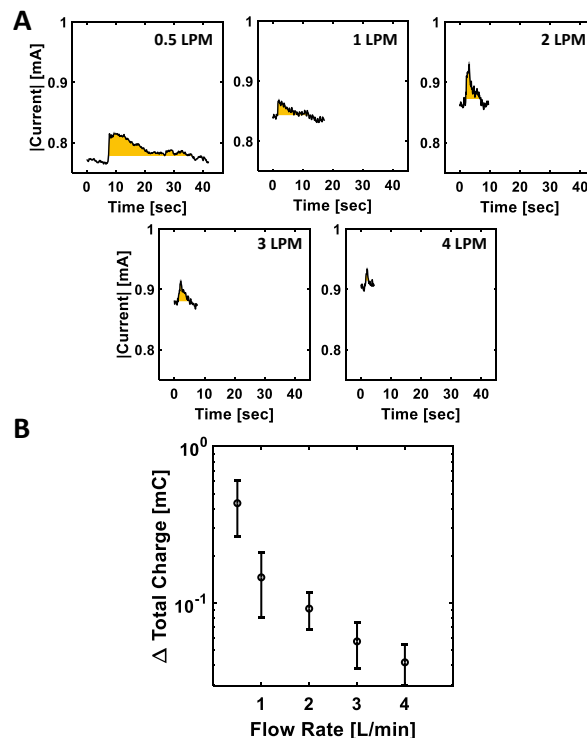

Figure 2: (A) Representative electrodilution curves for each flow rate tested. Shaded regions indicate $\Delta Total Charge$. (B) $\Delta Total Charge$ metric (mean and standard deviation for $n=5$) for five different pulsatile flow rates.

DISCUSSION

A novel electrodilution catheter was developed and tested for its ability to characterize flow rate under high-fidelity physiological conditions (see Figure 1B). The catheter has similar form factor to a clinically used PAC and is operationally identical to thermodilution. Figure 2B shows a summary of the key electrodilution metric for the novel catheter in blood under pulsatile flow conditions. Our results are consistent with our previous findings; there is a negative correlation with flow rate for $\Delta Total Charge$ ^[2].

We found that the electrodilution method using a novel electrochemical catheter is a feasible approach to characterizing blood flow rate in the body. This electrochemical approach to fluid flow measurement circumvents the major challenge that exists with thermodilution – measuring minute changes in temperature – providing the opportunity for more reliable flow rate measurement.

INTRODUCTION

Cell functional states can change rapidly, especially during development and differentiation¹. Changes in cell function can affect nearby cells, leading to the development of heterogeneous tissues that are different from the starting cell population. While cell states collectively set tissue homeostasis, disease processes like cancer are characterized by increases in state variability (heterogeneity) and changes in normal tissue composition². Proteins and their post translational modifications (PTMs) are thought to more proximally set cell state relative to its genome or transcriptome. However, elucidating single cell proteomes poses a major technical challenge as mammalian cells are estimated to contain $> 10^4$ types 400 different types of PTMs of each moment in time^{3,4}, and unlike transcripts proteins cannot be amplified to aid their detection. Antibody-based protein detection is highly sensitive relative to mass spectrometry but suffers from limited specificity and multiplexing limits imposed by spectral overlap of fluorescent labels. Therefore, single-cell proteomics has significantly lagged scRNA-seq, particularly in scalability to whole-proteome quantitation.

We are tackling this significant technological gap using a novel tool called single-cell proteome sequencing, or *scProteome-seq*. We analyze proteins from single cells using electrophoretic separations similar to existing scWestern technology⁵ and then perform DNA-based protein information encoding. The physical separation of analytes mitigates non-specific binding of analytes, while the use of DNA-labeled antibodies enables sensitivity by amplification and circumvents optical multiplexing limits. We developed readout of protein information comprising two barcodes 1) *Antibody ID* delivered via DNA-tagged antibodies to identify protein targets, 2) *Size ID* oligonucleotide delivered via a DNA microarray that encodes spatial coordinates. The size ID allows us to determine both the cell of origin of a particular analyte and to confirm antibody binding specificity by inferring the

molecular weight of the analyte from its migration distance. Our scProteome-seq workflow is performed as follows (see Fig.1). First, we settle single cell in microwells patterned in a polyacrylamide gel sheet, lyse them and separate proteins by single-cell SDS-PAGE, followed by protein immobilization on a nitrocellulose blotting membrane. Next, we add Antibody ID and Size ID and enzymatically couple, extend, and extract the full barcode. Lastly, we analyze barcodes by next-generation sequencing (NGS) for high throughput analysis. We can then compare cell-cell protein abundance and construct a profile of cell heterogeneity (see Fig 1). In this abstract, we present several performance aspects of technology development including protein immobilization efficiency, feasibility of protein DNA barcoding and compatibility of DNA barcoding with NGS. Our long-term research objective is to obtain high resolution snapshots of single-cell proteomes using our tool for applications in cell development, differentiation, and disease.

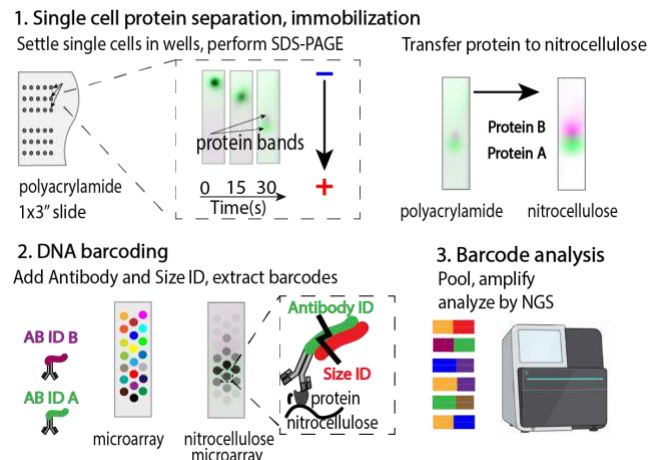

Figure 1: Schematic of the scProteome-seq workflow.

METHODS

1. Efficiency of protein transfer from polyacrylamide gel to nitrocellulose. We blotted 5 μ M GFP, Ovalbumin-Alexa 555, IgG-Alexa-555 on polyacrylamide gel and transferred to nitrocellulose while varying transfer time. We computed % efficiency as difference in AUC of fluorescence distribution peaks of protein post- and pre-separation divided by initial protein spot AUC, adjusted for background.

2. Single cell protein transfer resolution loss. We performed single-cell SDS-PAGE on GFP+ HEK-293 cells, transferred proteins to nitrocellulose and compared full width at half maximum (FWHM) of fluorescence distribution peaks adjusted for background to find increase in spot size during diffusive transfer.

3. Feasibility of DNA barcoding. We blotted serial dilutions (5 μ M to 5 nM) of purified GFP on nitrocellulose. We then performed scProteome-seq workflow as follows: blocked the membrane, fixed protein with paraformaldehyde and performed probing with anti-GFP-DNA conjugate. Next, we added size IDs via a DNA microarray spotted with 80,000 unique IDs. We used restriction enzymes to cut DNA and allow Antibody ID to hybridize to Size ID, Klenow polymerase to extend DNA. We then extracted and analyzed barcodes via qPCR.

4. Compatibility of the tool with NGS. We performed single-cell SDS-PAGE on GFP+ and tdTomato-FLAG+ HEK-293 cells. We then performed scProteome-seq workflow as described above. We used NGS to analyze extracted barcode library by mapping location of each Size ID as DNA “coordinate” and adding counts of extracted barcodes to each location to reconstruct protein information in DNA form.

RESULTS

1. Use of nitrocellulose as protein immobilization media in ScProteome-seq enables high protein transfer efficiency. Previous scWestern versions have relied on in-gel capture of proteins after separation, which severely limits antibody probing efficiency. We instead tested the feasibility of diffusive blotting to a nitrocellulose sheet as the protein immobilization strategy in scProteome-seq and studied transfer efficiency over a wide range of protein target molecular weights. We determined that purified protein transfer efficiency from polyacrylamide gel to nitrocellulose for low MW proteins like GFP (27kDa) exceeds 95% and exceeds 80% for high MW proteins like IgG (150 kDa) in just 2 minutes (see Figure 2A). Transfer efficiency decreases with increasing molecular weight and increases for all proteins with increase in transfer time.

2. Immobilization of single-cell protein on nitrocellulose membrane via diffusive transfer preserves single-cell separation resolution. One potential tradeoff for protein blotting is that target bands could spread significantly during transfer from polyacrylamide to nitrocellulose, especially for small band sizes (~100 μ m). We therefore studied resolution loss during this transfer. When comparing FWHM of protein spot on polyacrylamide pre-transfer and on nitrocellulose post-transfer, we found that band widths increase modestly over blotting times, up to 50% at 3 minutes, and does not increase after 3 minutes, thus adequately preserving single-cell separations on nitrocellulose (see Figure 2A).

3. ScProteome-seq DNA barcode output is linearly correlated with protein input concentration. We aimed to determine whether amount of detected DNA barcodes encoding protein information correlates with protein input as well as quantify limit of detection. To achieve this, we performed scProteome-seq workflow on serial dilutions of purified eGFP and used qPCR as readout of resultant DNA barcode abundance. We detected concentrations of eGFP as low as 5nM (see Figure 2A). In future work, we will study lower protein concentrations down to 5 fM.

4. scProteome-seq is compatible with next-generation sequencing. We next sought preliminary data that would establish the feasibility of

highly multiplexed analyte detection in scProteome-seq using next-generation sequencing. We added Illumina adapters to our barcodes extracted from a spatially restricted zone of nitrocellulose bearing single-cell separations of GFP+ and tdTomato-FLAG+ cells. We were able to reconstruct a spatially restricted distribution of barcodes corresponding to the correct region of interest on the nitrocellulose patch probed by scProteome-seq (see Figure 2B). While the separation map reconstructed from NGS was not yet at single-cell resolution, we anticipate that with a higher density of Size ID probes we will be able to read out single-cell levels of protein information.

A. Feasibility of scProteome-seq workflow

B. Confirmation of scProteome-seq compatibility with NGS

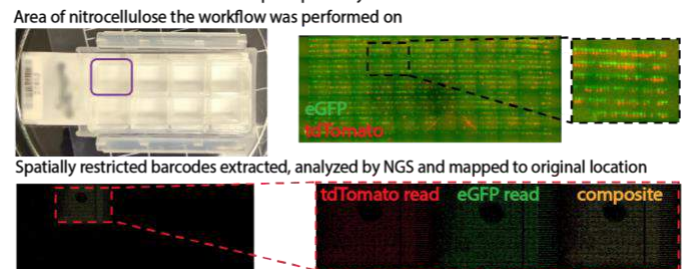

Figure 2: (A) Evaluation of scProteome-seq assay performance (B) scProteome-seq reconstruction of protein information via NGS

DISCUSSION

In this work, we evaluated feasibility of scProteome-seq as novel single-cell protein analysis tool and assessed several aspects of its performance. We effectively immobilized spatially separated single cell proteins on nitrocellulose while preserving single cell resolution. We also confirmed ability to encode protein information via DNA barcoding and made progress toward assay integration with NGS with the goal to increase throughput. In future work we will address the following gaps necessary for successful implementation of the scProteome-seq including 1) determine assay sensitivity and LOD, 2) assess multiplexing capacity and 3) optimize resolution for high-throughput single-cell protein detection. A full implementation of scProteome-seq would represent a major advance in single-cell proteomics including 1) increased multiplexing capacity due to DNA barcoding allowing us to encode many protein targets, 2) high throughput as we can simultaneously analyze ~1600 cells in a 75x25mm polyacrylamide gel, 3) high sensitivity as DNA-based readouts allow amplification of low abundance proteins.

ELASTUNET: THREE-DIMENSIONAL DISCOVERY OF ELASTIC MATERIAL PARAMETERS USING DEEP LEARNING

Ali Kamali (1), Kaveh Laksari (1,2)

INTRODUCTION

The ability to measure the spatially varying mechanical properties of solid materials is useful in biomedical engineering, materials science, and imaging. Soft biological tissues often have complex mechanical properties due to variation in structural components or fiber alignments.

Elasticity imaging is a technique to reconstruct distribution of mechanical properties using available deformation and force measurements. Quasi-static elasticity imaging, in particular, has been the subject of many experimental, theoretical, and numerical studies in 1D and 2D geometries over the past three decades, and various methods have been introduced to solve the inverse problem. These approaches include direct¹, virtual field methods², or domain decomposition³. While all these methods reveal distributions of elastic modulus (E) with varying levels of accuracy, they share two main drawbacks. First, they have been mostly validated using non-complex geometries, e.g., a stiff spherical inclusion inside a soft background. Second, they assume uniform Poisson's ratio (ν) distributions across the domain, an assumption which might not be valid for all biological tissues and might negatively affect the validity of the elastic modulus estimation⁴.

In recent years researchers have leveraged the power of neural networks as universal function approximators to solve elasticity imaging inverse problems^{5,6}. These studies are limited to 1D and 2D geometries and have their own shortcomings, as we reviewed in our previous work⁴. In this study, we introduce ElastUNet, an inversion algorithm based on convolutional neural networks, which discovers the distributions of E and ν using 3D strain distributions and normal stress boundary conditions on the sides of the domain.

METHODS

We generated a synthetic dataset by simulating the 3D deformation of brain tissue under compressive loading. We collected a T1 scan of the brain from a 28-year-old male using a 3.0 Tesla MRI scanner (Skyra, Siemens Healthcare, Germany) and a 32-channel head coil to perform

the simulation (human subject imaging approved by University of Arizona Institutional Review Board, February 2020). We used BrainSuite⁷ to segment the T1-weighted image volume and exported masks for different regions of the brain (Figure 1A). We simplified the segmentation by grouping deep brain structures under white matter. Therefore, the resulting geometry had three distinct regions: gray matter, white matter, and the ventricles. After manually refining some sharp edges of the geometry, we converted the masks to STL files using Slicer⁸, and re-meshed the STL's in InStep 3.0 (Solveering LLC, NM, USA) to reduce the number of triangles down to 10-15% to simplify the finite-element (FE) modeling.

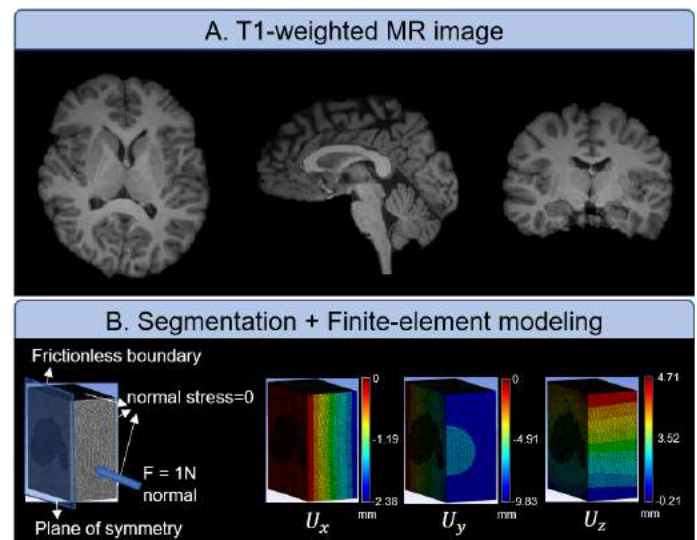

Figure 1: Creating the validation 3D deformation data.

Next, we performed the FE simulation steps on the geometry. We imported the remeshed STLs to SpaceClaim, part of the Ansys Workbench suite (Ansys, Inc, PA, USA), and created solid models out of the surface geometries, created a 200mm×200mm×200mm background region around the brain, and made a model of the right hemisphere only, with a symmetry boundary condition at the midsagittal plane. We performed this step to simplify the FE forward simulation. In Ansys Mechanical, we assigned E values of 1, 1.5, and 2kPa, and ν values of 0.45, 0.4, and 0.35 to the background, gray matter, and white matter regions, respectively. The ventricle's properties were assigned similar to the background. The geometry was discretized using tetrahedral mesh and uniaxial compressive loading was applied in the y direction by a uniform force of 1N (leading to maximum axial strain of about -0.07) on one side and frictionless boundary condition on the other. The other sides (other than the symmetry plane) were free boundaries. After running the simulation, we interpolated the unstructured data into a structured grid of 160×160×160 using the natural neighbor interpolation method due to the nature of convolution kernels requiring structured arrays as inputs. It should be noted that we exported the entire field by mirroring the results with respect to the plane of symmetry.

For solving the inverse problem, we developed ElastUNet, an encoder-decoder structure based on the original UNet architecture⁹ (Figure 2). In brief, compared to the original work, we used 3D convolutions instead of 2D, removed bias parameters and used batch normalization in the double-convolution sections, and transposed convolutions in the upward path of the network. The network takes in a 6-channel input, each channel containing the volumetric distribution of a strain tensor term (three normal and three shear terms) and estimates two volumetric distributions: first and second dimensionless Lamé parameters (λ and M). The algorithm then uses the isotropic linear elasticity constitutive equations to compute stress terms across the domain using the estimated Lamé parameters and given strains. It then computes the mean squared error loss values for balance of linear momentum in three directions (by using finite central difference approximation to compute the partial derivatives), and normal stress on the boundaries. We used the Adam optimizer with a learning rate of 0.001 to minimize the loss value and trained the model for 50,000 epochs on Nvidia v100 GPUs (taking ~6 hours to finish). The ElastUNet was not given prior knowledge about symmetry conditions of the domain.

Figure 2: ElastUNet overview.

RESULTS

Distributions of E and ν estimated through ElastUNet generally followed the ground truth values (Figure 3). The model accurately estimated the sharp transitions between the different regions of the 3D geometry, as can be seen in the complex folds of white matter and gray matter captured in the estimated fields. Absolute relative error values for elastic modulus estimation were the highest inside the brain reaching about 10% while Poisson's ratio errors remained below 5% in most

parts, including inside the brain. Mean absolute relative errors were 2.51% and 0.65% for E and ν , respectively.

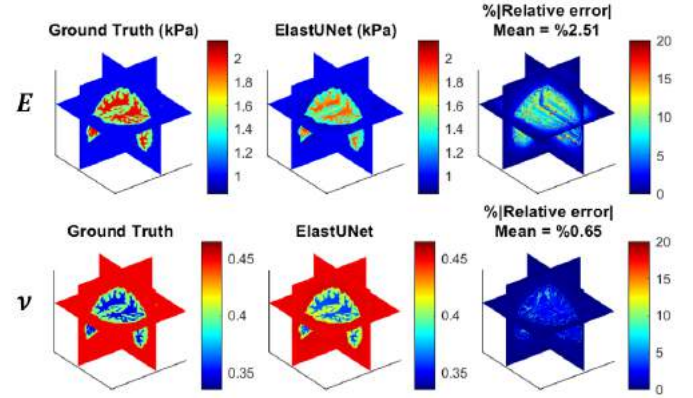

Figure 3: Comparing estimated distributions vs. ground truth.

DISCUSSION

We proposed a deep learning model to estimate the spatial distribution of linear elastic material properties in 3D given the strain fields and normal stress boundary data. In this approach, the network learns the material parameters by taking in normal and shear strain distributions, enforces constitutive equations, balance of linear momentum, and normal stress boundary conditions at the 6 sides of the model. The finite difference approximation to compute the partial derivatives is much faster than graph-based differentiation, which takes the derivative of the network with respect to inputs in the form of spatial coordinates, and is compatible with the convolutional neural network architecture. More generally, the current method improves existing models in two main aspects: It reconstructs both unknown material parameters in isotropic linear elasticity and is validated using a complex heterogeneous geometry.

Two main areas can be improved in future work. Although this model requires further development to show robustness in noisy datasets such as clinical and experimental applications, our study shows significant promise for solving the inverse mathematical problem. Secondly, we trained the on the entire volume and needed GPU memories exceeding 16 gigabytes to meet the demand from this large simulated dataset. Strategies to train the network in minibatches of data can be developed to tackle this problem in the future.

Our approach can be adopted in scenarios where 3D deformation fields can be obtained, especially MR or ultrasound, to aid diagnostics, in vitro or ex vivo tissue characterization, and defect analysis.

INTRODUCTION

Right ventricle failure (RVF) is the leading cause of death in patients of pulmonary hypertension (PH), heart failure with preserved ejection fraction and congenital heart disease. Moreover, the passive elasticity of the RV has been found to be associated to the organ function [1,2]. However, the myocardium is viscoelastic, meaning that there exist two types of resistive forces during the diastolic stretch: viscous and elastic. Historically, there has been a lack of experimental evidence of hysteresis from the myocardial tissue. Strong hysteresis was reported recently in adult human left and right ventricles (LV, RV) [3], neonatal porcine LV and RV [4], and adult ovine LV and RV [5]. But these studies did not examine the changes in ventricular tissue viscoelasticity during disease progression. In contrast, prior cellular research has shown increased cardiac muscle viscoelasticity with PH development [6-8]. However, these measurements were performed with 1D length-tension tests only. The changes in RV free wall (RVFW) anisotropic viscoelasticity with PH progression remain largely unknown. Therefore, **the aim of this study** is to investigate the changes in RVFW anisotropic viscoelasticity during PH development. We **hypothesize** that PH enhances RV viscoelasticity (elasticity and viscosity), and the RV exhibits different frequency-dependent elastic and viscous behaviors.

METHODS

All procedures and methods were approved by Colorado State University IACUC. 6-week-old male Sprague Dawley rats (n=8) were injected with monocrotaline (MCT) (60 mg/kg) and housed in normal conditions for three weeks to induce PH. Healthy age-matched rats (n=7) served as control (CTL). Echocardiography and pressure-volume (PV) measurements were then performed to confirm the establishment of RV failure. Animals were euthanized via urethane (1.2 g/kg) or CO₂. The tissue was harvested and placed in phosphate buffer solution (PBS) on ice. The entire RVFW was dissected in cardioplegic solution (CPS) and then placed in 30 mM 2,3-butanedione monoxime (BDM) solution

for 30 minutes to remove the muscle contraction. The outflow tract direction was defined as the longitudinal (L) direction. The tissue then underwent equibiaxial, sinusoidal cyclic tensile tests. All samples were preconditioned at 1Hz and 20% of strain before data collection. Next, the RV was stretched to a maximum strain of 20% and was loaded at 5 varied strain rates corresponding to: 0.1Hz (quasi-static), 1Hz and 2Hz (sub-physiological), 5Hz (resting heart rate), and 8Hz (heart rate under acute stress). A rest period was applied between tests to fully remove previous tests' effect on the tissue viscoelasticity. Stored energy (W_s ; elasticity), dissipated energy (W_d ; viscosity), the ratio of dissipated to stored energy (V/E ratio), and damping ($W_d/(W_d+W_s)$) were examined as previously described [5]. Student t-test was performed and $p < 0.05$ was considered significant.

RESULTS

RV failure establishment in MCT rats

In vivo RV function measurements showed the establishment of PH development and RV impairment in the MCT rats. There were marked RV dilation and reduced fractional shortening and cardiac output in the MCT rats ($p < 0.05$, data not shown), confirming the development of RV failure.

PH increased RV viscoelasticity in the longitudinal direction only

Compared to the CTL rats, the MCT rats had significant increases in RV dissipated energy (W_d) at 0.1Hz, 1Hz, and 5Hz (**Fig. 1A**). Similarly, the stored energy (W_s) was also significantly increased in MCT rats at 0.1Hz and 1Hz, with strong trends of increase in RV W_s at 5Hz and 8Hz (**Fig. 1B**). However, all these changes were observed in the L direction only, and there were no marked changes in the circumferential (C) direction. There were no changes in the V/E ratio or damping between healthy and diseased RVs at all frequencies.

PH led to significant anisotropy in RV elasticity and viscosity only

The healthy RV did not exhibit significant anisotropy in any viscoelastic parameter (**Fig. 2**). However, in diseased RVs, the W_d and

W_s in the C direction were significantly lower compared to those in the L direction at all frequencies, indicating strong anisotropy (Fig. 3A&B). We did not, however, observe any significant anisotropy in the V/E ratio or damping in the diseased RVs (Fig. 3C&D).

RV viscosity and elasticity had distinct frequency-dependent behaviors

In the healthy RVs, the W_d at 5Hz and 8Hz was significantly elevated compared to 1Hz in the L direction only (Fig. 2A). In the diseased RVs, we observed similar frequency-dependent behaviors. The W_d at 5Hz and 8Hz was significantly elevated compared to 0.1Hz and 1Hz and the increase was more pronounced in the C direction. However, there were moderate frequency-dependent changes in W_s in both groups (Fig. 2B, 3B). We further examined the relative change of RV viscosity to elasticity. In healthy RVs, there was no frequency-dependent change in the V/E ratio or damping up to 5 Hz. But in diseased RVs, the V/E ratio and damping were significantly elevated at 5Hz in the L direction (Fig. 3C&D). These results showed that the RV (both healthy and diseased) had different frequency-dependent viscous and elastic behaviors, and the diseased RV had pronounced frequency-dependent behavior in the V/E ratio and damping.

Figure 1. (A) The dissipated (W_d) and (B) stored energy (W_s) in CTL and MCT RVs in the L direction. $\pm p < 0.05$ compared to CTL.

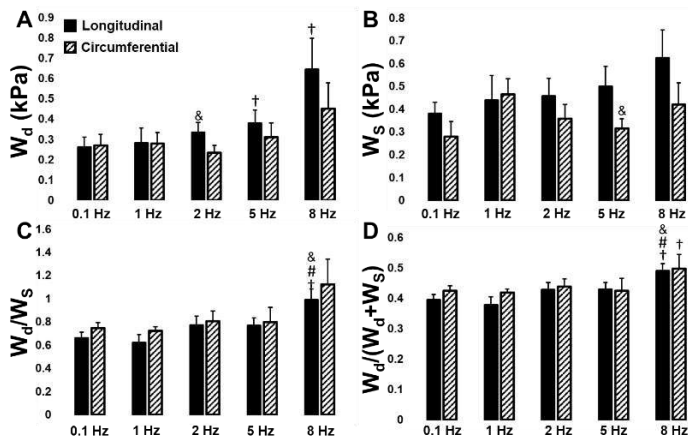

Figure 2. (A) The dissipated (W_d), (B) stored energy (W_s), (C) the ratio of dissipated to stored energy (W_d/W_s), and (D) damping ($W_d/(W_d+W_s)$) in CTL RVs. $\& p < 0.05$ compared to 0.1Hz; $\dagger p < 0.05$ compared to 1Hz; $\# p < 0.05$ compared to 5Hz.

DISCUSSION

In this study, we originally measured the RVFW anisotropic viscoelasticity by hysteresis analysis obtained across multiple testing frequencies, including the physiologically relevant frequencies of the rat (5Hz). We observed significant increases in RV viscoelasticity and altered frequency-dependent damping behavior with PH development.

Firstly, we observed an enhanced RV viscoelasticity (i.e., both viscosity and elasticity) in the L direction with PH progression. However, this increase was absent in the C direction. This led to an anisotropic viscoelastic behavior with pressure overload. It's known

that the PH RVs have marked cardiomyocyte hypertrophy and collagen accumulation, and both microstructural components are key to the tissue mechanical behavior. The increased RVFW viscoelasticity (mainly in the L direction) in MCT rats could be a result of reorganization of these microstructures such that the myo- and collagen fibers are more aligned along the L direction. This is consistent with prior findings of RV hyperelastic mechanics [1, 2, 10].

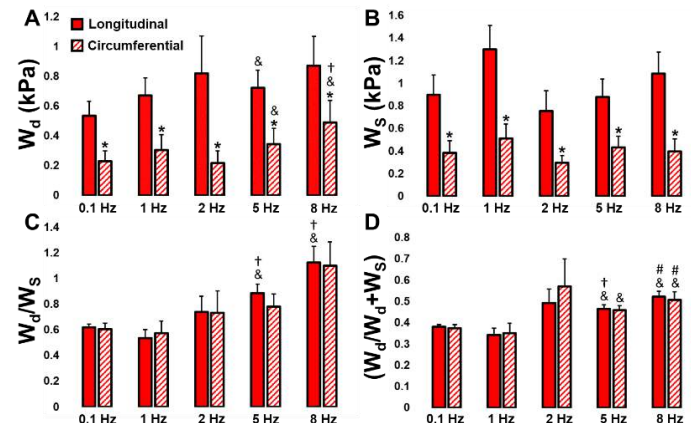

Figure 3. (A) The dissipated (W_d), (B) stored energy (W_s), (C) the ratio of dissipated to stored energy (W_d/W_s), and damping ($W_d/(W_d+W_s)$) in MCT RVs. $* p < 0.05$ compared to L direction in the same testing frequency; $\& p < 0.05$ compared to 0.1Hz; $\dagger p < 0.05$ compared to 1Hz; $\# p < 0.05$ compared to 5Hz.

Second, we observed that in both healthy and diseased RVs, the RV viscosity (W_d) at the physiological frequency was significantly higher than that at quasi-static testing frequency. But the RV elasticity (W_s) did not show such frequency-dependent behavior in either group. These data show that the RV display inequivalent elastic and viscous behavior at higher strain rates, and the potentially different “sources” of these mechanical properties should be investigated further. To better compare viscous and elastic changes, we used the parameters (W_d , W_s) with identical units. But we acknowledge that the use of W_s (instead of elastic modulus) to measure RV elasticity is non-traditional, and other elastic parameters should be investigated in the next step.

Finally, we found some frequency-dependent changes in the RV V/E ratio and damping, but the changes were more pronounced in the MCT rats. The V/E ratio and damping were elevated at 5Hz (resting heart rate of rats) and 8Hz compared to the sub-physiological frequencies. This indicates an enhanced ability of the tissue to damp mechanical energy at physiological strain rates during the pathological remodeling. Nevertheless, the MCT rats did not have an altered RV V/E ratio or damping compared to the CTL rats, indicating that the viscous and elastic changes in the pressure overloaded RV are equivalent. Future research should confirm this finding with other viscoelastic parameters and/or tests.

RISK OF VERTEBRAL ENDPLATE FAILURE DURING VERTEBRAL FRACTURE

Neilesh R. Frings (1,3), Elise F. Morgan (1,2,3)

INTRODUCTION

Vertebral fracture (VF) is the most common type of osteoporotic fracture¹ and is associated with back pain, loss of mobility, and excess mortality [1,2]. The *vertebral endplate region*, located at the superior and inferior end of each vertebra, is made up of the cartilage endplate, vertebral endplate (VEP), and underlying subchondral trabecular bone (STB). This region plays a critical role in how loads are distributed to the rest of the vertebral body [3] and is also frequently involved in VF. Depression of the VEP is a clinical diagnostic of fracture occurrence [4], but this deflection does not always involve fracture of the VEP [5,6]. This distinction is key: VF that do involve fracture of the VEP are associated with a higher risk of future disc degeneration and worsening of the fracture over time [6-8]. Despite the importance of VEP involvement in VF, the conditions responsible for these different modes of failure are unclear. Identification of these conditions can aid in evaluation of injury risk and need for preventative treatment [9]. Although compression testing of the vertebra is often used to create VF in the laboratory setting, finite element modeling provides an alternative that allows for precise identification of volumes of interest and evaluation of tissue yield at much higher spatial resolution. This study aimed to use high-resolution micro-finite element (μ FE) models to evaluate relative risk of failure in the VEP, STB, and other portions of the vertebral body at the point of onset of VF, and whether the relative risk of VEP failure is associated with VEP and STB microstructure.

METHODS

μ FE models (0.074mm cubic elements) were constructed from micro-computed tomography (μ CT) images of L1 vertebrae (n=18) that were previously scanned (μ CT 80; Scanco Medical; 70kV, 114 μ A) and mechanically tested [5]. Each vertebra was compressed axially in steps of 1 mm and imaged at each step after a resting period. Further, in that study, digital volume correlation (DVC) was used to compute internal displacements throughout the vertebra from the μ CT images.

In the present study, the μ FE models focused on the superior endplate region, as it is more likely than the inferior endplate region to fail during VF [10,11]. Therefore, models included the superior portion of the vertebra down to a depth 1.5 mm above the inferior boundary of the available DVC-computed displacements, or to a maximum depth of 29.6 mm; models typically included 80-85% of the total vertebral height. Models contained between 11-22 million nodes and 6-12 million elements. Bone tissue was modeled as an isotropic, linear elastic solid with Young's Modulus of 13 GPa and Poisson's ratio of 0.3 [12,13]. Superior and inferior boundary node sets for each sample were defined in Matlab and prescribed experimentally matched displacements by interpolating the DVC-measured values corresponding to the yield point identified on the load-displacement plot for the vertebra. μ FE simulations were run in parallel in Abaqus (Dassault). Simulations completed after 1-10 hours of runtime, using 10-90 hours of CPU time.

Using the μ FE-computed element strains, tissue yield was determined based on principal strain thresholds of 0.41% in tension and 0.83% in compression, as previously reported for trabecular bone tissue [14]. The amount of tissue yield was then computed for volumes of interest (VOIs) corresponding to the VEP, STB, and the rest of the vertebra. The VOIs were identified first in 2D on coronal slices of the μ CT image volumes and then mapped to the 3D model (Figure 1). The VEP VOI was identified from each superior surface bone pixel to the first empty pixel directly beneath it, after using an image dilation-erosion process to fill in endplate pores. The STB VOI extended 4mm below the inferior surface of the endplate. The remaining portion of the vertebra was defined as the mid-vertebral body (MVB). For each VOI, the *yield fraction* was computed as the ratio of the number of yielded elements in the VOI to the total number of elements in the VOI (eq. 1). This fraction was then divided by the *total yield fraction*, defined as the ratio of the number of yielded elements in the entire model to the total number of elements in the model (eq. 2), to obtain the *normalized yield fraction* for that VOI (eq. 3). The resulting value quantifies the yield in

each VOI normalized to that of the full model; a value above one indicates that the VOI contained a proportionally greater amount of yield than the vertebra as a whole.

$$VOI \text{ yield fraction} = \frac{\# \text{ yielded elements in } VOI}{\# \text{ elements in } VOI} \quad (1)$$

$$Total \text{ yield fraction} = \frac{\# \text{ yielded elements in model}}{\# \text{ elements in model}} \quad (2)$$

$$Normalized \text{ yield fraction} = \frac{VOI \text{ yield fraction}}{Total \text{ yield fraction}} \quad (3)$$

Pearson correlation was used to evaluate associations between the yield fractions and several measures of microstructure: VEP thickness, VEP BV/TV, and STB BV/TV. Repeated measures ANOVA tested for differences among VOIs in 90th percentile strains, yield fraction, normalized yield fraction, and tensile/compressive yield ratio.

RESULTS

High strains in the vertebrae were frequently observed in the superior endplate and cortical shell (Figure 2). In the VEP, tensile strains were typically of greater magnitude than compressive strains, whereas in the other two VOIs, the tensile and compressive strain magnitudes were comparable to each other. Given the lower yield point in tension, however, tension was the dominant mode of yield. In each VOI, the number of elements yielded in tension exceeded that in compression by at least three-fold in all vertebrae. Tensile/compressive yield ratio was highest in the VEP ($p=0.048$). Ninetieth percentile tensile strains were higher in the VEP than in the other VOIs ($p=0.003$), but 90th percentile compressive strains did not differ among VOIs ($p=0.600$).

VOI yield fraction varied among vertebrae (Figure 3A), and was not different across VOIs ($p=0.104$). Although the VEP constituted only 12-24% of the total number of elements in the models, the VEP's normalized yield fraction was greater than one for 15 out of the 18 vertebrae (Figure 3B), indicating a higher risk of yield in the VEP compared to the other two VOIs. The normalized yield fraction in the STB hovered around one, while that for the MVB was below one for most vertebrae, indicating that the portions of the vertebra outside the endplate region were at relatively low risk of yield. Normalized yield fraction was greater in the VEP than in the MVB ($p=0.001$).

VEP and STB yield fraction both correlated negatively with STB BV/TV ($p=0.018$, $p=0.023$). No other correlations were found.

DISCUSSION

Simulations of vertebral compression using high-resolution micro-finite element models indicated that at the onset of vertebral fracture—defined by the yield point on the force-displacement curve generated during compression testing—tissue-level yield typically occurs in the VEP, and to a lesser extent, the rest of the vertebral body. The normalized yield fraction was highest in the VEP, indicating a greater relative risk of failure in the endplate region compared to the rest of the vertebra. These results are consistent with prior observations that VF frequently involve the superior endplate region [10,11] and suggest that this region, and the VEP in particular, is where VF initiates.

Tension was the dominant mode of yield in all regions of the vertebra. This suggests that, during macroscopic compressive deformation of the vertebra, large deformations of the trabeculae and endplate are occurring that produce tensile tissue-level failure. Tensile strains were higher in the VEP than in other VOIs, in line with prior μ FE observations of higher tensile strains in the vertebral endplate relative to the underlying trabeculae [15]. However, the same prior study found the highest compressive strains during vertebral compression to occur in the trabecular centrum; in this study, compressive strains did not significantly differ across VOIs. This difference may be due to the difference in boundary conditions, as the prior study used uniaxial compression rather than physiologically matched displacements.

The associations between STB BV/TV and the yield fractions in the VEP and STB indicate that a vertebra with a more porous STB is at greater risk of failure in the endplate region during the onset of VF. Other factors may also influence which regions fail during VF; future studies are needed to determine whether the relative risk of VEP failure is affected by age, sex, and disc degeneration, which are known to influence VF risk and the microstructure of the endplate region [16,17].

TRANSVERSE CARPAL LIGAMENT ELONGATION AFTER INJECTION OF COLLAGENASE IN SITU

Jocelyn Hawk, David Margolis, Zong-Ming Li

Hand Research Laboratory, Department of Orthopaedic Surgery, University of Arizona College of Medicine, Tucson, Arizona, US

INTRODUCTION

The transverse carpal ligament (TCL) forms the volar boundary of the carpal tunnel, making it relevant compression neuropathy of the median nerve at the wrist. Although the etiology of carpal tunnel syndrome is unclear, it has been associated with higher carpal tunnel pressure, sometimes reaching above 200mmHg [1]. The current standard treatment for carpal tunnel syndrome is to surgically transect the TCL in order to increase carpal tunnel space and decompress the median nerve. However, this can disrupt the important biomechanical functions of the TCL and result in side effects such as pillar pain or hand weakness [2]. A potential alternative to surgery could be to increase TCL elasticity, allowing it to elongate in response to elevated carpal tunnel pressure. Collagenase Clostridium Histolyticum (CCH) is an enzyme that breaks down collagen fibers and can be injected into the TCL to increase its elasticity. The purpose of this study was to investigate the effects of CCH injections on the elongation of TCL tissue when carpal tunnel pressure is applied.

METHODS

Six fresh-frozen cadaveric hands were used in this study. The carpal tunnel contents were emptied, and a medical balloon connected to a pressure regulator was inserted into the tunnel. 18 retroreflective markers ($\Phi = 1\text{mm}$) were attached to the volar surface of the transverse carpal ligament in a 6x3 grid, such that the 3 rows were placed along the distal border, the proximal border, and centered between the proximal and distal border. The six markers in each row were evenly spaced between the radial and ulnar borders of the TCL. Nine evenly spaced injection sites were marked along the TCL midline (Figure 1) using tissue marking dye. Collagenase solution with a concentration of 50U/ μL was prepared by dissolving CCH in phosphate buffered saline. Each injection site was injected with 5 μL of the solution so that it received 250U of CCH, and the specimen was placed in an incubator set to 37°C.

The specimen was removed from the incubator 24 hours after injection and placed on a table with the wrist in a neutral position. Four Vicor cameras were set up to capture the marker positions (Figure 1). The medical balloon in the carpal tunnel was connected to a pressure regulator using plastic tubing. Using the pressure regulator, the carpal tunnel was inflated to 10, 30, 60, 90, 120, 150, 180, and 210 mmHg. At each pressure level, 3 seconds of video were recorded by the Vicor cameras.

Figure 1: Four Vicor cameras recording marker positions at each pressure level.

The 3D coordinates of each marker at each pressure level were obtained. The injection group for each row consisted of the centermost pairs of markers that contained a CCH injection between them. The control group consisted of all other pairs of markers. Distances between adjacent markers in the same row were calculated using MATLAB. Percent elongation was calculated for each pair of adjacent markers in the same row using the following equation:

$$\% \delta = \frac{d_i - d_{10}}{d_{10}} \quad (1)$$

Where d_{10} is the distance between the markers at the baseline carpal tunnel pressure of 10 mmHg and d_i is the distance between the markers at the i^{th} pressure.

Mean percent elongations of the injection group and control group were calculated for the proximal, middle, and distal rows. Pearson's correlation coefficient and linear regression analysis was used to determine the relationship between pressure and percent elongation for the injection group. Two-way RM ANOVA was performed to determine the effect of pressure and CCH injection on percent elongation. Pairwise comparisons were determined using Tukey's test.

RESULTS

Percent elongations of each group are shown in Figure 3. The proximal, middle, and distal TCL in the injection group had significantly greater elongation than the control group at pressure levels 60 mmHg and above ($p < 0.001$), 60 mmHg and above ($p < 0.001$), and 120 mmHg ($p < 0.002$) and above, respectively. For the injection group, the percent elongations at 210 mmHg for the proximal, middle, and distal rows were $6.3 \pm 0.7\%$, $5.8 \pm 1.0\%$, and $4.9 \pm 2.8\%$, respectively. For the control group, the percent elongations at 210 mmHg for the proximal, middle, and distal rows were $0.4 \pm 0.3\%$, $0.4 \pm 0.3\%$, and $0.5 \pm 0.3\%$, respectively. In some specimens, visible tearing of the TCL occurred at high pressure levels (≥ 180 mmHg) where CCH was injected.

In the injection group, Pearson's correlation coefficient showed a strong positive correlation between pressure and percent elongation for the proximal ($r = 0.79$) and moderate positive correlations for the middle ($r = 0.64$), and distal ($r = 0.53$) rows. The fitted regression models of the proximal, middle, and distal rows for the injection group were $y = 2.6 \times 10^{-4}x + 0.01$, $y = 2.2 \times 10^{-4}x + 0.02$, and $y = 1.68 \times 10^{-4}x + 6.5 \times 10^{-3}$, respectively. In the control group, weak positive correlations were found for the proximal row ($r = 0.13$), the middle row ($r = 0.23$), and the distal row ($r = 0.07$).

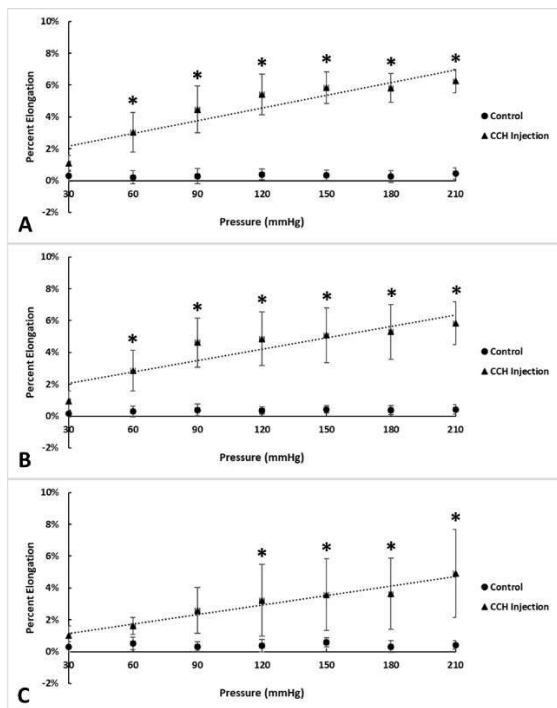

Figure 2: Percent elongation at each pressure level for the proximal (A), middle (B), and distal (C) regions of the TCL.

DISCUSSION

This study investigated the relationship between carpal tunnel pressure and percent elongation of TCL tissue injected with CCH. We found that the intact locations experienced no elongation, while the injection locations experienced significant percent elongation at elevated pressure levels and had a strong positive correlation between pressure and percent elongation.

The proximal, middle, and distal regions of the control group had percent elongations of 0.5%, 0.4%, and 0.5%, respectively, when 210 mmHg of carpal tunnel pressure was applied. These results agree with previous literature that the TCL is relatively unable to be stretched [3]. The proximal, middle, and distal regions of the injection group experienced 6.3%, 5.8%, and 4.9% elongation when 210 mmHg of carpal tunnel pressure was applied. While healthy people can have a carpal tunnel pressure around 2.5 mmHg, those with carpal tunnel syndrome tend to have tunnel pressures above 30 mmHg [1]. When CCH breaks down the collagen fibers in the TCL, the TCL becomes more elastic, allowing it to elongate and yield to carpal tunnel pressure. This elongation also creates more carpal tunnel space, alleviating pressure off the median nerve.

In the injection locations, the distal region of the TCL had lower percent elongations than the proximal and middle regions and required higher carpal tunnel pressure to reach significantly greater percent elongation than the intact locations. Because median nerve compression usually occurs at the distal end of the carpal tunnel [4], elongating the distal region of the TCL would be most important for nerve decompression. Previous studies have found that the TCL tends to be thickest distally in the center [5], which could explain the distal region experiencing less elongation than the middle and proximal regions. To account for this, a higher dose of CCH could be used in the distal region to achieve the same elongation as the proximal and middle regions.

In the injection group, tearing of the TCL occasionally occurred in the middle region when pressures of 180 mmHg or greater were applied. This tearing of the TCL could allow CCH to leak into the carpal tunnel and cause undesired effects to the tunnel contents. Also, tearing could disrupt the biomechanical functions of the TCL, such as providing an anchor for the thenar muscles. A possible solution to this is to decrease the amount of CCH injected to the middle region.

Our results suggest that CCH injection is effective in elongating the surrounding TCL tissue under elevated carpal tunnel pressure. One line of injections was delivered along the TCL midline to achieve these results, but multiple lines of injections could be delivered for greater elongation of the entire TCL. Also, the distal region of the TCL is less affected by CCH injection and may require a higher dose of CCH, while the middle region may require a lower dose to prevent tearing of the tissue. These findings support that CCH injection has potential as a treatment for carpal tunnel syndrome and should be further explored. While we investigated the local effects of CCH injection on TCL tissue, future studies can investigate the effects of CCH injection on total TCL length and carpal arch morphology.

A PARABOLIC MODELING OF CARPAL ARCH AREA EXPANSION

David Jordan, Hui Zhang, Zong-Ming Li

Hand Research Laboratory, Department of Orthopaedic Surgery, University of Arizona College of Medicine, Tucson, Arizona

INTRODUCTION

Treatment of carpal tunnel syndrome has been shown to be achievable through non-surgical augmentation of the carpal arch, leading to increases in tunnel space and decreases in median nerve compression [1]. The carpal arch is formed by the transverse carpal ligament, which has attachments at the hook of hamate and ridge of trapezium at the distal carpal tunnel. Methods of carpal arch space augmentation can take advantage of this anatomical configuration, either through compressing the distance between the ligament attachment points [1, 2], or through direct ligament lengthening [3]. The primary outcome of this method is to increase the carpal arch area. These methods have been evaluated individually, however, their collective influences on the carpal arch morphology and the identification of how this influence is affected by the initial arch morphological condition is unknown.

The efficacy of therapeutic treatments is determined by a multitude of factors, including the treatment method and the conditions of the patient. Therefore, it is important to identify which patients will benefit most from a particular treatment and the extent to which the patient-specific treatment needs to be implemented to achieve the desired degree of therapeutic outcome. With respect to carpal arch space augmentation, the primary augmentation outcome is the increase in the carpal arch area, which has been shown to decompress the median nerve in vivo [2, 3]. A primary variable in determining the magnitude of the carpal arch area is the arch height, which is variable between patients.

The carpal arch area depends on the arch height and width and has been geometrically modeled in previous studies [3], demonstrating the usefulness of the modeling approach. The benefits of modeling methods lies in the ability to simulate a wide range of effects, driven by a wide variety of tunnel morphology, which is necessary given the variability in tunnel characteristics between patients.

The purpose of this work is to examine (1) the change of carpal arch area in response to the shortening of the carpal arch width, (2) the

change of carpal arch area in response to the elongation of the TCL, and (3) the change of carpal arch area in response to the combined shortening and elongation of the carpal arch width and TCL, respectively. These effects will be evaluated with varying initial arch heights in order to determine the effect of initial patient morphology on carpal arch space augmentation effectiveness.

METHODS

The carpal arch was modeled as the following horizontal parabola function,

$$y(x) = H - 4H \left(\frac{x}{W}\right)^2 \quad (1)$$

where H was the length of the semi-minor axis and W was the length of the major axis. H and W represent the width and height of the carpal arch, respectively.

There were three simulation cases: (1) shortening the carpal arch width while keeping the carpal arch length (the curve length of the parabola) constant, (2) elongating the carpal arch length while keeping the carpal arch width constant, and (3) shortening the carpal arch width and increasing carpal arch length simultaneously. Each simulation was performed for an initial carpal arch height H_0 , of 0 and 2 mm.

The initial carpal arch width was specified as 20 mm for all simulations. For simulation (1), the carpal arch width was decreased by a maximum of 2 mm in steps of 0.2 mm. For simulation (2), the TCL length was increased by a maximum of 2 mm in 0.2 mm increments from the initial length value. For simulation (3), the arch width and length were simultaneously shortened and elongated in similar fashion. The carpal arch area A, was calculated using Equation 2. The arch length L, was calculated using the integral of Equation 3 and is given by Equation 4.

$$A = \int_{-W/2}^{W/2} y dx = \frac{2}{3} HW \quad (2)$$

$$L = \int_{-W/2}^{W/2} \sqrt{1 + \left(\frac{dy}{dx}\right)^2} dx \quad (3)$$

$$L = \frac{1}{2} \sqrt{W^2 + 16H^2} + \frac{W^2}{8H} \ln \left(\frac{4H + \sqrt{W^2 + 16H^2}}{W} \right) \quad (4)$$

RESULTS

The carpal arch formation was different between each simulation for the different combinations of morphological augmentation and within each simulation for the different values of H_0 . The arch formations for $H_0 = 0$ mm resulting from the conditions of each simulation are given by Figure 1 (a-c).

Figure 1: Carpal arch formation for an initial arch height of $H_0 = 0$ mm for (a) decreasing arch width with constant arch length, (b) increasing arch length with constant arch width and (c) simultaneously decreasing arch width and increasing arch length

For the initial arch heights of $H_0 = 0$ and $H_0 = 2$ mm, the maximum increase in arch area was 46.2 and 25.8 mm² for the decreasing of the arch width with constant arch length (Figure 2); and 53.8 and 34.4 mm² for elongating the arch length with constant arch width (Figure 3).

Figure 2: Carpal arch height (black) and area (red) as a function of arch width for initial arch heights of (a) $H_0 = 0$ mm and (b) $H_0 = 2$ mm

Figure 3: Carpal arch height (black) and area (red) as a function of arch length for initial arch heights of (a) $H_0 = 0$ mm and (b) $H_0 = 2$ mm

The simultaneous altering of the carpal arch width and arch length allowed the carpal arch height and area to increase in a bivariate formulation for the initial arch heights of $H_0 = 0$ mm (Figure 4) and $H_0 = 2$ mm, respectively. For the maximum 2 mm narrowing and lengthening of the arch width and arch length, the maximum change in carpal arch height was 5.7 and 4.1 mm, respectively. The maximum change in carpal arch area was 68.0 and 46.3 mm², respectively.

Figure 4. (a) Carpal arch height and (b) carpal arch area as a function of arch width and arch length ($H_0 = 0$ mm)

DISCUSSION

This study simulated the morphological changes of the carpal tunnel with the narrowing of the carpal arch width, the lengthening of the arch length and the simultaneous narrowing and lengthening of the arch width and length, respectively, for different initial arch heights. Large initial arch heights yielded less carpal arch morphological changes than small initial arch heights for equivalent degrees of arch width narrowing and arch length increase. These results show that patient specific morphology is critically relevant for carpal arch space augmentation.

Specifically, the initial arch height varied the gain of both the arch height and area for both the two arch space augmentation approaches. For the 2 mm narrowing of the arch width with constant arch length, the increase in arch height and area was decreased from a gain of 3.8 mm and 46.2 mm²; to a gain of 1.6 mm and 14.3 mm², for initial arch heights of 0 and 2 mm, respectively. Similar results were obtained for the 2 mm elongation of the arch length with constant arch width. The increase in arch area and arch height was decreased from a gain of 4 mm and 53.8 mm²; to a gain of 1.9 mm and 25.3 mm². These results show that a patient with a larger value of initial arch height may be less responsive to carpal arch space augmentation, with respect to increasing the arch area.

The simultaneous shortening of the arch width and lengthening of the arch length provided the greatest increases in arch area and arch height. More research is required for the development of a practical means of in vivo application of the arch length increasing, alongside the established method of radial-ulnar compression for decreasing the arch width [1, 2].

Limitations with the simulation include the parabolic assumption and the omission of the bony portion of the carpal arch. In conclusion, this work provides a foundation for determining the amount of carpal arch space augmentation necessary to achieve a specific degree of arch area increase, necessary for median nerve decompression, for carpal tunnel syndrome patients with different morphological characteristics.

JOINT SPACE OF THE FIRST CARPOMETACARPAL JOINT: CORRELATION BETWEEN COMPUTED TOMOGRAPHIC AND SIMULATED X-RAY MEASUREMENT

David Jordan (1), C. Kent Kwoh (2), Zong-Ming Li (1, 2)

(1) Hand Research Laboratory, Department of Orthopaedic Surgery, University of Arizona, Tucson, Arizona, US

(2) University of Arizona Arthritis Center, Tucson, Arizona, US

INTRODUCTION

The thumb carpometacarpal (CMC) joint has a highly complex morphology. This complexity presents difficulties with quantitatively evaluating the joint via two-dimensional x-ray radiography, which is commonly used to visualize and diagnose various joint pathologies, such as osteoarthritis [1]. This is particularly true when considering measurements of joint space, which is a crucial parameter for the scoring of osteoarthritic severity [2]. Conversely, computed tomography (CT) is an imaging modality that can readily evaluate the complex three-dimensional joint structure and make accurate measurements of joint space. Given that the two-dimensional x-ray visualization is derived from the three-dimensional joint structure, there may exist a relationship between the two visualizations that can be used to predict the true CMC joint space based on x-ray measurement alone.

X-ray visualization of the CMC joint has been extensively studied in regard to optimizing the resulting projection by finding complimenting combinations of hand, wrist and thumb postures. A clear view of the trapezium-metacarpal articulation has been achieved using a combination of wrist flexion, wrist supination, ulnar deviation and thumb pronation [3]. It is in such a view that the trapezium-metacarpal articulation can be clearly observed, absent of any overlapping projections from the adjacent bones. Such a view can potentially provide a foundation for a relation to the three-dimensional equivalent.

Evaluation of the CMC joint using CT imaging has been regularly achieved, producing accurate and varied quantifications of joint space. These can include distance maps, showing the distribution of the joint spacing within a given tolerance or singular values typically given as the minimum distance between the articular joint surfaces [4]. These CT measurements are considered the gold standard and can serve as guidelines for related expectations in the two-dimensional space.

Given the frequency of x-ray radiography in the evaluation of various hand pathologies, it is necessary to improve the quantifiable accuracy of the imaging modality with respect to joint space

measurement. The improvement of this accuracy could be achieved by the development of a relationship between the gold standard CT measurement and what is objectively visible within a clearly defined x-ray projection of the CMC joint, effectively combining the accessibility of x-ray imaging with the accuracy of analysis by CT.

METHODS

Seven full-arm cadaveric specimens (female, 68.2 ± 3 years) were prepared for testing. Each specimen was secured onto a custom platform that secured the upper forearm and wrist. The four fingers were wrapped around a cylindrical extension and the thumb was angled in 45 degrees of extension. The prepared specimen was placed into a CT machine. A custom device which allowed for the application of thumb traction within the CT machine was used to apply a 1 N load along the long axis of the thumb via a finger trap and a set of pulleys. A single CT scan was taken of each specimen in this configuration.

The metacarpal and trapezium of the first CMC joint were segmented and meshed. The articular surfaces of the two bones were manually identified (Figure 1a) and a fifth order polynomial was fit to each for the metacarpal PM (Figure 1b), and the trapezium PT. The saddle-point of the metacarpal polynomial surface has been used previously in CMC-related studies and was similarly determined in this work by calculating the gradient field of the polynomial surface, finding the critical points and using the second derivative test [5] (Figure 1b).

Two spheres of radii 1 and 2 mm, respectively, were centered at the saddle point of the articular surface of the first metacarpal (Figure 1b). The intersection of these spheres with the polynomial surface was defined as the three-dimensional contours κ_1 and κ_2 (Figure 1b), respectively.

The joint space was defined as the minimum distance between the metacarpal and trapezium polynomial surfaces calculated over a 100 x 100 grid, which was confined to lie within the boundaries of κ_1 and κ_2 . For each point on the constrained grid (x, y), the joint space D (Figure

2), was calculated as the solution to the unconstrained minimization of Equation (1). This equation describes the distance from a given point on the metacarpal polynomial surface (x_M, y_M, z_M) to an arbitrary point on the trapezium polynomial surface ($x_T, y_T, PT(x_T, y_T)$). The average and standard deviation of the joint space was calculated in both regions over the constrained grid.

$$D = \sqrt{(x_M - x_T)^2 + (y_M - y_T)^2 + (z_M - PT(x_T, y_T))^2} \quad (1)$$

A spherical projection region (Figure 3a) was then defined centered at the centroid of the CMC joint articulation and with a radius $R = 40$ mm (arbitrary for visualization purposes). At a discrete number of points ($n = 441$), along the spherical surface, a plane of projection was defined with unit normal vector \hat{R} . Every point of the metacarpal and trapezium articular surfaces was projected on the n planes (Figure 3a). The 2D projections were made into polygon shapes and the optimum projection, defined as the projection with the minimal amount of overlap between the polygons, was determined (Figure 3b). This optimum projection is meant to mimic an x-ray projection of the CMC joint with clear view of the trapezoid-metacarpal articulation [3].

In the optimum 2D projection, the 2D joint space was calculated as the distance between the corresponding projected points defining the 3D joint space within the two domains (κ_1 and κ_2) (Figure 3b). The average and standard deviation of the 2D joint space was calculated for both regions. The average 2D and 3D measures of joint space were plotted against one another and a Pearson correlation test was performed ($\alpha = 0.05$).

Figure 1: (a) First CMC joint with manually identified articular surfaces (b) Intersection of spherical regions with the metacarpal polynomial surface defining the three-dimensional contours κ_1 and κ_2 .

Figure 2: Representative example of the CMC joint space calculated within the boundaries of regions (a) κ_1 and (b) κ_2 .

Figure 3: (a) First CMC joint with spherical projection region, representative 3D planes of projection and 2D projections of articular surfaces. (b) Optimal 2D projection with joint space analysis regions κ_1 and κ_2 .

RESULTS

Figure (4) gives the results for the correlation between the average 2D and 3D measures of CMC joint space. The slope of the regression line for the regions κ_1 and κ_2 were 0.7807 and 0.7837, respectively. The Pearson correlation coefficients, $r = 0.965$ for κ_1 and $r = 0.963$ for κ_2 , were both statistically significant ($p < 0.001$).

Figure 4: 2D vs 3D joint space for regions (a) κ_1 and (b) κ_2

DISCUSSION

This work aimed to develop a relationship between thumb carpometacarpal joint space as measured in 3D, using conventional computed tomography, and 2D, using simulated x-ray radiography. The joint space was calculated within constrained regions in order to eliminate outliers which may exist closer to the boundaries of the respective bones. The joint space measures in 3D and 2D were taken between corresponding points whose designations were maintained through the 3D-to-2D projection, providing a one-to-one comparison.

The correlation between the 2D and 3D joint space was strong positive and significant. This may be a result of the measurements being taken around constrained regions centered at the saddle point, which defines the point on the articular surface where the derivatives in orthogonal directions are all zero. This would mean that the rate of change of the surface features in neighboring regions around this point would be minute, resulting in small deviations of space between these points and the trapezium.

Limitations with the work include the specimen sample size and simulated radiography, which needs to be validated using conventional radiography. In conclusion, the developed relationship between 3D and 2D joint space can potentially allow for the identification of the CMC joint space through x-ray analysis alone. This can result in an x-ray defined measure of joint space for measurement regions κ_1 and κ_2 , whose locations can be standardized between patients for similar x-ray views.

HETEROGENEITY OF RED CELL MECHANICAL PROPERTIES DRIVES PATHOPHYSIOLOGY IN SICKLE CELL DISEASE

INTRODUCTION

Sickle cell disease (SCD) is an inherited blood disorder that arises from a single nucleotide mutation in the β -globin gene [1]. This mutation leads to an abnormal hemoglobin, known as sickle hemoglobin or HbS. HbS monomers can bind to other hemoglobin proteins that are in the deoxygenated T-conformation. When sufficient HbS proteins bind together they form polymer domains that decrease the red blood cell's (RBC) oxygen carrying capacity and can develop into long inflexible strands that deform and stiffen the cell giving it the characteristic sickle morphology [1].

Sickled red blood cells are the main driver of the adverse effects of SCD [2]. The decreased oxygen carrying capabilities and mechanical changes in SCD blood lead to disrupted flow, vascular occlusions, and increased inflammation and cell adhesion. This can lead to thrombosis, stroke, ischemia, hemolytic anemia, and organ failure. In the United States, patients with SCD have an average life expectancy of 54 years compared to the national average of 76 years [3].

The molecular mechanisms of SCD have been well studied, and the mechanical differences between healthy red blood cells and SCD red blood cells have been measured at normoxic conditions [1]. However, there have been limited studies investigating the mechanics of deoxygenated, sickled red blood cells [4]. Since the stiffness of these sickled cells is a major driver of the pathophysiology it is imperative to understand their mechanics. Further, research has shown that for a given oxygen tension the fraction of cells with sickled morphology can vary greatly between patients [5]. In order to design targeted, patient specific treatment it is crucial to be able to measure both the mechanical changes of SCD red blood cells as they deoxygenate, and how this response varies between patients. To accomplish this, we have developed a high throughput microfluidic device that simultaneously measures single red blood cell deformability and oxygen saturation for up to 10,000 RBCs per patient at a range of physiological oxygen tensions (0mmHg-90mmHg).

Figure 1: Experimental setup for the RBC Mechanics assay. (A) The microfluidic and optical set up showing the alternating Soret Band LEDs, objective, and high speed camera. (B) ROI section of the microfluidic device showing cell deformation. (C) High Speed images of red blood cell deformation. (D) Taylor deformation parameters to calculate change in RBC shape

METHODS

A novel microfluidic technique, optical analysis instruments and software were developed to quantify saturation and deformability of individual red blood cells under controlled oxygen tension (fig. 1). A dilute solution of washed red blood cells in 25% human albumin serum was perfused through the microfluidic device at a controlled pressure of 800 mbar. The oxygen tension in the microfluidic device was regulated by PDMS channels supplied with a controlled mixture of air and nitrogen. Individual RBC oxygen saturation was calculated using

alternating LEDs in the Soret band and measuring the ratio of absorption (fig. 1A), similar to the method in the 2019 Di Caprio et. al paper [5]. After sufficient time to reach steady state oxygen saturation, red blood cells were subject to controlled stress by passing through a 6x8μm capillary channel (fig. 1B). A high speed camera imaged the RBCs at 1000 fps (fig. 1C) as they underwent this mechanical testing. Cells were imaged passing through the constriction at a rate of 30 cells per second, and the experiment was performed at eight different oxygen tensions ranging from 0 mmHg to 160 mmHg recording ~1000 cells at each oxygen tension.

A custom Python software package was developed to label each cell passing through the constriction and identify key parameters such as shape, velocity, saturation, and cross sectional area. From this data, cell deformation was calculated by taking the difference in Taylor deformation (eq. 1) of the cell inside and outside the constriction (fig. 1D).

$$\Delta Ta = \left(\frac{a-b}{a+b}\right)_1 - \left(\frac{a-b}{a+b}\right)_0 \quad (1)$$

Previous work has suggested that second order, non-dimensional shape parameters such as Taylor deformation and eccentricity are less sensitive to imaging noise making these parameters a robust choice for measuring changes in cell shape in this experiment [6].

RESULTS

Each patient sample displayed unique, heterogeneous behavior. A contour plot of saturation and deformability of every cell at the eight different oxygen tensions for one patient sample highlights the abnormal mechanical behavior of SCD blood cells (fig. 2). At normoxic conditions (90 – 160 mmHg) RBC saturations are high and the ΔTa of cells is normally distributed. As oxygen tension decreases two distinct populations appear, one with relatively lower saturation and decreased change in Taylor deformation; this stiffer population is the sickled cells.

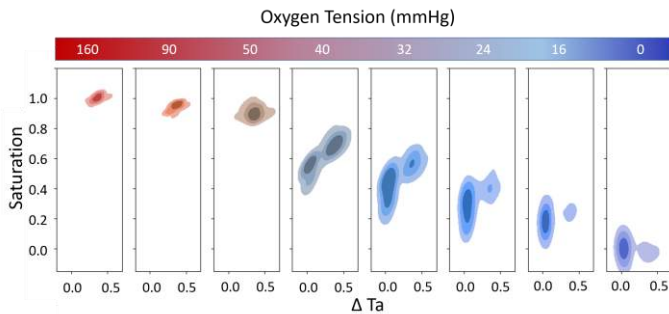

Figure 2: Density plots of one patient sample showing ΔTa and saturation for cells imaged at eight different oxygen tensions. As oxygen tension decreases two population emerge separated by both saturation and deformability

We used unsupervised k-means clustering to separate the stiff and deformable cells at each oxygen tension. Within each patient sample, changing oxygen tensions did not change the mean ΔTa for the two distinct populations, however it did change the fraction of cells in each population. This can be seen in Figure 2. For each patient sample we calculated an overall deformable ΔTa and stiff ΔTa by averaging each ΔTa across oxygen tensions. In a cohort of nine SCD patients (SS), three healthy patients (AA), and two Sickle Cell Trait patients (AS) the average stiff cell ΔTa was significantly decreased compared to the average deformable cell change in Taylor deformation with a p-value < 0.0001 in a Welch's t-test (fig. 3).

Figure 3: Average ΔTa for deformable and stiff cell populations for 9 SS patient samples, 2 AS patient samples, and 3 AA patient samples. The stiff cell populations show a statistically significant decrease in ΔTa with a p-value < 0.0001

DISCUSSION

The data in this study agrees with and extends the current understanding of SCD pathophysiology. As oxygen tension decreases, hemoglobin in SCD red blood cells will polymerize, and as a result oxygen carrying capacity will decrease and cell stiffness will increase [4]. Before now, the actual change in mechanical properties of stiffening RBCs had not been measured with high throughput at this level of precision. Current studies suggest polymerized hemoglobin fraction within the RBC will continuously increase with decreasing oxygen tension [2], and indeed in this study we see that as oxygen decreases, the fraction of stiff cells increases. However, after the initial sickling the stiffness of these cells does not seem to change. This suggests that despite constantly increasing hemoglobin aggregation, RBCs will reach a threshold in which they 'jump' from the deformable, high saturation population to the stiff, low saturation population and additional hemoglobin polymerization will not significantly increase stiffness. If this is the case, treatments strategies should focus on shifting this threshold to lower oxygen tensions. Once RBCs pass this point they significantly increase in stiffness and become hazardous, and further deoxygenation leads to little or no change. With this in mind, potential next steps for this project would be to test current FDA approved therapeutics to see how they affect this threshold point.

OVEREXPRESSION OF ENHANCED YELLOW FLUORESCENT PROTEIN FUSED WITH CHANNELRHODOPSIN CAUSES CONTRACTILE DYSFUNCTION IN SKELETAL MUSCLE

INTRODUCTION

Skeletal muscle activation with optical stimuli (i.e., optogenetics) is a novel alternative to established electrical stimulation approaches [1]. Direct optogenetic stimulation (OS) of excitable muscle cells can induce contraction noninvasively via transdermal light exposure [2-4]. Recently, we have used established transgenic mice (Ai32) to control expression of light-sensitive channelrhodopsin-2 (ChR2) fused with enhanced yellow fluorescent protein (EYFP) in skeletal muscle [4, 5]. When exposed to blue light (455 nm), the transmembrane ChR2 opens to allow non-selective cation flow for muscle cell depolarization and contraction [6]. EYFP is useful for detecting Cre recombination in our tissues, however we observed its unusual clustering in cryosections of skeletal muscle [4]. This high EYFP and/or ChR2 expression may lead to contractile and electrophysiological dysfunction [7, 8]. To address this concern, we have generated a new transgenic mouse to express ChR2 in skeletal muscle without the EYFP fusion gene. We hypothesized that muscles with ChR2 but without EYFP would mimic physiological contractility (i.e., electrical stimulation) similar to wildtype mice and more accurately replicate physiological properties when excited using optogenetic stimulation compared to muscles which express both ChR2 and EYFP. To test this hypothesis, we compared muscle contractility in three mouse strains (wildtype, muscle expressing ChR2 with EYFP, and muscle expressing ChR2 without EYFP) using electrical stimulation *in situ* and *in vitro* and OS *in vitro*. We also evaluated skeletal muscle structure using light and electron microscopy.

METHODS

The Institutional Animal Care and Use Committee at the University of Michigan approved all animal procedures. Mouse models: Mice expressed ChR2 with EYFP (ChR2-EYFP, i.e., Ai32) [5] or ChR2 without EYFP (ChR2-only) in skeletal muscle using doxycycline inducible Acta1-Cre (for contractility and imaging) or muscle creatine kinase (CK)-Cre (for imaging). ChR2-only mice (developed by BG laboratory) were generated by removing both the woodchuck hepatitis

virus post-transcriptional regulatory element (WPRE) and EYFP fusion gene and adding a non-fluorescent V5 tag. Wildtype Cre-negative littermates (WT) were used as controls. Microscopy: EDL muscle was flash frozen and cryosectioned (for confocal) or fixed and embedded (glutaraldehyde, Spurr's resin) then ultramicrotomed (for ultrastructure) of WT, ChR2-EYFP, and ChR2-only mice (n=1/group). Tissues were imaged with confocal and transmission electron microscope (TEM), respectively. In situ contractility: We compared isometric contractile properties of gastrocnemius muscles *in situ* with nerve stimulation [9]. In brief, mice were anesthetized using tribromoethanol and gastrocnemius muscles were carefully separated from surrounding musculature without damaging the blood vessels and nerves. Suture was tied around the Achilles tendon and then the tendon was dissected from the calcaneus. The knee and the foot were secured to posts to limit knee motion. The Achilles tendon was then tied to a dual mode lever system (6650LR, Cambridge Technology). The sciatic nerve was exposed and stimulated using bipolar platinum wire electrode. Voltage and muscle resting length were adjusted until maximum twitch force was achieved. Isometric contractile forces were then measured for three groups: WT, ChR2-EYFP, and ChR2-only mice (n=3, 3, and 5 respectively, all male) in response to increasing frequencies from 40 to 220 Hz. Maximum isometric tetanic force was normalized by the physiological cross-sectional area (PCSA) of individual gastrocnemius muscles. In vitro contractility with electrical stimulation: We measured isometric contractile properties of isolated extensor digitorum longus (EDL) muscles with electrical stimulation *in vitro* [10]. EDL muscles were dissected and placed in buffered Ringer's solution bath. Distal and proximal tendons were tied with suture to a fixed post and force transducer (BG-50, Kulite Semiconductor), respectively. Two platinum plate electrodes were placed on either side of the muscle parallel to its long axis. An electrical field was applied between the electrodes, and the muscle was tested using the same stimulation protocol as *in situ* test for the three groups: WT (n=2, male only), ChR2-EYFP (n=2, male

only), and Chr2-only (n=2, 1 male, 1 female). Maximum isometric tetanic force was normalized to PCSA of individual EDLs. **In vitro contractility with OS:** In the same setup as *in vitro* tests, EDL muscles were optically stimulated using a blue (455 nm) light emitting diode (LED; Thorlabs; ~140mW/cm²). We measured peak twitch force with incremental pulse duration ranging from 1 to 100 ms. The ability of muscle to undergo tetanus was also tested by varying LED pulse duration/frequency over 300 ms duration. **Statistics:** Data from experiments with n≥3 per group were compared using one- or two-way ANOVA in experiments with Tukey's multiple comparison tests on GraphPad. Akaike information criterion (AIC) was used to identify the best fit model to describe the relationship between OS twitch force and light pulse durations.

RESULTS

In addition to confirming EYFP overexpression in Chr2-EYFP muscle (Fig1A&B), we also found whorls/vacuoles along Chr2-EYFP sarcolemma (Fig1C), which were absent in WT or Chr2-only muscle (data not shown). Body weights were similar in WT, Chr2-EYFP, and Chr2-only mice (data not shown), however gastrocnemius muscle mass from Chr2-EYFP mice was significantly lower compared to WT and Chr2-only mice (p<0.01, Fig2A). Isometric tetanic force of Chr2-EYFP mice was significantly reduced compared to WT and Chr2-only mice at all test frequencies (p<0.05, Fig2B). We observed a significant reduction in max. specific tetanic force with nerve stimulation for gastrocnemius muscles of Chr2-EYFP mice compared with WT *in situ* (p=0.007, Fig2C). Reduced force was also observed in EDL muscles *in vitro* (Fig3A,B). However, both time to peak twitch tension and half relaxation time in EDL muscles were similar among groups (Fig3C,D). Based on AIC, force vs pulse duration response was modeled using one phase decay (R²>0.7). EDL twitch forces from Chr2-only mice were higher at shorter pulses than Chr2-EYFP EDLs (Fig3E,F) and plateaued at shorter pulse durations (Fig3E). Similarly, Chr2-only EDLs generated higher forces with partially fused tetanus at 50Hz (10ms pulse, Fig3G), which was not achieved in Chr2-EYFP muscles.

Fig 1. EYFP overexpression and vacuole formation in Chr2-EYFP EDL muscles. (A) Fluorescence microscopy of CKCre;Ai32 (longitudinal) and (B) Acta1Cre;Ai32 (transverse), as well as (C) TEM of CKCre;Ai32, showed (A,B) increased aggregates of EYFP overexpression and (C) vacuole formation.

DISCUSSION

In this study, we determined the contractile properties and ultrastructure of skeletal muscle expressing Chr2 with (Ai32) and without EYFP reporter. This study is of high importance for the field of musculoskeletal bioengineering as it elucidates a detrimental role of fluorescent Cre reporters in muscle physiology. Cre reporter strains are widely used for cell lineage tracing, validating recombination, tracking cellular processes, and monitoring expression in living tissues and cultured cells. However, we observed significant deficits in contractile properties of skeletal muscle that expresses Chr2 with EYFP (i.e., Ai32) using both electrical and optogenetic stimulation. When EYFP was removed (Chr2-only), we found a repeatable and significant improvement in muscle contractility and physiological response to stimulation. This work has significant impact to the field, as it has potential to improve Chr2 delivery and efficacy in skeletal muscle, strengthening the translational potential for use of optogenetics for controlling muscle function. The attenuated muscle force with Chr2/EYFP expression that we observed can be explained by at least

two mechanisms: (1) decreased calcium handling in muscle cells limited by Chr2/EYFP fusion protein, and (2) structural damage caused by excessive accumulation of EYFP in vacuoles. In our mouse models, Chr2-EYFP colocalizes at the sarcolemma, T-tubules and dihydropyridine (DHP) calcium channel ([2] and Fig1A,B). Although no major disruption was observed in these networks in microscopy, it is possible that Chr2/EYFP colocalization may hinder the functionality of voltage gated DHP channels, which could negatively impact the Ca²⁺ transient, thereby reducing contractile force. However, we did not see any change in the twitch times (Fig3C,D), suggesting that calcium handling during excitation-contraction coupling was not affected by Chr2/EYFP. Thus, we have ruled out the effects of structural changes as a driver of contractility dysfunction in EYFP-expressing muscle cells. In our new Chr2-only mouse model, it is likely that Chr2 expression is lower, as WPRE was removed in addition to EYFP. Elevated Chr2 can increase membrane capacitance [11] which could decrease conduction velocity of action potentials and inadvertently limit force generation capacity. However, if EYFP or Chr2 alone are responsible for functional deficit needs further study. In the future, we will measure Chr2 levels in our models.

Fig 2. *In situ* contractile forces were significantly decreased in gastrocnemius muscles expressing Chr2-EYFP but not in Chr2-only muscles. (A) Muscle mass, (B) force–frequency relationship, and (C) specific tetanic force were reduced in Chr2-EYFP compared to WT and Chr2-only muscles. **, p<0.01; *, #, p<0.05.

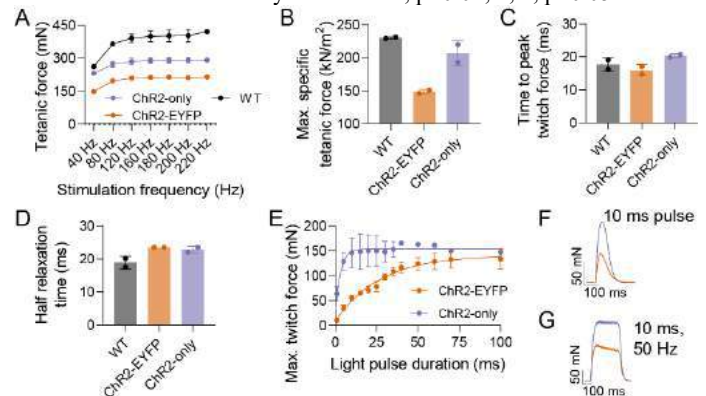

Fig 3. Chr2-only EDL muscles generated higher force in both electrical and OS compared to Chr2-EYFP EDLs *in vitro*. Using electrical stimulation, (A) force–frequency relationship and (B) max. specific tetanic force was reduced for Chr2-EYFP EDLs compared to WT EDLs. However, (C) time to peak twitch force and (D) half relaxation time were not different. Using OS, Chr2-EYFP had reduced (E) twitch force compared to Chr2-only. Representative (F) OS twitch force at 10 ms pulse and (G) 10 ms at 50 Hz.

INTRODUCTION

Over the past decades, the rapid development of tissue engineering has increasingly held promise for creating tissues for a variety of applications, including in vivo regeneration, and organ repair and replacement. Three-dimensional bioprinting now has potential to spatially controlled deposition of biomaterials and cells in 3D with remarkable accuracy. Our team is investigating creation of a bioprinted pulsatile conduit as a possible substitute for the standard Gore-Tex conduit used in the Fontan surgery. Fontan surgery, which places the pulmonary and systemic circulations in series, is the final stage of three palliative surgical procedures for single ventricle congenital heart disease patients. Lacking a ventricular power source to pump flow to the lungs, patients with Fontan physiology experience a condition known as the Fontan paradox, in which central venous pressure is abnormally elevated, while pulmonary artery pressure and pulsatility are decreased [1]. Overtime, this unusual physiology leads to multiple morbidities and mortality, including early demise, liver fibrosis, arrhythmias, and reduced exercise tolerance [2]. The bioprinted pulsatile conduit, which connects the inferior vena cava (IVC) to the pulmonary arteries, has the potential to improve the adverse Fontan hemodynamics by providing the missing power source.

Currently, bioprinting of large-scale contractile materials is an expensive and complex procedure. Computational modeling provides a means to accelerate design by allowing for efficient performance evaluation and exploration of the design space. Here, we construct a multi-physics computational framework combining electrophysiology, cardiac mechanics with active contraction, fluids mechanics, and valves. In this study, we first demonstrate the performance of the prototype of pulsatile conduit, then discuss its feasibility to resolve the Fontan paradox, and finally optimize the design by evaluating the different contraction mechanisms.

METHODS

The proposed pulsatile Fontan will be 3D bioprinted using a combination of two printing techniques: freeform reversible embedding of suspended hydrogels [3] and sacrificial writing of functional tissues [4]. The myocardial walls will be manufactured using a cardiac organoid-laden bioink, while the valves will be printed with a collagen ink. The vasculature will be created by bioprinting a sacrificial gelatin ink into the myocardial walls and later evacuating the ink to yield perfusable channels. We place the valves at both ends to prevent backflow in the conduit. Based on the standard conduit used in the Fontan surgery, our initial design is a straight cylinder with a height of 7.5 cm, an inner radius of 10 cm, and a thickness of 4.4 cm. The thickness is optimized based on hoop stress calculations. Given the current bioprinted myocyte's capabilities, the conduit is expected to have a 3 mN/mm² passive stiffness and generate a 5 mN/mm² active stress. A human value of 60 mN/mm² was also simulated for comparison.

Figure 1: Demonstration of the bioprinted Fontan Conduit

Simulations of the 3D finite element conduit model are performed in a multi-physics computational framework, which includes physics

modules for electrophysiology, active stress generation, fluid-solid interaction, and valves in a single solver. All the simulations are performed in the svFSI finite element solver provided by the open-source software SimVascular [5]. A representative Purkinje network is generated on the exterior surface and coupled to the myocardium wall at the node endpoint. Electric signal propagation is simulated using a diffusion equation, with the tenTusscher-Panfilov model chosen to model the electrophysiology [6]. Holzapfel's orthotropic material model is used for the solid mechanics simulations to represent the anisotropic nonlinear material behavior [7]. The action potential in the myocardium triggers its contraction along the defined directions; a rule-based method is used to prescribe fiber directions. The FSI simulation enables us to assess the performance of the conduit via local hemodynamics. We also obtain global physiologic parameters by coupling inlet and outlet boundaries to a lumped parameter model of the single ventricle circulation following prior work [8,9]. LPN values were tuned to match typical clinical values. Primary quantities of interest for evaluating pump performance include reduction in central venous pressure and pulsatility in the pulmonary arteries. We explore the impact of several design parameters on conduit performance, including pure circumferential contraction vs. twist motion by varying the fiber orientations, and simultaneous contraction vs. peristaltic pumping by defining the timing of fiber activation.

RESULTS

With a value of 5 mN/mm² active stress, representative of current bioprinted myocyte values, the simulated bioprinted conduit generates a 4.4-mmHg interior pressure rise and an 5.7% change in volume amplitude. This pumping source is unable to either lower the liver pressure, or alter the pulmonary mean pressure and pressure waveform, which indicates the conduit fails to transfer the generated pulsatility forward. These negligible changes in hemodynamics may at first lead to concerns about the feasibility of the bioprinted pulsatile conduits. However, with the higher human myocyte contractility value (60 mN/mm²), the model predicts a 21 mmHg pressure amplitude and a 48% volume amplitude. The liver pressure falls by 5mmHg to 11.7 mmHg, while the mean pulmonary pressure increases 2.5 mmHg (figure 2). Other hemodynamics are also affected by the implementation of conduit with strong contractility. The pressure in the superior vena cava (SVC) rises from 15.8 to 18.4 mmHg.

Figure 2: Comparisons of hemodynamics without pump, with bioprinted myocyte and with human myocyte.

By exploring different contraction patterns, we aim to maximize the myocyte's effectiveness. We assign the fibers helically around the conduit, varying the angle between the fibers and the horizontal plane. The circularly oriented fiber produces a pure circumferential contraction with a maximum volume pulse of 9.4% and a 5.8 mmHg pressure increment. Other longitudinal orientations create a twisting motion of conduit, and the change in volume lowers gradually to 2.6% with increasing helical angle. Moreover, we implement the peristaltic pumping by manipulating the activation time of the myocardium fibers. When we partition the conduit into two halves with one part before the other, the volume amplitude drops to 2.3% since only one portion is transporting blood. With the conduit divided into three parts, the volume amplitude decreases further to 2% as expected. Due to the small active stress, the effects of fiber angles or activation time on Fontan hemodynamics are insignificant. Further exploration of the parameter space is underway to optimize overall conduit performance.

DISCUSSION

We introduce a multi-physics computational framework to investigate how pulsatile conduit designs parameter choices can impact the hemodynamics and physiology of Fontan patients. The 5-mmHg reduction in central venous pressure demonstrates that adding a pumping source could improve adverse hemodynamics significantly and possibly reverse the Fontan paradox in the presence of strong contractility. However, the conduit implementation did not result in the expected increase in pulsatility in the pulmonary arteries. One reason is that the pulsatile flow from the conduit is dampened by the flow from the SVC at the Fontan junction. Future studies should examine more complicated geometries to maximize pump efficiency. The considerable increase in SVC pressure raises concerns about possible unfavorable clinical outcomes. Further conduit improvements or design changes could be considered to prevent high SVC pressure. By altering the contractility, fiber angles, and contraction mechanism, we have illustrated that contractility plays an essential role in the conduit's performance. To maximize the utility of contraction, the circumferential simultaneous contraction is preferred to generate as much volume amplitude as possible and further reduce the central venous pressure. However, this contrasts with the finding that the twist motion helps to produce a larger ejection fraction from the conduit. Such differences may arise from our boundary condition implementation. The clamped boundary conditions in the simulation fix the total length of the conduit and may negate the effects of the twist motion. Future work should explore alternative boundary condition implementations.

A NOVEL LASER ABLATION MODEL FOR STUDYING LOCAL MICRODAMAGE REPAIR IN LIVE TENDON EXPLANTS

Anthony N. Aggouras (1), Matthew T. Lim (1),
Jeroen Eyckmans (1), Brianne K. Connizzo (1)

(1) Department of Biomedical Engineering, Boston University, Boston, MA, USA

INTRODUCTION

Tendinopathy is a common pathology that affects 10% of adults under the age of 45 and results in pain, degradation of tendon structure, and diminished tissue function [1]. One factor thought to contribute to the pathogenesis of tendinopathy is overuse, or the accumulation of microdamage in the extracellular matrix [2]. While the accumulation of microdamage in response to overuse is well known, it is still unclear if resident tenocytes have an innate capacity to respond to and heal tendon matrix microdamage. Previous work has looked at the innate response of tenocytes to widespread load-induced microdamage and found that they were unable to heal [3]. However, few studies have explored localized microdamage. Current methods induce microdamage by the means of high strain, load, or loading cycles. This widespread microdamage may be far over the threshold of damage tenocytes can heal without support from extrinsic factors. In other tissue types, such as in cardiac tissue constructs, the healing response of resident cells to localized microdamage has been identified by using a laser ablation model [4]. Therefore, the purpose of this study was to establish a novel laser ablation model to induce localized microdamage to live tendon explants and characterize the response to localized microdamage. We hypothesized that resident tenocytes would have the ability to initiate healing by remaining closely around the site of injury and removing denatured collagen from the site of injury.

METHODS

Flexor digitorum longus (FDL) tendon explants were harvested from mature 4-month-old C57BL/6J mice (BU IACUC Approved), as described [5]. FDL explants were then loaded into custom grips with a gauge length of 10 mm. Samples were transferred to culture wells in a custom-built imaging bioreactor and standard culture media was added to each well (Figure 1A,B). Tendons were hand tensioned using a custom tensioning bar until taut. The bioreactor was then transported to stage of a Zeiss Axiovert S100 microscope equipped with a 10x

objective and a 1,064-nm pulsed Nd:YAG nanosecond laser (Minilite, Continuum). The midportion of the tendon was ablated using a single laser pulse of 10 mJ (Figure 1C), and a bright field image was captured before and after to ensure an injury was produced (Figure 1D). Explants were then cultured in place for up to 10 days. Collagen damage and cell location were determined by Cy3 Collagen Hybridizing Peptide (CHP) and NucBlue nuclear fluorescent stains, respectively, at day 0, 3, 7, and 10. Tendons were transferred to 1.8 μ M Cy3 CHP in PBS solution and incubated at 4C for 16 hrs. After incubation, tendons were stained with NucBlue (Fischer Scientific) for 5 minutes. Confocal image z-stacks of the ablation damage and hole were then captured on an Olympus FV3000 with a 20x objective. Volume of the damage was estimated by using the equation for an elliptical frustum [6], with the measured length and width of the damaged region stained with CHP and distance between z stacks. Cells in the damaged area were determined by tracing

Figure 1: (A) 3D model of the bioreactor and (B) an image of the bioreactor in use. (C) Before and (D) after images of an ablated tendon. Yellow box highlights area of damage after ablation.

the area of CHP stain and counting the number of cells in the NucBlue channel. Peak and average collagen damage intensity were determined from a max intensity projection of the CHP channel using a rectangular ROI with dimensions equivalent to the max width and length of all damaged regions. Statistical evaluation was performed using one-way ANOVAs with post-hoc Bonferroni corrected t-tests. Significance was noted at $*p<0.05$.

RESULTS

We created a repeatable injury model that produced a $\sim 50 \times 100 \mu\text{m}$ elliptical hole in the tissue (estimated from day 0 images, not shown). Representative images show a progressive reduction in CHP stain around the hole during the culture period (Figure 2). By day 10, there is no visible CHP staining around the hole in most samples (Figure 2D). We found a significant reduction in the average intensity of collagen damage from days 0 and 3 to days 7 and 10 (Figure 3A). This was accompanied by a reduction in peak CHP signal (Figure 3B). There is also a significant reduction in the volume of damage marked by CHP staining from day 0 to day 7 and 10 (Figure 3C). There were no differences in cell number within the damage area until day 7, but the number of cells decreased from day 7 to day 10 (Figure 3D).

Figure 2: Representative max intensity projection images of collagen damage (magenta) and cell nuclei (blue) at days (A) 0, (B) 3, (C) 7, and (D) 10. White arrow highlights area CHP stain around cells. Yellow ellipse highlights area of ablation damage.

DISCUSSION

Our data demonstrate that resident tenocytes can initiate healing of localized microdamage by removing denatured collagen, and specifically that resident tenocytes are not reliant on extrinsic factors to initiate healing. The reduction in damage volume also demonstrates that this is not a superficial process occurring at the surface of the tendon, where tendon stem cells are expected to reside. The removal of stain is likely to be an active process by resident cell types, such as fibroblast-like tenocytes or a recently identified macrophage-like cell population, known as tenophages [7]. Both cell types can produce the collagen type 1 degrading matrix metalloproteinase MMP-9 [8], which has been shown to selectively remove denatured collagen in mechanically overloaded tendons [9]. Future studies will explore the local expression of matrix degrading enzymes around the injury site to identify mechanisms and cellular drivers of denatured collagen removal.

In agreement with our hypothesis, we did find cells co-localized with CHP stain in the damaged regions of ablated explants, particularly

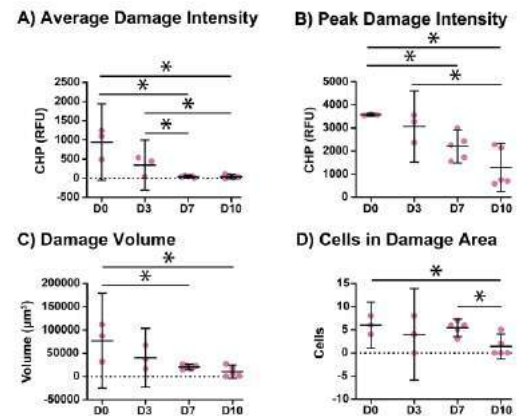

Figure 3: (A) Average intensity, (B) peak intensity, (C) volume, and (D) cell count of damaged area. Data is mean \pm 95% confidence interval.

at early time points. While cells in the damaged region were easily identifiable at earlier time points, identifying the borders of the damaged area at day 10 was more difficult as there was a lack of CHP staining. In addition, the cells at day 0 appeared to be small and fragmented, potentially indicating that they were dead. It's not clear whether damaged cells remained at the injury site throughout culture or at what point they were cleared, and we are now performing viability assessment to confirm cell health in these areas. Given the necessity of cell-mediated signaling to remove damaged ECM, we believe this process does directly involve tenocytes as observed in Fig. 2B and 2C. Areas with reduced stain clearly have visible tendon cells in the damaged area, suggesting that these cells are actively removing denatured collagen from those regions. Future studies will aim to identify the cells in the damaged region and characterize their behavior following the initial injury.

In summary, we present here a novel model for studying innate tissue healing processes following a microscale injury without interference from extrinsic factors. Future studies will take advantage of this model to explore thresholds of microdamage repair by modulating hole size and volume. We also aim to identify what provisional matrix is produced at the injury site, and the cell types responsible for this healing response. Regardless, this novel model system enables the direct visualization and study of local tissue repair, which will be a powerful asset for understanding mechanisms of microdamage accumulation and/or healing, as well as identifying local tendon-specific factors that can be leveraged for therapeutics.

INTRODUCTION

Implanted polymeric medical devices can pose a risk to human health when they contain potentially hazardous materials that leach into the body. Historically, extraction experiments and animal studies have been used to estimate the amount of material released. However, these approaches are changing. Fueled by increases in computational capabilities, computer models can now be used to predict the amount of material released over time. These simulations can complement traditional extraction studies and yield several benefits for regulatory science. First, the models can be used to simulate a more realistic environment than the harsh conditions used in extraction studies. Second, because the models contain system specific input parameters, they can be easily adapted to other polymer types or leachable chemicals making it easy to analyze a multitude of different systems. Third, once the models are developed and validated, simulations can often be run in seconds saving the weeks or months needed for extraction studies. This can help medical device companies to accelerate new product development getting new devices to market faster. Finally, reducing the effort needed to meet regulatory requirements will reduce overall product development costs.

The FDA has already developed regulatory science tools for rapid risk assessments of color additives in medical devices. These tools use physics-based models to predict the amount of material that may be released from an implanted polymeric medical device. In this research, models will be extended beyond a one component system (implant only) to a two-component system that also includes the surrounding tissue.

METHODS

A two-component mathematical model was developed to characterize the migration of leachable chemicals from an implanted polymeric device into the surrounding tissue (Figure 1). The model assumes that the leachable chemical is homogeneously distributed throughout the implant and that the implant will remain structurally

consistent throughout the duration of the simulation (i.e., no degradation or swelling). Human tissue surrounding the implant was also modeled. Tissue was assumed to be quasi-static with consistent material parameters over the duration of the simulation. The mathematical model estimates the amount of material released over a time period of one day (24 hours). When this quantity is less than the allowable daily dose for the leachable chemical, the risk associated with potential exposure to the chemical is considered acceptable.

Figure 1: Two-component model shows diffusion through the implant (blue), across the partition, and into the surrounding tissue (red).

Fick's law was used to predict diffusion through the implant and the tissue.

$$\frac{\partial C(x,t)}{\partial t} = D_p \nabla^2 C(x,t) \quad (1)$$

where, the concentration of the leachable substance, C , is a function of the position within the polymer, x , and time, t . D_p is the effective (macroscopic) diffusion coefficient of the leachable in the polymer. D_p is scalar and independent of C , x , and t .

The polymer-tissue partition coefficient, K , was used to predict migration across the polymer-tissue interface. Due to differences in hydrophilicity/lipophilicity, the migrating chemical can have a different affinity for the polymer than the tissue which can lead to a step change in concentration at the interface. Our model utilizes equations originally developed by Gandek to characterize migration of potentially hazardous

materials into food from its surrounding packaging [1]. The amount of material release, M_τ is, given by,

$$M_\tau(\tau) = \left[\frac{2\beta}{1+\beta} \right] \sqrt{\frac{\tau}{\pi}} \left\{ 1 - \frac{2\beta}{1+\beta} \sum_{n=1}^{\infty} \left[\frac{1-\beta}{1+\beta} \right]^{n-1} \left[e^{\left(\frac{-n^2}{\tau} \right)} - \frac{n\sqrt{\pi}}{\sqrt{\tau}} \operatorname{erfc} \left[\frac{n}{\sqrt{\tau}} \right] \right] \right\} \quad (2)$$

$$\tau = \frac{D_p \tau}{L^2} \quad (3) \quad \beta = K \sqrt{\frac{D_t}{D_p}} \quad (4)$$

where, τ is a dimensionless time parameter, β is a dimensionless parameter that consists of the partition coefficient, K , and the tissue and polymer diffusion coefficients D_t and D_p . Values for D_p for various chemical-polymer combinations were obtained from FDA databases and polymer tissue partition coefficients were previously developed by the co-authors [2]. Tissue diffusion coefficients were determined through literature review. Searches on Scopus, SciFinder, and Google Scholar were utilized. Forward and backward snowballing was also used to expand the search. Models were verified by comparing results to those developed by Crank [3].

$$M(\tau) = \begin{cases} 2M_0 \sqrt{\tau/\pi} & \tau \leq 0.2 \\ M_0 (1 - 8 \exp[-\tau\pi^2/4]/\pi^2) & \tau > 0.2 \end{cases} \quad (5)$$

Equations 2 and 5 are identical models with different boundary conditions that converge to the same solution at low values of K and high D_t . While it is not feasible to analyze all possible combinations of polymer types, leachable chemicals, and tissue types, several cases were considered that represent a broad range of input parameter combinations. Furthermore, results over the expected range of parameter values were calculated.

RESULTS

Tissue diffusion values were found for 307 different combinations of chemicals and tissues (Figure 2). These were grouped into barrier tissues (red) and non-barrier tissues (blue). Because an implanted device is often located against cut tissue the higher diffusion rates associated with non-barrier tissues were used for the model.

Figure 2: Tissue diffusion data as a function of molecular weight and octanol-water partition coefficient (hydrophobicity)

Table 1 shows the mean value by group and the two inner quartiles (25% and 75%). The 5% and 95% values were estimated from these inner quartiles, but values are only estimates because there is no confirmation that the distribution is normal.

Table 1: Diffusion for barrier and non-barrier tissues ($\times 10^{-6} \text{ cm}^2/\text{s}$)

Tissue Type	5%	25%	mean	75%	95%
Barrier	0.0010	0.0057	0.0201	0.0612	0.3387
Non-Barrier	0.1145	0.3510	0.6500	1.6657	5.1055

Using the values for K , D_t and D_p , the results of equation 2 were calculated. Large variability in D_p led to large variability in τ causing it to range in value from 10^{-13} to 10^1 . Similarly, β spans a large range from

10^{-3} to 10^9 . This yields material release quantities that span over 20 orders of magnitude.

One of the main objectives of the two component model was to determine conditions where use of the more complex model (Eq. 2) yields more clinically relevant results than the simpler one component model (Eq. 5). Several cases were considered. The case that yielded the greatest difference (1), several intermediate combinations (2 – 6), and the case that yielded the smallest difference (7). Results showed that for case 1, the one-component model could overestimate material release by as much as 445 times (Figure 4). Several intermediate cases are also shown in the figure. For case 7 (not shown), there was no difference in results between the one and two component models.

Figure 4: Ratio of one-component to two-component models. Results for case 1-5, respectively; 445, 188, 13.4, 12.6, 5.8

DISCUSSION

When analyzed over a large range of values, the more complex two-component model predicted lower quantities of leached material than the more conservative one component model. Differences in predictions could imply that the more clinically relevant two component model should be adopted. However, when clinically relevant values for K , D_t and D_p are used, it was apparent that the conditions where the two-component model is needed is limited. Conditions where this occurs include migration through high diffusion rate polymers such as silicones, hydrophobic leachables that have reduced transport across the implant-tissue barrier, and tissues with lower chemical diffusion rates. Overall, these findings have enhanced our understanding of chemical migration across multicomponent systems.

CYCLIC STRAIN INDUCES MATRIX TURNOVER TO BETTER MAINTAIN TENDON COMPOSITION IN EXPLANT CULTURE

Anthony N. Aggouras (1), Brianne K. Connizzo (1)

(1) Department of Biomedical Engineering, Boston University, Boston, MA, USA

INTRODUCTION

Resident tendon cells, called tenocytes, remodel the extracellular matrix (ECM) to repair normal microdamage and maintain mechanical function, balancing matrix production in response to increased exercise and matrix removal when unnecessary [1]. This balance is disrupted in tendinopathy, a common pathology affecting 10% of adults under the age of 45, leading to pain, degeneration of tendon structure, and diminished tissue function [2]. One factor thought to contribute to the pathogenesis of tendinopathy is excessive mechanical loading or exercise [2], termed overuse. While we understand that matrix turnover has a role in tendon degeneration, the innate cellular mechanisms that control the balance between matrix synthesis and degeneration are still unknown.

Explant culture allows for the maintenance of cell-cell and cell-matrix interactions and the assessment of the innate cellular responses without influence from the systemic environment. However, a major challenge to the field of tendon explant culture is establishing a consensus on the loading conditions that best maintain the tendon in culture [3]. While the field has learned much about adaptive changes to mechanical loading, previous work has mainly focused on changes to gene expression and tissue composition rather than alterations in cell behavior [4]. Studies that have focused on protein synthesis explored the short-term effects only [5]. Therefore, the purpose of this study is to investigate long-term effects of cyclic loading on matrix turnover at the protein level. We hypothesized that 3% cyclic strain would be sufficient to maintain baseline values of composition with balanced matrix turnover.

METHODS

Flexor digitorum longus (FDL) tendon explants were harvested from mature C57BL/6J (B6) mice at 4 months of age (BU IACUC Approved), as described [6]. Explants were then loaded into custom grips with a gauge length of 10 mm. Samples were transferred to culture

wells in our incubator-housed tensile loading bioreactor (Figure 1), and subjected to stress deprivation (SD), 3% static strain (SS), or 3% cyclic strain (CS) for 7 days in standard culture medium [6]. For SD, gripped tendons were placed into culture wells of the bioreactor and were left slack between the grips. Both static and cyclic loaded tendons were preloaded to a 0% strain of 20 g to ensure consistent loading between all explants. SS tendons were loaded on day 0 and held at 3% strain for the duration of the culture. CS tendons were loaded using a sinusoidal waveform from 0% to 3% strain at 1 Hz for 1 hour followed by a 5 hour hold at 0% strain. This protocol was repeated 4 times a day for the duration of the culture (Fig. 1). Explant metabolism, biosynthesis, and matrix composition were assessed on the last day of culture. Explant metabolism was measured using a resazurin reduction assay. Sulfate and proline incorporation, indicating sulfated glycosaminoglycan (sGAG) and total protein synthesis, respectively, were measured via the addition of 20 $\mu\text{Ci}/\text{ml}$ ³⁵S- sulfate and 10 $\mu\text{Ci}/\text{ml}$ ³H-proline to the media for the final 24 hours of culture. Activity of matrix metalloproteinases (MMPs) was determined in day 7 culture media. Finally, tendons were digested to facilitate the measurement of GAG

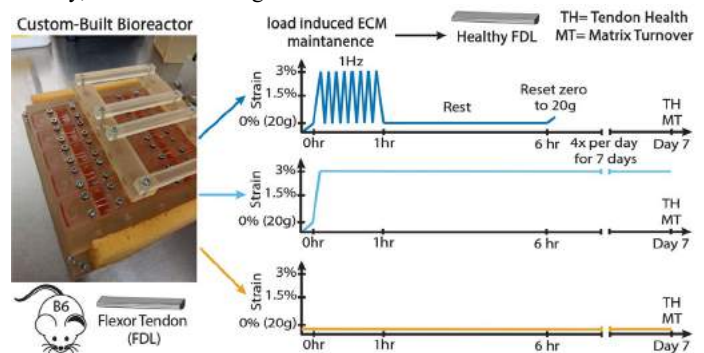

Figure 1: Study Design.

content (DMMB assay), DNA content (PicoGreen assay), and total collagen (OHP assay). All biochemical assays were normalized to tendon dry weight. Statistical evaluation was performed using one-way ANOVAs with post-hoc Bonferroni corrected t-tests. Significance was noted at $p < 0.05$. Significance from day 0 marked with an asterisk (*) and significance between the groups with a bar (-). All data is presented as mean \pm 95% confidence interval.

RESULTS

Water content of the SD group was significantly greater than that of the loaded groups and baseline value (Figure 2A), while cellularity reduced (Figure 2B). SS cellularity was also reduced from baseline values. The SD (not significant) and SS group had decreased GAG content compared to baseline values and was reduced compared to CS (Figure 2C). In collagen content, the SD group was significantly increased compared to baseline and loaded groups (Figure 2D). Metabolic activity was increased from day 0 in all groups with the CS group displaying the greatest increase (Figure 3A). There was no difference in MMP activity between groups (Figure 3B), although it appeared to increase with SD compared to SS and CS. In both protein synthesis and sGAG synthesis, the CS group has greater incorporation than the SS and the SD groups (Figure 3C,D).

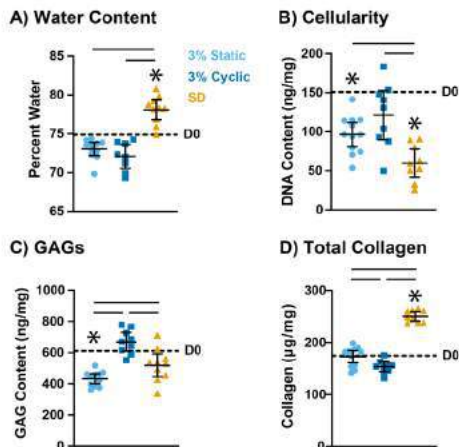

Figure 2: (A) Water content, (B) cellularity, (C) glycosaminoglycan, and (D) total collagen at day 7. Dashed line represents day 0 baseline measures.

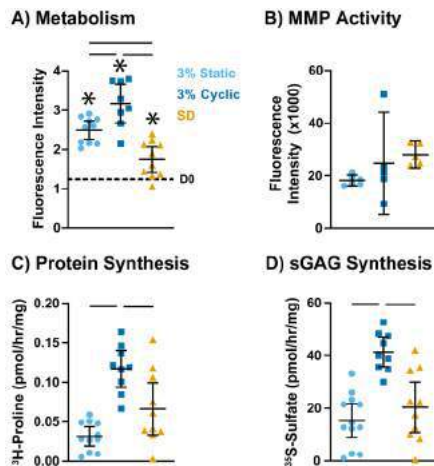

Figure 3: (A) Metabolism, (B) MMP activity, (C) protein synthesis, and (D) sGAG synthesis at day 7. Dashed line represents day 0 baseline measures.

DISCUSSION

Under SS and SD, the explants lose cellularity, indicating that static strain may not be sufficient for retaining cells within the tendon structure. This reduction in cellularity may be due to cells migrating out of the matrix or cell necrosis. While we did not measure either of these parameters, we know tenocytes rely on mechanotransduction for maintenance of cell viability and homeostasis [7] and without sufficient stimulus the cells may start to seek more favorable environments or die. We also found that SD has the greatest impact on the composition of the tendon with significant deviations from the other groups and baseline, suggesting potential pathological changes to the tissue. This is expected as SD is a common model for tendinopathy [8].

Cyclic loading appeared to maintain tendon composition throughout culture better than the other conditions, which could be a result of the higher metabolic activity and the greater synthesis in the CS group. The high synthesis rate and high metabolic activity may be sufficient to replace matrix loss while adjusting to culture conditions. Furthermore, the high MMP activity in the SD group may have led to increased breakdown of matrix. This is consistent with previous studies indicating that tendons may substantially increase matrix turnover to maintain function or to initiate repair [9]. It's also possible that higher matrix turnover is necessary to incorporate newly synthesized matrix effectively into the existing structure, but this remains unknown.

A noteworthy finding is the increase of collagen in the SD group, most likely due to an imbalance in collagen synthesis. While the higher protein synthesis appears to be balanced by an increase in MMP activity, these measures are non-specific. Although a good estimation of collagen synthesis given the primary function of tendon fibroblasts in synthesizing collagen, proline is used in the production of many other proteins as well. Furthermore, the MMP activity assay used measures many MMPs. More specific assays are necessary to truly identify type 1 collagen and collagenase levels, and this remains an avenue of inquiry in the lab.

Regardless, this study demonstrated that 3% cyclic strain is sufficient for maintaining tendon composition. It also indicates that an increased metabolic function and an increase in matrix synthesis may be helpful in tissue maintenance. Future studies will aim to explore more strain levels with the goals of identifying the optimum loading protocol for maintaining physiologic conditions and developing clinically relevant injury models. We also aim to look at the impact on the cells through gene expression, as well as matrix organization function to ensure a comprehensive analysis of tendon health. Regardless, this study identifies a baseline loading condition against which the effects of loading on matrix turnover can be explored, providing a strong model for exploring mechanosensitive cellular mechanisms that induce matrix adaptation or pathological degeneration.

ENDOTHELIN-1 EXPRESSION IS DEPENDENT ON THE STABILITY OF ENDOTHELIAL GLYCOCALYX HEPARAN SULFATE

Santiago Rivero (1), Solomon A. Mensah, PhD (1,2)

Worcester, Massachusetts, United States

INTRODUCTION

Endothelin-1 (ET-1) is a vasoconstrictor produced by the vascular endothelium [1]. After ET-1 is produced, it is secreted into the extracellular space where it binds to endothelial B receptor on the endothelial cells or endothelial A receptor on the smooth muscle cells [2]. Increased ET-1 has been observed in the endothelial and smooth muscle cells of patients with moderate to severe hypertension [3]. It has also been correlated with different stages of atherosclerosis [4]. Several studies suggest that the expression of ET-1 depends on the magnitude and time of the shear stress produced by the blood flow and that disruption of cytoskeletal structures could mediate its production [5,6,7]

Endothelial B receptor (ETB) is a plasma membrane bound receptor present in the endothelial cell surface [8]. Studies have revealed that G-protein-coupled receptors like ETB, are flow-sensitive and lectin based [9].

The vascular endothelial glycocalyx (GCX) coats the luminal surface of endothelial cells [10]. This component senses the flow of blood and then translates it into biochemical activities [11,12]. The GCX consists of several transmembrane solid core proteins like syndecans and glypicans [13,14]. Linked to the core protein is one or more glycosaminoglycan (GAG) chains, which are made up of lectins and N-acetylglucosamine [13,15]. There are five types of GAGs: heparan sulfate, chondroitin sulfate, dermatan sulfate, keratan sulfate, and hyaluronan (or hyaluronic acid) [13]. However, the most abundant is heparan sulfate (50 – 90%) [13]. Studies have shown that the GCX is connected to the cytoskeleton and the core proteins act as a torque on the cytoskeleton structures which then leads to rearrangement and several biochemical activities [16]. There has also been noted that a degraded GCX promotes endothelial cell disfunction which leads to several diseases like atherosclerosis [10].

Both the GCX and ETB are located in the surface of the endothelial cells and are flow sensitive, therefore we suspect that there is a relationship between these components. Figure 1 describes the main

hypothesis of this study. We hypothesize that the ETB is connected to the GCX, which is also connected to the cytoskeleton. The shear stress induced upregulation of the GCX could lead to an increase in ETB which will trigger the release of ET1.

Fig 1. Schematic of the proposed hypothesis: **A.** Introduction of shear stress results in the structural changes of GCX and ETB. **B.** Shear stress triggers an interplay between the GCX and ETB that results in cytoskeletal changes which causes conformational changes leading to the synthesis of ET-1 mRNA. **C.** EC nucleus synthesizes ET-1 mRNA and produces Prepro ET-1, which undergoes post transcriptional modifications leading to the release of ET-1 which **D.** then binds to ETB on the surface of EC.

Figure 1: Schematic of proposed hypothesis

The goal of this study is to understand the involvement of the GCX in the expression of ETB receptors and ET-1 expression. Once this pathway is understood, new therapies can be developed to mitigate the detrimental effect of ET-1.

METHODS

Human Lung Microvascular Endothelial cells (HLMVEC) were maintained in Microvascular Endothelial Cell Growth Medium (Sigma-Aldrich) at 37 °C. These cells were passaged using 0.05% trypsin-EDTA at 70–80% confluence. The cells will then be cultured on a 24mm X 60mm X 1mm glass slide (Fisher Scientific) at an initial

concentration of 100,000 cell/ml. Once the glass slide is confluent, it was placed in a parallel plat flow chamber. This chamber consists of a base plate with an inlet and outlet port, and a gasket that controls the flow chamber thickness. The setup was connected to a peristaltic pump (Cole Palmer) via silicon tubing (Cole Palmer) to create a continuous flow loop. Media flowed through the tubing and flow chamber, exposing the HLMVEC to 10dynes/cm² of shear stress for 12 hours. This shear stress is within the range reported for microvascular endothelial cells [17,18].

To mimic disease progression the GCX were degraded with two different enzymes. Neuraminidase targets the lectin components of GCX and Heparinase III targets the heparan sulfate of the GCX. An initial dose of 15mU/mL represented disease onset and 3645mU/mL represented extreme disease progression [15].

Immunostaining was used to determine the expression of GCX lectin and HS. GCX lectin was labeled using biotinylated maakia amurensis lectin II (MAL II) (Thermo Fisher Scientific) as primary antibody and Alexa-fluor 488 conjugated anti biotin (Thermo Fisher Scientific) as secondary antibody. HS was labeled using 10E4-epitope heparan sulfate antibody (Amsbio) for primary detection and Alexa Fluor 488 conjugated goat anti-mouse IgG/IgM (H+L; Life Technologies) for secondary detection. ETB was labeled using anti-endothelin B receptor/ET-B antibody (ab117529 from abcam) for primary detection and horseradish peroxidase (HRP)-conjugated secondary antibodies (Pepro Tech Inc) for secondary detection. ET-1 was labeled with endothelin 1 monoclonal antibody (MA3-005), secondary detection was achieved using goat anti-mouse IgG1 cross-adsorbed Alexa fluor 488. Image J was used to quantify the results. Western blotting will also be conducted to confirm the results of immunostaining.

RESULTS

Preliminary testing was performed with two different timepoints, 4 hours and 6 hours. Results are shown in figure 2. First, the HLMVEC were stained with Wheat Germ Agglutinin, which targets all the components of the GCX (Fig 2A, 2B, 2C). The green represents the GCX and the blue the nucleus. The coverage and thickness of GCX was quantified and revealed a statistically significance difference between the control and the flow conditions (Fig 2G, 2H). There was not statistically significance difference between the 4 to 6 hours in coverage and thickness. HS was also labeled and shown in green in fig 2D, 2E and 2F. The coverage of HS has a statistically significance difference between the control and the 6-hour flow cells (Fig 2I). The thickness of the HS increased with time and the quantification showed that in fact there was a statistically significance difference between the three conditions (Fig 2J).

Figure 2: The effect of shear stress and time on the expression of glycocalyx and its sub-component HS on HLMVEC

Fig 3. Effect of Hep III on HS/ETB/ET-1 Expression: A. HS control B. ETB control C. ET-1 Control. D. HS quantification. E. Hep III treatment showing reduced expression for HS and F. ETB. G shows increased expression of ET-1. H. Quantification for ETB. I, J, and K are negative control for HS, ETB, and ET-1 respectively. L. Quantification of ET-1 showing an increase in ET-1 expression. Green is HS, red is ETB, yellow is ET-1 and blue is the nucleus of the HLMVECs. The data trend shows that absence of HS affects ETB and ET-1 expressions.

DISCUSSION

The preliminary results from, immunostaining reveals a potential co-participation of GCX HS and ETB in the expression of ET-1. However, there is a possibility that HS is not the only glycosaminoglycans interacting with ETB. If that is the case, targeting other GCX GAGs and lectins independently will provide insight into the role of GCX in the regulation of ETB and ET-1.

Future work will be focused on understanding the cellular mechanisms and pathways by which cooperation between GCX and ETB could trigger the release of ET-1 in the endothelial cells.

INTRODUCTION

Aortic valves (AVs) undergo a unique stretch history which includes high stretch rate and magnitude [1,2]. While major differences in deformation patterns have been observed between normal and congenitally defective bicuspid aortic valves (BAVs) [1-3], the relation to underlying mechanisms of rapid disease onset in BAV patients remains unclear. Such altered deformation patterns in BAVs may be related to early onset of disease. Therefore, hydrogels impregnated with aortic valve interstitial cells (AVICs) were mechanically conditioned to determine how AVIC activation is affected by specific properties of strain waveforms (peak strain, strain rate, and average strain history). Since bicuspid AVICs have higher cytoskeletal polymerization, we hypothesized that altering strain waveforms would alter alpha smooth muscle actin (α SMA) and vimentin (VMN) polymer formation, modify the activity of the transcription factor SMAD 2/3, and affect the nuclear shape.

Figure 1: 3D Poly(ethylene) Glycol (PEG)-Imbedded Aortic Valve Interstitial Cell (AVIC) Cultures in the High-Throughput Biaxial Oscillatory Strain System.

METHODS

To evaluate how stretch histories affect AV interstitial cell (AVIC) activation, the high-throughput biaxial oscillatory strain system on which we have previously reported [4] was further developed to impart varied cyclical biaxial stretch histories into 3D poly(ethylene) glycol hydrogels impregnated with AVICs for 48 hours (**Figure 1**). Specifically, a physiologically-mimicking stretch history was compared to two subsequent stretch histories that separately varied peak stretch and stretch rate (**Figure 2**). Post-conditioned AVICs were imaged for nuclear shape, α SMA and VMN polymerization, SMAD 2/3 nuclear activity, and nuclear shape.

Figure 2: 1-Hz Waveforms Applied to 3D PEG Gel AVIC Cultures for 48 h. The physiologic waveform moved to the peak stretch of 1.1 as quickly as the motor could do so; the peak matching wave moved to 1.1 within 0.5 s; and the rate matching waveform maintained the same slope as the physiologic wave and the same root mean squared (RMS) value of the peak matching wave, making the peak stretch 1.062.

RESULTS

Results indicated that bulk gel deformations were accurately transduced to the embedded AVICs. Lower peak stretches lead to increased α SMA polymerization. In contrast, VMN polymerization was a function of stretch rate, with SMAD 2/3 nuclear localization and nuclear shape also trending towards stretch rate dependency (**Figure 3**).

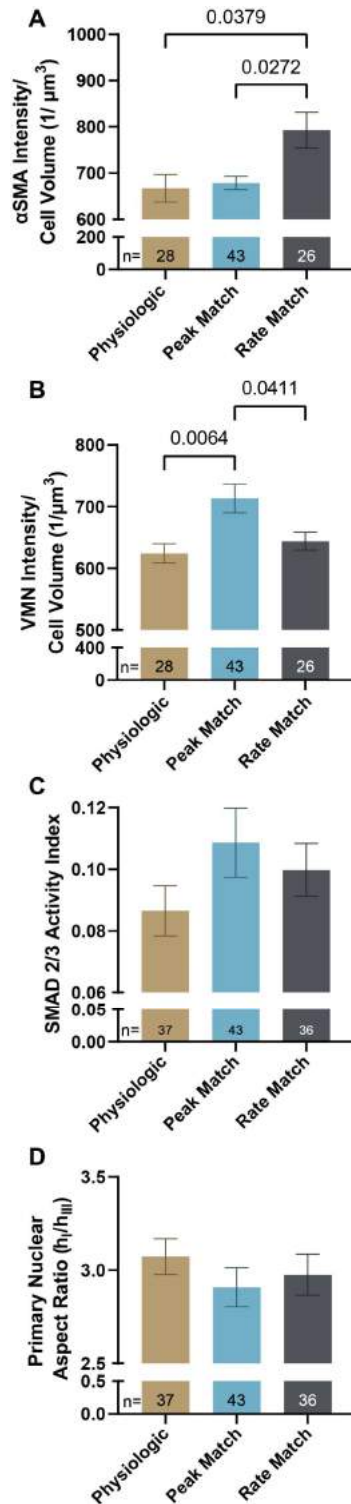

Figure 3: Waveform vs. AVIC Activation. (A) α SMA and (B) VMN intensity per cell volume in gels conditioned for 48 hours with designated waveforms. (C) SMAD 2/3 nuclear intensity divided by cell intensity from cells conditioned with indicated waveforms. (D) Primary nuclear aspect ratio measured as the longest hemi-axis divided by the shortest hemi-axis of the nuclear best fit ellipsoid from cells conditioned with indicated waveforms.

Lower than physiological levels of stretch rate led to higher SMAD 2/3 activity, higher VMN polymerization around the nucleus, and lower nuclear elongation. α SMA polymerization did not correlate with VMN polymerization, SMAD 2/3 activity, nor nuclear shape (Figure 4).

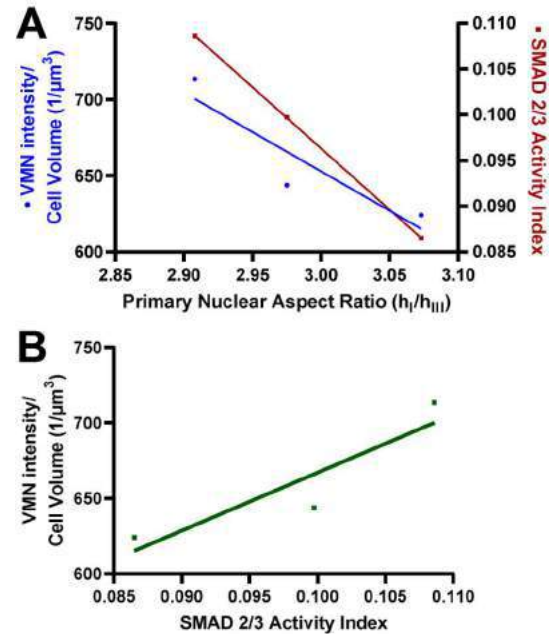

Figure 4: Strong correlations between VMN polymerization, SMAD 2/3 activity, and nuclear shape. (A) Average nuclear eccentricity correlated to average VMN intensity per cell volume ($y = -516.2x + 2201$, $R^2 = 0.8336$) and average SMAD 2/3 activity ($y = -0.1340x + 0.4982$, $R^2 = 1.000$) from AVICs conditioned for 48 hours of stretch waveforms. (B) Average SMAD 2/3 nuclear localization correlated to average VMN intensity per cell volume from AVICs conditioned for 48 hours of stretch waveforms ($y = 3843x + 282.7$, $R^2 = 0.8294$).

DISCUSSION

These results suggest that a negative feedback loop may form between SMAD 2/3, VMN, and nuclear shape to maintain AVIC homeostatic nuclear deformations, which is dependent on cyclic stretch rate. These novel results suggest that AVIC mechanobiological responses are sensitive to stretch history and provide insights into the mechanisms of AV disease.

INTRODUCTION

While survivable severe cervical spine (c-spine) injuries are rare in vehicle crashes, the rehabilitation is often difficult and long-term consequences debilitating [1]. Despite advances in the biomechanical understanding of c-spine injuries, not much is understood about ligamentous damage in severe injury cases, specifically in frontal impacts. Post-mortem studies on the c-spine ligamentous response to frontal impact have been performed in the past, but without active musculature the measured strains may be artificially high [2]. Human Research Volunteer (HRV) studies have been utilized to create and validate a human head-neck model that has been optimized multiple times for improved efficacy [3,4]. Additional HRV frontal impact studies available from the Air Force were performed at higher accelerations and shorter duration but have yet to be summarized for model development. Therefore, it is crucial to verify the available Head-Neck model to accurately represent this dataset by optimizing model parameters to the specific kinematics of the experiment. Once verified, the ligamentous response to frontal impact can be further studied at higher impacts in live humans.

METHODS

All HRV kinematic data was downloaded from the Collaborative Biomechanics Data Network (CBDN), courtesy of the Wright-Patterson Air Force Base, OH. HRVs were positioned on a seat fixture mounted to a horizontal accelerator sled and restrained with double-shoulder strap harness and lap belt. The peak frontal acceleration pulse ranged from 10 G-30 G in the -X direction. For present analysis, HRV runs with a rise-time of 13-20 ms were selected for consistency. All subjects were within 10% of 50th percentile male stature. A total of n=16 and n=9 subjects were selected from the 10 G and 30 G test series, respectively.

Linear accelerations were measured from accelerometers located on the upper thoracic spine and the subject's mouth (bite-block). An additional rotational accelerometer measured rotational head

acceleration from the subject's mouth as well. The first 0.1 seconds of measured kinematics was used for present study.

To simulate the c-spine response, the Global Human Body Model Consortium (GHBMC M50 v6.0) isolated Head-Neck model [4] was driven at T1 with the experiment measured upper thoracic X acceleration. According to frontal impact literature, the extensor and flexor muscles activate in response to impact approximately 74 ms after the start of acceleration [4]. Given the rise-times are no more than 20 ms for sled accelerations from the selected corridors, the impact event is already close to complete by 74 ms. Therefore, the first simulated condition studied was a passive muscle condition, meaning no muscle activity implemented. Given the subjects of this study underwent multiple sled tests, it is assumed that they would likely brace for the impact event. Under this assumption, the second condition had a muscle activation curve [4,5] started at 0 ms, the start of the sled acceleration. The activation curve starts at a magnitude of 0 and increases in activation peaking at 0.87 over 100 ms, progressively contracting the 1D muscle elements. Additionally, using GHBMC documentation and literature suggestions [5], flexors muscles were activated to 100% and extensors to 70% of maximum activation. All simulations were performed using LS-DYNA MPP version R8.0.0 and 64 cores on a high performance cluster..

A CORrelation and Analysis (CORA) method was used to score the biofidelity of the head-neck model. CORA was performed for two of the kinematic outputs measured from the simulation: Head X acceleration and Head Rotational Y acceleration, collected from the same area of the bite-block in the experiment. Biofidelity was deemed fair if CORA rating was between 0.440 and 0.650, and good if between 0.650 and 0.860 [6].

RESULTS

Figure 1 presents the output kinematics of the GHBMC Head-Neck model for both passive and active muscle conditions. Experiment kinematics include one standard deviation. The passive muscle

condition for both Head X acceleration and Head Rotational Y acceleration in 10 G and 30 G fall outside the standard deviation of the experiment, resulting in worse biofidelity. Table 1 describes the biofidelity of each metric using the CORA rating, color coded to indicate quality. In both 10 G and 30 G, Head X acceleration improves from fair to good when muscles are activated beginning at 0 ms under the proposed assumptions. Additionally, Head Rotational Y acceleration biofidelity increases by 0.09 or more in both 10 G and 30 G, to at least fair.

Figure 1: Head X-acceleration (top) and Rotational Y Acceleration (bottom) for 10G (left) and 30G (right) sled corridors.

Table 1: CORA rating for 10G and 30G, passive and active conditions. Orange is marginal, yellow fair, and green good.

Condition	Head X Accel	Rot. Y Accel
10G Passive	0.532	0.365
10G Active	0.758	0.640
30G Passive	0.503	0.545
30G Active	0.738	0.631

DISCUSSION

When comparing the passive simulations to the active simulations, it is clear that the muscle activation scheme implemented improved the model response outcomes compared to the human response corridor. The biofidelity increased significantly, with both Head X acceleration and Rotational Y acceleration being at least fair, and the Head X specifically being considered good. This would indicate the GHBM Head-Neck model is capable of validating multiple HRV datasets, with varying experimental characteristics. Further investigation is needed to improve oscillations in the 10 G corridor, as well as the peak response in the 30 G corridor. It is possible the muscle activation differs between the two, but as the muscle responses were not measured in the experiment, iterative optimization may be necessary.

The main difference in the methodology of the present study is the timing of the muscle activation in response to acceleration. As the literature suggests, the typical timing of the muscle response is 74ms after the start of acceleration [4]. However, 74 ms into acceleration for this dataset would be well past the peak response of the head, therefore

it was assumed this condition would be an overall passive response. As the experimental kinematics would suggest, however, there is a clear dampening effect on the linear and rotational accelerations of the head. This would indicate muscle activity starting much earlier. Many of the subjects in this study were well aware of the experimental set-up and had undergone multiple sled tests prior to the data shown. Qualitative analysis of video recordings of each subject presumably showed tension in the neck, further supported by the modeling outcome. Thus, adjusting the muscle activation to start at 0 ms is one assumption to account for muscle response in lieu of measured muscle activity from these experiments.

With this current set of data validated against the GHBM Head-Neck model, further analysis can determine the response of the ligaments in the c-spine during frontal impact at non-injurious Gs. Preliminary analysis suggests the passive simulation ligament strains were only moderately lower than isolated post-mortem studies [2], meaning the ligaments were on the borderline of failure. With the active muscle simulation, ligament strain was decreased by as much as 50% from passive muscle. The ligament strains in the active muscle simulations seems more reasonable than those recorded in post-mortem studies, or passive simulations due to the nature of using HRVs and having no reported injuries post-experiment. Further optimization of the active muscle simulations for this unique dataset will produce more accurate ligament strains along the c-spine and help to identify areas of injury in the c-spine during higher g-loading in real world frontal impacts.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the Collaborative Biomechanics Data Network (CBDN), Wright-Patterson AFB OH for use of their kinematic datasets (<https://biodyn.istdayton.com/CBDN>). The simulation was completed in part with computational resources and technical support provided by the Research Computing Center at the Medical College of Wisconsin.

Quantifying Lower Birth Canal Viscoelastic Properties During The First Stage Of Labor

Mariana Masteling (1), John O. DeLancey (2), James A. Ashton-Miller (1)

(1) Department of Biomedical Engineering, University of Michigan, Ann Arbor, MI, USA

INTRODUCTION

Up to 19% of nulliparous women sustain pelvic muscle injuries while giving vaginal birth. Since these injuries, which are not repairable, can have life-long sequelae, including pelvic organ prolapse and incontinence, we need better ways of preventing them. From a biomechanical perspective, it seems reasonable that if women have unusually stretch-resistant lower birth canals they should expect longer labors and perhaps a higher risk for muscle and tissue injury, a hypothesis yet untested.

In the present work, a novel vaginal dilator, (PREP, Maternal Medical, LLC, Mountain View, CA) used during the first stage of labor to ease the birth of the baby during the second stage of labor has allowed us to quantify inter-individual differences in lower birth canal hoop tension during dilation, as well as lower birth canal viscoelastic properties using a Fractional viscoelastic Zener Model.

METHODS

The PREP dilator was introduced into the first 4 cm of the vaginal canal in nulliparous women in their first stage of labor during the ongoing EASE clinical trial (NCT 03973281). A semi-automatic, dilation-controlled actuation system was programmed to mechanically expanded the device to ~80 mm diameter in a step-wise manner over ~60 minutes (Figure 1). The dilation force, time and diameter were recorded. The measured dilation force was then used to calculate the hoop tension, T , in the lower birth canal tissues.

We quantified the variation in T across 56 subjects at three points during PREP insertion: 1) at initial 20 s expansion to 55 mm of diameter (T_e); 2) after a 5 min “hold” at 55 mm of diameter (T_r); 3) at maximum diameter (T_m). Canal hoop stiffness during the 20s ramp (S_i) was calculated as the difference in hoop tension divided by the increase in dilation diameter (Figure 1).

The canal tissue 20 s ramp-and-5-minute-hold response was initially characterized using a Fung quasilinear viscoelastic model,

similar to that using a constant-force vaginal dilator during the first stage of labor [1] but we found it had no predictive power outside the fitting interval. Considering the strong linear relationship after the 5-minute hold (Figure 1), we also tried classical viscoelastic models but they also had poor predictive power. However, when using a fractional approach, the simplest model with predictive power was found to be the fractional viscoelastic Zener Model (FZM) (a SpringPot (constants C_α and α) in series with a spring in one arm (k_β), lying in parallel with a spring (k_γ) in the other arm). For each subject, RHEOS.jl – an open-source Julia-based rheology package [2]- was used to obtain the four FZM constants. First, dilation diameter and lower birth canal hoop tension data from the ‘hold’ relaxation were used to obtain the constants. Then using the four constants, the equivalent lower birth canal hoop tension, T , was predicted using the experimentally recorded dilation diameter and temporal data for the remainder of the insertion (Figure 1, peach colored background). Relative error of the prediction was calculated as the squared error relative to the maximum hoop tension, T , for each subject.

Data management and statistical analyses were performed using Julia and Python.

RESULTS

We found a remarkable variation (Figure 2) in the measured T across all subjects. Specifically, when reaching 55 mm dilation T varied 5.5-fold and was 22% greater in older women (age ≥ 30 years) ($p = 0.05$) and correlated strongly with both relaxation (T_r) during the 5-minute hold and with the maximum tension (T_m) ($r = 0.80$, $r = 0.59$ with $p < 0.001$). Hence the 20 s-ramp-and 5-minute-hold behavior of T was therefore a reasonable predictor of the resistance the lower canal would later develop during the full 60 minutes of dilation. The stiffness of the initial 20 s ramp (S_i) varied 6.8-fold and was 31% higher in older women.

When the four FZM constants were calculated from the 20 s ramp-and-5-minute-hold data the relative fit error was $8.1 \pm 3.6\%$. The relative prediction error of T after 60 minutes of dilation of $10.0 \pm 5.4\%$. FZM constants varied 742, 64 and 23-fold for C_α , k_β and k_γ ; α varied between its acceptable range of 0 and 1. k_β was 33% higher in the older versus the younger group ($p = 0.03$).

Figure 1: An example of *in vivo* PREP data from a single participant. Lower birth canal dilation is shown (in mm) on the left ordinate axis with the 20 s ramp-and-5 minute-hold dilation and subsequent cyclic 1 mm step dilation-and-hold cycles up to 80 mm dilation plotted in green, at top). The measured lower birth canal hoop tension, T , is shown on the right ordinate axis (arbitrary units and plotted in red) shows the effect of the initial ramp in tension (T_e) followed by tissue relaxation over the first 5 minutes (T_r) followed by the increases to T_m , the maximum. The predicted FZM tension in the lower birth canal over the 60-minute dilation protocol, based only on the initial 20 s ramp-and-5-minute-hold data, is plotted in black with a reasonable fit between the measured (red) and FZM predicted (black) curves.

DISCUSSION

This is the first quantification of normal human lower birth canal viscoelastic properties during the first stage of labor using a constant displacement dilator. These results reflect the response of the term-pregnant, nulliparous, lower birth canal to its first-ever dilation to 80 mm diameter in preparation for the second stage of labor when the fetus is pushed through the birth canal. T is a measure of the resistance of the canal to dilation: the stiffer and more viscous the canal wall is, the greater the tensional resistance to the passage of the fetal head during the second stage of labor. T was governed principally by the elastic nature of the lower birth canal, as seen from the linear course of the force-dilation curve (Figure 1) during a slow dilation regime. But clearly, the viscous behavior of the lower birth canal also played an important role in its response to step increases in canal dilation, as can be seen by its relaxation following the initial 20 s ramp-and-5-minute-hold dilation, as well as its relaxation following each 0.9 mm step every ~90 s (Figure 1).

[4]

Figure 2: Range of measured PREP lower birth canal hoop tensions over time across all 56 subjects in their first stage of labor. Red curves are $>99.7^{\text{th}}$ centile ($n = 4$) in maximum tension, orange between the 95^{th} and 99.7^{th} centiles ($n = 13$) and green those $<95^{\text{th}}$ centile ($n = 39$). Those $>99.7^{\text{th}}$ centile might be expected to endure longer second stages, and have elevated risk for injury, clinical outcomes will be available for analysis once the EASE trial ends in Fall 2023.

The large range in T_e , T_r , T_m and the FZM constants quantifies clinical experience that a large range of viscoelastic properties can lead to successful vaginal delivery (Figure 2). Those above the 95^{th} in T_m , however might logically be expected to have difficult vaginal deliveries. The insight that T_e and S_i , as well as, k_β , are higher in older women has direct bearing on the known risk of levator ani injury and longer second stage of labor in older women [3], [4].

A strength is that all the participants were nullipara, because they are the highest higher risk for long second stages and levator avulsions (compared with multiparous women). A caveat is that each PREP insertion time-displacement-tension dataset is unique for that subject at the specific time of insertion, somewhat limiting generalizability.

When the labor outcomes become available upon completion of the EASE trial in late 2023, we will be able to test the hypothesis that the PREP can be used to identify women abnormally stiff birth canals with a brief ramp dilation during the first stage of labor, so preparations can be made to ease her second stage delivery. When combined with existing obstetric variables, the PREP dilator could prove helpful in mitigating the risks of difficult vaginal deliveries.

EFFECTS OF EXTERNAL BATHING SOLUTION OSMOLARITY ON TRIBOLOGICAL REHYDRATION AND CARTILAGE LUBRICATION

Shamimur R. Akanda (1), David L. Burris (1), Chris Price (2)

(1) Mechanical Engineering, University of Delaware, Newark, DE, USA
(2) Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Articular cartilage, the unique biological bearing material of our diarthrodial joints sustains millions of articulation cycles while maintaining vanishingly low friction coefficients.^[1] This phenomenal lubricity has been ascribed to interstitial lubrication,^[1] a mechanism dependent on cartilage's triphasic nature. Triphasic tissue theory, developed by Mow et al., describes cartilage as a mixture of a solid phase (i) and a fluid phase containing water (ii) and monovalent ions (iii; *e.g.*, Na⁺ and Cl⁻)^[2] in which an ionic imbalance between cartilage's interstitial fluid and bathing solution generates a Donnan osmotic swelling pressure. Subsequently, tissue swelling is dictated by bath osmolality;^[2-5] hypotonic solutions result in stiffer cartilage.^[6-8]

While cartilage swelling supports interstitial lubrication and the maintenance of high fluid load support (FLS) levels and low tissue strains and frictions,^[1] habitual quasi-static loading drives fluid out of cartilage leading to high tissue strains and frictions. Such changes are detrimental to joint function unless they can be reversed/recovered (which was only thought to occur because of free swelling during cartilage unloading). However, using our convergent stationary contact area (cSCA) testing configuration, we recently discovered a sliding dependent fluid recovery mechanism that can combat fluid exudation absent unloading, via 'tribological rehydration'.^[9-10]

Tribological rehydration fosters active fluid recovery and the long-term maintenance of biofidelic strains, frictions, and fluid load support in a sliding speed dependent manner. However, whether bathing solution osmolality (and physiochemistry) influences tribological rehydration and lubrication remains unknown. Such a question has both basic science and clinical significance. Understanding the effects of osmolality on tribological rehydration may elucidate the underlying mechanisms by which cartilage fluid recovery during articulation sustains the tissues remarkable tribomechanical function and longevity. Furthermore, the synovial fluid of osteoarthritic joints exhibits altered osmolality (as well as composition),^[11] yet knowledge of the impacts of

such changes on cartilage tribomechanics is incomplete. Thus, the objective of this study was to investigate the influence of bathing solution osmolality on tribological rehydration and cartilage lubrication under the biofidelic sliding conditions of the cSCA configuration.

METHODS

First (study 1), the effect of bath osmolality on tribological rehydration and friction was examined when high-speed sliding was initiated from a condition of low FLS (*i.e.*, quasi-equilibrium compression). Φ 19mm osteochondral cSCA explants (N = 8) were removed from the femoral condyles of mature bovine stifles, then stored in 280mOsm PBS with protease inhibitors (1X PBS) for no more than 24 hours.¹² Explants were then compressed (in 1X PBS) against the glass counterface of a linear reciprocating tribometer^[12] to a specified compression value, the PBS was removed, and bathing solutions of various osmolality/composition were added. Explants were then slid for 8 min at 80mm/s while compression, normal and friction forces, and friction coefficients (μ) were recorded. Six bathing solutions were utilized: 1) 1X PBS (280mOsm), 2) sucrose in DI water (280mOsm), 3) sucrose in 0.5X PBS (280mOsm), 4) DI water (0mOsm) 5) 1X PBS plus sucrose (1350mOsm) and 6) 5X PBS (1350mOsm). Between testing conditions explants were allowed to free-swelling in 1X PBS (2-hours) before tribological characterization was repeated.

In study 2, the influence of bath osmolality on explant tribomechanics when slid from high FLS (*i.e.*, compression and sliding initiated simultaneously) was investigated. Explants (N = 10) bathed in either 1) 1X PBS (280mOsm), 2) 5X PBS (1350mOsm), or 3) DI water (0mOsm) were compressed to 7N (over ~2-seconds) while reciprocal sliding, at 80mm/s, was initiated simultaneously and maintained for 10-minutes. As in study 1, explants were allowed to free-swelling in 1X PBS (for 2-hours) before their characterization was repeated in subsequent bathing solutions.

RESULTS

Despite bathing solution osmolarity having a significant influence on the equilibrium compression behaviors of cartilage explants, which is explained by triphasic tissue theory, osmolarity had no meaningful effect on cSCA cartilage lubricity, regardless of the level of fluid load support at the start-of-sliding.

In study 1, when high-speed sliding was initiated from near-zero FLS (**Fig 1A**), explants exhibited robust tribological rehydration in all but the 1X PBS + sucrose (1350mOsm) bath. However, the degree of compression recovery observed during sliding varied with bath osmolarity (**Fig 1B**). Low osmolarity baths exhibited the largest recoveries and high osmolarity baths the smallest, a response aligned perfectly with cartilage's triphasic nature ($p < 0.05$ for all pairs). However, rates of compression recovery initiated by sliding (i.e., tribological rehydration rates) were indistinguishable across bathing solutions (**Fig 1C**) ($p > 0.05$ all pairs). Lastly, frictions at both start- and end-of-sliding appeared insensitive to bath osmolarity ($p > 0.05$).

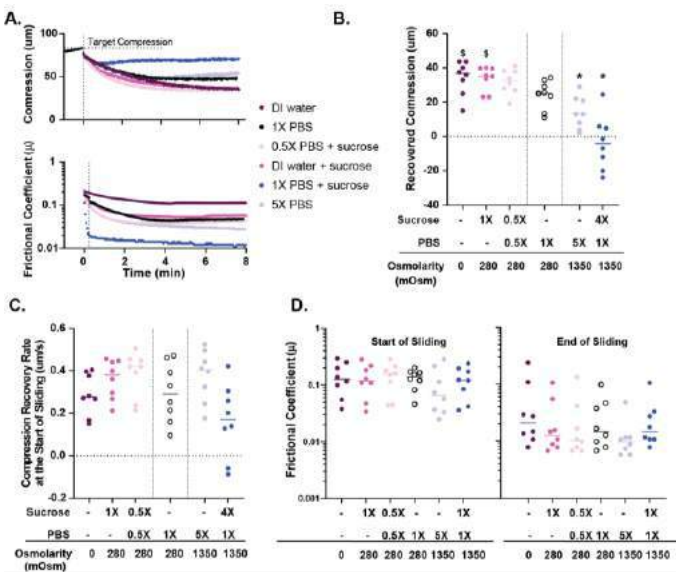

Figure 1: A) Representative compression and frictional behaviors of a cSCA bovine explant - study 1 (low FLS). B) Recovered compression, C) initial compression recovery rates and D) start- and end-of-sliding friction outcomes under different bathing solutions. Data analyzed via repeated measures one-way ANOVA; * and \$ denote significant differences from 1X PBS for hypertonic and hypotonic solutions respectively ($p < 0.05$).

Tribological outcomes in study 2, where sliding was initiated from near maximal FLS (**Fig 2A**) qualitatively reflected those of study 1. Again, equilibrium compression magnitudes varied with bathing solution (**Fig 2B**)—as predicted by triphasic theory; end-of-sliding compressions were less for DI water and greater for 5X PBS than for a given load and testing time (7N & 10 min) in 1X PBS ($p < 0.01$ for all pairs). Again, initial compression rates, which are dictated by the competition between rehydration and exudation rates during sliding did not differ among baths (**Fig 2C**) ($p > 0.05$). Frictional behaviors were again insensitive to bath osmolarity in the cSCA (**Fig 2D**) ($p > 0.05$).

These findings revealed a generalized lack of influence of bathing solution osmolarity on tribological rehydration and lubricity in the cSCA regardless of FLS levels.

DISCUSSION

The present study demonstrated the robustness of tribological rehydration in rescuing compression and lubricity under all bathing

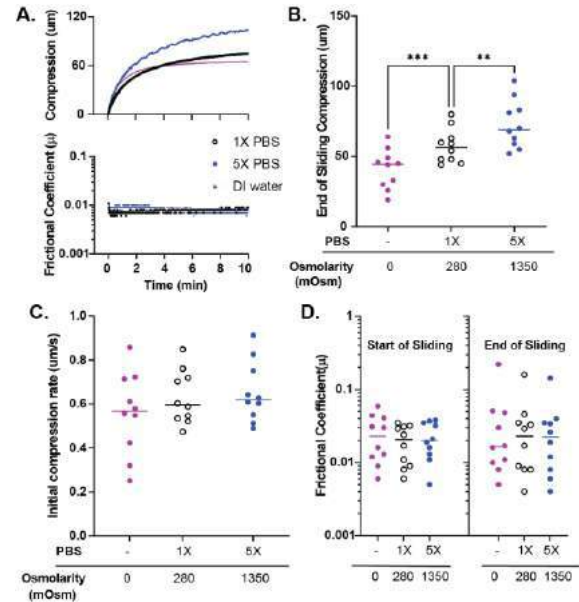

Figure 2: A) Representative cSCA explant compression and frictional behaviors - study 2 (high FLS). B) End-of-sliding compression, C) initial compression rates, and D) start- and end-of-sliding outcomes for different bathing solutions. Data analyzed via repeated measures one-way ANOVA ($p < 0.01$, *** $p < 0.001$).**

solutions except 1X PBS + sucrose (1350 mOsm). The defeat of tribological rehydration in the 1350 mOsm PBS + sucrose solution appears likely mediated by both the increased osmolarity and hygroscopic nature of the solution, which acted to “pull” water out of the tissue at a rate greater than sliding could replenish it, resulting in significantly increased equilibrium compressions. Nevertheless, both studies validated the triphasic-driven equilibrium swelling behavior of cartilage even in the face of tribological rehydration—hypotonic solutions “stiffened” explants and limited load-induced compression while hypertonic solutions resulted in tissue “softening” and greater overall compression.

Of more interest was the observation that both initial recovery (study 1) and compression rates (study 2) upon sliding were unaffected by bath solution osmolarity. Findings that support our postulate of tribological rehydration being dictated by sliding speed driven hydrodynamics, as opposed to Donnan swelling behaviors. The fact that high-speed cartilage lubrication in the cSCA was not meaningfully altered by extremes in bath osmolarity suggests that the hydrodynamic pressures generated by rapid sliding can be quite large. In fact, these rates appear large enough to “pump up” the interfacial surface fast enough to both compete against load-induced fluid exudation and mask the influence of large changes in bath osmolarity. Besides contributing to a better understanding of cartilage lubrication mechanisms, these results hold immense clinical significance for the cartilage lubrication field as they support a paradigm shift discounting the common wisdom that compromised osteoarthritic synovial fluid, with altered osmolarity, is an inherently inferior lubricant; it instead might be fully capable of supporting vanishingly low frictions in the cSCA.

INTRODUCTION

The golden standard treatment for an ankle arthritis is arthrodesis especially for the end-stage ankle arthritis [1]. Ankle arthrodesis is a salvage procedure that involves direct fusion of vital bones such as tibia, fibula and talus using standard orthopedic screws such as Herbert and cortical bone screws that can be made of stainless steel, cobalt chrome or titanium [2]. Baumhauer et al. reported that ankle arthrodesis was effective in pain alleviation, possibility of normal increased activities and lower infection rate postoperatively with minimal procedural cost [3].

Nevertheless, arthrodesis procedure is still far from an ideal treatment for the ankle arthritis patients. Short term complications upon post-arthrodesis procedure were bone non-union, malunion and contralateral joint arthritis as noted in previous studies [4]. Clinically reported non-union rates could be as high as 41% of the total patients whom undergo the arthrodesis procedure [4]. Patients were also subjected to difficulties relating to walking on an uneven surface, staircase ascent and descent, picking up objects on the floor and wearing shoes or boots. Long term follow up studies indicated that post-arthrodesis patients may be at risk of joint deterioration on the ipsilateral hind and midfoot [4] in which could cause severe handicap to the gait cycle leading to ambulation [5].

Alternative treatment to ankle arthrodesis would be the total ankle replacement (TAR). The main advantage of the TAR is the ability to preserve the joint motion and function of the ankle in comparison to the ankle arthrodesis procedure [6]. The resulted loading conditions of the patient on the ankle joint will be similar to the physiological walking gait cycle postoperatively thus lowering the risk of a long-term adjacent ankle arthritis [6]. Therefore, it is of interest of this study to understand further on the total ankle replacement in attempting to replace the arthrodesis as the golden standard.

METHODS

One of the commercial talar components of the cementless STAR Ankle (Stryker Corporation, Kalamazoo, Michigan) was used for this study. The STAR Ankle was selected as it has been the most widely used total ankle prosthesis in the market [7] and was generally having good short to intermediate term clinical outcomes [8]. This study employed both the simulation and experimental approaches. The three-dimensional model of the talar prosthesis was obtained through the scanning technique using Artec Spider (Artec 3D, Luxembourg). The polka dot design features were then modified from the scanned model through SolidWorks (Dassault Systemes, France) software. Material properties were assigned to the model using Abaqus CAE-SIMULA (Dassault Systemes, France) software for finite element analysis (FEA).

Figure 1: The STAR Ankle (A) and the polka-dot designs (B to F).

The three-dimensional model of the talus bone was obtained through computed tomography (CT) scanning of a right cadaveric foot and ankle joint of a female donor (48 years old, 182 cm tall, and weighed

60 kg with no osteoporosis complications). The CT radiographic images were then constructed into three-dimensional model using the software Materialise Mimics (Materialise, Leuven, Belgium). The heterogeneous material properties of the talus bone were assigned using the element-by-element method, with properties of each element mapped through linear relationship between the CT Hounsfield and apparent density [9].

The experimental study was conducted to validate the finite element analysis results, and mechanical responses of bone strain and bone-prosthesis interface relative micromotion (BPIRM) were measured. The simulation and experimental results were compared and correlated to validate the FE model that has been created.

RESULTS

The contour plots of the BPIRM for the STAR Ankle talar component and other polka-dot design features were obtained. The predicted results included three specified critical loading conditions of heel strike, midstance and toe-off of a gait cycle. The interface micromotion values extracted and mapped from Abaqus corresponded to three different contact output variables of COPEN, CSLIP1 and CSLIP2. In addition, the predicted minimum principal bone stresses (MPBS) extracted from FE analysis were compared as well.

Figure 2: The mean MPBS stack-up predicted results in comparison to the STAR Ankle.

The experimental validation study results were obtained through the STAR Ankle and the polka-dot designs. Results were compared through two different parameters of bone strain and BPIRM.

Figure 3: BPIRM measurement results.

Figure 4: Linear regression between experimental and finite element analysis bone strain values.

DISCUSSION

The FE predicted bone strain and BPIRM results have shown a good correlation with the strain and interface micromotion values measured, indicating the validity of the FE models generated and can be used for reliable future studies. Another prevalent finding of the study was to understand the specific primary stability issues of the TAR leading towards aseptic loosening. The clinical outcome studies [10] and FE results from this study also assimilated well with the predicted BPIRM and MPBS, showing the accuracy of the predicted simulation and experimental validation results from this study. In conclusion, this study has shown that the proposed new polka dot design is potentially able to mitigate aseptic loosening issue of TAR.

INTRODUCTION

Bicuspid aortic valve (BAV) is the most common congenital heart defect with an incidence of 0.4 – 2.25% in general population [1]. Unlike normal tri-leaflet aortic valves, BAV is marked by the fusion of two aortic leaflets with a thick, fibrous raphe present at the location of fusion in most cases. In addition to the abnormal valve fusion, BAV is also associated with other structural anomalies including aortic root dilatation and severe cusp asymmetry [2]. The structural malformation and altered hemodynamics result in an early onset of calcific aortic valve disease in most BAV patients, eventually leading to aortic stenosis (AS) and regurgitation, which often require these patients to undergo aortic valve replacement procedure. A minimally invasive and alternative to surgical aortic valve replacement, transcatheter aortic valve replacement (TAVR) has emerged as a lifesaving treatment option for severe AS. As current TAVR devices are intended to treat trileaflet aortic valves in AS patients, its initial use to treat BAV patients with AS was marked as an “off-label” use. Recently the FDA officially approved their use for treating BAV patients. Despite showing promising performances, TAVR is reported to be associated with various clinical complications including paravalvular leakage (PVL) and thrombogenicity. Currently, PVL remains one of the most persistent and significant post-TAVR clinical complications. PVL severity depends on the positioning and orientation of the device and device-tissue interaction, which are often hampered in BAV patients due to their morphological heterogeneity and severe leaflet calcification, exacerbating PVL complications in them. Post-TAVR PVL may eventually lead to life threatening complications including heart failure, hemolytic anemia and increased left ventricular load. In patients with PVL, high pressure gradient across narrow leaks during diastole creates a prothrombotic environment by increasing the shear stress on the platelets, which increases the risk of flow induced-thrombogenicity and may eventually lead to stroke in TAVR patients. Recently, few clinical studies focused on analyzing the impact of device orientation on post-

TAVR coronary occlusion [3]. However, none of these studies address its impact on PVL, which we hypothesize to be associated with the device orientation. Moreover, these studies excluded BAV patients due to their morphological variations and anatomical complexities. In order to maximize the benefit of TAVR in each patient, it is important to understand the complex device-tissue interaction, the risk of post-TAVR PVL and thrombogenicity, and how this risk varies with different devices and their orientation- in a patient-specific manner, which is challenging to do in clinical settings. Our goal is to address these concerns and optimize the post-TAVR outcomes using predictive computational modeling. In our current study, we analyzed the impact the TAVR device orientation on the post-TAVR PVL and associated flow-induced thrombogenicity using patient-specific BAV models. We also quantified the differences in severity and compared the outcomes between different devices, which has a tremendous clinical significance.

METHODS

Anonymized Pre-TAVR Cardiac CT scans of 3 type 1 BAV patients who had different degrees of post-TAVR PVL, were obtained from Rabin Medical Center (Israel) with the approval of the Stony Brook University IRB protocol. All of them received older generation 29 mm self-expandable (SE) TAVR devices (Medtronic plc, Minneapolis, MN, USA) (Patient 1 and 2 – CoreValve and patient 3 Evolut R). Patient-specific surface meshes were reconstructed and optimized for finite element (FE) analysis using ANSYS SpaceClaim and Fluent (Ansys, Inc. Canonsburg, PA). A 4-step FE simulation (crimping, insertion, deployment, and relaxation) was performed in order to deploy the original devices in virtual patient model, using Abaqus Explicit 2019 (Dassault Systèmes Simulia Corp., Johnston, RI). Computational fluid dynamics (CFD) analysis was then performed to assess PVL degree, location, and quantify stress accumulation (SA) on platelets, using a method that depicts the device “thrombogenic footprint” based on the accumulated shear stresses on the platelets [4]. In order to analyze the impact of device orientation, the skirt and leaflets were rotated by 24 ° increments

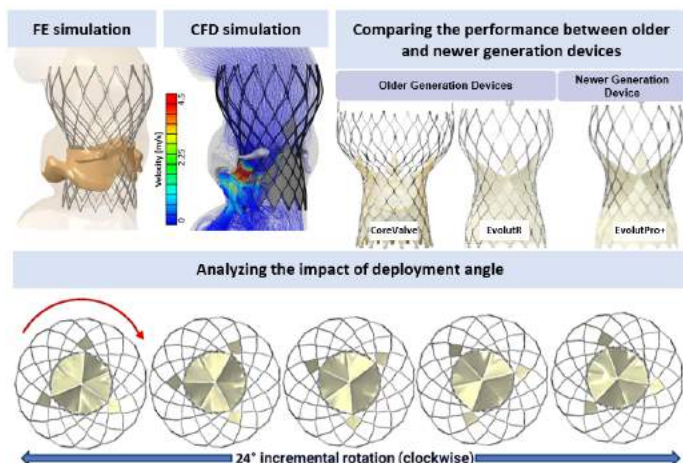

Figure 1: (Top row) – FE simulation of TAVR procedure, CFD simulation of PVL analysis in BAV patients and, comparing the performance between older and newer generation devices (Bottom row) –as a function of the device radial orientation

from the initial configuration (R0), resulting in four additional configurations (R1, R2, R3 and R4). R0 marks the initial orientation with which clinical validations were performed in our previous study [5]. PVL and thrombogenicity analysis were performed for each orientation case. All the in-silico steps were repeated in each patient model using newer generation device (Evolut Pro+).

RESULTS

In patient 1 CoreValve cases, the PVL volume difference between the worst and the best configuration was 22 mL/beat (Figure 2, table 1),

Table 1: Variation in PVL volume with device orientations

		Regurgitant volumes [mL/beat]					Average regurgitant volume
		R0	R1	R2	R3	R4	
Patient 1	CoreValve	17.87	6.86	9.11	26.31	28.89	17.81 mL/beat
	Evolut Pro+	11.17	2.88	4.42	19.56	21.16	11.84 mL/beat
Patient 2	CoreValve	28.49	28.16	28.14	26.43	17.84	25.81 mL/beat
	Evolut Pro+	1.83	1.82	1.62	0.93	0.50	1.34 mL/beat
Patient 3	Evolut R	1.1	0.71	0.67	0.65	0.63	0.75 mL/beat
	Evolut Pro+	0	0	0	0	0	0 mL/beat

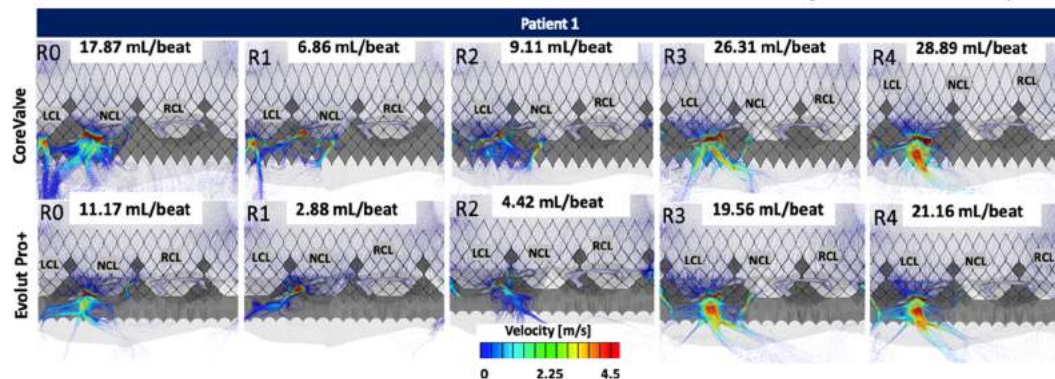

Figure 2: (Polar representation of CFD simulations) Velocity streamlines from peak diastole, highlighting the variation in PVL locations and severity with different generations and orientations of SE devices (NCL – non-coronary leaflet, LCL – left coronary leaflet, RCL – right coronary leaflet

which went down to 18.3 mL/beat for Evolut Pro+ cases. In patient 2 CoreValve cases, the PVL volume difference between worst and best configuration was 10.7 mL/beat, which went down to 1.3 mL/beat for Evolut Pro+ cases. The average regurgitation volume decreased significantly with Evolut Pro+ device, in both patient 1 and 2 (Table 1). In patient 3 Evolut R cases, the PVL volume differed by ~0.5 mL/beat between the worst and the best configuration (table 1). There was virtually no leak channel associated with any Evolut Pro+ orientation in this patient. All the patients have demonstrated an overall decrease in thrombogenic risk with the implantation of newer generation device (Figure 3).

Figure 3: Probability density functions of accumulated stress values on platelets, comparing the PVL flow-induced device thrombogenicity in one patient

DISCUSSION

This study highlights the importance of understanding the complex device-tissue interaction in BAV patients and how they get impacted by different procedural factors, affecting the post-TAVR outcomes. In all the patient cases, deployment of newer generation device demonstrated significant improvement in PVL complications regardless of the device orientation. This trend supports the effectiveness of design improvement in newer generation Evolut Pro+, which is marked by an outer pericardial skirt. While major leak channel locations were consistent in all patients, PVL volume varied with different device and orientation. In patient 1, simply changing the orientation decreased the PVL complications significantly, regardless of the device generation. Whereas in patient 2, implantation of newer device rather than modified orientation, improved the PVL. These observations indicate a complex relationship between the device and the native aortic root features, which determines the origin, flow path and severity of the PVL. Clinicians may find it challenging to predict the variations in possible outcomes, which emphasizes the significance of using personalized computational modeling approach during pre-TAVR planning, especially in complex BAV anatomies. Future study will focus on including additional patients with balloon-expandable devices, analyzing the impact of additional deployment parameters on PVL and other complications and finding optimum set of parameters based on the patient anatomies. An engineering design challenge that should be addressed in future study is - developing a delivery profile that allows complete re-orientability of the TAVR device, which will fulfill the translational potential of this study.

DMSO-FREE CRYOPRESERVATION OF MAMMALIAN CELLS USING AGAROSE HYDROGEL ENCAPSULATION

M Wang (1), A Mahajan (1), A Aksan (1)

(1) Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota
55455, United States

INTRODUCTION

With the rapid development of immunotherapy and regenerative medicine, there has been an urgent need to improve both the efficiency and safety of cell/tissue cryopreservation methods. During freeze/thaw, mechanical, thermal, and osmotic stresses associated with ice formation may cause damage and compromise cell function and viability. To minimize cryoinjury, cryoprotectant agents (CPAs) such as dimethyl sulfoxide (DMSO) are widely used. As a membrane-permeable CPA, DMSO can diffuse into cells and thus inhibit both intra- and extracellular ice formation during cryopreservation. However, DMSO is toxic. Also, mild to severe side effects have been reported for patients who were injected with therapeutic products cryopreserved with DMSO.

In recent years, hydrogel encapsulation has been proposed as a strategy for the cryopreservation of mammalian cells.^[1,2] Encapsulation of cells in hydrogels before freeze/thaw has shown the advantage of maintaining high post-thaw cell survival while decreasing the need for using higher concentrations of membrane-permeable CPAs.^[2,3] Two hypotheses for the protection offered by hydrogel encapsulation have been proposed through observations made in transmitted light cryomicroscopy experiments: (1) hydrogel enables vitrification of cells through inhibition of extracellular/intracellular ice crystallization during cooling, and (2) hydrogel inhibits devitrification and ice recrystallization during warming. However, these hypotheses have not been validated using thorough thermodynamic and kinetic analyses.

In this work, our objective is to develop a cryopreservation method for mammalian cells using agarose hydrogel encapsulation, eliminating the need for toxic membrane-permeable CPAs such as DMSO. As the sole CPA, trehalose was incorporated into the agarose solution before gelling to enhance the cryoprotective effect of the hydrogel matrix. We used MDA-MB-231 cells as a model. Also, we characterized the thermodynamics and kinetics changes of the hydrogel matrix with trehalose during freeze/thaw using Fourier Transform Infrared Spectroscopy (FTIR) and Differential Scanning Calorimetry (DSC) to establish the physicochemical mechanisms of cryoprotection offered by hydrogel encapsulation.

METHODS

(1) Hydrogel encapsulation

To encapsulate in an agarose-trehalose hydrogel, MDA-MB-231 cells were first suspended and incubated in a cell culture medium containing 10%, and then in 20% trehalose for 15 minutes. Stepwise exposure was conducted to minimize hyperosmotic stress on the cells. To encapsulate the cells in an agarose hydrogel, the cell pellet was resuspended in 1xPBS agarose solution containing trehalose at 37°C to achieve a cell concentration of 10⁷ cells/ml. The solution was gently and

thoroughly mixed in a microtube and then stored at 4°C to induce gelation.

(2) Freeze/thaw protocol and post-thaw viability measurements

The hydrogel with encapsulated cells was cooled down from 10°C to -150°C at a rate of 2°C/min. Once the temperature reached -150°C, the sample was rapidly rewarmed to room temperature at a warming rate of 100°C/min. Post-thaw viability of the encapsulated cells was measured using acridine orange (AO)/propidium iodide (PI) fluorescent dyes. The live (green) and dead (red) cells in the sample were counted in five representative areas for each sample, and the final percent viability was calculated with respect to the freshly harvested MDA-MB-231 cells.

(3) Differential Scanning Calorimetry (DSC) analysis

To prepare DSC samples, 2-10 mg solution or hydrogel was weighed in a Tzero hermetic pan and sealed with a lid. Each sample was initially cooled from room temperature to -150°C at 2°C/min, then heated back to 10°C at 2°C/min.

(4) Fourier Transform Infrared Spectroscopy (FTIR) analysis

0.1-1 µL of experimental and control samples were first cooled from 10°C to -150°C at a rate of 2°C/min, then warmed back to 10°C at 2°C/min, following the identical freeze/thaw protocol used in the DSC analysis. Infrared (IR) spectra were collected every 2°C, and 64 IR scans at a resolution of 4 cm⁻¹ were averaged in 9000 to 900 cm⁻¹ wavenumber range to obtain each spectrum. Changes in the ν-(OD) band (2500 cm⁻¹), δ-(OH) band (1650 cm⁻¹), and the glycosidic band (995 cm⁻¹) were examined as the sample was cooled and warmed.

RESULTS

(1) Post-thaw viability of cells encapsulated in agarose hydrogel with trehalose

Table 1. Viability of MDA-MB-231 cells cooled at 2°C/min to -150°C, and warmed at 100°C/min to 10°C

Sample	Normalized Viability (%)
1xPBS	0.4 ± 0.3 %
10% DMSO	70.9 ± 3.6 %
20% trehalose	28.7 ± 7.2 %
0.75% agarose	15.8 ± 3.6 %
0.75% agarose + 20% trehalose	78.7 ± 3.4 %

The viability of MDA-MB-231 cells frozen/thawed in different samples is shown in Table 1. Poor survival was observed when the cells were frozen and thawed in the presence of trehalose or encapsulated in agarose hydrogel alone. However, when MDA cells were encapsulated and frozen/thawed in 0.75% agarose hydrogel with 20% trehalose, the

post-thaw cell viability increased significantly (to $78.7 \pm 3.4\%$), which is comparable to the positive control group, where cells were frozen in a PBS solution that contained 10% DMSO ($70.9 \pm 3.6\%$).

(2) Identifications of the thermodynamic and kinetic transitions in agarose hydrogels during freeze/thaw

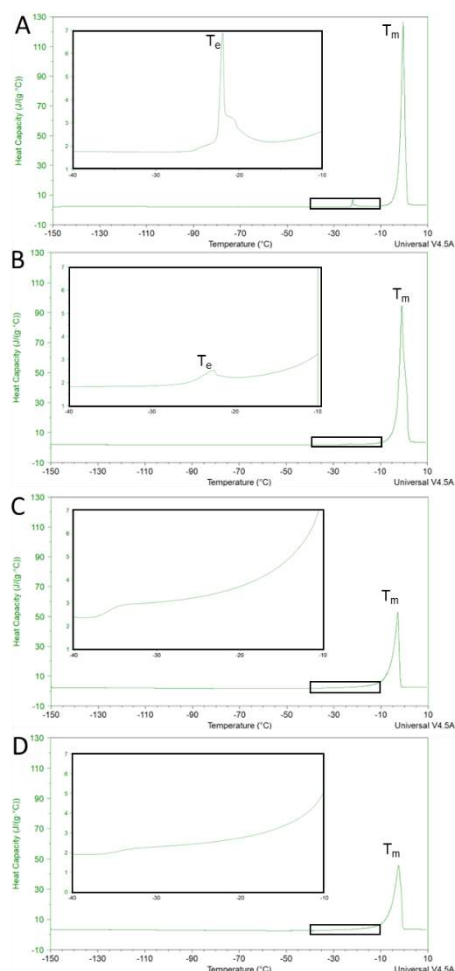

Figure 1. DSC warming scans of (A) 1xPBS solution, (B) 2.5% agarose in 1xPBS, and (C) 20% trehalose in 1xPBS and (D) 2.5% agarose + 20% trehalose in 1xPBS. (T_e : eutectic melting temperature, T_m : ice melting temperature)

The large endothermic peak around 0°C shown in each DSC scan corresponds to the melting of ice (T_m), and the area under the endotherm peak (heat of fusion, ΔH) is proportional to the total amount of ice crystals formed during cooling. The decrease of ΔH (from Figure 1A to Figure 1D) indicates that less amount of ice crystallized during cooling in the combination system of agarose and trehalose. On the other hand, the small endothermic peaks around -22°C seen in the 1xPBS (Figure 1A) and 2.5% agarose (Figure 1B) samples correspond to the eutectic melting of $\text{NaCl}\cdot 2\text{H}_2\text{O}$ -ice in the PBS solution.^[4] The significant decrease in eutectic melting peak in Figure 1B indicates that agarose hydrogel inhibited the eutectic crystallization/melting of PBS during the freeze/thaw process. Furthermore, no eutectic melting peak was observed in the sample with trehalose (Figure 1C and Figure 1D), suggesting that trehalose eliminated the eutectic crystallization/melting

of PBS and therefore minimize related kinetic/mechanical damage on cells during cryopreservation.

Figure 2. Peak shift of the glycosidic band ($\sim 995\text{ cm}^{-1}$) during cooling (blue) and warming (red) processes of 20% trehalose (A) and 4% agarose + 20% trehalose (B).

To investigate the water-trehalose and trehalose-trehalose HB interactions during the freeze/thaw event, temperature-induced shift of the trehalose glycosidic linkage peak was analyzed. During the warming process, three transitions were observed in the plots. The first transition located around -45°C corresponds to the glass melting temperature of the freeze concentrate liquid (FCL) in the sample.^[5] Similarly, a significant increase of peak shift was observed after the third transition, corresponding to the melting of the bulk ice. Transition 2 is a non-equilibrium process, and it only occurs in the temperature range between T_g and T_m , which corresponds to ice recrystallization. Therefore, the significant decrease of ΔR (the magnitude of ice crystallization) from 20% trehalose (Figure 2A) to 4% agarose + 20% trehalose (Figure 2B) indicates that the ice recrystallization was greatly inhibited by agarose in the combination system during warming.

DISCUSSION

Here, we report a hydrogel encapsulation method using agarose and trehalose for cryopreservation of MDA-MB-231 cells. The results demonstrate that the encapsulated cells were well protected from kinetic mechanical damage during the freeze/thaw process, as reflected by very high viability post-thaw even in the absence of DMSO. Through the identifications of the thermodynamic and kinetic transitions in agarose hydrogels during freeze/thaw, the mechanisms of cryoprotection offered by agarose encapsulation in the presence of trehalose can be attributed to: 1) agarose hydrogel encapsulation decreases the amount of ice formed in the combination system. 2) Ice recrystallization during warming is inhibited when water molecules are confined in the agarose hydrogel. 3) the eutectic crystallization/melting of PBS can be eliminated in the presence of trehalose.

INTRODUCTION

The facet capsule is a common source of pain in the neck and low back [1,2]. The capsular ligament is primarily composed of collagen fibers arranged in an extracellular matrix (ECM) network with afferent neurons embedded in that ECM [3,4]. Injury and/or damage to the capsular ligament can induce laxity and collagen disorganization in the ligament [5,6] and can induce pain and injury responses in afferent nerve fibers via mechanotransduction [1,7,8]. ECM biomechanics are not only associated with neuronal physiological responses, but such neuronal regulatory pathways are activated when strains exceed thresholds [9,10]. Both neuronal upregulation of phosphorylated ERK (pERK) and NMDA receptors, like the NR2B subunit, which are related to neuroplasticity and dysfunction, are sensitive to local strains [9,10]. In fact, pERK is not only correlated with tissue-level strains but the strain threshold (11.7%) for its increase corresponds to that strain at which collagen fiber reorganization occurs (11.3%) [9]. While that study found no difference in pERK expression following distractions sufficient to produce pain applied at 0.5mm/s or 3.5mm/s [9], those loading rates only vary by 7-fold. Yet, the biomechanical response of ligaments varies with loading rate [11-14], neuronal injury is rate-dependent [15-18], and higher rate loading affects matrix kinematics and kinetics [19]. If and how, a higher rate of loading alters the threshold for neuronal pERK activation has not been examined.

Our neuron collagen gel construct (NCC) in vitro platform enables the integrated investigation of macroscale and local mechanics, along with neuronal responses, and has been used to define relationships between local mechanics, collagen fiber responses and neuronal mechanisms relevant to nociception [9,10,20-22]. While most work with the NCC system to date has been limited to a slow strain rate (i.e. 1%/s) [9,10,20-22], ligament trauma occurs at much faster rates [13]. Tensile loading at 127%/s not only increases the failure force and stiffness, but also doubles the extent of collagen realignment over those responses observed for 1%/s [9,19,20]. Since neuronal responses may

similarly be differentially modulated by loading rate, this study extends that high rate tensile study of NCCs to characterize the neuronal pERK response to tensile failure loading at 10.5mm/s. Regional strains are also integrated with neuronal pERK expression to define a strain threshold for neuronal activation [9,10] after a high rate NCC failure [19].

METHODS

NCCs (n=6) were prepared using 2.0mg/mL of rat tail collagen I solution cast in 12-well plates [9,19-22]. Collagen gels self-assembled at 37°C in 5% CO₂ for at least 45mins and were seeded with DRG neurons (3x10⁵cells/mL) dissociated from embryonic day 18 rats [9,10,19]. Collagen was added after 3 days in vitro to encapsulate the neurons. Four days later, NCCs were transferred to sterile PBS and cut into a strip (21mm x 8mm). A grid was drawn on each NCC surface to facilitate elemental strain analyses (Figure 1). NCCs were affixed to a planar testing machine (TestResources) that was integrated with a high-speed camera (Phantom-v9.1; Vision Research), and gels were submerged in a 37°C PBS bath [9,19-22]. NCCs were stretched to failure with each arm distracted at 10.5mm/s. Force and displacement data were recorded at 500Hz; high speed imaging (500fps) was acquired and synchronized with the force and displacement data [19].

Force and displacement data were filtered using a 25-point moving average filter [9,20-22]. Failure was defined as the peak of the force-displacement curve for each loading arm. Each of the failure force and displacement was averaged across both arms for each NCC. Each NCC was marked with fiducial markers to define elemental nodes (Figure 1) and the nodal displacements were measured using ProAnalyst software (Xcitem). Those nodal displacements were input into LS-DYNA (LSTC) to compute the mean maximum principal strain (MPS) for each element and averaged across all elements for each NCC (Figure 1) [9,20-22].

NCCs were incubated for 24hrs after loading in warm culture medium supplemented with 1% Pen-Strep [10] and then fixed in 4% paraformaldehyde for immunolabeling of pERK and β III-tubulin. Matching unloaded gel samples (n=6) were similarly fixed and labeled

to serve as controls for analyses. Fixed NCCs were blocked using 10% normal goat serum with 0.3% Triton X-100 in PBS for 2hrs and treated with rabbit anti-pERK antibody (1:200; Cell Signaling) and mouse anti- β III-tubulin antibody (1:200; Biolegend) overnight at 4°C to label pERK and neurons, respectively [9]. After PBS washes, NCCs were incubated for 2hrs in goat anti-rabbit AlexaFluor647 (1:500; Invitrogen) for pERK and goat anti-mouse AlexaFluor568 (1:500; Invitrogen) for β III-tubulin. Images (3-6) were taken within each element of each NCC as defined by the markers (Figure 1) using a Leica TCS SP8 confocal microscope at 63X. Quantitative densitometry was used to determine the percent of pixels positive for pERK that were colocalized with β III-tubulin and averaged across images in each element [10]. The response of loaded NCC elements was assigned a value of 1 if expression levels were greater than the mean level plus one standard deviation in the matching unloaded control gel; an element was assigned 0 if expression in a loaded NCC element was less than or equal to that value [9,10].

Figure 1. MPS map and immunofluorescent images of NCC (#14) showing (A) elemental strain map at failure and confocal images from Element 6 (circled in A) for (B) pERK and (C) β III-tubulin. Their colocalization is in (D) with scale that applies to all panels.

RESULTS

The measured displacement rate across all NCCs is 7.9 ± 0.3 mm/s, corresponding to a strain rate of $122 \pm 16.5\%$ /s. At that rate of applied stretch, NCCs failed at 23.1 ± 16.4 mN and a corresponding displacement of 4.4 ± 0.5 mm. The mean elemental MPS at failure is 0.33 ± 0.07 . The pERK expression at 24hrs increases by approximately 2.5-fold to 1.02 ± 1.22 over expression in unloaded controls (0.40 ± 0.47). Corresponding colocalized neuronal pERK is generally unchanged after loading (0.95 ± 1.6 fold greater than unloaded controls). Logistic regression of the binarized neuronal pERK is significant ($p=0.005$) against elemental MPS and predicts a 50th-percentile threshold of 55.7% (95% confidence interval: 55.6-56.6%) and 95th-percentile threshold of 78.7% (95% confidence interval: 76.7-78.9%) (Figure 2).

DISCUSSION

This is the first study to define the relative levels of pERK expression after a tensile failure at a rate ($122\%/s$) consistent with that of ligament trauma. Indeed, the force at failure is comparable to that previously reported for similar loading conditions (26.5mN) and twice that using the same NCC system used here (12.6mN) at a measured strain rate much lower ($1\%/s$) than the rate used here [19,22]. The displacement at failure is similar regardless of the strain rate (4.68 ± 1.6 mm for $1\%/s$; 4.35 ± 1.1 mm for $122\%/s$) [19,22]. Interestingly, the mean MPS (0.33 ± 0.07) is higher than the average MPS (0.12 ± 0.07) found using a $1\%/s$ distraction rate [22].

Figure 2. Logistic regression of binarized pERK colocalized with β III-tubulin against elemental MPS. The predicted 50th-percentile and 95th-percentile thresholds for increases are 55.7% and 78.7%.

Consistent with increased failure forces and strains at this higher strain rate, the strain thresholds for pERK activation are also about 5-times higher than for the lower rate, with prior work identifying thresholds of 11.7% for 0.5 mm/s and 10.2% for 3.5 mm/s [9]. Those thresholds aligned with the transition point for collagen activation at 11.3% [9], suggesting that altered collagen fiber kinematics are associated with mechanotransduction signaling in neurons. Of note, that prior study did not stretch NCCs to failure, but to a degree known to generate pain with corresponding mean elemental MPS of 0.15-0.17 [9], which would skew the threshold lower. While analyses of the relationships between MPS and CV have not been performed at the faster loading rate in this study, CV values increase 10-fold after failure [19]. Additional studies defining relationships between strain, collagen alignment, and neuronal morphology and health are important in understanding trauma-related insults.

Since neuronal responses are known to be rate-dependent [15-18], it is not surprising that there is a lack of pERK upregulation despite a prior report of significant increases [9]. Notably, that response was detected immediately after loading, but was also found to correlate with MPS. Additional work is needed to better understand the relationship between rate of loading, its severity and the time after exposure, as well as additional physiological responses suggestive of injury, dysfunction and excitability, particularly for painful injury.

INTRODUCTION

The nervous system comprises many neurons with different morphologies [1]. A typically-developed neuron roughly consists of a soma/cell body, dendrites, a single axon, and synapses [2]. Neural dendrites are tree-like protrusions from the soma and receive incoming electrical signals from other neurons' synapses. The axon also protrudes from the soma. At the other end of the axon are synapses, where the fired electrical signal goes across and passes down to the subsequent neurons.

Neural dendrites, in particular among other neural components, are highly distinctive for their intricate morphologies, which perform vital functionalities and bring a sense of beauty. Its signature branching feature allows multiple connections between neurons, thus facilitating high connectivity in our brain [3]. The question of how neural dendrites morphology is formed needs to be better understood. This work aims to elucidate this myth via mathematical modeling and numerical simulation.

A critical feature of neural dendrite morphology is "tiling" – nonredundant innervation of a receptive area by the same type of neurons – which serves a universal organizing principle across the species. Experiments have shown that similar visual neurons in rabbits form their territory and barely overlap [4]. It makes functional sense because this arrangement allows the incoming light to fall onto visual neurons with as many types as possible. As for now, the molecular basis of "tiling" is still under debate, and no popular paradigm has been formed.

Many extrinsic factors could also influence dendrite growth. Endogenous electric field, in particular, changes in space and time throughout embryonic development, and such endogenous electrical cues influence neuronal migration [5]. Early work showed that neurites in embryonic chick grow faster towards the cathode than the anode in an applied electric field [6].

In this work, we propose a multi-physics model that captures the neural dendrite growth polarized by external electrical stimuli via an advective diffusion-reaction system and implement it by writing a user element subroutine (UEL) for the finite element program Abaqus/Standard [7]. Furthermore, we set up a convolutional neural network to identify physical parameters inversely from real neuron images.

METHODS

Evolution of neural dendrite: To capture the essence of the dendrite growth, we borrowed the idea of the Gray-Scott model and incorporated an advection term for electrical polarization [8, 9],

$$\begin{cases} \dot{u} = D_u \nabla^2 u - uv^2 + F(1 - u), \\ \dot{v} + \sigma \mathbf{E} \cdot \nabla v = D_v \nabla^2 v + uv^2 - (F + k)v, \end{cases} \quad (1)$$

where u and v are two diffusive morphogens that interact with each other through diffusion and reaction, D_u and D_v are diffusivities, F and k are "feed" rate of u and "kill" rate of v , respectively. Additionally, the parameter σ in Eqn. (1) controls the strength of the polarization induced by electric field \mathbf{E} .

Next, we use a phase variable c to track regions occupied by the neural dendrite, the evolution of which is given by

$$\dot{c} = \gamma c(a(v) - c)(c - 1), \quad (2)$$

where γ is a rate constant, $a(v)$ serves as a saddle point, at which the dynamic response of phase variable c flips.

Gauss's law: As a simplification, we treat the brain tissue as the dielectric material; thus, the governing equation of the applied electric field is given by

$$\nabla \cdot \mathbf{E} = 0, \quad (3)$$

where the electric field is given by the negative of the gradient of the electric potential $\mathbf{E} = -\nabla \Phi$.

Finite-element implementation: Our coupled system was numerically implemented in Abaqus/Standard [7] by writing user-defined element (UEL) subroutines, following our previous work [10].

Inverse pattern recognition via convolutional neural network To inversely obtain parameters of F and k from real neural dendrite images, we utilized a convolutional neural network (CNN) as a surrogate model and trained with our finite-element simulations.

RESULTS

We explored the impact of various material parameters, including diffusivity ratio D_u/D_v and rate constant pair (F, k) , on neural dendrite growth *without* any applied electric fields. We first varied the diffusivity ratio D_u/D_v while fixing the rate constant pair and then vice-versa. It shows that vibrant patterns emerge when $D_u/D_v \approx 3$, and the number of branching increases with an increasing diffusivity ratio. Next, holding at a constant $D_u/D_v = 3$, the simulated phase field variable c confirmed that intricate patterns emerge along the bifurcation curve $F = 4(F + k)^2$ (Figure 1, left). Various representative patterns in $F - k$ space have been identified and dubbed with fancy names [11].

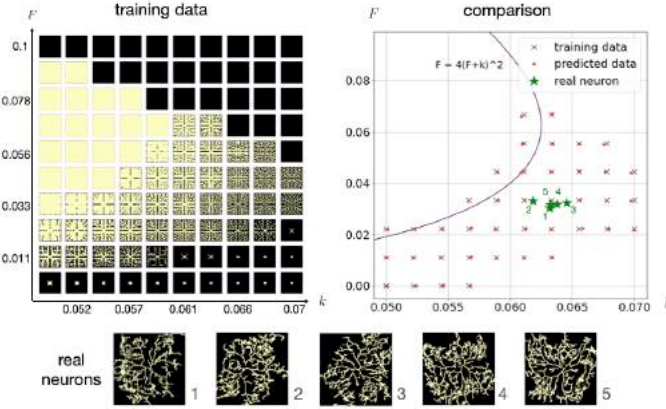

Figure 1: Results of inverse neural dendrite pattern detection via CNN.

To relate our model to real-world problems, we first trained a CNN with our simulated phase variable c covering a labeled parameter space of $k \in [0.05, 0.07]$ and $F \in [0, 0.1]$ (Figure 1, left). The fully-trained CNN can replicate the original model and give reasonable predictions of five real IV neural dendrites in drosophila larva (Figure 1, right and bottom). As we expected, our model resembles branching in real neurons.

Our model can also reproduce features of space-filling and self-avoidance. We simulated neural dendrite growth on ideal geometries with multiple soma seeds. Two neurons in the oval domain formed a “flat” boundary in between, while the pentagon domain with five neurons formed a pentagonal “pizza” (Figure 2).

Figure 2: The interactions between morphogen u and v accomplish features of space-filling and self-avoidance.

It has been reported that polarizations of neural dendrites could be guided by stimuli, such as chemo-attractant gradients, electric fields, and mechanical deformations [12–14]. Here we focus on simulating electric field-induced polarizations. We considered two different electrode setups in which the anode and cathode have potentials of $\Phi = \pm 75$ mV, respectively (Figure 3). As expected, our electrode setups yield highly inhomoge-

neous electric potential distributions. The neural dendrites’ growth aligns with the electric field \mathbf{E} (red unit vectors) pointing toward the cathode.

Figure 3: 3-D Simulation of neural dendrites growth with electrical polarization.

DISCUSSION

In this work, we have developed a multi-physics model for neural dendrite growth with electrical polarization. The model is a coupled PDE system that combines an advective Gray-Scott model with Gauss’s law. We have implemented it numerically in Abaqus/Standard [7]. The results show that our model accounts for critical features of branching, space-filling, self-avoidance, and polarization under the applied electric field. Additionally, we have set up a CNN pipeline for real neural dendrites pattern detection.

Looking toward the future, much has to be done to advance our understanding of the process and refine our mathematical formulations. Well-designed experiments are needed to confirm the underlying mechanism, such as the specific genes and pathways involved in the process. Additionally, we will incorporate other external stimuli, such as gradients of chemo-attractants and mechanical environments, into our multi-physics modeling endeavors.

A SINGLE-SENSOR APPROACH FOR TRACKING PHASE VELOCITY AS A PROXY FOR IN VIVO TENDON LOADING

INTRODUCTION

Shear wave tensiometry uses external excitation and skin-mounted accelerometers to noninvasively measure tension in soft tissues [1]. This exciting new technology holds promise in many clinical applications, ranging from intraoperative monitoring of ligament forces to evaluating functional tendon recovery through rehabilitation [2]. There are two notable challenges limiting the use of tensiometry. The first challenge is dispersion, or the frequency dependent nature of wave propagation in layered media, which is prevalent in soft tissues [3]. Our current approach tracks the waves emergent from an impulsive excitation. However, as inherent tissue stiffness modulates with loading, the system resonance changes as well. Consequently, dynamic loading conditions during movement cause changes in the dominant wave frequencies and could introduce variability into the measured wave speeds. A second challenge is that the overall footprint of the device (~30 mm) is not suitable on ligaments and tendons with short free lengths. The footprint size is predicated by the need for two accelerometers, which are used to monitor wave travel time between two fixed locations. This study investigated the use of a shaped excitation waveform to measure phase velocity at a prescribed dominant frequency using a single sensor.

METHODS

Shear waves were excited in the Achilles tendon using a miniature surface transducer (Fig. 1a). The input excitation ψ was an amplitude modulated harmonic wavelet:

$$\psi = \begin{cases} A \cdot \sin(\omega_A t) \cdot \sin(\omega_H t + \varphi) & \text{for } 0 \leq t \leq t_0 \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

where A is the excitation amplitude and ω_H is the dominant wavelet frequency. Amplitude modulation frequency ($\omega_A = \omega_H/7$) and wavelet duration ($t_0 = 3.5 \cdot (2\pi/\omega_H)$) produced a seven-lobe wavelet (Fig. 1b).

Surface mounted accelerometers (PCB Piezotronics, Depew, NY) were used to measure the wave propagation along the tendon (Fig. 1a). The envelope of the measured acceleration was computed via Hilbert

transform [4]. The envelope and intact signal were then used to compute the group and phase arrival times of the shear wave, respectively, by correlating the ideal input as defined in Eq. 1 with the measured signal [5]. Kalman filters were implemented for group and phase arrival times, with *a priori* estimates based on the changes in arrival time between consecutive excitations [6]. Phase velocity for the shear wave was computed from the known distance from the transducer (20 mm) to the accelerometer and the arrival times. A frequency-based excitation latency was determined via a system response characterization (Fig. 1c).

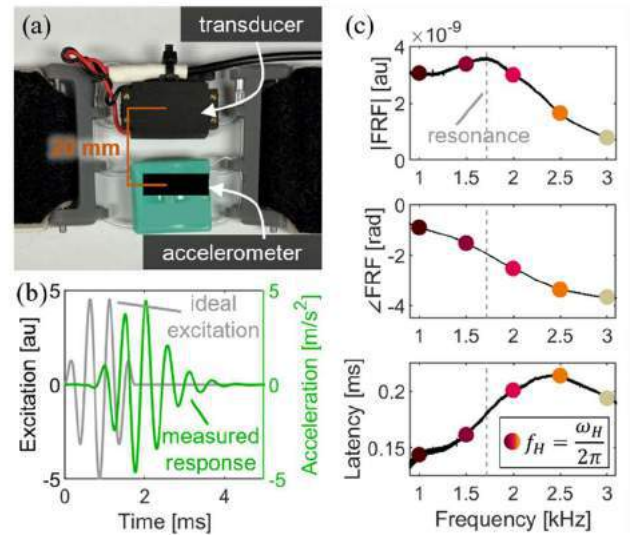

Figure 1: (a) Shear wave tensiometry was performed using only the first sensor in a standard two-sensor device. (b) Example of the input modulated harmonic wavelet and measured response. (c) Measured frequency response of the transducer.

Two healthy young adults (1F/1M) were recruited to participate in the study (2018-0487-CP019). The tensiometer was placed over the right Achilles tendon. The test conditions included 3 walking speeds (1.33, 1.67, 2 m/s) and 3 running speeds (2, 2.33, 2.67 m/s) with the wavelet frequency f_H set to 2 kHz. Additionally, f_H was varied from 1-3 kHz in 500 Hz increments at the 1.33 m/s walking speed. Wave speed profiles were ensemble averaged across multiple (15-26) strides per trial. Statistical significance was tested using ANOVAs ($p < 0.05$). Significant results are in **bold**.

RESULTS

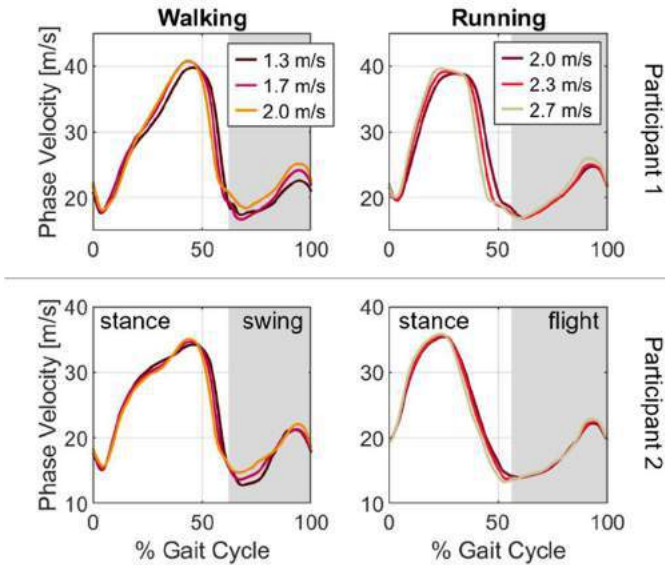

Figure 2: Phase velocity across speeds for each participant.

Phase velocity modulated with load in walking and running (Fig. 2). Peak phase velocity during stance showed a minor increase with walking speed (**2.5-2.6%**) and running speed (**0.4-1.7%**). Only participant 2 showed a significant increase in peak velocity from walking to running.

Figure 3: (a) Phase velocity for walking at 1.33 m/s. (b) Peak phase velocity vs. the dominant wavelet frequency f_H .

The computed phase velocities were frequency dependent, consistent with the dispersive nature of biological tissues [7]. Most notably, an increase in the excitation frequency resulted in an increase in the magnitude of the peak phase velocity, which varied by 25 m/s across the excitation frequencies considered (Fig. 3).

DISCUSSION

This study introduces a promising single-sensor approach for tracking tendon phase velocity during dynamic movement. Wave speed profiles were consistent with stance phase ankle torque measured via inverse dynamics and wave speeds measured with a two-sensor approach [1,8]. Peak wave speeds tended to increase with speed for a fixed locomotion pattern, though changes were relatively small and did not change substantially between walking and running [9]. From a tensioned beam model [1], tendon force scales with wave speed squared such that the relative changes in force may be greater than the change in wave speed. It is also worth noting that tensiometry is designed to monitor loading in specific tendons, whereas net ankle torque superimposes contributions from all agonistic and antagonistic muscles active about a joint. Hence, wave speed can modulate with locomotion speeds differently than torque.

The tendons exhibited dispersive behavior as expected for soft tissues. Peak wave speeds increased with wavelet excitation frequency for both participants. Analytical models of wave propagation suggest that wave speed can increase with frequency due to wave-guided behavior [3] or the viscoelastic nature of the tissue [7]. Data collected above f_H of 2.0 kHz yielded the most consistent results. This is likely due to the physical constraints of the device implementation, as well as the transducer resonances. Further investigation is needed to determine if there is a single optimum frequency in this range, or whether the best choice for ω_H is device and individual specific.

A primary outcome of this study is the single-sensor tensiometer that may greatly expand the range of ligaments and tendons that can be monitored. The footprint of the device on the tendon is reduced by ~30%, allowing the tensiometer to be used on children and shorter structures such as quadriceps and hamstring tendons. Additionally, since the wave speeds can be computed using only one sensor close to the excitation source, the overall signal to noise ratio should be higher. Finally, the hardware resources required to acquire the necessary data to perform tensiometry are essentially halved. This further expands on the potential of this implementation to simultaneously quantify the loading patterns on multiple tendons using fewer resources.

To conclude, we have demonstrated a single-sensor approach to shear wave tensiometry which can noninvasively track tendon wave speeds under dynamic loading conditions. We believe this advance could significantly expand the use of tensiometry for biomechanical studies, and in orthopedic and rehabilitation applications.

INTRODUCTION

Mesenchymal stromal or stem cells (MSC) are one of the most promising candidates for a myriad of cell therapy applications because of their multipotency, trophic properties and immunomodulatory properties. Despite showing promises in numerous preclinical and clinical studies, MSC based therapy is not yet a reality for regenerative medicine due to their suboptimal outcome at the clinical endpoint. Suboptimal function of MSC is often attributed to the monolayer expansion process on cell culture plate, which is a necessary condition to reach the therapeutically relevant number, and also to their response to a fibrotic environment post transplantation. In both scenarios of plastic culture and fibrotic conditions, the substrate mechanical stiffness experienced by the MSC is completely different from the natural mechanical niche of the MSC. Accordingly, the role of mechanical environment has been shown to be a critical determinant of MSC gene expression, function, and heterogeneity as shown by the work from our group and other groups [1, 2]. Despite several mechanisms that have been proposed to explain how the MSC gene expression is affected by the substrate mechanical stiffness, new mechanisms that involve the epigenetic modifiers are emerging [3].

In this present study we investigated how the chromatin architecture, specific histone modifiers and chromatin remodelers in bone marrow-derived MSC are affected by the substrate mechanical stiffness over multiple passages. Subsequently, we show preliminary evidence that targeting the epigenetic mechanism of histone modification and chromatin remodeling in MSC can enhance their functionality, as shown by the enhanced gene expression of the Vascular Endothelial Growth Factor (VEGF).

METHODS

Design of experiment: Soft substrates mimicking the bone marrow is known to maintain the MSC phenotype over multiple passages. P3 MSC (Lonza) were seeded on mechanically soft (sylgard 527 PDMS) or stiff (plastic) substrate until P5 in order to understand how chromatin

architecture changes over passing in a stiffness-dependent manner (Figure 1A). Cells were cultured in a petri dish (with or w/o PDMS) for passing and on ibidi 8-well plate (with or w/o PDMS) for imaging.

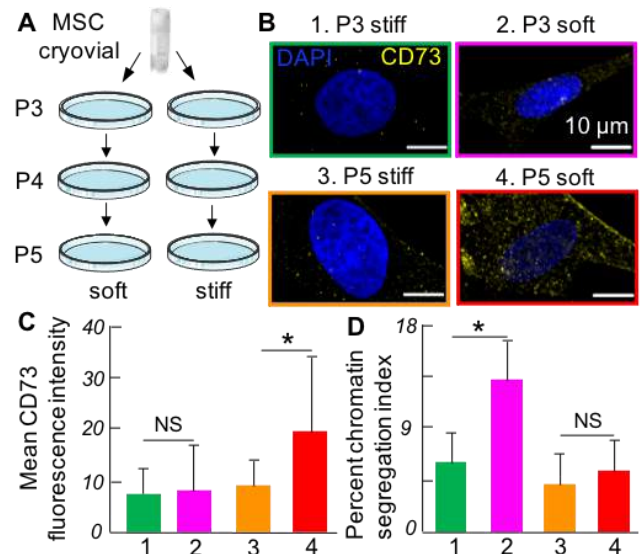

Figure 1: (A) Passaging of MSC on a soft and a stiff substrate. (B) Images of chromatin and MSC-specific marker CD73. (C) CD73 expression increases but (D) chromatin is less segregated in MSC on the soft substrate at the later passage. (* $p < 0.001$, $n > 20$ cells).

Immunofluorescence: Cells were fixed, permeabilized and blocked prior to antibody (Invitrogen) staining. Dilution of primary antibodies were as follows: CD73 - 1:100, ARID1A - 1:400, H3K9me3 - 1:400, H3K9Ac - 1:400. All secondary antibodies were used at 1:200 dilution. Cells were imaged across their midsection using a confocal microscope

(Zeiss LSM 980) using a 63X oil objective and the Airyscan mode. **Gene expression analysis:** All gene expression data was normalized to the reference genes *GAPDH*. Pre-designed and validated primers was purchased from IDT. **Statistical analysis:** Statistical analysis was performed using Student's t-test (RStudio). Results are expressed as mean \pm standard deviation. Sample and replicate numbers and p-values are provided in the figure legends.

RESULTS

The expression of MSC specific marker CD73 increases with priming on soft substrate (Figure 1B,C) but decreases with priming on a stiff substrate. Interestingly, although an open chromatin architecture, characterized by a higher chromatin segregation index (CSI), which is a hallmark of MSC, by passage 5, the CSI value was the same in cells on both substrate stiffness (Figure 1D). Therefore, in contrast to previous report [2], openness of the chromatin architecture is not the absolute phenotype of MSC stemness.

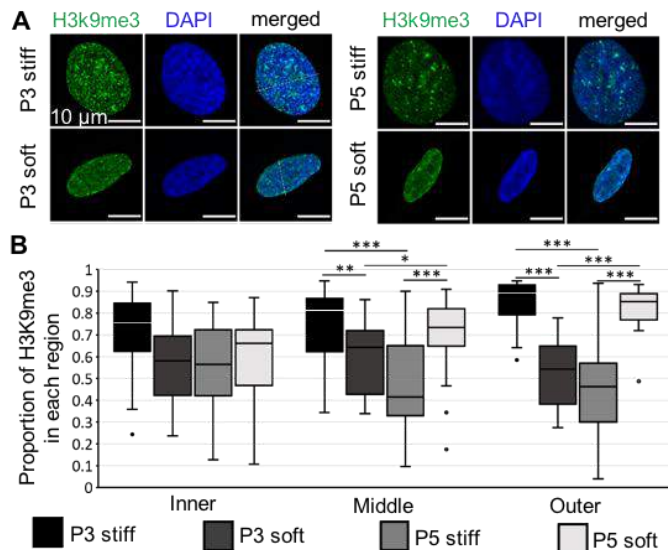

Figure 2: The repressive epigenetic marker H3K9me3 showed more peripheral enrichment on soft substrate in later passages compared to early passage. On stiff substrate, they are homogeneously located in the nucleus, with larger puncta size in later passages. *p<0.05, **p<0.01, *p<0.001. n>20 nuclei for each group.**

Loss of stemness and hence, transcription of genes is associated with global repression. Therefore, we investigated the expression and localization of the repressive epigenetic marker H3K9me3 in the nucleus. Interestingly, when we looked into the distribution of H3K9me3, we found that it was more localized in the nuclear periphery in soft substrate at passage 5, compared to passage 3 (Figure 2). For stiff substrates, H3K9me3 tends to be more localized as puncta in the entire nucleus and those puncta grew bigger over passing on the stiff substrate. Overall, a key finding was that MSC culture on soft substrate promotes the localization of H3K9me3 to the periphery, opening more regions inside the nucleus for gene transcription. Moreover, the intensity of the H3K9me3 remained the same on the soft substrate while they increased on stiff substrate by serial passaging. Overall, this data shows that H3K9me3 is a key driver of mechanics-mediated chromatin architecture and repressive status during serial passaging of MSC.

Histone acetylation and methylations are signatures of chromatin architecture status in MSC. However, it is not clear what really causes the chromatin architecture change. Of note, H3K9me3 showed more peripheral enrichment on the soft substrate, especially during serial passaging. This suggests that the chromatin is dynamic on soft substrate.

To investigate the possible cause of such dynamic chromatin architecture, we visualized ARID1A, the core subunit of the Chromatin Remodeling Complex (CRC) SWI/SNF. SWI/SNF is highly conserved in mammalian cells and has never been investigated before in the context of mechanobiology of MSC. We found that on soft substrate the intensity of ARID1A is high, but also, large clusters form, which further increases in the later passage (Figure 3B,C). On stiff substrate, the intensity is not only low, but also, they make smaller puncta which further decreases in size in later passages. We further found that the gene expression of several SWI/SNF CRC complex subunits also increased on soft substrate (Figure 3A). When the MSC on stiff substrate is treated with cytoskeletal mechanics disrupting drugs, their expression increases again, indicating a clear role of mechanics in the gene expression. Overall, this data suggests that SWI/SNF CRC-mediated chromatin remodeling is critical to maintain the stemness and to maintain the dynamic chromatin architecture for MSC on the soft substrate. Very interestingly, when MSC were treated with GSK126, an inhibitor of ARID1A, the dynamics of chromatin remodeling was stopped. As a result, even on a stiff plastic substrate the MSC secreted VEGF expression remains high (Figure 3D).

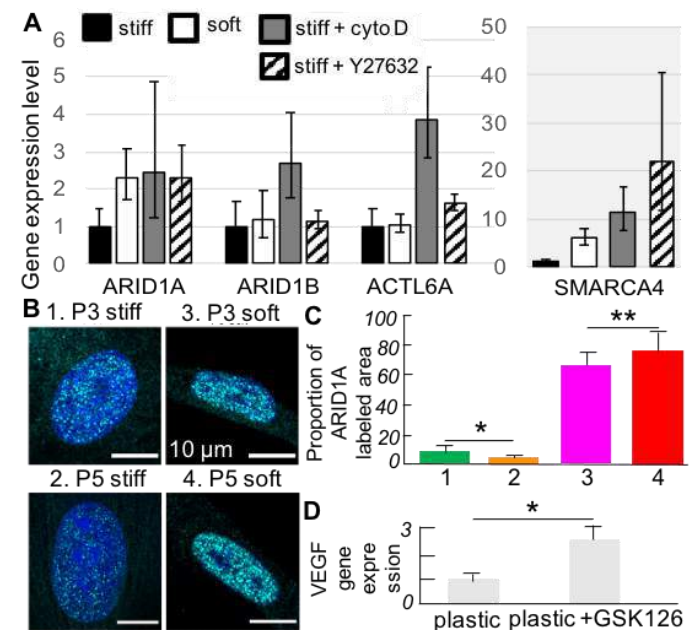

Figure 3: (A) The gene expression of SWI/SNF CRC associated proteins is high on soft substrate. On a stiff substrate, the gene expression increases with the application of 0.05 µM cyto D and 10 µM Y27632. (B, C) ARID1A distribution in nucleus is stiffness and passaging dependent. *p<0.01, **p<0.05. n>20 nuclei for each group. (D) Application of ARID1A inhibitor GSK126 (10 µM) increases the VEGF expression in MSC even on a plastic surface.

DISCUSSION

We report the discovery of mechanics-driven H3K9me3 and SWI/SNF CRC regulation in MSC. We show that inhibition of the chromatin remodeling can enhance the quality of MSC. In the future we will investigate if the inhibition of SWI/SNF CRC and H3K9me3 can improve the MSC stemness, thus increasing the MSC functionality.

THE ROLE OF HYALURONIC ACID IN THE SYNERGISTIC LUBRICATION OF ARTICULAR CARTILAGE

INTRODUCTION

Articular cartilage is a phenomenal lubricating material, facilitating remarkably low friction coefficients *in vivo* ($\mu \leq 0.005$).¹ Only recently have innovative *ex vivo* studies been able to recapitulate cartilage's unmatched *in vivo* lubricity on the benchtop, a feat enabled via our re-deployment of the convergent stationary contact area (cSCA) testing configuration.^{2,3} In the cSCA, and in the presence of PBS, sliding promotes the speed-dependent, hydrodynamically mediated recovery and maintenance of high fluid load support (FLS), interstitial lubrication (ISL), and low friction values ($\mu \sim 0.03$), via a mechanism termed 'tribological rehydration'.² Intriguingly, when synovial fluid (SF) was introduced into high-speed cSCA studies, truly *in vivo*-like equilibrium frictions ($\mu < 0.004$) were recorded on the benchtop for the first time.³ We have termed this frictional benefit, arising from the presence of SF and hydrodynamically driven recovery of ISL by tribological rehydration, 'synergistic lubrication'.

The unanticipated discovery of SF-mediated 'synergistic lubrication' in rapidly articulated cSCA contacts raises two critical questions: 1) What is the mechanism underlying lubrication synergy in cartilage? And 2) what aspects of SF mediate this synergy? SF is composed of numerous macromolecules postulated to influence cartilage lubrication in a variety of ways, from mediating viscous to boundary lubrication.^{3,4} One of these is hyaluronic acid (HA). HA is a non-sulfated high-molecular weight glycosaminoglycan (typically $> 7\text{MDa}$) found in SF at concentrations ranging from 1-3mg/mL.⁵

While HA contributes to increasing the viscosity of SF⁵⁻⁷ and has been traditionally thought to provide boundary lubricating activates to articular cartilage^{5,8,9}, the role that HA plays in promoting/regulating synergistic lubrication is unknown. Here, we explored friction mitigating interactions among hydrodynamics and ISL recovery (both titrated through sliding speed-dependent behaviors in cSCA explants) and HA presence (titrated by varying HA concentration and molecular weight [MW]) on the benchtop.

METHODS

$\Phi 19\text{mm}$ osteochondral explants were extracted from the femoral condyles of skeletally mature bovine stifles.^{2,3} Explants were rinsed and stored in 1X PBS to which sucrose was added to approximate the osmolality of synovial fluid (400mOsm¹⁰; hereon referred to as PBS).

Two studies were performed to examine the effects of HA concentration and MW on cSCA explant lubrication using a custom reciprocating tribometer.² All explants were preconditioned (**Fig 1A**) by being statically compressed against a glass counterface for 30 min at 9N, followed by a load reduction to 5N for 15 min, before being slid at 10, 80, and 10mm/s for 15 min each (under 5N).

Figure 1: Schematic showing: (A) cSCA explant preconditioning and (B) the “speed sweep” conditions of HA concentration/molecular weight tests. All sliding tests were conducted under a constant 5N compressive load ($\sim 0.2\text{MPa}$).

In study 1, after preconditioning, sliding “speed sweep” tests were conducted (at 5N) to investigate the effect of HA concentration on speed-dependent friction coefficients in the cSCA (**Fig 1B**). 1-1.8MDa. HA dissolved in PBS was sequentially tested at 0, 0.1, 1.5, and 5.0mg/mL. For all tests, sliding conditions (*e.g.*, sliding speed or bathing solution) were only changed when deformation and friction equilibria (*i.e.*, rates of change $< 1\mu\text{m/min}$ & $< 0.01\mu\text{m/min}$ or $< 0.001\mu\text{m/min}$ [for $\mu > 0.1$ & < 0.1 , respectively] were achieved at the prior condition).

In study 2, “speed sweep” tests, as described in study 1, were performed to explore the effect of HA MW on cSCA lubrication (**Fig**

1B). Tested HA MW included 20-40kDa, 301-450kDa, and 1.01-1.8MDa HA (each at 1.5mg/mL).

Equilibrium compression and kinetic friction coefficients for each sliding speed and HA combination were recorded in LABVIEW and analyzed in MATLAB.

RESULTS

In a manner unique to the cSCA configuration, the lowest observed equilibrium friction (μ_{eq}) values always occurred at sliding speeds $>40\text{mm/s}$, while maximum μ_{eq} values occurred at speeds $<5\text{mm/s}$ regardless of HA concentration (Fig 2A). Both maximal and minimal μ_{eq} (at slow and high-sliding speeds, respectively) decreased with increasing HA concentration (Fig 2B,C). The lubrication benefit associated with tribological rehydration at high sliding speeds in the cSCA ranged from 8.8-fold in PBS to 25-fold in 5mg/mL HA; with increasing HA concentration associated with increased lubrication synergy. Finally, increasing HA concentration monotonically reduced the sliding speeds at which equivalent levels of lubrication—defined as μ_{eq} corresponding to that of PBS at 80mm/s—was achieved (Fig 2D; e.g., for 5mg/mL HA equivalent lubricity was achieved at 20mm/s).

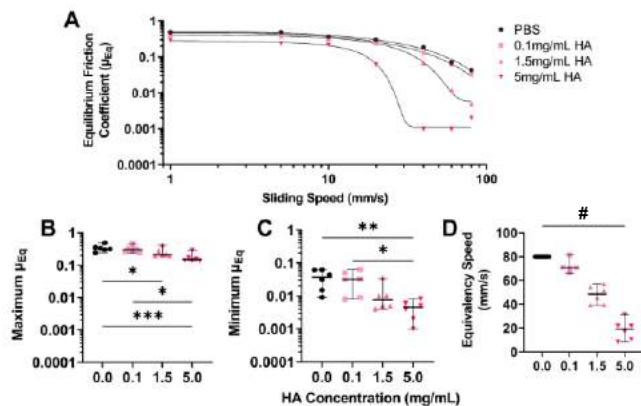

Fig 2: (A) Representative equilibrium friction (μ_{eq}) vs. sliding speed curves for a sample in PBS (black) vs. three HA concentrations (pink). (B) Maximum, (C) minimum μ_{eq} values, and (D) equivalency speeds at each HA concentration. (* $p<0.05$, ** <0.01 , * <0.001 , one-way ANOVA; # all comparisons $p<0.05$).**

Study 2, investigating the impact of HA MW—at 1.5mg/mL—on cSCA lubrication, produced results consistent with the speed-dependent synergistic lubrication effects seen above (Fig 3A). Tests using HA of increasing MW—from ~30kDa to ~1.4MDa—suggested a trend of molecular weight-dependent reductions in μ_{eq} at high sliding speeds (Fig 3B,C) and reduction in sliding speeds at which equivalent levels of lubricity were encountered (Fig 3D). Studies on further samples will be required to power this data similarly to synergy experiments in study 1.

DISCUSSION

The cSCA configuration, because it can precisely titrate interfacial hydrodynamics and FLS through speed-dependent control of tribological rehydration represents a novel tool for studying the role of HA (and other SF components) in mitigating articular cartilage friction.

In the absence of hydrodynamics and tribological rehydration (e.g., at slow sliding speeds), HA appears to function as a modest, classically understood boundary lubricant - one that is marginally impacted by concentration and MW. However, as hydrodynamic forces are generated by increasing cSCA sliding speeds the effect of HA on friction evolves dramatically. As sliding-induced tribological rehydration drives the recovery of interstitial pressure (i.e., FLS), HA

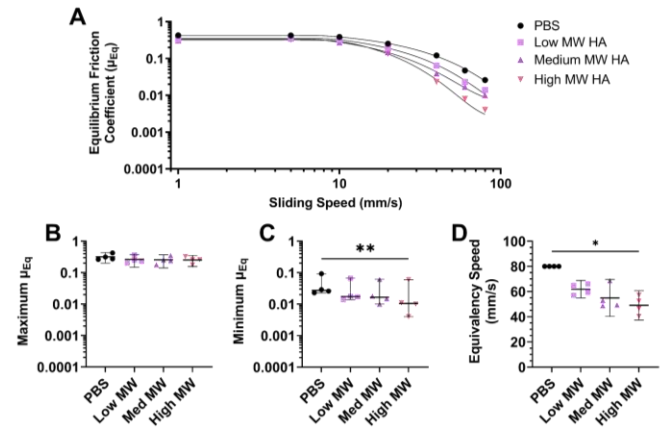

Fig 3: (A) Representative equilibrium friction (μ_{eq}) vs. sliding speed curves for a sample in PBS (black) vs. three HA molecular weights (purple). (B) Maximum, (C) minimum μ_{eq} values, and (D) equivalency speeds at each HA molecular weight. (* $p<0.05$, ** $p<0.01$, paired t-test or ANOVA)

transitions from a modest boundary lubricant to one having tremendous synergism with ISL.

High concentration and high MW HA provided the largest synergistic benefits (e.g., friction reductions) upon ISL recovery, generating μ_{eq} values at the limit of our detection ($\mu \sim 0.002$) at high sliding speeds. Furthermore, these benefits increased in proportion to HA concentration; findings that were confirmed through refined “concentration sweep” tests on 1.01-1.8MDa HA at 0, 0.1, 0.5, 1, 1.5, 2, 3, 4, and 5mg/mL under 50mm/s sliding (data not shown)—50mm/s was chosen because it was the sliding speed (in study 1) associated with the largest variance in μ_{eq} across HA concentrations due to its fostering of sub-maximal levels of tribological rehydration and FLS.

Because lubricant viscosity increases with HA concentration and MW⁵⁻⁷, careful consideration of the sliding-speed and HA-dependent behaviors of the cSCA contact suggest—indirectly—the renewed possibility of interfacial fluid film-mediated lubrication of cartilage. However, such fluid films only appear to be generated upon the ‘full’ recovery of interstitial pressure and ISL by TR. Considering mass/fluid-balance under such conditions, the ‘porous’ cartilage interface could be made ‘effectively’ impermeable to fluid influx by the presence of large interstitial pressures and maximal FLS; presenting a possible solution to the nagging paradox of how a ‘porous’ cartilage surface could support fluid film-based lubrication.^{4,11,12} Studies characterizing the effect of bath viscosity, in the presence and absence of HA, are continuing to explore the role of viscosity in articular cartilage lubrication (and in fluid film generation).

Overall, the present study highlights a crucial synergy between interstitial hydration and HA-presence in regulating cartilage lubrication under biofidelic conditions of high FLS and high sliding speeds. These insights continue to advance our objective of identifying a unifying framework to explain cartilage’s unmatched lubricity *in vivo* and to better understand how healthy and diseased cartilage works.

BLEBBISTATIN AS A METHOD TO IMPROVE OUTCOMES FOLLOWING JOINT CAPSULE RELEASE SURGERY IN AN *IN VIVO* RAT ELBOW MODEL

INTRODUCTION

Elbow trauma can lead to joint contracture and a reduced range of motion (ROM) that can limit one's ability to perform activities of daily living¹. Contracture is characterized by thickening and stiffening of the joint capsule. Nonsurgical interventions such as physical therapy or splinting may be able to improve ROM. When these approaches are not always successful, capsule release surgery is a treatment option. While surgery can improve ROM, ROM typically does not return to pre-injury ranges. Thus, alternative or adjuvant therapies are needed².

Activated myofibroblasts are a common feature found in fibrotic tissue³. Myofibroblasts, which can be distinguished by their expression of alpha smooth muscle actin (α -SMA), can generate large traction forces and deposit collagen and other extracellular matrix (ECM) proteins at the site of injury⁴. Biomechanical and biochemical interactions between myofibroblasts and their environment produce a feedback loop that can result in either normal or pathological healing³. We hypothesize that this feedback loop can be manipulated so that myofibroblast activity is reduced, normal healing is achieved, and ROM is improved or restored.

One strategy for controlling this feedback loop we are exploring is to temporarily block non-muscle myosin II (NMMII)-actin engagement in myofibroblasts with the drug blebbistatin. We have previously demonstrated that blebbistatin and blebbistatin-loaded PLGA microparticles significantly reduced fibroblast force development and collagen production *in vitro*^{5,6}. Use of this drug in conjunction with capsule release surgery might offer a way to improve and maintain outcomes. Thus, we tested the effects of capsule release surgery with and without blebbistatin in an established Long-Evans rat model of elbow contracture developed by Lake et al.⁷

METHODS

Injury Model: This protocol was approved by the University of Iowa IACUC (Protocol 2072222-004). Joint contracture was induced in 9 groups of 4 rats (n=36) using the procedure described by Lake et al.⁷ Briefly, the left elbow of each rat underwent an anterior capsulotomy,

transection of the lateral collateral ligament, and joint subluxation. The injured arm was then immobilized for 6 weeks.

Blebbistatin: Blebbistatin was administered two different ways. First, racemic blebbistatin was delivered using poly(lactic-co-glycolic acid) (PLGA) microparticles. These were produced using an oil-in-water single-emulsion technique described in our previous work². Microparticles were delivered in a hydrogel solution made up of 22.3% F-127 PluronicTM, 1% GelOne®, and 1x phosphate buffered saline with proportions of 76.4%, 20%, and 3.6%, respectively. The hydrogel and microparticles were delivered to the elbow after capsule release surgery. Second, daily systemic injections of blebbistatin were also tested following capsule release surgery. Blebbistatin was diluted to 1 mg/mL in a vehicle of 0.9% saline with 6.7% dimethyl sulfoxide (DMSO) and 25% hydroxypropyl β -cyclodextrin (w/v). Blebbistatin was delivered at a dosage of 5 mg/kg. For the first 4 days post-release, rats received injections intraperitoneally to ensure that peak drug concentrations were reached quickly during the early phases of healing. Subcutaneous injections were performed thereafter to reduce handling of the forelimbs during injection, which could aggravate the healing elbow and to lessen the potential for internal injury or injection into organs.

Mechanical Testing: At the end of the study, all arms were mechanically tested. The uninjured contralateral arms of each rat were used as a control group. Mechanical testing for this study was similar to the protocol outlined by Lake et al.⁷ Briefly, the upper limb was disarticulated at the glenohumeral joint, and the paw was removed at the wrist. The humeral head and wrist were mounted into polycarbonate tubing. A custom-built flexion-extension device interfaced with an ElectroForce® Planar Biaxial Test Bench Instrument (shown in figure 1). It was operated in load control and cycled between 10 N-mm in flexion and extension.

Statistical Analysis: One-way ANOVA with post-hoc Tukey's tests were used to assess significant differences ($p < 0.05$) between groups. Statistical analysis was performed in Prism GraphPad 9.4.1.

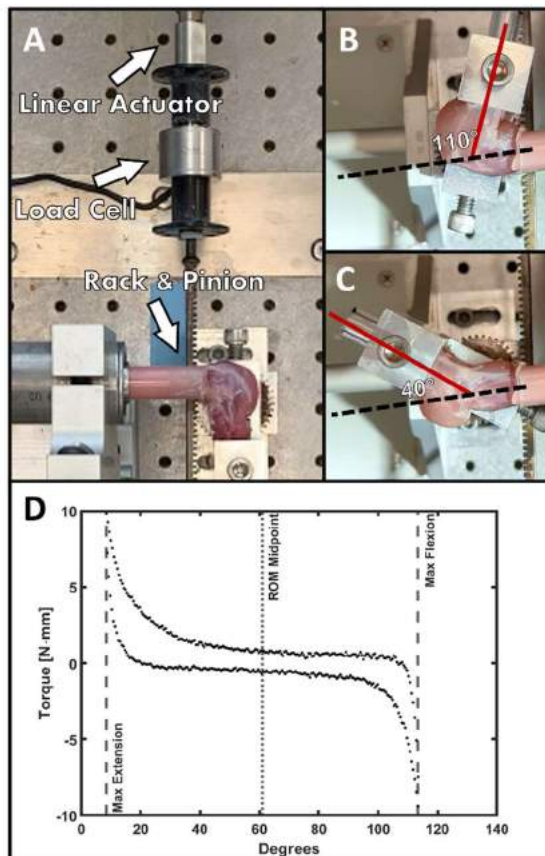

Figure 1: (A) Image of the mechanical testing setup. (B & C) Examples of how flexion and extension angles are measured. (D) Plot of typical torque-angle curve for an uninjured arm.

Study Timeline: After contracture was established (6 weeks post-injury) the first group of 4 rats was euthanized. The remaining 8 groups had restraints removed and were allowed to freely use their injured arms (remobilization) for 3 weeks. At this point (9 weeks post-injury), the second group of rats was euthanized. The last 7 groups received the following treatments:

- 3 additional weeks of free use of injured arm (euthanized 12 weeks post-injury)
- Capsule release surgery with a 1-week recovery period (euthanized 10 weeks post-injury)
- Capsule release plus blebbistatin hydrogel and a 1-week recovery period (euthanized 10 weeks post-injury)
- Capsule release with a 3-week recovery period (euthanized 12 weeks post-injury)
- Capsule release plus hydrogel and a 3-week recovery period (euthanized 12 weeks post-injury)
- Release followed by 3 weeks of daily vehicle injections (euthanized 12 weeks post-injury)
- Release followed by 3 weeks of daily blebbistatin injections (euthanized 12 weeks post-injury)

RESULTS

Remobilization: Free use of the injured arm did not improve max extension angles significantly after either 3 or 6 weeks (9 or 12 weeks post-injury). Remobilization was also not significantly different from capsule release 3 weeks after surgery. Note that a lower max extension angle equates to a better outcome.

Capsule Release: By itself, capsule release significantly ($p < 0.05$) improved the angle of maximum extension 1 week after surgery (10 weeks post-injury) compared to the injury-only group and was not significantly different from the uninjured group. Three weeks after surgery (12 weeks post-injury), the max extension angle was also significantly better than injury but was also significantly ($p < 0.05$) worse than the uninjured arms.

Microparticles: One week post-release, the max extension angle for arms that received blebbistatin microparticles was significantly greater than that of the uninjured arms ($p < 0.05$) while the arms that did not receive blebbistatin were not significantly different from the uninjured. Three weeks post-release, both the release-only and the blebbistatin groups had significantly worse max extension.

Injections: Maximum extension angles between the groups that received daily blebbistatin and daily vehicle injections were not significantly different. Both groups were significantly different from the uninjured control ($p < 0.05$). Comparisons between groups can be found in figure 2.

Figure 2: Comparison of maximum extension angles (mean \pm standard deviation) between all groups. Dashed lines mark the mean angles for the uninjured and injury-only arms; dotted lines mark the standard deviations. Note that a lower max extension equates to a better outcome.

DISCUSSION

Overall, capsule release surgery improved maximum extension. However, the improvement seen at 1 week was reduced at 3-weeks post-surgery, indicating that the contracture may return following surgery. This is often observed clinically in patients undergoing capsular release surgery. Blebbistatin did not provide a significant improvement in maximum extension compared to capsule release surgery alone, but it may have reduced the loss of ROM observed three weeks after release surgery. Future work will investigate the long-term effects of capsule release and other treatments on this contracture model.

ACKNOWLEDGEMENTS

Support for this work was provided by the National Institutes of Health (NIH 1R21AR075137-01A1). We would also like to thank the Lake lab at Washington University for their assistance

INTRODUCTION

Extracellular matrix (ECM) collagen fibril anisotropy and density have mechanoregulatory roles during cellular growth and guidance. The configuration of matrix fibril alignment and density are thought to affect the development of new vasculatures during pathologic and homeostatic angiogenesis [1]. For instance, healing and disease progression may be influenced by gradients and discontinuities in ECM density and anisotropy such as those in entheses (bone-tendon/ligament/fascia attachment sites) and in peri-tumoral regions.

We recently demonstrated that microvascular growth rate and orientation simultaneously depend on the ECM density and anisotropy [1]. While ECM density generally reduced neovessel growth, microvessel growth rate returned to baseline levels when the degree of anisotropy (DA) was high. These results suggested that the spatial configuration of ECM density and anisotropy influence neovascularization at tissue boundaries and structural gradients.

Computational simulation is emerging as a tool to investigate the role of matrix structural configurations on cell guidance. Prior computational models of angiogenesis and cell guidance have only been sensitive to ECM density and the dominant ECM collagen direction regardless of the DA [2]. Thus, the objective of this study was to incorporate our prior experimental finding that angiogenic neovessels are simultaneously sensitive to ECM density and ECM anisotropy (orientation and DA). We found that high DAs embolden neovessels to migrate long distances and persist through high ECM collagen density.

METHODS

Simulations of microvascular guidance: Biomechanical simulations of angiogenesis were performed using Finite Elements for Biomechanics (FEBio) [3]. The mechanical model was coupled with AngioFE, a growth model that simulates angiogenic neovessel growth from parent microvessels suspended in hydrogels [2]. The ECM was

represented as a biphasic viscoelastic material with a solid mixture comprising a neo-Hookean ground matrix and a continuous collagen fibril distribution governed by an exponential-power law response. During model initialization, AngioFE suspended parent microvessel fragments within the ECM and prescribed the local ECM density and collagen fibril orientation distribution function (ODF). Microvessel tips sprouted into neovessels that grew and contracted the ECM during simulation. We modified AngioFE such that the growth rate simultaneously depended on the ECM density and the DA. Growth parameters were calibrated from prior experiments [1].

Initial collagen ODFs, \mathbf{P}^0 , were assumed to be ellipsoidal, symmetric, positive-definite (SPD) tensors. \mathbf{P}^0 were constructed via: the spectral-decomposition:

$$\mathbf{P}^0 = \sum_{i=1}^3 \beta_i^0 \mathbf{n}_i^0 \otimes \mathbf{n}_i^0, \quad (1)$$

where β_i^0 were the initial semiprincipal axis lengths of the ellipsoid and \mathbf{n}_i^0 were the initial directions of the semiprincipal axes. As the ECM deformed due to cellular tractions some ODFs became distorted and were no longer elliptical (SPD). For the mechanical model, the directional response of deformed collagen fibrils at each finite element integration point was calculated via Gauss-Kronrod-trapezoidal integration [4]. For the growth model the deformed ODF was approximated as an SPD via ODF pseudo-deformation [5]. This was necessary to allow spatial interpolation of ODFs because neovessel growth was sensitive to the local collagen ODF [6].

Simulations of anisotropy gradients: Microvessel growth was simulated across an isotropic matrix or an anisotropy gradient to determine how structural configurations affect neovascular recruitment. A rectilinear geometry was separated into 3 regions (near, middle, far) with microvessels originating in the near region. Anisotropy increased (positive) or decreased (negative) between the near and far regions.

Simulations of tumor associated collagen signatures: Tumor-associated collagen signatures (TACS) are configurations of matrix density and structure found near some tumors [7]. To explore how different TACS affect tumor angiogenesis, microvessels were suspended in a tissue separated from a nearby tumor by an interface. The interface structural properties were modified to include high-density collagen (TACS-1), circumferential alignment (TACS-2), radial alignment (TACS-3), or a combination (TACS-1+2, TACS-1+3).

RESULTS

Anisotropy gradients recruit neovessels: In the baseline case (isotropic ECM), microvessels modestly vascularized the middle but not the far region (Fig. A). In the cases with anisotropy gradients, neovessels grew into the middle and far regions. Microvessels grown in a negative anisotropy gradient more thoroughly vascularized the middle region of the simulation domain than those originating near a positive gradient but there was no difference in vascularization of the far region.

Anisotropy enhances neovessel recruitment at TACS: In the baseline case (no TACS), microvessels grew from the periphery into the tumor (Fig. B). A high-density interface (TACS-1) greatly reduced tumor vascularization. Circumferential fibril alignment (TACS-2) led to microvascular growth along the interface but baseline levels of tumor vascularization. Radial fibril alignment (TACS-3) facilitated the highest level of tumor vascularization. The combined presence of elevated density and circumferential fibril alignment (TACS-1+2) resulted in the least tumor vascularization. Alternatively, the combined presence of elevated density and radial fibril alignment (TACS-1+3) resulted in a similar level of vascularization as the baseline case.

DISCUSSION

This research improved predictive tools to understand the impact of ECM structural configuration during cell guidance. Previously, the DA was not used as a model input in studies of cell migration, despite evidence that the DA affects cell behaviors and guidance [1].

Anisotropy gradients potentially recruited neovessels across long distances regardless of gradient orientation. However, the middle region of the positive gradient was less vascularized in comparison to the negative gradient; thus, positive gradients are more efficient at vascularizing across long distances since. As neovessels grew up the positive gradient, the potency of matrix growth and guidance cues increased. In contrast, the potency of guidance cues decreased as neovessels grew along the negative anisotropy gradient.

To explore the roles of matrix density and anisotropy in tumor angiogenesis, we simulated angiogenesis between a host and a tumor. Radial fibril alignment (TACS-3, TACS-1+3) dramatically increased tumor vascularization. This is consistent with clinical observations that TACS-3 appears in aggressive cancers with poor prognoses [7]. Interestingly, circumferential fibril alignment (TACS-2, TACS-1+2) had a negligible effect on tumor vascularization since the DA increased the persistence of deflected neovessels. Such neovessels would likely be susceptible to tumor cytokines which were absent in our simulations.

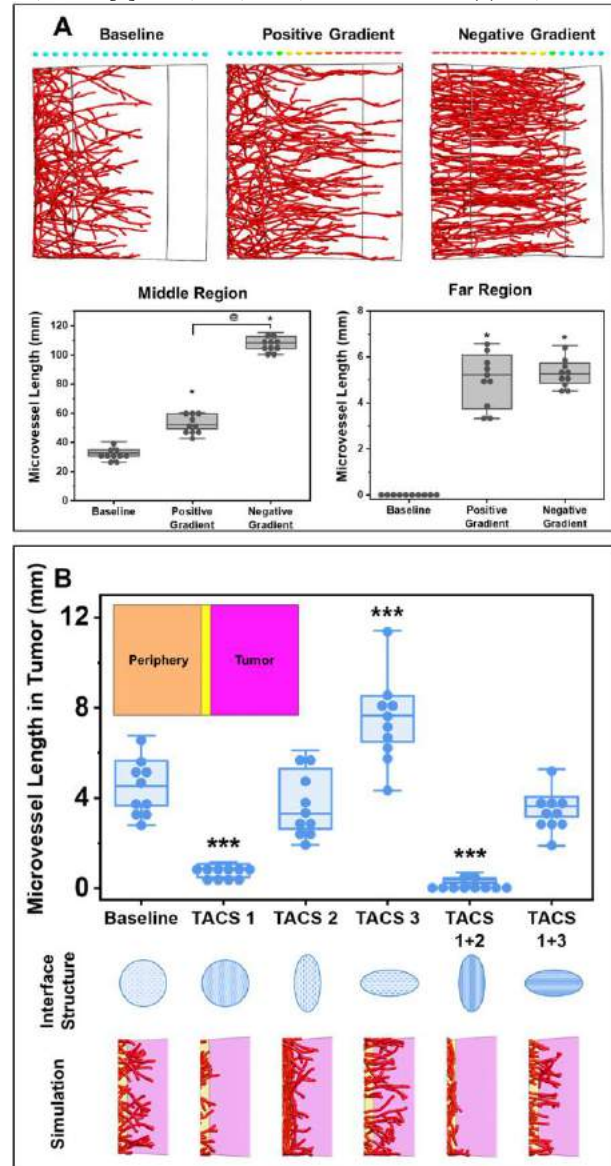

Our simulations were performed in the absence of biochemical signaling which allowed us to explore the isolated role of matrix structural patterning during neovessel guidance. AngioFE will be expanded in the future to include biochemical signaling to understand the coordination of biophysical and biochemical stimuli.

TOWARD REAL-TIME SIMULATION OF CARDIOVASCULAR FLOWS BY INTRODUCING A STABILIZED TIME-SPECTRAL FINITE ELEMENT METHOD

Dongjie Jia (1), Mahdi Esmaily (1)

(1) Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, New York, USA

INTRODUCTION

The finite element methods for the solution of the Navier-Stokes equation have found common use for simulating cardiovascular flows [1]. These simulations typically use periodic boundary conditions for physiological relevance. In another word, it is common to impose a periodic pressure or flow-rate profile at the boundaries given that the heart beats in cycles. This results in a solution that is unsteady and often periodic. To capture this behavior, a conventional finite element method uses time-stepping to resolve the unsteady behavior of the flow. That is done so by starting from a zero-velocity field and simulating multiple cardiac cycles to wash the initial condition and obtain cycle-to-cycle convergence. As a result, the overall cost of these simulations is significant, potentially taking days for a typical cardiovascular simulation to complete. For example, the cardiac flow in a Norwood procedure requires simulating 10 cardiac cycles to ensure numerical convergence (Figure 1) [2]. In the end, results are only taken from one cardiac cycle after the simulation is converged. More than 90% of the computational cost is spent on numerical convergence due to the unsteady and periodic nature of cardiovascular simulations.

What we propose is an alternative way of simulating these flows that can significantly reduce this cost. The key idea here is to perform simulations in the frequency rather than the time domain, thereby obviating the need to simulate many cycles for convergence. Also, since the periodic flows can be represented with a few frequency modes (spectral modes) in the frequency domain, we no longer need to rely on thousands of time steps to resolve the unsteady nature of these flows. It is by exploring these two major cost savings strategies that a time-spectral formulation can reduce the overall cost of a cardiovascular simulation from hours or days to seconds or minutes.

Figure 1: Pressure history for a cardiovascular simulation starting from a zero-velocity field. The converging phase is colored in red, and the converged solution is colored in green.

In our previous study, we introduced a stabilized finite element formulation for solving the linear Stokes equation in the frequency domain [3] that improved upon a non-stabilized earlier formulation of the same problem [4]. By decomposing the Stokes equation into different modes and separating the real and imaginary parts. This formulation eliminates the need for time-stepping, thus eliminating the computational cost of reaching a cycle-to-cycle converged solution. In addition, due to the periodic nature of the cardiovascular simulation, the flow information can be fully represented with a handful of modes. Furthermore, since the spectral modes are independent, they can be calculated in parallel, which further shortens the simulation wall-clock time. Using a patient-specific geometry, we achieved a 1% error with less than 1% of the simulation time compared to the conventional finite

element method. However, due to the Stokes limit, this method is only realistic for the blood flow in the smallest blood vessels in the human circulatory, where Reynolds number approaches zero. Extending this method to finite-Reynolds numbers for most cardiovascular simulations requires solving the Navier-Stokes equation in the frequency domain.

In this talk, we will introduce the spectral-Navier-Stokes finite element formulation that solves the Navier-Stokes equation in the frequency domain. First, we will present the formulation and numerical methods we used to build this formulation. We will use two cases, one single vessel flow, and one Norwood flow, to compare our method to the conventional method in terms of both accuracy and computational speed. Lastly, we will discuss the real-life clinical indications of our method and potential shortcomings.

METHODS

The Spectral-Navier-Stokes equation is formulated as the following. For each spectral mode m ,

$$\begin{aligned} i\rho\omega_m \mathbf{u}_m + \mathbf{u}_a \nabla \mathbf{u}_b &= -\nabla p_m + \mu \nabla^2 \mathbf{u}_m \quad \text{in } \Omega, \\ \nabla \cdot \mathbf{u}_m &\quad \text{in } \Omega, \\ \mathbf{u}_m &= \mathbf{g}_m \quad \text{on } \Gamma_g, \\ (-p_m \mathbf{I} + \mu \nabla \mathbf{u}_m) \cdot \mathbf{n} &= \mathbf{h}_m \quad \text{on } \Gamma_h, \end{aligned} \quad (1)$$

where a and b are all modes that satisfies $a + b = m$, $i = \sqrt{-1}$, ω_m is the oscillation frequency, \mathbf{u}_m is the velocity, p_m is the pressure, \mathbf{g}_m is the imposed modal velocity on the Dirichlet boundary Γ_g , and \mathbf{h}_m is the imposed modal traction on the Neumann boundary Γ_h .

We will derive an appropriate stabilized finite element method that will be similar to the Streamline upwind/Petrov-Galerkin method [5]. Mode-coupling techniques for the non-linear term in the Navier-Stokes equation between different spectral modes will also be developed and presented.

RESULTS

This is an ongoing study. The first planned simulation result is a flow in a straight pipe, which is the simplest flow in a blood vessel. We will use this case to demonstrate the stability, accuracy, and speed of our numerical method by comparing the solution to that of the conventional method and the analytical solution.

Afterward, we plan to simulate a realistic cardiac flow, namely the Norwood procedure with a Blalock-Taussig shunt (Figure 2), using both the proposed spectral method and the conventional finite element method. With this complex simulation, we can demonstrate the significant simulation speed advantage of our method. We will also show that the difference in simulation results is within acceptable margins.

Expected results should show a significant reduction in computational cost and overall simulation time. The differences in results between the conventional method and the introduced method should be within 1%.

Figure 2: Simulation setup for the Norwood procedure with Blalock-Taussig shunt. A flow rate profile is imposed at the ascending aorta

DISCUSSION

Earlier studies have shown that the proposed method at the Stokes limit significantly shortens the simulation time and reduces computational costs [3,4]. It is the goal of this study to show the same cost-saving advantage for the finite Reynolds number periodic flow simulations, such as simulating cardiovascular flow. This improvement will enable various clinical and surgical applications, such as same-day diagnostic, surgical planning, and virtual surgery. Currently, CFD is mostly used as a diagnostic tool in the clinical environment, where the simulation will be built from a patient-specific MRI scan but must be run on a dedicated computer cluster for several days. With the proposed method, the CFD simulations could potentially be run on an on-site computer within the same day, or even within an hour, which provides critical hemodynamical information to clinicians in a timelier manner. This improvement in computational efficiency can also help advise surgical planning, where multiple geometries and flow configurations need to be simulated, which was not possible due to prohibiting large computational costs using the current CFD methods.

A limitation of the proposed method is that it relies on the assumption that the simulation can be resolved with a small number of frequency modes, which is the case for most cardiovascular simulations. However, there could be instances that a significant number of modes need to be used, most likely when an assist device is present in the circulatory system. In this case, the cost advantage might not be as significant.

INTRODUCTION

Fragment impact injuries are one of the most common cutaneous injuries observed, often caused by flying glass shards in vehicle accidents, impacting debris in construction blasts, and from improvised explosive devices [1]. These injuries can lead to infection, function loss, and extensive scarring, particularly in the facial and extremity regions, severely deteriorating the affected individual's wellbeing. However, despite their significance, there is a poor understanding of the damage processes involved and the influence of projectile attributes on injury severity.

Previously, we characterized the damage mechanisms involved in cutaneous fragment impact injuries through experimental techniques and by developing a high-fidelity finite element (FE) model to predict cutaneous injuries [2]. We found that the two prevalent damage mechanisms were epidermal tearing, where the epidermis layer is peeled from the dermis layer, and dermal crushing, where permanent compression and damage to the dermis layer is observed, see Figures 1a and 1b, respectively. However, the contribution of each damage mechanism can vary significantly depending on fragment attributes, such as projectile shape and orientation at impact, necessitating a deeper understanding of the factors affecting these injuries. Here, we utilize our model to ascertain the effect of projectile shape on cutaneous injury severity and illustrate that fragment shape asymmetry can alter the injury type and damage process.

METHODS

A 3D multi-layered finite element damage model of skin was developed using ABAQUS EXPLICIT (2019) to analyze partial-thickness cutaneous injuries caused by projectile impact, see Figure 1c. To capture all the damage mechanisms involved in the injury process, it was essential to incorporate the three layers of the skin individually, including the stratum corneum, the living epidermis, and the dermis, as well as the hypodermis, which is the subcutaneous fatty tissue.

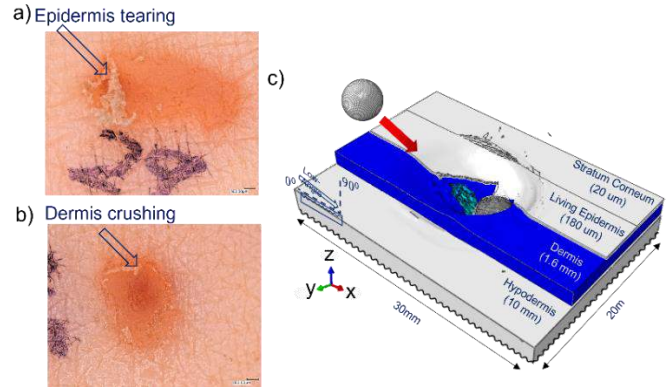

Figure 1: a) Epidermal tearing. b) Dermis crushing. c) Multi-layered 3D FE model for cutaneous fragment impact injuries.

The Ogden hyperelastic constitutive model was used for skin layer, apart from the dermis which was supplied the Gasser-Ogden-Holzapfel (GOH) constitutive model to capture its anisotropic behavior. The Ogden strain energy density, W , can be written in the form

$$W_{Ogden} = \sum_{i=1}^N \frac{2\mu_i}{\alpha_i^2} (\bar{\lambda}_1^{\alpha_i} + \bar{\lambda}_2^{\alpha_i} + \bar{\lambda}_3^{\alpha_i} - 3) \quad (1)$$

where λ_1 , λ_2 , and λ_3 are the principal stretches, $N=1$, and coefficients μ_i and α_i are temperature-dependent material parameters. The GOH strain energy density, W , can be written in the form

$$W_{GOH} = C(\bar{I}_1 - 3) + \frac{k_1}{2k_2} \sum_{i=4,6} [\exp\{k_2[\kappa \bar{I}_i + (1 - 3\kappa)\bar{I}_i - 1]^2\} - 1] \quad (2)$$

where C , k_1 , and k_2 are temperature-dependent material parameters. I_1 is the first deviatoric strain invariant, relating to the pressure, and I_4 and I_6 are the invariants relating to the stretches in the fiber directions for two families of collagen fibers. Finally, κ , describes the level of dispersion in the fiber direction.

Viscoelastic Prony series parameters were applied to the dermis and hypodermis, and inverse analysis was used to determine the failure parameters of each layer, using a critical stress damage criterion.

Displacement boundary conditions were implemented along the base of the hypodermis in the z-plane, and perpendicularly along the side surfaces in the x-direction and y-direction. 8-node linear hex elements with reduced integration (C3D8R) were used to mesh the model. A dynamic explicit analysis was performed for a 1.5ms duration.

The model was validated experimentally using a kinetic impact system designed to accelerate projectiles to impact full-thickness samples of near-live cadaverous abdominal human skin. The impact process and resulting wound morphology were analyzed using high-speed imaging techniques. Further details on the experiments and the parameters of the model can be found in our previous publication [2].

RESULTS

Spheres and cylinders were used in our analysis as they are the two most common fragment shapes found in explosive devices [3]. Due to the symmetric attributes of the cylinder, three impact orientations were tested, see Figure 2a, at impact angles varying from 15° to 90° and at 5.6 J/cm^2 . The resulting wound depths were measured both computationally and experimentally, averaged among the differing orientations, and a plot of the results, see Figure 2b, revealed a bifurcation in the cylinder curve with increasing impact angle. R^2 values of 0.71 and 0.91 were obtained for the sphere and cylinder projectiles, respectively. Wound depths for each individual orientation were also plotted for 90° impacts at energy densities ranging from $5.6\text{--}16.8 \text{ J/cm}^2$, see Figure 2c. The results indicate that the edge orientation (red) caused the largest wound depths and was the first orientation to cause injury perforation (wound depth $\geq 1.8\text{mm}$) where the projectile penetrates through all skin layers. However, both spheres and cylinders exhibited a positive relation between wound depth and energy density.

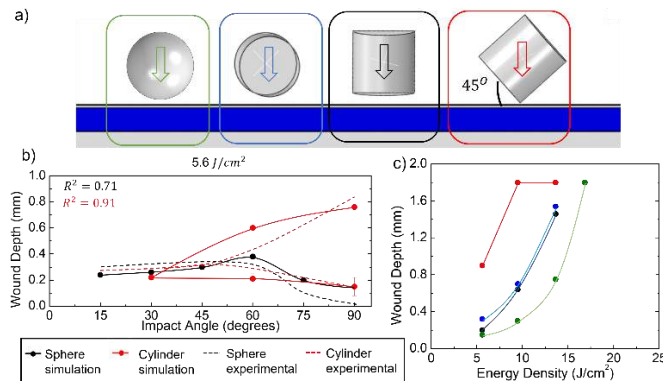

Figure 2: a) Projectile orientations at impact. b) Wound depth vs impact angle for spheres and cylinders at 5.6 J/cm^2 . c) Wound depth vs energy density for spheres and cylinders at 90° impact.

In addition to spheres and cylinders, common fragment shapes include cubes, tetrahedrons, and stellate octahedrons [3]. Simulations of projectile impact at 30° and 90° impact angles and at 5.6 J/cm^2 were performed for three times for each projectile, at different impact orientations, apart from the sphere due to its perfect symmetry, see Figure 3a. The results show significant differences in wound shape for the same impact input parameters. Stellate octahedrons showed a large chaotic wound pattern along with multiple wound depth segments. Tetrahedrons also had three wound depth segments, though its wound shape was not as complex as the stellate. The results also show an increasing trend in wound depth with shape complexity, and, apart from the sphere, a larger wound depth for 90° impacts compared to 30° , see

Figure 3b. However, large variations in wound depth (standard deviation of $\pm 0.58\text{mm}$) were observed for cubic projectiles at 90°

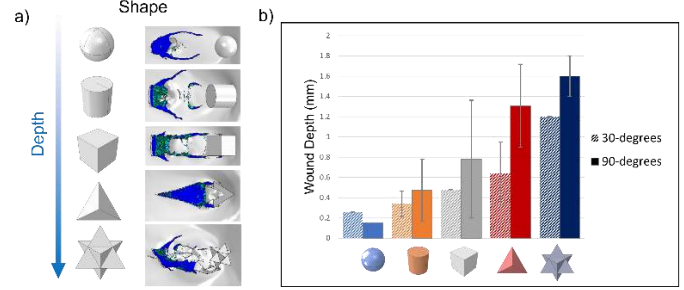

Figure 3: a) Fragment shapes and resulting injury at 30° impact. b) Wound depth vs fragment shape for 30° and 90° impact.

DISCUSSION

Results indicate that cylinders whose first point of impact with the skin was an edge showed a larger wound depth than other orientations. The edge effect was more significant at high-angled impacts due to larger perpendicular forces relative to low-angled impacts at the same energy density, causing a larger variation in wound depth for the former, leading to the bifurcation of the wound depth curve for cylindrical projectiles. Wound depths caused by spherical projectiles were shallower than cylindrical projectiles due to a lack of edges.

Comparing the five shapes, projectiles with sharper edges caused larger wound depths for both low-angled and high-angled impacts, and the sequence of increasing wound depth with projectile shape can be seen in Figure 3a. However, the orientation at impact was a key factor in determining the severity of the edge effect, causing a large variation in wound depth for the cubic projectile at 90° impacts. Depending on impact orientation, cubic projectiles could have lower or higher wound depths at low-angled impacts than at high-angled impacts. Moreover, due to larger forces perpendicular to the skin, wound depths were, on average, larger at 90° impacts than at 30° impacts, with spheres being the exception due to their reliance on friction to remove the epidermal layer at 30° impacts; thus, increasing the wound depth. However, the effect of friction is reduced at high-angled impacts, and so, spheres caused larger wound depths for low-angled impacts at small energy densities, since they were unable to peel off the epidermal layer.

It should be noted that due to the heterogenous nature of biological material, continuum-based models cannot perfectly replicate the microscopic mechanical behavior of human skin. Furthermore, the model can overestimate wound depth as element deletion removes mass and energy from the system, causing the removal of dead tissue that would have otherwise carried compressive load. However, reasonable results were still obtained when compared to experimental data.

These results indicate the importance of accounting for projectile shape and impact orientation when analyzing cutaneous fragment impact injuries. We expect our data to be used to guide the design optimization process for personal protective equipment that aim to reduce these types of injuries.

COLLECTIVE AUTOLOGOUS CHEMOTAXIS IN CANCER CELLS

Louis González (1), Andrew J. Mugler (1)

(1) Department of Physics and Astronomy, University of Pittsburgh, Pittsburgh, Pennsylvania, USA

INTRODUCTION

In complex dynamic microenvironments, cells are subjected to multiple stimuli that yield contradictory outcomes. How cells integrate these multiple signals into a collective action is an open question. A tumor and its surroundings is one of the many complex environments in which this question is relevant and fundamental. One of the hallmarks of cancer progression is an increase in interstitial fluid pressure which facilitates signal transport to provoke cellular migratory response. A ubiquitous mode of migration is a process called ‘autologous chemotaxis’ where cells use self-secreted signaling molecules that are biased by flow and then bind to receptors [1]. A simplified schematic is shown below, where tumor cells secrete a diffusible autocrine (CCL21) that is biased in the direction of lymphatic drainage that binds to the receptor CCR7 which causes the cells to travel to the lymphatic vessel during cancer metastasis (Figure 1, from [2]).

Figure 1: A depiction of tumor cells performing autologous chemotaxis in an attempt to migrate to the endothelium to begin intravasation, a necessary step in cancer metastasis. Both the tumor cell and the endothelium secrete the signaling molecule. This contributes to an autocrine concentration background.

In contrast, cells also use the pressure exerted on their surface membranes generated by fluid flow to stimulate mechanotransduction pathways for a variety of functions, including cell migration. The former induces downstream migration in cells due to the flow biasing molecules along the flow direction and the latter induces an upstream response as the cell travels

along higher pressure gradients.

Experiments have shown that at low density, tumor cells travel downstream using autologous chemotaxis. However, at high density, the cells travel upstream, suggesting that autologous chemotaxis fails, and that the pressure-sensing mechanism takes over [3]. We found that this is due to a saturation in secreted molecule concentration, distorting a cell’s ability to determine a directional bias in the signal and consequently act upon it [4]. Previous work in our group found that cells can sense chemical concentrations better when acting together as a collective unit by integrating each cell’s molecule count and then averaging amongst all cells in the collective [5]. Given that tumors are multicellular environments and cancer cells often travel as clusters, here we ask whether cancer cells can overcome the density-dependent failure of autologous chemotaxis by acting as a collective instead of as individuals.

METHODS

To this end, we assumed a simplified model of a human breast cancer cell as a spherical cell in the presence of other identical cells within a spherical cluster. To model chemo-sensing, we solved the N -body advection-diffusion equation, with N being the number of cells within the cluster. Each cell thus produces a local concentration gradient that is biased in the flow direction, with cells downstream being in the path of upstream secreted molecules. The molecules bind asymmetrically along the surface of the cell, creating a surface concentration anisotropy. Whereas individual cells would integrate the anisotropy to determine flow direction, a cluster would instead integrate whole cells and average each cell’s singular measurement with its position in the cluster. This approach will directly compare the effectiveness of single-cell integration versus multi-cell integration. Since solving the N -body advection-diffusion equation only yields a stationary solution to an evolving concentration field, we introduced a dynamical simulation to simulate autologous chemotaxis. We then turn to Monte Carlo simulation to create a biased random walk where the cells choose subsequent steps that are weighted by the static solution at each time step.

RESULTS

We found that collective chemo-sensing outperforms individual chemo-sensing, similarly to the findings of cells responding to externally sourced gradients in other works [5] as the anisotropy is found to be

$$A_C = \left(\frac{4}{3}\pi\epsilon\right) (V^{1/3}a^3)\rho^{4/3}. \quad (1)$$

Whereas the anisotropy for individual-based chemo-sensing goes as $A_I \sim \rho^{-1}$. This is shown in Figure 2 where collective sensing avoid the density-dependent falloff in concentration sensing as individual sensing as the local cellular environment becomes more crowded.

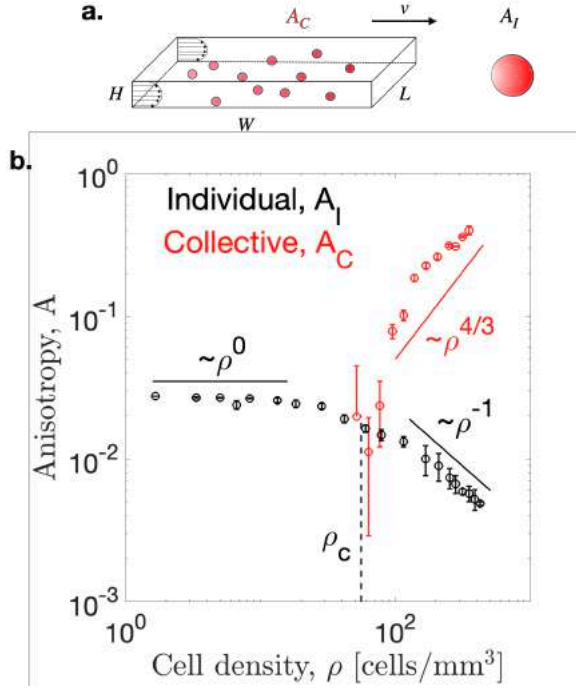

Figure 2: (a) A schematic that shows the difference in how a cell cluster computes collective anisotropy by summing the molecule counts over all cells and weighting it with the position of the box with respect to the cluster center, $\cos \theta_0$ (left diagram) and how an individual cell computes individual anisotropy sums the molecule count across its surface weighted by $\cos \theta$ of the cell (right diagram). **(b)** Anisotropy as a function of cell density for both individual and collective autologous chemo-sensing regimes.

The individual anisotropy A_I represents the failure of autologous chemotaxis at high cell density, a result found in our previous work [4]. As cell density increases, the cells fail to determine flow direction and consequently act (migrate) on it. This is due to a homogenization of the autocrine concentration field. On the contrary, cells performing collectively instead improve as more cells contribute and sense autocrine. This allows clusters to avoid density-dependent failure.

The N -body simulation represents a stationary solution so we must therefore turn to dynamical simulation. Using Monte Carlo simulation, we found that a cell collective will also outperform single cells here as cells are able to resolve more concentration by using the entire cells as “probes” instead of receptors on a single cell’s surface in the individual autologous chemotaxis case. Example trajectories of the collective and individual regimes are shown in Figure 3 below.

Figure 3: Example trajectories of both the collective and individual regimes using a lattice-based Monte Carlo simulation. In the collective regime, the cells are attracted to one another, forming a cluster and constraining their intercellular distance. This increases their speed and their chemotactic index, the distance moved in the direction of the gradient. The opposite is true in the individual regime, however, as the cells do not maintain a cluster formation and instead travel as individual agents. This causes a slowdown despite moving in the flow direction as well. Fluid flow is in the positive z direction.

Thus, we found that not only do cell clusters resolve concentration anisotropy better than single cells, but that this leads to increased speed. This shows that it is advantageous for cancer cells to travel together, something that has been observed experimentally [6]. This increased speed is the result of resolving the flow direction more efficiently and with higher fidelity than the individual regime.

DISCUSSION

Understanding how cancer cells can overcome apparent failure of their sensory mechanism by operating as a collective unit can provide new insights on drug treatment and therapies. Interrupting or completely disrupting this collective could be a target for a treatment regimen for patients. Our results importantly do not cover why pressure-sensing is subdominant to chemo-sensing at low cell density. We hypothesize that this is due to cells being able to more precisely determine flow direction through chemo-sensing than with pressure-sensing. Whether or not that is the case remains an open question.

INTRODUCTION

As NASA prepares to send astronauts on longer duration spaceflight missions, understanding the detrimental effects of microgravity on human health is important. It has been well established that spaceflight negatively affects bone, with bone loss up to 1-2% for every month in space [1, 2]. Furthermore, astronauts are 4.3X more likely to experience lumbar disc herniation after returning to Earth [3]. While measures have been established to counteract bone loss, there are outstanding questions regarding the impact of spaceflight on spine mechanobiology.

Previous reports from short duration missions (≤ 15 days) showed changes in rodent disc biochemical content and mechanical properties after spaceflight [4-7]. However, the impact of longer duration microgravity on disc biomechanics is not well understood and may provide insight into elevated risk of herniation after spaceflight. Thus, the primary aim of this study was to examine murine disc biochemical content and lumbar vertebral body microstructure after 30-days on the International Space Station (ISS).

METHODS

Rodent Research-10. Lumbar spines from the Rodent Research-10 (RR-10) mission were collected as part of a collaboration with the RR-10 Investigator Team. Mice (B6129SF2/J) were 16 weeks at launch (day 0) and included four groups: a baseline control (BL, euthanized on day 0, $n=10$), a ground control (GC, Rodent Research housing on Earth, $n=10$), a vivarium control (VIV, normal mouse housing on Earth, $n=12$), and a spaceflight experimental group (SF, $n=10$). After 30 days, mice were euthanized in orbit and carcasses were flash frozen and returned to Earth for dissection. Lumbar spines were collected and stored at -80°C until processing for biochemistry and μCT imaging.

Biochemical Analysis. The L1-L2 discs were removed and refrozen at -80°C . Frozen discs ($n=8-10/\text{group}$) were lyophilized overnight before digestion in papain. Digests were evaluated for DNA content with the PicoGreen Assay, sulfated glycosaminoglycan (GAG) content with the Dimethylmethylene blue (DMMB) assay, and collagen

content with an oxidized hydroxyproline content (OHP) assay. GAG content and OHP content were normalized to DNA content, as the weights of the small discs could not be reliably measured.

μCT . The L3-L5 lumbar columns were wrapped in saline-polyethylene glycol-soaked gauze to maintain hydration and scanned at $4.0\ \mu\text{m}$ voxel size (60 kV, 166 μA , 0.25 mm aluminum filter) using a Skyscan 1272 (Bruker). The L4 vertebra was reconstructed and segmented in nRecon to isolate the middle 50% of the vertebral body. Trabecular bone was manually segmented from cortical bone, and automated analyses for bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), and trabecular number (Tb.N) were conducted by CT Analyser.

Statistics. To provide robust statistical analysis against normality assumptions, a one-way ANOVA and permutation test combined approach was used. Briefly, the F-statistic generated by the one-way ANOVA was compared to a distribution of F-statistics generated from 10^3 permutations of the experimental data. Post-hoc pairwise comparisons were conducted similarly, using a combined t-test and permutation approach. A Bonferroni post-hoc adjustment was used to account for multiple comparisons. Significance was determined at $p \leq 0.05$ and data is presented as mean \pm standard deviation.

RESULTS

Biochemical Analysis. Spaceflight did not affect intervertebral disc DNA, GAG, or OHP contents (**Figure 1**). Discs from the spaceflight group had an average of 1771.8 ± 294.2 ng of DNA per disc, which did not differ from discs in the baseline control, ground control, or vivarium control groups ($p > 0.6$). Similarly, loading did not affect GAG or OHP contents, with spaceflight discs containing an average of $21.94\ \mu\text{g}$ GAG/ μg DNA and $15.59\ \mu\text{g}$ OHP/ μg DNA ($p > 0.4$).

μCT Analysis. Similarly, spaceflight did not affect lumbar vertebral body bone microstructure (**Figure 2**), with one-way ANOVA indicating no statistically significant effects of loading on BV/TV

($p=0.17$), Tb.Th ($p=0.056$), Tb.Sp. ($p=0.44$), and Tb.N ($p = 0.37$; Figure 3).

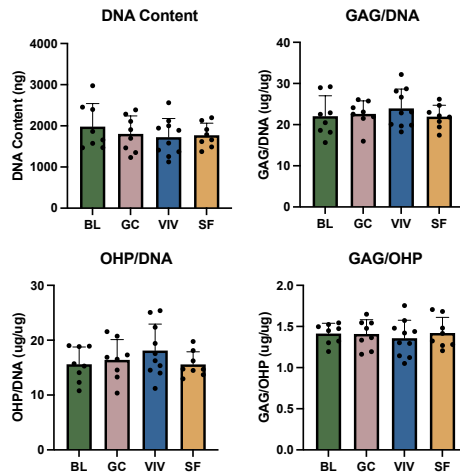

Figure 1. Disc biochemical content is not significantly affected by spaceflight ($p > 0.4$). BL=baseline control, GC=ground control, VIV=vivarium control, SF=spaceflight.

DISCUSSION

Results presented here differ from previously reported data. In one of the first studies on spaceflight and the intervertebral disc, Pedrini-Mille et al. reported decreases in the proteoglycan/OHP ratio in the annulus fibrosus of lumbar discs from rats flown on COSMOS 2044 (14-day flight) [4]. This was supported by a later publication from STS-48, which reported decreases in proteoglycan/OHP ratio in lumbar and thoracic discs of neonatal rats after 5 days of spaceflight [5]. While data presented here investigates GAG content, sulfated GAGs compose the major proteoglycans of the disc, and GAG content is directly proportional to proteoglycan content. Furthermore, numerous studies utilizing simulated weightlessness demonstrated decreases in disc GAG content after unloading [8, 9]. Thus, the consistency in disc biochemical content between spaceflight and control groups in this study was unexpected.

Similarly, the lack of changes in trabecular bone of the vertebral body were also surprising. While data presented here show no significant spaceflight effect on BV/TV, Gerbaix et al. report a 36% decrease in L3 BV/TV after 30-days of spaceflight on Bion-M1 [10]. Berg-Johansen et al. report similar results from the same flight in the caudal vertebrae [11]. On the contrary, a recent study from Rodent-Research 4 demonstrated less bone loss, with changes in L4 BV/TV marked as significant by two-way ANOVA, but not after pairwise post-hoc comparisons [12]. Notably, preliminary results from other weight bearing sites such as the femoral head (unpublished), show significant losses in BV/TV, suggesting that bone loss may be dependent on anatomical location and loading modality rather than spaceflight itself.

There are several factors that may contribute to differences between previous reports and observations presented here, including flight duration and animal housing. While Bion-M1 was the same duration as RR-10, Bion-M1 housing utilized smooth walled cylinders that limited ambulation [13], whereas the Rodent Research hardware has wire mesh. After 14 days in the wire mesh habitat, mice have been observed to develop a unique compensatory mechanism of “race tracking”, which involves highly repetitive, fast running in circles around the habitat. Another behavior is backflipping, whereby mice somersault repeatedly [15]. Though not quantified, these behaviors were observed in the mice used for this study. Lastly, the Animal Enclosure Module (AEM), used in the space shuttle era, also utilized

wire mesh, but experiments did not last longer than 15 days [14]. Given that axial spinal loading of quadrupeds is primarily due to muscle contraction, the lack of differences seen here may be explained by the compensatory mechanisms developed by mice in longer duration spaceflight (> two weeks).

Figure 2. Representative reconstructions of lumbar vertebral body.

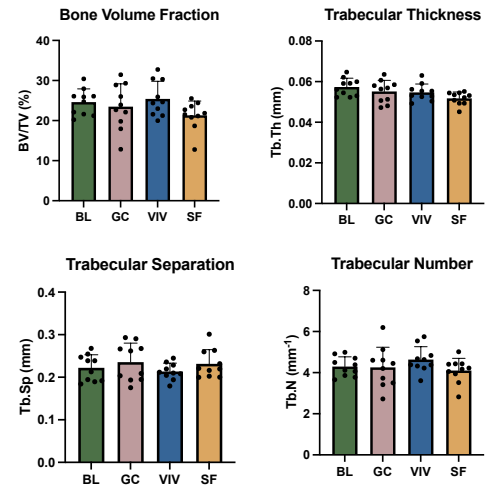

Figure 3. Vertebral body microstructure ($p > 0.05$).

However, as with all spaceflight studies, there are challenges that limit these findings, including a small sample size limiting statistical power. Furthermore, it is possible that other properties, such as mechanical behavior, bone remodeling rates, and other skeletal sites in the same mice experience more drastic differences with longer spaceflight.

Rodent spaceflight studies are extremely helpful in understanding the effects of microgravity on the human body, but the difference in loading modalities between quadrupeds and bipeds is critical for lumbar spine loading. Data presented here suggests that adaptation to the Rodent Research hardware after 30-days of spaceflight may reload the quadruped spine, compensating for microgravity. Further research into this topic may help clarify appropriate rodent models for understanding the impact of long duration spaceflight on spine health in humans.

SEMI-AUTOMATIC QUANTIFICATION OF EARLY STRUCTURAL REMODELING FOLLOWING MYOCARDIAL INFARCTION

Catherine C. Eberman (1), Colleen M. Witzenburg (1, 2)

INTRODUCTION

Following myocardial infarction (MI) there are significant changes in the cellular and extracellular content and structure of ventricular tissue. This highly dynamic response is commonly separated into three healing phases: necrotic, fibrotic, and long-term remodeling [1]. The latter two phases have been extensively studied for their role in heart failure [2]. There has been less focus on the short-term changes that occur during necrosis, despite associated rupture events being a leading cause of sudden death [3] and its importance as the foundation for long-term adverse remodeling and ventricular dysfunction [1]. In more recent years, quantitative or computational histology has become more widely used, particularly in cancer diagnosis [4]. However, algorithmic image processing methods can also be utilized to identify pathologies and assess regional heterogeneities [5]. Here we applied algorithmic image processing methods to quantify structural changes in the left ventricle during the necrotic phase of post-MI healing. We hypothesize that image processing methodology can be used to quantify tissue remodeling post-MI semi-automatically, including immune cell infiltration, changes in collagen content, and border topology.

METHODS

Animal Experiments. For this study, 3 male Sprague-Dawley rats (440-490g) were subject to infarction by permanent ligation of the coronary artery. Animal experiments were reviewed and approved by the University of Wisconsin Institutional Animal Care and Use Committee. Hearts were harvested on day 1, 3, and 5 post infarction. The heart was arrested by retrograde aortic perfusion with phosphate-buffered saline and frozen at -80 degrees. Upon thawing, the left ventricle was dissected from the heart and fixed in 10% formalin for 24hrs prior to histological staining.

Histology. The ventricles were cut to produce longitudinal slices in the plane of the heart wall. Samples were stained with H&E, Masson's Trichrome, and Picrosirius Red (PSR) with two replicates for a total of

6 slices per heart. Histology sections were imaged using brightfield and polarized light microscopy (Nikon Eclipse, OpenPolScope).

Image Processing and Data Analysis. Images were processed using custom MATLAB code to determine immune cell infiltration, collagen content, as well as infarct and border topology. The images were analyzed to determine immune cell content in the infarcted region by spatial variation in color of H&E stained slides (Fig. 1 top row). Immune cell density was calculated as the ratio of segmented immune cell pixels to total image area. Regional collagen content was determined from pixel density of PSR slides (Fig. 2 top row). A polarizing filter isolated collagen from the muscle fibers. Images were segmented into 100x100 pixel blocks and the ratio of light to dark pixels within each region was determined via a binarization threshold to assess collagen density. Infarct collagen density was determined from blocks localized within infarct region. Infarct regions were segmented by applying a K-means clustering algorithm to the Trichrome stained slides (Fig. 3 top row). The pixels were clustered into six color bins to group regions of similar coloration, which allowed for separation of the infarct core, border, and periphery.

RESULTS

Cell Infiltration. Fig. 1 (bottom row) shows the immune cell infiltration into the infarct region. The immune cell density, quantified by percent cell area, was largest at day 3 post MI, with percent areas of 5.34, 12.32, and 9.18% at days 1, 3, and 5 respectively.

Collagen Density. Fig. 2 (bottom row) shows the change in collagen content within the infarct region over the 5-day period. Initially there is a decrease in the collagen level at day 1 compared to the remote regions. At day 3 the collagen level in the infarct region appears to have returned to the level of the healthy surrounding tissue, and by day 5 the infarct region has increased collagen content in comparison to the surrounding tissue. The infarct regions have a collagen pixel density of 0.0033, 0.0064, and 0.0156, respectively.

Area and Border Topology. Fig. 3 shows the segmented infarct regions. This segmentation shows the change in the infarct core, as well as the development of the border over time. On day 1 no clear core or border are present, on day 3 a core and border region are present, and on day 5 the infarct core shows a sharper delineation compared to day 3. Finally, Fig. 4 shows the transition from infarct core to periphery, at higher resolution on day 5. Here, the transition from the highly collagenous infarct core, through the variable border, to healthy myocytes with clear sarcomere units and Z-discs can be seen.

Figure 1: Immune cell infiltration surrounding suture point from H&E stained images; bright field images (top), immune cell density (bottom); left to right: day 1, day 3, day 5, scale = 500µm

Figure 2: Collagen content in infarct region in PSR stained images; polarized light images (top), regional collagen density (bottom); left to right: day 1, day 3, day 5, scale = 1000µm

DISCUSSION

Semi-automated image processing can be used to assess changes in the tissue structure and content post-MI. Previous work has shown immune cell upregulation during the early stages of healing [2]. Here, we were able to verify this response using image processing by segmenting out the immune cells. Additionally, collagen content in the tissue is known to drop during the early stages of healing prior to the new collagen matrix being laid down. Again, we were able to verify this finding by isolating the collagen using a polarizing filter and determining local collagen density. Finally, we were able to segment and separate the infarct region from the surrounding border region. This allows for quantification of the change in regional topology of the infarct and the border over time. Quantification of the structural changes during this early healing phase could provide important insights into later structural changes during remodeling and the occurrence of rupture events.

A BIPHASIC FLUID-STRUCTURE INTERACTION MODEL OF BACKFLOW DURING INFUSION INTO AGAROSE GEL

Arthur D. Ayers and Joshua H. Smith

Mechanical Engineering, Lafayette College, Easton, PA, USA

INTRODUCTION

Convection-enhanced delivery is a medical procedure in which therapeutic agents are infused directly into the brain to treat diseased tissue. However, its efficacy is limited by a phenomenon called backflow, in which the infused fluid flows preferentially along the side of the catheter toward the surface of the brain, resulting in a poor distribution of the therapeutic agents. Experimental studies have explored novel step-design catheters with a geometry that involves a sudden increase in the radius of the catheter a short distance from its tip. These designs are successful at preventing backflow during infusions into agarose gel, even at infusion rates that were significantly higher than the standard for convection enhanced delivery [1].

Analytical [2] and numerical [3] methods have been employed to explore the physics of backflow but have done so only for catheters with straight geometries. Furthermore, the existing finite element model of backflow [3] is predicated on an assumption of Poiseuille flow in the annular gap that forms around the catheter and, therefore, cannot be extended to stepped catheters. As a first step towards developing a model of backflow in a stepped catheter, in this study, we present a model of backflow for a straight catheter in FEBio using biphasic fluid-structure interaction that avoids the assumption of Poiseuille flow.

METHODS

Our finite element model was created in FEBio [4]. Consistent with experimental infusions into agarose gel [2], we modeled backflow for infusions from catheters of radii 0.33 mm, 0.5 mm, and 0.98 mm. The geometry consists of an upper

cylindrical portion, 40 mm in height, with a hemispherical bottom, both of which have outer radius of 20 mm. This geometry was modeled using an axisymmetric wedge domain and, following a mesh convergence study, the mesh for the

Figure 1: Mesh (left) and boundary conditions (right) represented as surface traction t , fluid pressure p , displacement u , radial displacement u_r , fluid velocity q , radial fluid velocity q_r , and prescribed normal fluid velocity q_n .

0.98 mm catheter consisted of 11,736 linear hexahedral elements and 72 linear pentahedral elements (Figure 1).

Similar to the previous finite element model of backflow [3], a thin layer of elements was placed along the tip and side of the catheter to represent the fluid-filled gap that develops between the catheter and the tissue during backflow. The primary difference between our model and the previous one is in the formulation of this layer of elements. Whereas the previous model used biphasic elements with a hydraulic conductivity formulated to replicate Poiseuille flow, our model utilized FEBio’s fluid-FSI element type [5].

Fluid-FSI elements have a stiffness property that allows them to conform with their solid and biphasic interfaces. The fluid-FSI elements directly under the tip of the catheter were assigned a negligibly small stiffness value to allow those elements to freely deform, while the elements along the side of the catheter were assigned a stiffness value determined through a fit of backflow length and fluid pressure results from our 0.98 mm catheter model against those from experimental infusions into agarose gel [2]. Consistent with the previous model of backflow [3], the backflow length was defined to be the distance from the tip of the catheter to the nearest point along the side of the catheter where the radial tissue displacement is 5% of its maximum. The boundary conditions applied for this simulation are shown in Figure 1.

A neo-Hookean material model was used for the behavior of the biphasic domain, with property values taken from the previous study [3]. The infusion flow rate ranged from 1–8 $\mu\text{L}/\text{min}$, consistent with experimental gel infusions [2] and the previous model of backflow [3].

RESULTS

For the three catheter sizes and infusion rates ranging from 1–8 $\mu\text{L}/\text{min}$, our biphasic-FSI model yielded results for the fluid pressure and backflow length that showed good agreement with the agarose gel infusion results of Raghavan et al. [2] (comparisons not shown).

For the 0.98 mm catheter, our biphasic-FSI model produced a spherical fluid pressure distribution for an infusion flow rate of 1 $\mu\text{L}/\text{min}$ and ellipsoidal fluid pressure distribution for a flow rate of 8 $\mu\text{L}/\text{min}$ that is representative of backflow (Figure 2). The biphasic-FSI model produced flow distributions comparable to the previous model, with some differences at the larger flow rate (Table 1).

DISCUSSION

A biphasic fluid-structure interaction finite element model for backflow was developed that reproduces experimental results of backflow length and fluid pressure to a good degree of accuracy. Additionally, it produces flow distributions and fluid pressure profiles that align with our physical understanding of backflow.

Unlike other backflow models, our model does not require the assumption of Poiseuille flow in the annular gap that forms around the catheter. It, therefore, has the potential to be extended to stepped catheter geometries, for which it would be difficult to

Figure 2: Fluid pressure distribution (MPa) at steady state during an infusion of 1 $\mu\text{L}/\text{min}$ (left) and 8 $\mu\text{L}/\text{min}$ (right) through a 0.98 mm radius catheter.

Table 1: Comparison of distribution of infused fluid flow with the finite element model of Garcia et al. [3].

	Percentage of Flow into Region	
	Hemispherical	Cylindrical
1 $\mu\text{L}/\text{min}$		
Biphasic-FSI model	22.6%	77.1%
Garcia et al. [3] model	22.4%	77.6%
8 $\mu\text{L}/\text{min}$		
Biphasic-FSI model	7.4%	92.5%
Garcia et al. [3] model	9.8%	90.2%

apply that assumption. The results from this model have some differences with the ones produced by the model by Garcia et al. [3], which may be attributed to their assumption of Poiseuille flow.

In the future, this model may be used as a basis for models of backflow for infusions with stepped catheters. One challenge in extending it to a stepped catheter geometry may be determining an appropriate value for the stiffness of the fluid-FSI elements along the step.

INTRODUCTION

Atherosclerotic plaque rupture in arteries is a major cause of fatal or disabling cardiovascular events. Plaque rupture is a mechanical event, hence analyses of local mechanical stress in plaques can be of great help for clinical event risk prediction [1]. Plaque stress analyses require accurate information of plaque tissue material properties. However, the current knowledge is limited to average tissue properties based on tissue homogeneity and isotropy assumptions [2], although the fibrous plaque tissue has highly collagenous and heterogenous structure.

In this work, we aim to provide the currently missing critical knowledge on local anisotropic hyper-elastic material properties and strength of fibrous plaque tissue. Our pipeline comprises uniaxial tensile testing of human carotid plaques, digital image correlation (DIC) derived local deformation measurements, second harmonic generation (SHG) microscopy imaging for local collagen information, and a Bayesian optimization based inverse finite element modeling (iFEM) for sample-specific local material property prediction.

METHODS

Sample Collection and Structural Calcium and Collagen Imaging

Nine atherosclerotic human carotid artery (CEA) samples were collected at Erasmus Medical Center in Rotterdam, the Netherlands. Firstly, the samples were scanned with a micro-CT scanner (Quantum GX 2, Perkin Elmer) to identify non-calcified regions for rectangular fibrous plaque tissue strip preparation (n=9). Afterwards, strips were scanned by using a multiphoton microscope (Leica SP5) SHG imaging. Preliminary to the imaging, a tile scan was performed on each sample. In every other tile element (with size of 738 x 738 μm , 512x512 pixels), in-plane Z stack images were obtained at every 3 μm depth up to ~150 μm depth from the luminal side [3]. Maximum intensity projection (MIP) images were obtained per each tile, and were analyzed by using a combination of the Fiblab Software [4] and a custom-built Matlab script to obtain the collagen pre-dominant angle (pDA) and dispersion

(κ) information, as defined by Holzaphel et al. [5], by fitting a von Misses distribution to the obtained collagen orientation histogram data.

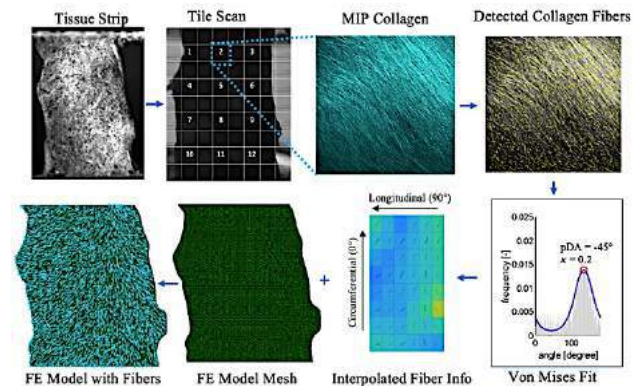

Figure 1: Second harmonic generation (SHG) imaging, collagen fiber predominant angle (pDA) and dispersion (κ) assessment, and element-specific fiber embedded finite element (FE) model.

Mechanical Testing and Digital Image Correlation (DIC)

Following the structural imaging, a speckle pattern was applied to the luminal side of the strips. Then, the strips were placed into the uniaxial tensile testing setup (filled with 37°C PBS), such that the tensile stretching was applied in the circumferential direction of the strips. A pre-load of 0.05N was applied, and in the pre-stretched configuration, samples were scanned by using a 3-D ultrasound (Vevo 3100, Fujifilm) with 21 MHz central frequency 2-D linear transducer (MX250) for thickness measurements. Then, they were preconditioned up to %10 strain for 10 cycles with a speed of 0.05mm/s and a final stretching was applied until complete tissue failure. The tissue stretching was recorded by a 5.3 MP CMOS camera (PL D 725,

Pixelink), and the videos were analyzed by NCorr 2-D DIC Software [6] to obtain local displacements until rupture.

Finite Element Modeling

For each tested strip ($n=9$), the pre-stretched reference image from the tensile testing was used to create finite element (FE) model geometry in ABAQUS (Dassault Systèmes). The tile specific collagen fiber pDA and κ information from the SHG was incorporated in the FE model, element-specific, based on the interpolation of measured parameters (Fig.1). The fibrous plaque was modelled as anisotropic, hyper-elastic, incompressible, Holzapfel-Gasser-Ogden solid [5]. The mesh was composed of plane stress, triangular CPS3 elements. For the thickness, global measured ultrasound-based thickness of ~ 0.7 mm was used. The experimental uniaxial stretching until rupture initiation was simulated by applying experimentally measured tensile loading in four force steps and local plaque displacements were computed for each step.

Inverse Finite Element Modeling (iFEM)

The iFEM framework [7,8] is used to iteratively run FE models with newly generated material model parameters C_1 , k_1 and k_2 until the normalized mean square error (NMSE) between the computed and experimentally measured displacements is minimized (Fig.2). The iFEM framework uses Deep Partitioning Tree based Bayesian Optimization (DPTBO) [9] that chooses a new sample set minimizing the NMSE by training a stochastic Gaussian Process at every iteration.

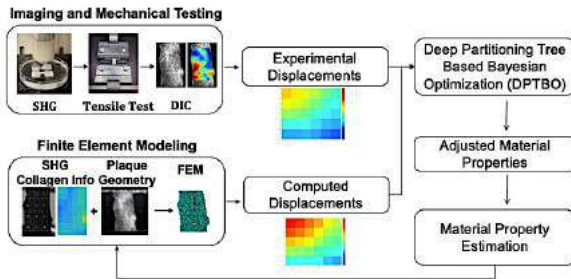

Figure 2: The Bayesian optimization based iFEM pipeline.

RESULTS

For all nine human CEA fibrous plaque tissue strips, structural imaging, collagen fiber measurements, mechanical testing and DIC were successfully conducted. For one sample, the iFEM approach was performed. At the end of the analysis, an NMSE of 4% was reached. The obtained C_1 , k_1 and k_2 values were 0.4 MPa, 0.4 MPa and 400, respectively. The representation of the iFEM predicted material constant-based computational and the DIC based experimental displacement results are shown in Fig.3. Their trends were similar with elevating levels of displacements from lower right to the top left region.

Based on the predicted material properties, tensile strain distribution on the test strip at the final loading step (1.2N) was computed for qualitative comparison with the experimentally measured strain distribution (Fig.4A and B). Both strain maps were observed to have similar patterns (high strains on the left corner and low strains on right top region of the strip), with a range up to 35%. However, local differences were observed in various regions.

The FE model predicted maximum principal stress patterns were observed to have also local variation (range up to 2 MPa) (Fig.4C). This behavior was similar to the observations in the measured and FE computed strain patterns. Interestingly, the rupture was observed to initiate at a local high strain (obtained by both measured and FE-based analysis) and stress (obtained by FE-based analysis) region for the representative case demonstrated in Figure 4.

Figure 3: iFEM predicted computational (A) and experimental (B) displacement results

Figure 4: Correlation of the rupture location and local DIC based strain (A), FE model predicted strain (B) and stress (C) patterns. Rupture initiation region was located within the white square.

DISCUSSION

In this study, we have developed an experimental-computational framework to characterize the anisotropic material properties of atherosclerotic human fibrous plaques. The analysis of the representative human carotid plaque case achieved a successful NMSE result. The FE strain simulation based on the iFEM predicted material properties was observed to have similar patterns to the DIC-based experimentally measured strains. Local differences between two modalities could be due to local thickness variations not captured in the FEM. Furthermore, incorporating the collagen fiber data in the FEM in higher resolution may also improve the final outcome. The FE stress simulation was observed to have local variations through the sample, similar to strain distribution. These local variations are not surprising for the heterogeneous structure of the fibrous plaque tissue. The rupture initiation spot on the sample demonstrated both high stress and strain, which may be an important indicator for further investigation. However, not all high stress and strain regions showed tissue failure. Hence, this could emphasize other structural metrics, i.e., collagen content or cross-linking, as possible candidates, in combination with structural stress and strain, leading to the complex pathways of plaque rupture. As the next step, the remaining eight strips will be characterized with the iFEM approach, and their local stress patterns will be obtained.

To the best of our knowledge, this is the first study on the characterization of local anisotropic material properties of fibrous plaque tissue. The findings of this research hold great potential for identification of local stress fingerprints that are highly crucial for fibrous plaque rupture risk assessment tool development.

MULTISCALE MODELING OF BAROREFLEX FEEDBACK LOOP IN RESPONSE TO ACUTE MYOCARDIAL INFARCTION

Hossein Sharifi (1), Kenneth S. Campbell (2), Jonathan F. Wenk (1,3)

(1) Department of Mechanical Engineering, University of Kentucky, Lexington, KY, USA

(3) Department of Surgery, University of Kentucky, Lexington, KY, USA

INTRODUCTION

Although the 30-day survival rate of patients who suffer from a heart attack (myocardial infarction, MI) is 87% [1], it can result in reduced cardiac function with increased incidence of cardiomyopathy and heart failure, which is the most common cause of death post-MI.

Infarcted hearts undergo various types of remodeling, including changes in structure and mechanics of the scar region, and changes in contractility and architecture of myofibers in the remote region. Such a change in contractile behavior of remote regions is mainly driven by acute response of the baroreflex loop to compensate for the loss of contractile properties of infarcted myocardium.

In this study we utilized a high-fidelity FE model of the left ventricle that is coupled with a baroreflex feedback loop that maintains arterial pressure at a setpoint level by modulating heart rate, intracellular Ca^{2+} handling, molecular-level function of both the thick and the thin myofilaments, and vascular tone. The baroreflex loop predicted higher heart rate with increased contractile function of remote regions and higher vascular tone in response to acute MI.

METHODS

The model described in Figure 1 is called MyoFE, which was built using the FEniCS open-source finite element software. This framework is an enhanced version of a simplified model of cardiovascular function named PyMyoVent [2] in which the 1-D model of LV mechanics was replaced with a high-fidelity 3-D finite element model of the LV. In the current framework, a pacing stimulus activates a 2-compartmental model of electrophysiology that drives the Ca^{2+} transient at each gaussian point across the mesh. The Ca^{2+} transient then triggers the contractile behavior of myocardium, which is being driven by a myosin-level model of contraction named MyoSim [3]. Finally, the LV chamber pumps blood through a lumped parameter model of systemic circulation.

Figure 1: Overview of MyoFE framework.

The baroreflex control was implemented using an algorithm mimicking the underlying biology. In this module, arterial pressure (P_{arteries}) transduces into a normalized afferent signal B_a via a sigmoidal relationship (1), where S is the slope of function around its midpoint, and P_{set} is the setpoint for arterial pressure.

$$B_a(t) = \frac{1}{1 + e^{-S(P_{\text{arteries}}(t) - P_{\text{set}})}} \quad (1)$$

B_a drives the balance signal (B_b) that is a normalized representation of the difference between sympathetic and parasympathetic efferent

activity. The rate of change of B_b is defined in (2) where k_{drive} is a rate constant.

$$\frac{dB_b(t)}{dt} = \begin{cases} -k_{drive} (B_a(t) - 0.5) B_b(t) & B_a \geq 0.5 \\ -k_{drive} (B_a(t) - 0.5) (1 - B_b(t)) & B_a < 0.5 \end{cases} \quad (2)$$

The control signals $B_{c,i}$ capture how each of the eight reflex-sensitive parameters in the cardiovascular model respond to the balance signal. Similar to equation (2), their rates of change were defined as

$$\frac{dB_{c,i}(t)}{dt} = \begin{cases} k_{control,i} (B_b(t) - 0.5) (1 - B_{c,i}(t)) & B_b \geq 0.5 \\ k_{control,i} (B_b(t) - 0.5) B_{c,i}(t) & B_b < 0.5 \end{cases} \quad (3)$$

where i ranges from 1 to $5n+3$, with n equal to the total number of integration points across the geometry and $k_{control,i}$ is the rate constant for system i . The final step in the algorithm used mapping functions M_i to link the normalized control signals $B_{c,i}$ to actual parameter values

$$M_i(B_{c,i}(t)) = \begin{cases} M_{base,i} + \frac{1}{2} (B_{c,i}(t) - 0.5) (M_{symp,i} - M_{base,i}) & B_{c,i} \geq 0.5 \\ M_{base,i} + \frac{1}{2} (B_{c,i}(t) - 0.5) (M_{param,i} - M_{base,i}) & B_{c,i} < 0.5 \end{cases} \quad (4)$$

where $M_{base,i}$ is the default value for parameter i , and $M_{symp,i}$ and $M_{param,i}$ are its limits during maximum sympathetic and maximum parasympathetic drive respectively.

RESULTS

Figure 3 summarizes how the baroreflex feedback loop responds to modeling acute MI. The simulation started with default parameters for ~5 cardiac cycles with heart rate of 65 bpm. Then the baroreflex module was activated (at first vertical dashed line) to start regulating the system to maintain arterial pressure at a setpoint level of 90 mmHg, representing a healthy subject. Once the simulation was at steady state, the infarct region was modeled by reducing the density of cross-bridge myosin heads to 0 for prescribed region of interest shown in Figure 2.

Figure 2: Simulated acute myocardial infarction by decreasing the density of cross-bridge myosin heads to 0 in infarcted regions.

In response to such a loss in contractile behavior within the LV (starting at 2nd vertical dashed line), arterial pressure started to fall below the setpoint level of 90 mmHg (i.e. between 2nd and 3rd vertical dashed lines). However, the baroreflex restored arterial pressure by increasing heart rate, vascular tone ($R_{arterioles}$, C_{veins}), contractility of remote regions (by increasing k_1 , k_3 and decreasing k_{on}), and Ca^{2+} transient of remote regions (via k_{act} and k_{SERCA}).

DISCUSSION

The current study demonstrated a multiscale computational model of cardiovascular function, which is coupled with a baroreflex feedback loop, and is able to maintain arterial pressure in response to a disease mimicking perturbation, such as acute MI. In addition to an increase of

heart rate and vascular tone, the baroreflex increased the contractility of remote regions to compensate for the loss of contractile properties in the infarcted region (Figure 4).

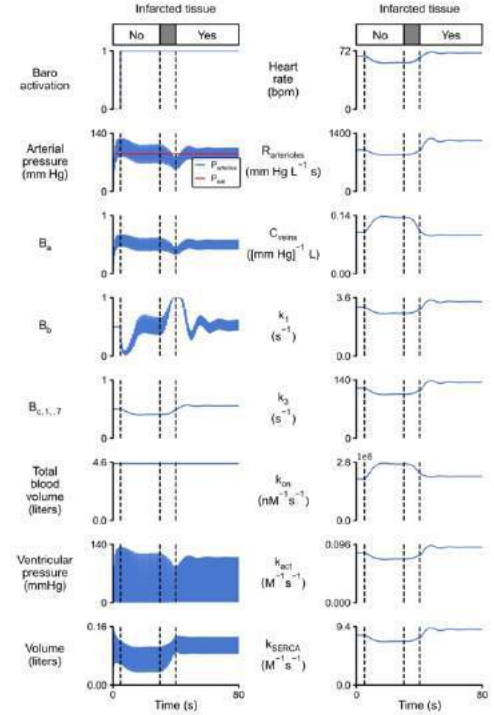

Figure 3: Baroreflex stabilizes the arterial pressure after perturbing the simulation of a healthy subject by mimicking acute MI.

In another simulation, the model was run in the absence of the baroreflex feedback loop, which predicted a non-physiological drop in arterial pressure range due to the loss of contractile function.

Figure 4: Effect of baroreflex in compensating for MI by increasing the contractile behavior of remote regions.

MEGA DATA ANALYSIS OF SEX DISTRIBUTION OF STUDY SAMPLES REPORTED IN SUMMER BIOMECHANICS, BIOENGINEERING, & BIOTRANSPORT ANNUAL MEETING ABSTRACTS

University, Boston, MA, USA

INTRODUCTION

For decades, the outcomes of biomedical research have been limited due to the exclusive use of male subjects. The inclusion of women as research subjects—both in hypothesis-driven investigations and in tool-development efforts—is vital to extend our understanding of medicine and to improve human health. It also ensures that generalized inferences about health and diseases can be made accurately. Evidence has shown that certain areas of biomedical engineering suffer from extensive disparity between its effects on women and men, including but not limited to cardiovascular disease, biomechanical response to concussion, and motor vehicle crash injury outcomes [1-3].

In recent years, rules and regulations have been implemented to encourage higher recruitment of women and minorities in research studies. In the US, title 42 U.S.C. § 289(a)(2) of federal statutes requires the National Institutes of Health (NIH) to ensure that women are included as subjects in clinical research. Additionally, in 1993 the NIH Revitalization Act was executed to further bridge the gap in sex inclusivity in research studies.

These measures have proven effective with data showing that approximately 50% of participants in NIH-funded research studies were women [4]. However, data for studies that were not funded by NIH are not readily available. Some research has been done to assess the inclusivity of sexes in studies that also encompass animals and cells. One of which was done by Bach et al. in 2015 [5] to evaluate the macroscopic trends regarding sex sampling in abstracts presented at the annual meetings of the American Society of Biomechanics (ASB). With similar motivations, the purpose of this study was to examine the sex inclusions in the abstracts of the Summer Biomechanics, Bioengineering, & Biotransport (SB³C) conference from 2015, the inception year of the conference, to 2022 (sans 2018). With increasing awareness of the scientific community, we hypothesized that the number of research projects with both sexes included would have increased over the past seven years.

METHODS

To assess trends of sex inclusion in biomedical studies, we analyzed abstracts from seven years of SB³C proceedings. The abstracts from 2018 were omitted since the conference was jointly run with the World Congress of Biomechanics. Identification of sex in human or animal experimental studies was straightforward. To identify sex in computational and mathematical studies, we examined if the animal or human data/geometry used as input parameters were reported.

For each abstract, the title, applicable population, and summary of the study were recorded. Given the large number of abstracts ($n = \sim 600/\text{year}$), each year was assigned to an examiner. For each abstract, we first examined if any information about sex was provided. If the answer was yes, we then identified if, only female, only male, or both sexes were included. If both sexes were included, we examined if a balanced number of both sexes were used. It was determined that a study was “balanced” if each sex accounted for $50 \pm 10\%$ of the total study population. If only one sex was included, we examined if the study had a sex-specific and biologically relevant purpose (e.g., biomechanics of pregnancy or prostate cancer) and thus the reason for using only one sex was considered “justified”. Once every abstract from each conference proceeding was analyzed, the examiners were randomly assigned a different year from their initial assignment, the process was repeated, and any discrepancies were rectified. A final review of all reported data in the studies that included sex was conducted by a single examiner to ensure the assessments were accurate.

Statistical analyses were performed in R (R Core Team). Unpaired Student’s t-test was used to determine differences between two groups when the distribution was determined to be normal using the Shapiro-Wilk test. If the distribution was not normal, a Mann-Whitney U test was performed. The differences were considered significant if $p < 0.05$. Additionally, a regression and/or correlation model was used to determine trends over the years where applicable.

Figure 1: Distribution of sex inclusion in SB³C abstracts per year

RESULTS

The overall number of abstracts that included sex in their study stayed at approximately 20% for every year ($R = 0.2$, $R^2 = 0.04$, $p = 0.7$; Fig. 1). The numbers for 2015 and 2022 were slightly lower than the rest. To better visualize the data from the abstracts that reported sex, a normalized distribution of female-only, male-only, or both sexes is provided in Fig. 2. It was determined that the number of female- and male-only abstracts submitted each year were not significantly different ($p = 0.2$) using an unpaired t-test.

Using a regression model, we found that the total number of abstracts that included both sexes increased over the years ($R = 0.91$, $R^2 = 0.82$, $p = 0.005$). However, of these abstracts, those with balanced sex groups did not increase significantly ($R = 0.70$, $R^2 = 0.49$, $p = 0.08$) as seen in Fig. 3. In fact, the number of balanced abstracts were significantly lower than the total number of abstracts that included both sexes according to an unpaired t-test ($p < 0.001$).

Figure 2: Normalized distribution of sex groups per year

Figure 3: Trend of abstracts that include both sexes and balanced inclusion of female and male sexes over the years.

Figure 4: Comparison of single-sex abstracts (green = justified; red = unjustified). The reasons for the exclusion of the other sex were based on the research purposes in the “justified” category.

Finally, the female- and male-only data were categorized for justification in each year. The percentage of justified versus unjustified abstracts were plotted using a waffle chart (Fig. 4). A Mann-Whitney U test determined that across all years, female-only group had significantly higher “justified” abstracts ($p = 0.002$).

DISCUSSION

The objective of this study was to obtain an overarching perspective of sex sampling in abstracts submitted to SB³C over the years. We hypothesized that the number of papers that included both sexes, and those with balanced sex groups would increase over the years. The results indicate that there was a significant increase in the inclusion of both sexes; however, the number of balanced abstracts is significantly lower than expected. Ideally, all studies that include *both sexes* should have a 100% rate of balanced groups, but current results leave more to be desired.

Additionally, it was hypothesized that *female-only* studies would be performed due to more justifiable research-specific reasons as compared to *male-only* studies. Such a hypothesis was chosen based on the historical male-only bias toward non-sex-specific research. The stark difference between the justification of male- and female-only studies is apparent from this analysis. Even though the number of female-only studies being justified is higher than the male-only studies, the need for more balanced studies in biomechanics is apparent.

One of the limitations of our analysis is the assumption that the SB³C abstracts encompass all the information of the full study. The papers that result from the abstracts might include a larger and more comprehensive subject population that has not been described in the abstracts due to space constraints. Additionally, there were many studies that included both sexes, but the abstracts did not include the number of male and female subjects, skewing the “balanced” assessment.

In summary, while the overall trend of using both sexes in biomedical research is optimistic, our analysis has shown that the disparity is still prominent. We encourage scientists to be mindful of sex (i.e., the biological differences between females and males) and gender (i.e., the socially constructed identity of the individuals) inclusion to ensure the full benefit of biomedical research.

INTRODUCTION

Coarctation of the aorta has an incidence of 0.3 to 0.6 in 1000 live births, accounting for 5% to 12% of all congenital heart disease [1,2]. Coarctation is associated with structural pathologies of the aortic wall and is considered as a continuum of a disease process which affects the entire aorta [3].

Balloon angioplasty of native coarctation *in vitro* was reported in 1982 by Lock *et al.* [4]. Intimal tears were observed in all patients but no cases of aortic wall rupture. Examination under light microscopy demonstrated intimal hyperplasia, medial thickening and confirmed the presence of tissue tears [4].

A prospective randomised trial by Shaddy *et al.* demonstrated the safety and efficacy of balloon angioplasty in native coarctation when compared with surgery [5]. In the angioplasty group, however, there was a higher rate of aneurysm formation and long-term data showed that aneurysms can occur as late as 5 years post procedure [6]. These early reports [4-6] demonstrate the importance of advancing the knowledge of the wall structure of coarcted aortic tissue and how, at a microscopic level, the vessel responds to intravascular interventions such as balloon angioplasty and stenting.

The ductus arteriosus is a foetal blood vessel which connects the pulmonary arteries to the aorta allowing blood to bypass the lungs. Ho *et al.* demonstrated that ductal tissue is a common cause of coarctation and that ductal tissue is histologically different to the surrounding aorta [7].

The current treatment for neonatal coarctation is surgery, however, the treatment has evolved for older children and adults to include percutaneous stent implantation [8]. Newer stent designs, such as the Minima stent (Renata medical, CA, USA) [9], have opened the door for percutaneous treatment in neonates but further understanding of the underlying vessel properties is needed.

The aim of this study is to examine the differences between neonatal vessels at coarctation sites, in terms of mechanical properties and histology. Understanding these differences is key to designing bespoke patient therapies and to understanding the potential impact of neonatal stenting.

METHODS

Five specimens of neonatal aortic coarctation tissue were harvested during surgery from Children's Health Ireland at Crumlin following ethical approval by the hospital research ethics board. The vessels were cut into 3mm ring samples and uniaxial tensile testing was performed after 5 cycles of pre-conditioning to predetermined stretch levels before being fixed for histological analysis, see Figure 1.

Figure 1: Neonatal aorta sample set-up for ring testing and demonstration of calculating stretch level, (outer diameter - inner diameter)/inner diameter.

RESULTS

Five sections were harvested of which three (samples 3 – 5) were further subdivided into two test specimens. Samples were labelled “A, B and C” with “B” being at the ductal-insertion point and “A” and “C” being proximal and distal, respectively.

Figure 2 shows the Force versus Diameter Change behaviour of the samples and highlights the inter- and intra-specimen variability. Specimens have quite variable mechanical properties depending on their relative location with respect to the ductus arteriosus insertion point (i.e. proximal or distal).

Figure 2: Force-Diameter Change (%) curves from uniaxial testing of neonatal coarcted tissue

Preliminary histological assessment of the ductus arteriosus tissue demonstrates the different histological structure of the ductal tissue when compared to the aortic wall tissue (Figure 3 & 4). The ductal tissue has very little elastin or collagen thus inferring that its load bearing capability is likely quite limited when undergoing stretch.

Figure 3: Neonatal aorta representative sample (Aorta 1) (a) Gross sample, (b) Verhoeff's stain (elastin), (c) Picrosirius red (collagen), (d) H&E stain (cell content). [Scale bars 2mm]

DISCUSSION

Neonatal coarcted aortic tissue has variable mechanical properties and the amount of ductal tissue which invades into the healthy aortic tissue likely plays a significant role in this variability. The composition of the coarcted tissue needs to be accounted for in any bespoke device-based patient treatment.

Previous work has demonstrated that bespoke titanium stents can be designed *in silico*, 3D printed and post-processed to match the patient specific geometry from a paediatric patient with coarctation of the aorta [10]. Our data will provide new insights into patient vessel properties and help inform such computational models to enable the optimum stent to be designed to achieve lumen gain while minimizing tissue damage.

Figure 4: Neonatal aorta representative sample (a) Gross sample, (b) Verhoeff's stain (elastin), (c) Picrosirius red (collagen), (d) H&E stain (cell content). [Scale bars 2mm]

CONCLUSION

Individualised treatment plans will be the way of the future for many conditions. This study confirms the need to further understand the complex interplay between mechanical properties and tissue composition when designing less invasive treatment options in neonatal coarctation of the aorta.

SHEAR STRAIN STIFFENING IN LIGAMENTS ARISES FROM UNALIGNED FIBERS AND IS AMPLIFIED BY AXIAL STRAIN

INTRODUCTION

Ligaments are hierarchical soft tissues that guide joint mechanics and prevent aberrant motion. In these roles, they often undergo a combination of tensile and shear loading. Resistance to shear is the primary mechanism by which ligament loading is dispersed across the tissue and is traditionally thought to arise from the non-collagenous matrix and interfibrillar bonds.¹ However, we recently showed using a computational model that the tissue's resistance to shear increases substantially with axial tissue strain when collagen fibers are not aligned in the loading direction.² These model predictions have yet to be empirically validated. It was previously shown that the shear modulus of ligament is shear strain-stiffening¹, but those tests were conducted in an axially unloaded state, which does not represent the combined loading that ligaments undergo *in vivo*.

The objective of this study was to characterize changes in the effective shear modulus of computational, electrospun nanofiber, and *ex vivo* models of human ligaments with axial loading. **Our primary hypothesis** is that effective shear modulus increases with axial load. **Our secondary hypothesis** is that the relationship between shear modulus and axial load is dependent on the shear region's fiber alignment.

METHODS

Finite element model: We created a finite element (FE) model of a ligament loaded both axially and in shear (Fig. 1 bottom). We modeled the tissue as transversely isotropic³ with distributed fibers⁴ according to a fiber alignment factor, k_f . Fibers were embedded in a Neo-Hookean matrix material. We simulated loaded shear with variable fiber alignment (i.e., from isotropic fibers, $k_f = 0$, to relatively aligned fibers, $k_f = 50$) on a high-throughput computing grid using FEBio v3.1.0.⁵

Electrospun nanofiber phantom: We dissolved PCL in hexafluoroisopropanol at 0.15 g/mL. The polymer was driven through a 22-gauge needle at 3 mL/hr with a 15kV potential through a distance of 15 cm. A rotating drum was placed in the polymer jet path. We controlled rotation speed to generate an isotropic nanofiber phantom.

Ex vivo ligaments: We procured 9 ligament specimens from the medial collateral ligaments (MCL) of three human donors (1M, 65.3 ± 7.0 years). We sectioned specimens to a uniform thickness of < 2 mm, ensuring that collagen fibers without overlying tissue constituents were visible on either side of the sample. We determined the tissue thickness using a portable ultrasound system (26 μ m resolution) prior to mechanical testing (1.27 ± 0.47 mm (mean \pm s.d.)).

Mechanical testing: We mounted specimens between sandpaper grips in a 1X PBS bath (ligament) or in air (phantom) on a custom axial-shear dynamic testing fixture (Fig. 1 top). The fixture consists of four motor-driven linear actuators (< 20 μ m backlash, 2 proximal, 2 distal) that load the specimen both in axial tension and shear. We preloaded each specimen to 0.05-0.1 N with approximately equal tension on either side. After preloading, we loaded the specimen in shear with a sawtooth displacement profile from 0-40% shear strain at a rate of 10%/s for 10

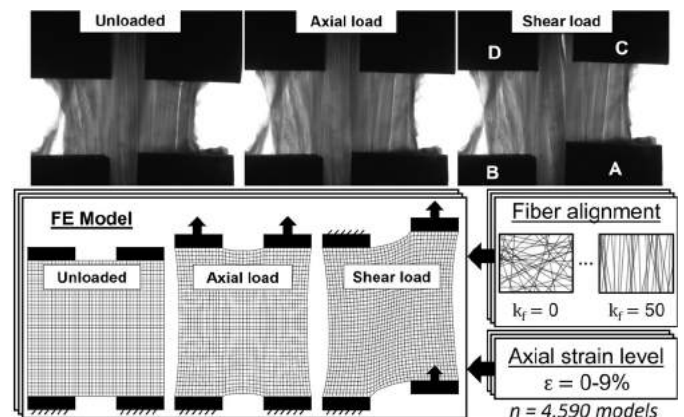

Figure 1: (top) Loaded shear force was computed as the force balance on the right side of the specimen ($F_C - F_A$). **(bottom)** Our FE model simulated loaded shear across fiber alignments and axial strain levels.

cycles. We then loaded specimens to axial strains of 3, 6, and 9% at a rate of 1%/s, and at each axial strain we applied the same sawtooth shear displacement profile. We recorded all measurements during the last cycle to minimize viscoelastic effects. The testing order of axial strains after 0% axial strain was randomized for all specimens.

Fiber alignment determination: We determined fiber alignment in our ligament samples using quantified polarized light imaging.⁶ A high-intensity backlight projected circularly polarized light through the specimen, and we captured images at 10 Hz using a machine vision camera (FLIR Blackfly S USB3). We computed the degree of linear polarization (DoLP), which represents fiber alignment, from interpolated polarized greyscale intensities.⁷ Our electrospun phantom was sputter-coated with gold and imaged using a scanning electron microscope (Zeiss Gemini 450) to verify isotropic fiber alignment.

Statistical analysis: We assessed the shear modulus (τ) at each axial strain level (ϵ). We determined the linear region of the shear stress response using an exponential-linear optimization function.⁸ In ligaments, we evaluated differences in shear modulus across axial strains using one-way analyses of variance (ANOVAs) with $\alpha = 0.05$. We additionally used a repeated measures ANOVA with an interaction effect between axial strain and fiber alignment (DoLP).

RESULTS

FE Model: The model predicted that shear modulus increased by up to 2.8 MPa at 9% strain when fiber alignment was varied. Increasing levels of axial preload increased shear modulus by up to 1.03 MPa in tissues with isotropic fibers (Fig. 2a,b) but were also present when fibers were relatively aligned (up to a 115 kPa increase) (Fig. 2a,c).

Figure 2: (a) The FE model revealed that changes in shear modulus ($\Delta\tau$) from the unloaded state were higher for (b) models with unaligned fibers ($k_f=0$) than those for (c) models with relatively more aligned fibers ($k_f=50$). Error bars represent standard deviation.

Electrospun Phantom: The shear stress-shear strain behavior of the electrospun nanofiber phantom (Fig. 3b) was qualitatively similar to that of the FE model with randomly aligned fibers ($k_f = 0$) (Fig. 3a). Both the model and phantom exhibited shear strain stiffening behavior when the tissue was not axially preloaded.

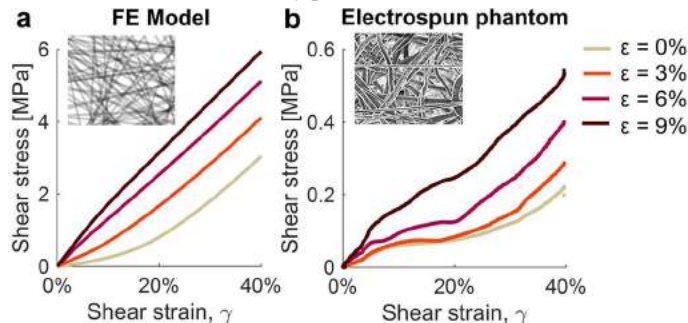

Figure 3: (a) The shear response of our FE model with unaligned fibers ($k_f=0$) qualitatively agreed with (b) the shear response of an isotropic electrospun phantom.

Ligaments: Ligament specimens exhibited shear strain-stiffening behavior on average for all levels of axial preload (Fig. 4a). The shear modulus of the linear region at 9% axial strain was greater than that at

0% ($p < 0.001$) and that at 3% axial strain ($p < 0.05$) (Fig. 4b). Axial strain was the primary contributor to an increase in shear modulus ($p < 0.01$). We did not detect a relationship between fiber alignment and shear modulus ($p=0.34$) or a significant interaction between fiber alignment and axial strain ($p=0.32$).

Figure 4: (a) The shear stress-shear strain relationship was nonlinear in the ligament specimens tested. (b) Shear moduli in ligaments generally increased with increasing axial load at both low and high-shear strains. Error bars represent standard error (* $p < 0.05$, *** $p < 0.001$).

DISCUSSION

The objective of this study was to characterize ligament shear modulus under combined axial and shear loading. Consistent with our primary hypothesis and prior FE model predictions,² the linear shear modulus increased up to 12-fold on average when ligaments were axially loaded prior to undergoing shear deformation (Fig. 4b). We also observed a nonlinear relationship between the ligament shear stress and shear strain, which agrees with prior studies.¹ However, we observed much smaller max shear stresses in ligaments than the same prior study (1.6-5.5 kPa vs 15-25 kPa) in the axially unloaded state. This may be caused by loss of ligament matrix material and supporting structures other than the fibers from cryosectioning or by changes to the shear loading setup (i.e., gripping anterior/posterior¹ vs proximal/distal).

Our secondary hypothesis that increases in shear modulus correspond to fiber realignment due to axial loading was not supported. However, our FE model suggests that the initial fiber alignment in the shear region of the tissue is an important factor that can affect shear modulus (Fig. 2a). Because this strain-stiffening relationship exists in electrospun nanofiber phantoms (Fig. 3b), we are currently expanding our study of the relationship between fiber alignment and shear modulus by systematically varying fiber alignment in the phantoms.⁹

The findings from this study have several applications. First, we developed and implemented a novel technique to measure shear modulus in axially loaded tissues, which can be used to study the mechanics of ligaments and other fibrous soft tissues. Second, we showed that axial loading modulates ligament shear modulus, a relationship that has functional relevance but is not captured in current constitutive models of ligament³ that are used most commonly. Third, because noninvasive sensing and imaging using shear waves, such as in tensiometry or elastography, is dependent on the tissue's axially preloaded shear modulus,² the analysis presented in this study may be useful for resolving how shear wave speeds can change with axial load and shear modulus.

MODELING ULTRASOUND-DERIVED ACOUSTIC RADIATION FORCES IN HYDROGELS USING 3D FORCE MICROSCOPY

INTRODUCTION

Biophysical stimuli have gained attention in the growing field of bone regenerative engineering for their potential to augment cell behavior and enhance bone repair. In an effort to treat large-scale bone defects not amenable to traditional grafting techniques, our group has combined hydrogel-based cell therapy with low-intensity pulsed ultrasound (LIPUS). Hydrogels serve as implantable, biomimetic, 3D environments in which encapsulated cells can be delivered to and retained within bone defects. LIPUS stimulation, an FDA approved treatment for fracture healing, is used in our approach to deliver low-level acoustic radiation force (ARF) to cells [1]. Physical forces are well-known as important regulators of cell behavior and bone homeostasis. Therefore, LIPUS-derived ARF applies supplementary mechanical forces to hydrogel-encapsulated cells. Previous work has demonstrated that LIPUS can upregulate osteogenic markers *in vitro* and stimulate bone formation *in vivo* in cells encapsulated in collagen hydrogels [2,3]. However, the local mechanical environment that LIPUS imparts on hydrogel-encapsulated cells is not well understood. Here, we have developed a 3D force microscopy (3D-FM) technique based on traditional traction-force microscopy (TFM) to predict the mechanical forces imparted to cells and their surroundings during LIPUS stimulation. Briefly, this technique involved tracking fluorescent microspheres embedded in cell-laden hydrogels and measuring their ultrasound-induced displacements. These displacements were then used to computationally reconstruct and predict the associated 3D forces applied locally to cells and their hydrogel environment. The objectives of the work herein were to: 1) develop the theoretical framework and MATLAB algorithm for the 3D-FM technique, 2) validate its performance using simulated displacement data from simple, user-defined force distributions, and 3) use 3D-FM to estimate the forces near isolated cells in a collagen hydrogel subject to ARF. Modeling the ARF-induced cell-scale forces across different ultrasound and hydrogel parameters will permit a better understanding of how these inputs

correspond to cell behavior, and ultimately optimize the regenerative capacity for bone defect repair.

METHODS

Theoretical Framework and Implementation of 3D-FM: The 3D-FM algorithm developed in MATLAB was an extension of traditional TFM techniques. While almost all applications of TFM focus on cell-generated forces and most analyze 2D culture conditions, our novel algorithm was designed to compute forces near cells fully encapsulated in 3D hydrogels resulting from externally-applied mechanical stimulation, outlined visually in Figure 1. First, fluorescent beads embedded in the hydrogels were tracked and their ultrasound-induced displacements were measured, representing local values of gel deformation. Interpolation of these bead displacements then produced a 3D displacement vector field $\vec{u}(\vec{r})$ for the region of gel imaged.

Figure 1. Diagram illustrating the concept and experimental setup of the 3D-FM technique for predicting the local forces in cell-laden hydrogels due to ultrasound stimulation.

The 3D force-density vector field $\vec{f}(\vec{r})$ was reconstructed from the displacement field via a regularized Fourier transform method for solving the otherwise ill-posed inverse problem of linear elasticity. This

method approximated the hydrogel as a linear-elastic, isotropic, homogeneous medium satisfying the conditions of mechanical equilibrium with ultrasound-induced deformations that were small compared to the bulk hydrogel dimensions. These assumptions for the medium admit a closed-form matrix Green's function $\mathbf{K}(\vec{r})$ in terms of its elastic properties (E_Y, ν) that characterizes the displacements produced from a concentrated force in the 3D medium. $\mathbf{K}(\vec{r})$ was then used as a mathematical "building block" for a general solution relating $\vec{f}(\vec{r})$ and $\vec{u}(\vec{r})$ (Eqs. 1 and 2).

$$\vec{u}(\vec{r}) = \int \mathbf{K}(\vec{r} - \vec{r}') \vec{f}(\vec{r}') d^3 r' \quad (1)$$

$$K_{ij}(\vec{r}) = \frac{1 + \nu}{8\pi E_Y (1 - \nu)} \left[\frac{3 - 4\nu}{r} \delta_{ij} + \frac{x_i x_j}{r^3} \right], \quad i, j = 1, 2, 3 \quad (2)$$

Inverting this general solution to obtain $\vec{f}(\vec{r})$ from $\vec{u}(\vec{r})$ involved transforming Eq. 1 into discrete Fourier space (denoted by tilde marks below) and employing zeroth-order L^2 Tikhonov-regularization (Eq. 3) to stabilize the reconstruction of $\vec{f}(\vec{r})$ [4].

$$\vec{\tilde{f}} = (\mathbf{K}^\dagger \mathbf{K} + \lambda^2 \mathbf{1})^{-1} \mathbf{K}^\dagger \vec{\tilde{u}} \quad (3)$$

Here, \dagger denotes the conjugate transpose of a matrix. The choice of the real-valued regularization parameter λ was based on the tradeoff between suppressing the undesirable amplification of high-frequency noise in $\vec{u}(\vec{r})$ and excessively dampening the entire reconstructed force-density field. Finally, the results of Eq. 3 were transformed back into physical space to yield the estimated local force-density field $\vec{f}(\vec{r})$ corresponding to the measured ultrasound-induced displacements within the cell-laden hydrogel.

Validation of 3D-FM Algorithm: To test the accuracy of the 3D-FM algorithm, simulated displacement data were generated without added noise from known, randomized point-force distributions. First, the ability for the algorithm to reconstruct accurate force magnitudes was assessed for 50 randomly-generated forces of various magnitude ranges. Second, the ability for the algorithm to accurately reconstruct force distributions of increasing complexity was tested, using 10, 100 and 1000 randomly-generated forces.

Cell-Hydrogel Construct Synthesis: Bone marrow stromal cells (BMSCs) were harvested from the long bones of reporter mice and cultured for 7 days before osteogenic induction to enhance expression of a green fluorophore. BMSCs ($10^6/\text{mL}$) were then co-encapsulated with red fluorescent beads ($1 \mu\text{m}$ diameter, $10^8/\text{mL}$) in 3 mg/mL (0.3%) collagen hydrogels formed on plasma-treated microwell dishes with glass coverslip bottoms and immersed in 3 mL α -MEM.

Estimation of Local 3D Forces near Encapsulated Cells: Continuous-wave ultrasound with $1000 \text{ mW}/\text{cm}^2$ intensity was applied to the BMSC/bead-laden hydrogels. Z-stacks containing an isolated cell were acquired with a Leica DMi8 epifluorescence microscope before ultrasound, 30 seconds after the onset of stimulation, and 30 second after the cessation of a 2 minute bout of stimulation. Tracking and displacement measurements were performed with Velocity software. Elastic parameters for the 3D-FM algorithm were derived from previous rheometry experiments on 0.3% collagen hydrogels. A user-defined Boolean mask enclosing the green fluorescence from a cell was used to isolate and quantify the estimated ultrasound-derived forces in the region occupied by the cell.

RESULTS

Figure 2 shows that the 3D-FM algorithm was able to reconstruct force-distributions with different magnitude ranges and complexity to with normalized errors less than 15%. Other data (not shown) showed that reconstructed force-density magnitudes increased with increasing magnitudes of simulated displacement, thereby demonstrating the validity of the algorithm. Figure 3 displays top-down views of the Z-

stack and tracked bead displacements for a representative region of collagen hydrogel containing an isolated cell and deformed by incident $1000 \text{ mW}/\text{cm}^2$ ultrasound. The 3D-FM results in Figure 4 reveal a cluster of ultrasound-induced forces localized around the cell.

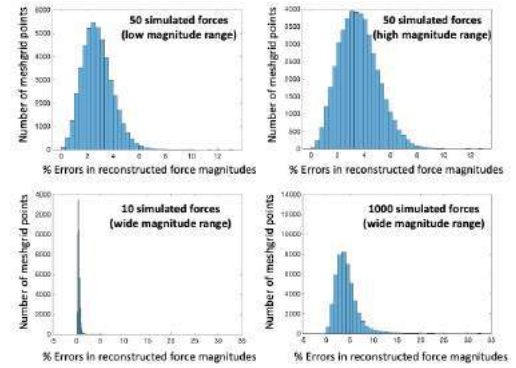

Figure 2. Histograms of percent normalized errors in the forces reconstructed from various simulated displacement datasets.

Figure 3. Top views of a cell and beads in a 3D hydrogel (left) and associated ARF-induced displacements of the beads (right).

Figure 4. Local ARF-induced force field (left) and estimated net force (right) around the cell, predicted by the 3D-FM algorithm.

DISCUSSION

Here we present a novel application and modification of TFM to quantify the local mechanical forces on cells encapsulated in hydrogels stimulated by LIPUS-derived ARF. The 3D-FM model suggested that mechanical forces are transmitted directly to cells and their immediate surroundings as a result of ARF propagating through the hydrogel. Quantifying these forces in various ultrasound and hydrogel conditions will contribute to a clearer picture of the mechanisms of LIPUS stimulation in order to improve bone regeneration.

INTRODUCTION

The acetabular labrum plays a crucial role in the hip, serving as a mechanical boundary to enhance joint stability and sharing load with the acetabular cartilage. Labral injuries can impair these functions, leading to instability and potentially accelerated degeneration of the acetabular cartilage. In individuals with cam-type femoroacetabular impingement syndrome (FAIS), secondary labral tears are common. Tears are often repaired during arthroscopic surgery for FAIS¹. Suture anchor repair is currently considered the gold standard for labral repair, though labral reconstruction procedures are also utilized to modify the labrum's natural morphology. There is ongoing debate among surgeons as to whether reconstruction or augmentation of hypotrophic (undersized) labra is necessary, as there is a lack of biomechanical or clinical data demonstrating reduced efficacy of such labra². The aim of this study was to assess the influence of labral size on the mechanical environment of the cam-type FAIS hip during gait. We tested the null hypothesis that there were not differences in contact mechanics between different sized labra, and thus the likelihood of cartilage damage would remain unchanged.

METHODS

For our finite element models, we adapted closed bounded surfaces of the bones, cartilage, and labrum segmented from CT arthrogram image data of a single patient with cam-type femoroacetabular impingement syndrome (FAIS)³. Three clinical morphologies were considered in our modeling cases: (1) an anatomically normal labrum, corresponding to the segmented geometry, (2) a hypotrophic labrum with an average

thickness less than 3mm, and (3) a hypertrophic labrum with an average thickness greater than 4 mm^{2,4}. The labrum and cartilage surfaces were discretized using quadratic tetrahedral elements in ANSA (BETA CAE Systems SA), and elements were manually offset, modulating the height and thickness, to reflect the hypertrophic and hypotrophic morphologies (Fig. 1).

Fig. 1: (Left) Surfaces from a volunteer with cam-type FAIS were used for FE model creation. (Right) The anatomically normal labrum was modified to reflect the hypotrophic and hypertrophic cases.

The acetabular and femoral cartilage layers were modeled as anisotropic hyperelastic materials with a continuous ellipsoidal fiber distribution of tension-only collagen fibers that varied in primary orientation through the thickness of the cartilage (tangent to the articular surface in the superficial zone, isotropic distribution in the middle zone, and perpendicular to the articular surface in the deep zone)⁵. The labrum was represented as a transversely isotropic material with circumferentially oriented collagen fibers⁵. Patient-specific kinematics from skin-marker motion tracking during gait and joint reaction forces collected by

Bergmann et al. were incorporated into the finite element models⁶. All models were analyzed in FEBio (www.febio.org). The labral load support was examined for the three modeling cases, defined as the total load across the labrum divided by the total load across the cartilage-labrum interface. Additionally, the magnitude of displacement for the labrum was evaluated for each morphology at heel-strike. Contact pressure, 1st principal (tensile) strain on the articular surface, and maximum shear stress at the osteochondral interface were also evaluated throughout the gait cycle to compare the distribution of load.

RESULTS

A larger labrum resulted in greater load supported by the labral surface (Normal – 2.1%; Hypertrophic – 3.0%; Hypotrophic – 1.8%) throughout the gait cycle. Greater load across larger labra also lead to greater displacement during heel-strike for the hypertrophic (2.63 mm) and normal (2.29 mm) cases compared to the hypotrophic cases (2.26 mm) (Fig. 2). However, this did not result in measurable changes in contact pressure anterosuperiorly at heel-strike (Fig. 3).

Fig. 2: Labrum displacement at heel-strike for each morphology. Larger labra lead to greater displacement across the three modeling cases.

Fig. 3: Contact pressure at heel strike for the three labrum geometries. Note the lack of difference in max contact pressure located anterosuperiorly.

There were small differences in the 1st principal strain, with the hypotrophic labrum model presenting the largest tensile strain within the same region for the cartilage (25.6%), followed by the hypertrophic (24.3%) and normal (20.2%) cases (Fig. 4). Similarly, the peak shear stress at the osteochondral interface was slightly elevated for the hypotrophic labrum (13.1 MPa) followed by the hypertrophic (12.8 MPa) and normal (12.2 MPa) labra (Fig. 5).

DISCUSSION

The difference in labral load support between the hypertrophic and hypotrophic morphologies indicates that labral size modifies the load transferred to the labrum during walking. These findings are consistent with the larger magnitude of displacement in both the hypertrophic and normal cases compared to that of the hypotrophic case. These results are also consistent with a study

Fig. 4: 1st principal strain at heel-strike for the three labrum geometries. Max strain was located anterosuperiorly with similar values for each case.

Fig. 5: Peak shear stress at heel-strike for the three labrum geometries. The highest shear stress occurred at the osteochondral surface for each case.

of acetabular dysplasia, where dysplastic hips with larger labra had higher values for labral load support⁷.

Despite the differences in load transmission between different sizes of labra, the contact pressure and tensile strain across the articular cartilage were minimally affected and were within similar ranges previously reported for normal and cam-type hips, respectively^{3,8}. Similarly, the variation in max shear stress was minimal between the three cases and was above the reported magnitude of shear stress within normal hips⁹. These findings indicate that the mechanical loading on the acetabular cartilage in cam-type hips is left unchanged regardless of labral size, suggesting similar levels of susceptibility to cartilage damage.

Our results could have implications for clinical decision making during primary arthroscopic surgery for cam-type FAIS, particularly regarding management of the labrum. Notably, model predictions for this patient suggest that labral reconstruction would not have a major effect on cartilage stress. It is possible that labral repair with native labral fibers may be enough to restore functionality to the hip regardless of labral morphology. Still, additional patients and asymptomatic controls need to be modeled to better understand the role of the size of the labrum. Future research could also evaluate the effect of labrum size by using more advanced approaches to scaling the dimensions of this tissue, and incorporating the use of statistical shape model to better represent anatomical variation in the size and shape of the labrum that occurs across this population.

MOLECULAR DYNAMICS STUDIES OF SUGAR SOLUTIONS FOR CONTROLLING WATER ROTATIONAL RELAXATION TIME

INTRODUCTION

Along with the advancements in therapeutic proteins, stabilization methods are in urgent demand to maintain their quality, given the necessity of protein stability for successful therapy. Protein drugs are usually in a liquid formulation and the dynamics of surrounding water (hydration layers, abbreviated as HLs hereafter) are known to have a significant influence on protein conformation. During the stabilization processes, protective agents are usually added to help the preserved biological materials overcome the induced physiochemical stresses, such as ice crystallization, low temperature, dehydration, etc. Therefore, the investigations of the effect of additives on water dynamics may advance our knowledge of controlling water dynamics, thus the design of protein stabilizers. Molecular dynamics (MD) simulations have been a powerful tool to probe the structure, dynamics, and interactions of biological molecules, providing adequate spatial and temporal resolution at a reasonable computational cost¹.

Among the protective agents, sugars have been widely employed to protect protein drugs and food during the freezing and drying processes. The sugar-water interactions are deemed to be responsible for its unique protection mechanism². It has also reached a consensus that water dynamics close to sugars are retarded relative to bulk water, by a variety of experiments³ and MD simulations⁴. However, the basic principles for retarding water rotational dynamics thus for the design of protective agents is rarely discussed, although all these above works explored how different additives influence water dynamics through water-structure-making or water-structure-breaking effect⁵. Therefore, a systematic investigation to extract the essential parameters for developing protective agents is of great significance.

In order to facilitate the design of the protein stabilizer, the present work aims to have a better understanding of how the protective additives slow down the water dynamics from a molecular level. Rotational relaxation times of individual water molecules in bio-protective sugar solutions (glucose, trehalose) are calculated by MD simulation. Water

relaxation time is found to increase exponentially with its residence time. Furthermore, the normal distribution of water residence time suggests how the solute size (specific surface area) governs water residence time. The basic laws acquired here for controlling water dynamics will have a meaningful impact on the development of protein stabilizers.

METHODS

MD simulation was adopted in the present work. Initial structures of glucose and trehalose were downloaded from the GlycoSciences Database. The corresponding topology files for MD simulation in GRMACS were prepared by the CHARMM Graphical User Interface (CHARMM-GUI). Sugars were described by the CHARMM36m force field, and the simple point charge (SPC/E) model was used for water. For these carbohydrate-water systems, tens of solute molecules were solvated in a cubic box of length around 3 nm with 6~10 hundreds of water molecules, corresponding to a mass percent ranging from 10 to 40 wt%. The subsequent simulation protocols such as the energy minimization, NVT equilibration, NPT equilibration, and the final production run were similar with those used for the simulation of aqueous lysozyme solution⁶.

The rotational relaxation time of water molecule was derived from its dipole moment time autocorrelation function (ACF), which is defined as

$$\psi(t) = \frac{\langle \mu(0) \cdot \mu(t) \rangle}{\langle \mu(0) \cdot \mu(0) \rangle}, \quad (1)$$

where dipole vector $\mu(t)$ is the summation of single water OH-bond vector e at time t . The dipole moment ACF obtained was then approximated with a multi-decaying exponential by the least squares method to extract the rotational relaxation time constants⁶.

By terahertz absorption measurements, Heyden et.al found that the THz absorption of the hydration water was increased in a range of 3.7

$\pm 0.9 \text{ \AA}$ and defined the HL thickness of 3-4 \AA , for monosaccharide solutions⁷. EDLS experiments by Lupi et al. suggested the evident retardation of water within 3.1 \AA from any solute atom relative to the bulk water, for monosaccharide and disaccharide solutions⁸. Based on these experimental determinations, the sugar HL in this work was also adopted as a 3 \AA water layer from the sugar surface. Consequently, the residence time which is the time water spends within the HL was obtained for each water molecule in all the studied sugar solutions.

RESULTS

The relationship between water rotational relaxation time and residence time is explored and shown in **Figure 1** where the abscissa, residence time t_R , is normalized by the sampling time (5 ns). For all the solutions studied here, water relaxation time shows a decent exponential correlation with its residence time, as suggested by the linear fit (the solid black line in **Figure 1**) between the relaxation time in a logarithmic scale and the residence time. The intercept ($t_R = 0$) of around 0.68 corresponds to the relaxation time of HMW, which is ~ 5.0 ps. The slope is around 0.40 for monosaccharide (glucose), while it is about 0.56 for disaccharide (trehalose) solutions. Obviously, the increasing rate of the water relaxation time with the residence time is faster in disaccharide solutions than that in monosaccharide solutions. Particularly, this observation implies that slowing down water rotation dynamics might be achieved by promoting the increment rate and elongating the water residence time.

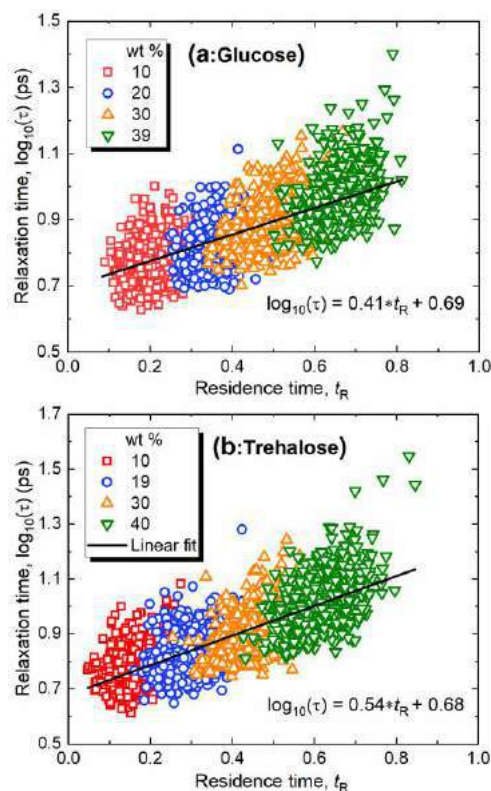

Figure 1: Correlation between rotational relaxation time and residence time for water in sugar solutions. Each symbol represents one single water molecule. (a) glucose, (b) trehalose.

Achieving a broader distribution of water relaxation time necessitates a longer residence time spectrum. In light of this, PDF of the water residence time in various concentrations of trehalose solutions

together with the approximated Gaussian curve is obtained and shown in **Figure 2**. For each condition, water residence time PDF is perfectly fitted to a normal distribution. This observation suggests that residence time distribution of water in sugars solutions is uniform and that water molecule has an equivalent probability of entering the sugar HLs. This result was also observed in glucose solutions.

Figure 2. PDF of normalized water residence time in various concentrations of trehalose solutions.

DISCUSSION

According to the geometric definition of HL in this work, a water molecule is hydration water when its distance from the solute surface is less than 3 \AA . Water residence time is obtained by counting the time it stays within the HLs. Now that the normal distribution of water residence time in sugar solutions (**Figure 2**) has suggested the random walk of water within sugar solutions, the ratio of sugar HLs volume to the total solvent-accessible space should be equivalent to the normalized water residence time on the assumption that water density is uniform within the sugar solutions. Ignoring the HL overlapping, the volume of sugar HLs is the geometric summation of a single HL space. Therefore, the ratio of sugar HLs volume (V_{HLs}) to the total solvent-accessible space (V_{access}) is

$$\frac{V_{HLs}}{V_{access}} = \frac{SSA \cdot \Delta L}{1/(\rho_{solute} V_{solute}) - 1}, \quad (2)$$

where SSA is the specific surface area of the solute, ρ_{solute} is the solute number density, and V_{solute} is the molecular volume of solute. Eq. (2) indicates that a larger solute SSA is necessary for a longer residence time. Therefore, in the design of a protective agent, the molecular size is one of the keys to controlling water rotational dynamics. A smaller protective agent with larger specific surface area is more effective.

INTRODUCTION

The introduction should establish the importance of the subject, briefly explain what is known, state what is unknown or problematic, and then provide a clear statement of the objectives and/or research questions associated with the study.

Figure 1: (A) Image showing an overlay of the 960 cm⁻¹ phosphate peak intensity over an optical image of the murine DEJ. (B) representative spectra showing the 960 cm⁻¹ in enamel and dentin.

METHODS

Data acquisition:

All animal protocols were completed in accordance with the UConn Health Institutional Animal Care and Use Committee. The lower left incisors of 5-6 month old CD-1 mice (n=5) were extracted, mounted onto glass slides and polished with a diamond embedded polishing wheel. A Witec Alpha 300 Raman Spectrometer was used to obtain spectra over a 25x25 μm² area encompassing the DEJ near the incisal edge of the tooth (Fig 1). Spectra were collected every 0.5 μm with a 785 nm laser, 50X objective, and a 20 sec integration time.

Data analysis:

All spectra were corrected for cosmic rays and background subtraction using Witec Program 5.1 software. The 960 Δcm⁻¹ v₁ phosphate peak, Fig 1B, was then fit using the MATLAB Voigt-fit function to calculate

the peak maximum intensity (Max Int) and full width half max (FWHM). Matrices of Max Int and FWHM were then aligned such that line profiles were taken perpendicular to the DEJ. Max Int and FWHM values were then averaged across the line profiles in order to obtain average values for each as a function of position across the DEJ (Fig 2). These plots exhibited 3 distinct gradients: a 1st shallow gradient in Max Int, a 2nd sharp gradient in Max Int, and a single gradient in FWHM. The 2nd Max Int gradient and the FWHM gradient were fit with a logistic function using MATLAB. The derivative of this function was then used to determine the center of the gradient (location of the derivative peak) and the gradient width (FWHM of the derivative peak). The first Max Int gradient was not accurately fit by a logistic function. Its width and center were thus determined manually by an experienced user.

Figure 2: Representative plots of the gradients in 960 cm⁻¹ peak intensity (blue) and peak FWHM (orange) with the identified gradients. Dotted lines indicated the optical DEJ.

Modeling:

The logistic function fits were used to predict the change in moduli of the tissue as a function of position considering both the mineral content and crystallinity. Changes in mineral crystallinity were assumed to follow the logistic fit of the FWHM experimental data. The relationship between modulus and crystallinity was determined to be positive and linear based on previous work using Raman spectroscopy and X-ray diffraction to link modulus, compositional changes, and crystallinity [1, 2]. From this we predicted the change in modulus based on crystallinity as a function of position across the DEJ. The mineral content as a function of position was assumed to follow the logistic fit of the 2nd Max Int experimental data. The modulus was then calculated as a function of position assuming an isostrain system where the mineral content varies according to the MaxInt and the mineral modulus varies as a function of FWHM (Fig 3). Using a span of 10 μm , the total tissue modulus was estimated by averaging the varying moduli across the tissue.

RESULTS

Gradient widths: The Max Int, which is an indicator of mineral content across the DEJ, exhibited two graded regions in all samples. Both gradients indicated that the amount of mineral increased as one traveled from the dentin towards the enamel. The first gradient was a shallow gradient which had an average gradient width of $7.7 \pm 2.5 \mu\text{m}$. The second gradient was a much sharper gradient and had a calculated average width of $2.9 \pm 0.8 \mu\text{m}$.

The FWHM of the 960 cm^{-1} peak, which is inversely correlated to the mineral crystallinity [3], was also graded across the DEJ showing a decrease as one travels from dentin to enamel. The width of this gradient was $6.7 \pm 0.7 \mu\text{m}$.

Gradient locations: The inflection point positions for the three measured gradients were staggered. The sharp increase seen in the 2nd Max Int gradient aligns well with the optically determined DEJ and remained on the enamel side of the gradient compared to the other two gradient centers. The center of the FWHM gradient was located $1.3 \pm 0.8 \mu\text{m}$ away while the 1st Max Int gradient was located $5.6 \pm 2.3 \mu\text{m}$ away from the center of the 2nd Max Int gradient.

Modelling: The overall calculated modulus of the tissue surrounding the DEJ was significantly reduced when the gradient in crystallinity was considered in addition to the gradient in mineral content. It decreased by 13% from an estimated 80 GPa to 69.6 GPa. The gradient in modulus as a function of position when only the change in mineral content, as determined from Max Int, is considered is shown in blue in Fig 3. When the gradient in crystallinity is considered, the mechanical gradient is broadened as shown in orange.

DISCUSSION

The murine DEJs investigated here exhibited 3 distinct gradients: 2 separate gradients in Max Int and one in FWHM. The presence of two Max Int gradients suggests that there are likely two features present at this interface regulating mineral content. The 1st gradient has a width of approximately $8 \mu\text{m}$ located within what is visually considered the dentin. Although this width is slightly smaller than those previously reported [4], this 1st gradient is likely representative of changes in mineral content in the mantle dentin near the DEJ. The 2nd much steeper gradient is likely the “true” interface between the dentin and enamel tissues. This gradient exhibits a width of $\sim 3 \mu\text{m}$. This is in agreement with previous studies using nano-scratch and X-ray techniques [5-7] but smaller than that previously reported with Raman spectroscopy [8, 9].

Interestingly, the slope of the FWHM of the 960 cm^{-1} peak did not correlate with the intensity slope across the junction. It was found to be broader and its inflection point did not coincide with that of the intensity slopes with a total width of transition for the FWHM from dentin to

enamel being $\sim 7 \mu\text{m}$. This difference of the inflection point positions suggests that the crystallinity of the mineral around the DEJ is not associated with a specific tissue, like the mantle dentin, but instead spans the regions of varying composition. Mineral crystallinity, or atomic order, is often correlated with changes in mineral composition or maturity. Reduced crystallinity has been associated with reduced crystal size and stiffness as well as increased solubility [1, 2]. These studies have shown that reduced crystallinity caused by changes in composition lead to significant decreases in the mineral stiffness. Biologically, this gradient in mineral crystallinity may play a role in reducing stress concentrations at the DEJ by broadening the gradient in mechanical properties.

Figure 3: Plot of the estimated modulus as a function of position across the DEJ considering changes in mineral content (Em) as well as changes in mineral crystallinity (E).

To examine this, we developed a basic model examining the effect of gradients in both mineral content and crystallinity, based on the measured gradients of Max Int and FWHM respectively. We find that the added gradient in crystallinity broadens the overall mechanical gradient helping to reduce the formation of possible stress concentrators. In addition, it reduces the overall tissue modulus around the DEJ. This local reduction in modulus has been previously proposed as a possible mechanism for crack absorption at the DEJ [10].

LASER ABLATION: A NEW LEAFLET MODIFICATION STRATEGY TO PREVENT CORONARY OBSTRUCTION IN REDO TAVR

John T. Brlansky (1), Masod Sadipour (1), Ali Azadani (1)

(1) Department of Mechanical and Materials Engineering, University of Denver, Denver, Colorado, United States

INTRODUCTION

Transcatheter aortic valve replacement (TAVR)-in-TAVR is a promising treatment option for transcatheter aortic valve degeneration. This involves implanting a secondary valve internal to the degraded valve, and pinning the degraded leaflets to the first TAVR stent (Fig. 1).

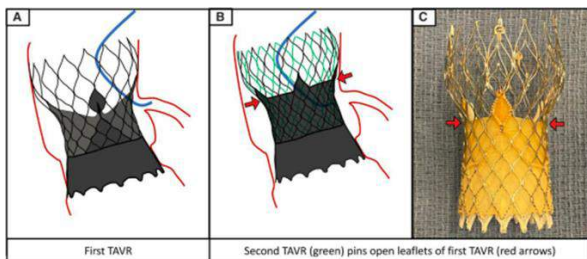

Figure 1: Coronary Obstruction in Repeat TAVR [1].

The prevalence of TAVR-in-TAVR is expected to grow significantly in the immediate future. The risk of coronary obstruction after redo-TAVR is affected by several factors, including the first TAV design, implantation depth, commissural alignment, degree of frame expansion, and choice of the second TAV type for redo-TAVR. CT simulations have predicted that the supra-annular leaflet position and tall frame of Evolut devices may cause coronary obstruction in 23% and hinder future coronary access in 78% of redo-TAVR patients. [2].

Leaflet modification techniques may be required in case of high coronary obstruction risk. BASILICA has been utilized to prevent coronary artery obstruction by creating a bisecting incision on the leaflet (Figure 2). However, this procedure may not be effective in the presence of commissural misalignment (Figure 3) and a high depth of implantation of the second valve. Furthermore, BASILICA may not be feasible or suboptimal in patients having challenging anatomy (minimal valve-to-coronary distance) and diffusely calcified and rigid leaflets.

Figure 2: BASILICA leaflet modification procedure [3].

Figure 3: TAVR implantation with aligned commissures (A) and misaligned commissures (B) [4].

We sought to develop a new leaflet modification strategy using laser ablation (Figure 4) of the initial TAVR leaflets to prevent coronary obstruction and reduce leaflet blood residence time repeat TAVR.

Figure 4: Laser ablation leaflet modification.

METHODS

Initial pericardium lasing feasibility testing was conducted using a Philips laser system and fiber optic laser ablation catheter, with full ablation of the tissue observed (Figure 5).

Figure 5: Pericardium laser ablation feasibility testing.

To quantify the impact of increased coronary flow due to laser ablation modification of the initial TAVR leaflets, a two-way fluid-structure interaction (FSI) model was generated, which evaluated flow over two heartbeat cycles at a rate of 60 beats per minute. The geometry for the model was constructed in SolidWorks using patient CT data and Medtronic CoreValve geometries. Simulated laser ablation modifications were then made by inserting 10F size holes in the initial TAVR leaflets oriented at the left coronary, right coronary, or the non-coronary. For analysis, a control model (Figure 6A) and the following laser ablation models were considered:

- 1. Single ablations at the left and right coronary (Figure 6B).
- 2. Single ablations at the left and right coronary, one on the non-coronary (Figure 6C).
- 3. Double ablation at the left coronary, single at the right coronary (Figure 6D).
- 4. Double ablation at the left and right coronary (Figure 6E)

Figure 6: Model geometries. Aorta pictured in translucent blue, initial TAVR in yellow, and secondary TAVR in green.

A mesh was generated for each model using Pointwise, and simulations were run using ANSYS Fluent. The working fluid, blood, was modeled as Newtonian, and flow was modeled as laminar. The density and the viscosity of blood was 1,060.0 kg/m³ and 0.0035 kg . s/m², respectively. Moreover, mesh densities were optimized by conducting mesh dependency studies for all models. FSI modeling was conducted using ANSYS Fluent within the Workbench. Simulations were run over three cycles at 60 beats per minute.

RESULTS

Laser ablation modification of TAVR-in-TAVR improved coronary flow in all cases resulting in left coronary artery flow increases

of 87% to 96% from total occlusion and right coronary artery flow increases of 40% to 74% from total occlusion (Figure 7).

Figure 7: Impact on coronary flow due to laser ablation modification of initial TAVR leaflets.

This improved coronary flow resulted in a proportional reduction in blood residence time due to the increased flow velocities in the coronary arteries, which increased with the number of ablated openings, as shown in Table 1.

Table 1: Coronary flow velocities.

Maximum Flow Velocity (m/s)		
Ablated Openings	LCA	RCA
1 Left 1 Right	0.3191	0.0492
1 Left 1 Right 1 Non	0.3338	0.0645
2 Left 1 Right	0.3394	0.0630
2 Left 2 Right	0.3436	0.0724
Control (Native Valve)	0.3516	0.0885

DISCUSSION

Laser ablation is a viable treatment strategy, especially for patients who are ineligible for BASILICA. The new leaflet modification strategy resulted in increased coronary flow and velocity in the sinus and neo-sinus, which may allow safer redo-TAVR in selected patients at high risk of coronary obstruction and coronary access impairment. Moreover, this may also reduce the risk of leaflet thrombosis due to the decrease in leaflet blood residence time.

QUANTIFICATION OF CATIONIC SOLUTE DIFFUSION AND FIXED CHARGE DENSITY IN HUMAN SYNOVIUM

Alexandra L. Davis (1), Ashish Vaidyanathan (1), Milad Rohanifar (1), Lori A. Setton (1,2)

- (1) Department of Biomedical Engineering, Washington University in St. Louis, St. Louis, MO, United States

INTRODUCTION

The synovium is a thin, multilayer tissue that lines the diarthrodial joint. Its blood and lymphatic vessels rapidly clear both small and large molecules, respectively, from the joint space, hindering the efficacy of intra-articular (IA) drug delivery to treat degenerative joint diseases such as osteoarthritis (OA) [1,2]. In vivo models may underestimate drug clearance times due to parameters that vary across species such as synovial thickness and synovial fluid volume. However, experimental-computational approaches can be used to quantify intrinsic solute diffusivities that enable comparisons across species, solutes, and pathologies. We previously developed a multiphasic finite element model (FEM) to study diffusion through synovium and found that solute effective diffusivity (D_{eff}) decreased with increasing molecular weight (MW) [3,4].

Factors other than MW such as charge could affect solute diffusivity through synovium. Like cartilage, synovium contains collagen and anionic glycosaminoglycans (GAGs) that may contribute to solute-matrix interactions during drug transport. Therefore, the aim of this study was to quantify the D_{eff} of a cationic solute through human synovium using our FEM optimization and compare it to that of an uncharged solute of similar MW. In doing so, the fixed charge density (FCD) of synovium was also reported for the first time.

METHODS

Tissue preparation: Human synovium was harvested from anonymized donor knee tissues procured through an agreement with the Mid-America Transplant Foundation (St. Louis, MO). Synovium was isolated from the posterior aspects of the knee joint into $\sim 10 \times 10$ mm pieces that were cryoprotected by immersing in 15% sucrose in PBS for 24 hours followed by 30% sucrose for 24 hours at 4 °C. The samples were devitalized by flash freezing in an isopentane (Sigma-Aldrich) bath cooled by liquid nitrogen and stored at -80 °C for at least 48 hours before trimming, where a sledge microtome (Leica SM2400, Allendale,

NJ) was used to trim the tissues to less than 1-mm thickness. Trimmed samples were soaked in PBS overnight at 4 °C to remove any remaining sucrose, after which their thicknesses were measured with a scanning profilometer (Keyence LJ-V700, Itasca, IL).

FCD quantification: A 1,9-dimethylmethylene blue (DMMB) assay was performed to quantify the sulfated glycosaminoglycan (sGAG) concentration and subsequently the FCD of synovium. Synovium samples (~ 50 mg each) were lyophilized and digested overnight at 60 °C in papain digest buffer (125 $\mu\text{g/mL}$ in PBS; 1 mL/100-mg dry mass). Digested human synovium was diluted 1:2 to ensure that its sGAG concentration fell within the linear range of a chondroitin sulfate (CS) standard curve (0–80 $\mu\text{g/mL}$). DMMB (Sigma-Aldrich) dye was prepared as previously described; however, its pH was shifted to 1.5 to minimize DNA interference [5]. 200 μL DMMB dye were added to three 20- μL replicates of each sample, whose sGAG concentrations were quantified based on the absorbance difference between 525 nm and 595 nm to compensate for reduced sensitivity to CS at lower pH. The amount of sGAG per dry weight of synovium {mg/g} and FCD {mM} were calculated assuming two moles of charge per sGAG and using the MW of CS (502.5 g/mol).

Diffusion experiment: Unsteady diffusion of a 4-kDa cationic dextran, fluorescein isothiocyanate-diethylaminoethyl-dextran (FITC-DEAE) (TdB Labs, Uppsala, Sweden) through devitalized human synovial explants ($n=4$) was studied as previously described. Briefly, each explant was secured between two platens that separated “donor” and “sink” baths of a custom-built diffusion chamber. One mL of FITC-DEAE at a known concentration ($C_0=0.25$ mg/mL) was pipetted in the donor bath, while a syringe pump (New Era Pump Systems NE-300, Farmingdale, NY) replenished PBS in the 1-mL sink bath at a rate of 2 mL/hour to maintain dilute downstream conditions. The diffusion chambers remained under ambient pressure at 37 °C on a 3D rotating shaker (Benchmark Scientific Biomixer™, Sayreville, NJ) to establish one-dimensional, unsteady diffusion. The concentration of FITC-DEAE

in the donor bath was determined by measuring the fluorescence intensities of eight 5- μ L aliquots collected over a three-day period using a multimode plate reader (Perkin-Elmer, Waltham, MA). The zeta potential of FITC-DEAE was measured separately using a Zetasizer ZEN3600 (Malvern Instruments, Malvern, UK).

Model predictions of unsteady diffusion: An FEM model of cationic solute diffusion through synovium was created in FEBio [6]. The synovial matrix was modeled as an uncharged, porous, and fluid-saturated mixture based on the negligible FCD calculated from the DMMB assay results. The solid phase was assumed to be neo-Hookean and assigned previously measured material properties [7]. Specimen-specific meshes of thickness L contained eight-node hexahedral elements that were refined at the interface between the synovium and the donor bath. Notably, the model was adapted to simulate charged solute transport using two steps to satisfy electroneutrality and ensure convergence:

- 1) A 100s-phase during which FITC-DEAE and an anionic counter-ion were introduced into the donor bath at $t=0$; their concentrations were linearly ramped up and down, respectively, to C_0 and 0 mM at $t=100$ s.
- 2) Modeling of unsteady diffusion of FITC-DEAE through human synovium after $t=100$ s.

Freely mobile Na^+ and Cl^- ions were also included at a physiologically relevant concentration (150 mM) to ground the electrical potential and match experimental conditions. Together these four ions dictated the effective fluid pressure

$$\tilde{p} = p + RTC\varphi \quad (1)$$

in the synovium, donor bath, and sink bath (Figure 1), where R is the ideal gas constant (8.314 J/mol K), T is the absolute temperature (310 K), and C is the total concentration of solute and ion. The hydrostatic fluid pressure (p) and osmotic coefficient (φ) were taken to be zero and unity, respectively [3,4].

Figure 1: Finite element mesh and boundary conditions to model charged solute diffusion through human synovium of thickness L [3,4]. The solute and its counter-ion, whose initial concentrations in the model sum to C_0 , as well as Na^+ and Cl^- contribute to an effective fluid pressure in the donor bath, sink bath, and synovium.

Statistical analyses were performed in GraphPad Prism 9.0 (La Jolla, CA). The Mann-Whitney U Test was performed to determine if the D_{eff} of FITC-DEAE through human synovium was significantly different ($p<0.05$) from that of 3 kDa Texas Red dextran measured in our previous study. Data are presented as mean \pm standard deviation.

RESULTS

According to the DMMB assay, human synovium contains low amounts of sGAG (0.112 ± 0.0213 mg/g synovium) and therefore a

negligible FCD (-0.013 ± 0.0025 mM) orders of magnitude lower than that measured in other soft tissues (Table 1). Thus, the synovial matrix was assigned a FCD of zero in FEBio to model charged solute diffusion. The zeta potential of FITC-DEAE was 1.69 ± 0.342 mV.

Table 1: Fixed charge density (FCD) of synovium measured here compared to that of articular cartilage and nucleus pulposus.

Tissue	Species	FCD (mM)	Reference
Synovium	Human	-0.013	–
Articular cartilage	Bovine	-150	[8]
Nucleus pulposus	Bovine	-138	[9]

The D_{eff} of 4-kDa FITC-DEAE ($2.21\text{E-}4 \pm 2.66\text{E-}5$ mm²/s) through human synovium was significantly greater ($p=0.0286$) than that of 3-kDa Texas Red ($9.73\text{E-}5 \pm 2.66\text{E-}5$ mm²/s from prior study). Table 2 summarizes the data on FITC-DEAE and Texas Red diffusivity through human synovium.

Table 2: Effective diffusivity (D_{eff}) of cationic FITC-DEAE and neutral Texas Red through human synovial explants of thickness L .

Solute	MW (g/mol)	Charge	n	L (μ m)	D_{eff} (mm ² /s)
FITC-DEAE	4 kDa	Cationic	4	921 ± 64.1	$2.21\text{E-}4 \pm 2.66\text{E-}5$
Texas Red	3 kDa	Neutral	4	813 ± 148	$9.73\text{E-}5 \pm 2.35\text{E-}5$

DISCUSSION

Here, a cationic solute of low MW diffused faster than a neutral solute of similar MW through human synovium in vitro. This suggests that factors other than MW regulate solute transport through synovium such as tissue porosity and charge in addition to solute size, shape, and charge. In vivo studies should also consider cell-mediated uptake, IA pressure, and the density of draining lymphatic vessels. Here, human synovium had a low sGAG concentration that agrees with previous studies [10,11] and a FCD orders of magnitude lower than that of other soft tissues [8,9]; therefore, the FCD of synovium was not expected to accelerate diffusion of a cationic solute. However, sGAG content may decline with age and should be measured in synovium from younger donors to further elucidate the role that FCD plays in solute transport. Although DMMB assays cannot measure hyaluronic acid (HA), an unsulfated GAG largely produced by synovial fibroblasts, it likely does not contribute to significant negative charge in the matrix [10]. HA may instead elicit a boundary-layer effect at the synovial intima and impede transport through an alternative mechanism. Altogether these results invite further studies on charged solute-matrix interactions in synovium that inform drug design for IA drug delivery.

APPLIED STRESS PROMOTES MINERALIZATION OF SUBSTITUTED BIOAPATITES: A THERMOCHEMICAL EQUILIBRIUM STUDY

Pierre A. Deymier (1), Marat Latypov (1,2), Krishna Muralidharan (1), Alix C. Deymier (3)

INTRODUCTION

Bone's ability to increase its mineral content and mass in response to mechanical loads, also known as Wolff's law [1], has been well established with Galileo describing this effect in 1638[2]. This ability of bone to adapt to the mechanical environment has primarily been attributed to cellular mechanotransduction. Specifically, it has been shown that osteocytes respond to changes in fluid flow through the bone porosity by increasing pro-osteoblastic signaling [3]. These signals recruit and activate osteoblasts resulting in the deposition of greater quantities of more highly mineralized bone tissue. This process has been shown to be in part responsible for the increase in bone density in high-intensity athletes and conversely the bone loss seen in astronauts [4, 5].

However, mineralization of bone has also been shown to be physiochemically controlled in the absence of cellular activity. Many studies have shown that the chemistry of the protein matrix enhances the nucleation and growth of bone mineral by reducing the energy barriers to mineralization [6, 7]. Further, recent investigations of the effects of fluid shear stress and cyclic loading on collagen matrix mineralization, have shown that increased loading promoted induced matrix mineralization due to improved fluid transport [8, 9]. These results suggest that, beyond cellular activity chemistry and mechanical loading may play a central role in the physiochemical mineralization of bone tissue.

Biological apatite is not hydroxyapatite but a highly substituted apatite that undergoes both anionic and cationic substitutions. In terms of anions carbonate (CO_3^{2-}) substitutes for phosphate (PO_4^{3-}) in bone mineral. This charge imbalance is then rectified by a sodium (Na^+) substitution for calcium (Ca^{2+}). These substitutions give the apatites unique properties, but they also allow the material to act thermodynamically as a substitutional solid. Larché and Cahn showed that thermodynamically the composition of substitutional solids is significantly affected by applied stress [10]. This huge advancement in thermodynamics was recently experimentally confirmed [11]. Here we

use the Larché and Cahn theory to predict not only the change in mineral composition but the effect of mechanical loading on bioapatite mineral growth.

METHODS

Assumptions: Based on the known chemistry of bioapatite we established a closed system with a number of assumptions. The system is composed of an apatite crystal containing CO_3^{2-} , PO_4^{3-} , Ca^{2+} , and Na^+ in equilibrium with water containing the same ions. We assume the exchange only occurs between the $\text{Na}^+/\text{Ca}^{2+}$ and $\text{CO}_3^{2-}/\text{PO}_4^{3-}$ and that the system has charge conservation. Finally, the total volume of the system cannot change although the relative volumes of solid and liquid can change. In addition, using literature values, we assume that the lattice deformation caused by the exchange of Na^+ for Ca^{2+} is negligible compared to that of CO_3^{2-} for PO_4^{3-} .

The system is designed as shown in figure 1, where the mineral centered on the origin and has an initial thickness of $2l$. The mineral is surrounded by liquid water on both sides with the total length of the system adding up to $2L$. The reference state is a state of hydrostatic

Figure 1: Schematic of the setup showing the ionic distribution, geometry, and loading states being studied.

pressure while the stressed state undergoes uniaxial stress (σ) along the x-axis. A change in the mineral size is denoted by Δl .

Variables: We define the following compositional variables for the cationic and anionic species in aqueous solution, $C_{Na}^L, C_{Ca}^L, C_C^L, C_P^L$. The upper script refers to a liquid solution. We use short-hand notation for the lower indices, Na, Ca, C and P for Na^+, Ca^{2+}, CO_3^{2-} and PO_4^{3-} , respectively. The ionic compositions in the solid apatite are defined as $C_{Na}^S, C_{Ca}^S, C_C^S, C_P^S$ where the upper script S stands for solid. We use a bar ($\bar{C}_{Ca}^L, \bar{C}_{Na}^L, \bar{C}_C^L, \bar{C}_P^L, \dots$) as an accent above thermodynamic quantities to denote that they are under hydrostatic pressure. Δ'_{Ca} and Δ'_C are the change in cation and anion compositions due to stress relative to the compositions under hydrostatic conditions.

Calculations: Using the work of Larché and Cahn and Johnson et al. [10, 12] we can establish the cationic condition for equilibrium as:

$$\Delta'_{Ca} \sim -\frac{\Delta l}{L-l} \left[\frac{\bar{C}_{Ca}^S}{\bar{C}_{Ca}^L} - \frac{\bar{C}_{Na}^S}{\bar{C}_{Na}^L} \right] / \left(\frac{1}{\bar{C}_{Ca}^S} + \frac{1}{\bar{C}_{Na}^S} + F \left[\frac{1}{\bar{C}_{Ca}^L} + \frac{1}{\bar{C}_{Na}^L} \right] \right) \quad (1)$$

where F is the ratio of solid and liquid volumes under uniaxial stress.

Similarly, the anionic condition for equilibrium is:

$$\Delta'_C \sim -Z - \frac{\Delta l}{L-l} \left[\frac{\bar{C}_C^S}{\bar{C}_C^L} - \frac{\bar{C}_P^S}{\bar{C}_P^L} \right] / \left(\frac{1}{\bar{C}_C^S} + \frac{1}{\bar{C}_P^S} + F \left[\frac{1}{\bar{C}_C^L} + \frac{1}{\bar{C}_P^L} \right] \right) \quad (2)$$

where Z is a function of mineral mechanical properties and composition. Finally, we can approximate the condition for dissolution/recrystallization by:

$$\mathcal{E} - \bar{C}_{Ca}^S - Z \bar{C}_C^S = \left[\frac{1}{\bar{C}_{Na}^S} \left(1 + F \frac{\bar{C}_{Na}^S}{\bar{C}_{Na}^L} \right) \right] \Delta'_{Ca} + \left[Z + \frac{1}{\bar{C}_P^S} \left(1 + F \frac{\bar{C}_P^S}{\bar{C}_P^L} \right) \right] \Delta'_C + \frac{\Delta l}{L-l} \left[\left(1 - \frac{\bar{C}_{Na}^S}{\bar{C}_{Na}^L} \right) + \left(1 - \frac{\bar{C}_P^S}{\bar{C}_P^L} \right) \right] \quad (3)$$

where $\mathcal{E} = \frac{\sigma^2}{2Y}$, σ is the applied stress and Y is the mineral Young's modulus. By inserting Eqs 1 and 2 into Eq 3 we can solve for $\frac{\Delta l}{L-l}$,

which represents the change in crystal size, as a function of the magnitude of the uniaxial stress σ .

To obtain information about the relative concentrations of Na^+, Ca^{2+}, CO_3^{2-} and PO_4^{3-} in the liquid and solid at equilibrium, we turn to Moynahan et al. [13] where concentrations were measured for biomimetic apatites in equilibrium with water. This gives us the values of $\bar{C}_{Ca}^L, \bar{C}_{Na}^L, \bar{C}_C^L, \bar{C}_P^L, \bar{C}_{Ca}^S, \bar{C}_{Na}^S, \bar{C}_C^S$, and \bar{C}_P^S . Relationships between the mineral modulus and the composition have also been identified by Wingender et al. [14] that allow us to approximate $Z \sim 5 \times 10^{-5} \mathcal{E}$.

Figure 2: Plot of the change in Ca^{2+} (a) and CO_3^{2-} (b) in the solid with applied stress. (Note the negative y-axis)

RESULTS

Compositional changes with applied stress

Using equations 1 and 2 and the known compositions for biomimetic apatites under hydrostatic stress, we were able to predict how an applied uniaxial stress would affect the substitutional exchange of Na^+/Ca^{2+} and CO_3^{2-}/PO_4^{3-} . We find that increasing applied stresses lead to preferential substitution of Na^+ for Ca^{2+} and of PO_4^{3-} for CO_3^{2-} in biological apatite.

Crystal growth with applied stress

Using Equations 1, 2, and 3 we find that the normalized crystal thickness, $\frac{\Delta l}{L-l}$, increases with increasing applied stress. This suggests

that the substitutional nature of biological apatites allows them to crystallize upon loading instead of dissolve.

Figure 3: Plot of the relative thickness of the solid apatite in equilibrium with an aqueous solution as a function of applied uniaxial stress

DISCUSSION

The recommendations that individuals engage in weight bearing exercise to promote bone growth and mineralization have mainly centered on the idea of cellular mechanotransduction. Only recently has physiochemical stimulation of mineralization been suggested as possible benefit of exercise [8, 9]. However, the results presented here show another layer of benefit, indicating that applied stress during weight bearing activities promotes mineralization via crystal growth irrespective of cellular and matrix contributions.

In addition, the bone mineral composition is shown to shift towards reduced calcium and carbonate content with applied stress. This would suggest a decrease in Ca^{2+}/PO_4^{3-} and CO_3^{2-}/PO_4^{3-} ratios with applied stress. Reduction in these markers has historically been associated with bone immaturity or increased cellular remodeling [15, 16]. However, the measurements presented here report these compositional changes in response to applied load irrespective of cellular or maturation behaviors. Therefore, it is important to understand the thermodynamics of bone mineral in stressed environments like bone when considering the meaning or cause of compositional changes.

In conclusion, we have shown thermodynamically that applied stress promotes compositional changes and crystal growth in biological apatites in equilibrium with aqueous liquids. This reinforces the importance of understanding both cellular and physiochemical process when studying biological materials.

ADVANCE IN HYBRID CARDIOVASCULAR MODELING: COUPLING VOLUMETRICALLY DYNAMIC IN-VITRO EXPERIMENTS TO NUMERICAL PHYSIOLOGY SIMULATION

Abraham, E. Umo (1), Ethan, O. Kung (1,2)

(1) Bioengineering, Clemson University, Clemson, SC, USA
 (2) Mechanical engineering, Clemson University, Clemson, SC, USA

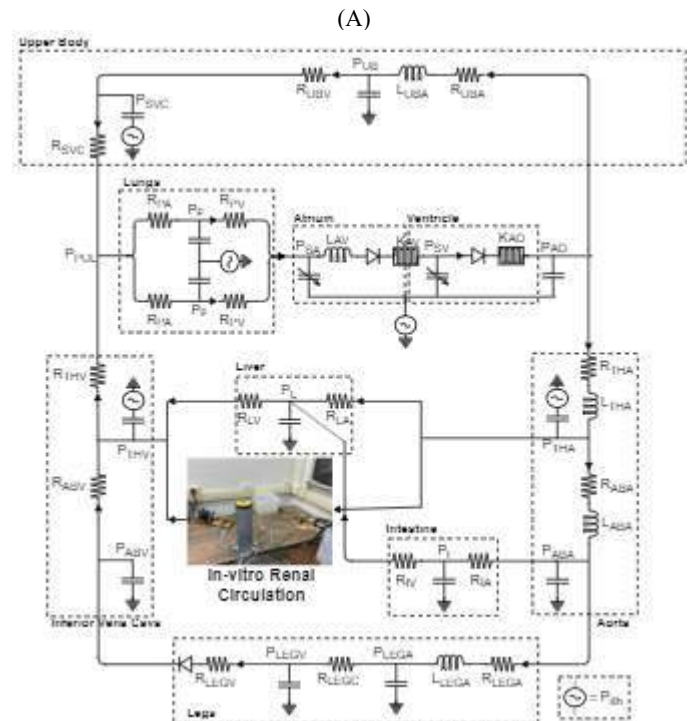

INTRODUCTION

The Physiology Simulation Coupled Experiment (PSCOPE) is a cardiovascular modeling approach that couples an in-vitro experiment to a numerical physiology simulation in a hybrid framework. This framework enables investigation of the closed-loop physiological response of the cardiovascular system in the context of dynamic conditions modeled in a physical fluid experiment. The experiment is coupled to the simulation via a protocol that directs the exchange of pressure and flow rate information to identify the hybrid model's solution. Previous PSCOPE coupling methods^{1,2} successfully coupled rigid and multi-branch experiments to a lumped parameter physiology simulation (LPN) but are incompatible with volumetrically dynamic experiments where fluid volume is not constant. In this study, we present an iterative protocol for coupling several types of physical experiments, including rigid, multi-branch, and volumetrically dynamic in-vitro experiments to an LPN.³

METHODS

The protocol begins with an initial guess of the model's solution and utilizes a weighted averaging algorithm to iteratively generate boundary conditions (pressure or flow rate) prescribed to each in-vitro and numerical domain. The prescribed boundary conditions ensure that both domains share identical pressure waveforms and minimize the differences between their corresponding flow rate waveforms (residual). The exact model solution corresponds to a residual of zero; we can specify the target accuracy of our coupling solution via setting an NRMSE threshold. We first confirm the accuracy of the PSCOPE solutions by using mathematical surrogates for in-vitro experiments. The mathematical surrogates were directly integrated into LPNs to derive the reference solutions, which serve as the gold standard to validate the solutions obtained from using our proposed method to couple the same mathematical surrogates to the LPNs. We also demonstrate the real-world applicability of the protocol by coupling an

in-vitro renal circulation model to a fontan LPN (Fig.1a). A <5% NRMSE threshold was set as the target residual between the LPN and in-vitro renal flow waveforms.

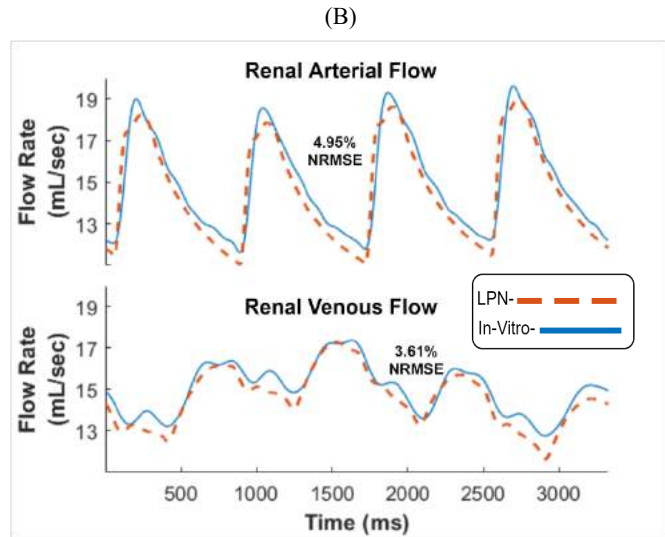

Fig. 1 (A) Illustration of a hybrid model setup coupling an in-vitro Renal circulation model to an LPN—(B) Renal Flow waveforms from the LPN and in-vitro model were successfully converged below the 5% NRMSE threshold; (C) Convergence trend of flow waveforms.

RESULTS

The NRMSE values (0.001% - 1.36%) between the reference and PSCOPE solutions obtained from integrating and coupling mathematical surrogates to LPNs, respectively, demonstrate a high degree of accuracy achieved by the coupling method. The in-vitro renal circulation model was successfully coupled to the LPN with the algorithm converging their corresponding renal flow waveforms below the 5% NRMSE threshold (Fig. 1b) after 9 iterations. Subsequent iterations were continued to confirm stabilization of the model solution convergence (Fig. 1c).

DISCUSSION

This work introduces a protocol capable of coupling volumetrically dynamic in-vitro experiments to a lumped parameter physiology simulation, overcoming the limitations of previous PSCOPE coupling methods. Its real-world applicability includes experimental investigation of medical devices and anatomies that exhibit volume changes within the context of a closed-loop hybrid model.

INTRODUCTION

Blood clots play critical roles in both health and disease. On the one hand, blood clotting prevents hemorrhage after vascular injury and is thus vital to our survival. On the other hand, blood clotting and blood clot embolization (i.e., fracture) lead to deadly diseases such as heart attacks, strokes, and pulmonary embolisms. In both diametrical roles, the mechanical behavior of blood clots is clearly important. Despite its importance in health and disease, significant gaps in our knowledge about blood clot mechanics persist. We have developed experimental techniques to robustly characterize the fracture mechanics of blood clots coagulated in vitro with the aim of probing this clinical question. Bovine, porcine, and ovine blood have all been used to understand clot mechanics [1-3], but the correlation between the behavior of these clots and clots made from human blood is unclear and variability in experimental modalities limits direct comparisons across studies. Towards understanding this relationship, in this study we describe the viscoelastic and fracture properties of clots made from human and bovine blood measured using identical protocols.

METHODS

Blood collection: Bovine blood drawn in CPDA-1 anticoagulant was purchased from a commercial vendor (Lampire Biological Laboratories, PA, USA). Human blood was drawn into ACD anticoagulant. Time between draw and testing was 48 hours for both samples.

Sample preparation: Samples were prepared according to previously published protocols [4]. Briefly, samples were mixed with calcium chloride to a final concentration of 20 mM and cast into rectangular molds lined with Velcro (see Figure 1A). After 60 minutes, the samples were assigned to one of four experimental groups: (i) mode-I, (ii) pure shear, (iii) cyclic loading, or (iv) stress relaxation (see Figure 1B). Mode-I samples received a notch of 1/3 the width of the sample.

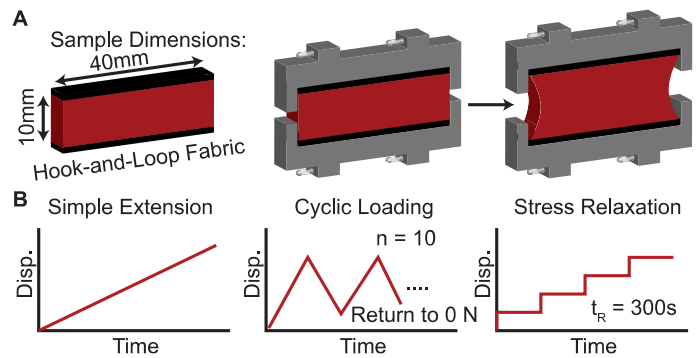

Figure 1: (A) Sample dimensions are 40 mm x 10 mm x 3 mm and molds are lined with Velcro so they can be tested without gluing or clamping. (B) We used a tensile tester to displace the samples using three protocols: simple extension, cyclic loading, and stress relaxation. Figure adapted from [5].

Note that both mode-I and pure shear samples underwent simple extension.

Mechanical testing: Mode-I and pure shear samples were extended to failure. Cyclic loading samples were extended to 40% clamp-to-clamp strain and returned to 0 N force for ten cycles. Finally, stress relaxation samples were consecutively displaced to 10%, 20%, 30%, and 40% clamp-to-clamp strain with 300 s holds after each loading step. All tests were conducted at a displacement rate of 0.2 mm/s (equivalent strain rate 2%/s). High-resolution images were captured of the mode-I samples at a rate of 5 Hz.

Statistics: For direct comparisons between two groups, we used two-tailed Student's t-tests implemented in R. We fit a linear mixed model to our stress relaxation time constants using the “afex” library in R and used the “emmeans” library to run pairwise comparisons. Differences with p-value ≤ 0.05 were considered significant. All data are reported as mean \pm standard deviation.

RESULTS

Figure 2 shows that human blood clots are softer, weaker, and more susceptible to fracture than bovine blood clots. In Figure 2A, Cauchy stress-stretch curves for pure shear (left) and mode-I (right) samples show that bovine clots (gray) yield higher stress for a given stretch value. Figure 2B compares scalar metrics derived from these curves. Bovine clots have higher fracture toughness, calculated as

$$\Gamma_c = W(\lambda_c)H, \quad (1)$$

where H is the reference sample height and $W(\lambda_c)$ is the strain energy density of the pure shear sample at the fracture stretch λ_c . They also have higher strength (peak stress in pure shear geometry), tangent modulus, and work to rupture.

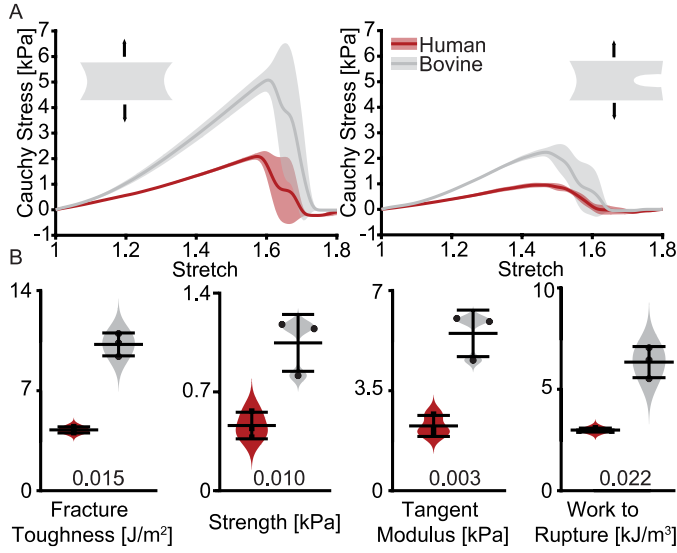

Figure 2: (A) Stress-stretch curves of pure shear and mode-I experiments (B) Bovine clots show higher fracture toughness, strength, stiffness, and work to rupture than human clots. P-values are from two-tailed Student's t-tests.

Cyclic loading experiments showed that both human and bovine blood clots equilibrate after ten cycles but differ in magnitude of work lost in hysteresis, peak force, and set (data not shown). Work lost to hysteresis and peak force are higher in bovine samples while the amount of set is greater in human samples. Set is measured as the effective strain that samples return to when unloaded to zero force. The presence of set implies that the samples lengthened during loading. Each of these metrics change substantially from the first cycle to the second with the difference between cycles decreasing steadily and trending toward an equilibrium response by the tenth cycle.

Figure 3 shows the strain-dependent stress relaxation response of clots made from human and bovine blood. Each clot relaxes at every strain step. To compare the stress-relaxation response, we fit each step with a two-term exponential decay function

$$\hat{\sigma} = 1 - \sum_i^n c_i \left(1 - \exp\left(-\frac{t}{\tau_i}\right)\right), \quad (2)$$

where $\hat{\sigma}$ is the normalized stress at each strain step, t is time, c_i are scaling parameters, and τ_i are the time constants. We have previously reported that this two-term exponential decay function captures the response well and that additional terms are not beneficial [5]. The first time constant, τ_1 , does not differ significantly between bovine and human samples. The second time constant, τ_2 , differs significantly at each strain level ($p = 0.011$) though the values are within the same order

of magnitude. This similarity may suggest that time-dependent dissipative mechanisms are conserved between species.

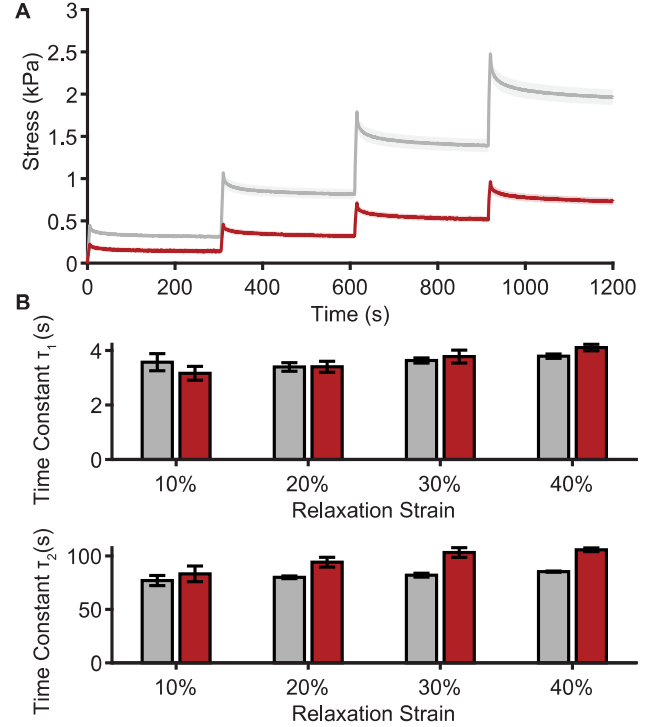

Figure 3: (A) Stress relaxation curves for bovine (gray) and human (red) samples (B) Time constants of a two-term exponential decay function fit to each strain step vary across species within the same order of magnitude.

DISCUSSION

While animal blood is more easily accessible than human blood, our findings suggest that the mechanical behavior of clots made from bovine blood are not interchangeable with the behavior of those made from human blood. The data presented here are based on one subject, and data from five additional subjects will be included in the final presentation to better assess this relationship. Many of the same phenomena are present in both clots, including preconditioning effects, hysteresis, set, and stress relaxation, however the magnitude of these effects differs. There are many possible mechanisms for this discrepancy, and further study will help us distinguish between inter-species variability and subject-to-subject variability.

MULTISCALE, CELL-RESOLVED SIMULATIONS OF RED BLOOD CELLS IN MACROSCALE FLOWS FOR HEMOLYSIS PREDICTION

Grant J. Rydquist (1), Mahdi Esmaily (1)

(1) Sibley School of Mechanical and Aerospace Engineering, Cornell University, Ithaca, NY

INTRODUCTION

The rupture of red blood cells (RBCs), known as hemolysis, is a common problem in many blood flow scenarios. In particular, hemolysis commonly occurs when the flow of blood has been artificially altered, such as in blood pumps or surgical treatments, since this can expose the RBCs to unphysiologically large shear stresses. There are several medical problems associated with hemolysis, so it is important to be able to predict its incidence. However, most algorithms for detecting hemolysis use empirical relationships [1] that may not be general in all situations (e.g., any turbulence may make the results unreliable). One approach that has yet to be fully explored is to simulate the RBCs in these types of macroscale flows directly to obtain a cell-resolved picture of the RBCs' response to it. If the effects of the flow on the cell are properly represented, the resulting framework will be fully general and agnostic to the actual character of the flow. Additionally, the results provide a more mechanistic, realistic picture of the cells' response to the flow than the empirical relationships typically used to evaluate the amount of hemolysis in a flow. The purpose of the current work is to construct a computational framework to resolve the behavior of individual RBCs in macroscale flows.

The main difficulties in the construction of this framework lie in the accurate reproduction of the flow's effect on the RBCs. For example, the number of cells in the flows this framework is intended for is larger than is computationally feasible. Thus, only a sample of the total number of cells are used, and the behavior of the cells is resolved in a statistical sense. However, cell-cell interactions are an essential component of the way RBCs behave, and these interactions have long decay distances relative to the size of the RBCs, so a collection of cells need to be simulated with periodic boundary conditions to mimic these long-range interactions.

METHODS

Since there is a difference in scales of multiple orders of magnitude between the characteristic lengths of the RBCs and the macroscale flow, some assumptions must be made to couple the simulations of the two. First, since the effects of the cells on the fluid are typically modeled, for example by using a shear-thinning viscosity, only the effects of the fluid on the cells are resolved. Thus, the periodic box containing the collection of cells is advected through the flow as a one-way coupled tracer. At each time step, the fluid velocity in the vicinity of the cells is used in conjunction with their current deformation to evaluate their relative velocities. Since the curvature and higher order terms of the velocity become negligible at the scale of the cells, only the velocity gradient is used.

Since the RBCs are small, the Stokes equations can be used to solve for their relative velocity. A suitable method of solving for this velocity is the boundary integral method. This method utilizes the Stokes equations recast into integral form. Taking account of the above assumptions, this equation is

$$\begin{aligned} u_j(\mathbf{x}_0) - \frac{1-\lambda}{4\pi(1+\lambda)} \sum_p \sum_{k=1}^N D_{ij}^k [u_i^p](\mathbf{x}_0 - \mathbf{x}_p) \\ = \frac{2}{1+\lambda} u_j^\infty(\mathbf{x}_0) \\ - \frac{1}{4\pi\mu(1+\lambda)} \sum_p \sum_{k=1}^N S_{ij}^k [\Delta f_i^p](\mathbf{x}_0 - \mathbf{x}_p). \quad (1) \end{aligned}$$

The above equation is evaluated at the point \mathbf{x}_0 , which must be on the surface of a cell. μ is the viscosity of the ambient fluid, λ is the ratio of the viscosity of the fluid inside the cell to the viscosity of the ambient fluid, \mathbf{u}^∞ is the ambient fluid velocity in the absence of the cells (i.e., the velocity gradient obtained from the macroscale simulations), and $\Delta \mathbf{f}$ is the jump in the hydrodynamic traction over the cell membrane. This last term is obtained using the Skalak constitutive model [2] to represent the

cells' resistance to shear and area dilatation and the Helfrich constitutive model [3] to represent the cell's resistance to bending. k describes the sum over the total number of cells N in the box, and p describes the sum over the infinite periodic lattice, where \mathbf{x}_p describes the distance from the primary periodic box to the p^{th} box. D_{ij} and S_{ij} are the boundary integral operators taken over the surface of the cells γ , described by

$$D_{ij}[\phi](\mathbf{x}_0) = \int_{\gamma} T_{ijk}(\mathbf{x}, \mathbf{x}_0) n_k(\mathbf{x}) \phi(\mathbf{x}) dS_{\mathbf{x}}, \quad (2)$$

$$S_{ij}[\phi](\mathbf{x}_0) = \int_{\gamma} G_{ij}(\mathbf{x}, \mathbf{x}_0) \phi(\mathbf{x}) dS_{\mathbf{x}}. \quad (3)$$

T_{ijk} and G_{ij} are fundamental solutions of Stokes flow, known as the *stresslet* and *Stokeslet*, respectively. Due to the singular nature of these operators, these integrals require special care to evaluate accurately. Additionally, to truncate the sum over the periodic lattice, fast Ewald sums [4] are used to split the *stresslet* and *Stokeslet* into two components, one that decays rapidly in Fourier space and one that decays rapidly in real space. This leaves the velocity of the cells as the only unknown, so once all other items are calculated, the equation is discretized and inverted to solve for the velocity.

RESULTS

One major test of the validity of the framework is whether it can reproduce the macroscale behavior of blood. For example, blood is shear-thinning, and the solver should show a decreasing effective viscosity of the blood as the shear rate increases. This behavior is illustrated in Figure 1, where the effective viscosity (relative to the viscosity of the plasma) of the entire periodic box in shear flow at 45% hematocrit is compared against experimental measurements.

Figure 1: Relative effective viscosity calculated over a periodic box (blue circle) and experimental measurements of relative effective viscosity gathered from Chien [5] (red square) plotted against shear rate.

A primary goal of the solver is to accurately evaluate stresses and strains on a statistically significant sample of cells to gain a statistical picture of how they respond to a given flow. A representative example of this process is displayed in Figure 2, where the deformation of RBCs is tracked through a Blalock-Taussig shunt [6]. The parameter λ_1/λ_2 is a representation of the shear strain on the surface of the cells, where λ_1 is the larger principal strain on the surface of the cell and λ_2 is the smaller principal strain.

Figure 2: Maximum value of shear parameter λ_1/λ_2 on the surface of 20 cells (dashed grey) and their average (solid red) as they travel through a Blalock-Taussig shunt [6].

DISCUSSION

The current framework provides a novel method of understanding the way RBCs behave in macroscale flows. However, it is important that it faithfully reproduces what the cells actually experience. Figure 1 demonstrates an important characteristic of the solver in this regard: the microscale behavior of the cells is consistent with some of the macroscale properties of blood. One difficulty with this solver is that properties of the blood can vary, especially between patients. That considered, however, the agreement between the experimental and computational cases is good.

Figure 2 demonstrates an expected use of the solver: obtaining a statistical picture of the cells' response to a flow. However, the solver also provides additional information other than only average maximum strain on the cell, including the peak strain experienced overall, expected time over which the cell will experience this strain, and potential information on fatigue. Such information could be useful in obtaining a mechanistic understanding in how hemolysis occurs in flows on this scale.

The immediate extension of this work involves modifying it to include a measurement of hemolysis. Hemolysis occurs in multiple stages, with initial stages being the formation of pores that cause hemoglobin to leak from the cells, and later stages being the full-scale rupture of the cells [7]. Incorporating these effects in a way that accurately captures the release of hemoglobin is essential for using the solver to predict hemolysis. Additionally, there are several ways that the solver can be reduced in cost before it is used in time-sensitive procedures. However, even without these extensions, the current work provides a high level of detail about the behavior of RBCs not typically available for macroscale flows.

MECHANICAL CHARACTERIZATION OF SHEEP LYMPHATIC GROWTH AND REMODELING

Sophia M. Mavris (1), Zhanna V. Nepiyushchikh (2), J. Brandon Dixon (1,2), Rudolph L. Gleason (1,2)

(1) Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology and Emory University, Atlanta, GA, USA

INTRODUCTION

Approximately 1 in 1000 Americans are affected by secondary lymphedema (SL), a vascular disease characterized by excess fluid buildup in the extremities from severe damage to the lymphatic system [1,2]. This form of lymphatic dysfunction can disrupt proper function and maintenance of the cardiovascular system and of nearly every organ in the body [3,4]. The lymphatic system is responsible for maintaining fluid and protein homeostasis and transporting lipids, immune cells, and antigens [5,6]. The leading cause of SL is a secondary complication to the surgical removal of lymph nodes for breast and gynecological cancer treatment [7]. If left untreated, patients with SL have an increased risk of developing lymphangiosarcoma, infection, and cardiovascular disease [1,2].

Standard SL treatments are limited to pressure garments and lymphatic drainage massages [8]. While these methods help to temporarily reduce pressure within the affected limb, there is a lack of evidence that these methods aid in the repair of the lymphatic vasculature itself in the presence of disease [9]. Little data is available regarding growth and remodeling (G&R) of the lymphatic vasculature in health and disease; however, previous literature suggests the mechanical properties and behavior of the lymphatic vasculature are vital for lymph flow [10,11]. With the absence of impactful therapies and no available cure, there exists a pressing need to better characterize the G&R response of the lymphatic vasculature following disruption or damage to the lymphatic system.

In this study we introduce a large-scale lymphatic model to characterize post-injury changes in the geometry and mechanical behavior of lymphatics. This large animal model considers the impact of gravitational force on the lymphatic network within the hindlimbs of female sheep - an element that is absent in previous rodent models yet substantial in clinical cases [12]. We aim to progress towards better preventions and treatments for patients with lymphatic injury by

investigating how the lymphatic vasculature adapts to alterations in its mechanical environment.

METHODS

The caudal popliteal lymphatic vessel in one hindlimb of the sheep (n=12) was occluded with an ~1cm in length excision, while the other hindlimb received a sham surgery. The experiment was terminated at 2, 4, and 8 weeks (n=4 at each time point). Post-euthanasia, the cranial popliteal lymphatic vessels from each hindlimb were isolated and sutured onto two opposing glass cannulas within a 37°C calcium-free PSS bath connected to a custom cylindrical biaxial mechanical testing device. The computer-controlled device comprised of a trinocular stereoscope at 0.7x magnification with an attached camera to visualize the cannulated vessel, an edge detection subroutine in LabView for measuring diameter, inlet and outlet pressure sensors, a 50 g load cell force transducer, manual axial length actuators, and a syringe pump. This system controls transmural pressure and axial stretch, while measuring outer diameter and axial force. To evaluate passive mechanics, vessels underwent one cycle of preconditioning of a pressure range of 3-40 cm H₂O at stretches below in vivo, at in vivo, and above in vivo, respectively, followed by three loading cycles with the same pressure range and stretches. The in vivo stretch for each vessel was determined by finding the intersection point of axial stretch versus axial force curves for fixed pressures. Pressure-diameter and pressure-compliance curves were plotted at the in vivo axial stretch. Compliance was calculated as

$$C = \frac{\Delta D / \bar{D}}{\Delta P} \quad (1)$$

where D is vessel outer diameter and P is transmural pressure.

RESULTS

At each termination time point, the cranial popliteal vessels from the injured hindlimbs exhibited an increased outer diameter compared to the sham hindlimbs when exposed to pressures of 3-40 cm H₂O (Fig 1). No significant difference in compliance (Fig 2), in vivo axial stretch (Fig 3), or axial length (Fig 4) were observed between the injured and sham vessels at any of the time points. The ratio of in vivo stretches from the injured to sham vessels from the same animal showed a high degree of variability (Fig 4).

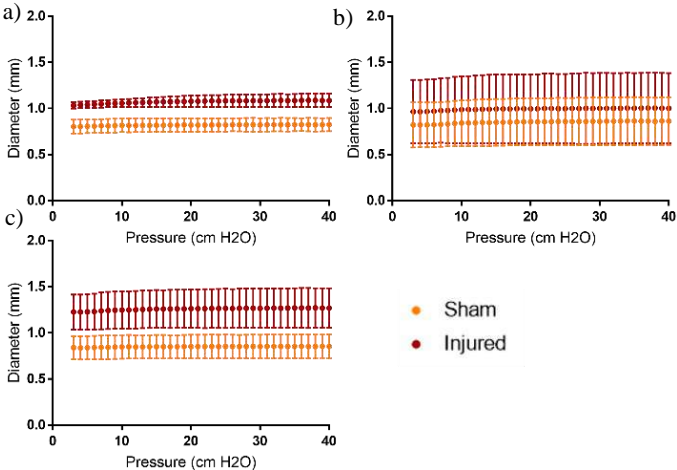

Figure 1: Pressure-diameter curves for sham and injured lymphatic vessels at 2 week (a), 4 week (b), and 8 week (c) time points.

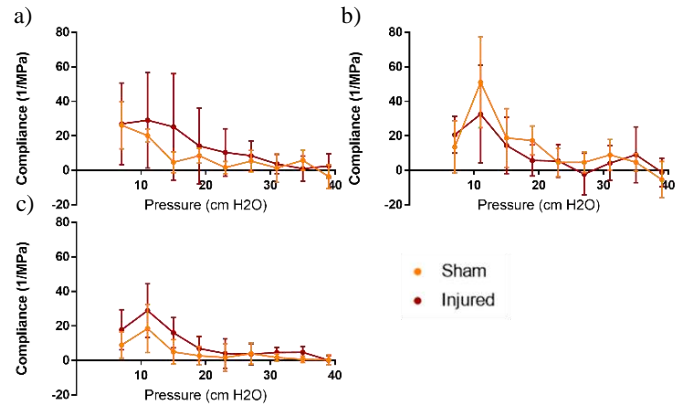

Figure 2: Pressure-compliance curves for sham and injured lymphatic vessels at 2 week (a), 4 week (b), and 8 week (c) time points.

Figure 3: Comparison of in vivo stretches between sham and injured vessels at each time end point (2, 4 and 8 weeks).

Figure 4: Comparison of the in vivo stretch ratio between the injured and sham vessel for each sample at all time points.

DISCUSSION

This study highlights that remodeled lymphatic vessels adapt by growing with a significant increase in circumferential size (outer diameter) while showing no observable changes in mechanical properties (compliance), in vivo stretch, and axial length. Another observation was that there was a high degree of variability in vessel diameters and in vivo stretch ratios between the samples. This showcases that the lymphatic vasculature anatomy within a standardized experimental group (adult female sheep) can differ greatly, indicating that there may not be a “one-size-fits-all” treatment for lymphatic injury. Some limitations of this experiment include having a small sample size within each termination group and the presence of systematic inflammation within the sheep due to the sham and injury vessels being isolated from the animal. There was also observed local inflammation at the site of both the sham and injured surgical wounds at the time of tissue collection. Our findings help to create a better understanding of lymphatic biomechanics and its relation to disease progression by translating these findings to improve and uncover better treatments and preventions for SL.

BOVINE PERICARDIUM DENSITY MEASUREMENT AND ITS IMPLICATIONS ON LEAFLET STRESS DISTRIBUTION IN BIOPROSTHETIC HEART VALVES

Masod Sadipour (1) and Ali Azadani (1)

(1) Department of Mechanical and Materials Engineering, University of Denver, Denver, Colorado, United States

INTRODUCTION

Bovine pericardium (BP) is one of the common materials in manufacturing BHVs. It has been shown that valve performance is highly dependent on leaflet material properties. Finite element analysis (FEA) has been widely used to study prosthetic and natural heart valves, reducing the costly and lengthy process required for in vivo and in vitro analysis. To obtain reliable solutions in computational modeling, it is essential to consider accurate properties of bioprosthetic heart valves (BHVs), such as density and mechanical properties. Previous computational studies assume BP density to be close to the density of water or blood. However, BP leaflets undergo multiple treatments, such as fixation and anti-calcification. The goal of the present work is to measure the density of bovine pericardial patches and analyze the impact of density on BHV leaflet stress and strain distribution. To the best of our knowledge, this is the first study to measure the density of commercially available bovine heart valves and compare leaflet deformation and stress with different densities.

METHODS

First, we measured the density of eight square BP samples laser cut from Edwards BP patches. The weight of specimens was measured using an A&D Analytical Balance, and volume was measured by high-resolution imaging. An FE analysis was then conducted on the effect of density deviation on the deformation and stress distribution of PERIMOUNT Magna aortic heart valve (Edwards Life Sciences, CA), a well-known and commercially available surgical valve. For this purpose, we conducted a dynamic analysis on the 25 mm PERIMOUNT Magna Bioprosthesis with different densities based on our findings in the first part of the study. Abaqus/Explicit was used to carry out the FE analysis. A thickness of 0.56 mm was taken into account in the simulations. A non-linear anisotropic Fung-type elastic constitutive model was employed for the leaflets:

$$w = \frac{c}{2}(e^Q - 1), \quad Q = E : (\mathbf{h}E) \quad (1)$$

where E is the Green–Lagrange strain tensor and \mathbf{h} is a non-dimensional symmetric tensor entailing 21 independent coefficients of the Fung model. Material orientation was given to the leaflet's elements utilizing a homemade MATLAB code [1]. A pressure waveform obtained from a previous study using in vitro analysis was used as the simulation physiological loading condition²⁴. Finally, A material optimization was carried out for the leaflets based on the deformation experimental results obtained by Mostafa et al. [1].

Figure 1: (a) 25-mm PERIMOUNT Magna surgical bioprosthetic aortic valve (b) The FE model showing the leaflets' geometric configurations attached to the frame.

RESULTS

The average density value of the BP samples was 1,410 kg/m³, and the standard deviation (SD) was 0.07 kg/m³. In previous simulations and analyses [1-3], the density of bovine and porcine pericardium was considered 1,000 kg/m³ and 1,100 kg/m³. We compared the stress on the leaflets with different densities (1,000 and 1,410 kg/m³) in both the acceleration and deceleration phases of the cardiac cycle (Figure 2). As

presented in the figure, the leaflet stress distribution was dependent on the density of the leaflets. In the acceleration, high-stress regions were detected in the fixed edges between the middle of the fixed edge and commissure, and the maximum principal stress reached to 1.89 MPa for a density value of 1,410 kg/m³, and 2.47 MPa for a density of 1,000 kg/m³ (30.7% difference). The maximum principal stress of the higher density showed lower stress during the acceleration. However, high-stress regions were observed mainly near the commissures during deceleration, and the maximum stress reached 0.713 MPa. A decrease in density from 1,410 kg/m³ to 1,000 kg/m³ resulted in decreased magnitudes of the maximum in-plane principal stress in the deceleration.

Figure 2: Max in plane principal stress of 25 mm premium Magna surgical valve in the acceleration and deceleration with 1,000 kg/m³ and 1,410 kg/m³ density

In addition, the maximum in-plane principal stress histogram of the leaflets in the acceleration is presented in Figure 3. The histogram indicates that 2% of the leaflet elements with density of a 1,000 kg/m³ had a maximum in-plane principal stress of more than 1.2 MPa while in the density=1,410 Kg/m³ case we just have 0.5% of elements within 1.2-1.87 MPa and no elements more than 1.87 MPa.

Figure 3: The maximum in-plane principal stress histogram of PERIMOUNT Magna leaflets in the Acceleration with 1,000 kg/m³ and 1,410 kg/m³ density

DISCUSSION

This study improves our understanding of the structural performance of surgical heart valves. To obtain the mechanical behaviors of bioprosthetic aortic valve leaflets, accurate properties of tissues are essential, helping us design and manufacture novel prosthetic valves. Stress distribution and deformation of the BHV leaflets depend on the magnitude of density; by considering 1,410 kg/m³ as the reference value for density, the difference of taking the value of 1,000 kg/m³ into account as the density value would be remarkable. Through dynamic simulations of a 25-mm PERIMOUNT Magna aortic valve, it was shown that the maximum principal stress was significantly higher in the acceleration phase of the cardiac cycle than the deceleration phase in all

cases. Relevant differences in stress distribution have a strict correlation with different kinematics of the leaflets. In computational models, it is essential to consider an accurate value for the density of BHV leaflets. Simulating the interaction between fluid and structure could offer a simulation with a higher level of precision which we will consider in future studies. Also, adding more samples could increase the accuracy of the current study.

INTRODUCTION

Blood flow within an artery is a key determinant of its susceptibility to the development of atherosclerotic plaques [1, 2]. Unidirectional blood flow at a normal velocity (i.e., normal flow) in straight arterial segments protects against plaque development. Multidirectional blood flow at a low velocity (i.e., disturbed flow) in curved or bifurcated arterial segments promotes plaque development [3]. These relationships are well established, yet our understanding remains incomplete. It is unknown how normal blood flow affects plaque fate, and whether flow can be restored within an atherosclerotic artery. To address this knowledge gap, a blood flow-modifying cuff was initially placed around the left carotid arteries of ApoE^{-/-} mice to induce plaque development and then it was removed to allow restoration of normal blood flow. Restored normal blood flow was confirmed using magnetic resonance imaging (MRI) for lumen area and Doppler ultrasound for blood velocity. Serially-collected histology sections demonstrated that plaques in decuffed mice exhibited compositional changes indicative of a more stable phenotype compared to those in untreated mice. Because the primary therapeutic strategy for atherosclerosis is systemic lipid lowering via statins, we also evaluated the effects of atorvastatin. Plaques in mice treated with atorvastatin also exhibited plaque stabilization comparable to those treated with restored normal blood flow via decuffing and the combination promoted both plaque stabilization and regression.

METHODS

Mouse Model. A total of 56 mice were acquired from Jackson Labs at 11 weeks of age and immediately placed on an atherogenic diet for the duration of the experiments. Two weeks later, mice were instrumented with a blood flow modifying cuff around the left carotid artery and the contralateral carotid artery served as a control. The cuff induces an unstable plaque in the upstream artery segment and stable plaque in the downstream segment. Mice were randomly assigned to

one of four experimental groups: (1) untreated with the cuff maintained for nine weeks (9U), (2) treated with decuffing (to restore normal blood flow) after five weeks of cuff placement and maintained without the cuff for an additional four weeks (9D), (3) treated with atorvastatin daily after five weeks of cuff placement and maintained with the cuff for an additional four weeks (9A), and (4) treated with the combination of atorvastatin plus decuffing (9AD). All mice were humanely sacrificed nine weeks after initial cuff placement.

Histology. Carotid arteries were serially cryosectioned at 8 μ m thickness. Three stains were evaluated: oil red O for lipids, picrosirius red for collagen, and CD68 for macrophages. The stained sections were imaged with a Zeiss Axio Observer 5 microscope at 10x magnification for basic stains and a Zeiss LSM 800 confocal microscope for the immunostain. Sections were segmented with a custom MATLAB program that quantified percentage of stain area to intima area.

Medical Imaging. Magnetic resonance imaging (MRI) and Doppler ultrasound were used to quantify lumen patency at the point of maximum artery stenosis and peak blood velocity, respectively, at -1, 1, 4, 7, and 9 weeks after initial cuff placement. Both quantities are normalized to week -1.

Statistics. All quantities are reported as mean \pm standard deviation. Normality was determined by a Shapiro-Wilks test and either a *t*-test or Mann Whitney U test with equal or unequal variances (F-test) were performed. Multiple comparisons were accounted for using a Bonferroni-Holm correction and an adjusted *p*-value of less than 0.05 was considered statistically significant.

RESULTS

MRI and Doppler ultrasound demonstrated that placement of the blood flow-modifying cuff caused a significant reduction in lumen patency and blood velocity, while latter cuff removal in the 9D mice restored these quantities to near baseline values (Figure 1B & C). One week after cuff placement, MRI revealed a dramatic reduction in

lumen area ($13.7 \pm 5.2\%$ versus $99.6 \pm 17.4\%$, $p < 0.0001$), which was similar at 4 weeks. However, two weeks after decuffing, the maximum stenosis had improved ($74.8 \pm 21.2\%$ versus $103.9 \pm 19.5\%$, $p = 0.005$) and, after 4 weeks, there was no significant difference between the left and right carotid arteries ($84.3 \pm 18.1\%$ versus $97.3 \pm 14.6\%$, $p = 0.07$) (Figure 1B). Similarly for peak systolic blood velocity, the left carotid artery exhibited a dramatic reduction compared to the control at week 1 ($55.9 \pm 8.8\%$ versus $107.9 \pm 16.8\%$, $p = 0.0002$) and 4 ($56.5 \pm 10.6\%$ versus $113.8 \pm 18.5\%$, $p = 0.0002$). Two weeks after decuffing, the peak blood velocity had increased in the instrumented arteries and was no longer statistically different from the control arteries (Figure 1C).

Figure 1: MRI and Doppler ultrasound of decuffed carotid arteries compared to right contralateral control arteries. (A) MRI and ultrasound images before (week -1), during (week 1), and after (week 9) cuffing. (B) Quantification of lumen area from MRI. (C) Quantification of peak blood velocity from ultrasound.

Histological analysis revealed that restored normal blood flow alone promoted plaque stabilization and the combination with atorvastatin caused plaque regression. In the upstream (unstable) plaque region, decuffed mice exhibited significant changes in plaque composition compared to the untreated group (9D vs 9U), wherein lipid content was lower ($4.3 \pm 3.6\%$ versus $17.2 \pm 9.4\%$, $p = 0.003$), macrophage content was lower ($1.1 \pm 0.8\%$ versus $4.0 \pm 1.8\%$, $p = 0.0009$), and collagen content was higher ($9.3 \pm 3.1\%$ versus $4.9 \pm 2.0\%$, $p = 0.0009$) (Figure 2A). Similar results were seen with atorvastatin (9A). The combination of the two therapies (9AD) exhibited similar plaque lipid and macrophage contents, but a higher collagen content versus each therapy individually ($15.5 \pm 4.4\%$ versus $8.2 \pm 5.4\%$, $p = 0.01$ and $9.3 \pm 3.1\%$, $p = 0.013$ for the 9A and 9D groups respectively). Furthermore, the 9AD group was the only group that exhibited a significant decrease in plaque burden from the 9U group ($22.7 \pm 18.0\%$ versus $43.7 \pm 12.7\%$, $p = 0.013$).

In the downstream (stable) plaque region, there was no significant differences in lipid and macrophage content between the groups. However, collagen concentrations were significantly higher in all treatment groups compared to the untreated 9U group with 9AD having the highest collagen concentration compared to 9U and 9D ($9.6 \pm 5.4\%$, $p < 0.0001$ and $17.1 \pm 5.0\%$, $p = 0.04$, respectively).

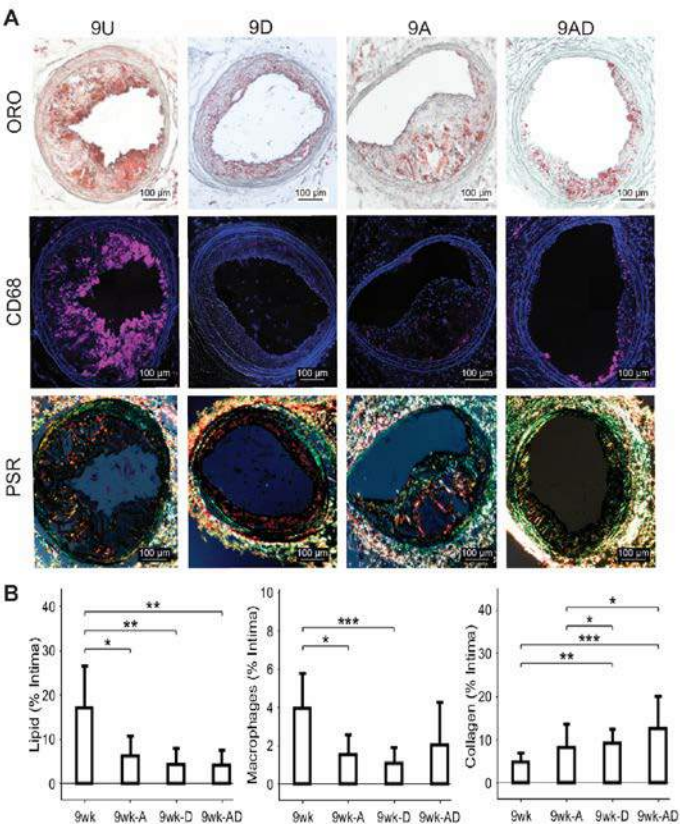

Figure 2: Histological results from the unstable plaque region upstream of the cuff. (A) Mouse carotid artery sections for lipids (ORO), macrophages (CD68), and collagen (PSR) in each mouse group. (B) Histology quantification of each group across each stain.

DISCUSSION

Atorvastatin is a first-line therapeutic for atherosclerosis that primarily causes plaque stabilization. Studies in patients have shown that it promotes increased fibrous cap thickness, decreased lipids, and decreased macrophages [4]. Remarkably, our study herein demonstrated a similar degree of plaque stabilization with restored normal blood flow. We also found that the combination of restored normal blood flow and atorvastatin had additive beneficial effects, including a significant reduction in plaque burden, lipid, and macrophage content, and increased collagen content compared to the untreated mice. This suggests that atorvastatin and mechanical stimuli operate along different cell signaling pathways and could be administered in parallel within patients for additive therapeutic effects.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive treatment used to treat severe aortic stenosis. The efficacy of TAVR has been shown over the past 20 years and the number of TAVR procedures is constantly increasing, surpassing surgical aortic valve replacement (SAVR). TAVR is expanding to younger, lower-risk patients, and is even being used for bicuspid aortic valve (BAV) patients in addition to the common trileaflet aortic valve (TAV) patients for

which TAVR was originally used [1,2]. However, TAVR is associated with several clinical complications, including long-term, life-threatening thrombotic events that may be a consequence of prolonged exposure of platelets to elevated cyclic stresses. Flow-induced thrombogenicity increases the risk of platelet activation, and microthromboemboli formation can lead to prosthetic leaflet thrombosis. The rapid expansion of TAVR into younger and lower-risk patients highlights the importance of developing alternatives to current

tissue-based TAVR devices that may suffer from structural deterioration and thrombus formation – as the device must remain functional and safe for the long-term. New polymer technologies facilitate the creation of more durable TAVR valves and mitigate such adverse complications [3,4].

Optimization of polymeric TAVR leaflets can reduce the risk of flow-induced thrombogenicity and mitigate the need for post-TAVR anticoagulation therapies, which are widely debated. Optimizing the valve design to improve its hemodynamics and minimize the associated potential thrombotic events is the preferred approach. Furthermore, given that current devices deployed in BAV patients are designed for treating common trileaflet aortic valve patients, having a dedicated TAVR stent and leaflet design for BAV patients can lead to better device performance. The goal of this study is to use advanced computational modeling approaches, including fluid-structure interaction (FSI) simulations, to assess the thrombogenic potential and hemodynamic performance of current commercial TAVR valves. We demonstrate how these devices compare to our dedicated polymeric TAVR leaflet designs for both trileaflet and bicuspid AV patients, which are optimized in multiple steps involving various design features. Specifically, in this work we highlight a thrombogenic risk

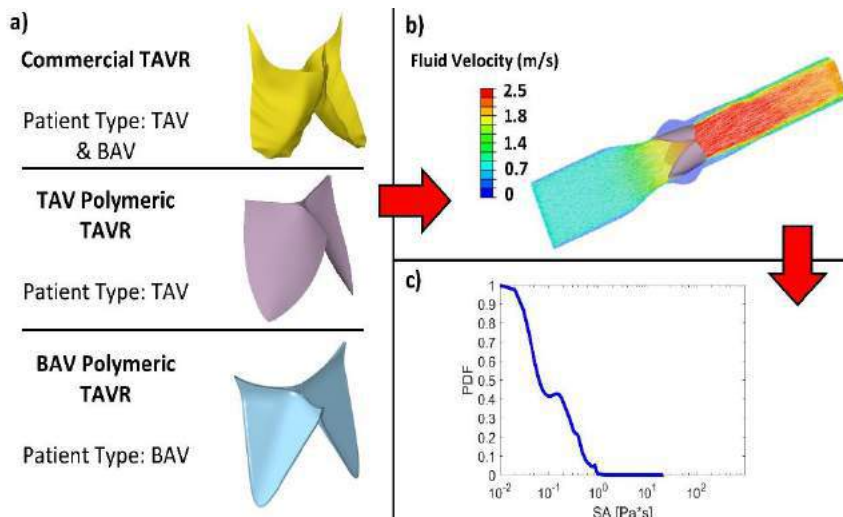

Figure 1: Thrombogenic optimization workflow in which the various valve types in (a) are used to simulate TAVR and run hemodynamic analyses via FSI (b). The thrombogenic risk of each valve can be examined via PDFs (c).

assessment workflow that utilizes a fully integrated TAVR FSI approach, leading to reduced thrombogenicity.

METHODS

Commercial TAVR models were generated for older, self-expandable CoreValve (23 and 26 mm) and newer generation Evolut (23 and 26 mm) devices, in addition to the balloon-expandable SAPIEN (23 mm). The valve models were generated along with their stents as described in our previous work [5]. With the constructed leaflets and stents, a TAVR deployment was simulated in ABAQUS Explicit v2019 (Dassault Systemes, Vélizy-Villacoublay, France) and the resulting post-deployment geometry - with a native trileaflet valve - was taken into ANSYS LS-DYNA to perform FSI analysis for two beat cycles (Fig. 1).

To validate the constructed TAVR valves, FSI flow data for the commercial devices were compared to particle image velocimetry (PIV) data in the literature [6]. Following the validation, each FSI simulation was post-processed using ANSYS EnSight in which ~150,000 platelets were seeded in the systolic flow via the implementation of Lagrangian particles. Stress accumulation (SA) was calculated and tracked for all the particles seeded in the fluid domain, with the continuous seeding of particles at the inlet to accurately model new platelets introduced into the flow [7]. With this data, the probability density function (PDF) of the accumulated stresses of the large population of flowing platelets was computed for each valve type, which represents the “thrombogenic footprint” for each respective device [7]. To analyze the thrombogenic potential of different leaflet designs, the PDFs of the various commercial devices were compared amongst each other and to multiple parametric trileaflet valve geometries that have varying belly and attachment profiles. Additionally, the thrombogenic potential of our BAV-dedicated TAVR design, PolyV-B, was assessed and compared to commercial devices currently used for BAV patients by utilizing this workflow with an idealized native geometry consisting of a bicuspid aortic valve (Fig. 2).

Figure 2: Deployment of the PolyV-B polymeric valve in a patient-specific anatomy.

RESULTS

The FSI results for the commercial valves showed peak systolic jet velocities in the range of 2.5 to 3.0 m/s (Fig. 3), comparable to the PIV velocity data found in the literature [6]. Data was also compared for the

Figure 3: Flow results from the FSI simulation for the Evolut 29 mm commercial valve.

CoreValve and SAPIEN, and after validation, the thrombogenic risk simulations were performed for the commercial valves, followed by the polymeric TAV valves and PolyV-B. Upon comparison of the PDFs for the polymeric TAV valves, different degrees of stress accumulation were highlighted. In particular, the B1A1 valve showed more stress accumulation on a much larger number of platelets than the B1A2 or B1A3 valves. Valves designed with attachment regions with large tapering angles (least-gradual curvature), and comparatively large surface areas tended to show higher thrombogenic risk due to excessive leaflet fluttering, irregular GOA shapes, and other characteristics that would likely activate platelets over time (Fig 4.). Various commercial valves also showed comparatively high thrombogenic risk, thereby highlighting that the commercial leaflets are not optimized for mitigating flow-induced thrombogenicity.

Figure 4: PDFs for three of the polymeric TAV leaflet geometries showing variation in thrombogenic risk due to changes in leaflet design.

DISCUSSION

This study demonstrates the ability to analyze post-TAVR thrombogenic risk by studying hemodynamics of prosthetic devices via a fully integrated TAVR FSI approach. The devices studied here include both self-expandable and balloon-expandable commercial valves currently on the market, old and new generation devices, novel polymeric TAV devices, and our BAV-specific device, PolyV-B. More specifically, we can analyze the impact of TAVR leaflet designs on hemodynamics and thrombogenicity to develop novel devices that are safe and durable with reduced thrombogenicity for younger patient cohorts. Limitations of this study include the use in few cases of idealized anatomies for TAVR deployments. Nevertheless, this study points to key parameters of TAVR leaflet design most critical for the mitigation of thrombogenic risk and other essential hemodynamic criteria. Optimized TAVR devices of the future may finally reduce the need for post-TAVR antithrombotic therapies. In the future, we wish to use patient-specific anatomies, especially for the PolyV-B device. Additionally, we plan to perform our own in-vitro hemodynamics testing (ViVitro) with TAVR devices that we are developing.

SUCCESSFUL TRANSPLANT OF CRYOPRESERVED KIDNEYS ENABLED BY ENGINEERING-BASED PROTOCOL OPTIMIZATION

INTRODUCTION

A method to cryopreserve or “bank” kidneys prior to transplant would effectively remove the influence of time from the organ transplantation process. It would transform transplantation from an emergency procedure that must be accomplished within hours of organ acquisition to a planned procedure that can equitably reach patients regardless of geographical and time constraints. A promising approach to organ banking is vitrification – that is, cooling organs perfusion-loaded with cryoprotective agents (CPAs) so quickly that they cannot undergo the phase transition from liquid water to ice and instead enter a stable glass-like state wherein viable storage is theoretically indefinite. While vitrification of rabbit kidneys was first successfully demonstrated decades ago[1], the ability to reproducibly rewarm whole organs while preserving viability and function has proven elusive. Addressing this long-standing issue requires mitigating the effects of two interrelated sources of damage to the organ: CPA toxicity (including osmotic stress) during perfusion loading/unloading and ice crystallization or cracking due to slow or non-uniform rewarming. Here we apply engineering-based optimization of CPA loading and vitrification to allow fast and uniform rewarming (i.e., RF nanowarming) and demonstrate the first repeatable organ cryopreservation and rewarming with success in an in vivo transplant model.

While CPAs help mitigate damage due to ice formation, the required concentrations can become toxic. The toxicity to the organ is determined by the CPA components, exposure time, temperature, and osmotic stress during loading. Carefully balancing these factors allows vitrifiable concentrations to be achieved within the organ while minimizing toxicity. Successful rewarming then becomes critical; if rewarming is too slow, ice crystals form (i.e., devitrification), and if rewarming is not uniform, thermal stress causes cracking. Increasing the CPA concentration reduces the rewarming rates required but can increase toxicity, so overall protocol optimization is a delicate balance between

these factors. Traditional rewarming approaches (i.e., convection, microwave, or dielectric) fail to meet both requirements[2]. While whole kidney vitrification has been achieved with a high concentration CPA (9.3 M M22), rewarming has been largely unsuccessful. Only a single kidney has been successfully transplanted with any function [3], and that kidney was cryopreserved for only 8 min and only restored partial function. Further, even that partial success has never been repeated.

In this work, we show the ability to load, vitrify, and store (up to 100 days) kidneys at lower concentrations of CPA than M22 and the ability to use RF nanowarming to achieve a robust fast and uniform rewarming protocol with transplantation success. Physical success with RF nanowarming has been reported in earlier work from our group. Briefly, the technique employs alternating magnetic fields to remotely couple to and heat iron oxide nanoparticles (IONPs) that are perfused in CPA throughout the organ vasculature. Once the organ is vitrified, the IONPs provide the ability to rewarm in a fast and uniform manner in an RF field, which allows rewarming to occur independent of organ size [4, 5]. We systematically modeled the CPA transport and toxicity to achieve lower CPA concentration (8.4M) while still allowing vitrification. To demonstrate organ function and viability, we nanowarmed and transplanted the rat kidneys and showed restoration of renal function that solely sustained the lives of nephrectomized transplant recipients for 30 days post-transplant.

METHODS

We first established a target CPA concentration of ~7.8M based on our ability to nanowarm at rates of ~60 °C/min (needs to exceed CWR of 7.8 M CPA which is ~51 °C/min)[6]. We then applied combined CPA transport and toxicity models to predict the tissue CPA concentration and toxicity “cost function” to achieve vitrification and minimize toxicity for loading with 8.4M VMP, a vitrifiable CPA with acceptable toxicity in kidneys[7]. Here 8.4 M CPA concentration is used to drive rapid CPA loading in the tissue to 7.8 M without seeking full equilibration. To study this process, we used a two-compartment Krogh cylinder

model as a representative unit to study the CPA transport and osmotic stress between the vascular and cellular compartments of the organ, where the transport kinetics between the compartments are described by Kedem-Katchalsky (KK) equations[8]. The 3 parameters (L_p , P_s , and σ) related to compartmental exchange in the Krogh model were measured by fitting the observed pressures and flow during organ perfusion (as described below and previously by Pegg et al.). Then, the model was used to predict the CPA concentration inside the organ. We also applied a toxicity cost function model ($J = \int_0^t \beta C^\alpha dt$) to study the cumulative toxicity during CPA exposure[9]. The parameters in the toxicity cost function were determined by fitting viability data of kidney slices after exposing them to a range of CPA concentrations and times. All the models are coded in MATLAB R2020b (MathWorks). The combined models were then used to identify a CPA loading protocol that achieved vitrifiable organ-CPA concentrations (i.e. 7.8 M) while minimizing osmotic stress and CPA toxicity to the organs. The organ CPA concentration after loading and vitrification was then assessed by micro-CT [10]. The organs were vitrified following previously demonstrated cooling protocols at 20 °C/min with annealing [5].

Once established, the loading protocol was used to perfuse load CPA and IONP into rat kidneys, followed by vitrification and storage. The viability/function of the organ was then tested after nanowarming, CPA removal, and transplantation. First, the rat kidney was harvested from the donor and flushed with cold University of Wisconsin (UW) preservation solution and connected to a pressure- and flow-controlled multi-thermic (20 °C to -4 °C) perfusion system. CPA was loaded following the optimized VMP protocol. IONPs were perfused along with the final step of CPA loading assuming the IONP as an inert additive (<1 wt.%). Following CPA and IONP loading, the organ was placed in a controlled rate freezer and vitrified. The vitrified organ was then transferred to a -150 °C freezer for storage. At pre-determined times (n = 5 kidneys, 1-100 days), organs were removed from cryogenic storage, rapidly placed in an RF coil, and rewarmed at > 60°C/min. The CPA and IONPs were then unloaded in a gradual fashion.

Organ function and viability were tested in a rat transplant model. The recipient had both native kidneys removed, followed by transplant of the nanowarmed and CPA-unloaded donor kidney. Thus, renal function and survival of the animal depended solely on the transplanted organ. The animals survived for the full 30-day study period, over which the organs were assessed by blood serum and urine analysis (e.g., creatinine level and venous blood gas). The animal's body weight was also measured. Nanowarmed kidneys were compared directly to fresh control kidney transplants (n = 5).

RESULTS

In the Krogh model, the water permeability (L_p), CPA permeability (P_s), and reflection coefficient (σ) were measured as $1.5 \times 10^{-14} \text{ m}^3/(\text{N} \cdot \text{s})$, $7.0 \times 10^{-13} \text{ mol}/(\text{N} \cdot \text{s})$, and 0.10 (mean values), respectively. The toxicity cost function parameters were estimated as $\alpha = 3.12$ and $\beta = 9.39 \times 10^{-6}$ for VMP (n=3 for each parameter determination).

Guided by the CPA transport model, we optimized existing perfusion loading protocols by modifying the perfusion pressure, CPA exposure time, and temperature. Using the toxicity cost function model, we optimized the loading to achieve a vitrifiable concentration of 7.8 M (this value was predicted by the model and determined by DSC) as shown in Figure 1.

After vitrification, the rat kidneys were stored for 1-100 days followed by nanowarming and transplant. Intraoperatively, all nanowarmed kidneys reperfused rapidly and homogeneously upon restoration of blood flow (Fig. 1f) and grossly appeared similar to fresh control organ transplants. Postoperatively, all fresh control and nanowarmed kidney transplants continued to produce urine, and all animals survived for the full 30-day study period. During the first two postoperative

weeks, nanowarmed kidney recipients experienced more metabolic dysfunction (e.g., higher creatinine level) than control transplants, but all the nanowarmed kidney values reached the control kidney levels by day 14 and renal function was completely normal at sacrifice on day 30.

(c) The model-predicted CPA concentration inside kidney tissue for the case shown in Fig. 1b. (d, e) Photo and micro-CT image of vitrified kidney after perfusion loading. (f) Intra-operative photo of nanowarmed transplanted kidney showing reperfusion.

DISCUSSION

This work presents several new findings: 1) Krogh cylinder permeability parameters (L_p , P_s , and σ) for rat kidney and VMP loading, 2) toxicity cost function parameters (α and β) for kidney and VMP exposure, 3) combination of Krogh and toxicity cost function modeling to achieve a vitrifiable kidney with improved viability, and 4) demonstration that these viable vitrified kidneys can be nanowarmed, transplanted, and used to preserve the life of a recipient after cryobanking for up to 100 days. While we demonstrate success in the rat kidney, our approach is scalable to human-sized organs, and we are conducting further studies to demonstrate this. Further, this systematic approach to protocol optimization can be broadly applied to other organs.

This result is an important step on the path to clinical organ banking. Cryobanking would improve donor/recipient matching, allow for better patient preparation and scheduled procedures, facilitate tolerance induction protocols in recipients, and increase organ utilization – all while supporting graft and patient survival.

CORRELATIONS BETWEEN MASS TRANSPORT, ELASTIC FIBER FRAGMENTATION, AND THORACIC AORTIC ANEURYSM SEVERITY

INTRODUCTION

Thoracic aortic aneurysm (TAA) is characterized by a >50% dilation in the aortic diameter and can lead to aortic dissection, which is often fatal. Some TAAs are linked to genetic mutations that affect elastic fiber formation and cross linking, and elastic fiber fragmentation is a common pathology in TAA [1]. However, the mechanisms relating elastic fiber fragmentation to TAA formation and growth are not well understood. In this study, we investigate the connection between elastic fiber fragmentation and TAA severity by quantifying transmural mass transport as a possible mechanism contributing to TAA progression.

Previously we reported that enzymatic degradation and genetic mutations in fibulin-5 or lysyl oxidase facilitate arterial mass transport [2,3]. These studies showed that elastic fiber fragmentation can impact transmural convection and diffusion, yet, did not specifically model TAA. This study uses a TAA mouse model with a missense mutation in fibulin-4 (E57K), a protein necessary for elastic fiber formation [4]. *Fbln4*^{E57K/E57K} mice develop TAA with 50% penetrance, and when bred with lysyl oxidase (a crosslinking enzyme) haploinsufficient mice, *Fbln4*^{E57K/E57K};*Lox*^{+/-} mice have 100% TAA penetrance.

We present data from transmural mass transport experiments measuring hydraulic conductance and solute permeability of the mouse ascending thoracic aorta (ATA). We then compare mass transport properties with ATA geometries and quantification of elastic fiber fragmentation. We hypothesized that elastic fiber fragmentation would cause an increase in mass transport properties that would correlate with increased TAA severity, as measured by ATA diameter.

METHODS

Mouse Model. Mice with a missense mutation in fibulin-4 (E57K) were used and compared to wild-type (WT) littermates. *Fbln4*^{E57K/E57K} *Lox*^{+/-} mice were categorized into MU-A (aneurysm, >50% dilation) and MU-NA (non-aneurysm, <50% dilation) groups by comparing the ATA diameter to the average WT diameter. *Fbln4*^{E57K/E57K};*Lox*^{+/-} mice are

referred to MU-XA (extreme aneurysm) and always had >50% diameter dilation. Mice were sacrificed at 3-4 months of age and the ATA was isolated by dissection. All procedures were approved by the IACUC.

Mass Transport. ATAs were mounted into a Myograph (DMT). The outlet was closed off, and a hydrostatic fluid column was attached to the inlet to maintain an internal pressure of 100 mmHg. An air bubble was introduced into the lead tubing and the bubble displacement was tracked over time. This measurement was performed with phosphate buffered saline (PBS) in the fluid column, and then PBS containing 5 mg/mL of 4 kDa FITC Dextran. When Dextran was present, the concentration of the external bath was recorded over time. These values were used to calculate hydraulic conductance, with (L_{ps}) and without (L_p) solute present, and solute permeability (ω) [2, 3].

Elastic Fiber Fragmentation. After experimentation, a subset of ATAs were fixed while pressurized for 12-20 hours in 4% paraformaldehyde. Samples were flash frozen and 5 μ m thick cross sections were cut using a cryostat microtome and cover slipped. Samples were imaged using a Leica Sp-8 DIVE multiphoton microscope with a 40x objective. Collagen and elastin were excited at 880 nm and imaged using second-harmonic generation (emission: 420-460 nm) and autofluorescence (emission: 495-540 nm), respectively. After imaging, the elastin channel was isolated and analyzed in ImageJ (NIH). A 144 x 192 μ m section was thresholded to create a binary image of the laminae and the built-in skeletonize function and analysis was used to measure end points, junctions and slabs, which are defined by pixels with <2, >2, and 2 neighboring pixels, respectively.

Statistics. Statistical analysis was done using GraphPad Prism. Data are presented as means and standard deviations. Experimental groups were compared using one-way ANOVA and Sidak's multiple comparisons. Correlation matrices were made using the Pearson r correlation test. Pearson r values >0.6 can be considered moderate correlation, and >0.8 strong correlation. P-values <0.05 were considered significant.

RESULTS

Hydraulic conductance was calculated from the velocity of an air bubble in the fluid system and assumed 1-D advection-diffusion flow. Hydraulic conductance's are 60% and 68% lower in aneurysm groups (MU-A and MU-XA) compared to WT (Fig. 1A-B). Solute permeability of these groups, however, is no different compared to WT, but MU-NA solute permeability is 397, 52, and 81% higher than WT, MU-A, and MU-XA (Fig. 1C). These results demonstrate distinct mass transport differences between TAA and non-TAA groups.

Figure 1: Calculated values of hydraulic conductance with solute absent (A), and solute present (B), and solute permeability (C) from 1-D advection diffusion analyses. N = 5 – 10/group.

Cross-section images of the elastic laminae (Fig. 2A) were analyzed to quantify elastic fiber fragmentation. Thickness measurements show a 54% thicker wall in MU-XA groups only compared to WT. Using a skeletonized thresholded image, limited differences are found in the measurements of junctions and average slab size, but end point voxels are 81, 76, and 70% higher in MU-NA, MU-A, and MU-XA groups compared to WT, respectively.

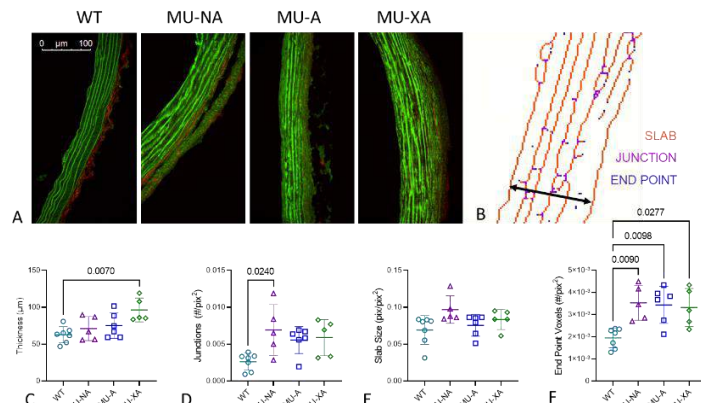

Figure 2. Representative cross section images (A) where elastin is shown in green and collagen in red. Skeleton analysis was used in ImageJ (B). Measurements of thickness (C), and skeleton values for junctions, branches, and end points (C-E) from the cross section images. N = 5-6/group.

Data from MU groups only were compared using correlation matrices which show the Pearson r values (Fig. 3). Hydraulic conductance values (L_p , L_{ps}) are significantly, negatively correlated with diameter ($p = 0.021$, 0.003), demonstrating mass transport properties that correlate with aneurysm severity. Solute permeability (ω) is not well correlated with any of the other metrics (Fig. 3A-B). The number of elastic fiber endpoints and average slab size are positively correlated with L_p and L_{ps} , ($p = 0.0010$, 0.015). Slab size is negatively correlated with diameter ($p = 0.012$) and thickness ($p = 0.009$), which demonstrates elastic fiber remodeling that correlates with TAA severity.

Figure 3. Correlation matrices for all measured MU data from mass transport experiments (A, N = 19-21) and elastic fiber fragmentation images (B, N = 8-9).

DISCUSSION

We investigated the effect of TAA caused by elastic fiber fragmentation on transmural mass transport in the ATA. Because *Fbln4*^{E57K/E57K} mice have only 50% TAA penetrance, we were able to compare pathological, but non-aneurysmal (MU-NA) to aneurysmal (MU-A and MU-XA with *Lox*^{+/+}) conditions. We found a decrease in hydraulic conductance specific to aneurysm groups (Fig. 1) and an increase in solute permeability specific to pathological, non-aneurysm groups. Previously, we studied mass transport in a different genetic mouse model which causes TAA in humans, but does not independently cause TAA in mice [2]. These ATAs had similar properties to our MU-NA, suggesting that an initial increase in solute permeability due to elastic fiber fragmentation may allow confounding conditions, such as increased cytokine trafficking, to contribute to TAA formation and growth. Increased growth factors and matrix metalloproteinases are found in human TAA [1]. As TAA progresses with extensive matrix remodeling, solute permeability returns to normal, but hydraulic conductance decreases which could cause hypoxia in medial layer cells and contribute to ongoing pathology.

Our elastic fiber quantification shows fragmentation in all MU groups and does not explain the linkage between TAA and elastic fiber defects. Using just the MU data, we further investigated these relationships through correlation analyses. The results show that hydraulic conductance is correlated with diameter dilation and also with elastic fiber endpoints and slab size. Formed elastic fibers may increase initially in compensation for the genetic mutation, and fragment further during TAA progression due to the genetic mutation. Areas between elastic fibers may be filled with proteoglycans which could affect mass transport and weaken the ATA wall due to their highly charged nature.

Overall, our results suggest that convective flow (hydraulic conductance) is decreased in fully-developed TAA and diffusion of small molecules (solute permeability) is increased at early TAA stages. These data could inform drug treatments for TAA or computational models of the TAA process. Limitations include only consideration of 1-D flow and the use of a mouse model, which differs in structure from human ATA. However, our work provides an initial understanding of how elastic fiber fragmentation may contribute to TAA pathology through alterations in mass transport.

INTRODUCTION

The knee meniscus supports dynamic joint motion and load transmission through its specialized extracellular matrix (ECM). The meniscus contains an outer vascularized zone, an inner avascular zone, and two horns that anchor the meniscus to the tibia. Covering the entire tissue is a thin, specialized superficial layer. Cells within this superficial layer express progenitor cell markers and play a critical role in meniscus injury response [1]. Specifically, in both small and large animal models, these cells migrate to injury sites, proliferate rapidly, and deposit a disorganized repair tissue [2]. Thus, while these cells appear to direct some level of endogenous repair, the disorganized ECM they form lacks in mechanical integrity relative to native tissue [3], and so may not provide for a durable repair.

To determine whether differences in response to the injury microenvironment and matrix formation arise from cell origin or is a consequence of the wound repair environment, this study investigated the response of superficial cells to changes in the mechanical environment as well as their migration and proliferation potential, relative to cells from the central region of the meniscus body. We additionally probed the functional matrix production capacity of these cells, relative to body cells, via culture in nanofibrous scaffolds and evaluation of their mechanical properties and ECM deposition. Understanding of the differences in functional ECM-deposition potential between the superficial and body cells may guide tissue engineering approaches to enhance the quality of meniscus repair.

METHODS

***In vitro* culture:** Juvenile bovine medial menisci were dissected, and biopsy punches (12 mm diameter) used to isolate samples (**Figure 1**). A custom device was used to separate the superficial (~100 μ m depth) from the deeper (body) zones (1 mm depth). Tissue segments were minced and cultured at 37°C in basal media (BM – DMEM with 10% fetal bovine serum and 1% penicillin / streptomycin / fungizone).

2D Wound Healing Assay:

Cells were plated in six-well tissue culture plates and cultured until confluence. Next, a 200 μ l pipette tip was used to scratch the cell monolayer. Brightfield images were taken every 2 – 4 hours and wound closure was computed using ImageJ. **Proliferation and Mechanosensation Assays:** 5, 10, and 55 kPa polyacrylamide gels were prepared as in [4]. Cells

were seeded on substrates for 24 hours and then incubated in Hoechst 33342 (nuclear stain), phalloidin (f-actin stain), and goat anti-YAP/TAZ (1:1000 in 1% BSA) or Click-iT EdU reagent (Proliferation) followed by confocal imaging. **Traction force microscopy (TFM):** 10 kPa gels polyacrylamide gels were prepared on glass coverslips and seeded with cells from the superficial or body zones. Phase and fluorescent microscopy was used to measure substrate displacement, followed by image analysis using a TFM plugin for ImageJ and a MATLAB code to generate traction force maps [5]. **Nanofibrous Scaffold Fabrication and Analysis:** Aligned poly(ϵ -caprolactone) (PCL) and polyethylene oxide (PEO) sheets were co-electrospun (40% PEO) and seeded with superficial or body cells as in [6]. Constructs were cultured for 12 weeks in basal media supplemented with Transforming Growth Factor Beta-3 (10ng/mL), changed three times weekly. On weeks 3, 6, and 12, constructs were mechanically tested in uniaxial tension, and the tensile modulus and yield strain calculated. Additional scaffolds were fixed, cyrosectioned (10 μ m), and stained Picrosirius red or Alcian Blue. Additional scaffolds were digested and assessed for collagen and proteoglycan content [6]. Statistics: Fig 2: t-test, Fig 3, 4, 5B: ANOVA.

Figure 1: Experimental Layout

RESULTS

Scratch assay results showed that superficial cells migrated faster than body cells (**Figure 2A**). 36 hours after the scratch wound, superficial cells completely closed the gap, whereas the wound remained ~50% open for body cells. TFM analysis showed that superficial cells had a smaller cell area than body cells, and that the total force exerted by superficial cells was lower than that of body cells (**Figure 2B**).

Figure 2: 2D Migration Assay and Traction Force Microscopy. A) Superficial cells closed the wound faster than cells from the body of the meniscus. Sample number: 5 per group, B) Superficial cells had a smaller area and generated less force than body cells.

*** $p < 0.001$, ** $p < 0.01$. Scale bars: A) 150 μm , B) 10 μm .

When placed on substrates of differing stiffness, superficial layer cells showed differences in mechano-response (**Figure 3A**). Specifically, superficial cells had a decreased level of nuclear YAP/TAZ across all substrate stiffnesses, in comparison to body cells. This indicated that superficial were not as responsive to substrate stiffness as body cells. Superficial cells also showed a higher proliferation rate across all substrate stiffnesses (**Figure 3B**). Notably, superficial cells were highly proliferative, even on softer substrates (5 and 10 kPa).

Figure 3: Response to Substrate Stiffness. A) Superficial cells showed no change in nuclear YAP with an increase in stiffness, unlike cells of the meniscus body. B) Superficial cells proliferated more at a lower stiffness (5 kPa) compared to body cells. Dashed line: % Edu+ cells on glass, N/C: Nuclear/Cytoplasmic ratio, sample number: 5 per group, **** $p < 0.0001$, ** $p < 0.01$, * $p < 0.1$.

Scale bars: A) 150 μm B) 150 μm .

When seeded in nanofibrous scaffolds and subjected to long-term culture, analysis showed that superficial cells produced a similar amount of collagen as body cells (**Figure 4A**). Proteoglycan (GAG) assessment showed that constructs seeded with body cells produced more proteoglycans by week 12 in culture than those seeded with superficial cells (**Figure 4B**). Superficial- and body-cell seeded constructs increased in tensile moduli and yield strains as a function of time in culture and were not different from one another (**Figure 4C**).

DISCUSSION

This study highlights that superficial cells are less mechanosensitive and exert less force/cell on their surrounding ECM. This, coupled with their higher proliferative potential (compared to body cells) may explain their superior performance in the 2D wound closure assay. In the context of wound repair, the finding that superficial cells proliferate more, even in softer environments, may explain why these cells colonize meniscus injury sites faster than cells from the body. Interestingly, when these superficial cells were placed in a 3D context, they produced functional tissue, with mechanical properties that were similar to scaffolds seeded with body cells. These findings indicate that, despite their decreased response to change in substrate stiffness and lower traction forces, superficial cells are able to produce functional tissue. In the setting of tissue repair, this may suggest that superficial zone cells can be functional contributors to new tissue formation. However, supplemental scaffolds and factors at the site of tissue repair that can direct the organization of ECM produced by these superficial cells may improve repair outcomes. Taken together, these results establish the regenerative potential of superficial meniscus cells and direct future tissue engineering and drug delivery approaches to harness their full potential for functional meniscus repair.

LEARNING DFFEOMORPHIC DEFORMATIONS FOR WHOLE HEART MESH GENERATION

Arjun Narayanan¹, Fanwei Kong², Shawn C. Shadden¹

INTRODUCTION

Image-based computer modeling is playing an increasing role in understanding the mechanisms of cardiac disease and personalized care.¹ Broadly, this paradigm uses medical imaging (CT or MR) to construct an anatomically accurate computer model of the heart in order to mathematically model physiological processes and probe functional information. Reconstructing an accurate, personalized computer model of the heart is challenging because of imaging artifacts, limited resolution and difficulty differentiating between cardiac and surrounding tissues.

Segmentation is the process of identifying structures of interest in an image. Machine learning has been utilized to automate segmentation of cardiac structures from CT or MR images.² However, segmentation often generates artifacts that are unfit for simulation-based modeling. Recently, we have developed alternative template based deep-learning methods that are able to generate simulation-ready computer models of cardiac structures automatically from cardiac images.³ However, these are mostly surface models of the blood pool boundaries since only these boundaries can be discerned from clinical imaging. Developing models wherein *tissue thickness* is assigned to all cardiac structures has remained challenging since most tissues are too thin to be accurately discerned.

We present here a deep learning method to produce whole-heart meshes with tissue thickness from clinical image data. We employ a template-based method to ensure accurate, simulation compatible models. Briefly, we use deep learning to deform a template mesh using a combination of linear-transformations and diffeomorphic flow deformations.⁴ We present a novel physics-informed loss term that penalizes vanishing volumes thereby preventing self-penetrations in thin walled structures. The model can be trained on data containing no thickness information and subsequently evaluated on a template with thickness. We demonstrate that this approach is able to successfully deform this new template in a realistic manner without interpenetration. The predictions of our model can be readily used to generate full 3D tetrahedral meshes.

METHODS

Dataset information. We used the multi-modality whole heart segmentation challenge (MMWHS)² dataset. We split the

dataset into 16 CT and 16 MR samples for training and used the remaining 4 CT and 4 MR samples for validation. We augmented the training dataset by introducing small perturbations including random scaling, translation, rotation, shear and local b-spline deformations to produce a final dataset size of 1920 samples.

Neural network architecture. We observed a large difference in scale and position across the data-set. This can be attributed to the different field-of-view in the image samples along with inter-patient variations. Hence, our framework consists of two modules (1) a 3D convolutional neural network (CNN) that performs a linear transformation on the template, and (2) a 3D Unet that learns to deform the template by integrating mesh vertices along a diffeomorphic flow vector field. The linear transformation is effective at scaling and positioning the template, and the flow deformation captures the finer details. For memory reasons the modules are trained separately. We use a weighted sum of the 2-way chamfer distance and geometrical regularizations such as normal consistency, mesh edge loss, and laplace loss as objective. We introduce a novel physics-informed loss term that penalizes vanishing volumes. A reference volume V_0 at time t_0 evolves to a volume V_1 at time t_1 in a flow vector field f as,

$$\frac{V_0}{V_1} = \exp \left(- \int_{t_0}^{t_1} \text{div}(f) dt \right) \quad (1)$$

If a finite initial volume V_0 collapses to an infinitesimal volume V_1 after deformation, equation 1 evaluates to a very large value. We incorporate this term into the objective function to discourage collapsing volumes. The divergence of the flow field is computed using a central finite difference scheme. Fig. 1 shows a schematic of our network architecture.

RESULTS

Dice scores. We use 4 CT and 4 MR samples from the MMWHS training data for validation. The predicted final meshes are converted to segmentations. We compute the dice score between predicted and ground truth segmentations which is presented in Table 1. The predictions of our model for a typical validation sample are shown in Fig. 2.

Self-intersections. We measured self-intersections using PyMesh. The predicted final meshes contained *zero* self-intersections within cardiac structures. For the predictions to

Figure 1: 128^3 input image processed by 3D CNN to produce 4×16^3 encoding. Linear network predicts 3 scale, 3 translate, and 3 rotate parameters from encoding to transform the template mesh. Transformed vertices embedded in an occupancy map and passed with image as input to 3D Unet which generates 3D flow vector field. Vertices are integrated along flow field to produce final prediction.

Table 1: Median and minimum dice scores on validation data for the converged model.

Cardiac structure	CT		MR	
	Median	Min	Median	Min
Myo	0.83	0.78	0.80	0.72
LA	0.91	0.87	0.83	0.75
LV	0.91	0.82	0.94	0.88
RA	0.89	0.86	0.84	0.76
RV	0.90	0.85	0.89	0.85
Ao	0.94	0.86	0.83	0.70
PA	0.73	0.63	0.70	0.10

be intersection-free it is important that the initial template is also intersection-free.

Patient-specific myocardium. An advantage of our framework is that once the network is trained, different templates can be used without re-training. For example, Fig. 3(a) shows a myocardium template that was produced by fusing the myocardium mesh with parts of the left atria and aorta and adding thickness to these openings. It is important that these regions have thickness because (a) they are used for solid modeling in FSI simulations (b) we apply boundary conditions on these surfaces. Note that this template contains about 47k triangular faces which is significantly more than the template used for training. Fig. 3(b) shows a patient-specific prediction for a model trained without the loss term eq. 1. This model collapses the thickness of the mitral and aortic tissue into an unphysical thin surface. It is not possible to generate a 3D volumetric mesh from such a surface mesh. The worst case predicted mesh contained 234 self-intersecting faces. Fig. 3(c) shows a patient-specific prediction for a model trained with the loss term eq. 1. This model preserves the thickness of the mitral and aortic openings. The worst case predicted mesh contained 8 self-intersecting faces which is a 97% improvement. The remaining self-intersections can be readily eliminated by running a constrained smoothing algorithm. Subsequently, we were able to generate full 3D tetrahedral meshes from these surface

meshes.

Figure 2: Predictions of the model for a typical validation sample. Red surface is the ground truth and black wireframe is the template. (a) Undeformed initial template (b) after linear transformation (c) after flow deformation. The final average dice score was 0.86 for this sample.

Figure 3: (a) Initial myocardium template with added thickness for mitral and aortic openings (b) prediction of model trained without divergence loss collapses thin walls resulting in self-intersections (c) prediction of model with divergence loss preserves thickness.

DISCUSSION

We have developed an automated deep learning method for generating patient-specific meshes of the human heart directly from biomedical images. These meshes are anatomically accurate and physically realistic. We presented a novel physics-informed loss term that penalizes collapsing volumes. This enables us to represent cardiac structures with tissue thickness even when this information is missing in the image data. Our predictions are almost entirely free of self-intersections, and the few that remain can be fixed by simple smoothing procedures. Our model predictions can be used to generate full 3D tetrahedral meshes with tissue thickness. We hope to soon present results of our model trained on a larger training dataset, provide detailed comparisons of our results against prior state of the art, and utilization of this method to applications of cardiac physiology simulation.

TEMPORAL AND SPATIAL DYNAMICS OF NEW BONE FORMATION IN CYCLIC TREATMENT REGIMENS OF PARATHYROID HORMONE-RELATED PEPTIDE (PTHrP)

INTRODUCTION

Anabolic agents, such as PTH and PTHrP, rapidly promote new bone formation and improve bone mass but are initially administered for only up to 24 months of combined use in a patient's lifetime. Interestingly, our recent *in vivo* micro computed tomography (μ CT) and histomorphometry studies in ovariectomized (OVX) rats demonstrated an extended anabolic period (EAP) during the first week of PTH/PTHrP discontinuation, where alkaline phosphatase activity by osteoblasts was found on over 60% of newly formed bone surfaces, resulting in continuous mineral deposition and an increased bone volume fraction (BV/TV) [1,2]. These data support the use of a cyclic treatment regimen to improve the efficacy of existing anabolic treatments. However, by testing a cyclic PTH-vehicle (VEH) treatment regimen (3-week PTH, 3-week VEH, repeat for 3 cycles) in OVX rats, we found that the EAP was not enough to fully prevent PTH discontinuation-induced bone loss by the end of an off-PTH cycle [1]. Indeed, a histomorphometry study indicated that after 1 week of discontinuation from PTH/PTHrP, BV/TV began to decrease and TRAP activity by osteoclasts over newly formed bone surfaces increased from 8% in week 1 to 71% in week 3 [2]. This supports the addition of an antiresorptive during the off-PTH/PTHrP cycle to inhibit bone resorption during the off-treatment period. Furthermore, we hypothesized that a cyclic treatment regimen is able to activate new bone formation sites on quiescent surfaces with each new anabolic cycle. To test these hypotheses, we investigated the dynamics of new bone formation and changes in trabecular bone microstructure in cyclic treatment regimens of alternating PTHrP and either VEH or alendronate (ALN, an antiresorptive agent), and a standard PTHrP treatment regimen followed by ALN. We hypothesized that the cyclic PTHrP-ALN treatment regimen would yield the greatest new bone formation and bone microstructure.

METHODS

Animal protocol and treatment: All animal experiments were IACUC approved. Female Sprague-Dawley (SD) rats received bilateral ovariectomy (OVX) surgery at 4 months of age to simulate post-menopause estrogen deficiency and developed osteopenia for 4 weeks. For histomorphometry (n=6/group), rats underwent either two cycles of 3 wk PTHrP followed by 3 wk VEH (CPV), 3 wk PTHrP followed by 3 wk ALN (CPA), or 6 wk PTHrP followed by 6 wk ALN (Standard PTHrP-ALN, SPA). For μ CT (n=8-9/group), three cycles of treatments were performed for a total of 18 wks and the SPA group received 9 wk PTHrP followed by 9 wk ALN. PTHrP (PTHrP 1-34, 20 μ g/kg/day for histomorphometry, 40 μ g/kg/day for μ CT) and saline (VEH) were administered 5x/wk, and ALN (28 μ g/kg/day) was administered 2x/wk. Histomorphometry: Fluorochrome labels of calcein green (G), alizarin complexone (red/R), and tetracycline (yellow/Y) were injected in the sequence of G-G-R-R-Y at wks 0, 3, 6, 9, and 12 (Fig.1A). Two 8 μ m-thick, undecalcified cryosections were obtained from the left proximal tibia and imaged with darkfield and a fluorescent microscope to capture trabecular structure and multi-color fluorochrome labels. A 1.5 mm-thick region of the metaphysis from each section was analyzed by OsteoMeasure to assess mineralizing surface (MS/BS), mineral apposition rate (MAR), and bone formation rate divided by bone surface (BFR/BS) for each double label. Total new bone formation from all double label periods was also quantified. μ CT: For longitudinal analysis, a 4-mm region of the proximal tibia was scanned at 10.5 μ m voxel size using *in vivo* μ CT (Scanco vivaCT40) at wks 0, 3, 6, 9, 12, 15, and 18. Bone volume fraction (BV/TV) and trabecular thickness (Tb.Th) were obtained. Statistics: A one-way ANOVA or Student's t-tests were used to compare histomorphometry groups. A two-way, repeated measures ANOVA was used to compare μ CT treatment groups over time.

RESULTS

Histomorphometry (Fig. 1B-P): Throughout two cycles of treatment, various double labels were observed: mineralization during PTHrP treatment of cycle 1 (C1-ON, G to G) and cycle 2 (C2-ON, R to R) of PTHrP, as well as the off anabolic periods of C1 (C1-OFF, 2nd G to 1st R) and C2 (C2-OFF, 2nd R to Y). Most C2-ON sites mineralized on existing C1-ON sites, as C2-ON sites that did not form on or adjacent to existing C1-ON sites only accounted for 2% of C2-ON sites. MS/BS and BFR/BS for C1-ON were 64% and 77% greater in CPA vs. CPV, indicating that ALN minimized resorption of C1-ON sites during the PTHrP-OFF cycle. C2-ON MS/BS, MAR, and BFR/BS were 32%, 51%, and 95% higher in CPV vs. CPA, respectively. During C1-OFF, MAR and BFR/BS trended towards a 110% and 187% greater difference in CPV vs. CPA, respectively. There was minimal but non-zero C2-OFF bone formation activity for CPV, but none during C2-OFF was detected in CPA. These data suggest that ALN blunted bone formation during C2-ON and the off anabolic periods. For histomorphometry groups, BV/TV was not different between CPA and SPA or CPV and SPA but was 47% greater in CPA vs. CPV. SPA gained 36% more total new bone than CPV and there was no difference between that of CPA and SPA. Therefore, CPA and SPA resulted in the greatest bone gain.

In vivo μ CT (Fig. 2A-B): By wk 18 in CPA and SPA, BV/TV was 119% and 109% greater and 92% and 107% greater for Tb.Th compared to baseline, respectively. For CPV, although Tb.Th still increased by 76%, BV/TV decreased by 20% at wk 18 compared to baseline. Adding ALN during the off anabolic periods in CPA vs. CPV minimized discontinuation-induced bone loss and resulted in a 21-138% greater BV/TV and a 9-16% greater Tb.Th during wks 6, 9, 12, 15, and 18.

DISCUSSION

This study elucidated how new bone is formed and maintained during cyclic treatment regimens of PTHrP with and without an antiresorptive. We originally hypothesized that an additional cycle of PTHrP would activate new bone formation sites on quiescent bone surfaces. Surprisingly, most of the new bone formation during C2-ON occurred on existing mineralizing sites activated during C1-ON, regardless of treatment during the off-PTHrP period.

Without the addition of ALN, there is a greater withdrawal effect in both histomorphometry and μ CT groups, supporting our hypothesis that adding ALN between cyclic anabolic treatments helps minimize the withdrawal effect and maintains newly formed bone. However, the finding that ALN may blunt new bone formation during the EAP and into the next PTHrP cycle contradicts our original hypothesis. Since resorption of newly formed bone occurs in CPV following C1-ON and C2-ON [1, 2], we expected more bone formation observed in the anabolic periods of CPA vs. CPV groups. However, greater new bone formation parameters in CPV vs. CPA during C2-ON suggest that ALN may have blunted the effect of PTHrP in the second anabolic period. There may also be a blunting effect in the CPA group for μ CT, however, we only observe a net increase at the end of the 3 wk anabolic periods.

Considering complete treatment cycles, SPA and CPA resulted in a similar BV/TV, suggesting that a CPA regimen can yield similar results as a SPA regimen with the added benefit of extending the duration of active bone formation under anabolic treatments. We conclude that the timeline of different cyclic treatment regimens of an anabolic agent and an antiresorptive need to be further explored to account for the blunting effect of ALN while still minimizing bone loss upon discontinuation of an anabolic agent.

INTRODUCTION

The cornea is a transparent tissue with precise curvature that contributes significantly to the total refractive power of the eye while protecting the delicate internal components of the eye. The cornea consists of several different layers, among them corneal stroma accounts for 90% of total corneal thickness. The stroma consists of several hundreds of collagen lamellar layers containing regularly organized collagen fibrils [1,2]. The precise spacing of collagen fibrils in the corneal stroma is believed to be maintained by proteoglycans (PGs) that exist in between and around the collagen fibers [3]. PGs are composed of a core protein to which glycosaminoglycan (GAG) side chains are attached. Our recent studies have shown that PGs and their GAG side chains are one of the microstructural elements of the cornea that play a role in providing strength to the cornea. The present study investigates their effects on corneal microstructure and arrangement of collagen fibers in corneal stroma.

The imaging techniques such as transmission electron microscopy (TEM) and X-ray scattering technique have been used to study the collagen fibril diameter and interfibrillar spacing of the corneal stroma. For example, Hayes et al. quantified collagen fibril diameter and interfibrillar spacing of porcine cornea using the X-ray scattering technique [4]. The second-harmonic-generated (SHG) images have also been used to show the nearly orthogonal corneal collagen organization [5]. The electron microscopy of bovine corneal tissue revealed the arrangement of PGs around the collagen fibrils, suggesting that they are important for highly regular corneal collagen fibril spatial order, Fig. 1 [6]. Here, we removed enzymatically keratan sulfate (KS) GAGs from the cornea and used TEM to characterize their effects on collagen fibril diameter and interfibrillar spacing of porcine cornea.

METHODS

The excess muscles were removed from porcine eye globes by a sharp scissor. Then, a scalpel and scissors were used to prepare corneal

samples with a 2 mm scleral ring from eyeballs. Corneal strips of about 5 mm width were cut in the nasal-temporal direction using a custom-made double bladed device. The strips were divided into control and enzyme treated groups. In order to remove KS GAGs from corneal strips in the enzyme treated group, they were first dried completely in a desiccator. The dried corneal strips were then kept in a container filled with 0.1M sodium acetate buffer and 0.1 U/ml keratanase II enzyme at pH of 6.0 for 18 hours at 37°C. The success of this method of removing KS GAGs from the corneal strips was previously shown by performing biochemical and histological studies using Blyscan assays and Alcian blue staining [7].

Figure 1: Schematic of the (a) eyeball, (b) corneal stroma, and (c, d) ultrastructural features of the corneal stroma. IFS and FD indicate interfibrillar spacing and collagen fibril diameter, respectively.

For TEM studies, small blocks excised from each corneal strip were fixed in 2.5% phosphate-buffered (0.1M) glutaraldehyde. The specimens were washed in 0.1M Sorensen's sodium phosphate buffer (SPB, pH 7.2) and were then fixed in buffered 1% osmium tetroxide to

sharpen the contrast of the ultrastructure. After further processing, the 70 to 80 nm thick sections were cut using an ultra-microtome (Leica Ultracut UCT model). The ultra-thin sections were collected onto 200-mesh copper grids and contrasted with 6% uranyl acetate and Reynolds lead citrate stains. The grids were dried, inserted into the specimen holder, and were examined using a JEOL JEM-1400 Flash transmission electron microscope (operating at 80 kV). Several images were captured around the viewing area. The image analysis was performed using the open-source software Image J. Two-way ANOVA and t-test were performed to find any significant difference between the results. A p-value less than 0.05 was considered statistically significant.

RESULTS

The ultrastructural features were shown for typical control and enzyme-treated specimens in Fig. 2. The hexagonal arrangement of the collagen fibrils (CF) was visible in the images. The dark clouds situated in the interfibrillar spacing between collagen fibrils were considered as PGs. The PG clouds appeared significantly reduced in the enzyme-treated specimens (Fig. 2c-d), which was because KS GAGs were removed from these specimens. The collagen fibrils appeared to be hexagonally arranged in the control samples (Fig. 2a) whereas hexagonal patterns seemed to collapse in images obtained for enzyme-treated specimens (Fig. 2c-d).

Figure 2: Electron micrographs of control (a and b) and enzyme-treated (c and d) corneal samples. Collagen fibrils (CF) and proteoglycan (PGs) are shown by arrows. (a) and (c) represent transverse direction fibrils whereas (b) and (d) represent longitudinal direction fibrils. The enzyme-treated specimens showed significant PG reduction.

Using TEM images (Fig. 2), the collagen fibril diameter and interfibrillar spacing for both control and enzyme-treated specimens were quantified, Table 1. No significant difference was observed in the fibril diameter (FD) of the control and enzyme treated samples but the interfibrillar spacing (IFS) increased significantly in the enzyme-treated specimens ($P < 0.05$).

Table 1: The collagen fibril diameter and interfibrillar spacing of each specimen group.

group	Fibril Diameter (nm)	Interfibrillar Spacing (nm)
Control	34.77 ± 1.66	54.28 ± 0.23
Enzyme-treated	35.85 ± 1.26	57.71 ± 1.94

DISCUSSION

The main goal of this study was to reveal the porcine corneal ultrastructure and the quantitative analysis of the effect of KS GAG removal using transmission electron microscopy. The TEM images

showed that the mean collagen fibril diameters were 34.77±1.66 nm and 35.85±1.26 nm in control and enzyme-treated specimens, respectively. The previous X-ray scattering measurements gave the collagen fibril diameter of 35.7±0.6 nm for control porcine cornea, which agrees very well with the present measurements using TEM [4]. The slight differences could be because of different measuring techniques and intrinsic difference in the specimens. The quantified values presented in Table 1 imply that the keratanase enzymatic digestion did not affect collagen fibril diameter, i.e. we did not observe a significant difference in fibril diameter (FD) of two specimen groups.

Similar to the collagen fibril diameter, the interfibrillar spacing (IFS) of control specimens of the present work was in agreement with previous studies. The IFS in enzyme-treated specimens significantly increased compared to that of the control specimens. Furthermore, the collagen fibrillar arrangement showed slight distortion in enzyme-treated specimens compared to control samples, Fig. 2. The enzyme treatment significantly reduced GAG content in enzyme treated group, Fig. 2c-d. GAGs work as structural elements and binders connecting neighboring collagen fibrils [1-2, 7]. Since GAG density was reduced in the enzyme-treated specimen, the collagen fibrils move away from each other causing the IFS to increase.

The present study had a number of limitations. First, we used a limited number of samples for each group. However, we took extra precautions during dissection, fixation, and all other steps to ensure the accuracy of the results, which was confirmed by comparing our data with previous studies. Another limitation of our work was that Cuprolineic Blue stain was not used to enhance the contrast of PGs. Using Cuprolineic Blue during the fixation process could allow better visualization of PGs between collagen fibrils. However, the absence of dark cloud in enzyme treated samples, seen here, was because of removing GAGs from samples. The present work provided valuable and novel data for the influence of KS GAGs on corneal microstructure and can be used to interpret and explain the changes in mechanical response of GAG depleted samples. Furthermore, the crosslink group may be included in future studies to identify any role of PGs visually and quantitatively in crosslink treatment.

INTRODUCTION

The mortality and morbidity rate of patients with Aortic Dissection (AD) in the United States has been on a steep rise since 2012 [1]. This could be attributed to the lack of proper diagnostic criteria and our inadequate knowledge about the progression of the disease. It has been shown recently that AD could be predicted from the vortex flow pattern in the ascending aorta and the consequent changes in Time Averaged Wall Shear Stress (TAWSS) and Oscillatory Shear Index (OSI) [2]. The current standard of care among clinicians for deciding on a surgical intervention is based on the size of the aorta. If the diameter of the artery is larger than a threshold value (usually 5-5.5 cm), the condition is severe [3]. This is based on a crude approximation using Laplace's law, where the hoop stress (or the circumferential stress on the artery wall) is given as

$$P_{\theta\theta} = \frac{PD}{2t} \quad (1)$$

Where P is the pressure inside the artery, D is the diameter and t is the thickness of the wall. It is clear from the equation above that for a given blood pressure and thickness of the artery wall, the wall stress increases with an increase in diameter. However, more than sixty percent of AD occurs at a diameter less than 5 cm [4][5], which means this practice cannot be followed for a successful diagnosis of the disease.

Use of Computational Fluid Dynamics (CFD) for the simulation of flow inside human arteries is gaining popularity due to its capability of predicting the flow physics accurately inside the aorta without the involvement of any invasive methods. The current study focuses on the CFD simulation of patient-specific geometries of AD using the Immersed Boundary Method (IBM) [6]. We will demonstrate that this method could predict the velocity variation in the artery with good accuracy based on comparison to ultrasound data of the patients.

METHODS

Figure 1 shows the workflow that is adopted for the simulations. The CT scan data is pre-processed to attain the mesh using the open-source software, 3D slicer. The mesh is further cleaned using a commercial tool, STAR-CCM+. The CFD simulations are performed using an in-house code that solves the incompressible Navier-Stokes equations in three dimensions. The solver solves the mass conservation and momentum conservation equation using a fractional-step method on collocated grids [7]. The boundary conditions for the Navier-Stokes equations are obtained from the Duplex ultrasound data. The velocity data were fitted with polynomials, which are used as the inlet boundary condition and at the five outlets; pressure boundary conditions were prescribed based on a 3 element Windkessel model. In this model, the pressure (P) and flow rate (Q) are related by the equation

$$P = (R_1 + R_2)Q - R_2C \frac{dP}{dt} + R_1R_2C \frac{dQ}{dt} \quad (2)$$

In the equation, R_1 , R_2 and C are different parameters that are tuned to achieve the desired flow rate at the outlet. The ultrasound data is also used to compare the results from CFD.

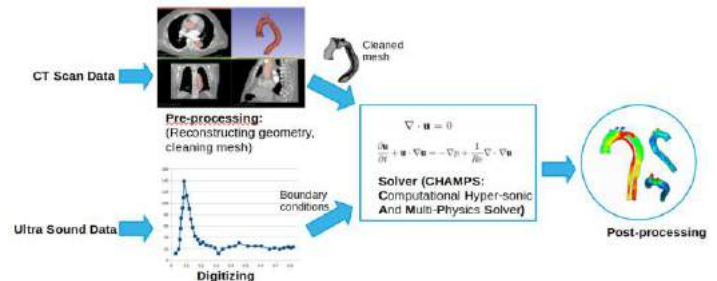

Figure 1: Process flow chart

The study protocol complies with the Declaration of Helsinki and was approved by the University of Kentucky Institutional Review Board and Ethics Committees.

RESULTS

Simulations were performed on the aorta of a patient with Stanford- type B dissection. A small entry tear is located at the arch of the aorta, approximately 2 cm away from the root of the left subclavian artery. The ultrasound scans show that there is a retrograde flow in the false lumen. The flow is directed towards the heart in the false lumen and away from the heart in the true lumen. For simulating this flow, the Windkessel model at the false lumen outlet is tuned in such a way that the flow is reversed. Figure 2 shows the variation of the velocity in z-direction (longitudinal from bottom to top) over the course of a complete cardiac cycle. The velocity peaks at systole (approximately 0.1 s) and the magnitudes of velocity are high everywhere in the artery. The direction of velocity is reversed in the false lumen during this phase. In addition to the major tear, there were some minor tears further downstream of the artery (near the pelvic region). These minor tears could be partially responsible for the retrograde flow.

Figure 2: Cross-section view of aorta with z-component of velocity at different time points.

Figure 3 shows the comparison of velocity magnitude variation in the root of Common Carotid Artery (CCA) and Left Subclavian Artery (LSA) obtained from the ultrasound data with the CFD results. There is good agreement in the variation of velocity during the cardiac cycle. It should be noted that there are potential uncertainties in the ultrasound measurements, regarding the location and timing of the measurements. These could be a reason why there are minor variations in the comparison (especially in the diastolic phase).

Figure 3: Velocity comparison at different branches of the aorta. Measurements were taken at the centerline of the artery.

TASS and OSI are metrics used for the prediction of occurrence and progression of several cardiovascular diseases, including AD. A high TAWSS at the wall near the dissection (Figure 4) could suggest that there is a good chance of progression of the disease as the tear could enlarge over the course of time due to high stress. The OSI values are observed to be relatively low in the true lumen as compared to the false lumen and this suggests that there is a large variation in the velocity field of the false lumen. This could also suggest that the flow is more turbulent in the false lumen. It has been reported that high OSI is associated with the production of reactive oxygen species in endothelial cells, which leads to injury of these cells. Although it is not certain what value of OSI would lead to a tear, it could be assumed that there is a higher probability of tear development in the places where there is abnormally large OSI.

Figure 4: TAWSS and OSI

DISCUSSION

A significant advancement in performing CFD simulations using IBM for patient-specific models of AD is presented in the current study. Even though IBM was developed for studying blood flow simulations in the heart and arteries, earlier studies were limited to over simplified geometric models and boundary conditions. For example, the inlet boundary velocities were assumed to be that of a healthy artery and outlet pressures were assumed to be constant. These assumptions affect the accuracy of predicted velocity variation and shear stress development in the artery. In the current work, it is also shown that pressure values close to physiological (for example, 80 to 120 mm Hg) could also be achieved in the simulations. A well-defined and reliable protocol is established through this study that could be used for clinical decision making. The major limitation in the current study is the use of rigid wall for the simulations. Even though the rigid wall assumption could be made for the arterial wall and obtain reliable wall shear stresses for a healthy artery, studying the role of flap (that separates true and false lumen) is a big challenge. For this, Fluid Structure Interaction (FSI) would be performed in the future.

ACKNOWLEDGEMENTS

The authors would like to thank the Gill Heart and Vascular Institute for providing the patient-specific data and the Center for Computational Sciences at the University of Kentucky for the computing time for performing the simulations pertinent to this study.

INTRODUCTION

The effect of myofiber architecture on cardiac muscle mechanics has a direct impact on global pumping performance. In a healthy heart, muscle myofibers are transmurally arranged in parallel with helical angles ranging from $\sim +60$ degrees at the endocardium to ~ -60 degrees at the epicardium. However, abnormal helical angles of myofibers can lead to a deterioration in cardiac performance. [1]

Myofiber disarray is one type of adverse remodeling, which is characterized by disorganized cardiomyocyte spatial distributions. Cellular level heterogeneity in cardiac muscle (material properties and contractile behavior) can lead to myofiber disarray. “Replacement fibrosis” is an example of a heterogeneous change (stiffening) in muscle material properties, which is a collagen-based healing mechanism observed, but not limited to hypertrophic cardiomyopathy (HCM) [2].

In this study, we have developed a myofiber remodeling approach (Figure 1) for addressing disarray induced in the LV with HCM, due to replacement fibrosis. The models are developed in our modular cardiac modeling framework (MyoFe), which was built using the FEniCS open-source finite element software, enabling us to model cardiac diseases such as HCM that affect the heart at different scales.

Figure 1: Schematic of fiber reorientation using the stress-based reorientation law. Fiber is initially oriented in the $e_{f,0}$ direction and would reorient gradually toward the traction vector $S e_{f,0}$.

METHODS

Many cardiac models have been developed using rule-based assignment of myofiber distributions based on experimental measurement. Considering the importance of cardiac myofiber organization on global pumping performance, and disorganization of cardiac myofibers due to some cardiac disease conditions, myofiber orientations in cardiac models may need to change due to the effects of remodeling.

In the current study, we present a novel fiber remodeling algorithm that is inspired by previous fiber adaptation algorithms by Kroon et al [3] and Washio et al [4]. Our work establishes a stress-based reorientation law in which fibers tend to reorient towards local traction vectors, which optimizes force generation during contraction (maximizing pumping capacity) and elevates the load bearing capacity of the fibers (by redirecting them in a direction with pure normal stress).

In Figure 1, $e_{f,0}$ represents the initial unit vector along a muscle fiber, and its multiplication to the referential stress tensor (S) (known as second Piola-Kirchhoff stress), generates the traction vector on the fiber ($S e_{f,0}$). Our stress-based reorientation law incrementally reorients each fiber to be aligned with the traction vector ($S e_{f,0}$) as below:

$$\frac{d e_{f,0}}{dt} = \frac{1}{\kappa} \left(\frac{S e_{f,0}}{\|S e_{f,0}\|} - e_{f,0} \right)$$

where κ is a time constant which allows us to employ the idea of separation of time scales, i.e., where the change in fiber orientation over a long time-scale (say days to weeks) can be achieved in several heart beats. Gradual reorientation would minimize the difference between $S e_{f,0}$ and $e_{f,0}$ until each fiber is aligned with the direction of its experienced traction. The stress tensor S is the summation of both active and passive stress, which reflects required remodeling for optimized systolic and diastolic performance.

We have developed a multiscale framework called MyoFe, where an implicit finite element scheme is implemented with MyoSim [5] as the contraction law and a Windkessel model of circulation. The main goal is evaluation of fiber disarray and cardiac performance induced by heterogeneous (het) fibrosis of different severity (Figure 2 (a)). Therefore, we prepared 4 different LV models based on an idealized ellipsoidal geometry that matches the dimensions of a rat LV with different percentages (0, 10, 20, 30) of stiff regions (representing necrotic cells replaced by diffuse fibrosis). Regions in the LV with fibrotic characteristics are distributed randomly throughout the LV and are set to be 15 times stiffer, as well as being isotropic. Additionally, the cross-bridge density in these regions is zero, representing dead myocytes that cannot contract. To reach steady state, models were run for 2 cardiac cycles of normal performance and then 5 additional cycles for fiber reorientation purposes.

RESULTS

The epicardial fibers are shown in Figure 2 (b), with their final angle from the last time step of the model overlaid on the fibers with their initial angles. It is observed that fibrotic regions in the LV induce considerable myofiber reorientation.

Figure 2: (a) Distribution of stiff regions within the LV mesh (Dark blue: Cells with 4 normal gaussian points, Dark red: Cells with 4 stiff gaussian points) (b) Epicardial fiber representation before (blue) and after (red) fiber reorientation in model with 30% heterogeneous stiffness.

Figure 3 shows the disarray of myofibers in 5 different transmural layers of the LV wall. The mean and standard deviation of fiber angle values were calculated within each transmural layer. As a result of the normal variation in transmural distribution of fiber angles, a baseline standard deviation is expected in each layer. Standard deviation bars vary

Figure 3: Disarray of myofibers in 5 transmural locations in LV wall (LV top view of each region is shown on the top). Standard deviation bars and mean of fiber angles are plotted to show the disarray and dominant fiber angle in each layer.

proportionally to the percentage of heterogeneity, and when the location is closer to endo or epi, the standard deviation increases substantially. Myofibers become more circumferential (seen in the mean value of fiber angles) and disorganized as stiffness heterogeneity increases. Both of these phenomena become more pronounced at the endo and epi.

Heterogeneity of cardiac muscle stiffness also affects the final PV loop in a proportional manner. The ejection fraction (EF) and stroke volume (SV) are reduced from 71% and 0.17 ml at baseline to 58% and 0.1 ml in the model with 30% heterogeneity. An increase in heterogeneity is associated with a substantial reduction in end diastolic (ED) volume. Increasing material stiffness due to diffuse fibrosis, which replaces dead myocytes, is responsible for such ED volume reduction. The induced myofiber disarray could also contribute to the reduction of ED volume. A disorganized distribution of myofibers is expected to reduce passive relaxation of heart muscle during filling.

It is also evident that muscle heterogeneity affects the pressure in the same way as LV volume. The primary cause of such pressure reduction is the absence of cross bridges in the fibrotic regions, which thus reduces the active stress in the LV thereby lowering systolic pressure. It has also been shown that induced myofiber disarray can reduce cardiac pumping performance [4], which is another contributing factor for pressure reduction. As a result of fiber disarray, not all cardiac muscle cells are oriented in their most efficient angle for muscle contraction and LV torsional motion. Thus, LVs with greater myofiber disarray will generate lower systolic pressures.

Figure 4 Pressure-volume loops for LV models with no heterogeneity (blue), 10% (orange), 20% (green) and 30% (red) heterogeneous stiffness.

DISCUSSION

This study developed a multiscale modular framework to simulate cardiac behavior with a stress-based myofiber reorientation law. The prominent mechanical effects of replacement fibrosis (increased stiffness and lack of contraction in the necrotic cells) were applied to the model at the cell level. Considerable disarray is observed relative to the percentage of fibrosis in the LV. Fibrosis and its consequent disarray highly affects the global pumping performance of the heart.

AN OPTIMIZED METHOD FOR CONSTITUTIVE MODEL FITTING OF SOFT TISSUES BI-DIRECTIONAL MECHANICAL STRESS-STRETCH DATA

Sayed Ahmadrza Razian (1), Alexey Kamenskiy (1), Majid Jadidi (1)

(1) Department of Biomechanics, University of Nebraska at Omaha, Omaha, NE, USA

INTRODUCTION

The mechanical properties of arteries are often assessed with biaxial testing. Mathematical relations, often known as constitutive models, are then used to describe the experimental stretch-stress response to determine relations describing the intrinsic mechanical characteristics of the material. If these models describe the complex experimental data well, they can be utilized in computational models investigating repair devices and treatment methods[1].

Several constitutive models are proposed to describe the mechanical behavior of soft tissues and capture their response. A constitutive model inputs the experimental stretch tensor and calculates the theoretical stress tensor. Each model has one or several parameters, referred to as material parameters, that need to be determined from the experimental data[2]. Values of these material parameters cannot be predicted analytically, and numerical methods are utilized to iteratively try different sets of parameters and find the optimal convergent solution that minimizes the error function.

The Levenberg-Marquardt and Trust-Region-Reflective algorithms are two of the most commonly used numerical methods for nonlinear least square optimization in tissue biomechanics[3]. They are used to find the material parameters which yield the best fit, i.e., the lowest error. However, these techniques may not always produce the best fit for the experimental data.

In this work, we utilize a different optimized fitting routine based on Differential Evolution (DE) [4] algorithm, and Minkowski and Chebyshev Distance relations as the objective function (OF) to improve the constitutive model fit quality.

METHODS

Human arterial specimens from 60 donors of a wide range of ages (average 42±19 years, range 14-92 years, 45% male) were obtained within 24 hours of death after obtaining consent from next of kin. Samples were selected from a wide range of ages and both sexes to

include different mechanical properties in the analysis. Tissues were tested fresh within 4 hours of procurement. We performed planar biaxial tests (Figure 1) on 13×13 mm stress-free specimens using a CellScale BioTester at 37°C PBS. The experimental stresses, $T_{\theta\theta}^{exp}$ (circumferential) and T_{zz}^{exp} (longitudinal), and stretches, λ_{θ} (circumferential) and λ_z (longitudinal), were determined from the experimental tests and used in constitutive modeling.

Figure 1. Schematic of the planar biaxial test. The right panel displays the experimental stress-stretch response. f_{θ} and f_z represent the applied forces in the circumferential (θ) and longitudinal (z) directions of the arterial wall specimen, respectively.

In this work, we used the Four-Fiber Family constitutive model [5] to assess the optimization routine based on the DE algorithm. DE is a population-based evolutionary method that iteratively improves the fit to minimize the objective loss function and find the global minimum. There are different loss functions to measure the difference between the experimental and theoretical stresses calculated through constitutive modeling and determine the parameters that produce the best fit. Among them, Mean Absolute Error (MAE), and Root Mean Square Error (RMSE) methods are common. Herein, we implemented an error function based on the Minkowski Distance function as follows:

$$MD = \left[\left(\sum_i^n |T_{\theta\theta}^{exp,i} - T_{\theta\theta}^{fit,i}|^p \right) + \left(\sum_i^n |T_{zz}^{exp,i} - T_{zz}^{fit,i}|^p \right) \right]^{\frac{1}{p}}, \quad (1)$$

where n is the total number of experimental data points.

If $p = 2$, we obtain Root Square Error (RSE), or Euclidean Distance, and if $p = 1$, we obtain the Absolute Error (AE), or Manhattan Distance. In addition to the Minkowski Distance relation, we used an extended version of the Chebyshev Distance with a power of $p > 0$ for the error function:

$$CD_{ext} = \left[\left(\sum_i \max \left\{ |T_{\theta\theta}^{exp,i} - T_{\theta\theta}^{fit,i}|^p, |T_{zz}^{exp,i} - T_{zz}^{fit,i}|^p \right\} \right) \right]^{\frac{1}{p}} \quad (2)$$

RESULTS

We first found the best fit for each sample using the Levenberg-Marquardt and Trust-Region-Reflective algorithms by RMSE objective relation implemented through the MATLAB lsqnonlin function. These results are represented in Figure 2.A,3.A,4.A,5.A, and 6.A for five representative samples.

The Four-Fiber Family model was then fitted on the same datasets using DE and the described Minkowski and Chebyshev distance functions. The DE algorithm has several parameters, such as the number of individuals in each population (NP), the maximum number of generations (G_{max}), scaling factor (F), and crossover rate (CR). Therefore, for each sample, we performed a hyperparameter tuning to find the optimized DE settings as well as the best objective function. These results are represented in Figure 2.B,3.B,4.B,5.B, and 6.B.

Figure 2.A) The MATLAB lsqnonlin function fit, and **B)** the DE algorithm fit obtained by hyperparameter tuning ($NP = 32$, $G_{max} = 200$, $F = 0.35$, $CR = 0.5$, $OF = MD$, and $P = 1$) for a 63-year-old female subject.

Figure 3.A) The MATLAB lsqnonlin function fit, and **B)** the DE algorithm fit obtained by hyperparameter tuning ($NP = 32$, $G_{max} = 200$, $F = 0.35$, $CR = 0.5$, $OF = CD_{ext}$, and $P = 2.5$) for a 33-year-old subject.

Figure 4.A) The MATLAB lsqnonlin function fit, and **B)** the DE algorithm fit obtained by hyperparameter tuning ($NP = 32$,

$G_{max} = 200$, $F = 0.35$, $CR = 0.5$, $OF = CD_{ext}$, and $P = 1.5$) for a 35-year-old subject.

Figure 5.A) The MATLAB lsqnonlin function fit, and **B)** the DE algorithm fit obtained by hyperparameter tuning ($NP = 32$, $G_{max} = 200$, $F = 0.35$, $CR = 0.5$, $OF = MD$, and $P = 1.5$) for a 25-year-old male subject.

Figure 6.A) The MATLAB lsqnonlin function fit, and **B)** the DE algorithm fit obtained by hyperparameter tuning ($NP = 32$, $G_{max} = 200$, $F = 0.35$, $CR = 0.5$, $OF = MD$, and $P = 1.5$) for a 92-year-old male subject.

DISCUSSION

In this work, we introduced a metaheuristic population-based algorithm and implemented the Minkowski and Chebyshev Distance functions to improve the quality of the constitutive model fit to bi-directional experimental stress-stretch data. Constitutive modeling of soft tissues involves multiple aspects, from experimental data collection to developing or selecting a physics-based mathematical relation and estimating the material parameters. If a model does not represent the experimental data very well, it is common to choose a more complex constitutive model with more material parameters. However, in this work, we highlighted that instead of using a more complex relation, by using algorithms, such as the implemented DE and Minkowski Distance function, we could obtain a superior fit with fewer material parameters. In addition, by using the DE algorithm with hyperparameter tuning, we were able to decrease the error between experimental and theoretical, i.e., fitted, data.

ROLE OF SEX AND SEX HORMONES IN PULMONARY ARTERY ADVENTITIAL FIBROBLAST MECHANOSIGNALING

Yufan Lin (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California, San Diego, La Jolla, California, United States

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive disease driven by the abnormal activities of mechanosensitive cells in pulmonary arteries (PAs) [1]. PAH is more prevalent in women than men, but pre-menopause females have better outcomes than man and post-menopausal women [2]. To investigate the cellular-level mechanism behind this estrogen paradox, we are currently studying how the mechanosignaling activities of pulmonary artery adventitial fibroblasts (PAAFs), the cell type that is attributed for vasculature stiffening in PAH, and how they are regulated by the intrinsic sex of the animal and the presence of sex hormones. Our approach include combining *in-vitro* experiments with *in silico* experiments to test our understanding and validate the PAAF signaling network model. Based on studies relating 17 β -estradiol (E2) to collagen type I and III expression, we hypothesize that E2 regulates the pro-fibrotic PAAF mechanosignaling via components including BMPR2 and apelin, which are found to be downstream of E2 and its receptor in right ventricle [3].

METHODS

PAAFs isolated from healthy male, female, and ovariectomized (OVX) female rats are cultured in polyacrylamide gels. These scaffolds are made to represent healthy (0.5 kPa), mild (3 kPa) and severe (10 kPa) disease stages as previously done [4]. Strain due to the increase in pulmonary blood pressure ranges was mimicked by stretching the substrates 10% biaxially for 24 hours [4]. Cells are then harvested and lysed for RNA isolation, which is followed by cDNA synthesis and quantitative PCR (qPCR) to measure the expression levels of profibrotic genes and myofibroblast-activation marker shown previously to be upregulated in PAs from animals treated with sugen-hypoxia (SuHx), a well-established animal model of PAH. After being normalized against housekeeping gene *18S*, qPCR results are analyzed with 3-way ANOVA followed by Dunnett's *post-hoc* multiple comparisons test.

A logic-based differential equation model is constructed to represent the target signaling network, where:

$$\frac{dy_i}{dt} = \frac{1}{\tau_i} (\sum_j \omega_j f_j y_j^{max} - y_i) \quad (1)$$

where y_i is the activation level of species i , τ_i and y_i^{max} are the time constant and maximal fractional activation, while f_j and ω_j are the associated Hill activation/inhibition functions and corresponding reaction weights, respectively [5]. Based on the PAAF signaling model [6], we isolated and modified a portion of the network to study the role of E2 in regulating fibrotic genes. The logical relationships between components are generated based on literature data [3,7-9].

RESULTS

The study is currently in progress. Preliminary data (**Figure 1**) show that stretch and stiffness generally up-regulate the mRNA level of fibrotic genes. Female PAAFs exhibits a higher stiffness response threshold and lower stretch sensitivity compared to both male and OVX cells, while OVX cells show higher general response levels than males.

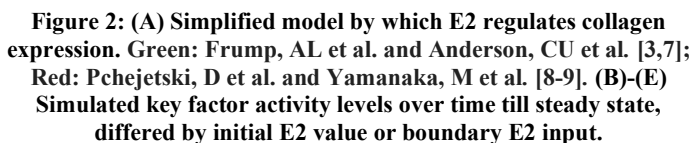

Figure 1: Effect of stiffness and stretch on *Col3a1* expression in PAAFs derived from male rats and female rats (A), and intact vs. OVX female rats (B). Note that the groups have different response thresholds, degrees, and patterns, both when male is compared to OVX (A) and when OVX is compared to female (B).

This study suggests that the presence of estrogen would down-regulate fibrotic gene expressions during PAAF mechanosignaling activities, while the intrinsic sex of the cells plays an also significant but unclear role in the process. The suggested signaling model helps decipher and explain how estrogen plays a role in the mechanosignaling network by connecting it to BMPR2 and apelin, providing a potential direction for further investigation and understanding of sex dependent PAAF mechanosignaling and PAH development in general.

INTRODUCTION

Globally, calcific aortic valve disease (CAVD) is becoming more common and causes significant mortality and morbidity [1]. When calcific nodules form on aortic valve leaflets, the valve becomes stenotic. This makes it hard for the heart valve to open and close properly, prevents the heart from pumping blood to other parts of the body easily, and can lead to a stroke or other diseases. There is no proven effective pharmacological treatment for CAVD and the underlying mechanisms in CAVD development are not fully understood. A 3D, *in vitro* model of CAVD can provide a method for an improved understanding of the biological mechanisms in CAVD development [2].

The initiation and progression of aortic valve calcific nodules can be caused by inflammatory processes that are induced by numerous stimuli such as aging, hypertension, and metabolic disease, resulting in increased oxidative stress. H_2O_2 is a critical molecule in oxidative stress and is produced during normal metabolism in mammalian cells. H_2O_2 diffuses across cells and tissues as a messenger molecule, causing rapid biological effects such as cell shape changes, proliferation, and migration [3]. However, greater levels of exposure cause immune cell recruitment, inflammatory response, growth inhibition, and cell apoptosis through a variety of pathways (Figure 1) [3]. This inflammatory environment induces macrophages, valvular endothelial cells (VECs), and valvular interstitial cells (VICs) to produce extracellular vesicles, and triggers apoptosis in macrophages and VICs, which results in the production of apoptotic bodies. Both processes result in

dystrophic calcification, which causes macrocalcifications [4]. The goal of this work is to study the role of monocytes and macrophages in the development of aortic valve calcification as a result of elevated reactive oxygen species (ROS) (in this study by adding H_2O_2) in a 3D *in vitro* model of the aortic valve.

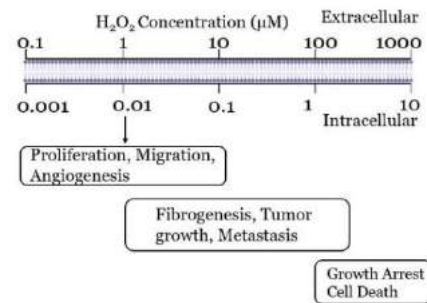

Figure 1: Hydrogen peroxide concentrations in oxidative stress and biological responses of the cell. Reproduced from [3].

METHODS

Porcine aortic VICs (PAVICs) were seeded within a 3D collagen type I hydrogel at 1×10^6 cells/mL and porcine aortic VEC (PAVECs) were seeded on top of the matrix at 95,000 cells/cm² in a 24-well plate. 100 mM H_2O_2 was added to the DMEM + 10% fetal bovine serum (FBS), which was changed every other day for up to 7 days. On the 8th day, THP-1 (a human monocyte cell line) was seeded onto 3D gels at 1×10^5 cells/mL in fresh medium with 200 ng/mL phorbol 12-myristate-13-

acetate (PMA) for 12 hours to induce differentiation to M₀ macrophages. M₀ macrophages were then differentiated toward M₁ with 12 hours incubation with 200 ng/mL of lipopolysaccharide (LPS). Then the both tri-culture matrix were fed with 400 µL of fresh medium, and then fed every other day by adding 100 µL to the old medium until the 14th day. Alizarin Red Staining (ARS) was used to show and quantify calcified nodule formation. The microstructure of calcified nodules was assessed by scanning electron microscopy with energy dispersive X-ray (SEM/EDX) spectroscopy. EDX was used to quantify calcium-phosphate atomic ratios (Ca/P). Crystal violet and live/dead assays were used to quantify THP-1 monocyte activation. Results were analyzed using Kruskal-Wallis tests and the Wilcoxon rank-sum test at each time point with adjustment for multiple comparisons with P-value < 0.05.

RESULTS

H₂O₂ induced calcification in PAVIC-only, PAVEC-only, and co-culture (Figure 2). While the ARS results show that calcific nodules were present in the co-culture and PAVIC-samples but not in the PAVEC-only samples, the SEM images showed calcified nodules in all three conditions. The PAVEC-only calcified nodules have a higher Ca/P ratio than other samples. The ARS and SEM images showed H₂O₂ induces calcification in tri-culture samples and causes monocytes to differentiate toward M₀ macrophages. According to EDX results, tri-culture samples with monocytes and macrophages have a lower Ca/P ratio compared to both mono-cultures (PAVIC-only and PAVEC-only culture) and co-culture samples. However, the number of calcific nodules of tri-culture samples (according to quantified ARS results) is significantly increased compared to mono-culture and co-culture samples.

Figure 2: Alizarin Red Staining (ARS) qualitative images, Scanning Electron Microscopy (SEM) shows the existence of calcified nodules in samples treated with H₂O₂ (100 µM).

DISCUSSION

The amount of mineralization is shown by Ca/P ratios which indicates the pathobiological calcium phosphates range in different diseases such as cardiovascular diseases and cancer [5]. Pathobiological calcium phosphates can develop which is resulting in the creation of hydroxyapatite (Ca/P = 1.67). The primary calcium phosphate phases leading to the formation of

hydroxyapatite are monocalcium phosphates (Ca/P = 0.5), dicalcium phosphates (Ca/P = 1), and octacalcium phosphates (Ca/P = 1.33) [6, 7]. The Ca/P ratios of calcified nodules in PAVIC-only, PAVEC-only, and co-cultures treated with H₂O₂ (100 µM) samples were determined to be 1, 1.53, 1.32, which shows that the calcific nodules of these three conditions were made of different forms of calcium phosphates found in the body. Ca/P = 1.53 of PAVEC-only culture is close to the Ca/P ratio of hydroxyapatite (Ca/P = 1.67). SEM/EDX results indicated Ca/P ratio in tri-culture samples with monocytes (Ca/P = 0.83) is higher than in tri-culture samples with macrophages (Ca/P = 0.52).

Based on the SEM images with calcified nodules in all conditions, H₂O₂ likely induces PAVECs to differentiate into endothelial-derived PAVICs which further differentiate into osteoblastic PAVICs and result in valve calcification. ARS images showed the presence of the calcified nodules in tri-culture samples pre-treated with H₂O₂ (100 µM). Compared to tri-culture samples with monocytes, the concentration of ARS stain increased in the presence of activated macrophages (M1), which shows an increase in the number of calcified nodules.

According to SEM/EDX results, the model forms calcified nodules of different calcium phosphate maturity phases as found in *ex vivo* calcified human aortic valves. This 3D aortic valve model can be useful for understanding the role of immune cells including both macrophages and monocytes in disease progression in response to increased oxidative stress. These tri-culture models could be used to test new pharmacological treatments for CAVD in the presence of immune cells.

MECHANICAL PROPERTIES OF CARDIAC TISSUE SURROGATES AND HOW THEY COMPARE TO HUMAN CADAVERIC CARDIAC TISSUE

Emily A. Bermel, PhD¹, Kevin O'Brien¹

[¹Medtronic, Cardiac Rhythm Management, Therapy Delivery Systems, Mounds View, MN, USA

INTRODUCTION

During development of implantable devices and their delivery systems, mechanical testing is required to ensure the devices will function properly during its implanted life. Many different medical devices interact with many different types of tissue, for this study we focused on cardiac tissues and their surrogates. Many different cardiac therapy devices interact with cardiac tissue, creating a need for tissue surrogates suitable for accelerated bench testing. Current surrogates in use are Ballistic gel¹, SynDaver synthetic tissues², LifeLike Bio Tissues³ and 3D printed materials⁴. Mechanical characterization of these surrogates is required to determine their suitability for replicating cardiac tissue behavior.

There are several modes of mechanical loading that surrogates can be compared. In this study we looked at three types: Uniaxial tension, uniaxial compression, and friction.

METHODS

Sample Preparation

Ballistic gel was cast in molds to create samples. SynDaver sheets and LifeLike Bio sheets were cut using a sample punch. Tissue was resected from cadavers, dissected into flat sheets, and the samples were punched out. Tissue samples were stored in a fridge, wrapped in saline soaked gauze and synthetic tissue surrogates were stored as directed by the manufacturer when not in use.

Testing Types

To fully characterize each material three different types of testing were done: Uniaxial Tension, Uniaxial Compression, and Friction.

Uniaxial tension tests were done on dog bone samples, shown in Figure 1. Each test included pre-strain to account for relaxation, 10 preconditioning cycles to 10% strain, then five cycles of 25%, 50%, and 100% strain, then a pull to failure. Uniaxial compression was done on one inch diameter samples, Figure 1. Each test included a pre-load of

1% and then five cycles of 50% strain was applied. All testing was done at a rate of 1.2mm/sec in saline at 37°C.

Friction testing was done to characterize the interaction of the surrogates with a needle. A 0.020-inch stainless steel wire was sharpened at the distal end. The tissue and surrogate samples were clamped in a fixture that allowed the wire to fully penetrate the sample, while trying to minimize tenting of the tissue. The test pushed the needle through a sample's thickness to a maximum displacement of 25 mm, then pulled back at a rate of 25mm/min so that there was a constant surface area interacting with the needle during pull-out.

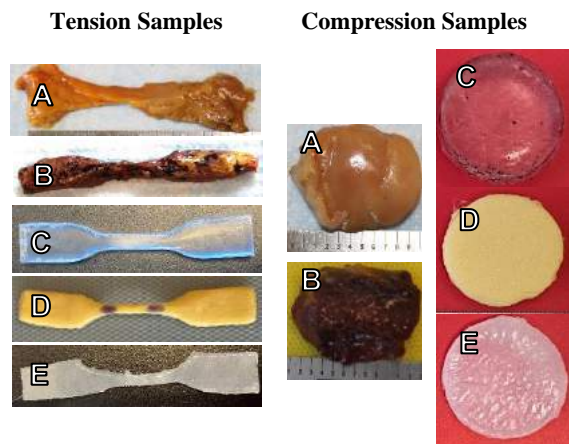

Figure 1: Tension and Compression Samples. A) Cadaveric Cardiac Fat, B) Cadaveric Cardiac Muscle, C) Ballistic Gel, D) SynDaver Bulk Fat, and E) SynDaver Cardiac Muscle

Data Analysis

Force and displacement data was collected for all tests at a sampling rate of 100Hz. To compare surrogates to cadaveric tissue we looked at the average tension and compression moduli for the linear loading region of the data. For friction data analysis, the maximum pull-out force was used to as the representative frictional force and had comparable results to using the average pull-out force (Figure 2).

Figure 2: Maximum Frictional Force. Red dot indicates the max force during retraction of wire and the blue line represents average pull-out force.

RESULTS

Figure 3: Cadaveric Tissue Tension.

Figure 4: Cadaveric Tissue Compression.

Figure 5 : Tension Moduli

Figure 6 : Compression Moduli

Figure 7: Max Friction Force Normalized by Sample Thickness. LifeLife Bio (LLB) Fat, Porcine Cardiac Muscle, and SynDaver (SD) Fat.

DISCUSSION

SynDaver materials are stiffer than cadaveric tissue in tension, but the SynDaver fat seems to mimic the compression modulus of the cardiac muscle and fat the best. In addition to a tissue's response to tension and compression, friction between cardiac tissues and medical device engineering materials is critical for chronic fixation of a device inside the body. Real tissue has higher frictional forces than any surrogate tested to-date, further testing of surrogate materials is needed. We have developed a reproducible test that is representative of use conditions and may be used to evaluate surface coatings, tip sharpness, and device-tissue interactions relevant for medical implants.

INTRODUCTION

Mechanical ventilation is often used to support gas exchange and lung function during surgery, since pulmonary muscles relax under anesthesia. However, the lungs may undergo regional atelectasis (partial lung collapse) if improperly ventilated, which can be harmful and lengthen recovery [1]. To mitigate this, maneuvers are performed during ventilation to improve alveolar recruitment, protecting against atelectasis [2-3]. Common recruitment maneuvers include escalation of pressure with incremental cycling to sufficiently recruit alveoli, or a sustained inflation maneuver, where inhalation is followed by a pause and volumetric hold of air.

Previous studies discourage sustained inflation methods, as they may heterogeneously over distend open alveoli adjacent to closed alveoli groups, resulting in lung damage [4-5]. In contrast, recent research suggests that escalation maneuvers more homogeneously recruit non-aerated alveolar groups, which gradually open as the air is incrementally cycled, and may be a more ideal method [2, 5-6]. Previous studies have employed global mechanical characterization, such as pressure-volume curves, or non-continuous time methods, such as internal imaging with magnetic resonance imaging (MRI) [2,6] to examine the effect of differing recruitment maneuvers. However, such methods neglect local lung mechanics, including the development of lung strains during ventilation [2], which can reveal critical information about regions susceptible to damage [7]. Measuring tissue-level stretch during these maneuvers may provide insights regarding each maneuvers' comparable efficacy [8].

This novel study characterizes regional tissue-level lung mechanics recruitment maneuvers using digital image correlation (DIC). Strains on the surface of the ex-vivo lung are compared between the sustained inflation and the escalation maneuvers when specimens are inflated to matched lung volumes, complementing established global insights with new local assessments of pulmonary mechanics. The results of the study can contribute to identifying optimal maneuvers

and provide clinically applicable insights regarding pulmonary overdistension during ventilation.

METHODS

Six male C57BL/6J mice were obtained from Jackson Laboratories (Bar Harbor, ME, USA), aged 12-15 weeks, and were anesthetized and sacrificed according to IACUC protocol. Lungs were removed and cannulated to enable mechanical ventilation and were speckled for digital image correlation measurements. Specimens were placed in a custom-designed, electromechanical pressure-volume tank for ventilation testing [9], where three lungs were subjected to an escalation maneuver (EM) and three to the sustained inflation maneuver (SIM).

For both recruitment maneuvers, lungs were preloaded to 6 cmH₂O [10], then preconditioned to a volume of 0.3 mL for 3 cycles, at a rate of 20 breaths per minute (Figure 1). For the EM, the lungs were subsequently cycled with incrementally increasing volumes to 0.9 mL. For the SIM, the preloading and preconditioning process was repeated 5 times to match the number of cycles of EM; then, a volumetric hold to 0.9 mL was performed. DIC data [Trilion Quality Systems, King of Prussia, PA, USA] was recorded for analogously matched inflation legs of the SIM and EM, as highlighted in Figure 1 [8].

The major strain was tracked over time for randomly selected locations points between a representative EM and SIM mouse for qualitative comparisons (Figure 2A and B); the reduced Jacobian was calculated to ensure equivalent DIC surface areas and displaced volumes between specimens [11]. Histograms (average \pm standard deviation) were generated from the DIC tissue surface strains at peak inflation (0.9 mL) for both maneuvers and all mice (Figure 2C and D). The coefficient of variability (CV) was also calculated to compare the strain distribution and tissue deformation heterogeneity [12]. Metrics were compared between the two maneuvers using a one-way ANOVA with a significance level of $p < 0.05$ [GraphPad Prism, San Diego, CA, USA].

Figure 1: Illustrated escalation and sustained inflation recruitment maneuvers. The red highlighted inflation limb is analyzed by DIC to assess the temporal strain evolution (Figure 2A-B), and the strain distributions at the peak volume stage (dotted circle) are evaluated (Figure 2C-D).

RESULTS

For both maneuvers, lung tissue surface strains were found to increase over time with greater air delivery as expected (Figure 2A and B). Qualitatively, the EM demonstrated a more steady and progressive increase in strains, whereas the SIM demonstrated decreased strain slopes followed by a sharp increase, resulting in more populated high peak strains at the maximum volume.

Statistically significant differences were not found between the peak strain values, mean, standard deviation, and CV between EM and SIM (Figure 2C and D). However, EM strains were more uniformly distributed about the mean value of 22% with a CV of 63%, compared to SIM, which demonstrated reduced mean strain of 19% with greater strain heterogeneity with a CV of 82%.

DISCUSSION

In this study, the SIM group was associated with a greater fraction of low strains across the analyzed left lung and superior and inferior right lobes, which is considered to be associated with more unopened alveolar groups compared to EM [1-2,13]. The higher CV value within the SIM group exhibits greater surface strain spread and implies greater alveolar recruitment heterogeneity. Analogously, the comparatively reduced CV value for EM implies more uniform recruitment of alveolar units and therefore, greater lung homogeneity.

Previously, based on MRI imaging and global pressure-volume hysteresis curves, Cereda et al. [2] found that the EM in rat lungs led to the opening of smaller alveolar groups versus over aeration of opened alveoli, associated with a homogeneous versus heterogenous response respectively. However, such methods are limited in that they cannot characterize the progressive behaviors nor the regionality of tissue strains that result from alveolar recruitment, which may yield an understanding regarding the development of lung damage [7-8]. Nonetheless, our local findings substantiate the conclusions of these discrete and global mechanics studies, observing that EM results in more homogenous lung tissue expansion, while also tending to do so continuously throughout inflation.

Although EM and SIM are both utilized clinically, these studies and recent clinical research [1] has led to a consensus highlighting the benefits of EM and the risk of injury with SIM. The mechanical substantiation for these results is still currently debated, and our local to lung injury [5,6]; in this study, the inflation limb of EM results in

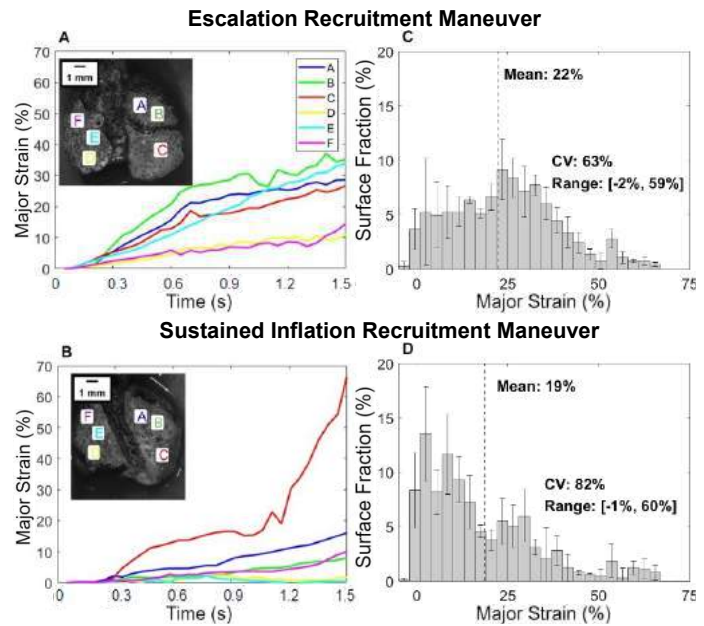

Figure 2: Representative major strain temporal evolution for the escalation recruitment maneuver (A) and sustained inflation maneuver (B) are shown. Histograms quantify the fraction of the surface exhibiting various strain levels and corresponding distributions for the escalation maneuver (C) and sustained inflation (D).

steadier and more homogenous strain response when compared to the heterogenous and abrupt tissue expansion found in SIM. This may lend insights into the cause of lung damage during ventilation and help to improve identifying optimal methods of lung recruitment.

While our findings did not exhibit statistical significance, more conclusive results may be revealed with greater mice sample sizes, as currently planned for future work. Additionally, this study was conducted ex-vivo, without the presence of the chest cavity encapsulating the lungs, which may change deformation measures during tissue expansion; however, relative measures, such as tissue strains and regional patterns, would likely persist [8]. Despite these limitations, this study is the first of its kind to characterize the development of strain during different recruitment maneuvers, with future work aimed at connecting global to local mechanical characteristics to lend additional clinically applicable insights.

INTRODUCTION

Intracranial aneurysms (ICA) affect approximately 3-5 % of the overall population. 3-50 in every 100,000 ICAs will rupture if left untreated, making prophylactic treatment a pressing urgency. Current methods for ICA treatment involve surgical clipping or endovascular embolization: the latter being preferred for its low invasiveness and lower in-hospital mortality. Nonetheless, endovascular therapies face challenges related to incomplete ICA occlusion, which can lead to aneurysm recurrence and rupture [1,2]. Therefore, research efforts can be made towards advancing technologies for ICA endovascular embolization that aim to promote complete occlusion and improve the long-term effectiveness.

Traditionally, endovascular embolization using Guglielmi detachable coils (GDCs), or other biomaterials for the occlusion of ICAs, have non-patient-specific approach (i.e., the material does not match the aneurysm geometry). In this study, we aim to develop a *paradigm-shifting* technology for ICA endovascular treatment: shape memory polymers (SMP) that can be tailored to *aneurysm-specific* geometries. Specifically, our polymeric formulation and manufacturing show great promise for ICA embolization, as demonstrated by the occlusion of *in vitro* aneurysm models. In addition, our material is fabricated using a facile method that allows fast production of foams. Overall, our SMP device exhibits potential to improve complete occlusion rates of ICAs.

METHODS

SMP Synthesis and Material Fabrication: Polyurethane was synthesized using hexamethylene isocyanate (HDI), triethanolamine (TEA) and N,N,N',N'-tetrakis (hydroxypropyl) ethylenediamine (HPED), as described previously [3], in a nitrogen-rich environment. SMP solution was poured on a polyvinyl alcohol (PVA) 3D-printed template with a grid infill structure. SMP was cured in a vacuum oven and, once solid, PVA was washed out using a sonicator. SMP foams (Fig. 1) were then dried in a vacuum oven and stored in a desiccator.

Figure 1. Schematic of 3D SMP foam fabrication pipeline: (a) 3D printing of (b) PVA template with a grid infill design. (c) Pouring of SMP solution and (d) the final SMP foam after washout.

Calorimetry and Shape Recovery Analysis: Differential scanning calorimetry (DSC) was used to quantify the glass transition temperature (T_g) of the synthesized SMP foams ($n = 3$). Further, shape recovery of the SMP specimens ($n = 3$, $1 \times 1 \times 1$ cm) was characterized by bringing the material above T_g and measuring the shape recovery using:

$$SR\% = \frac{h(t) - h_c}{h_0 - h_c} \quad (1)$$

where $SR\%$ is the shape recovery percentage, $h(t)$ is the height of the foam at a given time, h_c is the height of the compressed foam, and h_0 is the original (prior-to-compression) height of the foam. The shape recovery experiments were performed at both the room temperature and the freezing condition to characterize the shape storage. A heat ramp from room temperature to $T_g + 10^\circ\text{C}$ was also applied to characterize the triggering of shape recovery as a response to heat stimuli.

Thermo-mechanical Testing: An Instron 5969 machine was used to characterize the compressive properties of the SMP foams: Foams ($n = 6$) of $1 \times 1 \times 1$ cm were uniaxially compressed up to 80% strain, with mechanical parameters derived from the stress-stretch curves.

Polypyrrole Coating & Thermal Analysis: To induce conductivity of the polyurethane matrices, polypyrrole (PPy) was polymerized on the surface of the foam [4]. Cubic foams were first submerged in FeCl_3 for 10 min and subsequently suspended over 1 mL of pyrrole in an air-tight container for 2 h at -20°C . PPy-coated foams were then dried overnight in a fume hood and stored in a desiccator.

Fabrication of Patient-Specific Foams and Aneurysm Models:

Aneurysm geometries were obtained via segmentation of computerized tomography angiography (CTA) images of human subjects (IRB #7932) using AMIRA software. Geometries were used to print PVA templates for foam synthesis and for phantom fabrication. Phantoms were fabricated by pouring polydimethylsiloxane (PDMS) on solid PVA 3D-printed templates. PDMS was cured at 70 °C for 1 h and PVA was thoroughly rinsed in a sonicator until completely dissolved.

RESULTS

Material Synthesis and Microstructure: SMP foams replicated the computer-designed infill structure of PVA templates (Fig. 1). Wall thickness of the infill design was significantly higher in SMP foams than in PVA templates ($p < 0.01$, not shown here), demonstrating that the SMP solution cured around the PVA filament, thus creating a sheath-like structure. Overall, the SMP foam mimicked the PVA template geometry and infill producing a porous compressible 3D SMP foam.

Calorimetry & Shape Recovery Analysis: DSC demonstrated that the 3D-printed foams exhibited significantly lower T_g than solid SMP specimens (not shown). By fine-tuning the molar compositions, we found that a TEA-to-HDI ratio of 0.22 yielded a $T_g \approx 41^\circ\text{C}$ that is the desired working temperature for the endovascular embolization procedure. At this molar ratio, we found that the material maintained its deformed configuration when stored at freezing temperatures ($<0^\circ\text{C}$, Fig. 2a), but an average of 40 % shape recovery was observed when foams were stored at room temperature after 10 min. In addition, we observed that a heat ramp from room temperature to $T_g + 0^\circ\text{C}$ increased the rate of shape recovery (Fig. 2b). These experiments demonstrate the thermal dynamic behavior of our SMP with customized T_g .

Figure 2. (a) Shape recovery storage at -20°C . (b) Shape recovery measurements as a response to a heat ramp.

Mechanical Properties: SMP foams exhibited a nonlinear anisotropic mechanical behavior. The x - and y -axes did not exhibit significant differences in the characterized mechanical parameters, while the z -axis exhibited significantly *greater peak stresses* and *elastic moduli* than the other two axes. Overall, the foam exhibited a unique behavior that promoted guided compression along the x - and y -axes.

Occlusion of Patient-Specific Phantoms: SMP foams with patient-specific geometries (Fig. 3a) were successfully used for the occlusion of aneurysm models. The foam was transported in its deformed configuration into the aneurysm and shape recovery was triggered by applying external heat. The SMP foam successfully recover and completely occlude the aneurysm space (Fig. 3b).

Figure 3. (a) 3D aneurysm model obtained from patient CTA imaging. (b) SMP foams with patient-specific geometry and a grid infill pattern design. (c) Proof-of-concept aneurysm occlusion using a patient-specific aneurysm model and our 3D-printed SMP foam (arrow).

Joule-Heating Properties of the PPy-Coated Foams: The PPy-coated foams had a black appearance, demonstrating pyrrole polymerization [4]. Resistivity measurements ($n = 3$) of the PPy-coated foams yielded an average of $6.16 \pm 1.94 \text{ k}\Omega$. In addition, the uncompressed foams were able to conduct heat during electrical stimulation (30V DC) using a parallel copper plate setup, reaching temperatures $>T_g$ in less than 10 s, as demonstrated in an infrared (IR) thermal analysis (Fig. 4).

Figure 4. IR camera snapshots of a PPy-coated SMP foam with a grid infill pattern being subjected to DC voltage at different timepoints.

DISCUSSION

In this present work, we have developed a facile method for the fabrication of porous SMP foams with customized T_g and patient-specific geometries. For the first time, we have developed a biomaterial that can be fabricated with aneurysm-specific geometries, custom infill microstructure, and anisotropic mechanical properties. A material with these properties and unique features had been elusive in our previous efforts [5], where SMP shape recovery could be triggered using Joule-heating but had less desirable mechanical behaviors and structural integrity, preventing its fabrication with guided compression patterns nor with patient-specific geometries. Overall, these features are the cornerstone to develop a coil-free endovascular device that can achieve higher complete occlusion than the currently available technologies.

To achieve this longer-term goal, the ongoing research will optimize the polypyrrole coating methods to obtain low resistivity, while maintaining T_g of the pure SMP matrix without deteriorating its mechanical behavior. With this future optimization process, testing of phantom occlusion using PPy-coated foams will be performed in dry and wet conditions. In addition, we will characterize the biocompatibility of the material via cell culture with endothelial cells. Future directions of the project will also include the preclinical effectiveness assessment of the device using our established New Zealand rabbit animal model [6].

Overall, this research presents a novel technology for the treatment of ICAs using an SMP-based endovascular approach. Our 3D SMP foam material exhibits features with great potential for improved aneurysm occlusion using endovascular embolization.

SPATIOTEMPORAL EVOLUTION OF COLLAGEN MICRO-MECHANICS UNDER BREAST CANCER CELL DRIVEN REMODELING

Adil Khan (1), Jacopo Ferruzzi (1)

(1) Department of Bioengineering, The University of Texas at Dallas, Richardson, TX, USA

INTRODUCTION

Mechanical interactions between cells and the surrounding extracellular matrix (ECM) play a key role in regulating physiological processes as well as numerous diseases [1]. Cell-ECM interactions are particularly relevant in breast cancer, where rogue signaling from transformed epithelial cells leads to increased deposition, alignment, and stiffening of peritumoral collagen. While mechanical remodeling of the collagenous ECM continues to be implicated with cancer cell invasion and overall patient survival [2], the underlying relationship between cancer cell driven remodeling and collagen micro-mechanics remains poorly understood. This is primarily due to inherent complexities in measuring 3D micro-mechanical properties of the collagen networks, which are known to be highly heterogeneous, nonlinear, and anisotropic. To describe such complexity, an integrated method for defining the local structure-function relationship in collagen networks is of the essence, though not currently available.

To address this unmet need, we have developed a novel approach for characterizing the micro-mechanics of fibrous ECM scaffolds. Our method employs iron oxide beads embedded into collagen networks as localized micro-scale actuators. Through the application of coordinated magnetic fields, the beads experience a homogenous torque and generate heterogeneous deformations, which depend on the local material properties of the network. By combining magnetic twisting, confocal microscopy, and finite element analysis, we have thus established a platform capable of interrogating local cell-ECM mechanical interactions. Here, we demonstrate this capability by mapping the spatial and temporal evolution of mechanical heterogeneities in a collagen matrix as it is remodeled by breast cancer cells of different invasive potentials.

METHODS

Ferromagnetic beads made of pure iron oxide with an average diameter of 4.8 μm were distributed evenly in a collagen solution, which

was polymerized using established protocols [3]. To enable the beads to bind with collagen fibrils, their surface was functionalized with NHS groups [4]. In brief, the beads were incubated in a solution of nitrodopamine (ND) – polyethylene glycol (PEG) – succinimidyl carbonate (NHS) in 0.1 M triethylammonium acetate (TEA) for 2 hours, following which they were washed 4 times by centrifugation and resuspension in TEA. Finally, the beads were resuspended in 20 μL of TEA and mixed with the unpolymerized collagen solution at a density of 10^5 particles/ml. Micro-mechanical experiments were conducted on acellular collagen gels of varying density (1 to 4 mg/ml) and on collagen networks of fixed collagen density (2 mg/ml) populated with either a homogenous distribution of single cancer cells ($\sim 250 \times 10^3$ cells/ml) or with embedded tumor spheroids ($\sim 10^3$ cells/spheroid).

The micro-structural organization of the collagen network around selected beads was assessed using a Nikon AX confocal microscope equipped with a 20 \times objective lens and operating in reflection mode with an excitation wavelength of 488nm. The Nikon NIS-Elements software was used to control independently two orthogonal sets of coils mounted on a custom microscope insert. A strong magnetizing pulse B^M in one direction, followed by a weaker twisting field B^T in the perpendicular direction were used to impose a magnetic torque (T) on all the beads within a sample (Figure 1a). Confocal image stacks acquired before and after the magnetic stimulation were compared using an augmented Lagrangian digital image correlation algorithm to measure the displacements generated in the collagen network [5]. The magnitude of the 3D displacement field around each bead was compared with that produced by a finite element model (Figure 1b), and the difference was minimized to estimate the unknown material properties of the local collagen network. For the sake of simplicity, collagen was modeled as a neo-Hookean material $W = \mu/2 (I_c - 3)$ and the associated Young's modulus $E = 2\mu(1 + \nu)$ was used to report local material properties, where the Poisson's ratio ν was determined in preliminary experiments by means of uniaxial unconfined compression.

RESULTS

To validate our novel approach, we imposed finite element-based synthetic deformations onto experimentally measured confocal stacks taken from acellular collagen gels. Our method was able to recover the imposed Young's moduli with a mean error of 6.8%. Direct measurements via magnetic twisting in acellular collagen gels indicate that material stiffness gradually increases with increasing collagen density: $E = 11 \pm 5$ Pa for 1 mg/ml, $E = 14 \pm 7$ Pa for 2 mg/ml, $E = 20 \pm 4$ Pa for 3 mg/ml, and $E = 25 \pm 11$ Pa for 4 mg/ml.

Next, we used the non-tumorigenic MCF-10A and post-metastatic MDA-MB-231 breast cancer cell lines to investigate the mechanical signatures of cancer cell mediated matrix remodeling. First, we performed a collagen gel contraction assay by dispersing single cells in 2 mg/ml collagen gels. Once polymerized, the cylindrical collagen matrices were physically detached from their Petri dish, leaving them floating and free to contract over the course of four days. The more contractile MDA-MB-231 cells compacted the collagen matrices by up to 60% of their original area. While acellular gels remained mechanically stable over time, cell-mediated compaction was accompanied by a near 3.7-fold increase in material stiffness (Figure 1c). Subsequently, we embedded multicellular tumor spheroids in 2 mg/ml collagen gels and monitored their growth and invasion over time. By day 4, the more epithelial MCF-10 spheroids invaded collectively with modest remodeling of the surrounding collagen. During the same time frame, the more mesenchymal MDA-MB-231 spheroids aligned collagen fibers radially and invaded as single cells in a highly dynamic manner. This heterogeneous reorganization of the peritumoral collagen network (Figure 1d, left) resulted in spatially varying material properties, with a marked stiffening in areas of elevated compaction and alignment of collagen fibers (Figure 1d, right). Magnetic twisting is therefore capable of monitoring the spatiotemporal evolution in material properties driven by highly contractile and invasive breast cancer cells.

DISCUSSION

During invasion and metastasis, breast cancer cells interact with the surrounding ECM to enable mutual regulation of cell signaling and ECM mechanics, ultimately resulting in cellular migration into adjacent tissues. While various endogenous and exogenous fluorescent reporters are already available to track intracellular signaling in a spatially and temporally resolved manner, methods to measure extracellular micro-mechanics in a 3D setting are still limited. Currently available methods, such as atomic force microscopy (AFM) and optical tweezers (OT) are limited, respectively, by the fact that AFM is a 2D technique and that OT involve complex and low-throughput 3D measurements. More importantly, other approaches are limited by the often implicit assumption of linear and isotropic elasticity [4,6]. Similarly, this work is currently limited by the adoption of a neo-Hookean material model, but our approach lends itself to the exploration of more realistic constitutive models as it inherently incorporates both structural and mechanical information by combining confocal reflection imaging and magnetic twisting.

Future work will focus on evaluating structure-based constitutive models of collagen network mechanics and on investigating the mechanisms of cancer cell driven remodeling by selectively inhibiting key processes mediating cell-ECM interactions such as contractility, proteolysis, and cross-linking. Furthermore, the capacity of measuring evolving material properties in 3D can potentially improve the accuracy of traction force estimation in 3D [7]. We conclude that our method represents a new semi-automated approach to map 3D spatiotemporal heterogeneities in nonlinear collagen micro-mechanics. This capability will enable mechanistic studies on cell-ECM interactions in the context of breast cancer and other fibrotic conditions.

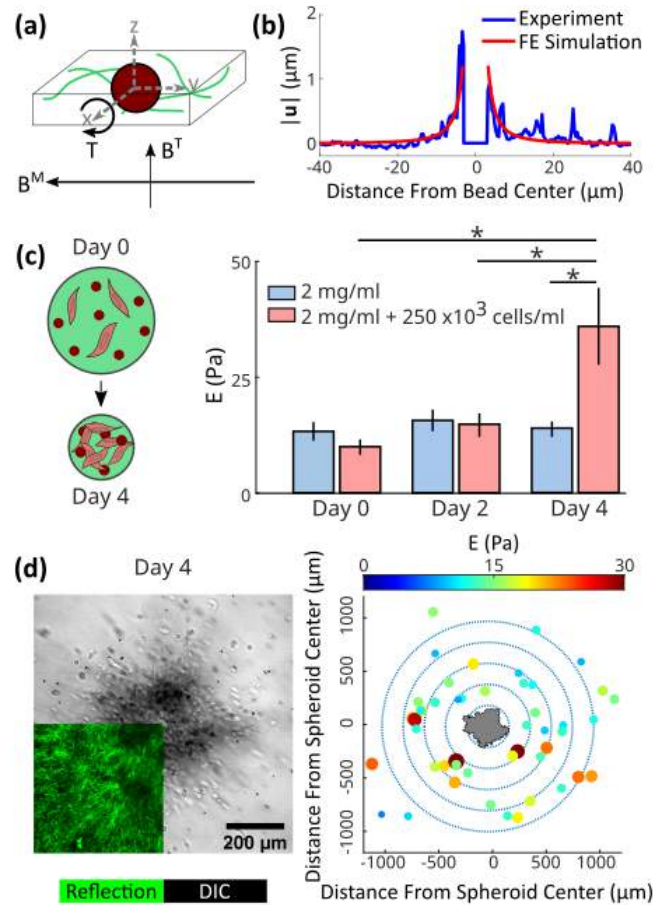

Figure 1: (a) Schematic representation of a ferromagnetic bead (red) embedded into a collagen network (green) and torqued about a specific axis (herein indicated as x) using coordinated magnetic fields B^M and B^T . (b) Iterative simulations are conducted to match the experimental and computational displacements and estimate the local material properties of the collagen network. (c) Compaction of collagen gels seeded with MDA-MB-231 cancer cells (250×10^3 cells/mL) occurs gradually over time and is accompanied by a corresponding increase in Young's modulus. (d) Confocal imaging (left) and spatial mapping of Young's moduli (right) around an invading MDA-MB-231 tumor spheroid reveal a correspondence between structural and mechanical remodeling of collagen after 4 days of culture. Data presented as mean \pm standard deviation. Statistical significance was determined using a one-way ANOVA with a Tukey post-hoc test. (* $p < 0.05$).

HEMATOCRIT IS A POTENT DRIVER OF PLATELET ADHESION AT SUPRAPHYSIOLOGICAL SHEAR RATES

INTRODUCTION

Supraphysiological shear rates ($>1\text{--}2,000\text{ s}^{-1}$) have been well established as a driving factor in the incidence of pathological and device-mediated thrombosis [1]. Excessive shear rates cause not only increased platelet activation but amplified unfurling of the von Willebrand factor (vWF), leading to increased tethering of platelets and thrombus formation [2]. vWF is an ultralarge, mechanosensitive glycoprotein circulating within plasma, acting to permit platelet arrest within arterial shear stress ranges at sites of injury. Supraphysiological shear forces drive the upregulation of vWF-mediated platelet capture. This clinically relevant phenomenon is tied to the shear-sensitive structure of vWF multimers, leading to pathological thrombosis by increased platelet activation and vWF unfurling [3].

Due to the severity of adhesion associated complications, it is crucial that the mechanisms behind vWF-mediated platelet deposition are further mapped to improve predictive modeling and inform the development of novel anticoagulant and antiplatelet agents. The unfurling behavior of vWF is tied to local fluid dynamics, chiefly the wall shear rate or shear rate gradient, of a potentially adhesive surface [4]. Flow perturbation during or following a period of exorbitant shear rates ($\geq 5,000\text{ s}^{-1}$) can cause sudden wall contact following a period of acceleration or deceleration. Similarly, margination by red blood cells displaces vWF and platelets into the near wall region of high shear and has been demonstrated to play a role in vWF adhesion efficacy [5]. Hematocrit (HCT) is therefore hypothesized to play a crucial role in thrombus deposition at supraphysiological shear rates. The primary objective of this study was to observe the effect of variable hematocrit and shear rate on platelet deposition in a sudden expansion model.

METHODS

Using established methods of soft lithography [6], polydimethylsiloxane (PDMS) microchannels were fabricated to act as a testing platform for shear-altered deposition. A sudden expansion

geometry was fabricated to induce rapid deceleration, with an expansion ratio of 2:1 at a backwards facing step (BFS). Microchannels had a cross-section of $200 \times 50\text{ }\mu\text{m}$ in the upstream region and a cross-section of $400 \times 50\text{ }\mu\text{m}$ in the downstream region. PDMS chips were cleaned in 70% ethanol and sealed to glass microslides using a plasma cleaner (Harrick Plasma, Ithaca NY). Shear rates were calculated in ANSYS FLUENT (ANSYS, Canonsburg PA) and verified by acquiring velocity data with a micro-PIV system (TSI Inc., Shoreview MN). Prior to experiments, channels were coated with human type I collagen at 50 or $100\text{ }\mu\text{g/mL}$ as noted to create a reactive surface. Human blood was acquired via a Penn State IRB approved protocol and anticoagulated with sodium citrate at a final concentration of 0.32%. Blood was centrifuged at 300g for 30 min to obtain separated platelet rich plasma (PRP), which was used to quantify platelet concentration. Blood was then reconstituted to the desired HCT (0%, 20%, 40%) with PRP and buffered with saline, maintaining native platelet concentration ($264 \pm 55.3 \times 10^6/\text{mL}$). Platelets were stained with DiOC₆ and incubated for 30 min at 37°C. Blood was not recalcified to avoid triggering of the coagulation cascade. Blood was then perfused for 3 min through microchannels with a Harvard syringe pump (Kd Scientific, MA) at 5, and 25 $\mu\text{L/min}$ to achieve wall shear rates of 1,000 and $5,000\text{ s}^{-1}$, correlating to arteriolar and pathological shear rates, respectively ($n = 6\text{--}7$). Following these experiments, a second study was conducted using the A2A9 antibody (Biolegend, San Diego CA) to inhibit $\alpha_{\text{IIb}}\beta_{\text{III}}$ function ($n = 7$). Blood reconstituted to 40% HCT was incubated with 5 $\mu\text{g/mL}$ A2A9 for 30 min prior to perfusion through straight channels at 500 and $5,000\text{ s}^{-1}$. Real-time immunofluorescence images were acquired at 1 frame per second with an Olympus IX71 inverted microscope and DP74 4MP CMOS camera (Olympus, Tokyo Japan). Pixel resolution was $0.586\text{ }\mu\text{m/pixel}$ edge. Images were converted to binary and processed in ImageJ (NIH, Bethesda MD) and MATLAB (Mathworks, Natick MA).

RESULTS

Hematocrit was observed to have a notable effect on platelet deposition that was compounded by flow deceleration. Thrombus surface coverage (% total area) within the 50 $\mu\text{g/mL}$ collagen coated BFS channel was affected by hematocrit at all shear rates (**Figure 1**), and the increase in deposition was pronounced in the step region. A two-way ANOVA assessment followed by Tukey's multiple comparisons test was performed. Hematocrit was a very significant factor ($p < 0.01$) in thrombus deposition, while shear rate was positively correlated with surface area coverage of only 40% HCT.

Hematocrit had an additional notable effect on thrombus morphology, as measured by mean area of thrombus deposits (μm^2). Increasing hematocrit resulted in larger and more prevalent thrombus surface deposits. Hematocrit was a significant factor in determining mean thrombus area ($p < 0.05$). Shear rate was not a determining factor in mean thrombus area.

Figure 1: Surface area coverage (SAC) and mean thrombus area (MTA) related to increasing hematocrit and shear rate. Statistical significance of SAC is denoted by solid lines while significance of MTA is denoted by dashed lines. Data are presented as mean \pm SEM.

Additional experiments at 40% HCT were conducted to investigate the change in thrombus morphology observed. The function of the $\alpha_{\text{IIb}}\beta_{\text{III}}$ integrin was inhibited prior to perfusion over 100 $\mu\text{g/mL}$ collagen coated straight channels with a 200 x 50 μm cross section. A two-way ANOVA assessment followed by Tukey's test was performed. Shear rate and receptor inhibition were both significant factors in determining SAC ($p < 0.05$, $p < 0.01$) and MTA ($p < 0.01$, $p < 0.001$). Pairwise comparisons demonstrated that receptor inhibition significantly reduced both SAC ($p < 0.001$) and MTA ($p < 0.001$) at 5,000 s^{-1} . This effect was insignificant at 500 s^{-1} (**Figure 2**).

Figure 2: Surface area coverage (SAC) and mean thrombus area (MTA) related to receptor inhibition and shear rate. Data are presented as mean \pm SEM.

DISCUSSION

The presence of red blood cells is a critical contributor to vWF-mediated thrombus formation, despite remaining primarily biochemically passive. Platelet deposition at shear rates relevant to

arteriolar and pathological flow was quantified. Hematocrit was observed to mediate platelet adhesion at all shear rates investigated, and larger thrombi tended to form at higher shear rates at physiological hematocrit. Thrombus deposition for PRP was minimal at all shear rates, suggesting reduced platelet delivery to the collagen surface. While platelet deposition at 20% HCT was comparable to 40% HCT at 1,000 s^{-1} , attachment decreased as shear rate increased, indicating a lack of clot stabilization. Thrombus formation at 40% HCT was dramatically amplified at supraphysiological shear rates (**Figure 3**).

The observed changes in thrombus morphology suggest a switch from platelet-collagen binding to platelet-platelet binding, possibly linked to a change in platelet integrin activity. This potential mechanism was investigated by selective inhibition of the $\alpha_{\text{IIb}}\beta_{\text{III}}$ receptor in a subsequent experiment. This treatment resulted in a significant loss in surface area coverage and reduced platelet-platelet interactions, albeit only at the higher shear rate of 5,000 s^{-1} . This supports a shift in receptor binding activity at supraphysiological shear rates towards $\alpha_{\text{IIb}}\beta_{\text{III}}$ -dominated platelet adhesion.

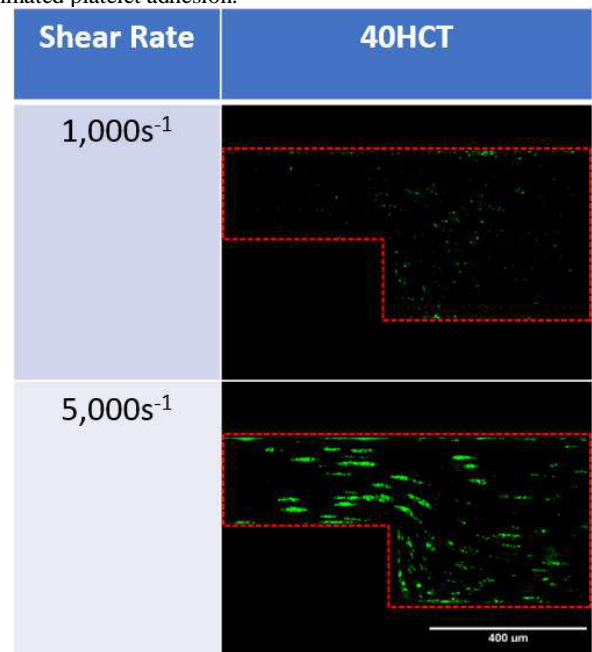

Figure 3: Representative images of thrombus deposition for 40% HCT blood perfused over 50 $\mu\text{g/mL}$ collagen at variable shear.

The increased thrombus deposition associated with supraphysiological shear rates was shown to be dependent on physiological hematocrit levels. Changes in thrombus morphology and an observed affinity for platelet-platelet interactions were linked to activity of the $\alpha_{\text{IIb}}\beta_{\text{III}}$ integrin. Further investigation of this phenomenon is required to determine clinical impact and how modulation of platelet binding receptors might influence adhesive behavior.

LOCAL ECM STIFFNESS MODULATES EPITHELIAL CELL RESPONSE TO MICROPATTERNS

INTRODUCTION

Cells respond to substrate mechanical confinements with changes in morphology, proliferation, and motility. It is widely observed that cells grown on narrow stripes stretch themselves along the orientation of the stripes [1-3]. Such cells develop thick stress fibers along the stripes suggesting a reinforcement of the cytoskeleton in response to the geometrical constraints [4]. Nucleus of the cell is connected to the surrounding cytoskeleton via linker of nucleoskeleton and cytoskeleton complex. The alteration of mechanical environments around the nucleus can also trigger the change in nucleus shape. In human endothelial cells, the mechanical confinement caused nuclear deformation is attributed to the enhanced apical stress fibers that press the nucleus envelope [5-7]. However, in epithelial cells, shear stress disassembles stress fibers, the nucleus shrinks through Piezo1 mediated Ca^{2+} signaling [8]. Thus, the cells utilize complex force transduction mechanisms in response to external mechanical signals.

In this study, we have created fibronectin stripe patterns on substrates of varying stiffness and investigated the roles of substrate stiffness on cell response to mechanical confinements in MDCK cells. To assess the involvement of Piezo1, we knockdown Piezo1 with miRNA. Our results show that cells grown on soft patterns are significantly longer than cells on stiffer patterns. The cell elongation coincides with nuclear deformation. Knockdown of mechanosensitive Piezo1 protein significantly reduced the elongation on stiffer substrates but has minimal effect in cells on soft substrates. This result shows that increasing tension in stress fibers is not required for MDCK cell expansion on soft substrate, thus, different mechanisms are involved.

METHODS

PDMS substrates of various stiffness were made using Sylgard 184 and Sylgard 527. Four stiffness were tested, hard substrate (184 sylgard 10:1, stiffness ~ 1 MPa), semi-soft substrate (184 Sylgard 40:1, stiffness ~ 25 KPa) and soft substrate (527 Sylgard 1:0.8 ~1 KPa), and glass

substrate (stiffness >1 GPa). To create micropatterns on the soft substrate, a reverse microcontact printing technique was used. Briefly, the substrate was plasma treated, followed by coating with monolayer of Fibronectin. The PDMS stamp (10 μm feature, 6 μm groove) was plasma treated for 30 s and then placed in contact with the substrate for 1 hr. The substrate was then treated with Pluronic F-127 for 1 hr to block non-selective cell attachment.

Prior to experiments, MDCK cells were seeded onto the patterned substrates and placed in incubator for 150 min. Following live-cell imaging, the cells were fixed and stained with Phalloidin Alexa Fluor 568 and Hoechst 33342 dye. Images were captured with a Zeiss inverted microscope with a CCD camera.

Statistical analysis used two-sample t-test. Values of $p < 0.005$ were considered statistically significant.

RESULTS

Substrate stiffness regulates cell elongation on micropatterns

To test the effect of substrate stiffness on MDCK cell response to narrow fibronectin stripes, we patterned micro-stripes (6 μm wide and 10 μm spacing) on substrates with various stiffness, namely, glass, hard, semi-soft, and soft. Cells have shown elongation on fibronectin stripes on all substrates. Interestingly, the cell elongation on soft substrate is significantly longer than stiffer substrates (Fig. 1a). The typical cells linear expansion on soft substrate are ~2 times longer than cells on glass. Cells showed similar expansions on semi-soft and soft substrates. The aspect ratio of cells on different substrates were analyzed using previously developed method [3]. Statistical analysis shows that the difference between soft and stiffer substrates is significant (Fig. 1b). Immunostaining F-actin with phalloidin showed that cells exhibit stronger actin stress fibers on the hard substrates compared with soft substrates. This suggests that stress fiber generated tension is not responsible for MDCK cell expansion on the soft substrates.

Figure 1: MDCK cell elongation on micropatterns with various stiffness. (a) Cells on soft stripes show maximal elongation but weaker stress fibers. (b) Aspect ratio of cell body on each substrate ($n = 50$ for all substrates, $*p < 0.05$, $**p < 0.005$). Scale bars represent $20 \mu\text{m}$.

Nuclear deformation coincides with cell elongation

To assess whether the ECM mechanical signals can be transmitted to the nucleus, we stained nucleus with Hoechst dye following the cell stretching and analyzed the shape of nuclei on different substrate. We found that nuclear deformation coincides with cell elongation in MDCK cells (Fig. 2). This effect is also modulated by substrate stiffness. On softer substrate, cells consistently show larger elongation and larger nucleus deformation. However, on soft substrate the thick stress fibers were not observed, therefore, mechanical stress arising from tension in stress fibers are not responsible for the nuclear deformation. We have previously reported that nuclear deformation in MDCK cell under shear stress is mediated by intracellular Ca^{2+} that increases through activation of Piezo1 channels [8].

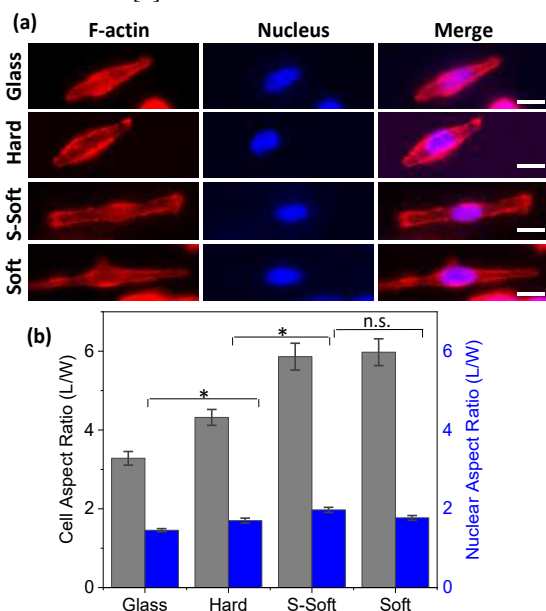

Figure 2. Nuclear deformation coincides with cell elongation. Images of actin (red) and nuclei (blue) in cells grown on micro-stripes on different substrates, showing soft substrate caused larger cell and nuclear deformation. Scale bar = $20 \mu\text{m}$. (b) Statistical analysis of cell elongation and corresponding nuclear deformation ($n = 40$ for hard and semi-soft substrates; $n = 30$ for glass and soft substrates. $*p < 0.005$).

Role of Piezo1 in cell response to substrate confinements

MDCK cells endogenously express mechanosensitive Piezo1 channels. To investigate the role of Piezo1 in cell elongation, we targeted Piezo1 miRNA to knockdown Piezo1 (PIKD). Cells were transfected with Piezo1 miRNA and co-expressed with EGFP to verify transfection (Fig. 3a). Knockdown of Piezo1 significantly reduced the elongation on patterns on glass substrate (Fig. 3b). The mean elongation of PIKD cells was ~ 2.5 , that was 40% lower than nearby control cells. The statistical analysis shows consistent results (Fig. 3c). This result shows that Piezo1 mediated Ca^{2+} uptake participated in the cell elongation on hard substrate, which is consistent with our previous findings [3]. Our recent results show that inhibiting Piezo1 only reduced the stress fibers, however, it did not alter the cell shape (data not shown). It suggests that different stiffness may activate different mechanisms for MDCK cell elongation.

Figure 3: Elongation of Piezo1 knockdown cells. (a) MDCK cells expressing miRNA that target *Piezo1* (green). (b) Elongation of control cell (left) and PIKD cell (right), showing that Piezo1 knockdown significantly reduced elongation. Scale bar = $20 \mu\text{m}$. (c) Mean cell elongation in PIKD and control, showing Piezo1 knockdown reduced elongation by 40% (Control: $n = 29$; PIKD: $n = 14$, $*p < 0.005$).

DISCUSSION

MDCK cells elongate on micropatterned stripes, the cell response depends on the substrate stiffness. Cells showed maximal elongation on the soft substrate compared to stiffer ones. Nuclear deformation coincides with the cell elongation. It has been reported that mechanical confinements change tension in actin stress fibers, causing changes in cell shape and nuclear deformation [5, 7]. Our results show that the cytoskeleton tension may not be responsible for deformation, depending on the substrate stiffness. On stiffer substrates, Piezo1 mediated Ca^{2+} uptake may cause increase in myosin contractility and cytoskeletal tension resulting in cell expansion. On soft substrates, stress fibers were reduced significantly, cytoskeleton may only serve as guidelines for cell adhesion. Epithelial cells utilize different force transmission mechanisms in response to varying local stiffness.

INTRODUCTION

Coarctation of the aorta (COA) is one of the most common congenital heart defects. It is characterized by a narrowing in the aortic arch or proximal descending aorta. Treatment procedures for COA include surgery, intravascular stent placement, and balloon angioplasty. However, the selection criteria for the optimal treatment strategy are not well defined, and interventionalists often rely on their preference rather than patient-specific conditions [1]. 1 in 3 COA patients have post-interventional secondary complications [2], likely due to suboptimal treatment.

4D Flow MRI is a diagnostic imaging technique capable of measuring time-resolved 3D blood velocities within a volumetric acquisition region. Numerous studies have used 4D Flow MRI to evaluate patient-specific blood flow information in COA [3-4]. 4D Flow MRI has high potential to be used as a tool for treatment planning, however, imaging on its own provides no predictive capabilities. Image-based computational fluid dynamics (CFD) can be used to complement medical imaging, such as virtually testing and simulating interventions [5]. A major challenge hindering image-based CFD from achieving widespread clinical adoption is its high computational cost. This calls for reduced order modeling strategies.

A distributed lumped parameter (DLP) model of blood flow was recently published by Mirramezani and Shadden [6]. The results of the DLP model were consistent with CFD. However, to our knowledge, the DLP model has not been compared against in-vivo 4D Flow MRI. The aim of this study was to compare hemodynamic flow rates from the DLP model against in-vivo 4D Flow MRI in COA patients.

METHODS

In-vivo 4D Flow MRI was performed in two male pediatric patients before and after COA repair following an IRB-approved HIPAA-compliant protocol. Patient 1 was 10 and 12 years old during the two scans, and Patient 2 was 4 and 12 years old during the two scans.

The thoracic aorta was segmented, and centerlines were generated using semi-automatic software Mimics (Materialise NV, Leuven, Belgium). Flow rates at the ascending aorta (AAo), brachiocephalic (BCA), left common carotid (LCCA), left subclavian arteries (LSA), and descending aorta (DAo) were obtained using EnSight (Ansys, Inc., Canonsburg, PA, USA).

Most image-based CFD models use medical imaging to define the geometry and numerically solve the 3D incompressible Navier-Stokes equations. The DLP model formulates the mass and momentum conservation as ordinary differential equations (ODEs) in terms of cross-sectionally averaged pressure $P(x, t)$ and volumetric flow rate $Q(x, t)$, where x denotes the axial coordinate along a given vessel and t is time. Conservation of momentum yields

$$\left(\frac{\rho}{\pi} \int_0^L \frac{1}{R(x)^2} dx \right) \frac{\partial Q}{\partial t} + \mathcal{R}Q + \Delta P = 0 \quad (1)$$

where ρ is fluid density, $R(x)$ is vessel radius, L is the length of the vascular segment, and \mathcal{R} is a resistance. Mirramezani and Shadden [6] explains how to implement \mathcal{R} as a function of viscous dissipation, curvature, expansions, bifurcations, and unsteadiness.

The flow rate in the AAo was imposed as the inlet boundary condition and 3-element Windkessel model was set as the outlet boundary conditions. The DLP model was implemented on MATLAB where the resistance \mathcal{R} was calculated for each patient case (pre- and post-repair). The system of ODEs (Equation 1) was solved using the Levenberg-Marquardt algorithm. The DLP model calculated the flow rates at the four outlets (BCA, LCCA, LSA, DAo) and these were compared against the in-vivo 4D Flow MRI data.

RESULTS

A total of four 4D Flow MRI scans were performed. Figure 1 shows the velocity contour during peak systole of the in-vivo data at peak systole.

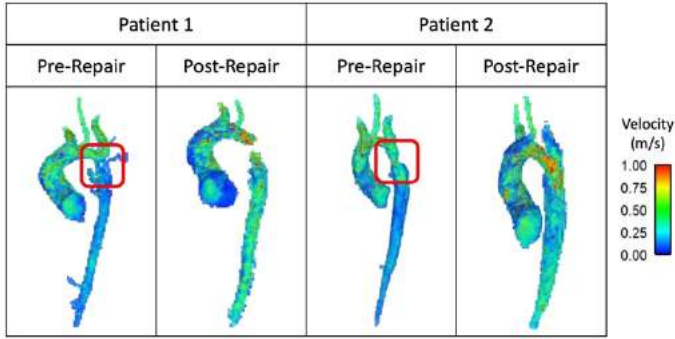

Figure 1: Peak systolic velocity contours from in-vivo 4D Flow MRI. Coarctations in red boxes.

The luminal narrowing (in red boxes) in the descending aorta caused by COA can clearly be seen in both patients' aorta pre-repair. Patient 1 underwent stenting, and the stent was not visible in the 4D flow MR images due to signal loss as a result of susceptibility effects caused by the stent material. Patient 2 underwent surgical repair.

For each patient case, the DLP model was successfully executed. Figure 2 shows the blood flow rates from the DLP model and 4D Flow MRI in the DAo of Patients 1.

Figure 2: Flow rates in the DAo from DLP model and 4D Flow MRI for Patient 1 pre-repair (left) and post-repair (right).

Table 1: Flow rates (mL/s) at outlets over one cardiac cycle

Patient 1					
Pre-repair	4D Flow MRI	DLP Model	Post-repair	4D Flow MRI	DLP Model
BCA	31.2	5.5	BCA	5.1	12.5
LCCA	3.2	12.4	LCCA	3.3	5.7
LSA	13.2	28.5	LSA	N/A	18.7
DAo	22.3	40.5	DAo	40.6	28.3
Patient 2					
Pre-repair	4D Flow MRI	DLP Model	Post-repair	4D Flow MRI	DLP Model
BCA	16.7	14.1	BCA	14.5	13.8
LCCA	3.9	6.4	LCCA	2.7	4.7
LSA	6.1	20.6	LSA	8.3	27.0
DAo	23.5	32.2	DAo	51.6	51.7

By visual inspection, flow curves from the DLP model matched closer to the in-vivo 4D Flow MRI data post-repair compared to pre-repair. The flow rates in the BCA, LCCA, LSA, and DAo were calculated for all four patient cases over one cardiac cycle. These values are given in Table 1.

The average flow rate in the ascending aorta over one cardiac cycle was approximately 70 mL/s. Previous 4D Flow MRI studies have shown a 10% flow rate discrepancy using mass conservation analysis [7]. Therefore, we categorized < 7 mL/s difference between in-vivo and DLP model flow rate to be good agreement (green), between 7 and 10 mL/s to be moderate agreement (yellow), and > 10 mL/s to be poor agreement (red). All DLP models ran in less than 5 minutes, which is significantly faster than standard image-based CFD simulations.

DISCUSSION

Overall, we conclude that the flow rates calculated using the DLP model agreed moderately with in-vivo 4D Flow MRI in COA patients. We made several assumptions in our DLP model implementation. Due to the lack of pressure data from catheterization, we assumed normal aortic pressures (120/80 mmHg) at each outlet. This could be the reason the DLP model performs poorer in patients pre-repair because COA stenosis exhibits higher blood pressure. Temporal resolution of 4D Flow MRI was not sufficient to reliably measure patient-specific pulse wave velocities. Therefore, we assumed pulse wave velocity to be 7 m/s [8] when calculating the Windkessel parameters. To our knowledge, this is the first attempt at comparing the novel DLP model against in-vivo 4D Flow MRI. Additional patient-specific measurements are warranted to better understand model versus 4D Flow MRI differences and improve agreement between methods.

The DLP model of blood flow is an attractive method for modeling hemodynamics. Particularly when flow rates and pressure drops need to be calculated quickly, this DLP model has potential to outperform CFD. In the future, methods for imposing patient-specific boundary conditions should be investigated, and validation studies with in-vivo datasets need to be performed. Despite significant reduction in simulation times, we still envision 3D CFD as the standard tool in studying wall shear stress or turbulence.

INTRODUCTION

Aortic aneurysm is a life-threatening pathology requiring immediate intervention. In absence of upstream symptoms, a better analysis of the causes and mechanisms leading to this abnormal dilatation of the aorta wall would support prevention and reduce preemptive surgery. In particular, Smooth Muscle Cells (SMCs) play an active role in maintaining mechanobiological homeostasis in the healthy aorta wall and the dysfunction of their contractile phenotype was established in case of aortic aneurysm [1]. Because SMCs change their mechanical behavior depending on the extracellular environment, a neat understanding of the biological, chemical and mechanical interactions occurring between the cells and their environment is clearly needed.

Traction Force Microscopy (TFM) is an *in vitro* method apprehending cell mechanoregulation, measuring traction forces between the cell and the extracellular matrix [2]. Initially performed on single cells grown on a hydrogel surface, research is now heading toward 3D models with embedded cells [3], [4] to better describe the *in situ* cell-matrix interface. However, the matrix itself can induce phenotypic transitions for SMCs.

There is still a pressing need for adapting hydrogel to host SMCs, maintain their contractile phenotype and measure their traction forces using TFM. Thus, the objectives of this study were 1/ to assess how SMCs behave when they are embedded in collagen hydrogels with variable microstructure, chemical composition and mechanical properties, 2/ to design a hydrogel where embedded SMCs keep a contractile phenotype for future TFM applications.

METHODS

Twelve chemically different hydrogels were prepared from a 10 mg/ml bovine Type I collagen solution (TeloCol-10, Advanced Biomatrix) varying the collagen solution dilution (from 2.5 to 10 mg/ml) and the pH (from 7.4 to 8 to allow cell viability). Solutions were prepared on ice to prevent early gelation, mixing 8 parts of collagen

dilution, 1 part of PBS 10X (Fisher, US), pH-corresponding NaOH volume and completed to 10 parts with basal medium (SmBM, Lonza).

Primary aortic SMCs (AoSMC, Lonza) were cultivated in growth medium (SmGM-2, Lonza) at 37°C with 5% CO₂. Cells at passage P10 were then detached (0.025% Trypsin, Sigma) and gently mixed with the hydrogel solutions at three cellular densities (from 50 000 to 150 000 cells/ml) thus reaching 16 different seeded hydrogels. The confection of the seeded hydrogels matched a Design Of Experiment (DoE) using a modified L16 orthogonal array [5]. Each seeded hydrogel was reproduced three times.

Hydrogels were formed at 37°C for 1h before immersion in basal medium. Embedded cells differentiated for 5 days. Then, cell nuclei and actin fibers were stained by fluorochromes, and imaged with confocal microscope (Axio Observer Z1 station, Zeiss). In each hydrogel, three volumes of interest (0.90 mm x 0.67 mm) were defined at three different locations near the center of the well, along the whole gel thickness (~1mm) (Figure 1). There, the number of observed nuclei was reported. Based on the observations, cells were sorted into five phenotypes based on their length and form: uniaxial cell length <100µm and >100µm, multiaxial cell length <100µm and >100µm, and round.

The 12 hydrogel compositions used before were also mechanically tested. The acellular hydrogel viscoelastic behaviors were characterized with a stress-controlled rheometer (Discovery HR 2, TA Instruments) with 15mm plate-plate geometry at 37°C in oscillatory uniaxial compression and shear at frequencies in the range 0.1-10.0 Hz.

Figure 1: Acquisition of the cell images in the collagen hydrogel (pink) by fluoroscopy. Three acquisitions per gel were made using blue (465 nm) and red (673 nm) channels.

RESULTS

Cells showed great diversity of behaviors among the 16 tested combinations. The overall number of cells in a hydrogel significantly depended on the collagen concentration ($p < 0.001$, Kruskal-Wallis test). Stable at low concentrations, the mean cell number reduced by a factor 2 from 5 mg/ml to 10 mg/ml.

The number of round cells was only significantly impacted by the collagen concentration of the hydrogels ($p = 0.004$, ANOVA 1-way), with a sudden increase for 10 mg/ml.

In vivo, the SMC contractile phenotype manifests with an elongated (length $> 100 \mu\text{m}$) uniaxial cell. The fraction of such elongated cells increased when the initial cell density increased ($p = 0.008$, ANOVA 2-ways) and when the collagen concentration decreased ($p = 0.001$, ANOVA 2-ways). Their average length ranged between 132 and 244 μm , depending on the seeded hydrogel. Only the initial cell density seemed to significantly affect this length ($p = 0.011$, ANOVA 1-way).

Using the DoE approach, we found that a collagen hydrogel concentrated at 2.5 mg/ml with a pH=8, and seeded with 100 000 cells/ml offers the maximum fractions of contractile SMCs and seems well suited for TFM investigations.

Oscillatory shear tests revealed a predominant elastic behavior for all hydrogels. The shear storage and loss moduli of each hydrogel had parallel variations across the frequency range (Figure 2). The storage modulus approximated Coulomb's modulus at low frequency and ranged between 0.05 and 3 kPa. It increased with the collagen concentration ($p = 0.037$, Kruskal-Wallis test). Conversely, oscillatory compression exhibited storage and loss moduli intersecting at various frequencies depending on the hydrogel. Variations of behavior in between hydrogels were observed, with a general increase of storage modulus at the lowest frequencies. At low frequencies, the storage modulus ranged between 0.03 and 7 kPa.

DISCUSSION

Our study showed that SMCs embedded in a collagen hydrogel may have different behaviors and phenotypes depending on the collagen hydrogel composition. Collagen concentrations above 5 mg/ml tend to induce significant rates of cell death. Dense hydrogel meshes could limit the diffusion of nutrients and cell respiration from the surface to the center of the gels. Thus, only the cells at the surface of the gels could grow and differ as observed in some 10mg/ml collagen hydrogels. Conversely, low-concentration collagen hydrogels tend to induce SMC contractile phenotype more homogeneously distributed. Sufficient initial cellular densities also seem to be crucial to induce a high fraction of SMC contractile phenotype, as they enable sufficient interactions and communication between cells. For TFM applications, an optimal initial cellular density would provide the largest fractions of contractile SMCs while avoiding cell-cell contact.

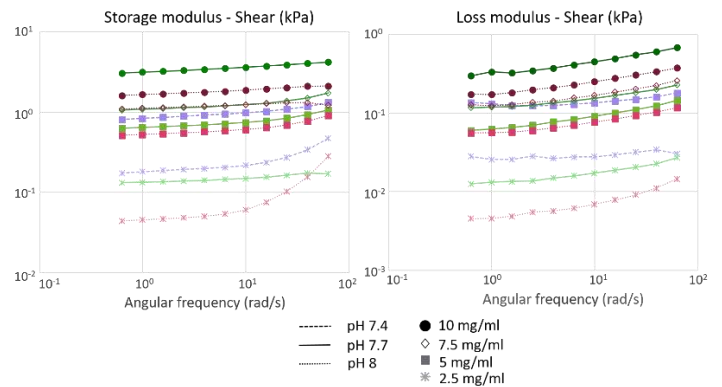

Figure 2: Variations of storage and loss moduli in parallel plates shear oscillations. The pH (line types) and concentration of collagen (symbols and brightness) varied among the hydrogels.

The acellular hydrogels demonstrated a viscoelastic behavior in shear and in compression. The hydrogel mechanical properties play a crucial role in the SMCs mechanobiology. First, SMCs adapt their basal tone to the changes of extracellular matrix stiffness [1], [6]. The cell contractibility also changes depending on the strain perceived by the cell membrane [6]. Thus, the design of an *in vitro* model for SMCs behavior study requires the management of the hydrogel properties. The difference of viscoelastic response observed between compression and shear suggested that hydrogels had a less isotropic fibrillary organization or a difference in cross-link point density along the axial axis. This supported the necessity to study embedded SMCs traction forces with 3D TFM in order to assess potential force heterogeneity.

Our study has a number of limitations such as the high passage number of the SMCs and the uncertainties of volumes during hydrogel preparation because of collagen high viscosity. Each was either controlled either taken into consideration in the DoE. Moreover, SMC phenotype was simply characterized based on the shape and length of the cells, but we will consider other markers (alpha-actin and myosin) in the future.

In conclusion, a hydrogel was designed to serve as a 3D *in vitro* model for the study of SMCs mechanobiology and their interactions with a collagen matrix. Future work will include the quantification of SMCs basal tone with 3D TFM and the analysis of their mechanobiological response to matrix loading.

INTRODUCTION

Recent evidence suggests that near-wall as well as intravascular hemodynamics are of pivotal importance in the onset and progression of atherosclerosis at the carotid bifurcation [1,2]. In detail, helical flow has been associated with *in vivo* markers of early atherosclerosis [1], and a 5-year longitudinal study has shown that intra-cycle variability of the wall shear stress (WSS) topological skeleton (i.e., contraction/expansion action on the endothelium) is associated with intima-media thickening after carotid endarterectomy [2]. However, all those studies relied on computational fluid dynamics (CFD) modeling under the rigid wall assumption. Here, the effect of wall distensibility on these emerging features of the carotid bifurcation hemodynamics is explored by implementing fully coupled two-way fluid-structure interaction (FSI) simulations accounting for prestress of the arterial wall, anisotropic material properties, and external tissue support. Furthermore, the relationship between hemodynamic and structural quantities is explored.

METHODS

The diastolic volumetric fluid domains of five ostensibly healthy carotid bifurcations were reconstructed from contrast-enhanced magnetic resonance (MR) angiography, including at least 15 radii of the proximal common carotid artery (CCA) [1]. The carotid structural domains were generated with constant subject-specific thickness derived from edge-enhanced black blood MR images. Subject-specific volumetric flow rates were extracted from phase-contrast MR measurements [1] and prescribed as boundary condition at the CCA inflow section. A 3D-0D coupling scheme was applied at the external and internal carotid artery (ECA and ICA) outflow sections with three-element Windkessel models tuned to match subject-specific measured flow splits and age-adjusted pressure curves [3]. On each geometry, FSI and CFD simulations were carried out using Simvascular [4]. For the

FSI simulations, the arbitrary Lagrangian-Eulerian formulation was used [4]. The anisotropic nonlinear Holzapfel-Gasser-Ogden model was implemented to simulate the wall mechanical properties accounting for the presence of two families of collagen fibers aligned along two directions $\hat{\mathbf{a}}$ and $\hat{\mathbf{b}}$, according to the following strain energy function:

$$\bar{\Psi} = \frac{\mu}{2}(\bar{I}_1 - 3) + \frac{k_1}{2k_2} \sum_{j=4,6} [e^{k_2[\kappa \bar{I}_1 + (1-3\kappa)\bar{I}_j - 1]} - 1] \quad (1)$$

where μ is the isotropic matrix shear modulus, $\bar{I}_1 = \text{trace}(\bar{\mathbf{C}})$, $\bar{I}_4 = \hat{\mathbf{a}} \cdot \bar{\mathbf{C}} \cdot \hat{\mathbf{a}}$ and $\bar{I}_6 = \hat{\mathbf{b}} \cdot \bar{\mathbf{C}} \cdot \hat{\mathbf{b}}$, with $\bar{\mathbf{C}}$ being the isochoric right Cauchy-Green tensor, $\hat{\mathbf{a}}$ and $\hat{\mathbf{b}}$ are the fiber orientation unit vectors obtained from the directions $\hat{\mathbf{e}}_1$ and $\hat{\mathbf{e}}_2$ of the principal stresses σ_1 and σ_2 , k_1 and k_2 are stress-like and dimensionless nonlinearity parameters respectively, and κ accounts for the dispersion of each fiber family around its principal direction. The material parameter values proposed in [5] by fitting experimental data were adopted. The fiber orientations were determined from the initial loading state [5]. To do so, the so-called prestress tensor was iteratively obtained by balancing diastolic intraluminal blood pressure from CFD simulations until zero displacement is obtained [4], as illustrated in Fig. 1. Viscoelastic support of the tissue surrounding the carotid outer wall was accounted for by imposing a Robin-type boundary condition [4]. For the purpose of comparison, rigid wall CFD simulations were carried out with the same fluid mesh and simulation settings as in FSI simulations. Maximum edge sizes of the tetrahedral radius-based meshes were 0.17 mm (fluid domain) and 0.39 mm (solid domain).

In addition to the canonical time-average WSS (TAWSS) and oscillatory shear index (OSI), the variability of the WSS contraction/expansion action along the cardiac cycle was quantified by the topological shear variation index (TSVI) [2], defined as:

$$\text{TSVI} = \left\{ \frac{1}{T} \int_0^T [\text{DIV}_w - \overline{\text{DIV}_w}]^2 dt \right\}^{\frac{1}{2}} \quad (2)$$

where DIV_w represents the divergence of the normalized WSS vector field [2] and T is the duration of the cardiac cycle. Data from all cases were pooled to identify the 20th percentile value of TAWSS and 80th percentile values of OSI and TSVI. These threshold values were used to obtain the burden of disturbed WSS by quantifying the relative surface area (SA) exposed to TAWSS below (OSI, TSVI above) the corresponding threshold value. Analogously, wall regions exposed to elevated structural stress and strain were obtained by calculating the 80th percentile of the cycle-average maximum principal stress (σ_1) and strain (ϵ_1) at the fluid-solid interface. The Similarity Index (SI, here defined as two times the SAs intersection over the SAs union) was adopted to quantify the co-localization of hemodynamic and structural quantities [1]. The intravascular flow was characterized in terms of cycle-average local normalized helicity (LNH) and helicity intensity h_2 , given by the cycle- and volume-average of the norm of the internal product of velocity and vorticity [1]. The bifurcation region was delimited by sections CCA3, ICA5 and ECA2 (Fig. 1).

Figure 1: Prestress iterations (left panel) to determine fiber directions (right panel) and the initial loading state.

RESULTS

FSI simulations provided average values of luminal area variation at the CCA3 of $14.5\% \pm 3\%$, consistent with in vivo measurements [6]. TAWSS, OSI, and TSVI distributions were comparable in distensible vs. rigid wall simulations, both qualitatively (Fig. 2; TAWSS and OSI not shown) and quantitatively (surface-averaged TSVI values $305.1 \pm 141.0 \text{ m}^{-1}$ vs. $313.1 \pm 172.4 \text{ m}^{-1}$, respectively). Counter-rotating helical flow patterns characterized the flow field of all models, as highlighted by LNH isosurfaces of opposite signs (Fig. 2). Rigid wall models were characterized by higher h_2 values (Fig. 2).

Maximum values of both σ_1 and ϵ_1 were localized at the apex of the bifurcation (Fig. 3). SI values for the couplets of hemodynamic and structural quantities are reported in Table 1. The highest co-localization was found between σ_1 and OSI or TSVI ($\text{SI}=0.55$, Table 1). Low SI values were found between low TAWSS and high σ_1 or ϵ_1 regions. SI values between high σ_1 and ϵ_1 regions were 0.88 ± 0.07 .

DISCUSSION

The near-wall and intravascular hemodynamic quantities investigated here were only moderately affected by wall distensibility. Thus, the rigid wall assumption seems to be acceptable when linking the considered emerging hemodynamic features and atherosclerosis initiation at the carotid bifurcation. Considering the increased complexity, cost, and inherent introduction of additional uncertainties to model wall distensibility, our findings suggest that rigid wall CFD

modeling might be considered reasonable in view of a future clinical translation. With that said, the implemented FSI approach allows exploring the synergistic action between hemodynamic stresses on the endothelium and wall structural stress [7], potentially uncovering distinct or synergistic effects of these biomechanical stimuli on atherosclerosis initiation.

INTRODUCTION

Bicuspid aortic valve (BAV) disease is the most common form of congenital valve defect present in 2-4% of the general population [1]. Calcific aortic valve disease (CAVD) is the progressive formation of calcium nodules within the tissue causing stiffening of the valve and aortic stenosis [2]. Currently, the only treatment for aortic stenosis is valve replacement where ~50% of patients with CAVD also have BAV disease [2]. Historically, BAV patients with aortic stenosis have been treated with surgical aortic valve replacement. However, in recent years clinicians have been transitioning to transcatheter aortic valve replacement (TAVR) in BAV patients due to fast patient recovery times and TAVR for low surgical risk tricuspid aortic valve patients showing similar results to surgery [3].

Stent under expansion and non circularity occur to varying degrees following deployment and have been correlated to poor hemodynamic outcomes [4-6]. Under expansion and non circularity are more of a concern in BAV patients due to their higher calcium volume on average and elliptical openings. Currently, it is unclear if fracturing the calcium nodules allows for increased stent expansion by lowering the resistance of the native valve. Additionally, it is unknown if intentionally over expanding the balloon beyond the nominal amount would expand the device closer to intended nominal values. The goal of this study is to determine if calcium fracture or balloon over expansion results in increased stent expansion and stent circularity.

METHODS

BAV patients treated with the Edwards SAPIEN 3 balloon-expandable device with both pre and post TAVR CT scans were analyzed (n=8). From the pre TAVR CT, the aortic valve (with leaflets and calcium), left ventricle, and ascending aorta were reconstructed in Materialise Mimics 23.0 (Leuven, Belgium) (**Figure 1A**). From the post TAVR CT, the TAV stent and calcium were reconstructed and the minimum and maximum diameter at the inflow, waist, and outflow was measured (**Figure 1B**).

The amount of stent expansion was assessed by calculating the expansion ratio which was defined by the ratio of the measured diameter derived area to the nominal area at the inflow, waist, and outflow (**Eq. 1**). The amount of stent non-circularity was assessed by calculating the aspect ratio defined by the ratio of the minimum to maximum diameter (**Eq. 2**). Any noticeable regions of calcium fracture were identified via qualitative comparison to the pre TAVR calcium reconstruction.

$$\text{Expansion Ratio} = \frac{\left(\frac{\text{Min Diameter} + \text{Max Diameter}}{4}\right)^2}{\left(\frac{\text{Nominal Diameter}}{2}\right)^2} \quad (1)$$

$$\text{Aspect Ratio} = \frac{\text{Minimum Diameter}}{\text{Maximum Diameter}} \quad (2)$$

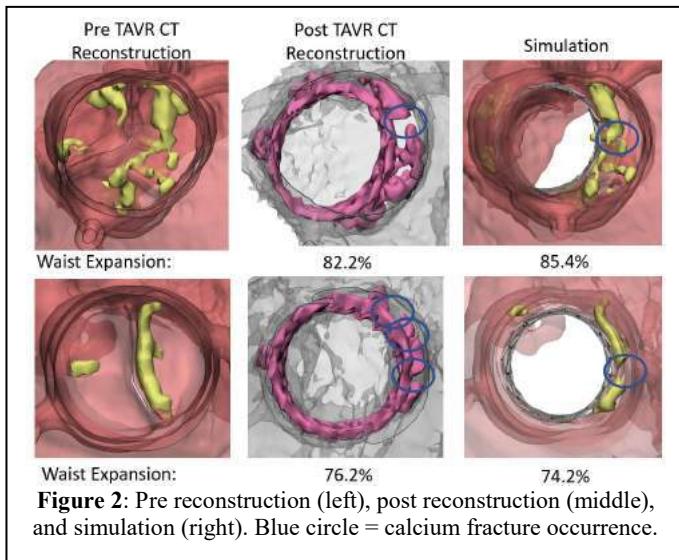

Using a finite element model, a balloon-expandable TAV stent was deployed in the pre TAVR reconstruction for each case (Abaqus, Waltham, MA, USA).

CAD models of the 23, 26, and 29 mm sizes were created from micro CT scans of the SAPIEN 3 Ultra device (Solidworks, Waltham, MA, USA) and meshed ensuring four elements through the thickness with hexahedral elements (Hypermesh, Powell, OH, USA). Balloons were created for each size from measurements taken from the device delivery system and meshed with rectangular membrane elements. Native tissues were meshed with tetrahedral volume elements with 0.7 mm element length. Material properties included the stent being elastic with a plastic yield stress, the balloon being elastic, native soft tissue with hyperelastic Ogden 3rd order, and calcium nodules elastic, all parameters used in previous studies [7-10]. To simulate calcium fracture, a stress fracture threshold was created at 1 MPa where if an element reached the threshold it was no longer mechanically included in the simulation [10, 11]. The stent was rigidly crimped and the balloon was folded using radial and circumferential forces to ensure uniform expansion. The balloon was then filled using a volumetric flow rate to a set end volume, tuned by deploying the device with no native anatomy to the manufacturer specified diameter, then the balloon was deflated.

The stent minimum and maximum diameter at the inflow, waist, and outflow were measured and the incidence and location of calcium fracture was recorded. The expansion ratio and aspect ratio were calculated and compared to the post CT measurements. Two additional simulation scenarios were then performed (1) removal of the calcium fracture threshold and (2) expansion using a balloon 1mm larger in diameter. Both scenarios were compared to the baseline simulation in terms of expansion ratio and aspect ratio in each case.

RESULTS

Patient characteristics included 62.5% female, 50% Sievers Type I and 50% Type 0, 3 patients each had the 23 and 26 mm devices and 2 patients had the 29 mm, and a range of calcium volume from 135 to 1718 mm³. Post CT device expansion ratio was < 100% at all levels in all cases with $90.1 \pm 5.3\%$, $79.9 \pm 4.7\%$, and $94.4 \pm 3.2\%$ averages and standard deviations for the inflow, waist, and outflow respectively. Noticeable calcium fracture was observed in 2/8 cases which were similar in location compared to the simulation (Figure 2).

The average and standard deviation in expansion ratio differences between the post TAVR CT and simulation were $6.72 \pm 3.9\%$, $2.50 \pm 4.5\%$, and $3.73 \pm 2.9\%$ for the inflow, waist, and outflow with a $2.95 \pm$

4.9% difference in waist aspect ratio. All data points had < 15% error indicating reasonable agreement between post CT and simulation. Simulation baseline expansion ratios and aspect ratio are compared to the no calcium fracture scenario and the over expansion scenario (Figure 3). Minimal differences were observed in the absence of calcium fracture with the exception of cases with extreme calcification (all average differences < $\pm 2\%$). Over expansion resulted in consistent increase in expansion with an average waist expansion increase of 13.7% but did not impact waist aspect ratio (-0.5% difference).

DISCUSSION

This study demonstrated a detailed analysis of a group of post TAVR CTs in BAV patients (n=8), validation of a TAV deployment computational model, and investigation of the impact of calcium fracture and balloon over expansion on the overall expansion of the device. Waist expansion was < 90% in 100% of cases and circularity was < 90% in 37.5% of cases. Currently, it is impossible for clinicians to predict the final stent expansion and circularity due to anatomical and procedural biomechanical complexities. Computational modeling has the potential to aid in pre procedural planning demonstrated by its high accuracy (all data points < 15% error). The impact of calcium fracture on the stent expansion was low even in the presence of very large calcium nodules (maximum -4.8% waist expansion difference). Balloon over expansion was found to have a significant increase in the overall device expansion bringing the waist much closer to nominal size, 96.1% compared to the post CT 79.9% waist expansion average. However, did not impact the stent circularity. In conclusion, calcium fracture has a low impact on the stent expansion and circularity in most cases and slight balloon over expansion can avoid significant waist under expansion, common in TAVR for BAV patients.

INTRODUCTION

Magnetic resonance elastography (MRE) is a technique for determining the mechanical response of tissues using applied harmonic deformation and motion-sensitive MRI¹. Performing MRE on human brain can provide information on different structures within brain tissue based on their mechanical properties, which can then be used to diagnose pathologies such as Alzheimer's disease (AD) and dementias, or indicate disease progression²⁻⁶. Studies using MRE to investigate the mechanical properties of the human brain are most commonly performed at conventional field strength (3 Tesla (T) or 1.5T), although there have been a few attempts at the ultra-high field strength, 7T, in an attempt to achieve higher resolution scans. Aiming for higher resolution scans of the human brain at 7T, MRE presents unique challenges of decreased octahedral shear strain-based signal-to-noise ratio (OSS-SNR)⁷ and lower shear wave motion sensitivity. Additionally, it has been shown that quantitative values of MRE, i.e., the magnitude of the complex shear modulus estimate ($|G^*|$), are sensitive to changes in OSS-SNR⁸, so 7T MRE can present a challenge of not only quality, but accuracy.

Performing MRE at 7T, and more specifically at high resolution, proves to be an attractive option for investigations into small brain structures, such as in the progression of Alzheimer's disease. Early diagnosis of Alzheimer's disease is still challenging, because of the subtlety of the microstructural changes it initially causes in the brain and the difficulty of identifying them with traditional neuroimaging techniques such as MRI, PET, or CT scans. Recent evidence has revealed that the neurodegeneration characterizing AD is accompanied by effective tissue softening, which can be quantified *in vivo* using MRE²⁻⁶. However, MRE at conventional field strengths has a resolution limitation in studying finer microstructure details, such as hippocampal subfields, that are important in the investigation of AD tissue microstructure. *Overall, this work seeks to investigate advanced reconstruction and noise reduction techniques to improve accuracy of*

ultra-high field (7T) MRE in determining the mechanical properties of small brain tissue structures, with applications in aging and early detection of dementias.

METHODS

Full brain coverage MRE using our custom 2D multi-slice SE-EPI 7T MRE pulse sequence^{9,10} was performed on twenty healthy human subjects (young adults, Avg. Age 26.9±3.4 years) at 1.1mm³ isotropic resolution at 50Hz vibration frequency, using a 32-channel head coil (Nova Medical) on a 7T Siemens Magnetom MRI Scanner. Using the same methods, MRE was also performed on a custom silicone MRE phantom (CIRS 049)⁹ with 20mm diameter spherical inclusions. The custom MRE sequence was synchronized with our custom pneumatic acoustic actuator^{9,11} by TTL triggering at the beginning of every TR (TR/slice=140ms, TE=65ms, GRAPPA=3, Partial Fourier=7/8). We also performed 7T MRE on our phantom at an isotropic resolution of 2.5mm³ for comparison (GRAPPA=2).

For the scanner-reconstructed image series, we employed the MP-PCA denoising¹² and our Algebraic Inversion of the Helmholtz Equation (AIDE) to calculate $|G^*|$ ¹⁰. To improve the default scanner reconstruction method, we used Gadgetron¹³, an open-source MRI image reconstruction software, on the raw data files to generate magnitude and phase images before performing the same pre-processing and inversion method. We also calculated OSS-SNR⁷ after

Figure 1: Custom Phantom with Spherical Inclusions Scanned at 7T Using Low and High Resolutions

Figure 2: (a) High resolution Elastograms and OSS-SNRs with Advanced Reconstruction methods in One Young, Healthy Subject. (b) Average $|G^*|$ for Young Adults, CN, and CD individuals in all Segmented Brain Regions (* $p < 0.05$, ** $0 < 0.01$)

each post-processing method after performing SEGUE¹⁴ unwrapping on the displacement fields. Segmentation of whole brain (WB), all gray matter (GM), all white matter (WM), the Entorhinal Cortex (EC), Frontal Lobe (FL), Parietal Lobe (PL), Temporal Lobe (TL), and Hippocampus (HC) were performed on the MP2RAGE T1scans (0.7mm³) using Freesurfer¹⁵ and were co-registered using SPM¹⁶. Differences between WB post-processing groups were analyzed using a one-way, repeated measures ANOVA with multiple comparisons.

Using the previously described 1.1mm³ 7T acquisition, denoising¹¹, advanced reconstruction, and segmentation, full brain coverage 7T MRE was performed on six human subjects that presented with cognitive deficits (CD, Avg. age 75.8 ± 6.5 years) and nine age-matched ($p > 0.10$) subjects with normal cognition (CN, Avg. age 69.0 ± 8.0 years). In our CD group, two subjects have previously been diagnosed with AD, two have been diagnosed with mild cognitive impairment, and two had no specific diagnosis. Average $|G^*|$ of each brain region listed were compared between CD and CN, and CN and young adult groups using one-tailed, unequal variance, t-tests.

RESULTS

Using our phantom as validation of accuracy and as a rationale for using ultra-high resolution MRE to investigate small brain regions, the calculated shear stiffness values are within the manufacturer's specified range (1.67 ± 0.33 kPa) at both 2.5mm³ (1.43 ± 0.01 kPa) and 1.1mm³ resolutions (1.42 ± 0.01 kPa). However, at 2.5mm resolution, the inclusion (specification 2.67 ± 0.33 kPa) is not in the correct range at a mean of only 1.77kPa, but is in the correct range at 1.1mm resolution at a mean of 2.39kPa (Figure 1).

Investigating the advanced post-processing techniques on the 20 young healthy human subjects, we observed a whole-brain average 127% significant increase in OSS-SNR using just denoising and a 375% significant increase using both advanced reconstruction and denoising. Using advanced reconstruction, we observed the removal of artifacts introduced by scanner reconstruction error (Figure 2a). Investigating differences between CN and CD groups in regional averages of $|G^*|$, we observe a significant decrease in $|G^*|$ in each brain region apart from the EC (12.6% decrease in WB*, 13.0% in GM*, 14.8% in WM*, 19.1% in FL*, 15.0% in PL*, 19.6%** in TL, and 17.9% in HC**); * $p < 0.05$; ** $p < 0.01$; Figure 2b). Additionally, we observe a significant decrease in $|G^*|$ between young adult and CN groups in WB (12.5%*), GM (11.6%*), WM (16.8%*), TL (11.4%**), and HC (20.6%**), simply due to the effect of aging (* $p < 0.05$; ** $p < 0.01$; Figure 2b).

DISCUSSION

Overall, in this work we successfully developed and implemented high resolution MRE at ultra-high field (7T) to determine the mechanical properties of small brain tissue structures, showing

regional differences in brain stiffness in subjects with cognitive deficits. Our initial phantom validation experiments clearly indicate the motivation for use of high resolution MRE in investigating small structures with accuracy, achieved using 7T. Additionally, we can achieve sufficiently high OSS-SNR for accurate quantification at this high resolution by using both denoising and post-hoc advanced reconstruction, as denoising removes thermal and gaussian noise while advanced reconstruction removes errors caused by the scanner reconstruction. Noise reduction in the case of scanning subjects with cognitive deficits is of particular importance, as it also allows us to keep the scan time relatively short.

Using these advanced techniques and high resolution allows us to observe differences in smaller brain structures than previous studies, and with a higher level of accuracy. Previous investigations at courser resolutions (3mm³ or 2.5mm³)^{2,3,5,6} typically only investigate larger regional or WB differences between groups, or report particularly low values of smaller regions such as HC⁶ compared to what is reported in this study. A more recent study using a slightly higher resolution (1.6mm³) reported changes in individual lobes of HC in subjects with AD⁴, which can likely be further observed with our ultra-high resolution. This more accurate information on smaller structures will allow us to better investigate neurodegeneration effects or other relevant brain disorders, e.g. traumatic brain injury, *in vivo*.

Our study has several limitations that need to be addressed as analysis continues. First, a more robust inversion algorithm, such as nonlinear inversion¹⁷ would benefit the high-resolution scan, resulting in even more detail. Additionally, individual corrections for changes in brain volume, age, and sex would allow for more accurate comparison between groups. Finally, this study has a relatively small sample size of individuals with CD, although recruitment is still ongoing.

VALIDATION OF STEERING WHEEL FORCES AND UPPER EXTREMITY LOADING DURING REAR-END COLLISIONS USING MADYMO

Dominic R. Demma (1), Stephanie M. Rossman (1), Nicole A. Johns (1), Steven A. Rundell (1)

(1) Explico Inc., Novi, MI, USA

INTRODUCTION

Rear-end collisions (RECs) are the largest portion of reported crash incidents in the United States. RECs with a change in velocity (delta-V) below 15 kph generally report minor, or no injuries at all [1]. Nevertheless, complaints of more serious injuries resulting from generally lower severity RECs continue to persist and require further investigation.

One injury type that remains scarcely discussed in the context of RECs is shoulder injuries. Lucas, et al (2009) began a discussion analyzing the potential for acromioclavicular (AC) and coracoclavicular (CC) ligament injuries in low-speed RECs [2]. This study used kinematic data collected via video during physical rear-end crash tests to mathematically calculate the resulting loads at the AC and CC ligaments and compared them to reported failure forces. Lucas, et al. concluded that the kinematics associated with a REC are not likely to result in injury to these ligamentous structures. However, this study did not directly measure upper extremity loads. Furbish, et al (2011) [3] conducted full-scale, rear-end crash tests, and directly measured the steering column loads resulting from the volunteers' grip on the steering wheel.

The objective of the current study was to develop and validate a computational occupant dynamics model that measures upper extremity loading during RECs by accurately predicting loading in the steering wheel column. We hypothesized that the computational model could accurately predict steering wheel column loads and therefore quantify the reaction loads acting at the occupant's upper extremity. Furthermore, the upper extremity loading experienced during low-speed RECs was hypothesized to be consistent with loads experienced during ADLs and generally non-injurious activities.

METHODS

Simulation Setup. Furbish et al. included 7 male subjects (average height 1.70 m and weight 91.6 kg) who were submitted to RECs with

delta-V's ranging from 8.5 to 11.6 kph (average 9.1 kph). Each subject experienced multiple, full-scale, rear-end crash tests as the driver of a 1996 Ford Taurus. For the purposes of this study, only subjects that maintained both hands on the steering wheel were evaluated. The steering column load time-histories reported for these subjects were digitized using Web Plot Digitizer (v4.2). These time-histories were averaged, and corridors (± 1 SD) were created.

A validated, scalable 50th Percentile Male Hybrid III (HIII) ellipsoid model from MADYMO (Siemens v.2020.1) [4] was scaled to the average subject anthropometry and placed into a virtual vehicle sled with geometry representative of a 1996 Ford Taurus. A publicly available REC sled test of an exemplar vehicle was used as a reference for positioning the virtual occupant.

The steering wheel-column was tilted to a position of 18 degrees above the horizontal, as reported in Furbish et al, and was positioned within the virtual subject's reach consistent with a normal driving position. A loadcell was positioned at the kinematic joint connecting the steering wheel to the steering column and the steering column was attached directly to the vehicle sled joint. The loadcell was oriented in accordance with Federal Motor Vehicle Safety Standard 203 and the steering wheel was given a mass of 4.3 kg. A finite element 3-point belt was added to the simulation in accordance with the documented subjects' restraint use (Figure 1).

Control Test Validation. Furbish et al. (2011) documented a control test in which one subject was seated in the target vehicle without his hands on the steering wheel. This test measured the inertial loading response at the steering wheel. A corresponding simulation was run using the MADYMO model without the HIII's hands tied to the steering wheel. A haversine, forward acceleration was applied to the virtual sled at a delta-V of 10.5 kph and a duration of 80 ms, followed by a triangular deceleration. These vehicle dynamics were designed to match the documented dynamics from prior physical testing [5] and included the immediate deceleration of the vehicle from braking.

Physical Test Validation. The acceleration profile for the control test was modified to represent an average delta-V of 9.1 kph. The hands of the HIII were secured to the steering wheel at clock positions 10-and-2 using restraint points. A triangular force-displacement function was applied to the restraint points that exerted a maximum force of 550 N at a displacement of 7.5 cm. This represents the average male grip strength reported in Young et al. (2009) [6].

Upper Extremity Loading. A series of simulations were conducted using the validated model to quantify the compressive loads experienced by the HIII's upper extremities. Loadcells were added to the HIII wrists to measure hand loads, and the simulations were rerun without subsequent vehicle deceleration. All steering column loads were filtered at CFC 60 and wrist loads were filtered at CFC 1000.

Figure 1: MADYMO build position matched to IHS SER01040 and steering wheel loadcell orientation.

RESULTS

Control Test Validation. The results of the physical control test [3] were compared with the inertial loading seen in the modeled MADYMO steering-wheel column (Figure 2). Qualitatively, the virtual steering-wheel column loadcell mirrors the tension-compression response reported in the control test. Quantitatively, the peak inertial tension recorded in the MADYMO is within 6% of the reported physical test. The results of the control test validation verified that the inertial response of the virtual steering-wheel column loadcell was consistent between the physical and virtual environments.

Physical Test Validation. The corridors along with the average time versus tension-compression response of the steering-wheel column was plotted with the MADYMO model's predictive response in Figure 3. The simulated sinusoidal tension-compression shape of the steering-wheel column loading follows the trends from the physical testing. The maximum compression and tension were within 5.2% and 6.1% of the peak corridors from the physical testing, respectively. The results of the physical test validation verified that the MADYMO model was a robust method for predicting steering-wheel-occupant loading interactions.

Upper Extremity Loading. The compression phase of the HIII hand loads during these tests was plotted alongside compressive hand loads in published activities of daily living (ADLs) and was found to be comparable with generally non-injurious loads (Figure 4). This was consistent with the result of the physical testing that did not result in traumatic injuries to the upper extremities of the subjected occupants.

Figure 2: Inertial steering column loads from the control test compared to the simulation.

Figure 3: Steering-wheel column time vs. tension-compression responses from the physical test compared to the simulation.

Figure 4: Comparing predicted hand loads to ADLs.

DISCUSSION

Results of the current study confirmed our hypothesis that a computational model could accurately predict steering-wheel column loads and be used to quantify the reaction loads acting on an occupant's upper extremity during a REC. The reaction forces experienced by the upper extremities during ADLs and generally non-injurious activity can provide context to the injury potential during a REC event. Specifically, the reaction forces occurring at the volunteer's upper extremities were relatively minimal, which was consistent with a) the lack of reported injuries during the physical testing, and b) the general lack of scientific studies and field data that links the potential for upper extremity injury to RECs.

Future development of this model should consider simulation of the deformation of the seat and belts per the data in Furbish et al. (2011). In the present study, average anthropometry and average time-history response from the physical testing was used. Future work might consider modeling each subject-specific anthropometry and delta-V reported in the study. A future study might also consider a peak strength switch for occupants who lose grip with the steering wheel during a REC. These scenarios may be used to analyze inertial shoulder loads for drivers who do not maintain their grip on the steering wheel.

In conclusion, this experiment was a modeling effort that presents a method to better understand upper extremity loading during low-speed REC utilizing MADYMO. This study also supports the hypothesis that RECs are not a physiologically relevant mechanism to shoulder injuries.

NUCLEAR EXPORT INHIBITION JUMBLES EPITHELIAL-MESENCHYMAL STATES AND GIVES RISE TO MIGRATORY DISORDER IN HEALTHY EPITHELIA

INTRODUCTION

Epithelial-mesenchymal (E-M) gradients support collective cell migration to facilitate normal physiological activities, like embryogenesis and tissue repair, as well as malignant processes, like cancer invasion. At the leading edge of a migrating group, cells exhibiting partial E-M transition (EMT) extend protrusions and apply traction to drive migration. Meanwhile, from behind, more epithelial-like cells supply lower tractions, retaining higher cell-cell adhesions to preserve the collective [1]. This E-M gradient transpires from tactful regulation of transcription factors (TFs) and migration-related proteins [2]. While it is known that these proteins individually promote or inhibit EMT, it is unknown whether opposing factors compete, cooperate, or cancel during the construction of cell phenotypes. To explore this question, we consider that transcription changes from EMT-TFs and related proteins hinge on their nuclear localization. Therefore, we perform nuclear export inhibition (NEI), using leptomycin B (LMB) to co-localize EMT-related proteins in the nucleus. We then survey interactions between opposing EMT factors by assessing changes in E-M cellular traits and collective migration characteristics (*preprint*: [3]).

METHODS

Polyacrylamide gels were synthesized using 4%:0.2% acrylamide:bis-acrylamide to yield 0.5 kPa stiffness, and were coated with type I collagen. MCF10A monolayers were seeded on each gel and treated with 100 nM LMB or 100% ethanol (vehicle) for 24 h. Time-lapse imaging was performed, acquiring phase contrast images every 10 min for 24 h with 10x objective. Particle image velocimetry was used to extract spatiotemporal velocity profiles from time-lapse images of migrating monolayers ($n > 6$). Fixed samples were immunostained for I κ B α , p120, vimentin, and YAP, and phalloidin was used to visualize F-actin. Images were captured using confocal at 40x objective. YAP nucleocytoplasmic ratio was quantified by dividing integrated density of nuclei by that of cytoplasm ($n = 8$). Actin coherency was measured

in OrientationJ ($n > 1000$). Expression of EMT marker genes PTEN and SNAIL1 was measured via reverse transcription quantitative polymerase chain reaction, using established protocols ($n = 12$).

RESULTS

Nuclear localization of I κ B α is an established measure for NF κ B inhibition [4], and junctional expression of p120 reflects the degree of cell-cell adhesion reinforcement [5] (Fig. 1A-i). We found that NEI contributed to higher I κ B α nucleocytoplasmic (N:C) ratios and increased p120 junctional intensity in both leader and follower cells (Fig. 1A-ii). To determine whether other traditionally epithelial markers were affected, we measured expression of the epithelial marker gene PTEN, and found it was upregulated following NEI (Fig. 1A-iii). These findings indicate that NEI reinforces epithelial characteristics. We then assessed mechanoactivation and mesenchymal features. NEI increased vimentin expression, YAP N:C ratio, and actin coherency, while giving rise to leader cells with highly polarized, protrusive morphology (Fig. 1B-i). NEI also elevated expression of the mesenchymal marker gene SNAIL1 (Fig. 1B-ii). Overall, these results indicate that NEI simultaneously enhances epithelial and mesenchymal cellular traits.

Because epithelial cells balance intercellular adhesion and mechanoactivation gradients to facilitate collective movement, we hypothesized that the observed disturbances could interfere with typical patterns of migration. Indeed, results reveal time-dependent changes in migration velocity and order. Previous studies have exclusively shown that NEI inhibits migration; yet, strikingly, on 0.5 kPa, NEI elevated collective migration velocity (Fig. 2A, B). Meanwhile, progressive disorder contributed to the decline of net velocity toward control levels (Fig. 2B, C). These findings depict changes to the conventional patterns of collective migration, where NEI initially promotes migration, while disorder predominates at later timepoints.

Force propagation through adherens junctions is fundamental to collective migration [6]. The protein α -catenin mechanically couples

cells, recruiting F-actin to E-cadherin-based cell junctions. To characterize the role of intercellular force propagation in the observed NEI outcomes, we used α-catenin depleted MCF10A cells (α-cat KD). α-cat KD cells treated with LMB exhibited higher YAP N:C ratios and higher actin coherency compared to wild type (WT) cells (Fig. 3A,B). However, this elevation of mesenchymal characteristics did not extend to functional cellular changes. Remarkably, during NEI, α-cat KD cells lost front-back polarity, formed discrete colonies, and dissolved leader-follower relationships (Fig. 3C). At the same time, while NEI elevated net migration velocity initially above that for control α-cat KD cells, net velocities were lower than WT cells across timepoints, and migration arrested by 24 h. Ultimately, these findings suggest that α-catenin functionally couples concurrent epithelial and mesenchymal traits.

Figure 3: Removing α-catenin from NEI enhances mesenchymal traits without translating functionally to cell shape or migration.

Graphs show mean as bar or solid line ± SEM, with significance levels for one- or two-way ANOVA.

DISCUSSION

Classically, epithelial (E) and mesenchymal (M) phenotypes exist along a single continuum, where cells traverse from E to M via the loss of epithelial characteristics precisely in step with the gain of mesenchymal ones. Here, we show that NEI promotes biological (gene, protein expression) and functional (morphological, migratory) changes that expand the traditional epithelial-mesenchymal continuum. We propose these changes constitute a concurrent E-M state in which highly epithelial and highly mesenchymal characteristics coexist. From this atypical phenotype, what results is progressively disordered cell migration during NEI. This outcome emphasizes that epithelial and mesenchymal characteristics can exist in high degrees concurrently but not necessarily cooperatively. Meanwhile, results from MCF10A α-catenin knockdown cells indicate that the simultaneous phenotype hinges on cooperation between intercellular adhesion and intracellular force, with adherens junctions emerging as the operative link.

Ultimately, the concurrent states we observe expand the classical interpretation of phenotypes, and indicate that epithelial and mesenchymal traits may exist on separate continua. These findings highlight an increasingly diverse range of epithelial-mesenchymal phenotypes and thus further encourage a more comprehensive assessment of E-M cellular features as a basis for phenotypic categorization. Overall, this expanded understanding of E-M states could help further characterize how cells manipulate phenotypes to promote cancer, wound healing, and embryonic development.

INTRODUCTION

Tissue expansion (TE) is a commonly used procedure to repair large skin defects including breast reconstruction after mastectomy and large congenital defects. Because skin grows in response to stretch, tissue expander, a balloon-like device, can be inserted subcutaneously and gradually inflated with saline to promote skin growth. After inflation, the excess skin can then be harvested for reconstructive purposes. However, due to the lack of ability of predicting the amount and shape of the newly grown skin, the postoperative complication rate can be as high as 20 percent [1]. We have done extensive work calibrating a mathematical model of skin growth in response to stretch based on a porcine animal model [2]. Here we leverage that model and adapt it to the clinical setting to predict deformation and growth of skin in a patient-specific model.

METHODS

Patient Protocol

One pediatric case of TE was studied shown in Figure 1. Three dimensional photos were taken before the insertion of the expander, before initial inflation of the expander, and after the expansion process right before the excess skin was going to be harvested. A tissue expander with base 50×80 mm² was inserted and inflated in increments over a 2 month period. The details of inflation protocol are included in Table 1.

Table 1: Inflation Protocol of Patient

Date [MM/DD]	Volume [ml]	Time [Days]
01/24	15	0
02/03	30	10

Finite Element Model of Tissue Expansion

The finite element model of tissue expansion is an extension on our previous work [2]. The initial state of the skin is discretized with C3D8 elements in Abaqus from the 3D scan after the insertion of the expander. The expander is modeled with shell elements CPS4 and fluid cavity elements. We also assumed no friction between the expander and the skin. Skin area deformation is split into growth and elastic parts, see Figure 2,

$$\theta = \theta^g \theta^e \quad (1)$$

with the area growth rate being proportional to the elastic deformation

$$\dot{\theta}^g = k(\theta^e - \theta^{crit}) \quad (2)$$

Figure 1: Photos of the patient with tissue expander at different states

Figure 2: Skin deformation schematic at the apex of the expander

where k is the growth parameter calibrated in our previous work [2].

Uncertainty Analysis

Our previous work has quantified the uncertainty in the biological parameter k . Furthermore, there are other uncertain quantities associated with the process, including mechanical properties for human skin [3]. Additional uncertainties are on boundary conditions. To account for the uncertainty analysis, we ran a series of simulations with different growth rate k , material properties, and boundary conditions. Among material properties, we varied shear modulus μ . For the boundary conditions, we varied the expander's distance to skin h to account for the inaccuracy in volume and the fixed skin distance from expander tol to account for the uncertainty in the procedure. The parameter sets were generated with Latin hypercube sampling. The ranges of different variables are detailed in Table 2.

Table 2: Ranges for Material Properties and Boundary Conditions

Parameter	Range
μ [MPa]	[0.1, 1.0]
k [hr ⁻¹]	[0.02, 0.1]
tol [mm]	[15, 30]
h [mm]	[1, 3.5]

RESULTS

With the expander inflated to the volume following the protocol, we are able to show the development of total deformation over time. To show the skin's recoil, we added a deflation process to the expander in the simulation as shown in Figure 3. The full simulation spanned the 80 days of the protocol.

Figure 3: Total deformation of skin over time.

Based on the post operation picture in Figure 1, we estimated the harvested skin area to be [23.8, 26.8]cm². Based on our simulations, the final skin growth area has a range of [13.0, 30.9]cm² with a median of 20.2 cm² (Fig. 4).

Figure 4: Skin growth area results from simulations.

To further confirm the accuracy of our model, we compared the final coordinate location of the nodes on the skin to the 3D scan of the patient after expansion. For each simulation, the shortest distance from the nodes to the 3D scan were calculated and recorded as shown in Figure 5. To compute the shortest distance, the simulation and scan were first aligned using software CloudCompare. For most cases, the average distance from the node at the end of the simulation to the scan is 3.5mm.

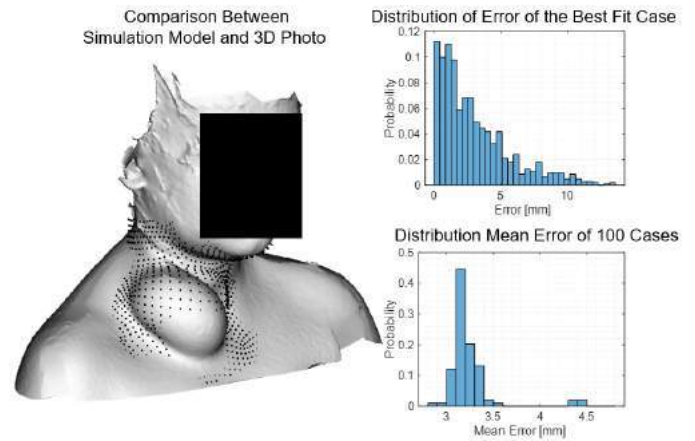

Figure 5: Error calculation comparing predicted geometry from finite element model to 3D scan at the end of procedure.

DISCUSSION

Currently, the designing of TE protocols solely relies of the surgeon's individual training and experience. This lack of standardization can limit the potential use of the technique and also lead to sub-optimal final results. Based on our understanding of skin mechanobiology from porcine models, we simulated skin growth in response to a clinical protocol. Our results show that computational modeling can not only be utilized in predicting the outcome of TE, but also take the uncertainty in the procedure into account. While we cannot fully validate the model, the geometry at the end of the process has very small error distributions. With ongoing

IN VIVO TESTING OF HYSTERESIS OF THE UTERINE SUSPENSORY TISSUE IN CHINESE WOMEN WITH PELVIC ORGAN PROLAPSE

INTRODUCTION

Pelvic organ prolapse (POP) refers to downward displacement and deformation of the female pelvic organs [1]. In the United States, more than 200,000 surgeries are performed each year [2], with a 25% recurrence rate 10 years after surgery [3]. In China, the prevalence of symptomatic pelvic organ prolapse was 9.6% [4].

Pelvic organ prolapse usually occurs about 20-30 years after vaginal delivery, which is most likely closely related to prolonged and repeated loading and unloading of the uterine suspensory tissue (UST) over many years. The UST, consisting of the cardinal ligament (CL) and the uterosacral ligament (USL), is thought to play an important role in resisting pelvic organ prolapse [5]. However, the underlying mechanisms of tissue damage of the UST and prolapse caused by long-term repetitive loading remains unclear. Therefore, the aim of this study was to develop an MRI-based preoperative measurement technique to quantify the *in vivo* hysteresis of the UST in women with pelvic organ prolapse and to help understand the temporal mechanisms of the occurrence of pelvic organ prolapse.

METHODS

Six Chinese women with POP scheduled for surgery were selected from an ongoing POP research at the Shanghai Jiao Tong University Affiliated Sixth People's Hospital (Shanghai, China) with the approval of the Institutional Review Board.

Prior to surgery, the mechanical behavior of the CL and USL was tested using a newly designed computer-controlled linear servo system (Figure 1), similar to our previous work [6]. First, the patient's information and the max force used were entered through the computer. To obtain the initial position, a force of 1 N was preloaded to remove the slack of the UST. Then the linear actuator pulls the uterine cervix until the force reaches its maximum. Finally, the linear actuator was reversed to gradually release the UST. Force and displacement were recorded in real time during the test. A total of three trials were

performed for each patient, with a two minutes interval for tissue recovery.

Figure 1: Schematic of the test setup. Zero indicates the location of the hymen, with $-/+$ meaning above or below the hymen. Cx, cervix; P, pubic bone; S, sacrum; U, uterus; A, B, and D denote the force sensor, linear actuator, and shell; C, the tripod; E, the motor controller; and F, the cervical forceps. The vertical dashed-dotted line represents the initial location of the hymenal ring. The green and blue dashed lines indicate CL and USL under load, respectively. Modified from [6].

Similar to our previous study [7], we used MRI scans of the CL and USL to create a specific 3D model for each individual, measuring the length, angle, and cross-sectional area of the CL and USL for each individual. A four-wire model was used to calculate the forces on the ligaments.

A typical loading and unloading of the UST is shown in Figure 2. The UST stiffness is defined by $\frac{f_2 - f_1}{d_2 - d_1}$, where f_2 and f_1 denote the maximum force and minimum force, and d_2 and d_1 denote the maximum displacement and minimum displacement. The hysteresis is defined by $\theta_1 - \theta_2$, where θ_1 is the area under the loading curve and θ_2

Figure 2: A typical loading and unloading test result (trial 1) for the UST (Patient #003).

is the area under the unloading curve of each trial. Python (v 3.7.2) and the corresponding NumPy (v 1.20.2) library were used to process the data and calculate the hysteresis and stiffness per person per trial.

For simplicity, CL and USL were assumed as incompressible isotropic hyperelastic materials, and the strain energy density was assumed to be a function of the first and second invariants of the strain tensor. A three-parameter hyperelastic Moony-Rivlin material model was thus selected to fit the CL and USL loading behavior, and the model was defined as follows:

$$W(0) = C_{10}(I_1 - 3) + C_{01}(I_2 - 3) + C_{11}(I_1 - 3)(I_2 - 3) \quad (1)$$

Where C_{01} , C_{10} , and C_{11} are material constants; I_1 and I_2 are the first and second invariants of rights Cauchy deformation tensor. A customized MATLAB (v.2019a) program was used to solve the strain and stress and fit the strain-stress curve.

Descriptive statistical analysis and two-sided T-test were used to compare the differences between the three trials.

RESULTS

The six Chinese women with POP had an age of 68 ± 12 years old (*mean* \pm *SD*), and parity of 1.8 ± 0.8 . They all had anterior vaginal prolapse. The stiffness and hysteresis of the UST for those Chinese women are shown in Figure 3.

Figure 3: Uterine suspensory tissue stiffness and hysteresis in Chinese women with prolapse from trial 1 to trial 3 (*, $p < 0.05$). For demonstration purposes, we change the unit of hysteresis from J to $10J$.

For the UST, the stiffness was 0.434 ± 0.235 N/mm for trial 1, 0.492 ± 0.227 N/mm for trial 2, and 0.560 ± 0.250 N/mm for trial 3. The hysteresis was 0.029 ± 0.006 J for trial 1, 0.021 ± 0.005 J for trial 2, and 0.019 ± 0.004 J for trial 3. As can be seen from the results, the UST continues to harden with repeated loading. The hysteresis of the UST was significantly reduced from trial 1 to trial 2, not significantly from trial 2 to trial 3.

The stress-strain behavior in each trial and the fitted curves of CL and USL are shown in Figure 4. The three-parameter hyperelastic

Moony-Rivlin material constants were fitted according to Eq. (1). For CL, C_{10} was -0.04 ± 0.05 MPa, C_{01} was 0.04 ± 0.06 MPa, and C_{11} was 0.04 ± 0.05 MPa. For USL, C_{10} was -0.02 ± 0.02 MPa, C_{01} was -0.02 ± 0.02 MPa, and C_{11} was -0.02 ± 0.02 MPa.

Figure 4: Stress-strain behaviors of the CL and USL. The calculated stress-strain data for each subject are shown as dotted lines, and the fitted stress-strain curves are shown as solid lines. The R^2 value for the CL is 0.6311 and for the USL is 0.6674.

DISCUSSION

This study is the first to examine *in vivo* hysteresis of the uterine suspensory tissue in Chinese women with pelvic organ prolapse. This helps us to understand the changes in uterine suspensory tissue and the temporal mechanism of pelvic organ prolapse under long-term repeated loading. This will allow us to better understand why vaginal delivery leads to pelvic organ prolapse after 20 to 30 years. So far, we have only provided partial results. In future work, a larger sample size might help us to find statistical differences between different categories of patients.

INTRODUCTION

The bodily soft tissues are naturally under tension, or, in other words, pre-strained. These pre-strains were first discovered by Chuong and Fung (1986) in their pivotal experiments measuring the opening angles of the blood vessels [1]. Following this seminal work, other researchers sought to quantify the pre-strains of other soft tissues, such as the heart valve leaflets. Of specific interest, Amini *et al.* (2012) measured the areal contraction of the ovine mitral valve anterior leaflet between the *in vivo* and *ex vivo* configurations and found 18% and 30% contractions in the circumferential and radial directions, respectively [2]. Inspired by this work, our laboratory recently characterized the pre-strains of the tricuspid valve (TV) leaflets using a novel 3D photogrammetry and reproducing kernel method [3]. Briefly, in that work, porcine hearts were acquired, fiducial markers were placed on the TV leaflets, and photographs were captured throughout the tissue dissection and biaxial testing process, including a standard equibiaxial loading preconditioning protocol. Overall, we found that the quantification of the tissue material behaviors was greatly influenced by the selected reference configuration, which will have a profound impact for the *in-silico* modeling of the *in vivo* TV behaviors. As a logical next step in our investigations, we proceed to implementing these pre-strains into finite element models to elucidate the implications of these findings for applications such as patient-specific modeling.

In this work, we will perform an *in-silico* investigation of the effects of pre-strains on modeling of the tricuspid valve closing. Utilizing the data from our previous work [3], we will conduct simulations for $n = 8$ porcine tricuspid valves to make comparisons between the valve closing predictions with and without consideration of the experimentally acquired, subject-specific pre-strains. Furthermore, we will investigate how the chosen reference configuration from the *ex vivo* material characterizations influences the simulated TV closing behaviors and biomechanics (e.g., tissue stresses).

METHODS

Building upon our existing parametric TV finite element analysis framework [4], we construct subject-specific valvular geometries based upon the leaflet and commissure heights measured from our experimental photographs (Fig. 1(a)). Due to the nature of our experiments, we are unable to acquire subject-specific annulus and free edge contours, and thus we use a simplified, flat, elliptical annulus geometry for our preliminary investigations. Afterwards, we generate the leaflet free edge curve using the measured valvular heights and a periodic smoothing cubic spline. Then, the leaflet surface is constructed between the two curves and discretized using 4-node shell elements (S4) in ABAQUS (Dassault Systèmes, Simulia Corp., Johnson, RI). The shell thicknesses are prescribed based upon our experimental measurements of the porcine leaflets. Meanwhile, the leaflet material parameters are determined by fitting an isotropic Lee-Sacks model to the biaxial tensile testing data:

$$\psi = \frac{c_0}{2}(I_1 - 3) + \frac{c_1}{2}(e^{c_2(I_1 - 3)^2} - 1) - \frac{p}{2}(J - 1). \quad (1)$$

Here, c_0 , c_1 and c_2 are the material parameters, I_1 is the first invariant of the right Cauchy-Green tensor ($\mathbf{C} = \mathbf{F}^T \mathbf{F}$, where \mathbf{F} is the deformation gradient), and p is a penalty parameter to enforce the incompressibility condition (i.e., $J = \det(\mathbf{F}) = 1$). For our preliminary investigations, the material parameters are prescribed uniformly across all three leaflets with the following values: $c_0 = 10$ kPa, $c_1 = 0.209$ kPa, and $c_2 = 9.046$.

Due to limitations with our photogrammetry-based analysis, we generate the chordae tendineae using the simplified representation from our previous work [5]. For the material behaviors, the chordae are modeled as linearly elastic solids, with a Young's modulus of 10 MPa. Finally, the model boundary conditions include a transvalvular pressure of 25 mm Hg applied to the ventricular surface of the leaflets, and pinning of the annulus and papillary muscles.

The pre-strains are embedded to the model using a three-step procedure [6] (Fig. 1(b)): (i) the original TV geometry is shrunk based upon the leaflet-specific pre-strains measured in our experiments; (ii) the shrunk TV geometry is imported to ABAQUS, and the nodes are displaced to restore the original TV shape, embedding the pre-strains; and (iii) the forward simulation of the valve closing is performed. To prescribe the pre-strains, all transformations are performed within the cylindrical coordinate system. For the radial pre-strains, the annulus-to-free edge distance of each node is adjusted using the Z-coordinates. Meanwhile, the circumferential pre-strains are prescribed by manipulation of the radius coordinate value (i.e., displacement of the nodes towards the valve origin), effectively contracting the annulus segment lengths. For numerical continuity, the pre-strains in the commissural regions are constructed as a gradient between the leaflet-specific pre-strains.

Following the completion of the valve simulations, post-processing metrics include quantities such as the projected regurgitant orifice area (ROA), the Green-Lagrange leaflet strains, and the Cauchy stresses. All values are reported as the mean \pm standard deviation.

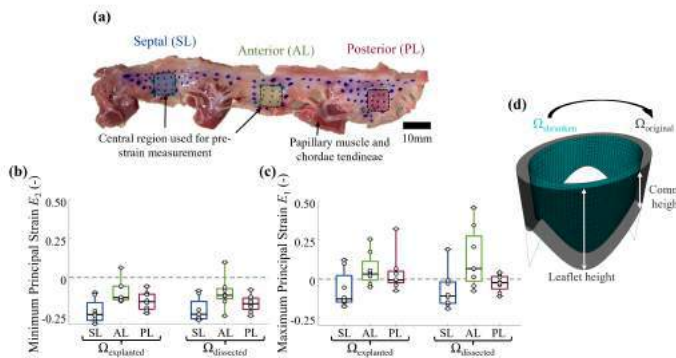

Figure 1: (a) Explanted TV for pre-strain and dimensional measurements; (b) measured pre-strains in the E_2 and (c) E_1 principal directions at the explanted and sectioned tissue configurations (Ω) from [3]; (d) surfaces constructed for embedding a homogenous 20% pre-strain by displacing the mesh from the shrunk to the original configuration

RESULTS

For our preliminary analysis, we performed a systematic investigation of the effects of pre-strains on the simulated TV closing by applying incremental, homogenous pre-strains (i.e., the same for all three leaflets) of 0% – 30% with a 10% increment. In this early study, we used the valvular measurements from Figure 1: septal leaflet (SL), 19.9 mm; anterior leaflet (AL), 15.8 mm; posterior leaflet (PL), 19.4 mm. Meanwhile, the commissure heights were measured as: posterior-septal, 9.6 mm; antero-posterior, 8.4 mm; antero-septal, 11.9 mm.

Figure 2: Superior view of the simulated TV closing and von Mises Cauchy strains for the representative specimen without and with embedded pre-strains.

In our preliminary results, we found that an increase in the pre-strains resulted in severely diminished valve coaptation (Fig. 2). Specifically, for

the models with 10% and 30% pre-strain, we calculated a projected ROA of 22 mm² and 514 mm², respectively. Analyzing the leaflet stresses, we noted profound increases with larger applied pre-strains, and comparing the 0% and 30% pre-strain levels we found von Mises stress increases of 116%, 89%, and 89% for the SL, AL, and PL, respectively. Similar trends were observed for the leaflet strains. For example, comparing the strains in the circumferential direction between the 0% and 30% pre-strain levels: SL, 35% increase; AL, 25% increase; PL, 20% increase. We also found 35% larger reaction forces at the papillary muscle tips between the 0% and 30% pre-strain levels.

DISCUSSION

Our preliminary investigation provided a clear demonstration that the inclusion of pre-strains in the simulated tricuspid valve results in the development of a regurgitant orifice. At the same time, the stresses, strains, and papillary muscle reaction forces became larger with increasing amounts of pre-strain. It is likely that the presence of TV regurgitation is caused by using the same leaflet material parameters across all of our simulations, and that the valve closing may be better simulated by performing data fitting to our biaxial tensile data using a different stress-free reference configuration (e.g., the explanted valve vs. the post-preconditioned tissue). Comparing our findings to the mitral valve-focused inverse finite element analysis study by Rausch and Kuhl (2013), they found that consideration of the pre-strains yielded variations in the estimated membrane stiffnesses by up to four magnitudes [6], providing support to our theory.

Motivated by these observations, as we continue this study, we will systematically test the influence of the leaflet- and subject-specific material parameters and pre-strains on the simulated valve closing. Through this experimentally supported *in-silico* work, we will provide *novel findings* for the effects of pre-strains on the TV closing, which will have major implications on the refinement of the protocols used in benchtop material characterizations. For example, the equibiaxial tensile preconditioning protocol typically used in previous studies may not effectively restore the *in vivo* tissue operating condition, and thus the material parameters obtained from subsequent tensile testing may not be an accurate representation [3].

Overall, our results demonstrate the necessity for considering pre-strains both during the experimental characterizations of tissue and while performing *in-silico* simulations of valve function. Specifically, a careful selection of the reference configuration is required to ensure proper material parameter estimation and accurate simulation results. In the long-term, advancements in pre-strain-focused research will lead to more improved finite element models and enable the next steps in simulation-informed, personalized medicine.

INTRODUCTION

The meniscus is a load-bearing structure that supports knee stability and motion and has a limited capacity for repair after damage [1]. Untreated torn menisci often result in the rapid progression of osteoarthritis in patients due to changes in joint loading, underscoring the critical need to develop therapeutics that promote meniscus repair. Injectable, acellular, and degradable biomaterials have been explored for tissue repair due to their ability to support and promote endogenous cell migration, proliferation, and extracellular matrix deposition. In our approach, we seek to introduce biophysical cues that are present in native tissues to enhance cellular infiltration into engineered hydrogels. First, we introduce tissue viscoelasticity, a property that has been shown to support cell migration within biomaterials [2]. Second, we investigate the micro-phase separation that occurs during hydrogel formation to introduce micro-scale heterogeneity and micro-interfaces at the cellular level. This study explores how these biophysical cues promote important cellular behaviors (e.g., migration) needed for meniscal repair.

METHODS

Material Fabrication: Interpenetrating network (IPN) hydrogels were fabricated through the mixing of guest-host (GH) physical networks (adamantane-modified hyaluronic acid (AD-HA) and cyclodextrin-modified HA (CD-HA)) with covalent gelatin networks (transglutaminase crosslinked) (Fig 1A). All studies performed were conducted with 5 wt% gelatin, 1 U/mL transglutaminase and 0, 1 or 3 wt% GH. **IPN Hydrogel Characterization:** Bulk mechanical properties were assessed with oscillatory time sweeps. Structural features of an 800 x 800 μm region were evaluated through confocal fluorescent microscopy. Microscopic mechanical characterization across a 105 x 105 μm grid was performed via atomic force microscopy (AFM). Heterogeneity was assessed by determining the spatial coefficients of variation across both fluorescent intensity and AFM measurements. **In vitro Cell Interactions:** Meniscal fibrochondrocyte (MFC) spheroids

were formed through 48-hour culture and then embedded within IPNs. Cell outgrowth was assessed by staining actin cytoskeletons and averaging radii of outgrowth from the spheroid edge. The 3% GH experimental group was treated with a broad spectrum MMP inhibitor (Marimastat), a DMSO vehicle control, soluble RGD, and a PBS vehicle control for 3 days and their influence on cell outgrowth was measured. **Cell Infiltration into Hydrogels:** 5 mm juvenile bovine meniscus explants were placed atop hydrogels and cells were allowed to infiltrate for 6 days. **Quantification:** Mechanical testing (n=3-5), spheroid outgrowth (n=3-8) and explant studies (n=5) were pooled per experimental group and timepoint and compared with 1- or 2-way ANOVA with Bonferroni posthoc or Student's T-Test.

RESULTS

We developed a viscoelastic (Fig 1B, C) IPN hydrogel due to the combined guest-host (GH) physical crosslinking [3] of HA and covalent (i.e., transglutaminase) crosslinking of gelatin (Fig 1). Injectability was possible at early times after mixing, prior to complete crosslinking. Increasing the physical network concentration (0 to 3 wt%) correlated with increased $\tan(\delta)$ (Fig 1C), a measure of viscoelasticity. Heterogeneity of the IPN networks was observed through labeling of the distinct microphases of gelatin and quantification of the domain variations (Fig 2A,B). Further, micro-scale heterogeneity was observed mechanically, as measured and quantified with AFM mapping of hydrogel films (Fig 2C,D). Single network gelatin hydrogels without the GH component exhibited less variation than the IPN hydrogels.

The combined attributes of these biophysical properties in the 1% and 3% IPN hydrogels promoted rapid migration of meniscal fibrochondrocytes (Fig 3) compared to pure gelatin 0% group. Cell outgrowth decreased when cell mediated degradation (Fig 3D) or cell adhesion to the hydrogel (Fig 3E) was inhibited. Finally, increased migration of cells into hydrogels from juvenile meniscus explants into the IPN hydrogels was greater (Fig 4A, B). Qualitatively, cells tracked along the borders of the gelatin-rich regions in these studies.

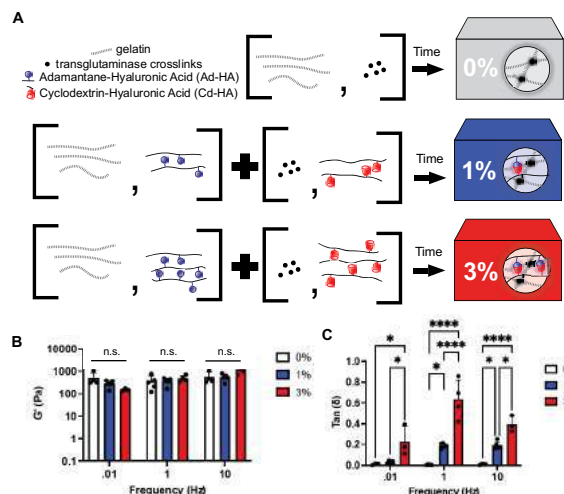

Figure 1: Schematic of control (0%) and IPN (1%, 3%) hydrogel fabrication (A) and resulting storage modulus (B) and tan (δ) (C) at various frequencies. * $p \leq 0.05$, ** $p \leq 0.0001$**

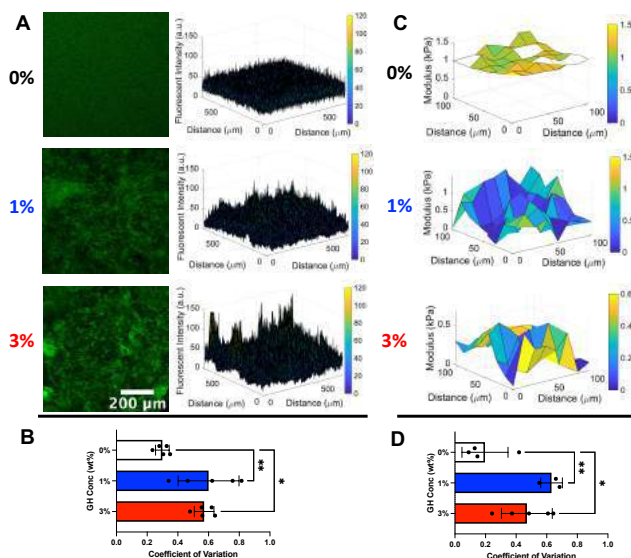

Figure 2: Representative fluorescent images (A; green: gelatin) and corresponding intensity profiles and coefficients of variation (CV) (B) and representative AFM maps (C) and CV (D) for control (0%) and IPN (1%, 3%) hydrogels. * $p \leq 0.05$, ** $p \leq 0.01$

DISCUSSION

This work addresses how key biophysical cues presented through the micro-phase separation of IPN hydrogels influences cell migration, looking towards improved platforms for mechanobiology and translational materials for tissue repair. The IPN hydrogel design allowed for both control over both the hydrogel viscoelasticity and micro-scale properties (e.g., gelatin content, mechanics) (Fig 1,2). This increased viscoelasticity and micro-scale heterogeneity altered cellular migration into hydrogels, including from embedded MFC spheroids or from adjacent meniscal tissues (Fig 3,4). Interestingly, the rapid migration was not observed for gelatin hydrogels alone and depended at least partially both on the cells' ability to remodel its extracellular environment (Fig 3D) and on adhesion to its extracellular environment via integrin-based interactions (Fig 3E). Given that gelatin is rich in these adhesive moieties and that hyaluronic acid is not, this behavior is dependent on both the structure and the composition of the hydrogels.

Figure 3: Schematic of cell outgrowth studies (A). Actin (red, dashed line of outgrowth) visualization (B; Scale bar=200 μm) and quantification (C). Outgrowth was assessed in the presence of matrix metalloproteinase inhibitor (MMPi, D) and soluble RGD (sRGD, E). * $p \leq 0.05$, ** $p \leq 0.01$, ** $p \leq 0.0001$**

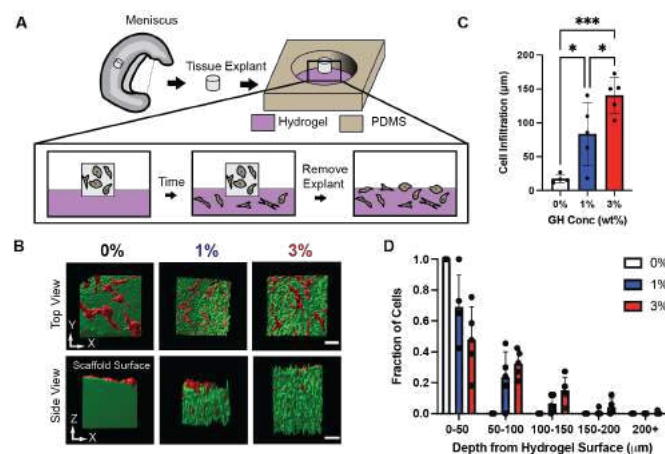

Figure 4: Schematic of experimental set up for outgrowth studies from explants (A; green: gelatin, red: actin). Rendering of outgrown cells within hydrogels (B; Scale bar=50 μm), quantification of maximum cell infiltration into hydrogels (C) and infiltration throughout hydrogel depth (D). * $p \leq 0.05$, ** $p \leq 0.001$**

Qualitatively, we have observed that migrating cells remain along the interfaces of regions of gelatin but did not necessarily infiltrate into these regions (Fig 4C,D). However, further analysis is needed.

Future work will further explore physiologic activities in migrating cells, namely exploring their proliferation, nascent matrix deposition and differentiation states. Gaining a greater understanding of the basis behind cell migration and other critical steps involved in tissue repair will enable a more targeted design of therapeutics to promote healing of connective tissues, such as the meniscus.

INTRODUCTION

The intervertebral discs (IVDs) are the soft tissues bridging adjacent spinal vertebrae, providing flexibility, load transfer, and shock absorption during multi-axial movement. IVDs are comprised of the highly organized annulus fibrosus (AF) that surrounds the gel-like nucleus pulposus (NP), which are separated from adjacent vertebrae by thin cartilaginous end-plates (CEPs). Trauma, overuse, or degeneration can result in AF tears or ruptures that disrupt the crucial role that the IVD plays in daily activities and can lead to NP herniation. The standard of care after herniation is microdiscectomy, where the herniated NP tissue is surgically excised. While effective in relieving symptoms that arise from herniation (i.e., pain, motor and sensory deficits), the mechanical integrity of the AF remains compromised, and a large defect persists through which remaining NP tissue can reherniate.¹

Successful annular repair following herniation offers immense potential in transforming clinical practice and creating superior surgical alternatives and outcomes for patients. To that end, next-generation multifunctional biomaterials enable complete customization to achieve ideal design criteria. In addition to common design criteria like biocompatibility and biodegradability, an ideal annular repair material would be injectable and have the capacity for controlled delivery of a therapeutic. Injectability enables the repair material to interdigitate with the AF to precisely fill the complex defect created by AF tears or ruptures. Controlled delivery of a therapeutic would not only minimize patient discomfort (by controlling inflammation, for example), but could also create a more favorable environment for tissue regeneration and annular repair. However, many proposed strategies for annular repair, such as hyaluronic acid and fibrin-based materials, lack this significant controlled delivery component.^{2,3}

Here, we developed an injectable hydrogel capable of spatiotemporal controlled delivery via click chemistry. Click chemistry describes a class of chemical reactions where two small molecules rapidly and strongly bind to one another. Specifically, we

utilize strain-promoted azide-alkyne cycloaddition (SPAAC) click reactions. Norbornene-modified hyaluronic acid (NorHA) hydrogels were azide-modified to click-functionalize the hydrogels, which was first confirmed using alkyne-modified fluorophores. Towards enabling controlled delivery, we demonstrate that alkyne-modified micelles can selectively attach to these azide-modified NorHA hydrogels. We confirmed that this azide-modification is cytocompatible with AF cells *in vitro*. While additional characterization and customization of these hydrogels is necessary for optimal use as an annular repair material, **this novel multifunctional biomaterial has the potential to revolutionize how we approach dense connective tissue repair and regeneration.**

METHODS

Hydrogel Synthesis and Click-Functionalization: NorHA synthesis was accomplished using well-established protocols.⁴ UV photocrosslinking of NorHA hydrogels was achieved using a di-thiol photocrosslinker that reacts with a portion of the pendant norbornene groups via a thiol-ene Michael addition. To click-functionalize these hydrogels, a thiol-PEG-azide (TPA) (MW: 1 kDa) was added to the hydrogel solution in a 50:50 ratio with the photocrosslinker (i.e., 50% of available norbornene groups were azide-modified and the remaining 50% were used to crosslink the hydrogel). Click Validation: Confirmation of click-functionalization was achieved by incubating non-modified (NorHA) and azide-modified (NorHA-TPA) hydrogels in an alkyne-modified fluorophore solution (30 μ M Alexa Fluorophore (AF)-488-Dibenzocyclooctyne (DBCO)) for 1 hour and assessing attachment via confocal microscopy. These same hydrogels were imaged after 1 week and 1 month of incubation in a PBS bath. The concentration of fluorophore was also varied to demonstrate concentration-dependent attachment via the click reaction. Quantification of the fluorophore attachment was carried out in ImageJ. Micelle Attachment: DBCO-modified micelles labelled with Rhodamine were fabricated as previously described.⁵ As a proof of

concept, these micelles were loaded with a secretory phospholipase A2 inhibitor (sPLA2i). sPLA2 mediates inflammation and tissue damage and is upregulated in injured AF scenarios.⁶ Non-modified (NorHA) and azide-modified (NorHA-TPA) hydrogels were incubated in a 30 μ M solution of these micelles overnight and then were vigorously shaken (500 RPM) for 24 hours prior to imaging via confocal microscopy. **Cytotoxicity Evaluation:** To ensure azide-modification did not impact hydrogel biocompatibility, we performed a non-contact cytotoxicity assay using bovine AF cells (P3-P4). AF cells were seeded in 96-well plates at a seeding density of 6,000 cells/cm². Cells were incubated at 37 °C in basal media for 24 hours before exposure. Cells either received no exposure or were indirectly exposed to NorHA-TPA hydrogels using 0.8 μ m transwell inserts (n=12/treatment group). AlamarBlue was used to assess cell viability and proliferation by measuring absorbance (at 590 nm) at days 1, 3, and 7 of exposure. Measurements were subtracted from media only (i.e., no cells) controls and plotted using GraphPad (Statistics: unpaired t-tests).

RESULTS

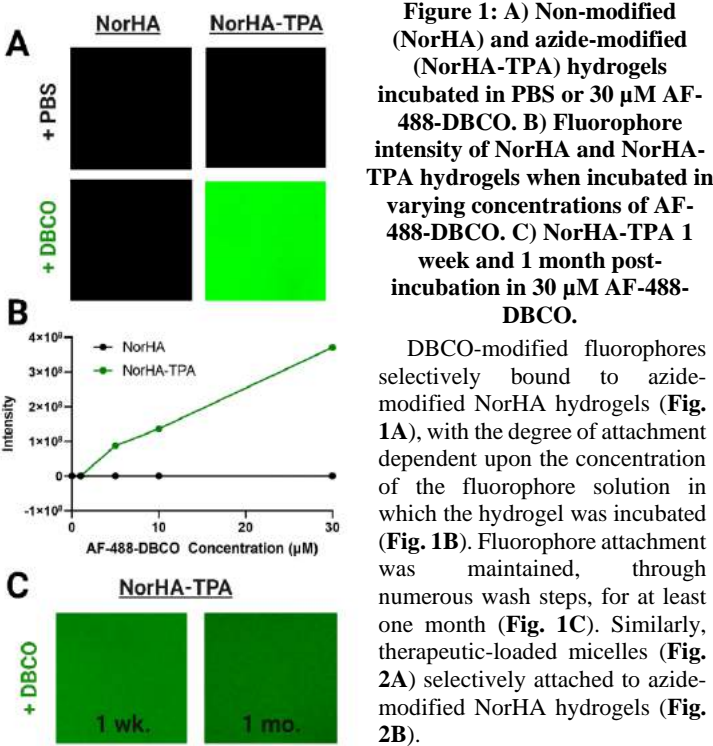

Figure 1: A) Non-modified (NorHA) and azide-modified (NorHA-TPA) hydrogels incubated in PBS or 30 μ M AF-488-DBCO. B) Fluorophore intensity of NorHA and NorHA-TPA hydrogels when incubated in varying concentrations of AF-488-DBCO. C) NorHA-TPA 1 week and 1 month post-incubation in 30 μ M AF-488-DBCO.

DBCO-modified fluorophores selectively bound to azide-modified NorHA hydrogels (Fig. 1A), with the degree of attachment dependent upon the concentration of the fluorophore solution in which the hydrogel was incubated (Fig. 1B). Fluorophore attachment was maintained, through numerous wash steps, for at least one month (Fig. 1C). Similarly, therapeutic-loaded micelles (Fig. 2A) selectively attached to azide-modified NorHA hydrogels (Fig. 2B).

Figure 2: A) Schematic of sPLA2i-loaded micelles, which were DBCO-modified for this study. B) NorHA and NorHA-TPA hydrogels incubated in 30 μ M micelles-DBCO labelled with Rhodamine.

The biocompatibility of NorHA hydrogels has been rigorously investigated and confirmed.^{4,7} As expected, NorHA-TPA hydrogels were not cytotoxic when cultured in the presence of AF cells (Fig. 3). Apart from day 1, there were no significant differences in viability for cells exposed to hydrogels and controls. Further, cell number increased over time in both groups.

Figure 3: Cell viability and proliferation for controls (no hydrogel, AF cells only, black dots) and with NorHA-TPA exposure (green dots). An increase in (negative) absorbance corresponds to an increase in cells number.

DISCUSSION

NorHA hydrogels are promising candidates for biomedical applications due to their injectability and inherent biocompatibility and biodegradability. However, these hydrogels lack a mechanism for controlled therapeutic delivery, which is desirable in nearly all biomedical applications. For instance, an ideal AF repair material would possess all these characteristics to precisely repair the wound defect while utilizing controlled delivery to minimize inflammation and promote tissue regeneration.

Here, we showed that the incorporation of thiol-PEG-azide (TPA) successfully click-functionalizes NorHA hydrogels. This was demonstrated through the selective attachment of DBCO-modified fluorophores to NorHA-TPA (Fig. 1A), which was stable for at least one month. This suggests that therapeutic-loaded nanoparticles could be attached to NorHA-TPA and subsequently localized to the site of injury for delivery. We demonstrated this with loaded DBCO-modified micelles (Fig. 2B). Notably, both the therapeutic and the specific type of nanoparticles (e.g., micelles, liposomes, polymeric, etc.) could be altered based on the specific delivery requirement for the hydrogel system. Additionally, the number of particles attached can be tailored by varying solution concentration (Fig. 1B) or by altering the ratio of photocrosslinker relative to the amount of TPA. Regardless, the attachment of DBCO-modified particles is highly stable for considerable durations (Fig. 1C). Importantly, TPA incorporation did not impact AF cell viability or proliferation (Fig. 3).

Future work will explore the fabrication and click-functionalization of injectable fibrous NorHA hydrogels, which may better mimic the microstructure of the AF.⁷ We will optimize injection parameters to best fill complex AF ruptures and examine total disc mechanics using *ex vivo* and *in vivo* AF injury models. We will also investigate the impact of sPLA2 inhibition in injured AF scenarios. Ultimately, this multifunctional material may improve outcomes in a variety of dense connective tissue repair scenarios.

BIOMECHANICAL EFFECTS OF ANNULOPLASTY RING SIZING FOR FUNCTIONAL MITRAL REGURGITATION REPAIR

Gediminas Gaidulis (1,2), Muralidhar Padala (1,2)

INTRODUCTION

Functional mitral regurgitation (FMR) is the leakage of blood through the mitral valve (MV), that occurs in nearly 60% of the patients with heart failure after surviving a myocardial infarction [1]. The geometry of the MV is distorted by the left ventricular dilatation and the restricted motion of the infarcted ventricular wall, causing the mitral annulus to dilate, and preventing proper valve closure during systole. The geometric distortions of the MV that lead to such a condition, however, differ between individual patients [2], thus making the effective surgical or transcatheter repair of FMR challenging.

Of the many FMR repair techniques available today, undersizing mitral annuloplasty (UMA) is a surgical technique that has gained the most clinical adoption [3]. In this technique, the dilated mitral annulus is reduced by placing sutures into the native annulus and tying them onto a prosthetic ring of a smaller size. Such surgery is hypothesized to draw the native leaflets closer to each other and enable easier and better systolic valve closure and correction of FMR. Though effective in some patients, clear guidance is lacking on which MV geometries may benefit from this repair, and which may not. The lack of standardization with this technique is reflected in the 29% persistent FMR rates at 30 days after annuloplasty procedure, and 58.8% reported recurrence rate of moderate or greater degree of FMR within 24 months after UMA [4]. Furthermore, the annuloplasty rings are available in several sizes, and optimal sizing of the ring to the patient remains a challenge [5]. Though the smallest size ring could be chosen in all patients, the risk of increasing the transmitral diastolic pressure gradient and creating MV stenosis after the repair is high [6]. Therefore, a better understanding of the individualized, patient-specific impact of UMA on MV mechanics could have a significant impact on FMR repair.

In this study, we present a patient-specific, clinically relevant, computational modeling framework to investigate the impact of different annuloplasty ring sizes on the outcomes of UMA for FMR repair.

METHODS

Three patient-specific computational disease models of the MV were created from the 3D epicardial echocardiography data obtained in three pigs with FMR. For each case, the geometry of the MV annulus, leaflets, and papillary muscle (PM) tips was reconstructed from echo images. The model was completed by adding a branched network of chordae, connecting the MV leaflets to the PMs. FMR state of the MV was created by displacing the PMs apically, thus stretching the chordae and imposing a pre-strain on both chordae and MV leaflets. To simulate the MV closure before the repair, physiological transvalvular pressure gradient was applied to the leaflets, and patient-specific annular contraction and movement of the PMs were prescribed as kinematic boundary conditions.

The outcomes of UMA were examined by simulating the effects of differently sized annuloplasty rings on each MV computational model. Seven annuloplasty ring models of different sizes (40, 38, 36, 34, 32, 30, 28 mm) were created based on the shape and measurements of Carpentier-Edwards Physio I ring. For each investigated case, all seven rings were used to downsize the mitral annulus in diastole, mimicking implantation of the ring on the arrested heart during surgery. After each ring was positioned, the mitral annulus was deformed to the ring configuration by prescribing appropriate displacements to the annular nodes (Fig 1A). Lastly, dynamic simulations of the valve closure were run for each model with different size rings. Physiological transvalvular pressure gradient was applied to the leaflets, and movement of the PMs was prescribed as a boundary condition. For the mitral annulus, fixed boundary condition was applied to avoid deformation of the annulus or the ring during the MV closure (Fig 1B).

After each simulation, i.e., pre-repair (or FMR) and UMA (7 ring sizes), the following parameters were evaluated for each investigated case: mitral annular area, regurgitant gap area, leaflet coaptation length, tenting height, stress distribution on the leaflets, and tension forces in the chordae.

Figure 1: Deformation of mitral annulus to annuloplasty ring dimensions (A) and simulation of MV closure (B).

RESULTS

The average simulation results for the three valves are presented in **Table 1** and **Table 2**. In all pre-repair models, regurgitant gaps at A1-P1 and A3-P3 segments of the valve were present, and poor leaflet coaptation as well as increased tenting height were observed. In addition, high leaflet stresses and chordal tension forces were present. After UMA, regurgitant gaps were completely eliminated only with annuloplasty rings smaller than 34 mm. Leaflet coaptation length increased with all ring sizes, still, a value considered clinically adequate for long term repair durability (> 5 mm) was acquired only with rings smaller than 36 mm. Similarly, tenting height was reduced with all ring sizes, however, clinically acceptable value (< 5 mm) was not achieved with any ring size. Annuloplasty rings larger than 36 mm were not able to reduce leaflet stresses. Tension forces in the strut chordae were reduced only with the rings smaller than 38 mm, while forces in the marginal chordae decreased with all annuloplasty ring sizes.

Table 1: Geometric parameters of the valve.

	Annular area (mm ²)	Regurgitant gap area (mm ²)	Coaptation length (mm)	Tenting height (mm)
FMR	1120.0±65.9	13.5±6.0	2.3±0.5	10.9±0.4
UMA 40	1049.8	16.0±3.8	2.7±1.1	8.2±1.5
UMA 38	944.0	6.3±3.2	3.9±0.7	7.4±1.0
UMA 36	846.7	1.9±2.2	4.8±0.6	6.7±0.9
UMA 34	758.4	0.9±1.5	5.5±0.5	6.4±0.8
UMA 32	649.7	0	6.5±0.3	6.0±0.5
UMA 30	578.8	0	7.1±0.3	5.6±0.7
UMA 28	510.8	0	7.8±0.6	5.1±0.9

Table 2: Leaflet stresses and chordal tension forces.

	Max leaflet stress (MPa)	Max strut force (N)	Max marginal force (N)
FMR	0.76±0.27	2.305±0.79	0.399±0.24
UMA 40	1.241±1.24	3.338±3.47	0.354±0.20
UMA 38	0.952±0.86	2.582±2.41	0.31±0.20
UMA 36	0.751±0.63	2.099±1.65	0.272±0.18
UMA 34	0.629±0.49	1.667±1.34	0.284±0.15
UMA 32	0.502±0.22	1.194±0.74	0.241±0.12
UMA 30	0.50±0.25	1.044±0.63	0.211±0.10
UMA 28	0.468±0.17	0.86±0.43	0.18±0.07

DISCUSSION

In this study, we presented the application of computational modeling approach to simulate and evaluate the outcomes of UMA and

the impact of different annuloplasty ring sizes on FMR repair. The results showed that large rings (≥ 34 mm) were not effective in repairing FMR. The use of smaller annuloplasty rings (< 34 mm) eliminated regurgitant gaps in all investigated cases and demonstrated better outcomes while reducing leaflet stresses and chordal tension forces.

The best results defined in terms of valve coaptation were achieved after annuloplasty with the smallest 28 mm ring (**Fig 2**). Such ring increased leaflet coaptation length, restoring an adequate (> 5 mm) coaptation level. Still, even with the smallest ring, post-repair valve biomechanics remained unphysiological. Firstly, while such ring greatly reduced leaflet tenting, an adequate (< 5 mm) tenting height was not achieved. Also, after UMA with 28 mm ring, peak leaflet stresses were still high, exceeding threshold value of 0.5 MPa for healthy valve in two investigated cases. Finally, while the smallest annuloplasty ring reduced tension in the chordae and rebalanced force distribution across the whole chordal network, peak marginal and strut chordal forces in all three cases were higher than those we measured earlier in the ex vivo model of FMR [7]. Therefore, even with 28 mm ring, the excessive valve tethering was not eliminated.

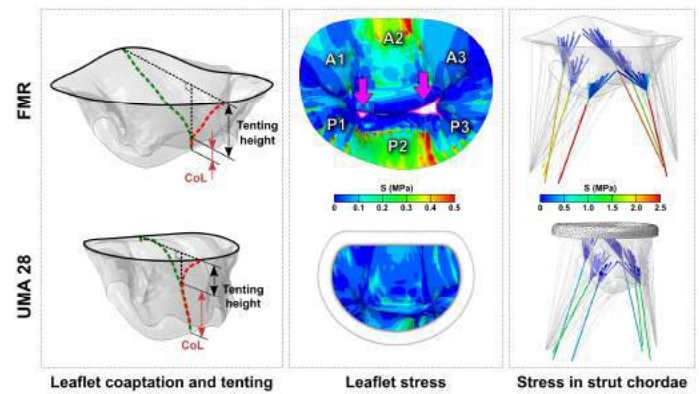

Figure 2: Simulation results: pre-repair vs UMA with 28 mm ring.

In addition, though the data from our simulations indicates that the smallest ring can eliminate FMR and aid in better systolic valve closure, the risk of creating MV stenosis after such excessive annular downsizing should be considered. On average, the 28 mm ring reduced annular area by $54.3 \pm 2.7\%$. From the Gorlin formula [8], 50% reduction of the annular area increases transmitral gradient by four times, worsening intracardiac hemodynamics, patient's functional capacity, and affecting repair durability. For this reason, UMA with the smallest ring might appear as a durable repair at first, but it may lead to greatly increased transmitral gradients later after the surgery, and that could limit the benefit of this repair technique.

We conclude that conservative annular downsizing with large annuloplasty rings (≥ 34 mm) is not suitable for FMR repair. The use of smaller rings (< 34 mm) provides better systolic valve closure but at the same time increases the risk of elevated transmitral gradients, and that could limit the repair benefits.

INTRODUCTION

The tumor microenvironment (TME) consists of extracellular matrix (ECM) proteins, secreted factors, and various populations of cells, all of which can change ECM properties that trigger tumor cell migration or metastasis. Metastasis of breast cancer can occur via collective cell migration (CCM), the coordinated movement of a cluster of interconnected cells. CCM is guided by a subset of cells at the front known as leader cells. Previous *in vitro* studies in our lab demonstrate that in order for CCM to occur, there is associated fiber alignment and stiffening of the collagen matrix, which correlates with *in vivo* observations [1]. Further, selective knockout of collagen receptor discoidin domain receptor 2 (DDR2) in stromal cells (i.e. cancer associated fibroblasts (CAFs)), resulted in loss of fiber alignment and matrix stiffening in the TME with associated decrease in metastatic lung lesions *in vivo*. [2]. Further, without DDR2, CAFs lost their ability to lay down organized, aligned fibers *in vitro* [2]. However, how these changes in the TME effect leader cell activation that is required for directional collective migration is not well understood.

The objective of this study is to investigate how changes in the TME due to stromal cell remodeling activate leader cells. Specifically, our goal is to investigate how changes in mechanical matrix properties effect leader cell mechanosensing. We hypothesize changes in collagen architecture and mechanical properties altered by stromal cells via DDR2 are used by leader cells to sense directional migration. Further, we hypothesize leader cells sense TME cues required for migration via cell protrusions and traction forces transmitted by focal adhesions. In this study, we used decellularized primary tumor tissue as a

biologically relevant microenvironment to investigate the response of breast tumor leader cells to ECM where CAFs are depleted of DDR2. Our work begins to reveal how leader cell mechanics and ECM cues work together to impact directional migration that contributes to cancer progression.

METHODS

We isolated primary tumors from established collective migration breast cancer mouse model, MMTV-PyMT (WT MMTV-PyMT) or where we depleted DDR2 in CAFs (FSP1cre;Ddr2^{-/-}), and generated decellularized matrix (dECM [3]). Using the dECM, we generated 3D dECM hydrogels and cultured WT MMTV-PyMT tumor organoids. After culture for 3 days, we quantified fiber orientation and changes in tumor organoid morphology. To study how tumor organoids interact with the matrix, we cultured primary MMTV-PyMT tumor organoids for 1 day on 2D plates coated with dECM, and stained for leader cell marker (cytokeratin-14 (K14)), focal adhesions (vinculin), and nuclei (DAPI). Finally, we measured forces exerted by tumor organoids onto their surrounding matrix using a HexForce method [4] in order to compare differences in force generation by leader (K14+) and follower (K14-) cells.

RESULTS & DISCUSSION

Findings reveal the action of DDR2 in CAFs contributes to matrix remodeling factors that are used by tumor organoids to reorganize their surrounding, as aligned collagen fibers were observed in FSP1cre;Ddr2^{-/-} dECM but not in WT dECM after culturing tumor organoids (Fig 1A-B). Additionally, organoids cultured in FSP1cre;Ddr2^{-/-} dECM were unable to spread out or

form protrusions, resulting in decreased invasion phenotype compared to organoids cultured in WT dECM, as indicated by the greater roundness, smaller spread area, and reduced aspect ratio (Fig. 1A-B).

Figure 1: (A) Representative immunofluorescence images of tumor organoids in 3D FSP1cre;Ddr2^{-/-} dECM and WT dECM hydrogels. (collagen = gray, K14= green, DAPI=blue; scale bar = 100 μm) (B) Quantification of matrix fiber orientation and tumor organoid morphology: roundness (1 = perfectly round), spread area, and aspect ratio (greater value = more elongated). n= 36-39 organoids from three independent mice. All data shown as mean ± SEM. *p<0.05, **p<0.01, *p<0.001, ****p<0.0001, ns=p>0.05, unpaired student's T-test.**

To understand what factors are responsible for leader cell sensing of the TME, we stained tumor organoids for mechanosensitive focal adhesion marker, vinculin, which has been shown to be crucial for directed cell migration [5]. On 2D dECM, K14+ leader cells formed fewer and smaller focal adhesions on FSP1cre;Ddr2^{-/-} dECM compared to follower cells (K14-) (Fig. 1C-D). The differences in number and size of focal adhesions suggest the K14+ leader cells are forming more mechanically active interactions with their surrounding matrix compared to follower cells and perhaps increased traction forces. Further, since focal adhesions are known to regulate force transmission between the cell cytoskeleton and ECM as a route of mechanosensing, we measured the traction forces exerted by leader cells on their surrounding environment: we observed leader cells (K14+) exert higher pulling forces on the ECM compared to follower cells (K14-) (Fig. 1E). Increased traction forces and focal adhesion number and area could be physical mechanisms utilized by leader cells to signal for collective migration. Further, these differences point to a distinct mechanical phenotype of K14+ leader cells when they are activated to collectively migrate where they generate increased traction forces mediated by focal adhesions.

Altogether, our findings suggest mechanical matrix cues modulated by stromal helper cells can activate leader cells to mechanically engage with their surroundings through the recruitment of vinculin at the focal adhesions as the cytoskeleton contracts and generates traction forces. This suggests a possible mechanism for how leader cells sense physical matrix cues in the TME and direct collective migration.

CONCLUSIONS

Together, this work demonstrates breast tumor leader cells are mechanically responsive to tumor microenvironment mechanical cues. Further, our findings reveal the importance of stromal helper cells in regulating leader cell mechanical behavior that contributes to metastasis. In future studies we will investigate specific ECM receptors activated in focal adhesions, such as integrins, and the downstream mechanosignaling pathways in leader cells that are responsible for driving collective cell migration. Ultimately, the outcomes of our work will inform the development of future therapies to target key cell types responsible for promoting metastasis.

CHARACTERIZING HEADFORM FRICTION COEFFICIENT FOR HELMET TESTING

Nicole E-P. Stark (1), Steve Rowson (1)

(1) Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, USA

INTRODUCTION

Evaluating the impact response of helmets is essential in reducing the number of head injuries across varying sports. Helmets are evaluated using dummy headforms to simulate the impact response of the head. However, there are various standards and independent test methods that use different headforms, each with unique properties. The outer material composition of the headform differs significantly, resulting in different frictional interfaces between the headform and helmet lining. The head and helmet frictional interface affects the head's impact response during a helmeted impact. Reducing the friction between the headform and helmet correlates with lower head rotational velocity and corresponding injury risk during oblique impacts [1, 2]. Therefore, the headforms' frictional properties must accurately represent that of the human head.

Multiple studies have evaluated the frictional characteristics of Hybrid III and magnesium/EN960 headforms. The Hybrid III headform, developed for automotive crash testing but now also used in helmet testing, has a vinyl plastisol skin with a high friction coefficient [3]. The coefficient of friction (COF) reported for Hybrid III is 0.75-1.07 [4-6]. Due to Hybrid III's high friction coefficient, some test methods cover the headform with a stocking to reduce friction [5, 7, 8]. The magnesium headforms, which are commonly used in standards for helmet testing, have no outer layer and have been reported to have a lower friction coefficient, 0.16-0.23 [1, 2, 5]. Other helmet test methods use a National Operating Committee on Standards for Athletic Equipment (NOCSAE) headform. The NOCSAE headform was developed exclusively for helmet testing, and its outer layer is composed of polyurethane skin [9, 10]. Though widely used for helmet testing [10], there are no reported friction coefficients for the NOCSAE headform.

Although there are defined friction coefficients for magnesium and Hybrid III headform, various testing methods and materials were used, making it hard to compare across headforms. Trotta et al. did evaluate the COF of a magnesium and Hybrid III headform against a helmet lining material, but the comparison to human heads was based on cadaveric samples [5]. Furthermore, no previous study has quantified the COF of the NOCSAE headform, and previous studies have yet to evaluate new headforms to older headforms that have been used for impact testing. Polyurethane and vinyl plastisol oxidize and degrade over time, and many headforms undergo repetitive impacts resulting in wear markings or scratches [11, 12].

This study's objectives were to (1) quantify the NOCSAE headform friction coefficient, (2) measure COF across three new and used headforms using the same methods, and (3) compare each headforms' biofidelity. Each headforms' biofidelity will be determined through the comparison against previously determined human head COF under similar testing conditions. Comparing COF between headforms and defining their biofidelity will lead to modifications of headforms and the development of more realistic helmet testing standards.

METHODS

Using a specially designed tribometer, the NOCSAE, Hybrid III, and EN960 headforms static friction coefficients were measured against multiple materials, including EPP high-density foam, a helmet liner, Teflon, aluminum, and polyester fabric. Each headform was weighted to apply an 80 N normal force to the tested material. The headforms tested included new and used NOCSAE, Hybrid III, and EN960 headforms to evaluate the effects of degradation and oxidation. The Hybrid III and NOCSAE were also tested with a skull cap applied.

The normal force was measured using a compression load cell, and tangential force was measured using an inline load cell during the five trials at 400 Hz. The raw force data for each trial were processed in MATLAB (Mathworks; Natick, Massachusetts, USA). The force and tension data were filtered using a 4-pole phaseless lowpass Butterworth filter with a 17 Hz cut-off frequency. Bias in the signals was removed, and the data were smoothed using a 50 ms moving average window. For each trial, the COF was calculated, and the static friction coefficient was extracted. The static COF was defined as the maximum friction right before movement occurred. The static COF of all the headforms was measured across five trials, averaged, and compared. An ANOVA and post-hoc Tukey test was used to evaluate the differences between headforms, materials, and new versus old. Each headforms static COF was also compared to the previously determined 95% confidence interval (CI) of human head static COF at 80 N.

RESULTS

The COF against each material varied and increased in order: Teflon, aluminum, polyester, helmet liner, then foam (Figure 2). The material also significantly affected COF ($P < 0.001$). Comparing headforms, the NOCSAE and Hybrid III ($P = 0.60$) are not significantly different from one another, but the NOCSAE and Hybrid III are significantly different from the EN960 ($P < 0.001$).

Figure 2: Static friction coefficients of the EN960, Hybrid III, and NOCSAE headforms against multiple materials.

The new headforms' static friction coefficients against foam and a helmet lining material varied compared to the used headforms ($P < 0.001$).

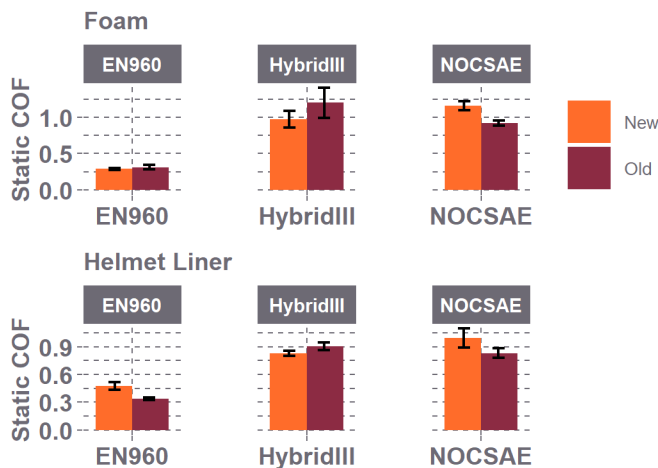

Figure 3: Friction coefficients against foam and a helmet lining material vary between new and old/used headforms.

The previously defined 95% CI of the human head static COF at 80 N against helmet foam was 0.30-0.34. The EN960 COF 0.29-0.31, NOCSAE with a skull cap COF 0.27-0.31, and the Hybrid III with a skull cap COF 0.27-0.30, all fall within the 95% CI for the human head at 80 N (Figure 4).

Figure 4: Comparing previously determined human head friction coefficients to different headforms against high-density foam.

DISCUSSION

At 80 N, the static friction coefficient of the EN960 headform is 0.30 ± 0.01 , the Hybrid III is 1.08 ± 0.07 , and the NOCSAE is 1.44 ± 0.06 against a high-density foam (Figure 2).

Previous studies reported a friction coefficient of 0.75 and 1.07 for the Hybrid III headform against a polyester material [4-6]. This study found a friction coefficient of 1.15 ± 0.05 for the Hybrid III against a polyester material. When a stocking cap or skull cap was applied to the Hybrid III, Bootlang et al. reported a COF of 0.26 comparable to the COF we found of 0.28 ± 0.02 . These differences could be due to differences in the polyester materials tested. The magnesium EN960 bare headform has reported COF of 0.16 ± 0.03 and 0.20 ± 0.02 against polyester [2,5], while we found a similar COF of 0.20 ± 0.02 for the EN960 against polyester. Another study found a COF of 0.23 for the EN960 against padding inside an HJC helmet [1]. Although we did not

test against similar padding, when compared against high-density foam, another compressive material, we found a higher COF for the EN960 0.30 ± 0.01 .

Previous studies have not compared the biofidelity of the NOCSAE, EN960, and Hybrid III headform to human head friction coefficients using similar testing methods. In an earlier study involving 74 participants, we defined the 95% CI for the static friction coefficient of the human head at 80 N against helmet foam to be 0.30-0.34. The NOCSAE and Hybrid III had over three times the COF of the human head against foam. However, when covered with a skull cap the static COF reduced and were within the 95% CI of the human head's COF (Figure 4). The EN960 static friction coefficient of 0.30 ± 0.01 was within the human head's 95% CI static COF (Figure 4). Therefore, the EN960 or similar magnesium headforms are the most biofidelic and should be used when considering friction properties to accurately represent the impact response of the human head and if a Hybrid III or NOCSAE headform are used a skull cap should also be used.

Furthermore, our results showed that the degradation and oxidation of the Hybrid III vinyl plastisol and NOCSAE polyurethane affect their static COF (Figure 3). The NOCSAE headform had the most extensive alteration in COF, most likely due to oxidation [11]. There was also an increase in COF for the new Hybrid III compared to the used Hybrid III against foam, polyester, Teflon, and aluminum, but not for the helmet liner. Due to the friction changes for each headforms with use and time, we suggest that each individual headform is tested before use.

One limitation of this study was quantifying the COF at an 80 N normal force. 80 N is well below the normal forces experienced by headforms during impact testing, and friction coefficients will follow a power law as friction is a function of normal force [13]. However, testing at 80 N allowed a direct comparison to the human head COF. Another limitation of this study was that there was no quantification of the degradation or oxidation of the used headforms tested. Quantifying the degradation or oxidation should be a consideration for future work. Future work should also investigate how frictional properties of these headforms affect linear and rotational impact kinematics.

Standardization of headform frictional properties is necessary to ensure accurate representation of the human head during helmet testing. This study was the first to quantify NOCSAE COF, measure COF across three headforms using the same methods with a defined normal force, and directly compare their biofidelity. These results will also lead to modifications of headforms, develop more realistic helmet testing standards, and aid the optimization of helmet designs.

COMPARISON OF MECHANICAL RESPONSE OF TMJ AND KNEE CARTILAGE UNDER DYNAMIC LOADING

INTRODUCTION

Disorders of the temporomandibular joint (TMJ), the only moving joint in the human head, affect over 10 million Americans. TMJ condylar cartilage however remains an understudied tissue [1]. It has a unique, hybrid bi-layered structure (Fig 1), distinctive from articular cartilage in other diarthrodial joints [2]. The top layer is fibrocartilage dominated by type I collagen fiber bundles. The bottom layer is primarily hyaline cartilage, composed of type II collagen fibrils and proteoglycans. The two layers are integrated by type I collagen bundles which extend from the top layer and root into the subchondral bone [3].

Figure 1. Porcine TMJ condylar cartilage (Safranin O).

A primary mechanical function of TMJ condylar cartilage is shock absorption through energy dissipative deformation to reduce concussion on the brain [4]. Previously, we found that in static loading the hyaline layer has a much lower modulus than knee cartilage, but the hybrid mandibular cartilage, reinforced by the fibrous layer, has a similar equilibrium stiffness [2]. In this study we hypothesized that the unique bilayer structure endows the TMJ condylar cartilage with a low dynamic stiffness, especially under small stress and high frequency loads, to minimize the impact on the brain from TMJ daily functions, *i.e.*, eating and talking.

METHODS

Cylindrical cartilage samples (diameter = 2.5 mm) were harvested from either TMJ condyles or the knee femoral condyle heads of the

same porcine (6-9 months old). Subchondral bone was removed (TMJ $h = 1.12 \pm 0.17$ mm; Knee $h = 1.03 \pm 0.20$ mm) and samples were stored at -80°C before testing ($n = 8$ for each group).

Dynamic Loading. Dynamic compression was applied on the samples with an ElectroForce 3230 test frame (TA Instruments) with previously described profiles [5]. In brief, a constant load of 0.2 N (~ 40.7 kPa) was applied to the cylindrical sample with an unconfined compression setup and held for 1 hr to reach equilibrium deformation. The final reduction in thickness under 0.2 N was $40.7 \pm 18.8\%$ for TMJ cartilage and $14.8 \pm 2.6\%$ for knee cartilage. Compressive Young's modulus was calculated based on the equilibrium strain.

Figure 2. Stress and strain vs. time response of a typical TMJ cartilage sample under dynamic compression at select frequencies.

Cyclic compressive loading was then applied in a sinusoidal waveform with an amplitude of 6 N (~ 1.0 MPa), consisting of 20 cycles at 20 Hz, 15 cycles at 15 Hz, 10 cycles at 10 Hz, 5 cycles at 5 Hz, 3 cycles at 3 Hz, 2 cycles at 1 Hz, and 1 cycle at 0.1 Hz (Fig. 2). Samples rested for 5-10 minutes between each loading frequency [5].

Theoretical Analysis. During the testing, cartilage was assumed to be incompressible and was evaluated with Cauchy normal stress component ($\sigma_{33} = hF/h_0A_0$) versus stretch ratio ($\lambda_3 = h/h_0$). To calculate dynamic modulus ($\partial\sigma_{33}/\partial\lambda_3$) as a function of strain, the slope of an exponential function $y = A(e^{Bx} - 1)$ was fit to the stress (σ_{33}) versus strain (λ_3) curve at each frequency [5]. The strain energy integral of the loading (W_l) and unloading (W_u) σ_{33}/λ_3 curves was used to calculate the phase angle δ according to $\tan\delta = 4(W_l + W_u)/\pi(W_l - W_u)$.

RESULTS

The equilibrium modulus of TMJ condylar cartilage under unconfined compression was significantly lower than that of knee cartilage (116±45 kPa vs. 276±44 kPa, $p < 0.001$). Representative stress-strain plots of dynamic loading are presented in Fig. 3a. For TMJ tissue, the dynamic modulus increased with the loading frequency, but this correlation diminished at higher stress levels. The dynamic modulus increased significantly with loading stress, e.g., > 100% increase from 0.2 to 0.8 MPa at all frequencies. At low stresses, the dynamic modulus of knee cartilage was higher than that of TMJ (e.g., 14.9±2.6 vs 10.6±4.0 MPa at 10 Hz), but the opposite was true at higher stresses (16.8±3.0 vs 22.0±7.8 MPa at 10 Hz) (Fig. 3b). The minimum dynamic modulus of TMJ was always lower than cartilage at all frequencies, while the maximum modulus was higher than cartilage (Table 1). Phase angle derived from energy dissipation analysis was similar for both knee and TMJ cartilage, and both decreased significantly with increased loading frequency (Fig. 3c).

DISCUSSION

The loading profile in this study reflects the low loading levels during daily functions of TMJ. The typical frequency of a pig chewing is 2-3 Hz, whereas a human chews at 1 Hz and achieves up to 5-6 Hz while speaking [4,6,7]. At low stresses, the dynamic modulus of TMJ cartilage was lower than that of the knee. This trend implies that during daily activities, such as talking, TMJ cartilage provides better shock absorption than knee cartilage, potentially reducing impact on the brain.

Table 1. Minimum and maximum modulus using the fit $\sigma_{33} = A(\exp[B(1-\lambda_3)] - 1)$, evaluated at the minimum and maximum λ_3 for each frequency (*: $p < 0.05$ vs Knee at each frequency).

Frequency	Minimum Modulus (MPa)		Maximum Modulus (MPa)	
	Knee	TMJ	Knee	TMJ
0.1 Hz	7.1±1.8	5.2±1.9*	12.0±2.5	15.1±6.6
1 Hz	8.7±2.2	7.3±2.8	15.9±2.9	20.1±7.7
3 Hz	10.4±2.2	8.2±3.3	16.4±3.0	20.8±7.5
5 Hz	11.9±2.2	9.3±3.3*	16.7±3.1	21.2±7.7
10 Hz	14.9±2.6	10.6±4.0*	16.8±3.0	22.0±7.8
15 Hz	16.3±2.6	11.5±4.5*	17.4±3.0	21.7±7.9
20 Hz	17.2±2.7	11.5±4.6*	18.1±2.9	22.9±7.8

We previously found that in static loading the hybrid mandibular cartilage has a similar equilibrium stiffness with knee cartilage under indentation tests [2]. In this study, cartilage was cut into cylinders with subchondral bone removed. The cutting significantly compromised the mechanical functions of the type I collagen bundles in TMJ cartilage, which resulted in the low equilibrium stiffness. The top fibrocartilage is essential for the mechanical function of TMJ condylar cartilage.

It is critical to note that the dynamic moduli here were obtained when the knee and TMJ tissues were under the same initial load (0.2 N), but different initial strains (15% vs 41%). Thus, the dynamic moduli of TMJ could be even lower than the knee with similar initial strain. We will quantify this trend by testing the TMJ tissue under 15% strain.

PARTIAL MENISCUS TRANSPLANT TO TREAT HORIZONTAL CLEAVAGE TEAR RESTORES CONTACT AREAS SIMILAR TO PARTIAL MENISCECTOMY

Farid Amirouche (1, 2), Eric Chang (1), Asher Lichtig (1), Jason Koh (2)

(1) Department of Orthopaedics, University of Illinois, Chicago, IL, USA
(2) Department of Orthopaedics, NorthShore University Health System, Skokie, IL, USA

INTRODUCTION

While partial meniscectomy is an established treatment for horizontal cleavage tear to allow for rapid return to sport at competitive levels, partial meniscus transplant is a newly emerging operative technique that has been studied as a non-inferior alternative for restoration of native knee biomechanics. Data from previous studies that delved into *in vitro* porcine knees demonstrated that partial meniscus transplant restored knee biomechanics to that of partial meniscectomy and that of intact knees.¹ In spite of the advancements made to better understand biomechanical outcomes of partial meniscus transplant, there is currently a paucity of data comparing the effects on contact area of partial meniscectomy and partial meniscus transplant in the human knee. We hypothesized that partial meniscus transplant, as treatment for horizontal cleavage tears, can produce contact areas that are not significantly different from those achieved by partial meniscectomy.

METHODS

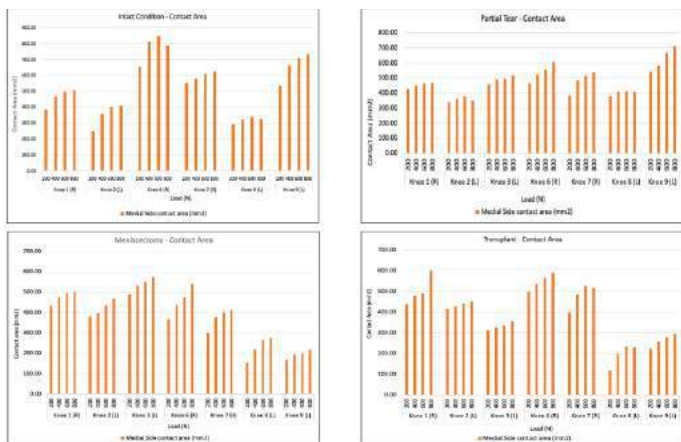

7 fresh-frozen human cadaveric knees were removed of muscular structures and extensor mechanisms while leaving ligaments intact. Femoral condyle osteotomy was performed to access the tibiofemoral joint, and submeniscal arthrotomy was performed to place pressure-mapping sensors (Tekscan). Knees were tested each at full extension and at 30 degrees flexion under the 4 experimental conditions of (1) intact medial meniscus, (2) posteromedial horizontal cleavage tear of medial meniscus, (3) partial meniscectomy, and (4) partial medial meniscus transplantation. Triplicate results of tibiofemoral contact pressure and contact area in the medial and lateral compartments were obtained at 200 N, 400 N, 600 N, and 800 N of axial load for each experimental condition using a uniaxial load frame (MTS 30/G machine).

RESULTS

The average contact areas at full extension and across the 3 non-intact, experimental meniscus conditions of the medial compartment in the knee was observed to be 477.93 mm², 383.29 mm², and 394.08 mm² for partial tear, partial meniscectomy, and partial meniscus transplant conditions respectively. There was a statistically significant difference between the tear and meniscectomy conditions ($p = 0.005256$) as well as between the tear and transplant conditions ($p = 0.00842$), while there was no statistically significant difference between meniscectomy and transplant conditions ($p = 0.58282$). The average contact areas at 30 degrees flexion of the knee in the medial compartment was observed to be 487.15 mm², 343.00 mm², and 413.69 mm² for the same conditions respectively. There was statistical significance found when comparing contact areas of tear to meniscectomy conditions ($p < 0.00001$) and tear to transplant conditions ($p = 0.000267$). Contact area comparisons between meniscectomy and transplant conditions yielded statistically significant differences ($p = 0.000979$).

Figure 1: MTS 30/G Machine with Tekscan sensors in knee.

Graph 1: Contact area comparisons of all knees at full extension.

DISCUSSION

Partial transplantation of the meniscal tissue showed no statistically significant change in contact area when compared to that of partial meniscectomy when the knee is positioned at full extension. Data obtained from the knee in a position of 30 degrees of flexion yielded considerably different results. It was found that comparisons of tear to treatment conditions, intact to treatment conditions, and treatment to treatment all yielded significantly different results. Solely comparing the average contact areas across all knees and all tested axial loads would reveal that the partial transplant condition was able to restore and increase contact area in a way that the meniscectomy condition was unable to. In this way, the data offers some support to the notion that partial transplantation is non-inferior to partial meniscectomy in terms of the contact area achievable in the repair of horizontal cleavage tears. These findings may provide evidence of partial meniscal transplantation as a viable treatment option for meniscal tears. While the results obtained from the knees at 30 degrees of flexion were inconclusive compared to the results obtained from the knees at 0 degrees of flexion, this study offers support for further investigation into the biomechanical differences between meniscectomy and partial meniscus transplant treatments. Due to the novelty of the partial transplant method, continued improvements to the surgical procedure, graft shaping and matching, and suturing method could play important roles in altering the outcome of this operative technique.

INTRODUCTION

Intervertebral disc (IVD) degeneration (IDD) is clinically considered as a significant source of back pain. While one of the most common causes is aging, traumatic injuries to the spinal joints including disc herniation, accounts for up to 2% IDD in people aged 30-50 years, and lead to IDD in adolescent and young adult discs. Current surgical and conservative treatment options for IDD cannot restore normal tissue integrity or function; thus, IDD remains a critical public health problem. We hypothesize that oxidative stress contributes to the progression of post-traumatic IDD and therapies targeting oxidative stress may prevent disease progression based on mounting evidence [1-3]. The objective of this study was to investigate the preventive effects of amobarbital (Amo) on the progression of disc degeneration.

METHODS

***In-vitro* study:** Rabbit nucleus pulposus (NP) cells were pre-treated with Amo for 2 hours (h) prior to exposure of 50 μ M *tert*-butyl hydroperoxide (tBHP) for 1 h. *N*-acetylcysteine (NAC) was used as a positive control. Toxicity of tBHP, Amo, and NAC were analyzed by CellTiter 96[®]Aqueous One Solution (Promega). Apoptotic and necrotic cells were quantified *via* Annexin V/propidium iodine (PI) staining. Further the levels of reactive oxygen species (ROS) generation and corresponding mitochondrial membrane potential were quantified with MitoSOX and JC-1 staining, respectively.

***Ex-vivo* study:** Amo (2.5 mM; Amytal[®] sodium; Bausch Health) was encapsulated in a lyophilized hydrogel (HG; PF-72[®]; TGel Bio) composed of F127 and hyaluronic acid. *In-vitro* release profile of Amo was performed by high-performance liquid chromatography incorporated with ultra-violet spectroscopy (HPLC-UV) (Agilent Technologies) at 220 nm. Thirty-six rabbit thoracic and lumbar motion segments (T11/L2) from New Zealand White (NZW) rabbit cadavers (10 months old) were subject to an IVD puncture using a 20-gauge needle and treated with HG with or without Amo. Following 2- or 7-day organ culture, the samples were harvested for histological examination with Weigert's iron hematoxylin/Fast Green/Safranin-O staining. A modified histological classification was adapted based on

two well-established grading systems [4,5]. Three blinded evaluators independently and blindly scored twice according to 4 categories: morphology of the annulus fibrosus (AF), border between the AF and NP, cellularity of the NP, and matrix of the NP. For oxidative stress response to NP cells, voltage-dependent anion channel 1 (VDAC1) and nuclear factor (erythroid-derived 2)-like 2 (Nrf2) immunohistochemical stains were performed. To quantify the amount of IHC positive expression, we followed a semi-quantification procedure using ImageJ Fiji software (Version 1.53c; NIH) [6].

***In-vivo* study:** A total of 24 (11 male and 13 female) young adult NZW rabbits (7-8 months old) were randomly assigned for intact control, injury + HG only, and injury + Amo/HG (n = 6/group/time-point). Under sterile surgical conditions, two of three randomly assigned lumbar IVDs (L2/3, L3/4, or L4/5 levels) were punctured percutaneously with an 18-gauge needle using fluoroscopic guidance. With the needle confirmed in the NP, a 5 cc syringe was attached to the needle, the plunger drawn back to the 5 cc line, and aspiration held for 5 seconds. After the puncture, the syringe was removed and an intradiscal injection of 100 μ l HG with or without Amo was performed using a 27-gauge needle inserted through the 18-gauge needle, then both needles removed. At 2 and 8 weeks, disc height index (DHI) was calculated by two independent observers using ImageJ (Fig. 3B) [7]. Additional glycosaminoglycan (GAG), glutathione, and histology are under analysis.

RESULTS

***In-vitro* study:** Concentrations of up to 10 mM NAC and 2.5 mM Amo were found to be non-toxic, and these doses were used for further studies (Fig. 1A). Amo and Amo/NAC pre-treatment significantly prevented the rate of apoptotic and necrotic cell death (Fig. 1B). The levels of mitochondrial ROS production and membrane potential were similar with control (Fig. 1C and D). Thus, Amo has potential for protection against tBHP-induced oxidative damage to mitochondrial function in NP cells.

***Ex-vivo* study:** Amo was more slowly released in higher concentration of F-127 and HA, however, there was no significant differences among

the groups. In contrast, Amo only (no HG) was completely dissolved within 24 h (Fig. 2A). Histological analysis revealed a superior preventative effect of Amo in the degenerative grading system and representative images (Fig. 2B and C). Scoring of the Amo-treated group were statistically significant at day 2 ($p = 0.002$) and day 7 ($p = 0.007$) compared to that of HG only group (Fig. 2B). VDAC1 quantification at day 7 was significantly higher in HG only group compared uninjured control ($p = 0.005$), but there was no difference between intact and Amo/HG (Fig. 2D). This result implies that Amo inhibits VDAC1 opening, eventually reducing the apoptosis of NP cells from oxidative stress-mediated discal injuries. Nrf2 found in the cytosol of protected cells from oxidative stress was significantly over-expressed in Amo/HG at 7 days ($p > 0.001$ vs. HG) (Fig. 2E).

In-vivo study: In representative images of rabbit IVDs, the treatment of Amo/HG induced less severe damages in the NP compared to HG only group represented by apparent water loss and color change (Fig. 3A). Quantified DHI values denoted protective role of Amo in disc height at week 2 ($p = 0.003$ vs. HG) and week 8 ($p = 0.002$ vs. HG) (Fig. 3C).

DISCUSSION

Taken together, in-vitro, ex-vivo, and in-vivo studies highlight the role of Amo in preventing mitochondrial damage. Next, we plan to analyze GAG and glutathione concentrations, alongside histological indications of disease and damage *in-vivo*. In conclusion, Amo treatment targeting oxidative stress has great potential for preventing degenerative disc degeneration.

MULTISCALE MODEL PREDICTIONS OF HEART GROWTH DURING HYPERTENSIVE RAT PREGNANCIES

Molly S. Kaissar (1), Kyoko Yoshida (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Throughout pregnancy, the patient's body adapts to accommodate the growing fetus. For example, the cardiovascular system meets rising demands by expanding total blood volume, reducing systemic vascular resistance, and increasing cardiac output.¹ Hemodynamic adaptations work alongside changing hormone concentrations to induce significant cardiac growth, culminating in a ~30% increase in both left ventricular (LV) mass and cavity volume by term pregnancy.² This heart growth often helps the pregnant patient maintain normal cardiac function to meet the increased workload.

In some cases, the heart can have a maladaptive response to the stresses of pregnancy and trigger cardiovascular conditions, which constitute the leading causes of pregnancy-related mortality in the United States. One of the biggest culprits is hypertension, which accounts for 10% of deaths during pregnancy and up to a year after delivery.³ Hypertension impacts 1 in 10 pregnancies worldwide, but only half of these cases can be attributed to pre-existing conditions.³ Gestational hypertension and preeclampsia are both hypertensive disorders of pregnancy identified by new elevated blood pressure after 20 weeks' gestation – when significant cardiac growth has already occurred.³ However, providers are left to treat unavoidable diagnoses without a clear etiology. To anticipate these conditions earlier, we must first uncover the mechanisms behind pregnancy-induced heart growth.

Towards this goal, we developed a multiscale model of heart growth, where we incorporated a set of hormonal and hemodynamic mechanisms that we hypothesize describe heart growth in normal and perturbed pregnancies. We previously demonstrated that this model could predict LV growth during a normal rat pregnancy.⁴ Here, we assessed whether our model could predict perturbed pregnancies by applying it to three different animal models of hypertensive pregnancies.⁵⁻⁷ We simulated case-dependent changes in hormones and hemodynamics and compared our predictions to the experimental results. We demonstrate that our multiscale model can capture heart

growth in some cases of perturbed pregnancies and illustrate the importance of considering both hormonal and hemodynamic cues in models of cardiac hypertrophy.

METHODS

Multiscale Model of Heart Growth We previously published a multiscale model of heart growth during normal pregnancy in rats.⁴ Briefly, an intracellular signaling network model (Fig 1A) that predicts cell-level growth in response to key pregnancy and cardiovascular hormones (Progesterone, *P4*; Estrogen, *E2*; Angiotensin II, *Ang II*) plus a generic stretch term (*myoStretch*) is coupled to a systemic mechanical compartmental model (Fig 1B) that predicts organ-level deformation in response to changes in heart growth and hemodynamics. Organ-level growth is simulated using the kinematic growth framework within the compartmental model, in which the total observable deformation of the heart is a product of the growth deformation tensor and the elastic deformation tensor ($F_{tot} = F_e F_g$). The growth deformation tensor is determined by the network model's predicted changes in the cell area. In return, the maximum elastic fiber stretch, calculated by the compartmental model, is fed into the network model as *myoStretch*, closing the loop between the two models.

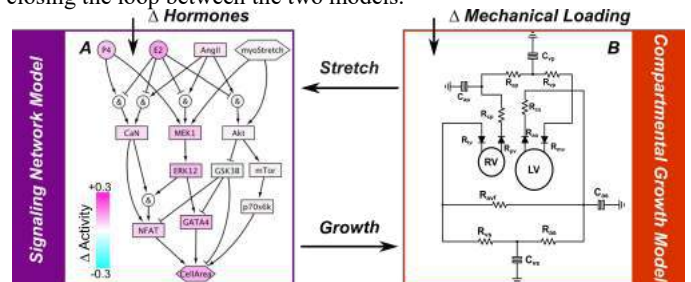

Figure 1: Multiscale model of heart growth during pregnancy. A schematic of (A) the cell-level intracellular signaling network model coupled to (B) the organ-level systemic compartmental growth model.

Simulating Hypertensive Pregnancies We simulated a range of hormonally and hemodynamically induced rat models of hypertensive pregnancy to test the breadth of our model. First, we simulated hormonally-induced hypertension, where osmotic mini-pumps containing a low pressor dose of *Ang II* (+**Ang II**) were implanted between days 8.5 and 9.5 of pregnancy.⁵ Second, we simulated hemodynamically-induced hypertension with a reduced uterine perfusion pressure (+**RUPP**) model, where the uterine arteries and the abdominal aorta below the renal arteries were banded on day 14 of pregnancy.⁶ Finally, we simulated a hormonally and hemodynamically induced hypertension, where transverse aortic constriction (+**TAC**) – known to elevate circulating *Ang II* levels – was induced between days 5.5 and 8.5 of pregnancy.⁷ All experimental studies saw elevated blood pressure and additional heart growth when compared to their gestation-day-matched normal pregnant counterparts.

Table 1: Changes in simulations of hypertensive rat pregnancies

Induced by...	+Ang II Hormones	+RUPP Hemodynamics	+TAC Hormones + Hemodynamics
Resistance (R_{as})	↑	↑	↑
Compliance (C_{as})	–	↓	↓
<i>Ang II</i>	↑	–	↑
<i>E2</i>	–	↓	–

For each case, normal pregnancy was simulated until the average time of pump implantation or banding. Then, we implemented the changes summarized in Table 1 to reflect each of the hypertensive models. To simulate hypertension, the systemic arterial resistance, R_{as} , was increased to fit the reported mean arterial pressure. The reported reductions in vascular compliance in the +**TAC** and +**RUPP** models were considered by decreasing the systemic arterial capacitance, C_{as} .^{7,8} Time-appropriate changes in hormones, such as increases in *Ang II* in the +**Ang II** and +**TAC** models and observed decreases in *E2* in the +**RUPP** models, were also implemented.^{7,9} Lastly, each simulation was re-run twice, once with only hemodynamic changes (R_{as} , C_{as}) and once with only hormonal changes (*Ang II*, *E2*), to investigate their influences on predicted heart growth.

RESULTS

During the 21-day pregnancy in rats, our model predicted additional heart growth in 2 out of 3 cases, which were quantitatively consistent with the reported data (Fig 2A). For +**RUPP**, our model predicted negligible increases in LV mass, which disagreed with the reported experimental growth.⁶

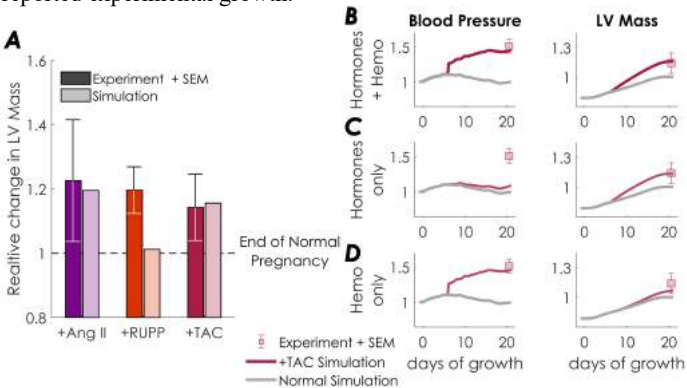

Figure 2: (A) Heart growth in rat models of hypertensive pregnancy. (B-D) Simulated changes in blood pressure and heart growth for the +TAC model. Y-axis values are reported as relative to the end of a normal pregnancy.

Next, we investigated the contributions of hormones and hemodynamics on the predicted growth in the +**Ang II** and +**TAC** simulations. Our model predicted the experimental increase in LV mass in the +**Ang II** and +**TAC** cases when both hormones and hemodynamics were included, suggesting that both cues are necessary to capture heart growth in our model (Fig 2A,B).^{5,7} When only hormonal changes were included, we could predict changes in LV mass on par with the experimental results for +**Ang II** and +**TAC**, but we could not induce the elevated blood pressure that defines these hypertensive rat models (Fig 2C). When only hemodynamic changes were included, we could not capture the mass changes in the experimental models (Fig 2D).

DISCUSSION

This work assessed if the mechanisms proposed in our multiscale model could predict heart growth in perturbed pregnancies. Our model correctly captured the additional heart growth in 2 of 3 animal models of hypertensive pregnancies (+**Ang II** and +**TAC**), demonstrating its ability to predict heart growth in these perturbed pregnancies.^{5,7} Further, our analysis indicates the need to incorporate both biological and mechanical cues to predict heart growth and hemodynamics. These results align with previous simulations of +**TAC** in non-pregnant mice, where a similar multiscale modeling approach required both hemodynamic and hormonal cues to predict appropriate growth.¹⁰

An important finding here is the inability of our model to capture the increase in heart growth associated with +**RUPP**, suggesting the need to include additional mechanisms into the model.⁶ Unlike +**Ang II** and +**TAC**, +**RUPP** does not elevate plasma levels of *Ang II*, which contributed to heart growth in these simulations.¹¹ Instead, +**RUPP** triggers other potent vasoconstrictors, including Endothelin-1 (*ET-1*).¹¹ *ET-1* is a good candidate to incorporate into our intracellular signaling network since it impacts cardiomyocyte growth and it is also elevated in preeclampsia in humans.^{11,12}

In conclusion, we demonstrate that our multiscale framework can capture heart growth in two animal models of hypertensive pregnancies. Based on our initial findings, we are improving our model to include *ET-1* to see if we can capture heart growth due to +**RUPP**. In future studies, we will explore our model’s capacity to capture other hemodynamic and growth parameters, such as changes in stroke volume and wall thickness, and its ability to accommodate biological perturbations, including heart growth in pregnant transgenic mouse models. Ultimately, we aim to apply this multiscale model as a clinical tool for screening and treating perturbed heart growth in pregnant patients to facilitate early diagnosis of cardiovascular disease and inform personalized patient care.

INTRODUCTION

Despite \$2 billion of public funding being dedicated to cardiovascular disease (CVD) research each year, CVD remains the leading cause of death in the US.¹ Vascular smooth muscle cells (VSMC) and extracellular matrix (ECM), which compose the medial layer of blood vessels, often play a role in CVD. Biochemical and mechanical stimuli influence VSMCs to contract and secrete ECM modifying proteins, ultimately impacting vessel geometry and mechanics.² The responsiveness of VSMCs, however, can drive maladaptation when signaling is perturbed due to disease, such as in pre-diabetic chronic hyperglycemia.³ VSMC behavior has been greatly investigated *in vitro*,^{2,4,5} but cell-scale results do not always translate to the tissue scale, hindering the development of VSMC-active therapeutics.

Multiscale computational and experimental techniques, applied together, can translate information across length scales and help tease out the role of perturbed VSMC behavior in CVD pathogenesis. Previously, multiscale models of perturbed biochemical signaling have been employed to predict tissue-scale behaviors, but they lack modalities to compare mechanical results at varying length scales.^{6,7} The objective of this study was to create a multiscale vasculature model connecting cell-scale biochemical signaling and cytoskeletal structure to arterial mechanics. We hypothesized that the multiscale model would capture VSMC contractile behavior observed in both *in vitro* cell-scale and *ex vivo* tissue-scale experiments, which was supported by the correct model prediction of hyperglycemic aortic hypercontractility.

METHODS

Overall Strategy. Our strategy consisted of construction of a multiscale computational model based on biochemical signaling and cellular mechanics, coupled with experimental characterization at the tissue-scale via an isometric ring contraction assay.⁸

Multiscale Model Formulation. The model consists of (1) biochemical signaling, (2) single-actin-filament mechanics in response

to the signal, (3) actin stress fiber / ECM fiber network mechanics, and (4) tissue-scale FE model. Each component is described in turn below.

Biochemical Signaling Model (Fig. 1). The signaling network model was based on a previous VSMC model validated against existing traction force microscopy data⁹, modified to include known glucose relationships. Elevated glucose levels increase VSMC contractility through RhoA pathway activation and Ca²⁺ sensitization.⁴ Following established methods⁶, the model reactions were defined by ordinary differential equations and connected by Boolean logic.

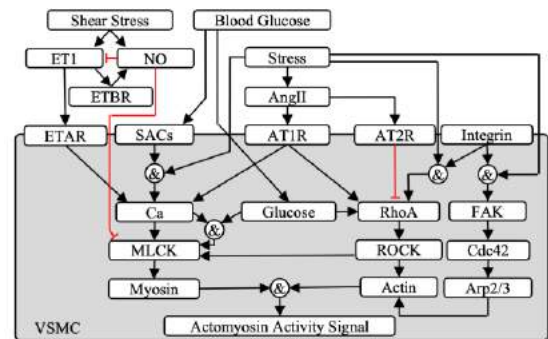

Figure 1: Biochemical signaling network.

Actomyosin Contraction. The resulting biochemical signal was transferred to stress fibers as an input signal for a contraction model.¹⁰ The actin stress was constructed from a Hill-type active component and a linear passive component. Similar, but purely passive models, were used for collagen and elastin fibers.

Cell-Scale Modeling. A 2D, cell-only model (Fig. 2A) was used to simulate traction force microscopy and cellular microbiaxial stretching (CμBS).¹¹ The network was anchored to a substrate by focal adhesions in each corner of the rectangular VSMC. Simulation results were compared to previously published experimental data.¹¹

Tissue-Scale Modeling. For tissue-scale predictions, the full multiscale model was implemented by imposing test deformations on the micro-network and fitting the output to a continuous macroscale model with a neo-Hookean matrix and three fiber families. Microscale contraction translated into a prestrain in the macroscale model, in which the finite-element model was applied to a tissue ring wrapped around two pins, which were modeled as rigid and in sliding contact with the tissue (Fig. 2B).

Figure 2: Fiber networks for A) cell and B) tissue modeling.

Ring Contraction Assay. Aortic ring contraction studies were performed with tissue explants from male wildtype (WT) and OGT^{KO} mice, the latter a well-established model of progressive, chronic hyperglycemia.¹² Tissue was dissected into ~2mm long sections and then loaded onto 0.2 mm diameter pins in a DMT Tissue Myograph with a 37°C PBS bath supplemented with 5.6 mM glucose. Contraction was induced with 100 mM KCl at each strain (10%, 20%, 25%, and 30%).

RESULTS

Multiscale Model Predicts Cell-Scale Strain Dependence. To investigate the strain-dependence of individual VSMCs, we compared the multiscale model to published *CμBS* data.¹¹ In the cell-scale predictions, the multiscale model predicts that the substrate deformation is localized near the focal adhesions in each corner (Fig. 3A). The displacements increase in prominence when the VSMC is transversely strained (Fig. 3B). The increasing strain results in increased passive actin fiber stress (Fig. 3C), as well as a small increase in active stress (Fig. 3D). With no fitting parameters, the model predicts experimental VSMC transverse traction stress-strain behavior (Fig. 3E).¹¹

Tissue-Scale Passive and Contractile Stresses are Captured by the Multiscale Model. When the multiscale model is expanded to the tissue scale, the stress near the pins and along the luminal side increases with increasing pin distance (Fig. 4A). The force on the loading pins prior to KCl addition, defined as the passive reaction force, increases with increasing pin strain both experimentally and in the model prediction without the need for additional fitting (Fig. 4B).

To demonstrate the power of the multiscale model, the value of the “Blood Glucose” signaling node (Fig. 1) was increased from 0.5 (normal) to 0.95 to mimic hyperglycemia, and the results were

Figure 3: Representative substrate displacement and fiber network for VSMC at A) 0% and B) 35% strain. Predicted C) passive and D) active fiber stress. E) Total predicted and experimental VSMC traction stress. Error is STD for n=10.

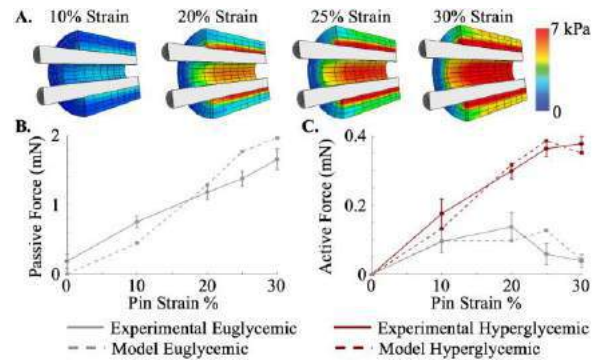

Figure 4: A) Predicted total stress distributions. B) Model-predicted and experimental aortic passive (prior to induced contraction) force. C) Model and experimental active (difference between during and prior to contraction) force for euglycemic and hyperglycemic aortas. Error is STD for n = 8.

compared to experimental data collected from hyperglycemic aortic explants. The euglycemic (normal) active reaction force, defined as the difference between total measured force and passive force, is well-predicted by the model (Fig. 4C). Additionally, the imposed *in silico* increase in glucose biochemical signaling was enough to capture the experimentally observed increase in hyperglycemic aortic contractility.

DISCUSSION

These results demonstrate the capability of our multiscale model to describe VSMC contractility observed in both *in vitro* cell-scale and *ex vivo* tissue-scale experiments. To our knowledge, this model is the first of its kind that predicts VSMC mechanical contractility across such a wide range of length scales. Previous models have been developed that predict the long-term growth and remodeling due to disease^{6,7}, however they did not consider short-term contractility changes due to chronic signaling perturbations.

The significance of our model is demonstrated in its recapitulation of the hypercontractile aortic phenotype observed in chronic hyperglycemia. VSMC hypercontractility due to hyperglycemia is subtle at the single-cell scale, and therefore it is easily lost in experimental techniques with large variability, leading to conflicting reports.^{4,5} However, at the tissue scale, endothelium-independent hypercontractility is consistently observed.¹³ The multiscale model reveals a possible source of this discrepancy in that the while the impetus is localized in cell-scale biochemical signaling, the phenotype must be amplified to be resolved experimentally at the tissue-scale.

In its current form, the model does not account for long-term ECM remodeling. For example, chronic hyperglycemia leads to ECM crosslinking.³ Currently, the model only considers contractility changes, leading to an inability to predict passive mechanical changes. Despite this limitation, the multiscale model still has potential to elucidate mechanisms behind contractile vessel hyperreactivity.

INTRODUCTION

Coarctation of the aorta (CoA) is a congenital heart defect characterized by a constriction of the aorta, and with an estimated incidence of 3 per 10,000 births.¹ The narrowing of the aorta causes a drop in blood pressure (BP) across the CoA which can be alleviated using surgical and catheter-based treatments. The current guideline for treatment is a BP gradient ≥ 20 mmHg at rest.

Computational fluid dynamics (CFD) simulations are used to characterize local hemodynamics in patients with CoA. Previous studies have demonstrated the capability of three-dimensional (3D) simulations in modeling CoA and predicting the trans-coarctation pressure gradient.^{2,3} However, these studies either had small sample sizes or assumed the aortic walls to be rigid. Additionally, 3D simulations are computationally expensive and time-intensive, which currently may limit the translation to routine clinical applications. Reduced-order models, specifically zero-dimensional (0D) models, that are less computationally expensive, can be applied to perform patient-specific simulations. 0D circuit analogy models have no spatial dependency; they only depend on time but can be evaluated at different locations along the cardiovascular system by creating models comprising multiple circuit elements. However, the simplified nature of 0D models and lack of features such as wave propagation can affect the accuracy of 0D hemodynamic estimates.

The objective of this study was to non-invasively predict the pressure drop across the CoA using patient-specific simulations. Both 0D and 3D simulations were performed for a cohort of patients using the open-source software SimVascular.⁴ The peak systolic pressure drops measured across the CoA using both 0D and 3D models (ΔP_{0D} and ΔP_{3D} respectively) were compared and validated using invasive cardiac catheterization measurements (ΔP_{Cath}).

METHODS

Acquisition of Patient Data: CT/4D-Flow MRI datasets (obtained as part of the standard clinical care for CoA patients and approved by the IRB) were acquired from the Lucile Packard Children's Hospital for 17 patients with CoA (12 CT, 5 MRI, age = 28 ± 10.99 years, 13 male/4 female) prior to their undergoing an invasive catheterization and stent placement. Invasive BP measurements were obtained via cardiac catheterization in the ascending and descending aorta. Cuff BP measured on the day of the catheterization was also acquired.

Anatomic Model Generation: Anatomic images were imported into SimVascular and manually segmented to generate 3D geometries of the aorta and branches arising from the aortic arch: brachiocephalic trunk, left carotid artery, and left subclavian artery (Figure 1). Centerlines were automatically extracted from the 3D geometry to create the 0D model which consists of individual lumped parameter elements (resistors, capacitors and inductors) that connect to form a lumped parameter network. The 3D volume was meshed using tetrahedral elements and contained 1.5-2 million elements. A boundary layer mesh consisting of three layers was incorporated to resolve velocity gradients at the wall. The mesh was refined at the CoA and the post-stenotic dilation region to capture the jet formed by the stenosis.

Boundary Conditions: Boundary conditions were tuned using flow measurements and cuff BP measurements. For patients who had MRI, eddy-current corrected images from the 4D-Flow MRI dataset were analyzed to measure 2D time-resolved flow at the inlets and outlets using Arterys (Arterys, San Francisco, USA). For patients who had a CT, a generalized waveform was created by averaging MRI-derived waveforms of 7 additional CoA patients from the Vascular Model Repository (vascularmodel.org). The waveform was then scaled to match the patient's cardiac output and heart rate measured during catheterization. The patient-specific temporally varying parabolic flow profile was prescribed to the inlet of the 0D and 3D models. A three-element Windkessel model (proximal resistance R_p , capacitance C , distal resistance R_d) was imposed at each of the outlets. Total resistance

($R_p + R_d$) for each of the branches was determined based on flow splits to each of the branches for patients who had MRI, and by vessel cross-sectional area for patients who had CT. 0D simulations were performed first and used to fine-tune the prescribed boundary conditions. The value of C , along with R_p/R_d ratio, were adjusted to fine-tune the boundary conditions until the calculated pressures matched the patient's systolic and diastolic cuff BP within 5 mmHg.

0D and 3D simulations: For the 0D simulation, the values of the lumped parameter elements were determined from the geometric and material properties of the blood and blood vessel: fluid density 1.06 g/cm^3 , viscosity 4cP , Young's modulus $3 \times 10^6 \text{ dyne/cm}^2$, and vessel thickness defined as 20% of the vessel radius. Simulations were run for ten cardiac cycles to reach a periodic state of the solution. A stenosis loss model was included to incorporate an additional non-linear resistance that would account for flow separation effects at the stenosis.⁵ Results from the last time step of the 0D simulation were projected onto the model's 3D mesh and used as the initial condition for the 3D simulation.⁶ 3D simulations were performed using a coupled-momentum method with the same boundary conditions as the 0D simulation. Deformable walls with Young's modulus $3 \times 10^6 \text{ dyne/cm}^2$, Poisson ratio 0.5, and shear correction factor 0.8333 were used. Simulations were run for ten cardiac cycles to reach a periodic state of the solution. Pressure along the centerline before and after the CoA were measured at peak systole in the 0D and 3D models. ΔP was calculated as the difference between the mean of the pressure measured in a region defined as the last 20% of the length of the ascending aorta, and the centerline pressure measured at a point in the descending aorta two vertebral spaces above the diaphragm to match typical catheter location. ΔP_{0D} and ΔP_{3D} were compared to ΔP_{Cath} .

Statistical Analysis: Paired Student's t-test was used to compare ΔP_{0D} and ΔP_{3D} to ΔP_{Cath} . A p-value of 0.05 was considered significant. The agreement of ΔP_{0D} and ΔP_{3D} with ΔP_{Cath} was characterized with Bland-Altman plots.

RESULTS

Figure 1. Pressure (left) and velocity (right) features captured in 0D and 3D patient-specific simulations.

CoA anatomy and hemodynamics were observed and captured in the simulations (Figure 1).

ΔP_{0D} and ΔP_{3D} resulted in an underestimation of ΔP_{Cath} on average but was more severe in the case of ΔP_{0D} as shown in Figure 2 (0D: $11.5 \pm 13.2 \text{ mmHg}$; 3D: $18 \pm 11.2 \text{ mmHg}$; Catheter: $18.8 \pm 10.4 \text{ mmHg}$).

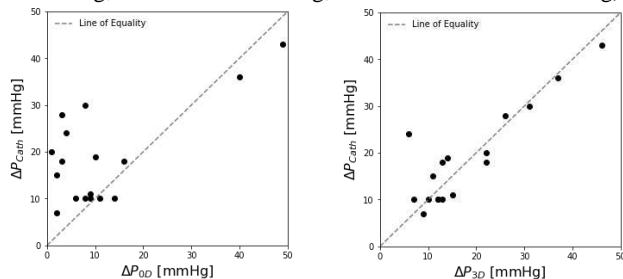

Figure 2. ΔP_{Cath} plotted against ΔP_{0D} (left) and ΔP_{3D} (right).

Using a BP gradient $\geq 20 \text{ mmHg}$ at rest as a treatment guideline, ΔP_{0D} and ΔP_{3D} would result in the right treatment recommendation in 76.5% and 94% of cases, respectively.

The root-mean-square error between simulation pressure drop estimates and catheter-derived measurements was smaller for 3D simulations, than for 0D simulations (0D: 12.05 mmHg ; 3D: 5.26 mmHg).

Paired Student's t-test between ΔP_{0D} and ΔP_{Cath} had a p-value < 0.001 indicating that the ΔP_{0D} was not always a good estimate of clinical catheter-derived pressures. The t-test between ΔP_{3D} and ΔP_{Cath} had p-value = 0.565, indicating that the null hypothesis was not rejected and that ΔP_{3D} can provide good non-invasive estimates of catheter pressures.

Figure 3. Bland-Altman plot of catheter-derived pressure drop and estimates from 0D (left) and 3D (right) simulations, difference plotted against the mean. Upper and lower dotted lines correspond to mean difference $\pm 1.96 \text{ SD}$.

DISCUSSION

This study demonstrates the capability of using CFD to non-invasively estimate pressure drops in patients with CoA. 0D models (constructed automatically from 3D models) were used to efficiently tune boundary conditions, to initialize 3D simulations, and to compute flow and pressure in patient-specific models of CoA. Methods were also introduced to generate patient-specific inflow waveforms for patients with CTs where such information is typically lacking. Pressure drops predicted from 0D and 3D simulations validated using invasive catheter measurements showed that the 3D model estimated pressure gradient within 5 mmHg in most cases. The 0D model was also a good estimator of catheter-derived pressure gradients in cases where the CoA was in a non-junction region. The significantly lower computational time of the 0D models makes them more feasible to use in a clinical setting in scenarios where the CoA is not located at a vessel junction. With improvements to 0D models, like more comprehensive stenosis loss models, they have the potential to become more accurate. Therefore, while 0D simulations cannot currently replace 3D simulations, they can be used to speed up the model personalization process. Future studies should explore the prediction of the CoA pressure gradient in exercise conditions, as well as before and after stent intervention.

INTRODUCTION

Tricuspid valve leaflets have long been considered inert tissues, or “passive flaps” [1]. However, recent studies indicate that they are highly complex, biochemically active, hierarchical structures populated by valve interstitial and endothelial cells, or VICs and VECs, respectively [2]. VICs and VECs maintain a homeostatic environment in the extracellular matrix (ECM) of leaflet tissue through regular collagen degradation and deposition. However, when “activated”, hypersecretory VICs drive an excess deposition of collagen in the ECM. This, in turn, may increase the thickness as well as stiffness of valve leaflets and alter the nonlinearity of their constitutive response. Interestingly, we recently observed such changes in sheep with functional tricuspid regurgitation (FTR) [3]. We posit that this increase in leaflet thickness as well as stiffness and change in material nonlinearity fundamentally alters the leaflets’ ability to bend and stretch, thereby affecting valve function. Furthermore, we hypothesize that the suppression of these changes in tricuspid valve leaflets will, in fact, promote leaflet coaptation and restore valve function. Thus, the objective of our current study is to test this hypothesis.

METHODS

To test our hypothesis, we use a reverse-engineered, openly available finite element model of the healthy human tricuspid valve, “Texas TriValve 1.0”, see **Figure 1**. Detailed descriptions of the creation and validation of this model are provided in our previous work [4]. To study the effects of excess collagen deposition by activated VICs on valve function, we alter three properties of our model. As seen in our animal studies, we increase leaflet thickness and stiffness. Additionally, we decrease the stretch at which the material enters the strain-stiffening regime, which we refer to as “transition- λ ”. Together, we call these changes maladaptive leaflet remodeling. Upon altering each of the above, we compare valve function between all cases by quantifying three metrics at end-systole: (i) average stresses in leaflet

Figure 1: Texas TriValve 1.0 reverse-engineering pipeline

centers, (ii) anterior leaflet opening angle, and (iii) leaflet coaptation area.

RESULTS

Effect of Isolated Changes: To study the sensitivity of valve function to maladaptive leaflet remodeling, we first increased leaflet thickness and leaflet stiffness, and decreased transition- λ in isolation. To this end, we increased thickness by 20-100%, increased stiffness by 20-100%, and decreased transition- λ by 1-5%.

We first examined the effect of isolated maladaptive changes on leaflet stresses. Specifically, we found that a 20-100% increase in leaflet thickness reduced average stresses by 14-69% in the anterior, 7-59% in the posterior, and 7-49% in the septal leaflet. In contrast, we found that a 20-100% increase in leaflet stiffness increased average stresses by 3-15% in the anterior and septal leaflets, and 6-35% in the posterior leaflet. Finally, we found that a 1-5% decrease in transition- λ increased average stresses by 10-22% in the anterior, 10-46% in the posterior, and 6-12% in the septal leaflet.

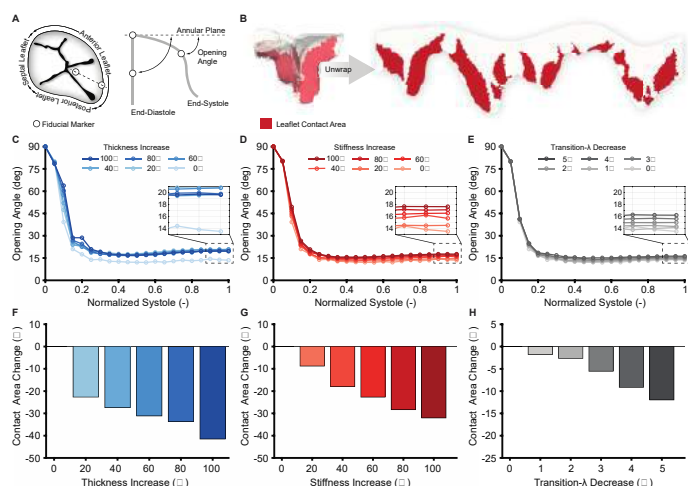

Figure 2: (A) Anterior leaflet opening angles and (B) end-systolic leaflet coaptation areas for valves with increased thickness, increased stiffness, and decreased transition- λ

Next, we examined the effect of isolated maladaptive changes on anterior leaflet opening angle, see **Figure 2A**. Here, we found that a 20-100% increase in thickness increased opening angle by 45-54% at end-systole (**Figure 2C**). Next, we found that a 20-100% increase in stiffness increased opening angle by 7-30% at end-systole (**Figure 2D**). Similarly, we found that a 1-5% decrease in transition- λ increased opening angle by 4-20% at end-systole (**Figure 2E**).

Additionally, we examined the effect of isolated maladaptive changes on leaflet coaptation area at end-systole, see **Figure 2B**. Here, we found that a 20-100% increase in thickness led to a 22-41% decrease in coaptation area (**Figure 2F**). Next, we found that a 20-100% increase in stiffness led to a 9-32% decrease in coaptation area (**Figure 2G**). In contrast, we found that a 1-5% decrease in transition- λ led to only a 2-12% decrease in coaptation area (**Figure 2H**).

Effect of Combined Changes: In addition to studying the effect of an isolated increase in leaflet thickness and leaflet stiffness, and decrease in transition- λ , we also studied their combined effect, see **Figure 3**. To this end, we combined a 40% increase in thickness with a 30% increase in stiffness and a 3% decrease in transition- λ , as observed in our previous animal studies. Furthermore, to contrast the combined effect of maladaptive changes with their isolated effects, we introduced four cases. A control case (I), cases examining isolated changes only (IIa/b/c), cases combining two changes together (IIIa/b/c), and a final case with all changes combined (IV), see **Figure 3**.

In case IV we found that simultaneously increasing leaflet thickness and stiffness and decreasing transition- λ by previously measured magnitudes led to a decrease in average stresses of 26% in the anterior, 17% in the posterior, and 20% in the septal leaflet (**Figure 3A**). This change was primarily driven by changes in thickness (case IIa) and less so by changes in stiffness or transition- λ (cases IIb and IIc, respectively). Next, in case IV we found that remodeling-induced leaflet changes increase anterior leaflet opening angle by 10% at end-systole (**Figure 3C**). This change was driven by the simultaneous increase in stiffness and decrease in transition- λ (case IIIb). To that end, an increase in stiffness and decrease in transition- λ by previously measured magnitudes led to a 26% increase in opening angle. Finally, in case IV we found that remodeling-induced leaflet changes decrease leaflet coaptation area by 29% (**Figure 3D**). This change was primarily driven by an increase in thickness (case IIa) and less so by an increase in stiffness or decrease in transition- λ (cases IIb and IIc, respectively).

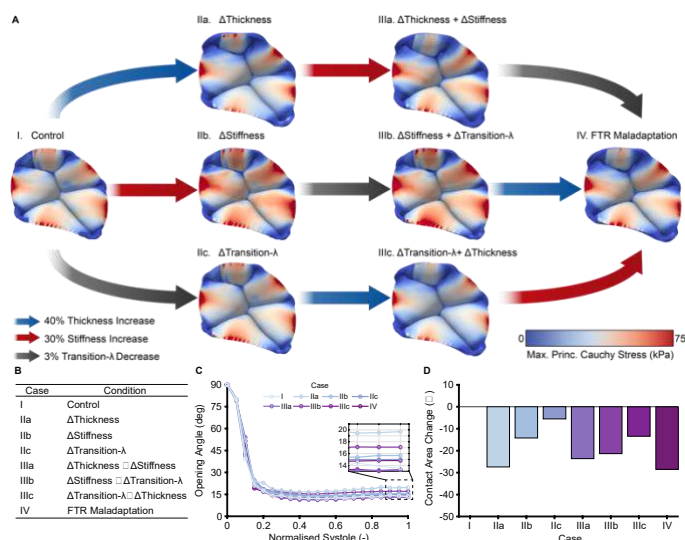

Figure 3: (A) Maximum principal Cauchy stress at end-systole varies among (B) the simulated cases. Similarly, (C) anterior leaflet opening angle and (D) coaptation area varies among cases.

DISCUSSION

Through structural finite element simulations, we show that isolated and combined changes to leaflet thickness, stiffness, and transition- λ disrupt tricuspid valve function. Specifically, in isolation, we found that thicker or stiffer leaflets increasingly resist both bending and buckling. Furthermore, thicker leaflets better support membrane forces and experience lower stresses. In contrast, stiffer leaflets experience greater stresses due to increased membrane forces. Notably, we also found that stresses decrease when maladaptive effects are combined. Here, the leaflets' buckling resistance likely dominates their material stiffness. That is, reduced buckling yields a larger area to support pressure loads, limiting leaflet inflation and reducing stresses.

The clinical significance of our findings is two-fold. Firstly, they may inspire new pharmacological targets for treating FTR. Specifically, pharmaceuticals may be used to suppress the thickening and stiffening of leaflets while preserving beneficial area growth. For example, Losartan was used to suppress leaflet thickening and stiffening in regurgitant mitral valves [5]. Secondly, our results may help understand the sub-optimal outcomes of surgical tricuspid repair. For example, mitral annuloplasty causes leaflet thickening and stiffening, leading to post-repair dysfunction [6]. Suppressing similar changes due to tricuspid annuloplasty may, thus, improve valve function and repair outcomes.

Here, we provide the first computational evidence that suppressing isolated and combined increases in leaflet thickness and stiffness may promote leaflet coaptation and restore tricuspid valve function. Future experimental studies will be needed to support our findings.

INTRODUCTION

Atrial fibrillation (AF) is the most common arrhythmia that can cause cardioembolic events. Stroke prevention is the main concern in the management of AF. Blood stasis in the atrium is associated with thrombus development and often occurs in the left atrial appendage (LAA). While anticoagulants are effective in mitigating strokes, bleeding risk, noncompliance, and other side effects make them unused in more than 50% of eligible patients. Instead, another method for reducing LAA related cardioembolic stroke, is left atrial appendage occlusion (LAAO) using an occlusion device such as the WATCHMAN™ (Boston Scientific Corporation, St. Paul, Minnesota). Although this device has shown improved long-term outcomes, studies have also shown that about 4% of patient's develop device related thrombosis (DRT)¹. The factors leading to DRT are still unclear despite several clinical studies investigating potential predictors.

The aim of this study is to evaluate the hemodynamic profiles of the left atrium (LA) in patients who have received a WATCHMAN™ device, and to identify potential predictors for DRT. We hypothesize that DRT is more likely to occur in patients with blood stasis and complex flow patterns at and around the WATCHMAN™ device. We propose a combined finite element analysis (FEA) and computational fluid dynamics (CFD) approach to investigate this hypothesis.

METHODS

Contrast-enhanced computed tomography (CT) and echocardiographic (ECHO) images of patients pre- and post-device implantation with DRT and without (control group) were obtained from Mayo Clinic under an IRB approved protocol. The datasets included full cardiac cycles and ECHO data of the mitral valve (MV) and pulmonary veins (PVs). The CT images were imported into Mimics Research 23.0 (Materialise, Belgium) and segmented to generate patient specific 3D digital models. Finite element analysis performed by FEops (Gent, Belgium) was used to deploy the WATCHMAN™ in the patient digital

models. The digitally implanted devices were deformed and positioned in the LAA to replicate the clinical deployment for each patient. The digital models were imported into Ansys Workbench 2020 R1 (Canonsburg, PA), where extensions equivalent to 10 times the diameter the MV and each PV were applied in order to overcome entrance effects and to have an appropriate velocity profile. The LA models were then meshed with a polyhedral mesh after mesh independent results were performed and an element size of 0.8mm was selected.

Computational fluid dynamic simulations were performed on the patient-specific models (pre- and post- device implantation) using Ansys Fluent (Canonsburg, PA). The simulations were transient, used a laminar flow model (Reynolds number < 2000), with blood properties being a density of 1060kg/m³ and a viscosity of 0.0035Pa.s. The boundary conditions (BC) for the PVs were set to pressure inlets with 0Pa total pressure. No slip BCs were imposed on the LA surface and WATCHMAN™ device. A velocity inlet BC was used for the MV, with the velocity magnitude following the patient specific MV profile from ECHO. In addition, the velocity direction was normal to the MV (0, 0, -1). The time averaged wall shear stress (TAWSS; **EQ1**), oscillatory shear index (OSI; **EQ2**), and endothelial cell activation potential (ECAP; **EQ3**) were calculated for the top surface of each WATCHMAN™ device.

$$TAWSS = \frac{1}{T} \int_0^T |\overline{WSS}| dt \quad (\text{EQ1})$$

$$OSI = 0.5 \left(1 - \frac{\left| \int_0^T \overline{WSS} dt \right|}{\int_0^T \overline{WSS} dt} \right) \quad (\text{EQ2})$$

$$ECAP = \frac{OSI}{TAWSS} \quad (\text{EQ3})$$

The patient-specific heart rates (taken from the ECHO reports) were used as the period for TAWSS and OSI calculations. An example schematic of the workflow used to generate the digital models and run CFD simulations in this study is shown in **Figure 1**.

RESULTS

TAWSS on the top surface the WATCHMAN™ device for each patient is shown in **Figure 2**. Elevated TAWSS values were observed in the control patients compared to the respective DRT patients.

ECAP quantifies the response of endothelial cells which can be used to determine regions where thrombus formation is more likely to occur. ECAP on the top surface of the WATCHMAN™ device is shown in **Figure 3**. More elevated ECAP was found with DRT patients compared with the control patients in the top region of the device.

DISCUSSION

Herein, various hemodynamic parameters were investigated using CFD in order to better predict the development of DRT in patients who have received a WATCHMAN device. This was accomplished using a combined FEA (for device deployment) and CFD approach. The DRT patients had higher ECAP and lower TAWSS on the surface of the device compared to the respective control patients.

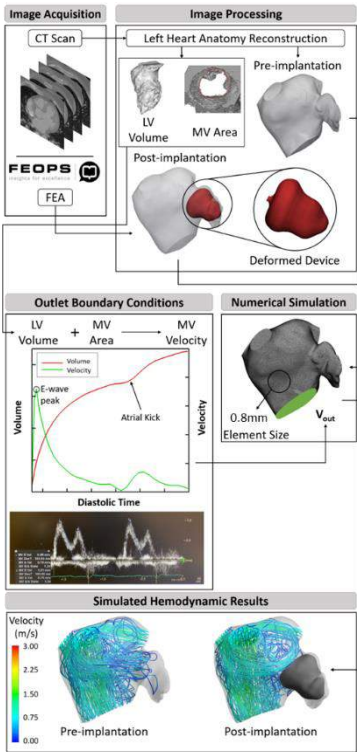

Figure 1. Combined FEA and CFD workflow.

It has been reported that non-physiological levels of WSS are associated with an increased risk of thrombus formation². In this study, we observed lower TAWSS on the top surface of the WATCHMAN™ device in DRT patients compared with the respective control patients.

Understanding ECAP is of particular importance due to the endothelialization — the formation of endothelial cells — that occurs after the deployment of the WATCHMAN™ device. Flow abnormalities/disturbances and stasis have been reported for patients with AF³. These disturbances can result in endothelial cell dysfunction which is associated with adverse cardiovascular outcomes like thrombogenesis⁴. Achille et al.⁵ proposes ECAP as a measurement for thrombogenic susceptibility for endothelial cells by taking the ratio of TAWSS and OSI. A high ECAP value indicates a high OSI and a low TAWSS, both of which have been shown to be related to increased likelihood of thrombus formation. Endothelial cells naturally provide an antithrombotic surface⁶, but when activated, this property is negated which can result in thrombus formation⁷. This activation can occur due to blood stagnation. Regions of high oscillatory flow can induce an inflammatory response⁸. This response may also promote thrombus formation.

Figure 1. ECAP on the top surface of the WATCHMAN™ device.

In this study, we have demonstrated the feasibility of a combined FEA and CFD approach for the assessment of DRT in the LAA after LAAO. Thus far, we have observed a higher ECAP and lower TAWSS values in the DRT patients. The addition of more patients is needed to better understand and predict DRT after LAAO.

INTRODUCTION

The extracellular matrix (ECM) of articular cartilage is characterized by a porous network of type II collagen fibrils that entrap aggrecan aggregates [1]. The meniscus, the loading counterpart of cartilage, is a fibrocartilage mainly consisting of collagen I fibers, with minor collagen II content [2]. Collagens V and XI are regulatory collagens that serve as the nucleation cores for initiating fibrillogenesis of collagens I and II, respectively [3,4]. To date, little is known about how these two regulatory collagens work in concert to regulate initial development and growth of the knee joint that encompasses both hyaline and fibrocartilage. Such knowledge could provide a crucial benchmark for designing novel regenerative strategies to repair and restore the function of degenerative joints [5]. This study aims to elucidate the role of collagen V by assessing the development phenotype of cartilage and meniscus resulting from targeted knockout of *Col5a1* gene in the knee joint.

METHODS

Immunofluorescence (IF) was applied to C57BL/6J murine knees to assess the protein distributions of collagens V (ab7046, Abcam) and XI (Ms #309–322, Zymed) for wild-type (WT) mice at embryonic (E17.5), newborn (P0) and adult (P90) ages, following established protocols [6]. To confirm that the gene expressions complement the protein expressions, *RNA-scope* was applied to assess the spatial gene expressions of collagens V (521291, ACD bio) and XI (439241, ACD bio) for WT mice at P0, following established protocols [7]. *Conditional Col5a1 knockout mice* (*Col5a1^{fl/fl}/Gdf5Cre*, or *Col5a1^{cko}*) were established by crossing *Col5a1^{fl/fl}* mice [8] with joint-specific *Gdf5Cre* mice [9]. Knee joints were harvested from newborn (P0), as well as 3 and 8 months of age (P90 and P240) *Col5a1^{cko}* and control *Col5a1^{fl/fl}* mice. We applied *histology* and μ CT imaging to assess cartilage and meniscus morphology, cell morphology, sGAG staining, and

subchondral bone structure, as well as *AFM-nanoindentation* to quantify the indentation modulus, E_{ind} , of the loading regions of articular cartilage and meniscus via a microspherical tip ($R \approx 5 \mu\text{m}$, $k \approx 8.9 \text{ N/m}$) [10]. Mann-Whitney U tests were applied to detect differences in E_{ind} between genotypes at $\alpha = 0.05$.

RESULTS

In WT mice, at both E17.5 and P0, as expected, we detected strong staining for collagen XI in epiphyseal cartilage (Fig. 1a, EC) and collagen V in meniscus (Fig. 1a, M). Surprisingly, articular cartilage showed higher staining for collagen V than for collagen XI (Fig. 1a). This finding was also validated by gene expression at P0 using *RNA-scope* (Fig. 1b), with *Col5a1* enrichment in the articular vs. epiphyseal cartilage and vice versa for *Col11a1*. In adult joints, staining of both collagens V and XI were low, with collagen V mainly localized to the pericellular domain of superficial layer cells (Fig. 1a).

Corroborating the presence of collagen V in developing articular cartilage and meniscus, we found profound developmental defects in newborn (P0), young adult (P90) and middle-aged (P240) *Col5a1^{cko}* mice. In *Col5a1^{cko}* mice, we confirmed the deletion of collagen V by the absence of IF staining at P0 (Fig. 2a). Also, even at the newborn age, loss of collagen V already resulted in disrupted joint formation, as marked by the formation of smaller menisci and wider cartilage plateaus (Fig. 2a). At young adult (P90) age, loss of collagen V resulted in much smaller menisci (Fig. 2b). For articular cartilage, although we did not detect changes in tissue thickness or sGAG staining, chondrocytes appeared to undergo aberrant clustering in *Col5a1^{cko}* group (Fig. 2b). Notably, both articular cartilage and meniscus of *Col5a1^{cko}* mice had significantly reduced modulus relative to the control (Fig. 3a), indicating impaired matrix integrity and mechanical functions with the loss of collagen V (Fig. 2b). Furthermore, μ CT analysis showed aberrant calcification in joints, with a loss of expected ossification at the

horns of lateral meniscus in P90 *Col5a1^{cko}* joints, and excessive osteophyte formation in P240 joints, which is a sign of severe osteoarthritis (OA) [11] (Fig. 3b).

DISCUSSION

This study highlights a crucial role for collagen V in the development and maintenance of articular cartilage. For years, the consensus has been that the fibrillar collagen network of hyaline cartilage consists of collagen types II, IX and XI [12], with collagen XI being highly expressed at embryonic and neo-natal stages [13]. While the high expression of collagen XI is confirmed in developing epiphyseal cartilage, we show here, for the first time, that developing articular cartilage is rich in collagen V, but not in collagen XI (Fig. 1) [13,14]. The importance of collagen V in cartilage integrity is further highlighted by the altered cartilage shape in newborn *Col5a1^{cko}* mice (Fig. 2a), and aberrant cell clustering and reduced tissue modulus in adult mice (Fig. 2b). Recent studies have suggested that collagen V may regulate stem cell quiescence in muscle through the Notch-Col V-CALCR axis [15]; it is thus possible that collagen V may play a similar role in regulating progenitor cell fate in developing articular cartilage. Collagen V is present at low concentrations in young adult cartilage, and according to our recent study, induced knockout of *Col5a1* during post-natal growth led to no clear phenotype in articular cartilage [6]. Therefore, the role of collagen V in regulating articular cartilage integrity is most likely limited to early embryonic and neo-natal stages, and the observed phenotype in *Col5a1^{cko}* mice is due to cell and/or tissue defects resulting from the lack of collagen V in early development.

The reduced size, modulus and absence of horn ossification in *Col5a1^{cko}* menisci (Figs. 2, 3) also suggest a crucial role of collagen V in the developing meniscus. The reduction of meniscus size cannot be explained by the canonical role of collagen V in regulating collagen I fibril assembly [16]. In early development, articular cartilage and meniscus are both initiated from *Gdf5*-expressing progenitors in the interzone [17]. Given the high expression of collagen V in this region, it is possible that collagen V regulates the activities of progenitors that give rise to multiple joint tissues, including the meniscus. In fact, the osteophytes in P240 *Col5a1^{cko}* knees (Fig. 3) support the importance of collagen V in the initial growth and development of the knee structures, which are critical to overall joint health in adulthood. Meanwhile, lack of collagen XI in this region suggests that collagen V may be more crucial than collagen XI in the initial development of articular cartilage, while collagen XI could be essential for the development of epiphyseal cartilage and secondary ossification. Building on these results, our ongoing studies aim to elucidate the mechanisms by which collagen V regulates cartilage and meniscus integrity, and delineate the roles of collagen V versus XI in initial joint development.

INTRODUCTION

Pathological wounds are a prevalent healthcare problem, affecting more than 40 million Americans [1]. Imbalanced healing often results in fibrotic scar formation, marked by excessive deposition and aberrant assembly of type I collagen fibers. Type V collagen, a minor fibril collagen, initiates the initial fibrillogenesis of collagen I [2], and thus, could be an important player in wound healing [3]. For patients with classic Ehlers-Danlos syndrome (cEDS), a genetic disorder caused by mutation of human *COL5A1* gene, one major symptom is the formation of atrophic scars [4]. Understanding the role of collagen V in wound healing will provide new insights for improved cEDS patient care and new targets for regeneration therapies. This study aims to determine the impact of collagen V insufficiency on the wound healing and scar formation in vivo using collagen V heterozygous mice, *Col5a1*^{+/-}, an established animal model of cEDS [5].

METHODS

Two 6-mm diameter circular full-thickness dermal punch wounds were created on the lower dorsal skin of *Col5a1*^{+/-} and wild-type mice at 7 weeks of age [6]. Both wound tissue and surrounding intact skin tissue were harvested on post-wound day (PWD) 14 and 21 [7]. We applied Picrosirius Red staining to assess scar size and collagen I fiber structure, and immunofluorescence (IF) imaging to assess the distributions of collagen V (1:200, Ab7046) and α -smooth muscle actin (α -SMA, 1:1000, Ab5694), a biomarker of myofibroblast activation [8]. Freshly dissected skin tissue was cryotomed into 20- μ m

thick cross-sections in OCT for scanning electron microscope (SEM) imaging and atomic force microscope (AFM) analyses. For SEM, cryo-sections were treated with trypsin and hyaluronidase and imaged at 10k \times magnification. AFM nanoindentation was applied to quantify the micromodulus, *E*_{ind}, using a microspherical tip (*R* \approx 5 μ m, *k* \approx 0.03 N/m) and a BrukerNano AFM in 1 \times PBS, following established procedures [9]. We separated the moduli of intact epidermis, dermis, wound edge (WE), as well as granulation tissue (GT) at PWD14, and scar tissue at PWD21 (Fig. 3a). Two-way ANOVA followed by Tukey-Kramer post-hoc test was applied to detect differences with region and genotype at the significance level of $\alpha = 0.05$.

RESULTS

The reduction of collagen V in *Col5a1*^{+/-} murine skin was validated by the decreased staining of collagen V (shown for granulation tissue, Fig. 1a). With the reduction of collagen V, we observed an appreciable increase in the size of scar tissue (Fig. 1b, dashed line), which was in alignment with aggravated activation of myofibroblast, as illustrated by α -SMA staining (Fig. 1c). Also, at the nanoscale, for both genotypes, the scar tissue showed more aligned, densely packed collagen fibers relative to the intact dermis, illustrating aberrant assembly of collagen fibrils (Fig. 2, arrowheads). Comparing to the WT control, both the intact dermis and scar tissue of the *Col5a1*^{+/-} skin exhibited thicker collagen fibrils, indicating aggravated scar formation with the loss of collagen V. Furthermore, *Col5a1*^{+/-} group also showed lower micromodulus relative to WT control throughout intact, granulation (PWD14) and scar tissues

(PWD21) (Fig. 3), supporting impaired biomechanical functions with the loss of collagen V.

DISCUSSION

This study highlighted the crucial role of collagen V in regulating the healing process and scar formation in dermal wounds. Here, we validated that collagen V insufficiency leads to widened scar and abnormal collagen density indicated by picrosirius red (Fig. 1b). Furthermore, SEM imaging confirms the difference between collagen fibril thickness of WT and *Col5a1*^{+/-} groups (Fig. 2). These thickened collagen fibrils within the *Col5a1*^{+/-} group might be an indication of excessive fibrosis which is a classic symptom of cEDS [4]. In addition, IF staining of α -SMA suggests that PWD21 *Col5a1*^{+/-} scar tissue retains aggravated activation of myofibroblast when compare with WT group (Fig. 1c). This indicates collagen V could play important role in mediating fibroblast migration and activation during cutaneous wound healing.

It has been well established that symptoms of cEDS include hyperflexible skin, easy bruising, retardation in wound healing, and widened scar [10]. However, the degree of pathological changes in tissue biomechanics of reconstructed tissue is affected by the insufficiency of collagen V is not well understood. Here, we show for the first time, that across all regions of skin, whether intact or regenerated tissue, collagen V insufficiency leads to significantly softer tissue stiffness when compared with tissue with normal collagen V quantity (Fig. 3b). Building on these results, our ongoing studies aim to investigate the fiber alignment and density of granulation and scar as well as healthy tissue, as well as the cell proliferation and general MMP activity during the remodeling of wound tissue.

EVOLUTION OF THE HEMODYNAMIC PROPERTIES AND ARTERIAL WALL REMODELING IN PULMONARY ARTERIAL HYPERTENSION

H. Mu (1), D. Valdez-Jasso (1)

INTRODUCTION

Pulmonary arterial hypertension (PAH) is characterized by sustained elevation of mean pulmonary arterial pressure and vascular remodeling. Recent studies have shown that changes in vascular compliance, characteristic specific attributed to the large pulmonary arteries, plays an important role in PAH. [1,2,3] Our studies on pressure and flow data analyzed using a three element Windkessel model have shown that female and male rats have different patterns of hemodynamic changes, with a significant decrease in vascular compliance for both sexes, but total resistance decreases to be specific to male rats [4]. This difference in the hemodynamic implies different types of vascular remodeling between female and male rats. To better understand wave propagation along the large vessels and impact of vascular remodeling, we investigated these hemodynamic measurements using a one-dimensional fluid model.

METHODS

Male Sprague-Dawley rats (Charles River Lab) were injected with sugen 5416 (SuHx) and kept in 10% O₂ hypoxia chamber for three weeks to induce PAH. Taking the injection day as week 0, SuHx rats of week 6 was selected for analysis. Control rats received no injection and were kept in normoxia. Rats underwent a thoracotomy to expose the heart and great vessel and simultaneously measure pulmonary arterial pressure and flow with a dual-pressure catheter and a flow probe (Transonic Science), respectively (Figure 1). The data were collected in LabChart Software (ADInstruments Inc.) and processed in a custom-built Matlab code. After obtaining the hemodynamic measurements, the lungs were harvested, and the left and right pulmonary arteries *ex-vivo* radius and length were measured using ImageJ. Biaxial tests were carried out using the BioDynamic chamber (ElectroForce Systems Group) as previously described [5]. Briefly, segments of the pulmonary arteries are cannulated, perfused, and in inflated using pulsatile flow, temperature-controlled PBS. Measured pressure, arterial diameter, and

axial tension were used to compute circumferential strain and stress, and modeled using the quasi-linear viscoelastic model to obtain the elastic modulus E .

Figure 1. *In-vivo* pressure and flow data measured at the inlet of main pulmonary artery.

Our model spans the main, left, and right pulmonary arteries (M, L, and RPA) with assumptions of incompressible, Newtonian blood and axisymmetric, inviscid, laminar flow. Blood flow is formulated with the conservation of mass (Equation 1) and momentum (Equation 2), and a linear thin-wall state equation (Equation 3). [6]

$$\frac{\partial A(x,t)}{\partial t} + \frac{\partial Q(x,t)}{\partial x} = 0 \quad (1)$$

$$\frac{\partial Q(x,t)}{\partial t} + \frac{\partial}{\partial x} \left(\frac{Q^2(x,t)}{A(x,t)} \right) + \frac{A(x,t)}{\rho} \frac{\partial P(x,t)}{\partial x} = - \frac{2\pi\nu r(x,t)Q(x,t)}{\delta A(x,t)} \quad (2)$$

$$P = P_0 - \frac{4Eh}{3r_0} \left(1 - \sqrt{\frac{A_0}{A}} \right) \quad (3)$$

Here A is the vessel's cross-sectional area, Q is the volumetric flow, P blood pressure, r is the artery radius, t is time, x is the longitudinal distance with inlet as $x = 0$, ρ is blood density, ν is kinematic viscosity, δ is the boundary layer thickness, P_0 is the end-diastolic pressure, E is the circumferential elastic modulus obtained from the mechanical tests,

h is the artery wall thickness, r_0 and $A_0 = \pi r_0^2$ are the end-diastolic radius and cross-sectional area.

Figure 2. One-dimensional model of the large, proximal pulmonary arteries is initiated with *in-vivo* flow to predict pressure waveforms.

The model is initialized using *in-vivo* flow measured at the inlet of the pulmonary vasculature. At the bifurcation, flow and pressure conservations are enforced. For the outlet boundary conditions of LPA and RPA, three-element Windkessel models are applied to quantify the effect of downstream vessels (Figure 2), in which the Windkessel parameters are previously calculated from the pressure-flow data measured at the inlet. [7]

Windkessel parameters and MPA elastic modulus are then optimized to best fit the measured hemodynamics. The minimization algorithm uses the sum of squares error between the simulated and measured pressure at MPA inlet as the objective function, where extra weight is added to the end-diastole pressure. After obtaining the baseline simulation for the control and PAH rats, the simulation parameters of the control rat are substituted with SuHx value to explore the effect of different PA remodelings on hemodynamics.

RESULTS

The simulated pressure resembles the *in-vivo* pressure measurement (Figure 3A). The baseline simulation parameters differ greatly between the control and SuHx groups (Figure 3B), with the elastic modulus of the MPA increased the most by about 17 folds. When the elastic moduli (stiffness) of the large pulmonary arteries in the control are substituted with the SuHx values, the simulated pressure greatly increases systolic pressure and the rate of change of pressure, while the diastolic pressure remains the same. In contrast, replacing the Windkessel parameters of the control simulation increases the diastolic pressure slightly with the unchanged systolic pressure. (Figure 3C)

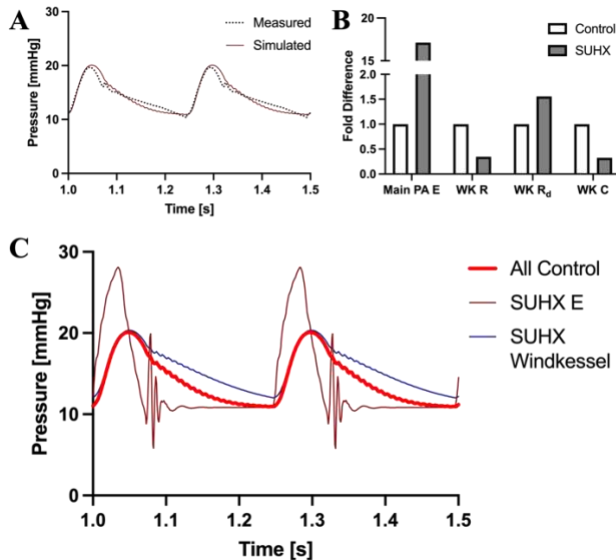

Figure 3: Simulated pressure waveforms at the inlet of MPA and the baseline simulation parameters in control and SuHx rats. (A)

Comparison of measured and simulated pressure. (B) Comparison of optimized baseline simulation parameters, where E is the circumferential elastic modulus, WK R and R_d are Windkessel proximal and distal resistances, and WK C is the Windkessel Compliance. (C) Comparison of control simulation, control rat with SuHx large artery stiffness (SuHx E), and control rat with SuHx downstream vessels (SuHx Windkessel).

DISCUSSION

Our one-dimensional model can predict the pulmonary arterial pressure waveforms. By substituting the simulation parameters based on the control simulation, the effect of different remodeling on the hemodynamics can be distinguished. The stiffening of the proximal pulmonary arteries produces a much greater change in the simulated pressure waveform than remodeling of the distal vasculature. When there is only the stiffening of the proximal pulmonary arteries, there is a much greater pulse pressure in the simulated pressure waveform which increases the afterload experienced by the right ventricle. In addition, the shortened and heightened pressure peak could direct more pulsatile flow to the distal pulmonary vasculature and cause damage. [3,8] The great hemodynamic change suggests the importance of proximal pulmonary stiffening in PAH. When there is only the remodeling of the distal pulmonary vasculature, the elevated diastolic pressure may indicate blood retention in the pulmonary arteries and slightly elevated right ventricle afterload.

When comparing the hemodynamics from control, normotensive animals to those of the SuHx rats, we find the MPA stiffness E and Windkessel resistance R_d to increase, while the compliance decrease. This finding generally aligns with other modeling studies [1,6].

The limitation of this study includes the single SuHx group simulated. In the future, more SuHx groups will be added to show a time-course of pulmonary artery remodeling and how the hemodynamics is affected at different stages.

In conclusion, our modeling approach identifies the hemodynamics changes due to different aspect of vascular remodeling. With more SuHx groups to analyze in the future, we can see how the pulmonary arteries adapt to the raising pressure in different stage of PAH, and thus better understand the physiopathology of PAH.

A 1D MODEL CHARACTERIZING THE ROLE OF SPATIOTEMPORAL CONTRACTION DISTRIBUTIONS ON LYMPH TRANSPORT

Farbod Sedaghati (1), J. Brandon Dixon, PhD (1,2), and Rudolph L. Gleason, Jr., PhD (1,2)

- (1) The George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA.
(2) The Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, USA.

INTRODUCTION

The lymphatic system transports the interstitial lymph fluid from tissues back to the venous system (usually) against an adverse pressure gradient. To achieve this goal, secondary lymphatics contract autonomously to drive the lymph through one-way valves. This autonomous contractile behavior is governed by numerous factors and computational models have proven useful in characterizing the contractile behavior and lymph transport. It is becoming increasingly clear that the timing of contractions may be governed by pacemaking cells within the lymphatics but much is unknown regarding the orchestration of contractions across multiple lymphangions. Lumped-parameter models are the most commonly used approach to study the lymphatic mechanics and simulate lymph transport. The drawbacks of such models are that the pacemakers cannot specifically be located, the contraction propagation speed is not applied, and the pressure/flow waves along the lymphangions are missing. Therefore, this study aims to construct a 1-D mathematical model that is based on fluid-solid governing equations and utilizes a general activation function which is created based on pacemaking parameters and drives the lymph transport in the healthy and Connexin-45 knock-out (KO) mice.

METHODS

We modeled a lymphatic vessel consisting of three lymphangions and four secondary valves (Figure 1). The inlet and outlet pressures were set at 3.5 and 4 cmH₂O, respectively, for all illustrative simulations. Each lymphangion was modeled as a tapered, elastic tube in a one-dimensional pulsatile fluid flow framework. To determine the diameter for a given pressure and muscle activation, we employed a weighted-average of pre- and peak-twitch diameters where the weight function was a general activation function (Eq. 1). We used a sigmoidal valve behavior introduced by Bertram *et al.* [1]. A 2-D bivariate Gaussian function was used to quantify the temporal and spatial propagation of contractions (Eq. 2) (Figure 2). The normal case was

based on the wild-type (Cx45^{flx/flx}) (WT) mouse data and the abnormal case was from Smmhc-CreER^{T2}; Cx45^{flx/flx} [TMX] (2-4 weeks) (KO) mouse line (Table 1) [2]. The effect of the direction of contraction wave propagation is an ongoing challenge. To investigate the extent that direction of propagation would affect lymphatic pumping in the KO mouse, three scenarios were considered: 1) all signals were antegrade, 2) every other signal was retrograde, and 3) all signals were retrograde.

Equations

$$d(z, t) = (d_{peak} - d_{pre})t_{act} + d_{pre} \quad (1)$$

$$f(x, t) = \frac{1}{2\pi\sigma_x\sigma_t\sqrt{1-\rho^2}} e^{\left[\frac{1}{2(1-\rho^2)} \left(\frac{(x-\mu_x)^2}{\sigma_x^2} - \frac{2\rho(x-\mu_x)(t-\mu_t)}{\sigma_x\sigma_t} + \frac{(t-\mu_t)^2}{\sigma_t^2} \right) \right]} \quad (2)$$

RESULTS

The time-space mapping of contractions illustrates that the peak contraction arrives at different times within the lymphangion chain, depending on both the propagation speed and how close the vessel region is from the pacemakers (Figure 1). Ejection fraction (EF), which is the ratio of the volume of fluid dispenses at peak systole relative to the diastolic volume, was 0.78 for the WT model but only 0.20 to 0.33 in the KO models. In the WT model, all lymphangions experienced a pressure rise equivalent to the total pressure gradient of the chain and the mean pressure in all lymphangions was near the average of P_{in} and P_{out} (Table 2). However, in the KO models, only pressure in L3 oscillated between P_{in} and P_{out}, while the L1 and L2 pressures stayed near P_{in}, suggesting that the work done on the fluid was performed primarily by a single lymphangion. The flow patterns showed a sudden impulse in flow at the mid-point of each lymphangion that was concurrent to systole in the WT model followed by a dip due to relaxation and lumen expansion resulting in flow retracement and provided a net pumped lymph flow of 5.44 μL/hr (Figure 3). Similar behavior was not observed in the KO models. Although a relatively high

flow passed the last lymphangion during systole, simultaneously the first two lymphangions had opposing (zero or negative) flows. Similarly, in diastole the flow in L3 was reversed but L1 and L2 had forward flows. The net cycle-averaged lymph flow was 2.9, 2.8 and 1.17 $\mu\text{L/hr}$ in Cases 1, 2, and 3 of the KO models. It is notable that in all KO models, the peak systolic and diastolic velocities did not exceed 0.5 and -0.8 mm/s, while in the WT model they reached up to 2.4 and -3.8 mm/s.

Table 1: Contractility metrics used to prescribe the activation function.

Mouse line	Conduction Speed (cm/s)	Number of Initiation Sites (1/cm)	Contraction Frequency (1/min)	Contraction Period (sec)
WT	0.98	10	8.3	7.23

KO	0.07	31	15.8	3.80
----	------	----	------	------

Table 2: Mean pressure in each lymphangion during a contraction cycle.

Mean pressure (cmH ₂ O)			
(Average of P_{in} and P_{out} is 3.75 cmH ₂ O)			
Model	L1	L2	L3
WT	3.73	3.73	3.74
KO – Case 1	3.50	3.50	3.71
KO – Case 2	3.52	3.52	3.72
KO – Case 3	3.52	3.55	3.73

DISCUSSION

EF and fractional pump function for the WT and KO models resemble well published experimental results. Zawieja et al. showed that the mean WSS is 0.4 to 0.6 dyn/cm² with the peak of 3 to 10 dyn/cm², which are close to our model calculations [5]. If the KO model is comparable to the wounded case presented in a study, contractile frequency of the remodeled vessel is 2-3 times more than the control case, which is consistent with our results [6]. The current model could be a useful tool in studying the lymph transport in conjunction with an imaging technique. One limitation was that due to uncertainties the chemical couplings in the contractions were not included in the model. To advance the model, one may add pressure/WSS and contraction couplings that provide feedback to regulate contractions.

A 1-D mathematical model along with contractility metrics obtained from the experimental data of the WT and KO mouse lines were used to study the mechanical behavior and pumping function of a lymphatic vessel under the health and Cx45 knocked out conditions. The model proves that only by analyzing some aspects of the mechanical behavior of a lymphatic vessel, we cannot get a clear picture of the pump efficiency. For example, the model showed that a high contraction velocity and valve functioning, do not guarantee efficient lymph transport. Lastly, disparities between KO models suggest that the directionality of pacemaking signals matters and the antegrade contraction propagation seems to be more efficient in lymph transport which complies with the accepted paradigm.

INTRODUCTION

Borderline left ventricle (BLV) patients are neonates born with an undeveloped left ventricle, often resulting from aortic valve stenosis, hypoplastic aortic arch, and hypoplastic left heart complex.¹ They often undergo critical decisions as neonates between a biventricular repair (BiVR) or a single ventricle palliation procedure (SVPP). Current surgical decision-making is primarily based on morphological measurements,² and incongruent pursuit of any approach will increase the risk of multiple interventions and mortality. Providing the surgeons with the ability to predict hemodynamics post-intervention and inform decision-making will transform the treatment planning for these high-risk patient groups.

Novel tools have been developed recently for predicting hemodynamics in response to surgical intervention in complex congenital heart disease applications.³ A majority of these models rely on lumped parameter networks (LPN), resembling electrical circuits to simulate blood flow, due to their computational efficiency and robustness in representing organ-level hemodynamic interactions in complex pathologies. However, closed-loop LPN models involve tens of parameters that need to be tuned to personalize the model and are driven by clinically acquired data, including catheter-based and/or echocardiographic measurements, often associated with uncertainties.

We developed a computational framework to model the hemodynamics in BLV patients undergoing virtual BiVR and SVPP.⁴ A Bayesian-based semi-automatic tuning framework is applied to personalize the preoperative LPN model for a BLV patient and propagate the uncertainties in the clinical data through the model. In this approach, we treat the unknown LPN parameters are treated as random variables and apply a Metropolis-Hastings (MH) type Markov chain Monte Carlo (MCMC) algorithm: DREAM,⁵ to sample from their joint posterior distribution. We then perform a Monte Carlo simulation on all the parameter samples to obtain a set of preoperative LPN solutions and quantify the variability in the hemodynamic outputs. The framework

then allows simulating virtual surgeries (BiVR and Norwood – 1st stage SVPP) using the post-operative LPN models and quantifying the confidence intervals on the predicted hemodynamics.

METHODS

Data Collection: We selected four patients for this IRB-approved study who clinically underwent either BiVR or SVPP (P1, P2 for SVPP, and P3, P4 for BiVR). Patients were described as having ‘moderately hypoplastic left ventricle’ on their ultrasound reports, and their mitral (-3.11 ± 1.53) and aortic valve z-scores (-2.61 ± 1.46) are below average. In this study, we do not include any cath data and base our model entirely on echocardiographic measurements. Clinical targets include pressures and flow rates derived from Doppler measurements. Atrium and ventricular chamber pressures were derived based on Doppler-based transvalvular pressure gradients, and cuff-based aortic pressure.⁶ Patient-specific vascular resistances (PVR, SVR) were extracted as the ratios of the pressure gradients across the pulmonary and systemic arteries and the corresponding atria to the respective flow rates.

Uncertainty Quantification (UQ) and Parameter Estimation: We adopted a framework (Figure 1) that allows for both UQ and automatic parameter estimation.^{7,8} We define a set of parameters: $\mathbf{y} = \{y_1, y_2, \dots, y_n\}$ statistically characterized by their joint probability $\rho(\mathbf{y})$, where y^k is defined as a generic sample based on $\rho(\mathbf{y})$. We also define a set of model outputs $\mathbf{o} = \{o_1, o_2, \dots, o_m\}$ corresponding to m clinical targets outputs $\mathbf{d} = \{d_1, d_2, \dots, d_m\}$. Considering the LPN model as a map $\mathbf{G}: \mathbb{R}^n \rightarrow \mathbb{R}^m$, which satisfies $o^k = G(y^k)$, the error between model outputs and clinical targets is defined as, $\epsilon = \mathbf{d} - \mathbf{G}(\mathbf{y})$. Given the model observations \mathbf{y} , the Bayesian formulation describes the relation between posterior density $P(\mathbf{y}|\mathbf{d})$ and the prior density $P(\mathbf{y})$ as,

$$P(\mathbf{y}|\mathbf{d}) = \frac{P(\mathbf{d}|\mathbf{y})P(\mathbf{y})}{P(\mathbf{d})} \quad (1)$$

Here, we set uniform $P(\mathbf{y})$ as priors in reasonable ranges based on previous manual tuning experience. Due to the lack of knowledge about

how clinical measurements are correlated, we adopt a weighted Gaussian distribution as the likelihood function $P(\mathbf{d}|\mathbf{y})$ given by,⁷

$$\frac{1}{\sqrt{(2\pi)^m \prod_{i=1}^m \omega_i \sigma_i^2}} \exp\left(-\frac{1}{2} \sum_{i=1}^m \frac{[d_i - G_i(\mathbf{y})]^2}{\omega_i \sigma_i^2}\right) \quad (2)$$

where d_i denotes the i^{th} clinical targets with a weighting factor ω_i and variance σ_i^2 , $G_i(\mathbf{y})$ is the i^{th} model output. Since it is difficult to calculate the marginal density of $P(\mathbf{d})$, we applied the DREAM algorithm as an alternative route to sample only from the density $P(\mathbf{d}|\mathbf{y})P(\mathbf{y})$.⁹ We set 20 chains in parallel and ran DREAM algorithm for 1000 steps, resulting in 20000 samples from the joint posterior distribution of the parameters. Upon convergence, the results depict a set of parameters characterized by the maximum posterior probability. We then applied a Monte Carlo step for each parameter set by calculating the model outputs of the last 1000 sampled candidates generated to yield the mean and standard deviations for the hemodynamic quantities of interest. Finally, we performed LPN simulations of both virtual surgeries (BiVR, SVPP) for these parameter samples to predict post-operative hemodynamics with confidence intervals.⁴ Our framework allows for automatic parameter estimation by using the parameter set corresponding to the maximum posterior following MCMC as an initial guess for the subsequent Nelder-Mead optimization. However, we focus on UQ analysis in the current work.

Figure 1: Workflow for uncertainty quantification and automated parameter estimation.

RESULTS

We present the computed statistics for the post-operative hemodynamic indicators in BLV patients (Figure 2). Both the virtual surgeries significantly lower pulmonary artery pressures (Figure 2a, $p < 0.01$), except for performing BiVR in patient A (38.66 ± 0.98 vs. 38.42 ± 2.94 mmHg, $p = 0.02$). BiVR resulted in a significantly higher PAP_{mean} ($p < 0.01$) than Norwood for patients P1 and P2, but PAP_{mean} for patients P3 and P4 remained in the normal PAP range. Mean aortic pressure (AOP_{mean}) generally increased after surgery in all the patients (Figure 2b) except for performing BiVR on patient P1 (AOP_{mean} decreased from 49.76 ± 1.53 to 40.66 ± 1.73 mmHg, $p < 0.01$). Our LPN-based UQ model predicts a balanced pulmonary to systemic flow ratio after BiVR compared Norwood (Figure 2c; P1: 1.04 ± 0.03 vs. 0.66 ± 0.03 ; P2: 1.00 ± 0.04 vs. 1.27 ± 0.04 ; P3: 0.93 ± 0.01 vs. 1.42 ± 0.07 ; P4: 0.96 ± 0.01 vs. 1.67 ± 0.08 ; $p < 0.01$). Significant differences were also demonstrated in oxygen deliveries (O_2D) between BiVR and Norwood procedures for patients P3 and P4 (Figure 2d; P3: 864.53 ± 51.78 vs. 542.98 ± 64.52 ; P4: 796.48 ± 45.74 vs. 429.23 ± 76.48 ; $p < 0.01$).

DISCUSSION

We developed a robust and efficient computational framework to personalize and predict post-operative hemodynamics in BLV patients by considering the uncertainty in clinical data acquisition. Our model only relies on non-invasively acquired echocardiographic data and does not employ cath, although regarded as the 'gold standard' because these patients often do not undergo cath. We have analyzed the model outputs by comparing the hemodynamic characteristics of four patients who underwent either BiVR or Norwood.

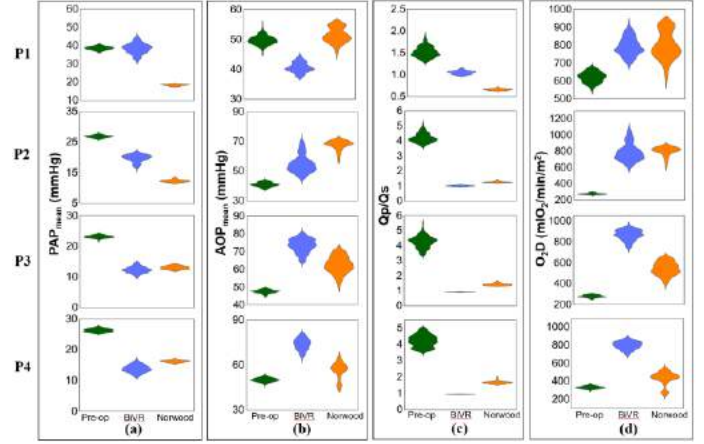

Figure 2: UQ analysis of predicted post-operative hemodynamic indicators in BLV patients. (a) Mean pulmonary artery pressure (PAP_{mean}) (b) Mean aortic pressure (AOP_{mean}) (c) Qp/Qs ratio (d) Oxygen delivery (O_2D) to the systemic circulation. Rows represent data for different patients (P1-P4).

Our results indicate that performing either virtual surgery in most cases will significantly affect the pulmonary and systemic pressures, flow rates, and oxygen deliveries. The utility of the model is demonstrated by comparing the predicted hemodynamics between the two surgical procedures. Our model predicts higher pulmonary pressures in patients P1 and P2 in response to BiVR but showed no significant differences in patients P3 and P4.

Further, our model predicts a more balanced Qp/Qs after BiVR with negligible variances but shows substantial variability after performing Norwood among the study group. These model findings suggest that SVPP is the better choice for patients P1 and P2. At the same time, the model suggests that BiVR is the optimal choice for patients P3 and P4, restoring two-ventricular circulation with an improved O_2D .

Limitations The current study has limitations we plan to overcome in the future. While the present study only considers uncertainty from model inputs, operator variability is not accounted for. We must also demonstrate the model's utility over a larger and a prospective patient group. We also aim to explore other surgical options for BLV patients, such as the staged LV recruitment following LV rehabilitation.¹¹

INTRODUCTION

It is estimated that 1 in 12 persons harbors an unruptured intracranial aneurysm (IA) [1]. Clinical evaluation of IAs requires clinicians to decide whether the aneurysm is likely to grow, rupture, and requires treatment or if it should be simply monitored. However, assessing an IA's risk of rupture remains challenging as the physiology of the aneurysm is complex and it exists in a dynamic environment. Both morphological and hemodynamic factors have been correlated to the growth and rupture of an aneurysm [2]. However, prior studies have reported conflicting results regarding the role of specific hemodynamic and morphological risk mechanisms [3].

The motivation for this study lies in addressing a major contributing factor to these conflicting results due to the varying and non-physiological assumptions which are made among hemodynamic studies in this domain. In particular, we focus on the assumption that *in-vitro* IA models are most often manufactured to be rigid and have no compliance contrary to expected *in vivo* conditions [4]. In part because of the use of this assumption, there is a lacking consensus as to whether or not the aneurysms deform *in vivo*, and if so, if the deformation is a significant parameter affecting its growth and rupture [8, 9]. Experimental particle image velocimetry (PIV) studies usually use a block model or models made of plastics/ glass [5, 6, 7]

In this work, we will compare hemodynamics in an IA using a rigid block model as well as a compliant, thickness-controlled model. We will conduct this study using 4D PIV and an in-house developed additive-manufacturing based method for making compliant IA models. Further, we will evaluate the conditions under which deformation is observed with the compliant aneurysm model.

METHODS

R MCA aneurysm: The aneurysm model in this study is based on a patient specific unruptured 7 mm right middle cerebral artery (R MCA) aneurysm treated at Penn State's Hershey Medical Center.

PDMS Block model: The block model manufactured in this investigation is a 1:1. Computed tomography (CT) images of the IA were obtained as a digital imaging and communications in medicine (DICOM) file as shown in Figure 1(a). Using this, a 3D reconstruction in Slicer 3D software is performed. Figure 1(b) shows the segmented SolidWorks part file. The segmented stereolithography (STL) geometry was 3D printed in polyvinyl alcohol (PVA). The 3D printed part was placed in an acrylic box and polydimethylsiloxane (PDMS) silicone was poured around the printed part. The PVA model was subsequently dissolved out with warm water. Figure 1(c) shows the final PDMS block model based on the R MCA aneurysm.

Compliant model: The compliant model was manufactured using a concentric mold in which the PDMS is encased. The PDMS model was then cured for 5-6 hours in an oven set to a temperature of 70°C. The compliant model is shown undergoing pressure testing in Figure 2.

Figure 1: (a) Patient specific R middle cerebral artery (MCA) aneurysm, Digital Imaging and Communications in Medicine (DICOM) file (b) Derived SolidWorks file (c) Block model (d) PIV setup

Experimental methods: The aneurysm models were subjected to physiologically-relevant flow. The inflow waveform was inferred from prior studies that reported flow rate waveforms in the MCA artery. A blood analog working fluid seeded with fluorescent particle tracers was used. We conducted time-resolved volumetric PIV experiments using four cameras for both models. Figure 1(d) shows the experimental setup used. Shake-the-box processing was used to evaluate velocity fields from the particle images [10]. Subsequently, relevant flow parameters such as wall shear stress (WSS), oscillatory shear index (OSI), relative residence time (RRT) and turbulent intensity were evaluated.

Deformation pressure test: To evaluate the expected amount of deformation using the compliant model, a preliminary test was conducted where the model was subjected to a total pressure difference of 100mmHg for 10 seconds and the deformation in the aneurysmal sac was measured.

RESULTS

Figure 2: (a) the setup of the model by closing the left side with tape, connecting the right side by a pressure transducer, and the inlet connected to the air compressor. (b) Graph illustrating the pressure measurements over 10 s taken using a pressure transducer. (c) Snapshot taken at $t = 0$ s. (d) Snapshot taken at $t = 1$ s showing a bulge visible as seen in the circles and by comparing the blue lines to the initial black square lines.

Figure 2 shows the results of the pressure test conducted using the compliant IA model. Comparing the observed deformation in Figures 2(b) and 2(c), it was observed that the aneurysm expanded by approximately 10% relative to its original size. It was qualitatively found that deformation was occurred uniformly in all directions. These results are preliminary; further experiments are needed to test across reduced pressure difference ranges as well as to account for natural cranial pressure. Moreover, the PIV results will further expand the extent to which this deformation affects the IA hemodynamics.

DISCUSSION

The preliminary results of this work highlight the importance of studying compliant geometries experimentally. Further studies can help to build a consensus on the role of deformation and wall compliance on IA hemodynamics *in vivo*. Compliant model deformation studies, such as ours herein, can be used in conjunction with fluid structure interaction (FSI) studies where deformation evaluation in cases of IAs with

irregular wall thickness is more easily controlled. However, the experimental study conducted in this work can be critical to validation of FSI models [11].

A limitation of this work so far is that only one compliant model and thus only a single value of compliance with a single value for material strength was assessed. Moving forward, other models with different material properties are needed to conclusively report differences in hemodynamic parameters in compliant models.

INTRODUCTION

Acute ischemic stroke (AIS) due to large vessel occlusions (LVOs) accounts for 90% of 6-month post-stroke mortality [1]. The standard treatment for an LVO AIS is mechanical thrombectomy (MT) that, when compared to standard therapeutic treatment, results in improved patient outcomes [2]. Current MT procedures require the use of stent retrievers (SRs) or aspiration techniques to restore blood flow. Despite the clinical success of MT, adverse outcomes including hemorrhage and thrombus embolization to distal vessels can occur [3]. To improve the degree of revascularization for SR MT, the interaction between SRs and thrombi, as well as the overall thrombus removal forces need to be better understood. Previous experimental research of SR MT has investigated the effects of vascular geometry on thrombi removal forces and found that they increase with tortuosity of the anatomical occlusion location [4]. These results are the motivation for investigating additional parameters of SR MT including the effects of clot hematocrit, length, and diameter on SR removal forces and for comparisons between different commercially available SRs on their removal forces. These findings will lead to better clinical training and inspire new SRs to further improve AIS patient outcomes.

METHODS

To accurately represent AIS in a benchtop model, a circulatory flow loop was developed with a peristaltic pump, flow meter, fluid reservoir, and a constricting cerebral artery model (PVC tubing) (**Fig. 1**). To ensure embolus analog (EAs) lodging within the artery model, the vascular geometry,

highlighted in **Fig. 1**, was tapered from 5.5 to 3.3 mm in diameter. To represent a MT procedure, a SR within a microcatheter was passed through a hemostatic valve into the flow loop. The SR was then connected to a force gauge attached to a stepper motor which ensured the SR was pulled at a constant speed and the maximum removal force was recorded. For these experiments, two different Medtronic microcatheters, Phenom21 and Phenom27, and three different Medtronic SRs of varying diameters and lengths were used (**Fig. 2A-C**): Solitaire Platinum (4x20 mm) and two sizes of Solitaire2 (4x15 and 6x30 mm).

Fig 1: Benchtop circulatory flow loop with the cerebral artery model highlighted.

Fig 2: Images of A) Solitaire2 4x15 mm, B) Solitaire Platinum 4x20 mm, and C) Solitaire2 6x30 mm SRs used. D) Example of microcatheter passed across the EA with E) SR deployment.

To fabricate EAs for these experiments, bovine blood was collected in CPDA-1 anticoagulated bags, centrifuged to separate red blood cells and platelet rich plasma, and reconstituted to achieve a specific hematocrit (0, 25, or 50%) before CaCl_2 was introduced to promote coagulation. The reconstituted blood was injected into 6 mm diameter tubing and placed in a Chandler Loop system where the EAs were formed under dynamic flow conditions for 2 hours. The EAs were removed from the Chandler loop, cut to length, and inserted into the flow loop upstream of the arterial model. The EAs flowed downstream and were allowed to lodge within the vascular geometry for 5 minutes. The microcatheter with the SR was then passed across the EA as shown in **Fig. 2D**. The microcatheter was pulled back to deploy the SR over the entire EA (**Fig. 2E**) and the SR was attached to the force gauge which pulled the SR while recording the removal forces. This protocol was also repeated for each SR without the presence of a lodged EA to collect baseline (control) removal forces. In these control tests, the removal forces represent the frictional interaction forces between the SR and the vascular model (PVC tubing).

RESULTS

The maximum removal forces for each of the experimental test parameters are summarized in **Table 1**.

Table 1: Sample size and removal forces for each test parameter

Test Parameter	Sample Size	Average Removal Force (N)
Solitaire Platinum		
4 × 20 mm		
Controls (w/out EA)	20	0.24 ± 0.012
50% Hematocrit	20	0.59 ± 0.162
Solitaire2		
4 × 15 mm		
Controls (w/out EA)	20	0.29 ± 0.011
50% Hematocrit	20	0.55 ± 0.076
25% Hematocrit	20	0.54 ± 0.071
0% Hematocrit	20	0.57 ± 0.075
6 × 30 mm		
Controls (w/out EA)	20	0.39 ± 0.025
50% Hematocrit	20	0.69 ± 0.093

As seen in **Fig. 3**, the removal forces varied only slightly between the different hematocrit EAs. However, there was a slight, but not significant, increase in the removal forces for the 0% hematocrit EAs, which was expected based on lower clinical removal success for fibrin-rich clots [5].

Fig 3: Maximum removal forces with the Solitaire2 4×15 mm SR.

Fig. 4 compares the removal forces for 50% hematocrit EAs of varying geometry using the 6 mm diameter SR. The results

are presented for EAs with diameters 4.5-6.5 mm and lengths 14.3-18.7 mm. The relationship between EA diameter and removal force indicates a slight positive correlation, while EA length does not appear to correlate with overall removal force. Similar trends in EA diameter and length were observed for all hematocrit and SR dimension test parameters.

Fig 4: Maximum removal forces with the Solitaire2 6×30 mm SR for EAs of varying A) diameter and B) length.

DISCUSSION

The results of the experiments indicate that EA hematocrit does not have a significant influence on their SR removal force. These data also supports previous work [4] which showed that vascular tortuosity significantly influenced EA removal force, while other factors were minor. A comparison of the control test data across the various model geometries is displayed in **Fig. 5A**. From the average forces listed in **Fig. 5B**, it is observed that increasing complexity will increase the force by at least 0.1 N.

Fig 5: Control test removal forces from flow loop experiments with varying model geometries.

The 0% hematocrit EAs with the 4×15 mm Solitaire2 had the highest removal force. This was expected since fibrin rich clots are associated with lower recanalization rates [5]. For 50% hematocrit EAs, the average removal force with the 4×20 Solitaire Platinum SR was 0.59 N, 4×15 Solitaire2 SR was 0.55 N, and 6×30 Solitaire2 SR was 0.69 N. Based on these results, we have shown that removal forces increase as the diameter of the SR increases. From this, we hypothesize that the diameter of the SR has a greater influence on the removal force than its length. However, further testing with SRs of the same length and varying diameters is necessary to prove this. Further investigation is also needed to observe the range of removal forces collected with the various SRs with varying EA hematocrits, although similar trends are expected.

INTRODUCTION

Aging is the leading risk factor for osteoarthritis (OA), which afflicts more than 10% of adults over 60 years of age [1]. Many efforts have been dedicated to elucidating the cellular hallmarks of aging [2]. In contrast, despite the importance of extracellular matrix (ECM) in cartilage biomechanical function and chondrocyte mechanosensing, there is limited knowledge regarding how aging impacts ECM integrity. Our recent studies found that decorin, a small proteoglycan, plays indispensable roles in regulating the integrity of aggrecan network in cartilage ECM [3] and mediating chondrocyte mechanotransduction [4] during post-natal growth. In post-traumatic OA, up-regulation of decorin delays loss of fragmented aggrecan and thus attenuates surface fibrillation [5]. Decorin is actively expressed in both young and old human cartilage [6], indicating a potentially important role of decorin in regulating cartilage aging. This study tests whether decorin plays a crucial role in cartilage ECM maintenance during aging.

METHODS

Animal model. Cartilage-specific knockout of *Dcn* was induced by i.p. injection of tamoxifen to conditional decorin knockout mice (*Dcn^{fllox/fllox}/AcanCre^{ER}*, or *Dcn^{CKO}*) at 3 months of age (3M), and the phenotype was evaluated at 9 and 18 months (9M, 18M), and compare to age-matched controls. Additional global decorin-null (*Dcn^{-/-}*) and wild-type (WT) mice were evaluated at 3M and 18M. **Histology and immunofluorescence** (IF) imaging were applied to sagittal sections to assess joint morphology, sulfated glycosaminoglycan (sGAG) staining and presence of collagen I, indicating surface fibrillation [7]. **SEM** was applied to measure collagen fibril nanostructure [5]. **AFM-nanoindentation** was applied to the condyle cartilage surface to quantify tissue modulus [3]. **IF-guided AFM-nanomechanical mapping** was applied to delineate the local modulus, E_{ind} , between the territorial and interterritorial (T/IT)-ECM and PCM using unfixed cryo-sections of tibial cartilage, guided by the PCM biomarker, collagen VI, following

our established procedure [4]. For *in situ intracellular* $[Ca^{2+}]_i$ signaling, tibial cartilage explants were labeled with intracellular calcium indicator Calbryte-520, and time-series of confocal images were taken in isotonic, hypotonic and hypertonic DMEM [4]. The responsive rate, % R_{cell} , was calculated as the fraction of responsive cells over a 15 min period. A non-parametric Mann-Whitney U test was applied to compare E_{ind} , and the proportion z -test was applied to compare % R_{cell} , between genotypes at each age and/or osmotic condition at $\alpha = 0.05$, followed by Holm-Bonferroni correction to account for family-wise errors.

RESULTS

In 9M *Dcn^{CKO}* mice, loss of decorin led to an overall reduction of sGAG staining in cartilage, as well as the appearance of a surface layer devoid of sGAGs (Fig. 1a). IF imaging further confirmed that this sGAG-depleted layer was rich in collagen I, evidencing surface fibrillation. Furthermore, the surface collagen fibrils formed highly aligned bundles along the mediolateral split-line direction (Fig. 1a). A more severe phenotype was observed in 18M *Dcn^{CKO}* mice, including nearly full depletion of sGAG staining, disrupted cartilage surface integrity, as signified by the increased collagen I at uncalcified cartilage layer and a phenotype shifting of the surface layer cell to more elongated morphology (Fig. 1b). Applying AFM-nanoindentation, we did not detect significant changes of E_{ind} in 9M *Dcn^{CKO}* cartilage relative to the control. However, we found a substantially increased modulus in both *Dcn^{CKO}* and *Dcn^{-/-}* groups at 18M, which was in stark contrast to our previously observed modulus reduction in 3-month-old *Dcn^{-/-}* mice (Fig. 2a). This increase in modulus was also associated with a change in the nature of the indentation response. Specifically, we observed a linear F - D curve in 18M decorin groups (Fig. 2b), instead of the non-linear F - $D^{3/2}$ Hertzian indentation response typically observed for cartilage [3].

Interestingly, contrary to the increased E_{ind} in *Dcn^{CKO}* femoral condyle cartilage at 18M, we detected significantly reduced E_{ind} in tibial cartilages for both T/IT-ECM and PCM relative control (Fig. 3a,b). The

disrupted local mechanical environment of PCM did lead to altered chondrocyte mechanotransduction. For both 9M and 18M groups, loss of decorin led to a reduction in chondrocyte $[Ca^{2+}]_i$ responses in situ, as marked by significantly lower $\%R_{cell}$, under both physiological (isotonic) and osmotically instigated (hypotonic and hypertonic) conditions (Fig. 3c,d).

DISCUSSION

This study highlights a crucial role of decorin in maintaining the integrity of the cartilage surface during aging. The surface of healthy cartilage is characterized by a transversely isotropic mesh of thin collagen II fibrils [8], which plays an important biomechanical role in resisting shear forces and mediating boundary lubrication [9]. The absence of sGAGs and presence of highly aligned collagen I fibers (Fig. 1) clearly evidence cartilage surface fibrillation. Also, the non-Hertzian, linear $F-D$ response in the 18M *Dcn* group (Fig. 2) is a typical indentation response of fibrous tissues with inherent tensile pre-stress, such as the meniscus [10]. This surface fibrillation may be attributed to several mechanisms. First, decorin increases the retention of aggrecan in cartilage during post-natal growth [3], and the loss of sGAG staining observed here suggests that decorin continues playing this role during aging. Second, decorin also directly provides collagen interfibrillar spacing through its GAG chain [11]. Thus, the loss of decorin and aggrecan together may result in reduced biophysical resistance against collagen fibril fusion and alignment under shear forces during aging, thus accelerating surface fibrillation.

In addition, our results illustrate a crucial role of decorin in maintaining the PCM integrity and chondrocyte in situ mechanosensing during aging (Fig. 3). This role is likely manifested through its regulation of aggrecan network integrity [3], and support decorin as an

indispensable constituent of cartilage throughout lifespan. Our ongoing studies aim to pinpoint the mechanobiological roles of decorin in regulating chondrocyte fate and signaling, which will provide justification for using decorin as a molecular therapy to modulate cartilage aging.

TROPOCOLLAGEN DENATURATION IS NOT RESPONSIBLE FOR SUB-YIELD SOFTENING

INTRODUCTION

Computational models suggest that the cerebrovasculature plays a significant role in the brain's structural response in traumatic brain injury [1]. However, recent studies have shown that cerebral arteries soften following supraphysiologic deformations [2]. Previous studies, such as that by Converse et al., have identified tropocollagen denaturation as a critical failure location in the collagen hierarchy of cerebral arteries, but have not evaluated its association with tissue softening after mechanical injury [3]. To understand the connection between softening of tissue and changes in the extracellular matrix (ECM), this study explores the relationship between tropocollagen denaturation and softening of the tissue following mechanical overstretch at various rates. By examining this link, this study aims to inform potential therapeutics to counteract the effects of TBI.

METHODS

We isolated middle cerebral arteries from Göttingen minipigs that had been euthanized under the supervision of the University of Utah Institutional Animal Care and Use Committee. We mounted the arteries onto cannulas attached to a custom high-rate tester using suture and cyanoacrylate. We then preconditioned the tissue according to a previously published protocol [4].

After preconditioning, we subjected the arteries to axial harmonic oscillations at five frequencies ranging from 0.32 to 32 Hz between stretch magnitudes of 1.0 to 1.1 times the in vivo length to define the baseline dynamic moduli of the tissue at various rates at near-physiologic stretch. We then axially overstretched the arteries to stretch magnitudes ranging from 1.1 to 1.4 times the in vivo length at one of four targeted strain rates ranging from 0.05 to 50 s⁻¹. We then repeated the harmonic oscillations to calculate overstretch-induced softening of the tissue.

After mechanical testing, we stained the samples with CHP using a previously published protocol. This involved staining the arteries overnight in 20 μM F-CHP (3-Helix, Salt Lake City, UT), rinsing them three times in phosphate buffered saline, cutting them open, and mounting them luminal side down on a glass slide for imaging. A confocal microscope (FV1000, Olympus Corporation, Tokyo, Japan)

Figure 1: Softening (% of baseline stiffness) as a function of overstretch for all samples; regression line shown. Note that softening happens following low degrees of overstretch and is independent of overstretch rate.

was used to image the fluorescence of stained samples. We also performed the same staining and imaging protocol on undamaged, animal-matched controls for comparison. All pixels having an intensity greater than two standard deviations above the mean control intensity

were taken as representing collagen denaturation. We then tallied the number of pixels in test samples that exceeded this threshold and normalized them by the total number of pixels, providing a tropocollagen damage metric of percent bright pixels.

Dynamic moduli were calculated by dividing the peak-to-peak change in the first Piola-Kirchoff stress by the peak-to-peak strain. Softening (% baseline stiffness) was defined by the average post-overstretch dynamic modulus divided by the average baseline dynamic modulus for each sample. A linear regression was fit to the softening data as a function of magnitude of overstretch. A softening threshold was identified as the intersection of the softening regression with 100 % of the baseline stiffness. Overstretch curves were evaluated for yielding by monitoring for a sustained decrease in stiffness.

RESULTS

Softening progressed linearly with magnitude of overstretch but was notably independent of overstretch rate (Figure 1). The slope of the softening regression was 2.73 ± 0.31 (mean \pm 95% conf) with the threshold of softening calculated to be 1.05 ± 0.025 . The substantial softening of the dynamic moduli (>80% reduction) was observed in the absence of tropocollagen denaturation; denaturation was not readily identified at overstretches up to 1.4 (at any strain rate), although several samples (possible outliers) showed high amounts of CHP expression (Figure 2). Inspection of the overstretch curves for these odd CHP samples did not show any unusual activity (not shown). The overstretch curves did not show evidence of yielding, indicating that all observed softening was due to sub-yield deformations.

Figure 2: CHP expression showing the amount of denatured tropocollagen in each sample. Note that seven samples from the present study show elevated levels of CHP at a relatively low (<1.3) magnitude of overstretch. Additional data from arteries pulled to failure either quasi-statically (QS) or at high-rate (HR) in a previous study are added for comparison.

DISCUSSION

The purpose of this study was to examine the connection between sub-yield softening and tropocollagen denaturation. Results demonstrate that tissue softening is dependent upon extent of overstretch but not overstretch rate. Further, this softening occurs in the absence of tropocollagen denaturation at sub-yield overstretch levels.

Error! Reference source not found. illustrates the current understanding of the relationship between the degree of overstretch, the softening of the tissue, and ECM damage. This illustration is consistent

with previous research linking tropocollagen denaturation to the yielding of the native stress-stretch curve [3, 5].

Figure 3: A schematic showing the relationship of softening with ECM alterations, including the following regimes: (a) undamaged (no softening); (b) large range of deformations with clear mechanical softening, yet no evidence of ECM alterations; (c) post-yield regime characterized by tropocollagen denaturation; (d) gross fibril failure leading to final tissue failure. Note that the softening regression becomes dashed as we exit the presently explored softening region. A stress-stretch curve (pink) is provided for the convenience of the reader to relate landmarks in the mechanical curve with softening and ECM alterations.

These findings suggest that even mild TBI causes significant changes in cerebral vessel properties. Given their role in the structural response of the brain, these changes could potentially lead to increased susceptibility to subsequent injury. Unrecoverable vessel changes and associated dysfunction could also lead to disease development. These risks highlight the need to determine what molecules or structures in the collagen hierarchy are being changed to cause the significant softening observed following sub-yield overstretch. This information may be key to the development of post-TBI therapies, even where injury is considered to be mild.

A MESOSCALE MODEL OF SKIN TO INVESTIGATE THE ROLE OF THE DERMIS-EPIDERMIS INTERFACE ON THE TISSUE BIOMECHANICS

O. Moreno Flores (1), M. Rausch (2) A. Buganza Tepole (1,3)

(1) School of Mechanical Engineering, Purdue University, West Lafayette, Indiana, USA

INTRODUCTION

Understanding and correctly simulating the mechanics of skin is crucial for many medical applications, e.g. planning reconstructive surgery or monitoring wound healing. The field of skin biomechanics has often modeled this tissue as a homogeneous material because its response at finite deformations is governed by its collagen content. However, skin consists of two main layers with different constituents and microstructure: epidermis and dermis. Additionally, there are skin appendages such as hair follicles. Recently, multi-layer models of skin have been developed to study wrinkling and transport [1]. However, these models have considered skin as a stack of the multiple layers but have ignored the interface geometry between layers and the presence of skin appendages. Here we fill this gap using a computational model of a representative volume element (RVE) of the skin mesoscale.

METHODS

The interface geometry between epidermis and dermis is a sinusoidal-like surface (Figure 1a). A RVE $0.4002 \times 0.4002 \times 1 \text{ mm}^3$ shown in Figure 1b consist was created, consisting of two layers. The epidermis is the top layer and has thickness 0.1 mm. The dermis below has thickness 0.9 mm. The two layers are separated by a parametric surface described by equations

$$\begin{aligned} x(t) &= t & (1) \\ y(t) &= A \sin(Bt) & (2) \\ z(t) &= A \sin(Bt_1) + A \sin(Bt_2) & (3) \end{aligned}$$

with $A=0.015 \text{ mm}$ and $B=78.5 \text{ mm}$ as seen in Figure 1b. The sine wave parameters were determined by measuring thickness variations in histological images of skin e.g. Figure 1a. Another RVE was created with a hair follicle according to an anatomical study in [2]. A control model with flat layers was also created.

The epidermis and epithelium surrounding the hair follicle were modelled using the Ogden model parameters based on [3]. The dermis was modelled using the Gasser–Ogden–Holzapfel (GOH) model with parameters from [4]. The hair follicle was modeled as neo-Hookean with parameters C_{10} of 789.57 MPa and D_1 of 0.0003 MPa^{-1} (notation corresponds to Abaqus) The geometry was discretized mostly with linear hexahedra with a hybrid formulation for incompressible behavior, C3D8RH in Abaqus. Due to the complexity of the geometry, a small number of elements are linear wedge or tetrahedral elements C3D6H. A mesh convergence study was performed to select the appropriate element number. The final mesh of the RVE in Figure 1b consisted of 195704 elements. The hair follicle mesh had 202074 elements. The control geometry needed 68850 elements.

We were interested in the response of skin under multiple modes of deformation, e.g. biaxial deformations and shear. For this study we focus on the equi-biaxial response. Periodic boundary conditions were enforced in the simulations with linear constraints between pairs of nodes in Abaqus. The top surface was assumed stress-free.

Figure 1: a) Porcine histology image used to create RVE. b) Finite element model of RVE with sinusoidal interface.

RESULTS

We first investigated the homogenized behavior of the composite by simulating the RVE under biaxial loading, averaging the stress over the RVE, and comparing against the analytical solution of homogeneous tissue made from either Ogden or GOH materials. We also compared against the homogenized response of the control RVE with flat interface. The interface geometry did not have an influence on the homogenized response, confirming that multi-layer models with a flat interface are accurate to capture the macroscale response (data not shown). Furthermore, the response matched closely the rule of mixtures. However, the sinusoidal interface resulted in a heterogeneous stress distribution with higher stresses at the valleys and lower stresses at the peaks on the dermis side (Figure 2a-b). We tested how changes in period and amplitude of the interface affected the stress distribution. Figure 2a shows that increasing the amplitude further increased the maximum stress at the high saddles and decreased the stresses at the low saddles. Changing the period in the RVE implies simply a different control volume and scaling. Thus, we didn't expect the change in period would affect the magnitudes of the stresses. Indeed, changing the period just scaled the pattern of stress but values remained the same at the locations of interest (Figure 2b).

One question we were interested in was whether or not the sinusoidal interface would have an effect on the stress jump across the dermis-epidermis junction. For the model with amplitude of 0.015 mm the average stress jump was lower compared to a flat surface (Figure 2d), with the difference increasing at larger stretches. This last result suggests that even though the homogenized response is the same regardless of the interface geometry, the stress variation and in particular the stress jump is affected by the non-flat interface. The sinusoidal interface could offer a protective mechanism against delamination. Indeed, fracture mechanics studies on curved interfaces suggests an increase in fracture toughness with wavy interfaces compared to flat ones [5].

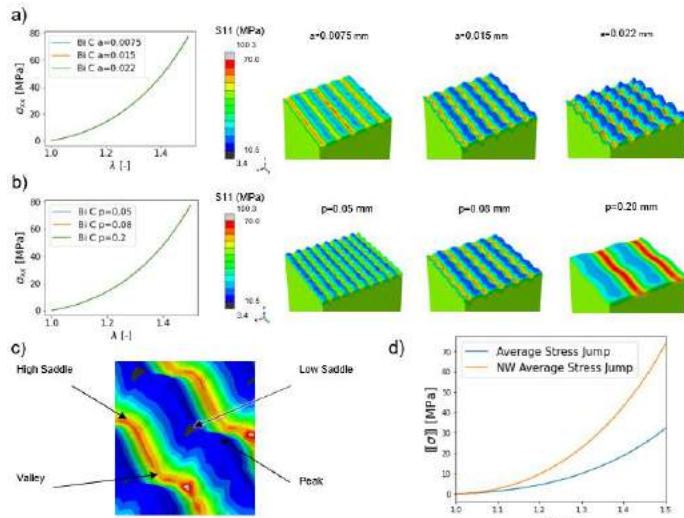

Figure 2: a) Stress vs stretch plots for amplitude variation along with their contour plots. Homogenized response remains unchanged but maximum stresses increases and minimum stresses decrease with increased amplitude. b) Stress vs stretch plots for period variation along with their contour plots. Neither the homogenized response nor the stress change at locations of interest change identified in c). d) Stress jump vs stretch plots comparing the sinusoidal interface and flat interface models.

We then looked into the RVE with the hair follicle. Hair follicles are known to be crucial in mechanosensation as part of our sense of touch [6]. The RVEs with the hair follicle exhibited strain concentrations in the epithelial tissue surrounding the hair follicle (Figure 3), where mechanoreceptors are expected [6].

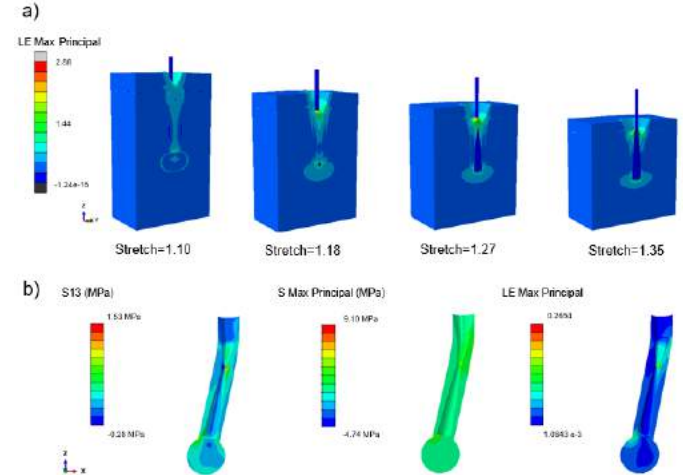

Figure 3: a) Contour plots of the strain as it progresses in a biaxial deformation. b) contour plots of the epithelium after experiencing shear.

DISCUSSION

Our analysis shows that the homogenized stress does not depend on interface geometry. Thus, flat interface models or even rule of mixtures can be used to predict the overall stress-stretch response of skin in biomechanics simulations (provided there is no damage or fracture). The interface geometry leads to heterogeneous stress at the mesoscale, in particular the dermis stresses are highest at the valleys and smallest at the peaks of the sinusoidal interface. It remains to determine if this heterogeneous stress distribution correlates with biological function. For example, do higher stresses and strains in some region of the epidermis correlate with different stem cell population density or presence of mechanoreceptors? This is an area of future research that we intend to pursue. From a purely mechanical standpoint, a sinusoidal interface does have the advantage of reducing the stress jump across the interface of the two materials and this has similarly been studied in the context of fracture of composites [5]. Future work will focus on modeling fracture at the interface for skin RVEs. Beyond the interface versus flat geometry, one of the salient features of skin is that it hosts several appendages. We show that hair follicles also cause heterogeneous mechanical response, with strain concentrations at specific locations in the epithelium surrounding the hair follicle. These result open research avenues for how the mechanics of the mesoscale can affect skin physiology, e.g. haptics and sense of touch.

THE INFLUENCE OF HEMODILUTED BLOOD VISCOSITY ON PATIENT HEMODYNAMICS DURING CARDIOPULMONARY BYPASS

Nafis M. Arefin (1), Allison R. Cripps (1), Bryan C. Good (1)

(1) Department of Mechanical, Aerospace, and Biomedical Engineering, University of Tennessee
Knoxville, TN, USA

INTRODUCTION

Perioperative complications with cardiopulmonary bypass (CPB) are still common and are associated with concerning rates of mortality and morbidity. Emboli formed during CPB can cause severe complications including thromboembolic stroke [1]. Therefore, it is critical to understand their delivery to the cerebral arteries to help minimize various neurological complexities. Previous experimental transport studies in the aorta have found that emboli trajectory paths are proportional to the flow rate split within the aortic branches during normal flow conditions [2]. However, no studies have investigated emboli distribution in hemodiluted blood during CPB. Hemodilution is an imperative procedure during CPB to reduce blood viscosity and improve microcirculatory flow and oxygen delivery. To address these shortcomings and inadequacies, an experimental mock circulatory flow loop (MCFL) was built and used to observe emboli distribution through the aorta under varying hemodiluted blood viscosities for the first time. This experimental dataset was then used to validate computational simulations of emboli transport in a patient aorta model, hence producing original and state-of-the-art results that can be used to help reduce stroke risk during CPB.

METHODS

A silicon model of an aorta consisting of the ascending aorta (AA), brachiocephalic artery (BCA), left common carotid artery (LCCA), left subclavian artery (LSCA), and descending aorta (DA) has been developed. A patient-specific CAD model of an aortic arch anatomy, 26-year-old male with no cardiovascular complications was obtained from the Vascular Model Repository [3] (Fig. 1) and 3D printed. The material used for 3D printing the CAD model was polyvinyl alcohol (PVA), which is a biodegradable polymer highly sensitive to moisture. A rectangular box was also 3D printed with polylactic acid (PLA). The PVA-printed aorta was kept inside the PLA-printed box and the box was filled with *SYLGARD 184*, a two-component silicone-based elastomeric kit. After curing in the box for 3 days, the model was submerged in hot

water for another 2 days to allow for the PVA aorta to dissolve out, leaving a cavity representative of the fluid domain within the aorta. Tube connectors were fixed to each of the model's inlets and outlets to allow for incorporation into an MCFL. The MCFL included a Sorin Stockert Roller Pump (10-10-00 CAPS Module 10H), a fluid reservoir, tubing clamps to control the flow rate, and a flow meter (Transonic) (Fig. 1).

Figure 1: CAD model of the patient aorta and the constructed MCFL with silicon aorta geometry

To cover the range of hemodiluted blood viscosities observed clinically during CPB, four blood analog solutions were created by mixing water and glycerin at specified ratios; 1) 80:20 for $\mu \approx 2$ cP, 2) 74:26 for $\mu \approx 3$ cP, 3) 70:30 for $\mu \approx 3$ cP, and 4) 67:33 for $\mu \approx 3.5$ cP. To represent emboli formed in the CPB system, nylon beads of two different diameters (3/32" and 1/16") were used. For each trial, run with a 3-LPM pump flow rate, a single bead was injected into the flow loop and its path and exit through one of the aortic branches was noted.

OpenFOAM, a C++ open-source computational software, was used for the computational studies. For meshing, high-grade unstructured meshes were developed using the *snappyHexMesh* utility. All four

outlets were prescribed resistance boundary conditions for pressure to achieve physiological flow splitting according to the following equation: $p=RQ+p_0$, where p is the pressure, Q is the flow rate, R is a resistance constant, and p_0 is the baseline mean arterial pressure. Several computational simulations were carried out to determine the correct resistance constants (R) at each outlet such that the total flow splitting into the vessels was 15.67%, 7.83%, 7.83%, and 68.67% in the BCA, LCCA, LSCA, and DA, respectively (based on patient data collected by Benim *et al.* [4]). For the hemodiluted blood viscosity of 3 cP, the resistance constants were found to be 2e3, 0.1e0, 4.3e3, and 4e0 Pa*s/m3 for the BCA, LCCA, LSCA, and DA, respectively.

Computational particle transport studies were also performed using OpenFOAM. Lagrangian particle transport capabilities to observe emboli distribution through the aortic arch branches (Fig. 3), mimicking the experimental study presented above. The simulations utilized OpenFOAM's validated solver 'particleFoam' for modelling the transport of a kinematic particle cloud.

RESULTS

Fig. 2 shows the experimental embolus trajectory results for both small and large beads and at each fluid viscosity investigated. It was found that for all the experimental blood viscosities, more small beads entered the BCA than large beads. Also, higher percentage of large beads were found to enter the DA compared to the small beads.

Figure 2: Distribution of two different-sized Nylon beads with fluid viscosities varying from 1.5 to 3.5 cP in the MCFL.

As shown in Fig. 3, a 6 mm diameter cannula was connected to the ascending aorta with a constant flow rate of 3 L/min to mimic anastomosis from the CPB circuit. Emboli transport is shown over time as the injected particles flow in through the CPB pump cannula and are distributed to one of the aortic outlets.

Figure 3: Visualization of emboli trajectories over time during computational emboli transport simulations in the aortic arch.

The particles were tracked until they exited through one of the aortic outlets. In phase II, the injection of the emboli into the aorta model is observed. The particles begin exiting through the outlets of the

model in phase IV until nearly all have been transported out of the fluid domain by phase VIII.

Figs. 4 and 5 compare emboli distribution in the 3-cP fluid during CPB in the experimental and computational studies, respectively.

Figure 4: Experimental emboli distribution with 3-cP fluid.

Figure 5: Computational emboli distribution with 3-cP fluid.

DISCUSSION

The computational simulations predict similar emboli distribution trends to those observed experimentally, with the small and large emboli entering specific aorta branches during CPB (Fig. 5). Similar to what was observed in the experimental study, the CFD simulation for 3-cP blood viscosity showed that the percentage of small emboli entering the BCA is greater than that of the large emboli. Likewise, the percentage of large emboli entering the DA was more than that of the small emboli. Also, for both embolic sizes, their tendency to enter the LCCA was found to be minimal. Figures 4 and 5 show that in both the experimental and computational studies, emboli distribution for small and large emboli was similar for each of the aortic branches.

The results of these experimental and computational studies indicate that larger emboli generated in CPB roller pumps are most likely to exit through the DA travelling to the abdomen and lower body. Likewise, smaller emboli have a higher tendency of exiting through the BCA which carries blood to the right arm and right side of the brain. Emboli exiting through the BCA thus increases the potential stroke risk in patients and can cause severe impairments due to a lack of oxygen supply to the brain. The experimental studies (Fig. 2) also observed that with decreasing hemodiluted blood viscosity, the beads have lower tendency of exiting through the LCCA and LSCA and higher tendency of exiting through the DA. Further studies will be carried out to understand how emboli travel to the brain during CPB and what techniques and pump operating conditions can be used to minimize this.

Further studies will be carried out to understand how emboli travel to the brain during CPB and what techniques and pump operating conditions can be used to minimize this. Also, future studies will also incorporate more realistic emboli sizes and compositions. Hence, through computational studies, the behavior of varying emboli sizes in the cerebral vasculature will be understood as to their risk of causing a stroke. Real embolus analogs (EAs) will also be injected into the MCFL to observe their distribution and to determine if the elastic properties of the EAs will play a role in their transport. Upon completion, this study will contribute to reducing stroke risk and CPB complications, hence increasing the overall safety of cardiovascular surgery.

INTRODUCTION

Measuring tissue deformations using medical images allows researchers to noninvasively track tissue mechanics with degeneration or rehabilitation. Researchers have used *image texture correlation* algorithms to compare pixel intensities between successive images and calculate the displacement field between pixels, which is then numerically differentiated to obtain a strain field. These techniques have been applied in various contexts, including quantifying forces in myocardial cells,¹ detecting breast cancer,² and studying impact of disease on tissue mechanics *in vitro*.³ However, these algorithms often struggle with *in vivo* images, partly due to low signal-to-noise ratio and out-of-plane motion.⁴ Therefore, the objective of this study was to develop a new technique using deep learning (called **StrainNet**) to accurately predict tissue deformation and ignore image artifacts (*e.g.*, noise). We hypothesized that **StrainNet** would outperform traditional image texture correlation algorithms on synthetic images with known deformations and a real dataset of a wrist flexor tendon undergoing contraction *in vivo*. Our results showed that **StrainNet** reduced error by up to 84% when compared to traditional image texture correlation algorithms in the synthetic datasets. Moreover, the measurements made by **StrainNet** in the *in vivo* experiments were strongly correlated with the measured grip force distributed to the wrist flexor tendons.

METHODS

Experimental Procedure. To investigate *in vivo* tendon mechanics, a participant was asked to perform maximum voluntary contraction (MVC) of their forearm using an IRB-approved protocol (IRB-2020-497). A dynamometer was used to track and measure applied forces during contraction, and the MVC was calculated as the average of three trials. Next, the participant was instructed to contract their forearm to 10%, 30%, or 50%

of their MVC in three seconds, hold the contraction for five seconds, and relax their forearm in three seconds. High-frequency ultrasound images (Vevo3100, FUJIFILM VisualSonics Inc., Toronto, Ontario, Canada) of the participant's *flexor digitorum superficialis* tendon were collected throughout the contraction and release. This protocol was repeated five times for each effort level, resulting in a total of 15 trials.

Synthetic Test Cases. To test the accuracy of our strain analysis method on a dataset with known deformations, five synthetic test cases were created by artificially imposing a non-linear strain field onto collected ultrasound images. These test cases simulated the process of contraction and relaxation in our experimental procedure described above. Additionally, the prescribed non-linear strain field was designed to reflect reported observations for *in vivo* tendon mechanics. Specifically, the strain in the superficial layer was set to 75% of the deep layer,⁵ and the tendon was modeled as an incompressible material.^{6,7} The five test cases differed in their maximum longitudinal strain, ϵ_{long}^{max} , which was set to 4%, 7%, 10%, 13%, and 16% to cover the range of strains observed *in vivo*.^{5,7-9} Noise was added to all synthetic test cases to simulate the level of noise present in the experimental dataset. By using synthetic test cases with known deformations, we were able to compare the performance and accuracy of our deep learning based approach with existing texture correlation algorithms.

StrainNet. **StrainNet** is a deep learning model designed to predict 2D Lagrangian strain from a sequence of ultrasound images of the wrist flexor tendon. It consists of a two-stage architecture, with the first stage classifying the type of bulk deformation present in the image pair (tensile, compressive, or rigid-body) and the second stage predicting the strains throughout the image. To train the model, a set of synthetic images with random deformations was utilized. The deformations in these images were generated using a generalized mathematical model of tendon mechanics, SB³C2023-163
Copyright 2023 SB³C Foundation, Inc.

with the governing parameters being randomly varied to produce a diverse range of strain distributions (e.g., 2% - 20% bulk strain in the longitudinal direction). The training set included 1,000 images in tension, 1,000 images in compression, and 1,000 images undergoing rigid deformation. The model was trained using the Adam optimizer for 100 epochs, allowing it to learn the patterns and features associated with different types of deformation and accurately predict strain in unseen images.

Data Analysis and Statistics. StrainNet, digital image correlation (DIC),¹⁰ and direct deformation estimation (DDE)¹¹ were applied to synthetic test cases and experimental images. For the synthetic test cases, the strain error was calculated as the ℓ_2 -norm between the ground truth strain tensor and the algorithm-predicted strain tensor. A pairwise permutation test was conducted on the median strain error for each of the five test cases, with significance set at $p \leq 0.05$. For experimental images, the true strain was unknown, so the analysis was limited to a qualitative assessment. However, linear regression was conducted between the maximum longitudinal strain predicted by the three algorithms during contraction and the percentage of MVC. A strong correlation was defined as an $|r| > 0.7$.

RESULTS

Of the 15 trials conducted, two trials were discarded due to corruption of data file containing the forces measured by the dynamometer.

Figure 1: Spatial distribution of errors incurred by StrainNet, DIC, and DDE during maximum contraction in the synthetic test case with maximum longitudinal strain of 10%. Black dashed line represents the boundary between the flexor tendon and the surrounding soft tissue.

In the synthetic test cases, errors were largest at the boundary between the tendon and surrounding tissue. StrainNet achieved pixel-wise strain estimation while DIC and DDE were limited to the central area of interest (Fig. 1). The median strain error from StrainNet was 48-84% lower than the strain error from both DIC and DDE (Fig. 2; $p < 0.001$ in all strain cases).

Figure 2: Median strain error across all five synthetic test cases. Median strain error was statistically significantly lower than DIC and DDE across all test cases ($p < 0.001$).

For the real experimental images, both DIC and DDE underperformed and many pixels were lost during image analysis. StrainNet, on the other hand, was able to learn around much of the noise and accurately predict the longitudinal strain in the tendon, which increased as effort level increased. There was a strong linear relationship between the predicted longitudinal

strain and percent MVC (Fig. 3; $r = 0.784$, $p = 0.002$), which is comparable to the expected linear relationship between strain and stress for tendon mechanics.

Figure 3: Median longitudinal strain predicted by StrainNet during tendon contraction across all of the trials ($n = 13$). \times 's, \bullet 's, and \blacklozenge 's correspond to 10% , 30%, and 50% MVC.

DISCUSSION

StrainNet was able to accurately measure and quantify the different strain levels using ultrasound images of the flexor tendon. For synthetic datasets, StrainNet detected subtle differences in deformations with a high degree of accuracy ($< 3\%$ error), outperforming existing approaches (e.g., DIC and DDE), which had median strain errors as high as 10%. Additionally, when applied to *in vivo* images, StrainNet predicted a strong linear correlation between the measured strain and effort level (percentage of the MVC), further validating the performance of the model. These findings suggest that deep learning models have the potential to significantly advance the accuracy of *in vivo* biomechanics studies.

There are several limitations to our model that will be addressed in future work. First, the model was evaluated on a single tissue type and location, so it is not clear whether it can be applied to a wider range of tissue types. Additionally, the current architecture is specialized to handle only three types of deformation, and it would be useful to explore expanding its capabilities to a wider range of deformations (e.g., shear). Lastly, improvements to the architecture or training the model on a larger dataset may also allow us to remove the need for the first stage of the model, which currently classifies the type of deformation present in the image pair.

The potential applications of StrainNet are numerous and exciting. Our results indicate that StrainNet greatly outperforms traditional image texture correlation algorithms in controlled settings, such as the synthetic test cases (Fig. 2). In more challenging environments where image texture correlation is prone to error due to image artifacts, such as *in vivo* measurements of tendon mechanics in real time, StrainNet has demonstrated the ability to provide reasonable and expected levels of tissue deformation (Fig. 3). Taken together, these findings suggest that StrainNet could be applied to a wide range of biomedical contexts, including *in vivo* studies of muscle function, blood flow, and tissue viability. Overall, the design and capabilities of StrainNet are ripe for continued research and development, with the potential for significant advancements in these areas.

The code, trained models, and tutorial for using StrainNet will be available at strainnet.net.

INTRODUCTION

Cardiovascular diseases (CVD) resulted in around 1 million deaths in 2017 in the U.S. [1]. Atherosclerosis is a form of CVD and a major cause of CVD-related mortality rate. In atherosclerotic arteries, fatty plaques are formed in the arterial wall and block the blood flow, depriving downstream tissue from nutrients and oxygen. This disease can affect both coronary and peripheral arteries. One of the treatments for these patients is bypass surgery using vascular grafts. One of the failure mechanisms of vascular grafts is thrombosis. Platelets are critical in formation of thrombosis. Particularly, non-homeostatic shear stress and the exposure to foreign material can trigger platelet activation. Variety of chemical methods have been studied to prevent thrombosis following vascular graft implantation. These efforts include but are not limited to conjugation of Heparin, Poly-ethylene Glycol, and vascular endothelial growth factor to the luminal surface of the vascular grafts. In contrast, there has been very limited number of studies focusing on mechanical approaches to interrupt coagulation cascade and thrombus formation process. In this regard, surface topology has been studied that has shown lower surface roughness decreases platelet adhesion. In another study, platelet adhesion was lowered using surface wrinkling during diastole. Herein, we have developed a layered and porous vascular graft to reduce thrombogenicity. During systole, fluid can penetrate through the porous structure of a vascular graft. We have optimized the porohyperelastic (PHE) response of the graft such that the fluid velocity through the vascular graft wall is reversed during diastole – Luminal Reversal Flow (LRF) – and the fluid is moved back into the luminal space. We hypothesized that the momentum carrying LRF can repel the platelets and drive self-cleaning.

METHODS

We have previously shown that the PHE response of a bilayered vascular graft can be optimized to promote luminal reversal fluid velocity [2]. Our results showed that a highly permeable inner

layer and a highly impermeable outer layer in a deformable vascular graft are required to boost the LRF. In another effort, we have shown that electrospun Polycaprolactone (PCL) fibers will fuse into each other under thermal treatment (thermobonding) and create a highly impermeable scaffold [3]. Leveraging the results of these two studies, we fabricated LRF- generating bilayered vascular grafts (1.1mm ID - rat aortic size) to assess the hemocompatibility. The Inner layer of the vascular graft is composed of electrospun Tecoflex and the outer layer is made of electrospun PCL. Following electrospinning, the bilayered grafts underwent thermal treatment in a convection oven at 60°C for 3 minutes. This post-processing creates a bilayered graft with an impermeable PCL outer layer that is relatively stiff. The outer layer thickness was minimized in the anti-thrombogenic grafts with high LRF to reduce its effect on deformability. Control grafts were fabricated using the same procedure but with a thicker outer layer to significantly reduce LRF. Both groups had the same blood contact area and material. We have also computationally predicted the LRF in each experimental group. **Figure 1** illustrates the geometry used in the axisymmetric PHE finite element model of a bilayered vascular graft. To predict the LRF,

Figure 1. Geometry used in the axisymmetric PHE finite element model of a bilayered vascular graft (computational predictions of LRF)

we mechanically characterized electrospun Tecoflex and thermobonded PCL constructs using a microbiaxial tensile testing device. We also measured the thickness of the layers and surface porosity of the scaffolds using SEM images. A void-dependent permeability finite element porohyperelastic model (ABAQUS) was used to inversely find the material properties and then computationally predict the LRF values. **Figure 2** represents cross-sectional SEM images of the LRF-generating grafts (Higher LRF) and controls (Lower LRF). These grafts were sutured and glued at both ends and connected to a mock flow loop (Figure 3). Fresh citrated ovine whole blood was circulated in the loop using roller pumps. The test was performed at 37°C for 1.5 hours. The flow rate was set to 10 mL/min. The grafts were then washed with PBS and stored in Triton-X and glutaraldehyde solutions for Lactate dehydrogenase (LDH) assay and SEM imaging, respectively. LDH assay was performed to measure the absorbance of the solutions containing blood contact samples. A standard curve was generated

Figure 2. Representative SEM images of the grafts with higher LRF (A) and lower LRF (B - controls).

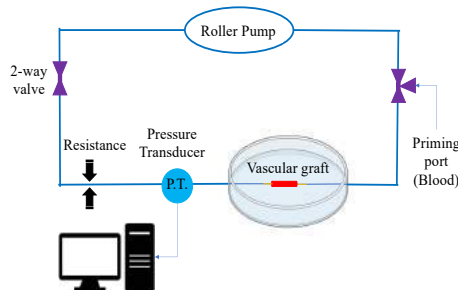

Figure 3. Mock flow loop for assessment of hemocompatibility

using fresh blood to correlate the absorbance values with the number of platelets. SEM imaging was done to visualize the platelets and validate the LDH results. A student t test was used to infer the statistical difference between groups ($p < 0.05$).

RESULTS

Figure 4 represents the number of platelets per luminal surface area of each experimental group. The vascular grafts with higher LRF had an average of 66% lower number of platelets. **Figure 5** shows the SEM images from the luminal surface of vascular grafts with higher LRF and the controls. The high LRF group had a lower number of platelets on the luminal surface of the grafts compared to the low LRF group which confirms the results of the LDH assay. Computationally predicted values of LRF for high LRF grafts were approximately -11.2 mm/s. The LRF value of the control group was about -4.2 mm/s. Higher LRF was associated with lower platelet adhesion.

DISCUSSION

Our results indicated an improved hemocompatibility in the vascular grafts with higher luminal reversal flow compared to the grafts

Figure 4. Number of platelets per luminal surface area of vascular grafts with higher (n=5) and lower LRF (n=4).

Figure 5. Platelet adhesion to the luminal surface of the vascular grafts. Control group (B) has significantly higher number of platelets on the surface.

that generated lower reversal flow. The presence of LRF has been computationally confirmed in another study on intraluminal thrombosis in abdominal aortic aneurysms [4]. Soldani et. al. have also demonstrated that the formation of thrombosis (in-vivo) is reduced in bilayered grafts with a highly porous inner layer and a low porosity outer layer compared to the grafts with a reversed porosity of the layers [5]. However, they attributed these findings to less available surface area in the inner layers of their grafts. This study had several limitations. The compliance of the high-LRF grafts was relatively low compared to rat aortic tissue. Therefore, a new method is required to achieve an impermeable outer layer. The pressure range of the roller pumps was 20-220 mmHg. The material model used for the computational predictions did not take material anisotropy into account. Thrombosis is considered a major clinical problem with no permanent solution. We have used local mechanics manipulation to improve hemocompatibility [6] and shown a significant reduction in platelet adhesion.

INTRODUCTION

Pulmonary emboli, blood clots that lodge in the small vessels of the lung, increase blood pressure in the lung circulation and can overload the heart. Chronic thromboembolic pulmonary hypertension (CTEPH) is a debilitating disease that is curable with early diagnosis and surgery, but, if left untreated, can lead to right ventricular failure and death [1].

CTEPH is diagnosed by a mean pulmonary artery pressure (mPAP) ≥ 20 mmHg at rest, pulmonary capillary wedge pressure (PCWP) ≤ 15 mmHg, and imaging data confirming clot burden [2]. Measurement of these pressures requires an invasive right heart catheterization (RHC). To study disease progression, large animal models of CTEPH have been developed, e.g., injecting microspheres into the pulmonary arteries (PAs) serially until a chronic disease develops. These data can be integrated with computational models to simulate subject-specific pulmonary hemodynamics and identify novel indicators of progression.

Here, we use an image-based nonlinear one-dimensional (1D) computational fluid dynamics (CFD) model to predict hemodynamics throughout the pulmonary arterial network in canines before and after CTEPH induction. We calibrate our model to available hemodynamic and imaging data and then use the model to quantify the impact of CTEPH on hemodynamic metrics not feasible to measure. Our image experimental-computational framework gives insight into the proximal and distal effects of CTEPH and provides a future tool for understanding changes in hemodynamic forces in the progression of the disease as seen clinically.

METHODS

All experimental data were obtained retrospectively; a detailed protocol and complete reporting of measurements can be found in [3]. Briefly, CTEPH was induced by injecting multiple microspheres into the PAs using an indwelling catheter in five, adult male canines (12 ± 1 kg body weight). Measured hemodynamic data included systolic and diastolic

proximal PA pressures and PCWP from RHC. Imaging data included time series velocity and area at the main, left, and right pulmonary artery (MPA, LPA, and RPA, respectively, i.e., the extralobar PAs) from chest magnetic resonance imaging (MRI). All data were collected at baseline and after CTEPH development. Dynamic flow was calculated as a product of velocity and cross-sectional area for each extralobar PA. From MRI, extralobar and intralobar PA geometries for fluid dynamic simulations were segmented using 3D slicer. We used the vascular Modeling Toolkit [4] to convert the segmentations to 1D centerline networks, and then post-processed the networks using custom MATLAB (Natick, MA) software to create the 1D CFD domain.

Assumptions include that: blood vessels are impermeable and cylindrical, that flow is axially driven, and that the blood is an incompressible, Newtonian fluid with a dynamic viscosity $\mu=0.049$ Pa·s and density $\rho=1055$ (kg/m³). The governing mass conservation and momentum equations are given by:

$$\frac{\partial q}{\partial x} + \frac{\partial A}{\partial t} = 0 \quad (1)$$

$$\frac{\partial q}{\partial t} + \frac{(\gamma + 2)}{(\gamma + 1)} \frac{\partial}{\partial x} \left(\frac{q^2}{A} \right) + \frac{A}{\rho} \frac{\partial p}{\partial x} = - \frac{2\pi\mu(\gamma + 2)}{\rho} \frac{q}{A} \quad (2)$$

where x and t represent the axial and temporal coordinates, and q , p and A are the volumetric flow (mL/s), pressure (mmHg), and cross-sectional area (cm²). We assumed the blood velocity follows a power-law profile,

$$u(x, t) = U(t) \frac{\gamma + 2}{\gamma} \left(1 - \frac{r^\gamma}{R(t)^\gamma} \right) \quad (3)$$

with $\gamma = 9$, where $R(t)$ (cm) is the time-dependent inner radius and $U(t)$ (cm/s) is the mean axial velocity. To close the system of equations, we assume that the vessels are linearly elastic, thin walled, incompressible, and isotropic. This gives the constitutive law

$$p = \frac{4 Eh}{3 r_0} \left(\sqrt{\frac{A}{A_0}} - 1 \right) + p_0 \quad (4)$$

where E is the circumferential Young's modulus (mmHg), h (cm) is the wall thickness of the artery, and $A_0 = \pi r_0^2$ (cm²) is the diastolic arterial area at the diastolic pressure p_0 (mmHg). Vessel mechanical properties are governed by $4Eh/3r_0$, which is determined analytically using systolic and diastolic pressure and area data.

Boundary conditions are specified at the inlet of the network and at each terminal vessel outlet. Dynamic flow from MRI is used at the network inlet, while 3 element Windkessel models including a proximal (R_1) and distal (R_2) resistance and one capacitance (C) are used at the network outlets. Nominal Windkessel resistance is calculated based on a Poiseuille argument, i.e. $R_T = 8\mu L/\pi r^4$ for each vessel. We assume that proximal and distal resistances are equal. Nominal capacitance is determined by fitting an exponential decay from systolic to diastolic MPA pressure over the time-course of diastole. We calibrate the Windkessel parameters of the 1D model using a combination of systolic and diastolic pressure-area data, as well as time-series LPA and RPA flow. All Windkessel parameters are scaled using the reduced parameter set $\phi_{wk} = \{r_1, r_2, c\}$ using weighted nonlinear least squares [5]. We investigate how CTEPH affects pressure, flow, and time averaged wall shear stress (TAWSS)

$$TAWSS = \frac{1}{T} \int_0^T |\tau| dt \quad \text{where} \quad \tau = \mu \left(\frac{\partial u}{\partial r} \right)_{r=R} \quad (5)$$

throughout the network. Here, τ (dyne/cm²) is the arterial wall shear stress and T (s) is the cardiac cycle length.

Figure 1: (a) MPA pressure, (b) LPA flow, and (c) RPA flow for a representative subject at baseline (blue; left) and with CTEPH (red; right).

RESULTS

Figure 1(a) shows model pressure predictions (solid lines) and measured systolic and diastolic pressure (dashed lines) for a representative animal in which mPAP increased from 20 to 51 mmHg from baseline (blue; left) to CTEPH (red; right) [3]. For the same animal, Figures 1(b) and 1(c) show LPA flow and RPA flow, respectively, from measurements (black) and model predictions (blue, left at baseline and red, right with CTEPH). The averaged R^2 between the measured and simulated flow improved after optimization: the averaged R^2 increased from 0.94 (± 0.04 SD) (without optimizing) to 0.96 (± 0.03) (after optimizing) in the LPA and 0.97 (± 0.025) to 0.986 (± 0.009) in the RPA at baseline. The average R^2 improved from 0.76 (± 0.2) to 0.88 (± 0.09) in the LPA and 0.94 (± 0.06) to 0.97 (± 0.027) in the RPA with CTEPH. All animals

had a reduced cardiac output and network flow after CTEPH induction. However, significant asymmetries and heterogeneity were evident. The animal shown in Figure 1 had a decrease in mean flow from 0.73 to 0.5 (mL/s) ($\approx 30\%$) in the distal pulmonary arteries of the left lung with CTEPH and an increase ($\approx 70\%$) in the distal arteries of the right lung. Figure 2 shows a 3D map of average TAWSS distribution in baseline (left) and CTEPH (right) in this animal. Despite high flows to the right lung, TAWSS decreased due to arterial dilation. Considering only the extralobar arteries (MPA, LPA, and RPA), on average CTEPH significantly decreased TAWSS in the LPA ($\approx 42\%$; $p=0.049$) and tended to decrease TAWSS in the MPA ($\approx 43\%$; $p=0.152$) and RPA ($\approx 60\%$; $p=0.144$), as shown in Figure 3.

Figure 2: 3D map of TAWSS distribution in the network for baseline(right) and CTEPH (left)

Figure 3: MPA, LPA, and RPA TAWSS under baseline (blue) and CTEPH (red) conditions; n=5.

DISCUSSION

We used a 1D CFD model to simulate arterial hemodynamic features (i.e., wall shear stress) that are infeasible to measure based on experimentally obtained pressure and imaging data. One novelty of this study is that we efficiently calibrated our model with systolic and diastolic pressures and areas, as well as dynamic flow data from each subject in both baseline and CTEPH conditions to increase accuracy. Qualitatively, the model matches measured pressures (Figure 1) and quantitatively, the model matches measured flows (high R^2 values). Our finding of asymmetry is supported by the experimental observation that more microspheres were delivered to the left lung [3]. We also investigated changes in TAWSS with CTEPH, and our results agree with previous clinical studies predicting reduced TAWSS with CTEPH [6]. Thus, our synergistic experimental-computational framework shows promise as a future, patient-specific simulator of proximal and distal hemodynamics under CTEPH conditions.

INTRODUCTION

Lung diseases are continually rising as one of the leading causes of death in the United States with no indication of major improvement [1]. While common respiratory illnesses manifest from airway obstruction [2], characterization of airway mechanics is still lacking. Airway morphology has been explored using optical coherence tomography (OCT) [3], but such methods are limited to stepwise regional analysis rather than a real-time assessment of whole airway evolution when inflated. Previous studies have employed mechanical testing on the trachea [4,5], and the bronchial airways [6,7], but tissue samples were isolated from the branch structure when subjected to uniaxial or biaxial loading. Physiological expansion of the airways however, includes multi-axial deformations, which has remained elusive to date.

This novel study aims to broaden our understanding of airway mechanical properties by utilizing digital image correlation (DIC) coupled with continuous global pressure-volume inflation to assess the stress and strains of whole and intact main airway branches for the first time. By analyzing the heterogeneous and anisotropic surface strains of the bronchial tree in real-time, we offer new insights regarding the compound structural effects of the soft tissue and cartilaginous constituents of the airway and compare our findings to past results from isolated tissue strips. These observations improve our understanding of the physiological strains present in the airway tree and enable future predictive computational modeling of the lung.

METHODS

Four porcine lungs were extracted from 6-8 month old, 200–250lb pigs obtained from an abattoir (IACUC exempt). Preliminary investigations observed no difference between right and left branching airway mechanics; as such, the primary left airways were used. Airways were cut 1cm above the anatomical accessory lobe and 14cm beyond the main left and right airway junction to ensure uniformly comparable samples between pigs. Regions were distinguished by their location and

inner diameters as follows: the trachea (>17mm) was above the main airway junction, the large bronchi (>9mm) was 7cm below the junction, and the small bronchi (>3mm) was 7cm beyond the large bronchi.

A latex condom was traversed within the airway; having a notable inner diameter greater than the airway allowed for unconstrained inflation which circumvented the need to suture shut each adjacent branch, thus providing a leak-free testing set up. The whole airway sample was speckled for DIC analysis using an airbrush and connected to our custom pressure-volume system [8,9]. Each airway was preloaded to 0.7 cmH₂O, which ensured the condom was inflated to fill the airway's resting state. Preliminary tests deemed the airways exhibited a reproducible response when cycled, and thus, there was no need for preconditioning [10]. The specimens were inflated once to 200ml at a rate of 15 breaths per minute, corresponding to physiological lung pressures of 30 cmH₂O [11], and DIC was simultaneously recorded [Trilion Quality Systems, King of Prussia, PA].

Virtual tissue sections (6x6mm) measured the strain of the compliant airway soft tissue between the cartilage fragments for each of the trachea, large bronchi, and small bronchi regions to compare with analogous regions from previous airway mechanical test samples [6, 7]. For the full inflation cycle, axial and circumferential strains of each region were averaged (Figure 1). Airway pressure, radii, and thickness were used to calculate stresses according to thin-walled cylindrical pressure vessel theory. Airway inflation stress-strain profiles for each region and orientation were compared to previous studies (Figure 2).

RESULTS

A contour map for both axial and circumferential strain of a representative porcine airway (Figure 1A), and the associated average strain temporally evolving during the inflation cycle is shown (Figure 1B). Highest tissue strains were observed at the junctures between cartilage rings of the trachea with values of nearly 30% strain in the circumferential direction and 8% in the axial direction.

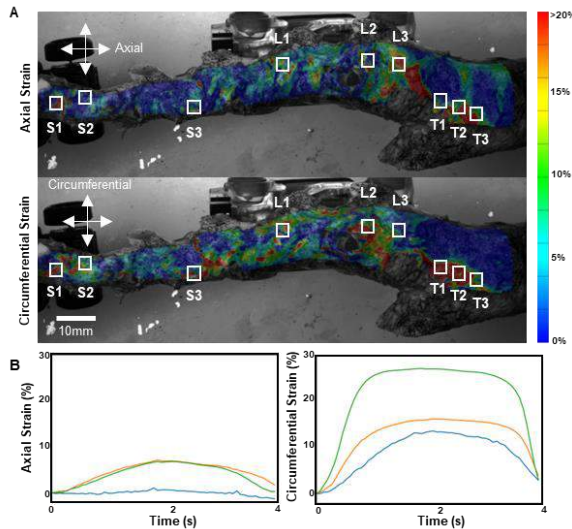

Figure 1: (A) Directional strain contour maps of a representative porcine airway sample inflated to 200ml corresponding to physiological pressures of 30cmH₂O [11]. (B) Strain values from three virtual soft tissue samples were averaged for each lung region and direction during the inflation cycle.

Axial strains were notably decreased compared to circumferential strains for all three lung regions, with nearly a two-fold difference within the trachea and small bronchi regions. The bronchial airway regions observed lower strains than the trachea in the circumferential direction. However, the large bronchi exhibited similar axial strains to the tracheal region, sharing a maximum strain value of 8%. Circumferentially, the trachea and large bronchi also shared an asymptotic stop-length response once the maximum strain was reached.

Stress-strain curves of the three lung regions and two orientations were compared to previous uniaxial and biaxial mechanical airway tissue studies as shown in Figure 2. This study found greater peak stress values at the maximum strain values seen during inflation. The tracheal samples showed consistently higher stresses compared to bronchial regions, similar to the biaxial and uniaxial data, except for the case of the uniaxial circumferential response, where the tracheal stresses were found to be lower than their bronchial counterparts. As with other testing methods, circumferential stress values at the maximum strain for this study were lower than their corresponding axial stresses, except for the uniaxial tests of the small bronchi region, which were found to be lower axially than circumferentially. Inflation test curves diverged from the planar isolated tissue strip studies at ~10% strain in the circumferential direction and at <5% strain for the axial orientation.

DISCUSSION

Our novel DIC divulged airway mechanics report notably higher circumferential and axial stresses in the trachea compared to the bronchial airways, in agreement with prior biaxial studies and axial trends from the uniaxial study [6,7]. Airway open angle experiments have concluded residual stresses in the trachea [12] and a lack thereof in the bronchial airways [13], posing a potential explanation for the noted heterogeneity between proximal and distal airways. Additionally, the cartilage structure varies within the airway tree, potentially dictating the high strain regional behaviors which further differentiate the trachea and bronchial regions: in the trachea, c-shaped cartilage rings are joined by smooth muscle [14], whereas the cartilage in the distal bronchi is segmented with multiple strips [15]. As such, the soft tissue response is evident in the strain contour maps (Figure 1A), where a single area of

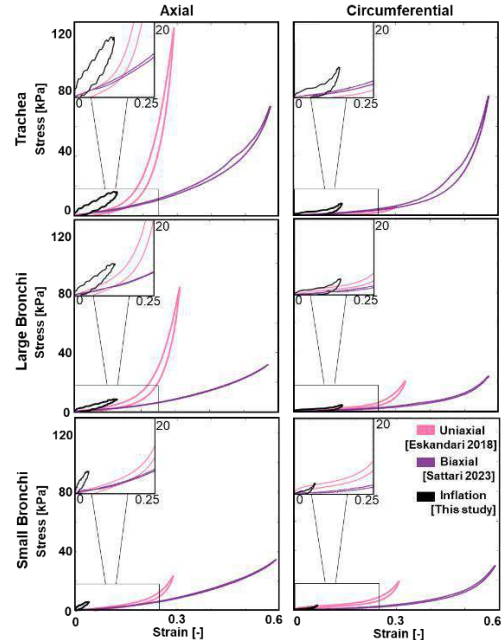

Figure 2: Regional stress-strain curves of airway tissue samples subjected to uniaxial, biaxial, and inflation mechanical testing in the circumferential and axial direction.

high strain is noted to develop axially and circumferentially within the trachea [16]; alternatively, high strain locations are observed to be scattered across the large and small bronchi, corresponding to the soft tissue sections of the discontinuous cartilage.

It is important to note that previous uniaxial and biaxial tests focused solely on airway soft tissue [6,7], excluding the role of the cartilage altogether due to the independence and asynchrony between the cartilage plates and airway tissue [3]; however, inflating the compound, whole airway with the unaltered presence of the cartilage layer in this study yielded a notably stiffer mechanical response compared to studies of isolated tissue strips. The role of the cartilage appears to not be negligible, stiffening the overall response while acting as a stop-length for the soft tissue; as such, comprehensively characterizing the intact airway structure is more physiologically representative and can better inform computational lung models.

INDIVIDUALS WITH ROTATOR CUFF TEARS REQUIRING SURGERY AFTER EXERCISE THERAPY HAVE LESS INFERIORLY DIRECTED MUSCLE FORCES POST-EXERCISE THERAPY

INTRODUCTION

Exercise therapy for individuals with rotator cuff tears fails in approximately 25.0% of individuals [1]. One reason for failure of exercise therapy may be the inability to strengthen and balance the muscle forces crossing the glenohumeral joint that act to center the humeral head on the glenoid. The coronal and transverse plane force couples are responsible for centering the humeral head on the glenoid in the superior-inferior and anterior-poster directions, respectively [2,3]. If the magnitude of the joint reaction force is decreased and the muscle forces are imbalanced, the humeral head may not be centered on the glenoid. The objective of the study was to determine the magnitude and direction of the joint reaction force in individuals with symptomatic isolated supraspinatus tears after a 12-week personalized exercise therapy program. Individuals that opted for surgery (exercise therapy failed) because exercise therapy did not resolve their symptoms were compared to individuals successfully treated with exercise therapy (exercise therapy successful).

METHODS

Twelve individuals (6 exercise therapy failed, 6 exercise therapy successful, 57.9 \pm 10.9 years) provided IRB-approved consent before participation. Primary inclusion criteria included: 1) symptomatic tear isolated to the supraspinatus tendon, 2) partial-($>50\%$) or full-thickness tear, 3) and age >40.0 years. Eleven individuals had a full- and one had a partial-thickness tear. Individuals underwent a 12-week personalized exercise therapy program. Time to surgery for individuals in the exercise therapy failed group was 1.6 \pm 0.9 years and all individuals completed the 12-weeks of exercise therapy. Isometric muscle strength was measured by a licensed physical therapist in four joint positions (each position biased a rotator cuff muscle). Tear size and location was measured by a musculoskeletal radiologist via ultrasound and glenohumeral kinematics were quantified during scapular plane abduction using a biplane radiography system and validated model-

based tracking technique (accuracy $\pm 0.5^\circ$) [4]. All variables were collected pre- and post-exercise therapy. Glenohumeral joint models were created in OpenSim [5] using individual-specific bone geometries segmented from computed tomography images (slice thickness 0.625mm) for the humerus and scapula.

The maximum isometric force a muscle could produce pre-exercise therapy was based on muscle volume from computed tomography images and scaled post-exercise therapy by percent changes in isometric strength [6]. Maximum isometric force for each muscle was determined pre-exercise therapy using muscle volume since utilization of individual specific muscle parameters has been shown to influence joint reaction forces [6]. The supraspinatus, infraspinatus and subscapularis were represented by 3 muscle-tendon units each and the teres minor and middle deltoid with one unit each. Maximum isometric force for each supraspinatus unit was scaled by the amount of tendon torn based on tear size, location and thickness measured.

The experimentally measured kinematics acted as the input to drive the model. The resulting motion was utilized to determine the muscle forces (static optimization, minimizing muscle activation) at each step of the simulation and muscle-tendon units were assumed to be ideal force generators. Joint reaction force analysis was used to determine the magnitude and direction of the glenohumeral joint reaction force during scapular plane abduction from the initiation of abduction to maximum humerothoracic abduction. The magnitude of the joint reaction force was normalized to bodyweight (BW). Elevation and deviation angles were calculated as previously described to report the direction of the joint reaction force (Figure 1) [7]. The movement was normalized from initiation of abduction to maximum abduction (0-100%). Statistical parametric mapping was used to compare elevation and deviation angles and the magnitude of the joint reaction force between the exercise therapy failed and successful groups post-exercise therapy [8]. Significance was $p < 0.05$.

Figure 1: Depictions of the direction of the joint reaction force: a) elevation angle in scapular plane and b) deviation angle in transverse plane.

RESULTS

For the direction of the joint reaction force, the elevation angle for the exercise therapy successful group was greater between 58-71% of the movement ($108.5\text{--}124.8^\circ$ humerotheracic abduction, $p=0.045$) compared to the exercise therapy failed group post-exercise therapy (Figure 2). No difference in deviation angle was observed between groups post-exercise therapy ($p>0.05$). For both groups, the direction of the joint reaction force pointed superiorly and posteriorly. No difference in the magnitude of the joint reaction force was observed between groups ($p>0.05$, Figure 3). For the successful and failed exercise therapy groups, the peak magnitude of the joint reaction force was $0.67 \pm 0.14 \times \text{BW}$ and $0.61 \pm 0.16 \times \text{BW}$, respectively. The magnitude of the joint reaction force either increased with abduction to a maximum and then decreased or continued to increase (Figure 3).

Figure 2: Average directions of joint reaction force post-exercise therapy.

Figure 3: Average magnitudes of joint reaction force post-exercise therapy.

DISCUSSION

The main findings of the current study were post-exercise therapy: 1) the exercise therapy failed group had less superiorly oriented magnitudes of the joint reaction force compared to the exercise therapy successful group and 2) no differences were observed in deviation angle and magnitude of the joint reaction force between the groups. The implications of the first finding are that the exercise therapy successful group has more inferiorly directed muscle forces, resulting in a more superiorly oriented joint reaction force. Biomechanically, this implies that the intact rotator cuff of the successful exercise therapy group produced more inferiorly directed forces that could prevent superior migration of the humeral head. Interestingly, the difference occurred within the range of motion in which individuals with rotator cuff tears typically experience a painful arc thought to be due to impingement. This novel finding may be used to identify individuals that will successfully respond to exercise therapy and provide motivation to modify current treatment algorithms. For example, improvements in the direction of the joint reaction force may be achieved by improving strength of the subscapularis, infraspinatus and teres minor. For individuals with lower elevation angles, additional exercise therapy sessions may be warranted to avoid surgery.

An experimental study using cadavers found contradicting results for the elevation angle but similar results for the deviation angle [9]. The joint reaction force for simulated incomplete and complete supraspinatus tears initially pointed inferiorly and became less inferiorly oriented with abduction. The discrepancy is likely influenced by the scapula being rigidly fixed preventing upward rotation that supports the humeral head. No differences were found in the magnitude of the joint reaction force, which is reasonable given both groups have similar pathology.

One limitation of the current study is that no electromyography data were collected to compare to the simulated muscle activation data. However, the muscle activation results were compared to the available literature and followed similar trends [10,11]. Thus, the current study produced novel models for individuals with rotator cuff tears that included individual specific muscle forces, tear characteristics and accurate in-vivo kinematics. The models were able to distinguish differences in joint function between individuals that required surgery after exercise therapy and those that were successfully treated with exercise therapy alone. Future directions will include determining if individuals with decreased elevation angles require additional exercise therapy sessions to improve joint function.

INTRODUCTION

Diabetic wounds are often chronic and show slow healing responses. Infection is common to these wounds and can lead to sepsis or amputation if not addressed. Combating bacteria requires effective antibacterial agents, in this case polyhexamethethylene biguanide (PHMB), which has been shown clinically to effectively clear wound infections. However, direct transdermal use of antiseptics requires high doses resulting in necrotic tissue effects or biocide resistance development; both of which impair endogenous healing. In addition, oxygen has been shown to improve collagen regeneration in diabetic wounds via our novel fluorinated methacrylamide chitosan (MACF) hydrogel dressings. The overall goal of this work is to examine the ability of MACF hydrogels to supply both oxygen and an antiseptic to combat infection in infected diabetic wounds while improving collagen network regeneration and regularity after infection is resolved.

METHODS

Figure 1: MACF hydrogels to supply oxygen and PHMB to treatment of infected diabetic wounds.

Materials synthesis: Chitosan and methacrylic acid were reacted together, then reacted with pentadecafluorooctanoyl chloride to result in MACF. After dialysis purification and freeze-drying, MACF was mixed with ultrapure water, loaded with PHMB, and photo-crosslinked to create hydrogel dressings that were saturated with ultrapure oxygen before application.

Wound Infection and treatment: Transgenic diabetic (db/db) mice (BKS.Cg-Dock7^m/+Lepr,^{db}/J) were confirmed to be diabetic via blood glucose readings of over 110 mg/dL. Under anesthesia, sterile silicon splints were sutured to prevent healing via contraction. Two 6 mm diameter full-thickness wounds were created in the center of each splint. Wounds were infected by applying 200 μ L of *P. aeruginosa* liquid culture to wounds. After 24 h, wounds were treated with oxygenated MACF hydrogels and/or PHMB, alongside a commercial PHMB dressing from Kendal, and controls. All wounds and treatments were covered with Tegaderm films. Dressings were changed approximately every other day. Samples were collected at the endpoint (D21) for histology, immunohistochemistry (IHC), and collagen organization/mechanical assessments[1].

Collagen analyses: Biaxial mechanical testing was performed on harvested tissues to determine tissue strength. Briefly, excised tissues were tested after 10 cycles of preconditioning using a five-protocol testing approach including stress ratios of 1:2, 3:4, 1:1 (equibiaxial), 4:3, and 2:1, similar to previous reports [2]. To explore the connection between strength of fiber networks and collagen organization, we used second harmonics generation (SHG) confocal microscopy to image type I fibrillary collagen and analyzed angle patterns of resulting images.

RESULTS

The equibiaxial stress versus strain curves (Fig. 2) showed that treatment with MACF mimicked the isotropic responses of the native tissues, whereas the commercial Kendal dressing revealed an anisotropic pattern similar to the no treatment infected control.

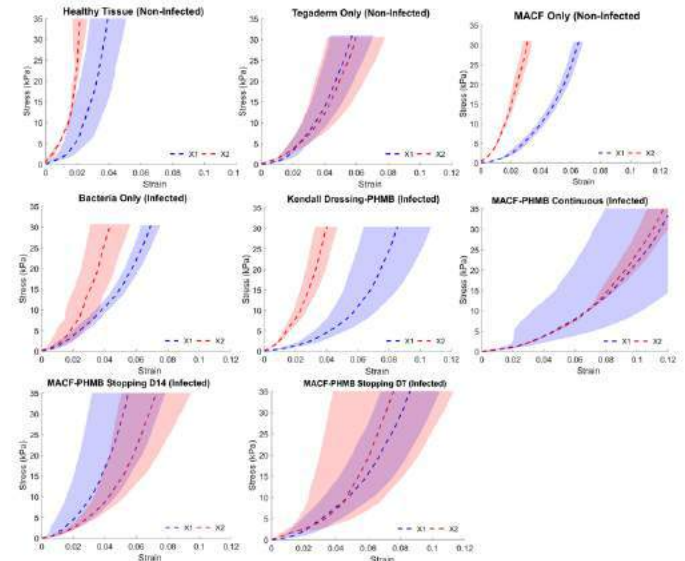

Figure 2: Average equi-biaxial stress-strain response curves for control groups and treatments (both n=3) from D21 post wounding with commercial dressing and MACF with PHMB application stopped at various time points (D7, D14) before completion of the study. Shaded regions represent standard error of the mean, X1 shows radial stretching and X2 shows circumferential stretching (1:1).

Figure 3: SHG images of wound margins showing organization of collagen networks from D21.

SHG was used to image granulation tissue (Fig 3), and organization of collagen networks present in biaxial testing was corroborated by mapping of angle of collagen fibers. As shown in Figure 4, collagen fiber angles showed more regularly organized collagen networks, reflective of healthy tissue, when treated with MACF. Treatment with commercial dressing and no treatment infected control showed increased grouping of angles in one principal direction instead of multiple directions, indicating improved network regularity.

Figure 4: Histograms of collagen fiber angles in D21 wound samples showing fiber angle distributions calculated from SHG images using DiameterJ plugin (ImageJ).

DISCUSSION

These data confirm the successful development of a non-healing chronic wound model infected with biofilm-forming bacteria (*P. aeruginosa*). Further, these data show that our treatment can both resolve infection and improve collagen synthesis and organization toward successful healing outcomes. Through these experiments we have narrowed the effective window (14 days) of localized topical PHMB treatment to effectively treat infection while minimizing necrotic effects of localized high dosages, as was seen in the commercial Kendal dressings. Our introduction of oxygen into the system via MACF hydrogels improved wound healing post infection and showed improved collagen network development with improved isotropic collagen patterning. This pattern is indicative of multi-directional strength, while treatment with bacteria only and commercial dressing showed stronger tissues in a singular direction. Tissues progressing toward isotropic collagen organization is representative of overall strength of healing tissues.

INTRODUCTION

Knee osteoarthritis (OA) is a degenerative joint disease that is a leading cause of joint pain, disability, and health care costs worldwide. OA affects the whole joint and is characterized by a gradual loss of articular cartilage often due to repeated microtraumas from injury, overuse, or ageing. A subset of OA, post-traumatic OA, often arises due to ligament injuries and occurs in a younger subgroup of patients than traditional ageing-related OA. Diagnosing early-stage post-traumatic OA can be difficult due to a lack of validated outcome measures for individuals with early knee OA [1]. The most common diagnosis metric, morphological changes to the cartilage, is limited to patients with moderate to severe OA, after irreversible changes to the joint have occurred. As post-traumatic OA may progress from an initial injury in the superficial zone of cartilage to more widespread biochemical and mechanical changes throughout the zonal tissue cartilage, quantifying changes to cartilage mechanical and biochemical properties non-invasively *in vivo* is of substantial interest.

MRI is unique among imaging tools as it can characterize tissues with high contrast and spatial detail, and has a deep penetration depth [2]. Recent work supports that T1rho MRI mapping, which is the time constant of spin lattice (T1) in the rotating frame, can discriminate between subjects with mild OA and controls.[1] In T1rho mapping the relaxation constants have been shown to be affected by both water and proteoglycan content in articular cartilage [1]. In other works, displacement encoded stimulated echo MRI (DENSE) has been used to calculate pixel level full field displacement maps of cartilage under repetitive motion [3]. In this study, we first utilized T1rho mapping before and after cyclic load along with DENSE MRI in a control cohort, in order to capture *in vivo* biochemical and biomechanical changes of the human knee cartilage exerted by the mechanical load. We then applied this technique to a cohort of patients who recently experienced an ACL reconstructive surgery (ACLR). This is our first application of the technique in a clinical population.

METHODS

Subjects: Research participants who underwent an ACL reconstructive surgery between 4 and 7 months (average 5.97 months) prior to the MRI date were recruited under IRB-approved protocols (n = 12, 6 females and 6 males). Participants received either a bone-patellar tendon-bone or quadriceps tendon autograft from one of our collaborating surgeons. Average subject age was 27.3 ± 4.8 and subjects had a mean BMI of 25.5 ± 3.5 . An age, sex, and BMI-matched group of control subjects with no history of knee pain or surgery were also recruited (n = 12, 6 females and 6 males). Average subject age in the control cohort was 27.1 ± 3.5 years old and subjects had a mean BMI of 24.6 ± 3.1 . A paired t-test was performed to determine that there were no significant differences in age or BMI between the ACLR and control groups.

MRI Scanning and Loading Protocol: Both ACLR and control groups underwent the same scanning and loading protocol (**Fig 1A**). Each participant's knee was imaged using a 3.0 T magnetic resonance (MR) scanner (Siemens Prisma^{fit}) with a knee coil (15-channel transmitter/receiver, Siemens). ACLR groups underwent imaging of their surgically reconstructed knee whereas all control participants were imaged on the leg of their choice. Prior to the application of load, T1rho-weighted MR images were acquired using the following parameters: Echo/repetition time (TE/TR)= 3/6 ms; spin-lock frequency = 500 Hz; spin-lock durations = 50,100,150,200 ms; field of view = 100×100 mm². Following imaging, medial compartment of participant knees underwent varus loading using a cyclic loading regime (0.5× body weight; pneumatic, 1s load, 1s unload) to mimic a walking cadence (**Fig 1B**). To apply the load, an MRI-compatible apparatus for varus-valgus loading was manufactured and validated, leading to compression of the medial condyle [4]. Moment conservation was used to estimate the load applied at the medial condyle. Importantly, eight (8) minutes of cyclic loading was applied prior to imaging to achieve a quasi-steady-state

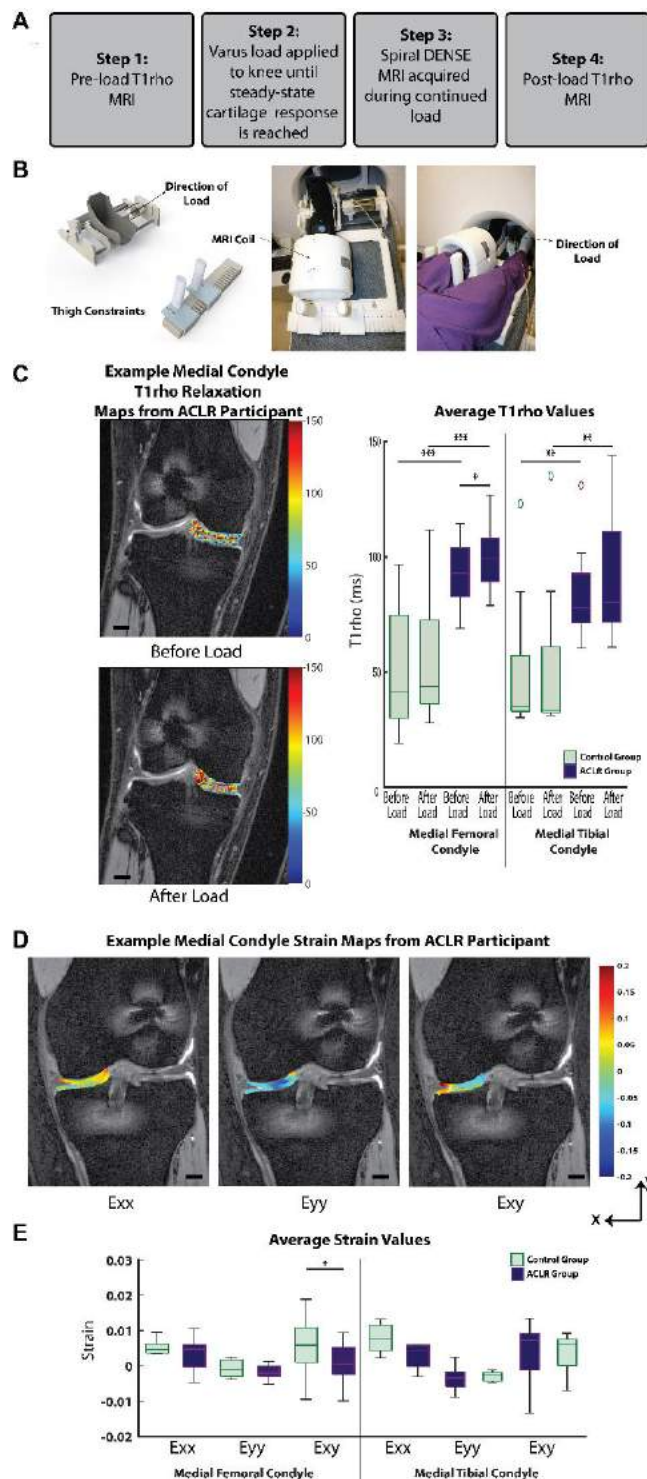

Figure 1: Multiple imaging techniques were used to assess cartilage response to load in control and ACLR cohorts. (A) MRI scanning session workflow. (B) Varus-valgus MRI compatible loading device. (C) T1rho relaxation maps and average values in control and ACLR groups. Scale bars indicate 10mm. *** indicates $p < 0.001$, ** indicates $p < 0.01$, * indicates $p < 0.05$ (D) Example strain maps from DENSE MRI. Scale bars indicate 10mm. (E) Average strain values. * indicates $p < 0.05$.

response and to minimize the viscoelastic response in the articular cartilage. Spiral DENSE MRI was collected following preconditioning. 27 time-sequenced coronal plane DENSE MR images were collected using 8 averages, 10 spiral interleaves, at a temporal resolution of 40 ms, TE was 2.5 ms and TR was 20 ms. FOV, slice thickness, and displacement encoding gradient were $160 \times 160 \text{ mm}^2$, 1.7 mm and 0.64 cycles/mm, respectively [5]. Total imaging time was 13.6 minutes. Following DENSE MRI, load was ceased, and T1rho-weighted MR images were acquired again using the same parameters as previously described (Fig 1C).

Data Analysis: The medial cartilage tibial and femoral regions of interest (ROIs) were manually segmented for all T1rho and DENSE images. DENSE MRI phase data was unwrapped using a custom Goldstein branch-cut phase unwrapping algorithm. Displacements for each pixel within the cartilage ROIs were determined from unwrapped phase data and smoothed using a locally weighted Gaussian filter with a kernel size of 3 [5]. A nearest neighbor transform was used to minimize bias at the ROI edges during smoothing. In-plane Green-Lagrange strains were calculated from the smoothed displacements [5] (Fig 1D). T1rho MR intensity images were fitted to a monoexponential relaxation model to obtain the T1rho relaxation map. An analysis of variance was used to determine the significance between control and ACLR groups for all strains and T1rho values (Fig 1C, Fig 1E).

RESULTS

There were significant differences in average T1rho values between control and ACLR groups. The medial femoral condyle and tibial condyle regions displayed significant differences between groups at before and after load timepoints (femoral condyle, $p < 0.001$, tibial condyle, $p < 0.01$). In response to load, only the ACLR group displayed a significant difference in T1rho values ($p < 0.05$). Shear strain (E_{xy}) in the medial femoral condyle was the only strain that displayed a significant difference between the ACL and control groups ($p < 0.05$) [6]. Multiple regression analysis was used to test if both group and change in T1rho value due to load can predict shear strain. The results of the regression indicate that there is a significant interaction between change in T1rho due to load and shear strain ($p < 0.05$).

DISCUSSION

This work provides a small cohort proof of concept of an MRI framework to non-invasively determine cartilage mechanical and biochemical information in a clinical setting. Although the cohort size is limited, the results support the use of both DENSE MRI and T1rho changes in response to load as a potential diagnostic tool to evaluate early cartilage degeneration in a clinical population. Ultimately, we hope to apply this framework in a larger population to further the development of diagnostic biomarkers for OA.

INTRODUCTION

As dental hard tissue, including enamel and dentin, is the major structure withstanding biomechanical loading, knowledge of tooth mechanical properties has been determined in bulk and nano scales. Previous studies have elucidated Young's modulus of enamel and dentin with a compression test and nanoindentation test¹⁻⁴. However, the previous research only determined tooth mechanical properties without consideration of tooth microstructure. In this research, the microstructure of enamel and dentin was characterized with scanning electron microscopy (SEM) and atomic force microscopy (AFM), and Young's modulus of enamel and dentin was determined through AFM. The enamel rod, dental tubules, and odontoblast processes were observed. Furthermore, the mechanical properties of dentin at the macro scale were determined by finite element method (FEM) simulation with a representative volume element (RVE) model. The influence of the dentin tubules on the mechanical properties of dentin was investigated.

METHODS

Extracted teeth was used. Before tooth sample preparation, the samples were stored in self-sealing sterilization pouches at room temperature. To prepare the tooth section, each tooth was embedded in resin for fixing. The fixed sample was machine-cut by a saw to get the occlusal section at the bottom of the tooth crown.

For SEM characterization of tooth occlusal cross-section, an unpolished tooth section was gold sputter coated. The section was imaged with JEOL JSM-6380 LV Scanning Electron Microscopy with an acceleration voltage of 15 kV to examine the microstructures of enamel and dentin at the occlusal section. Enamel micro-feature were observed under 600× magnification to see the enamel rods exposed through mechanical fracture after machine cutting. Dentin is the structure beneath enamel with tubules and odontoblast processes. To characterize dentin microstructure, the SEM image was obtained under

1200× magnification to observe the open dental tubules and odontoblast process.

For the AFM test, the sample surface was first exposed in 1× phosphate buffered solution (PBS) for 30 minutes to avoid the effects of surface charge. The AFM test was conducted with JPK force Robot 300. A probe, RTESPA-150 (Bruker, Billerica, MA), was utilized for morphology characterization, with a scanning area of $20 \times 20 \mu\text{m}^2$, and grids of 50×50 . A probe, RTESPA-525, was adopted for mechanical characterization with a scanning area of $5 \times 5 \mu\text{m}^2$, a grid of 8×8 . Six locations were selected in both enamel and dentin for mechanical characterization. The force-indent curves were fitted with Hertz Model to get Young's modulus at each point.

The FEM simulation of the compression test was implemented to quantify the mechanical properties of dentin in the presence of dentin tubules. A 2-dimensional (2-D) RVE model with a size of $38.4 \mu\text{m} \times 28.0 \mu\text{m}$ was reconstructed based on an SEM image (Figure. 1). Plane stress was set as 2-D behavior with $3.84 \mu\text{m}$ thickness to have the free movement horizontally. The material properties, Young's modulus of dentin, were determined by AFM test results. The boundary conditions were set as 2 nm downward displacement on the upper boundary and frictionless support on the lower boundary. The Young's modulus of dentin, E_{RVE} , was calculated from the simulation.

Figure 1: The selection of the region for FE simulation and meshes of selected dentin region in 2-D with tubules.

RESULTS

The morphology of enamel and dentin characterized with SEM and AFM are shown in Fig. 2. Different magnifications were adopted for each image to get a better visualization. The enamel rods and dentin tubules are observed (marked by white arrows in each figure). The dentin tubules observed with AFM showed a consistence with the SEM image. The enamel rod had a diameter of $\sim 5\mu\text{m}$, the tubules had a diameter of $\sim 2\mu\text{m}$. The odontoblast process in dental tubules was also observed. The alignment of enamel rods and dental tubules may indicate anisotropic mechanical properties of the teeth material.

Figure 2: Morphology of (a) enamel and (b) dentin characterized with SEM scanning, and (c) AFM scanning of dentin at a relative local region (enamel rods and dental tubules are marked with white arrows in each image).

The Young's modulus of enamel and dentin were quantified at six locations, as depicted in Fig. 3(a)&(b). The Young's modulus of enamel ranged from 19.8 to 77.8 GPa, with an average value 49.6 ± 20.4 GPa. The Young's modulus of dentin ranged from 16.0 to 47.4 GPa, with an average value of 35.4 ± 11.6 GPa. The representative Young's modulus mapping images indicated that both enamel and dentin show a highly heterogeneous behavior (Fig 3(c)&(d)).

Figure 3: Young's modulus quantified at six locations in (a) enamel and (b) dentin, and a representative Young's modulus mapping image of (c) enamel, (d) dentin.

The mechanical property of the dentin at the macro scale was determined by a compression simulation with an RVE model. Following simulation, the Young's modulus was determined by curve

fitting of the extracted stress-strain curve. The Young's modulus calculated by RVE model, $E_{RVE} = 29.2$ GPa, which is 17.5% less than the value quantified with AFM (35.4 GPa) due to the presence of dentin tubules, which undertook less load (Figure 4).

Figure 4: FEA simulated result of (a) reaction stress vs. strain curve of dentin for Young's modulus calculation, (b) the representative 2D dentin von Mises stress.

DISCUSSION

The mechanical property of enamel and dentin were determined through AFM nanoindentation, and the microstructure of dental hard tissue (enamel and dentin) is characterized by AFM scanning and SEM imaging. The Young's modulus of enamel and dentin is anisotropic with 49.6 ± 20.4 GPa and 35.4 ± 11.6 GPa, which are corresponding to previous compression and nanoindentation test results ranging from 1.3 GPa to 98.3 GPa for enamel and 1.6 GPa to 100 GPa for dentin⁴. The tested Young's modulus of enamel in general is higher than the value of dentin⁴. Since the difference in enamel and dentin microstructures leads to various mechanical properties, the compositions of dental hard tissue play an intrinsic role in the wear-resistant outer layer (enamel)⁵ and dental structure support (dentin)⁶.

Enamel rods and dental tubule structures with the odontoblast processes can be observed with SEM. Enamel rods are perpendicular to the dentinal-enamel junction (DEJ) with a diameter of approximately 5 μm. Rod sheath between enamel rods containing more protein than the mineralized enamel⁷⁻⁸. While dentin is main supporting structure of the tooth⁶ composed of tubules, peritubular dentin, and intertubular dentin⁹. Correspondingly, the superficial morphology of dentin cross-section is detected through AFM topography. The size of open tubules and the distance between tubules show consistency between AFM and SEM images.

The Young's modulus quantified with the RVE model is 17.24% less than that quantified by AFM due to the presence of dentin tubules. Combining the SEM, AFM, and FEM, we build a frame for multiscale mechanical characterization of the hard dental tissues considering the microstructures, which can be further applied to the study of enamel and the whole tooth.

INTRODUCTION

Cryopreservation of human organs has immense potential to save lives by increasing the shelf life and usage of donor organs, which may then help achieve long term banking and reduce or eliminate the organ transplant wait list [1]. Vitrification is a viable and promising approach to achieve cryopreservation of organs for theoretically indefinite time. To achieve this, an organ perfused with cryoprotective agent (CPA) is cooled rapidly to below its glass transition temperature to form an amorphous glassy state free of damaging ice crystallization [2, 3]. Cooling is typically achieved using forced convection of cold nitrogen vapor in a commercial freezer such as a Planar Control Rate Freezer [4]. Cooling is intrinsically size/volume dependent since it occurs through convective flux at the sample boundaries. While this approach works well for small systems, it can be a challenge for larger systems, both in i) achieving rapid enough cooling throughout the volume to avoid ice formation and ii) sufficiently uniform cooling to avoid significant thermal stresses that can lead to cracking [5,6]. Critical cooling (CCR) & warming (CWR) rates are thresholds to detect presence of ice formation (if cooling rate < CCR or warming rate < CWR- Table 1). To our knowledge successful vitrification has not yet been achieved for human organ scale systems (roughly ranging from 500 mL to 2.5L). Once vitrified, samples can be stored below the glass transition temperature (roughly < -120°C) and can be rewarmed at any time when needed. Rewarming of smaller vitrified samples (typically < 3 mL) in a water bath has been successful, however, alternative approaches intending to produce volumetric heating in larger samples, such as nanowarming or dielectric heating are being investigated [7,8]. Water bath rewarming is again a convective approach, where rewarming rates in the middle of the organ will naturally drop as organ size increases. To address this, a recent technique termed nanowarming was developed by our group. In this approach, magnetic iron oxide nanoparticles suspended in CPA are perfused throughout the vasculature of an organ to couple directly with

a radiofrequency field, thereby achieving more uniform rewarming independent of the size of the organ [7]. So far, successful vitrification and rewarming has been demonstrated in models such as rabbit kidneys and rat hearts, kidneys and livers, where the total preserved volumes were around 10-30mL [9-12]. To extend these results to the scale of human organs this study shows that vitrification and rewarming of up to 2.5L volumes of CPAs without crystallization or cracking is possible. This includes testing with three common CPAs including VS55, M22, and 40%EG+0.6M-sucrose (EG-Suc), all of which have been studied for use in cryopreservation of mammalian organ systems. Further, we present here the first demonstration of uniform nanowarming at the liter scale, performed with a state of art 120kW RF coil capable of 0-34 KA/m field strength at 360 kHz (2.5L uniform field volume).

Table 1: Critical rates of the studied three CPAs

CPA	CCR(°C/min)	CWR(°C/min)	Ref.
VS55	~2.5	~50	[10]
40%v/vEG+0.6MSucrose	<~1	45	[12]
M22	0.1	0.4	[3]

METHODS

A controlled rate freezer (CRF) is used to convectively cool the CPA samples in a polyethylene bag. Standard thermometry is employed to record temperature for estimating cooling/rewarming rates (3 fiber optic temperature probes at center, left & right edge of the CPA inside cryobag). Visual photos are used for confirmation of vitrification success (ice results in white clouding) and verified by μ CT imaging. Expected ice crystallization at the observed cooling rates is also compared to results measured on the same CPAs measured using differential scanning calorimetry (DSC). For nanowarming, magnetic field is mapped in 120kW RF coil using a 2D high frequency probe.

RESULTS

Using a CRF, a cooling protocol is designed by introducing fast cooling ($-40^{\circ}\text{C}/\text{min}$ in the chamber was chosen to avoid ice crystallization by achieving cooling rate above CCR) from a starting temperature (0°C) until reaching an annealing temperature (-122°C , just above the glass transition) at which point the sample is held for complete thermal equilibration. This helps to alleviate thermal stress prior to entering the brittle glassy phase. The protocol ends with a very slow cooling step ($< -1^{\circ}\text{C}/\text{min}$) in the glassy state until reaching the storage temperature of -150°C . This step is needed to avoid introducing additional thermal stresses. VS55 formed ice during cooling (i.e. failed to vitrify) at all volumes whereas EG-Suc and M22 vitrified without crystallization or cracking at volumes of 0.5L, 1L. M22 seems to be best cocktail for vitrification as we were able to vitrify up to 2.5L due to its exceptionally low CCR (Table1). Average center cooling results vs. volume are also listed below Figure 1.

Figure 1: Examples of 0.5 L cryobags of CPA cooled in a CRF. Photos of A. CRF; B. M22 (vitrified); C. VS55 (crystallized); D. EG-Sucrose (vitrified). (Note: 0.5 L cryobag can hold a human kidney) (Center cooling rates: 0.5L $\sim 1.4^{\circ}\text{C}/\text{min}$; 1L $\sim 1^{\circ}\text{C}/\text{min}$)

To achieve sufficiently uniform & rapid rewarming of these larger systems through nanowarming we used a new state of the art 120kW RF coil with a sample capacity of up to 2.5L (Figure 2A). A magnetic field strength of up to 34 kA/m (at 360 kHz) is generated at the full 100% operational power of RF coil. Figure 2C shows the variation of generated magnetic field with the % power output of the 120kW RF coil. The magnetic field variation in axial and radial direction inside the coil is uniform (within $\pm 5\%$) as in Figure 2B. Finally, to demonstrate uniform rewarming of these vitrified large volumes, a solution of 1L M22 with 7 mgFe/mL iron oxide nanoparticles (Ferrotec EMG-308) was vitrified with the protocol above, stored at -150°C , and then nanowarmed in the RF coil. Heating rates of $\sim 100^{\circ}\text{C}/\text{min}$ were measured with negligible temperature variation measured at three different points ($\sim 3\text{cm}$ spacing) within the volume (Figure 2D) exceeding highest CWR of all CPAs (VS55 $\sim 50^{\circ}\text{C}/\text{min}$).

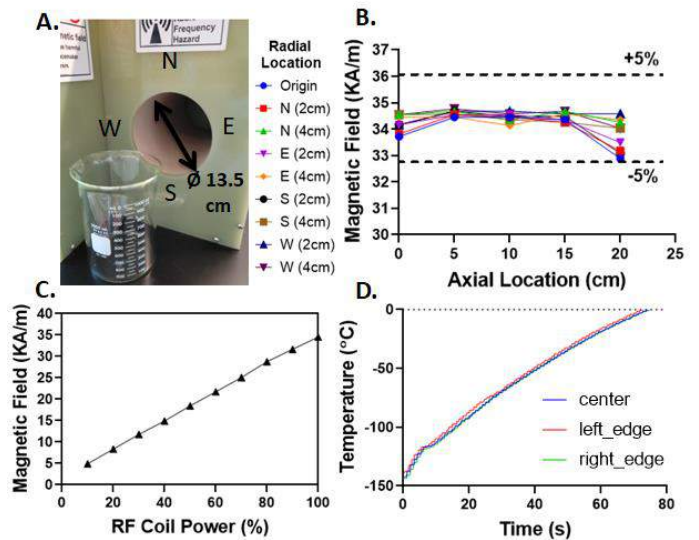

Figure 2: Nanowarming system characterization: A. 120kW RF coil (AMF Life Systems); B. Magnetic Field variation within coil (N, S, E, W vs. axial depth); C. Magnetic field vs. % Power in coil; D. Temperature curve for 1L nanowarming of EMG-308+M22.

DISCUSSION

Cooling rates at center decrease with increasing volume of CPAs ($\sim 1.4^{\circ}\text{C}/\text{min}$ at 0.5L to $\sim 1^{\circ}\text{C}/\text{min}$ at 1L). Thus to maintain cooling rate greater than CCR we would need to either utilize CPAs with extremely low CCR such as M22 ($\sim 0.4^{\circ}\text{C}/\text{min}$) or new technologies are needed to enhance cooling in larger volumes. Long annealing time is required (~ 2 hrs at 0.5L to ~ 4 hrs at 1L) to achieve isothermal equilibration prior to final cooling and storage. Furthermore, a very slow cooling rate ($< 1^{\circ}\text{C}/\text{min}$) is then needed when cooling below the glass transition temperature ($\sim -123^{\circ}\text{C}$). Both of these approaches are designed to minimize thermal gradients which can induce fractures. Once the system is vitrified, we show that nanowarming in a 120KW RF coil (0-35KA/m at 360 KHz) can uniformly rewarm CPA volumes up to 1L and our characterization suggests further scaling to 2.5L will be possible. This study demonstrates physical success in vitrification and rewarming of human organ scale systems (0.5-2.5L), suggesting that vitrification and nanowarming of human organs will be possible, an provided needed "organ banking" technology for the future.

INTRODUCTION

Traumatic brain injury (TBI) is a major cause of injury and death in the United States [1]. Due to difficulties in studying the mechanics of TBI in vivo, finite element (FE) simulations have become an important tool in studying TBI. These simulations require accurate material parameters of brain tissue to achieve relevant results. Due to the viscoelastic nature of brain tissue [2], experimentally derived constitutive models should be validated over a large range of strain rates relevant to TBI, ranging from on the order of tens per second to several hundred per second [3]. To date, high-rate characterized models of brain tissue in shear in literature either achieve low strain amplitudes and high strain rates [4] or higher amplitudes but lower peak strain rates below 100 s⁻¹ [5].

We previously performed oscillatory shear frequency sweeps, between strain rates of 0.025 and 250 s⁻¹, on cerebral tissue from freshly euthanized Göttingen minipigs. The objective of the present study was to fit a hyper-viscoelastic constitutive model to the experimental data using both an inverse FE model and MATLAB and to compare the results.

METHODS

Previously, cerebral tissue from freshly euthanized Göttingen minipigs was cut into 8 x 8 x 5 mm samples and subjected to a simple-shear frequency sweep having an amplitude of 20% shear strain, with strain rates ranging from 0.025 s⁻¹ to 250 s⁻¹ for 5 cycles each.

First Piola-Kirchhoff (1st PK) stress and shear strain were calculated from the recorded load and displacement data, respectively, and used to generate average strain vs time and stress vs time curves. We then fit these curves with a hyper-viscoelastic constitutive model with the stress defined by

$$\mathbf{S}(t) = \int_0^t G(t-s) \frac{\partial \mathbf{S}^e}{\partial s} ds \quad (1)$$

where the elastic stress \mathbf{S}^e is given by a one-term Ogden model defined by the strain energy function

$$W^{matrix} = \frac{\mu}{\alpha} (\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3) \quad (2)$$

where μ is the shear stiffness, α is a non-linearity parameter and λ_i is a principal stretch. The reduced relaxation function $G(t)$ is defined by a six-term Prony series

$$G(t) = \sum_{i=1}^6 g_i \exp\left(-\frac{t}{\tau_i}\right) \quad (3)$$

where τ_i are fixed time constants, each spaced one decade from another and ranging from $\tau_1 = 1$ s to $\tau_6 = 1 * 10^{-5}$ s, and g_i are viscoelastic coefficients. The parameters μ , α , and g_i were fit to the average stress and strain curves in MATLAB using the *fmincon* function.

In addition to the MATLAB fits, we also constructed an inverse FE model of the experiments in FEBio [6]. Briefly, we modeled an 8 x 4 x 5 mm half-symmetry cube of brain tissue. The top face was attached via rigid contact to a fixed 8 x 4 x 1 mm rigid body representing the load cell-attached plate in our tester, while a displacement corresponding to the average experimental displacement waveform was applied to the bottom face in the X direction.

To correspond with the constitutive model fit in MATLAB, we used an uncoupled viscoelastic material for the brain tissue cube with an uncoupled Ogden model selected for the elastic material. All analysis was performed with the implicit dynamics solver. A convergence was performed study using the material parameters from the MATLAB fit. We selected a mesh of 400 20-node hex elements for the brain tissue and 16 20-node hex elements the rigid plate. We then used the FEBio optimization module to define the 8 material parameters by minimizing the error between the X reaction force at the rigid contact and the

average experimentally recorded force. Finally, we performed a forward simulation using the optimized parameters, converting the X reaction force at the fixed plate back to 1st PK stress, for comparison with the experimental and MATLAB fit curves.

RESULTS

The MATLAB and inverse FE fits for the first two loading cycles of selected strain rates are shown in **Figure 1**. At the lowest rate (0.025 s^{-1}), both the MATLAB and inverse FE fits underpredict peak stresses. At intermediate rates from 0.25 s^{-1} to 12.5 s^{-1} (not shown), the inverse FE model tends to overpredict stresses while the MATLAB model tends to underpredict them. At 50 s^{-1} and 100 s^{-1} , both models underpredict maximum stresses and overpredict minimum stresses, though the inverse model provides a better prediction. At the highest rate (250 s^{-1}), both models show a marked phase shift, with the MATLAB model leading the experimental data while the inverse model slightly lags it. Additionally, both models substantially underpredict minimum stresses.

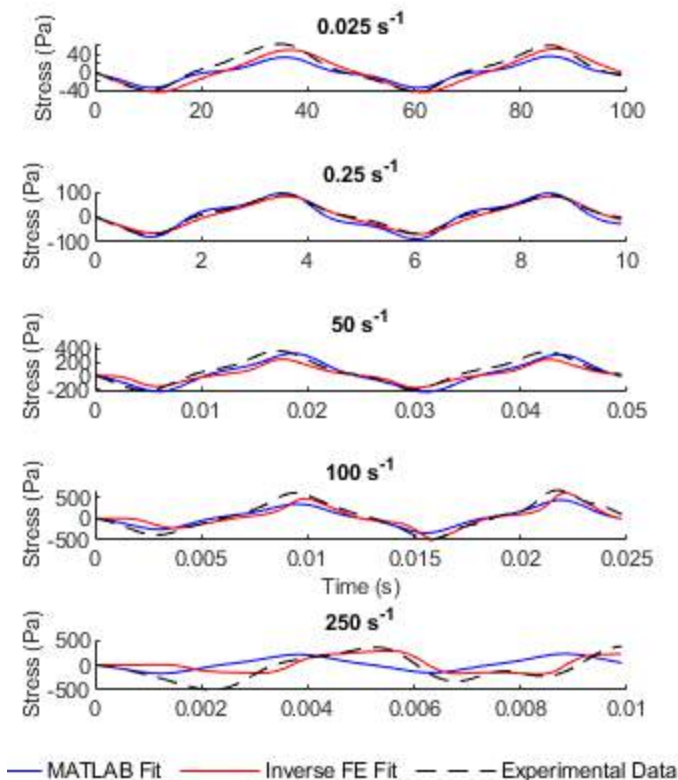

Figure 1 | Comparison of MATLAB and FE fits and experimental data for the first two loading cycles of selected rates.

R^2 values for overall fit quality show that the FE fit performs better than the MATLAB fit (0.75 vs 0.58), though both perform relatively poorly. Examining R^2 values for each oscillation, the FE model performs best for rates below 50 s^{-1} (0.81-0.94 vs 0.60-0.85) and above 100 s^{-1} (0.48-0.66 vs -0.42-0.51), while the MATLAB fit performs best at 50 and 100 s^{-1} .

DISCUSSION

The purpose of this work was to fit a hyper-viscoelastic constitutive model to previously acquired oscillatory shear data from brain using both conventional fitting in MATLAB as well as inverse FE methods.

Generally, the inverse FE model performed better than the MATLAB model. Overall, both models perform worse at rates above 100 s^{-1} , with the worst performance at 250 s^{-1} . While this was somewhat expected, due to increased noise and variation present in the experimental data at these rates, it is clear that additional revisions of the model may be needed to capture this, especially at 250 s^{-1} .

At rates of 100 s^{-1} and above, noticeable wave propagation is present in the FE model, suggesting that inertial effects are playing an important role at these rates. This is consistent with the experimental data, which show a noticeable leftward shift of the strain-time waveform relative to the stress waveform present at higher rates. For a viscoelastic material, stress should always lead or be in phase with strain, but strain should never lead stress. This suggests that there is some degree of shear wave propagation through the tissue from the moving platen, where displacement was measured, to the fixed platen, where load was measured. This is further evidenced by thicker samples tending to exhibit more phase shift at these rates compared to thinner samples. Because our MATLAB methodology assumes a homogeneous deformation and does not account for inertial effects, it cannot account for wave propagation, helping explain why it is typically outperformed by the inverse FE approach. Further constitutive model refinement will thus use inverse FE.

Attempts to weight the g_i terms corresponding to the smallest τ_i values in the inverse FE model in order to better fit high-rate oscillations led to better fitting of the first cycle of all oscillations above 100 s^{-1} but caused the stresses of subsequent cycles to be substantially overpredicted, up to several times peak stress values for the 5th cycle. This may suggest that either the model is in need of increasing damping or possibly that the tissue does not exhibit frequency independent damping as assumed by the Fung quasi-linear viscoelastic formulation used here [7]. However, we are unable to verify this from experimental data as the phase shift present at high rates precludes accurate calculation of the loss modulus at high rates. Fitting may still be improved by implementing a material model with frequency dependent damping [8]. Future work will aim to improve predictive accuracy of the inverse FE models by both investigating different materials as well as implementing anisotropy to model additional experiments.

INTRODUCTION

The Rho family of small GTPases coordinate actin cytoskeletal rearrangements underlying crucial cell processes including migration and mechanotransduction [1]. Rho GTPase signaling is tightly controlled in space and time: GTPases are activated by guanine nucleotide exchange factors (GEFs) and inactivated by GTPase accelerating proteins (GAPs) at the plasma membrane. RhoA activation and interaction with downstream effector proteins leads to actin polymerization, which drives transcriptional mechanotransduction in part through Yes-associated protein (YAP) [2,3]. Previously, we found that YAP is not only activated by RhoA-signaling, but also regulates RhoA by a negative feedback loop through expression of RhoA-inactivating GAPs, including ARHGAP7. This negative feedback loop is necessary for persistent cell motility. However, in order to define the role of this loop in cell motility, which is dynamic and spatially regulated in the cell, we need to understand its temporal and spatial control during cell migration. Solving this problem requires a new set of tools.

Here we describe the engineering of a novel set of single-component (i.e., one-protein) optogenetic tools to control activation and termination of RhoA signaling using the BcLOV4 membrane recruitment platform [6]. These tools allow us to control the subcellular localization of the RhoA GTPase and its associated GEF and GAP domains and systematically perturb signaling interactions involved in cell motility and mechanotransduction with precise spatial and temporal control.

METHODS

We generated both RhoA-activating and RhoA-inactivating tools. For activation, we generated tools for RhoA itself as well as the RhoA-activating GEF11. For inactivation, we generated tools for RhoA-inactivating GAPs (GAP1, GAP7/DLC1).

Fusions of BcLOV4, effector protein (wildtype RhoA GTPase, the Dbl homology domain of ARHGAP11, and the GAP domain of

ARHGAP1 or ARHGAP7), and mCherry visualization tag were Gibson cloned into the pcDNA3.1 backbone. To measure RhoA activation-induced cell contraction, mCherry fluorescence was imaged before and after a 5-second pulse of whole-field blue light activation (N = 82-93 cells per condition). Change in cell area was calculated using a custom Python script. Cytoskeletal changes were assessed by fixing tool-expressing cells in the dark-adapted state and after two hours of pulsed blue light stimulation and staining with Alexa Fluor 488-tagged phalloidin (N = 40 cells per condition).

For mechanotransduction assays, HEK293T cells were co-transfected with mCherry-tagged tools and EGFP-tagged YAP in a 4:1 ratio. EGFP-YAP was imaged every 15 seconds using a 250 msec excitation pulse that also stimulated BcLOV4, and mCherry fluorescence was imaged every minute. Nuclear and cytosolic fluorescence normalized to the area of each region was calculated every minute by manual segmentation in ImageJ, with N = 20 cells per condition.

YAP-TEAD-dependent transcriptional activity was quantified using a dual luciferase reporter system (Promega, E1910). HEK293T cells were serum starved and co-transfected with plasmids encoding 8XGT1C-luciferase, a YAP-sensitive promoter driving firefly luciferase expression; *Renilla* luciferase; and mCherry-tagged tool in a 1:1:3 ratio. Half the cells were incubated under pulsing blue light with a 1.6% stimulation duty cycle for 12 hours. Cells were lysed and luminescence was measured in white 96-well plates with a 10 second integration time. The firefly luminescence value for each sample was normalized to its *Renilla* luciferase readout. N = 8 lysate samples per condition.

RESULTS

Activation tools: Blue light stimulation of cells expressing opto-RhoA (RhoA-BcLOV4-mCherry) and opto-RhoGEF (BcLOV4-ARHGAP11-mCherry) drove robust cell contraction and actin polymerization measured by phalloidin staining, compared to control

BcLOV4-mCherry (Figure 1). To assess whether synthetic RhoA activation using optogenetic tools was sufficient to drive transcriptional mechanotransduction, we next co-expressed tagged YAP with either opto-RhoA-mCherry or BcLOV4-mCherry and observed that blue light stimulation of the opto-RhoA condition again caused cell contraction and a rapid increase in nuclear localization of YAP. A synthetic YAP-sensitive promoter driving luciferase expression showed a significant increase in YAP-mediated transcription in photoactivated opto-RhoA-expressing cells compared to dark-state cells or control BcLOV4 (Figure 2).

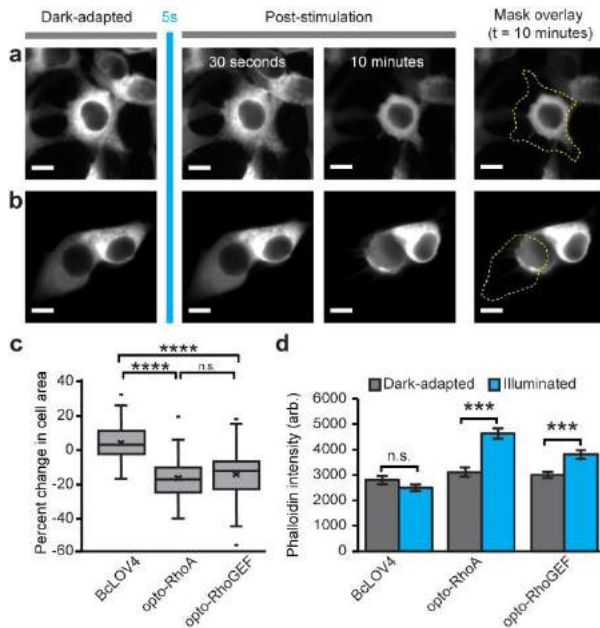

Figure 1: Characterization of optogenetic RhoA activation in HEK293T cells. Opto-RhoA (a) and opto-RhoGEF (b) drive potent cell contraction after one 5-s pulse of whole-field blue light illumination, leading to a significant change in cell area (c) and a significant increase in actin polymerization measured by phalloidin intensity (d). (*) $p < 0.001$, (****) $p < 0.0001$, n.s. not significant by Mann-Whitney U test.**

Inactivation tools: Cells expressing opto-ARHGAP1 (ARHGAP1-BcLOV4-mCherry) exhibited less actin polymerization in the photoactivated state compared with dark-adapted cells (Figure 3), measured by phalloidin staining. Untransfected cells observed in this assay exhibit higher actin signal than the GAP tool-expressing cells in the photoactivated state, suggesting that opto-GAP-mediated RhoA inactivation lowers cytoskeletal tension.

DISCUSSION

We created single-component optogenetic tools to both activate (opto-RhoA, opto-RhoGEF) and inactivate (opto-ARHGAP1, opto-ARHGAP7) RhoA signaling in mammalian cells. The use of a single protein for optogenetic signaling perturbation in this toolbox reduces the genetic payload of plasmid delivery to targeted cells and eliminates the need for stoichiometric tuning of multiple optogenetic components. The toolbox also occupies only one visualization channel for tool excitation, freeing up optical bandwidth in experimental setups.

We plan to use these tools to investigate how RhoA signaling protein identity and subcellular localization drive mechanotransductive feedback and cell migration with greater spatiotemporal precision than is afforded by traditional inhibitors or cell-wide genetic manipulations.

Opto-RhoA activation generated sufficient cytoskeletal tension to drive YAP nuclear localization and transcriptional co-activation, presenting an opportunity change the mechanical and transcriptional state of the cell using light. Finally, opto-ARHGAP1 is one of two reported Rho-family optogenetic termination tools [8], expanding the capabilities of optogenetics to control cell physiology.

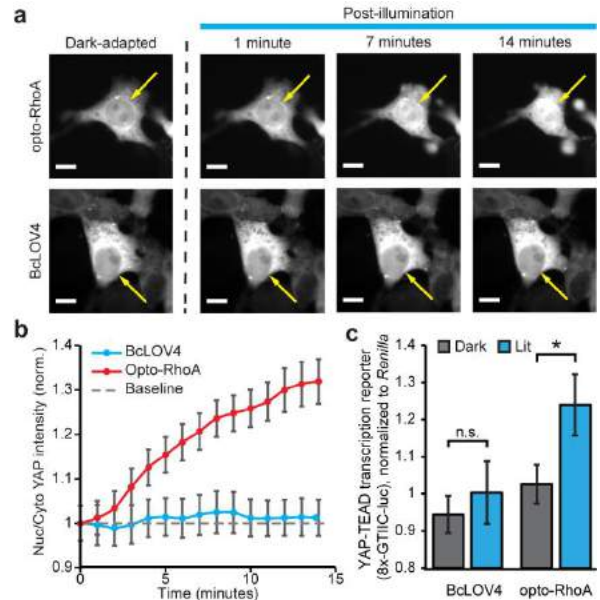

Figure 2: Opto-RhoA drives YAP-EGFP nuclear localization in HEK293T cells (a-b) and an increase in YAP-TEAD-mediated transcription (c). (*) $p < 0.05$ by Mann-Whitney U test.

Figure 3: Opto-ARHGAP1-expressing cells HEK293T cells show lower actin density in their photo-activated state.

INTRODUCTION

Kidney development is a dynamic and highly coordinated dance between branching of the future urinary collecting tubules and induction of nephrons. While genetic and biochemical factors involved in this process have been the primary focus in the past, the role of mechanics is an emergent interest in the field. Studies from other branched organ systems suggest that mechanical factors are crucial in guiding branching morphogenesis [1, 2, 3]. However, the role that mechanics play during kidney development has yet to be elucidated. Our lab recently reported that the mechanical stress generated by jamming of nephron-forming progenitor niches at the tips of tubules may serve as a pace-making cue that instructs nephron commitment. We also showed that pharmacologically inhibiting tension in an iPSC-derived model alters nephron commitment outcomes [4].

To further understand the signaling-level regulation of mechanotransduction during kidney development, we are now perturbing the physical environment at the cellular and whole-organ scales. In this abstract, we present preliminary data on the effect of matrix stiffness on YAP nuclear localization in nephron progenitor cells (NPCs) and on 3D branching in kidney explants. We show that NPCs plated on substrates of different stiffness have varying levels of YAP nuclear localization. Jumping to the whole-organ level, we first develop a 3D explant culture system that enables ex vivo development in a controlled mechanical environment. Current thought in the field is that 3D explant culture is impossible due to nutrient or oxygen transport limitations, necessitating flattened culture at air-liquid interfaces [5]. However, our preliminary work demonstrates that embedding kidney explants in a high-concentration collagen gel supports ex vivo, 3D branching morphogenesis and nephron development for the first time. Future experiments will focus on altering the 3D gel's stiffness to study the impact of the mechanical 3D environment on kidney branching morphogenesis and nephrogenesis..

METHODS

Kidney microdissection and progenitor dissociation: Kidneys were microdissected from CD1 mouse embryos at different embryonic age. For progenitor dissociation, E17 kidneys were further dissected to remove the capsule and ureter. Mouse nephrogenic zone cells were dissociated from E17 kidneys following published protocol [6].

PA gel fabrication and fibronectin coating: Polyacrylamide (PA) gels were fabricated and coated with fibronectin as described by Prah et al. [7]. Soft gel contained 3% Acrylamide (Am) and 0.1% Bisacrylamide (Bis) and stiff gel contained 7.5% Am and 0.25% Bis. After fabrication, the gels were incubated in 10 µg/ml bovine serum fibronectin at 4°C overnight and sterilized under UV light before use.

Cell culture on PA gels: Culture media was made by adding maintenance factors except ROCK-inhibitor Y-27632 to advanced RPMI media [6]. Fibronectin solution was aspirated before adding progenitor cells of various densities. Rock inhibitor was added to half of the chambers and removed 24 hours after cells were plated.

Kidney explant culture at air-liquid interface: Protocol modified from Sebinger et al. [5]. 10% Polydimethylsiloxane (PDMS) was casted to a dish and baked at 60°C overnight. The cured PDMS was first cut into rectangles and a 12 mm circular hole was punched in the center. The PDMS was then plasma-bonded to a 35mm glass-bottom dish. Dissected E12 kidneys were placed in the circular cutout and cultured in 85µL DMEM with 10% FBS. The space between the PDMS and the dish was filled with DI water. The inner surface was coated with 10% Matrigel before culture.

3D kidney explant culture: 3D explant culture utilized the same PDMS dish. In addition to placing the kidney in the dish, a drop of Matrigel or neutralized 3mg/ml rat tail collagen I was added to cover the explant. The embedded kidney was left at room temperature for a few minutes for the gel to solidify and the media was added.

Immunofluorescence: Immunofluorescence staining was performed as described before [4]. Primary antibodies used were YAP,

SIX2, JAG1, and E-cadherin. Secondary antibodies used were donkey anti-rabbit Alexa 647, anti-mouse Alexa 488, anti-mouse Alexa 555 and anti-goat Alexa 555. PA samples were also stained with DAPI. Explants were further cleared with scale A and scale B for two days each.

Imaging and data analysis: PA gels were imaged at 20-40x magnifications on a spinning-disk confocal microscope. Z-stacks of the explants were taken at 4-10x magnification. Fluorescence signals were thresholded using FIJI to assign identity to each cell. YAP nuclear translocation is defined as the ratio of nuclear signal to the cytoplasmic signal. The ratio was calculated using CellProfiler and compared within each cell identity group. Prism was used to perform unpaired t-test to determine statistical significance.

RESULTS

We previously showed that jamming of NPC niches is instructive for cell commitment. We also reported that ROCK-pathway inhibitor (RI), which decreases cell collective tension, promotes stem cell plating efficiency and nephrogenesis in vitro [4]. Moreover, crosstalk between the mechanosensitive YAP pathway and ROCK pathway can regulate stem cell fate in many contexts [8, 9]. Therefore, we decided to characterize NPC's sensitivity to the mechanical environment with and without RI. We fabricated fibronectin-coated PA gels and seeded NPCs obtained from either dissociating mouse embryonic kidneys or differentiating human iPSCs (h-iPSCs) [6, 7, 10]. NPCs were cultured on PA gels of different stiffness at varying density (Figure 1a) with and without RI. The elastic modulus (E) for the soft gel was ~8.7kPa and the stiff gel was ~36.3 kPa. NPCs were stained for undifferentiated NPC marker SIX2, committed NPC marker JAG1, and YAP two days after. h-iPSC-derived NPCs plated at higher density expressed more mature markers, agreeing with published result [10] (Figure 1a). We hypothesized that cells expressing different NPC markers have different YAP nuclear translocation levels which is indicated by the YAP nuclear-to-cytoplasmic (N/C) ratio [8] (figure 1b). We built an analysis pipeline to segment NPCs based on their identity and calculate the YAP N/C ratio in individual cells. We compared the YAP N/C ratios of JAG1-expressing cells and found significant higher N/C ratio in cells on soft gel with RI than in cells on stiff gel with and without RI (figure 1c). Currently, we are determining the mechanosensitivity of other NPC subtypes and the link between NPC commitment and the mechanosensitive YAP activation.

We also sought to study the effect of the physical properties of the matrix on the whole-organ level. Studies of mechanical regulators in cultured kidney explants are limited by the need for an air-liquid interface which disrupts the 3D morphology of the tissue. We aimed to develop a culture system that preserves the 3D architecture of the explants and supports ex vivo branching morphogenesis. The current standard culture method places the explant in a silicon ring exposed at an air-liquid interface [5]. We incorporated a 3mg/ml collagen I gel with reported $E \sim 2.48$ kPa to fully encapsulate the explant (figure 1d) [11]. We also added a 3D Matrigel droplet with reported $E \sim 331$ Pa to the culture device as a separate control [12]. All the groups were cultured under the same conditions and fixed after two days. Kidneys were stained with SIX2 and E-cadherin to visualize the mesenchyme and the ureteric tree (figure 1e). The explant cultured in the 3D Matrigel failed to develop (data not shown). However, the kidney cultured in collagen gained a spherical morphology as compared to the flattened tissue at air-liquid interface while maintaining comparable branch numbers. These data indicate that explant viability may depend not on nutrient or oxygen availability, but rather on an appropriate stiffness and/or adhesive microenvironment. Ongoing experiments are investigating optimal biomaterial and mechanical properties both to achieve a step-change in long-term 3D explant culture capabilities, translate our findings to

regenerative medicine applications, and to understand the fundamental mechanobiology of kidney morphogenesis.

DISCUSSION

In the present study, we have presented preliminary data effects of the physical environment on kidney development at both the cellular and whole-organ scales. On the cellular scale, this work contributes preliminary characterization of nephron progenitor mechanosensitivity. We are also testing different tension inhibitors in ongoing work to illuminate the cell-scale details of niche geometry, mechanics, and pace-making of nephron progenitor differentiation. On the organ scale, we introduce a culture technique that supports 3D, ex vivo branching morphogenesis of kidney explants for the first time. We are currently determining the role of gel stiffness, adhesion, and viscoelasticity on branching timing and geometry in this system. A 3D culture method that resembles the in vivo environment offers tremendous opportunities for future studies of kidney branching morphogenesis. This work will create a new cell-to-organ-level mechanics perspective that impacts kidney regenerative medicine efforts seeking to address the high burden of congenital and adult kidney disease.

ACKNOWLEDGEMENTS

We thank members of the Hughes laboratory for helpful discussions and assistance with experimental protocols, especially Louis and John for the gel fabrication and animal work.

FLUID-STRUCTURE INTERACTION SIMULATION AND EXPERIMENTAL VALIDATION OF BIOPROSTHETIC HEART VALVES

Masod Sadipour (1) and Ali Azadani (1)

(1) Department of Mechanical and Materials Engineering, University of Denver, Denver, Colorado, United States

INTRODUCTION

Bioprosthetic heart valves (BHVs) are designed to closely resemble the flow patterns of a normal human aortic valve, reducing the need for long-term chronic anticoagulation treatment. However, BHVs are usually prone to failure after 10-15 years of being implanted, often due to calcification and degeneration, which can lead to additional surgical procedures to replace the bioprosthetic valve. Design and development of bioprosthetic heart valves (BHVs) require extensive and expensive pre-clinical and clinical testing. The process limits opportunities to thoroughly refine BHVs' design and explore novel ideas. In the past decade, the role of computational modeling has been becoming increasingly important in the design of BHVs. Computational modeling provides a framework for a quantitative description of BHVs' function to address concerns such as long-term valve durability, hemodynamic performance, and thrombogenicity. Several studies have primarily concentrated on modeling the valve using finite element techniques and did not consider the valve interaction with blood flow [1-3]. Fluid-solid interaction (FSI) simulations can examine the interaction between the flow of blood and the mechanics of the valve. In the present study, we have developed a 3D FSI computational model representing a surgical bioprosthesis (25-mm PERIMOUNT Magna Ease) inside a pulse duplicator system (BDC Labs). The simulation results were validated against experimental data obtained by particle image velocimetry (PIV) measurements.

METHODS

A 25-mm PERIMOUNT Magna Ease valve was examined in a BDC pulse duplicator to acquire both valves dynamic and hemodynamic data. We used experimental measurements of pressure gradient and flow rate data as boundary conditions in the FSI simulation [5]. A conventional two-dimensional TSI PIV system was also employed to measure planar velocity downstream of the bioprosthetic valves [5]. PIV data were used to validate the FSI simulation. A NextEngine 3D Laser Scanner was used to obtain the geometry of the surgical valve leaflets [6]. The final geometry model of the leaflet and one-third of the pulse duplicator was created in Solidworks (Figures 1a and 1b). We used Ansys Workbench for the FSI modeling.

Figure 1: (a) Computational model; (b) magnification of leaflet area; (c) Fluid computational mesh near the valve region.

For solving the structural part of the simulation ANSYS Transient structural and for fluid dynamics, ANSYS FLUENT was used. HyperMesh FE preprocessor was employed to discretize the leaflet geometry using a mapped mesh with 18,610 hexahedral elements. The mesh was then imported to Ansys Transient structural. Leaflets were assumed to be hyperelastic isotropic materials. Yeoh 3rd order strain energy function was used to model the mechanical properties of the leaflets. The strain energy potential equation is:

$$W = \sum_{i=1}^3 C_i (I_1 - 3)^i \quad (1)$$

where C_i are the material mechanical constants and I_1 represents the first deviatoric invariant of the deviatoric right green deformation tensor. The mechanical constants were found by fitting Yeoh 3rd order equation to the experimental strain-stress results of the biaxial test by Mostafa et. al [7]. The fluid domain was discretized via approximately 1.2 million tetrahedral elements using Pointwise- Mesh Generation Software for CFD (Figure 1-c). Mesh independency for both the structure and the fluid mesh was done through four different element numbers. The blood passing through was specified as a homogeneous, Newtonian incompressible fluid with a density of $\rho = 1,060 \text{ kg/mm}^3$ and a viscosity of $\eta = 0.0035 \text{ Pa.s}$. Because the fluid and structure behavior are mutually dependent and data was exchanged in both directions between the solid and fluid domains, we employed a two-way coupled FSI solver. Figure 2 illustrates the flow chart of the system coupling. The process of iterating between FEM and CFD solvers continues until a converged solution was achieved in each FSI iteration.

Figure 2: Flow chart of each FSI iterations (data exchanging)

RESULTS

Instantaneous velocity contour from 2-way FSI simulation of the 25-mm Carpentier-Edwards PERIMOUNT Magna bioprosthesis is compared with PIV results at peak systole (presented in Figure 3). At the peak flow, the maximum jet velocity in FSI and PIV are 2.07m/s and 2.1 m/s at the center of the jet respectively, with a diameter of about 14.6 in FSI and 15.2 mm in PIV. Also, jet length is the same in both FSI and PIV. As can be seen, the velocity dropped significantly from the central jet to the surrounding area in both FSI and PIV results. The plane at which the flow parameters are shown in Figure 3 (left) is the mid-plane cutting through the bioprosthetic valve. Good agreement between the experiment and the simulation results was observed.

Figure 3: Two-way FSI simulation results (left) and PIV measurement (right) of 25-mm surgical Carpentier-Edwards PERIMOUNT Magna at peak of systole.

DISCUSSION

This study has developed an FSI simulation of a BHV in a pulse-duplicator platform. The study improves our understanding of structural and hemodynamic performance of BHVs. The simulation results were validated against experimental data obtained by flow velocity measurements using PIV. We found a good agreement between them. Our validated platform is applicable for different bioprosthetic and transcatheter heart valves. FSI methodology offers a reliable tool to assess the structural and hemodynamic performance of BHVs. This project is a step toward the experimental validation of this FSI modeling platform for evaluating tissue heart valves. The methodology can be used effectively for the quantitative description of the structural and hemodynamic performance of BHVs and mitigate the need to perform time-consuming bench-top and pre-clinical animal testing.

INTRODUCTION

Transthoracic echocardiography is important for the diagnosis and monitoring of aortopathy involving the proximal aorta (e.g., bicuspid aortic valve, Marfan syndrome) [1]. Maximal aortic diameters measured from the parasternal long axis (PSLAX) window often guide treatment strategies. However, these measurements remain an incomplete marker of disease status and even the slightest inter-observer variability may lead to vastly different management plans [2]. Gross displacement and aortic root expansion across the cardiac cycle may further complicate precise measurement. Here we present a feature tracking algorithm that accounts for these factors to extract aortic root information accurately and efficiently from routine echocardiography data.

METHODS

This algorithm simultaneously estimated aortic root expansion and gross displacement from PSLAX echocardiography images, and automatically extracted diameter measurements across the length of the aortic root. The Indiana University School of Medicine IRB approved the collection and de-identification of all echocardiography images.

Algorithm Development: A feature tracking algorithm was developed in MATLAB, which specifically quantifies five parameters at every time point across the cine loop: x-displacement, y-displacement, rotation angle, aortic root expansion, and slope (**Figure 1**). Simultaneous tracking of these parameters reduced the impact of translation and rotation of the aorta to align measurements perpendicularly to the axis of the vessel. To mitigate effects of image artifacts during tracking, the algorithm iteratively built a reference template-image based on previously tracked frames. Image artifacts were identified through regional variability of image intensity across time, from which a new iteration of temporal template weights was estimated.

Figure 1: Algorithm Parameters A) x- and y-displacement and rotational component ($\Delta\theta$) are used to track gross movement B) Change in diameter and slope are used to estimate aortic root size and function. (Asc. Ao.= ascending aorta, Ann.= annulus, SoV= sinus of Valsalva, STJ= sinotubular junction).

Algorithm Verification: To ensure that derived maximum diameter measurements were comparable to standard clinical techniques, we compared our algorithm against manual aortic root diameter measurements obtained in the clinic. Clinical transthoracic echocardiography images were obtained in the PSLAX view from a group of healthy control patients (11.5-21.5 years old; $n=7$) and patients with known aortopathy (0.2-18.6 years old; $n=3$). Diameter measurements were obtained at the aortic annulus, sinus of Valsalva, sinotubular junction, and ascending aorta segments in up to three cardiac cycles using 1) the feature tracking algorithm and 2) manually by a board-certified pediatric cardiologist. The maximal systolic diameter measurements at each aortic segment were then compared between estimation methods using linear regression and goodness-of-fit statistics.

Healthy vs. Diseased: After preliminary assessment of our algorithm against clinical methods, the patient data set was expanded.

The algorithm was used to compare healthy and aortopathy patients. Automated tracking was performed on clinical PSLAX echocardiograms of 43 control patients ($n=21$ female, 0.2-16.5 years old; $n=22$ male, 2.6-18.6 years old) and 45 patients with known aortopathy ($n=21$ female, 2.2-17.7 years old; $n=24$ male, 5.0-14.3 years old). Aortic root diameter measurements were estimated with the algorithm for each patient. Linear regression analysis of tracking results focused on maximum systolic diameters extracted from curves at the sinus of Valsalva compared against patient age and body surface area (BSA).

RESULTS

Image Stabilization: The algorithm successfully tracked the anterior and posterior surfaces of the proximal aorta in the PSLAX window. Stabilization of the aorta with respect to gross translation facilitated measurement of aortic diameters in consistent anatomic planes throughout the cardiac cycle at the sinus of Valsalva (**Figure 2**) and other specified segments. Stabilization of the PSLAX B-Mode allowed for retroactive generation of M-Mode images in which the aortic valve movement and anatomy were more clearly seen in stabilized M-Modes (**Figure 2A**) compared to non-stabilized M-Modes (**Figure 2C**).

Figure 2: A) Stabilized M-mode at the sinus of Valsalva (SoV) retroactively generated from B) B-Mode image, across the green marker. C) Original, non-stabilized M-Mode.

Diameter Extraction & Algorithm Performance: After stabilizing the inputted PSLAX echocardiograph images, the algorithm successfully estimated the diameters across the aortic root from the annulus to the start of the ascending aorta across all periods of time (**Figure 3**). When compared to standard of care techniques, the algorithm derived and manually derived diameter measurements were highly correlated ($r^2 > 0.96$) for each analyzed segment in both healthy and aortopathy groups.

Figure 3: Diameter time courses from tracking results across aortic root throughout cardiac cycle.

Application in Aortopathy Cohorts: The maximum diameters at the sinus of Valsalva were larger in the aortopathy patient cohort compared to the controls across both BSA and age. In both the control and aortopathy cohorts, a stronger linear relationship was observed between maximum diameter and BSA than between maximum diameter and age: control males ($r^2=0.82$ vs. 0.75), control females ($r^2=0.54$ vs. 0.49), aortopathy males ($r^2=0.57$ vs. 0.40), and aortopathy females ($r^2=0.64$ vs. 0.60; **Figure 4**). Aortic diameters extracted by the algorithm do not appear to vary significantly between sexes.

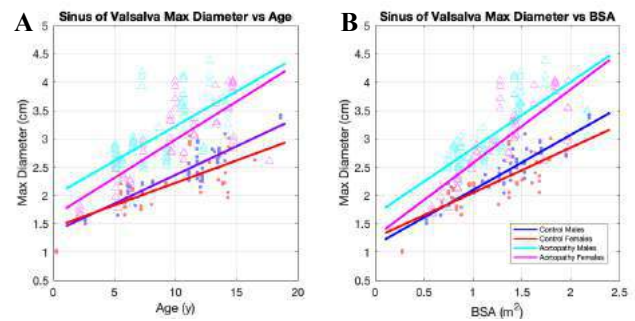

Figure 4: Maximum diameter at sinus of Valsalva versus A) age and B) body surface area (BSA) in controls and aortopathy patients. As expected, the aortic diameter extracted by the algorithm are higher in the aortopathy cohort versus controls across a range of ages and body sizes.

DISCUSSION

Our novel tracking algorithm successfully stabilized images and precisely measured aortic diameters when compared to manual measurements. Ultimately, our algorithm may reduce inter-observer variability and significantly increase throughput compared to current standard manual measurement techniques. Initial results suggest that differences in aortic root diameters are detectable between healthy and aortopathy cohorts, and that BSA and maximum diameter have a strong linear relationship. This further supports the use of our algorithm, as it reflects current clinical guidelines in which Z-scores for aortic root dimensions are assessed with respect to BSA [3]. A notable limitation, however, is that the data utilized in this study was collected from patients at a single timepoint. Applying the algorithm to a longitudinal study to assess disease progression overtime may allow us to better test the robustness and predictive capabilities of our algorithm. This study provides a foundation for expanding the algorithm to include machine learning techniques and biomechanical analyses, such as Green-Lagrange strain [4], vessel diastology, and aortic root pulsatility. We anticipate that further development and application of this algorithm to incorporate other rigorous biomechanics estimates will help elucidate vessel wall dynamics throughout the cardiac cycle and eventually improve the quality of care for patients with aortopathy.

SEX DIFFERENCES IN RIGHT VENTRICULAR CHAMBER ELASTANCE AND STIFFNESS IN AN ANIMAL MODEL OF PULMONARY ARTERIAL HYPERTENSION

ED Kwan (1), TM Wang (1), H Mu (1), BA Hardie (1), D Valdez-Jasso (1)

(1) Department of Bioengineering, University of California San Diego, La Jolla, California, USA

INTRODUCTION

The health and function of the right ventricle (RV) is the most important predictor of outcomes in patients with pulmonary arterial hypertension (PAH). Both clinical and preclinical studies have demonstrated the association of sex with RV hemodynamic function¹. Women present less severe RV remodeling and improved function compared to men, for unknown reasons. Importantly, women also show different responses pre- and post-menopause, with more severe RV remodeling and worse health outcomes post-menopause¹. Despite this, most animal studies have focused on males so sex-dependent RV remodeling data is particularly sparse. Previous studies have correlated endogenous estrogen to improved RV function as well as demonstrated positive effects of exogenous estrogen², however the regulation and role of estrogens in progressive human PAH remains unclear.

In a recent 10-week study of male PAH-treated rats, we found that RV hypertrophy and diastolic stiffening explained almost all measured changes to RV chamber end-systolic and end-diastolic pressure-volume relationships³. While RV hypertrophy and diastolic stiffening are well established prognostic indicators in PAH patients⁴, their relative contributions to RV function in both male and female PAH remains unclear. It is possible that sex-differences in RV myocardial structural and material remodeling may also underlie the progression of PAH disease often attributed to estrogens. Therefore, we designed a study to investigate the pathology of RV remodeling by combining hemodynamic and morphologic measurements with a biomechanics model previously described. We investigated RV remodeling in PAH-induced male and female rats, as well as ovariectomized female rats to model the effects of estrogen depletion post-menopause.

METHODS

Seven-week old male and eight-week old female and ovariectomized female rats were treated with a subcutaneous injection of 20mg/kg sugen, a vascular endothelial growth factor receptor

inhibitor, then placed in a hypoxia chamber (10% oxygen) for 3 weeks to induce PAH. The animals were then returned to normoxia for 5 weeks. Age-matched normotensive animals kept in normoxia were the control groups. During terminal surgeries, a 1.9F admittance catheter (Transonic Scisense, Ontario, Canada) was inserted apically into the RV chamber and used to take invasive pressure-volume (PV) measurements during steady state and during occlusion of the inferior vena cava. Right ventricular pressure, myocardial wall mechanics, and morphology were analyzed using a Laplace-type reduced-order model³. Briefly, the RV geometry was modeled as a fraction of a sphere comprised of RV chamber, RV free-wall, and septum wall volumes. The geometric model-derived RV radius to wall thickness remained greater than 5:1 in all three SuHx-treated groups, so the thin-walled assumption was used to relate RV blood pressure to myocardial circumferential wall stress using Laplace's Law³. Here, passive stress (T_p) was modeled as an exponential function with two material stiffness parameters optimized to match the model to end-diastolic (ED) PV measurements. Passive stress plus an additional active fiber stress (T_a), modeled as saturation equation, was computed and matched to end-systolic (ES) PV measurements by optimizing a third material parameter of calcium-dependent myofilament activation. Fitted rat-specific model parameters were then used to predict and analyze resting and active sarcomere length-stress relations.

Measurements of right-ventricular myocyte mechanics were taken to validate model predictions of myofiber contractility upregulation. Right ventricular myocytes were isolated using enzymatic digestion (.001M collagenase II, .0015M protease) *via* Langendorff's perfusion⁵, then incubated in [1.8mM]_{Ca2+} Tyrode's solution (.0018M CaCl₂, .134M NaCl, .00268M KCl, .00556M glucose, .0119M NaHCO₃) with 2uM Fura 2-AM. RV myocytes were field stimulated at 1Hz and fluorescence at 340nm and 380nm excitation wavelength. Sarcomere length was recorded with a laser scanning fluorescent photometer (IonOptix, MA, USA). Myocyte shortening was measured as the

difference between baseline sarcomere length at rest and peak sarcomere length during contraction.⁶

Descriptive statistics were performed in JMP Pro Statistical software (version 16, SAS Institute Inc., NC, USA)). For normally distributed data, two-factor ANOVA were used to test for differences based on the two factors treatment and sex, followed by the Dunnett's *post-hoc* test for treatment and the Tukey test for sex. Otherwise, non-parametric Wilcoxon-Kruskal-Wallis statistic was used followed by the Dunnett's *post-hoc* test for treatment and the Dunn test for sex. Statistical significance was determined at a level of $\alpha < 0.05$.

RESULTS

Male, female, and ovariectomized female rats treated with SuHx reached hypertension (mean pulmonary arterial pressure >20 mmHg), with group mean pulmonary arterial pressure of 39.1mmHg in males, 42.7mmHg in females, and 42.8mmHg in OVX female rats. End-systolic RV chamber pressures were almost identical across sex groups at baseline (22.4-23.1mmHg), but with the largest increases in male SuHx (62.7mmHg male compared to 60.4mmHg female and 58.7mmHg OVX female). While RV mass was greater in males than females at baseline and in SuHx, the Fulton index (not shown) indicated similar relative RV mass hypertrophy in all three SuHx groups when normalized by the LV+septum masses. End-diastolic pressure increased in SuHx groups, with the largest increases in the male rats (6x increase vs 2x increase in females compared to controls). End-systolic pressures increased in all three SuHx groups, with similar increases across sex.

Figure 1: RV ES and ED chamber elastance increased in all SuHx groups (solid bars) compared to respective controls (dashed bars). Increases to ES and ED chamber elastance were the largest in the male SuHx group.

From rat-specific models fitted to PV data, sarcomere length-stress relations were predicted (Figure 2). Male, female, and OVX passive and active sarcomere length-tension relations were similar at baseline, so only a single control group curve is shown (dashed). Active length-tension relations showed small increases (n.s., $p>0.05$) in all three SuHx groups compared to controls.

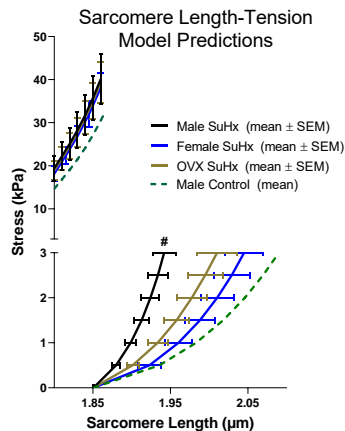

Figure 2. Model predictions showed significant increases ($p<0.05$) in passive stiffness (bottom) in male SuHx (black)

compared to control (green dashed) that was not seen in female (blue) and OVX (gold) groups ($p>0.05$).

RV myocytes isolated from SuHx-treated rats showed small increases (between 0.1-2.8% shortening, n.s.) with the largest changes in the male and OVX groups.

Figure 3. RV myocytes showed no significant increases in contractile shortening from baseline (dashed) to SuHx (solid).

DISCUSSION

Elevated pulmonary pressures resulted in RV remodeling as shown by hemodynamic and morphologic measurements and showed sex-dependent changes to end-systolic and end-diastolic chamber mechanics. End-systolic chamber elastance increased in all SuHx-treated groups. Model predictions of sarcomere length-tension relations showed only small changes in the active length-tension relation, indicating the significant RV wall hypertrophy and geometric remodeling identified by the model largely explained the increases to end-systolic chamber elastance. Significant contributions of RV hypertrophy to remodeling of ES chamber mechanics were found independent of sex or ovariectomy. Small increases in model-predicted myofiber contractility were validated by myocyte contraction experiments which showed small increases in sarcomere shortening in myocytes isolated from SuHx-treated rats. Both compensatory RV hypertrophy and contractility upregulation have been reported in clinical⁴ and preclinical studies⁷ of PAH.

Model predictions of sarcomere length-tension relations found significant passive myocardial stiffening in male SuHx rats, that was not present in female or ovariectomized female rats, which reflects the large increases to diastolic elastance seen at the organ level. Correspondingly, diastolic stiffness, found to be most severe in male rats, has been correlated to RV dysfunction in PAH patents. While diastolic stiffness in this study was not associated with significant extracellular matrix collagen accumulation, it could be explained by fibrillar collagen structural changes. Diastolic stiffness has been well established as a prognostic indicator⁴, yet this study identifies sex-differences in the severity of chamber stiffening and myocardial passive stiffening. Further studies investigating sex-differences in addition to the role of estrogen in the remodeling of the RV myocardium would address the gaps between results reported in isolated myocytes⁶ (increased calcium transient amplitudes and improved cell contractility) and the progressive loss of RV function⁴ reported *in vivo*.

INTRODUCTION

Nephrogenesis is the process by which collections of mesenchymal progenitor cells within a stem cell niche transition to form the epithelial filtration units of the kidney. The nephron progenitor stem cell niche must balance differentiation and self-renewal of nephron progenitor cells as new nephrons form continuously throughout development¹. Understanding how this balance is maintained for continuous nephron formation is crucial for creating nephron-dense and structurally organized kidney organoids or replacement tissues. *In vivo*, the nephron progenitor niche exists in a dynamic environment at the actively branching tips of a rapidly growing epithelial tubule network and is surrounded by stromal cells. Therefore, biochemical and physical properties within the niche that oscillate due to the migration and branching of the adjacent epithelial tissue are promising targets to regulate this balance in nephron progenitor differentiation outcomes.

We have shown through modeling and physical measurements that newly branching tips must overcome mechanical resistance from neighboring niches, which generates increased mechanical stress within the niche that then dissipates over time before the next branch event². In a reductionist human iPSC-derived nephron progenitor spheroid model that also contains stromal cells, we saw increased early nephron differentiation in the presence of the cell tension inhibitors². To further examine the role of a changing mechanical environment on nephron formation outcomes in the niche, we separately purified nephron progenitor and cells surrounding the niche specifically including stroma from the mouse embryonic kidney and found that the inclusion of stroma in a co-culture model changes the nephron progenitor differentiation response to mechanical perturbations. Crosstalk between these two cell types impacting nephron formation has been identified in other work³, however the nature of this crosstalk in the context of cyclic mechanical stress remains unexplored. Understanding the mechanisms

by which nephrogenic niche cell types interact with each other and the mechanical environment to influence nephrogenesis could allow for new engineering control strategies for nephron formation *in vitro*. This advance would contribute to development of kidney replacement tissue for the estimated 15% of adults that experience kidney disease⁴.

METHODS

Kidney immunofluorescence imaging. Immunofluorescence staining and imaging was performed as previously published^{5,6}.

Force inference. Bayesian force inference was applied according to a recently published procedure that infers maps of tissue tension and pressure based on observed variations in edge lengths and angles at cell vertices. Ureteric tip Voronoi diagrams were processed in the *Tissue Analyzer* plugin in FIJI⁷, and anisotropic stress was computed using Batchelor's formula using previously published MATLAB code^{8,9}.

Laser ablation. E17 mouse embryonic kidney explants were incubated in Alexa Fluor 488-PNA to label the ureteric bud and CellTracker red in culture media and placed in PDMS wells plasma bonded to a quartz coverslip. Individual cap mesenchyme niches at the kidney surface were ablated using an ultraviolet laser through a 10X objective. Cut opening time-lapses were imaged from the microscope monitor using an iPhone 8 video camera.

Nephron progenitor and stroma co-culture differentiation assay. Mouse embryonic kidneys were partially dissociated to isolate nephron progenitor and niche surrounding cells including stroma from the organ surface per published protocols¹⁰. Nephron progenitor cells were sorted using magnetic activated cell sorting by previously published protocols to generate nephron progenitor spheroids¹⁰. 50,000 nephron progenitor or stromal cells were plated in low attachment round bottom plates and centrifuged to generate spheroids. Cells were plated directly into treatment media that was removed after overnight

incubation and replaced with control media for overnight incubation. Spheroids were then fixed and stained by immunofluorescence.

Quantification of spheroid cell differentiation. Maximum intensity projections of spheroids were generated and further processed in FIJI. LHX1 and SIX2 signals were segmented using 200 pix rolling ball background subtraction and thresholded to remove background signal. The total numbers of positive pixels were divided by total number of pixels within the spheroid to normalize by spheroid area.

RESULTS

In kidney development the urinary collecting duct tree is formed through iterative branching of the epithelial precursor tissue, the ureteric bud. The nephrogenic stem cell niches exist at the tips of this branching tissue and periodically form nephrons that will later merge with the nearest collecting duct. As branching continues and more niches are generated, they become crowded at the surface of the developing organ (fig. 1A). Each niche is separated from others by a thin layer of stromal cells. Recent work has shown that niche positions at the surface are partially predicted by a physical model that includes mutual repulsion and crowding¹¹. We used a force inference model^{8,9} to infer interfacial tensions at niche boundaries as well as internal niche stresses (fig. 1B). We found that higher niche anisotropic stress is positively correlated with shape index of individual niches (fig. 1C). Shape index is highest just as the ureteric bud tip is bifurcating, and then steadily decreases until the next bifurcation event. We confirmed this result experimentally through measuring rebound velocity of laser ablated niche boundaries in mouse embryonic kidney explants (fig. 1D). These data suggest a model in which the niche is cycling between low and high internal stress states during branching cycles of the ureteric bud.

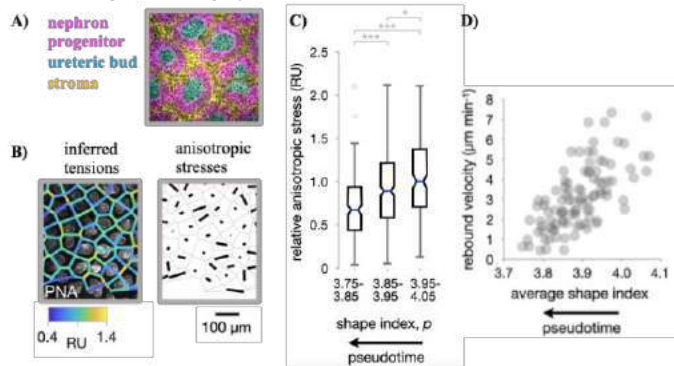

Figure 1. Nephron progenitor niche mechanical environment is correlated with shape index **a.** Immunofluorescence image of whole mount E17 mouse embryonic kidney **b.** PNA stained ureteric bud tips overlaid with Voronoi diagram showing inferred tensions and anisotropic stresses by force inference modeling **c.** Plot of relative anisotropic stress in niches grouped by shape index. **d.** scatter plot of rebound velocity after laser ablation of the interface between two neighboring nephron progenitor niches.

Cell membrane tension is influenced by cell crowding, can be predicted by cell shape, and affects signaling outcomes within the cell^{9,12}. We hypothesize that, at the larger scale of the developing kidney, stromal cell boundaries between stem cell niches may play an analogous role to the cell membrane. As the stromal cell boundaries are sculpted through niche shape index changes, they experience different tensional loads depending on niche life cycle. It has also been shown that stroma - nephron progenitor contact signaling affects differentiation³. Therefore, we asked if changes in mechanical state are instructive to nephron progenitor cell differentiation outcomes either directly or mediated by nearby stromal cells. To test this, we partially

dissociated and sorted mouse embryonic kidney tissue per published protocols¹⁰ to isolate either nephron progenitor cells along with surrounding niche cells including stroma or nephron progenitor cells only. We then cultured these cells as spheroids in the presence of pulse treatment of cell tension inhibitors as well as a low level of a Wnt signaling agonist to mimic the mechanical and biochemical environment of the niche *in vivo* (fig. 2A-D). We found that in spheroids consisting of nephron progenitor cells only, differentiation decreased compared to controls. However, in spheroids consisting of nephron progenitor cells and stromal cells, differentiation increased compared to controls. These results suggest that stromal cells could mediate niche mechanosensitivity. Future work will determine the mechanosensitivity of stromal - nephron progenitor signaling for nephron induction.

Figure 2. Nephron progenitors have different differentiation responses to mechanical transients in the presence of kidney stromal cells **a.** Immunofluorescence of nephron progenitor spheroids after pulse treatment of Wnt agonist (CHIR) +/- cell tension inhibitor (Y-27632). Stained for differentiation marker LHX1 and progenitor marker SIX2. **d.** Quantification of **c.**

DISCUSSION

Here, through modeling and physical measurements, we show that the nephron progenitor niche is subject to cyclical mechanical stress. We then show that mechanical perturbations are sufficient to alter nephron progenitor differentiation outcomes *in vitro*. However, co-culture with native kidney stroma that borders the niche *in vivo* alters the nephron progenitor differentiation response to mechanical perturbations. In future work, we aim to uncover how the niche as a whole interprets mechanical signals to influence nephron formation.

INTRODUCTION

In the United States, nearly one half of all females between the ages of 50 to 79 years old have uterine prolapse, which is characterized by the descent of the uterus from its normal anatomical position, or other forms of pelvic organ prolapse (POP) [1]. The strongest factors known to be associated with POP include parity (i.e., the number of times a woman has given birth), and vaginal childbirth, but the mechanisms in which these lead to prolapse remains unknown [2,3]. The uterosacral ligament (USL), which connects from the cervix to the sacrum, is the primary suspensory support structure for the uterus, which provides apical support and suspends the uterus [3]. Damage to and failure of the USL due to biomechanical injury may result in the protrusion of the uterus and/or vagina, or POP; hence, we focus our research on understanding how the mechanics of the USL change during pregnancy and parturition, and how that may lead to POP.

Ligaments, like the USL, serve primarily mechanical functions; therefore, it is critical to have a mechanistic understanding of the USL to elucidate mechanisms of ligament deformation and damage. USL mechanical behavior is governed by the extracellular matrix (ECM), which primarily derives tensile support from collagenous fibers [2,3]. A constitutive model describes the material mechanical behavior in a mathematical framework. In particular, structural constitutive models incorporate information on tissue composition and microarchitecture to study the structural and functional relationship in response to changes in mechanical loading. The Holzapfel-Gasser-Ogden (HGO) is a hyperelastic anisotropic model that includes terms that represent the tissue histoarchitecture, including collagen fiber stiffness and alignment, to describe the tissue mechanics [4]. The free energy of the HGO model is a combination of energy from the non-collagenous surrounding matrix, the collagenous substance, or the fibers, and a volumetric correction due to assumptions of incompressibility.

Although this model is commonly used to describe biological tissues with one main axial loading direction, to the authors knowledge

it has not yet been used to describe the USL mechanical behavior. In this study, we used the HGO model to capture the tensile loading behavior of the murine USL before, during, and after pregnancy to understand how changes in the USL microarchitecture influence the mechanical behavior of intact ligaments under tension.

METHODS

Female C57BL/6J mice were obtained and euthanized as nulliparous (NP, $n = 4$), late pregnancy gestation day 18.5 (E18.5, $n = 2$), and 1 day postpartum (PP1, $n = 2$), according to the University of Colorado Boulder's Animal Care and Use Committee. USLs were isolated and a suture was tied at the cervical end. The USL was then cut proximal to the suture. The other USL was removed and saved for later biochemical analysis. The pelvic tissue, with the one USL still attached to the sacrum, was dissected from the mouse, yielding a cervix-USL-pelvis complex. Each sample was placed at 4°C in Ghost Dye Red 780 (Tonbo Biosciences) and stained for 2 hours followed by Sytox Deep Red Fluorescent Stain (Thermo Fischer Scientific) for 10 minutes.

Each USL sample was placed under a confocal microscope (Leica STELLARIS) in a custom loading chamber with PBS bath and connected to a 100 mN FemtoTools microforce load sensor. The sample was placed in a reference configuration based on a 500 μ N preload, and then subjected to four displacement-controlled stress relaxation tests, returning to the reference configuration after each test. Applied displacements were 1000 μ m, 1500 μ m, 2000 μ m, and 2500 μ m at a loading rate of 50 μ m/s, and the sample was held at each displacement state for 5 minutes. In each reference and relaxed configuration, the sample surface was imaged at 10 \times magnification. The confocal images of the stained USL were used to map deformation with the Matlab function 'imregdemon'. Global displacement was calculated from the maximum and minimum image-tracked displacement values.

The strain energy density function of the HGO model with an additional fiber dispersion parameter (Gasser et al., 2006) is given as:

$$\Psi_{HGO} = c \left(J^{-\frac{2}{3}} I_1 - 3 \right) + \frac{k_1}{2k_2} \{ \exp[k_2(\kappa I_1 + (1 - 3\kappa)I_4 - 1)^2] - 1 \} + \frac{B}{2} (J - 1)^2 \quad (1)$$

where c is the isotropic shear modulus, k_1 is a measure of the fiber phase stiffness, k_2 describes fiber nonlinearity, κ measures the degree of collagen fiber alignment ($\kappa=0$ is perfectly aligned, $\kappa=1/3$ is perfectly isotropic), and B is the bulk modulus. We followed methods outlined in [5] to characterize the USL samples with the HGO model. Briefly, with the image-based deformation fields, we utilized the virtual fields method to construct a cost function from the equilibrium equation, and we iterated through model parameters to minimize the difference between internal and external virtual work.

Fig 1. Average stress relaxation curves for the nulliparous, late gestation, and postpartum USL.

RESULTS

The USL stress relaxation response differed across the NP, E18.5, and PP1 groups as evaluated by the magnitude of stress relaxation, tangential loading stiffness, and average peak stress (Fig 1). Image-based deformation tracking showed that USL deformation is inhomogeneous (Fig. 2). Strains and global displacements increased with increased applied displacement. Deformation maps demonstrate heterogeneous tensile and compressive strains in the transverse loading direction, as well as large shear strains.

Figure 2: Representative deformation maps at increasing levels of applied displacement for a nulliparous murine USL exhibit heterogeneous axial (11), transverse (22), and shear (12) Lagrangian strain fields.

Initial model parameter values show slight differences in USL material parameters before, during, and after pregnancy (Table 1). The nulliparous USL had a larger fiber stiffness, k_1 , as compared to the late pregnancy and postpartum USLs. The measure of fiber alignment, κ ,

was smallest for the postpartum and nulliparous USL, both reaching values on the order of magnitude of $1e-14$, and was largest for the late pregnant USLs. The fiber nonlinearity, k_2 , and bulk modulus, B , parameters often converged on their default values and are not currently identifiable.

Table 1: Model parameters for nulliparous (NP, n=4), late pregnancy (E18.5, n=2), and 1 day postpartum (PP1, n=2), given as mean \pm standard deviation.

	c (MPa)	k_1 (GPa)	$k_2 \times 10^{-2}$	$\kappa \times 10^{-14}$	B (kPa)
NP	18 \pm 33	57 \pm 73	5.8 \pm 11	2.9 \pm 0.77	1.1 \pm 0.17
E18.5	1.7 \pm 1.6	5.9 \pm 0.22	12 \pm 16	3.5e07 \pm 5.0e07	950 \pm 380
PP1	51 \pm 70	5.3 \pm 3.0	0.1 \pm 0	2.4 \pm 0.24	1.0 \pm 0

DISCUSSION

The nulliparous USL exhibited a different mechanical response under stress relaxation than the late pregnant and postpartum USL. This finding is consistent with studies that have observed changes in the ECM and mechanical behavior of the cervix and vagina in pregnancy and postpartum [6]. It is well-documented how the microarchitecture and mechanics of the cervix and vagina evolves with pregnancy, but a similar analysis has yet to be done for the USL. Elucidating how the microarchitecture of the USL evolves due to pregnancy and leads to an altered mechanical response will allow us to better understand how parturition can lead to POP.

Two important parameters of the HGO model are the fiber stiffness and fiber alignment. Of the three groups evaluated, fiber stiffness was greatest in the NP USL, like the NP cervix [4]. The USL directly integrates with the cervix, and therefore may behave similarly to the cervix during pregnancy to allow for childbirth. Thus, we hypothesize that fiber stiffness decreases due to a decrease in fiber density during pregnancy which facilitates stretching of the USL during parturition. Similarly, the increase in κ in the E18.5 samples suggests that fiber alignment in the USL may decrease during pregnancy, further decreasing axial stiffness in preparation for childbirth.

This work provides preliminary results for describing the mechanical behavior of the USL using the HGO model. These methods adopted for the USL will allow us to further characterize its stress-strain relationship. Current limitations of this study are being addressed by ongoing work and include a limited sample size, inconsistent global displacements, and lack of direct measurement of USL microstructure to validate our results. Future studies seek to attain $n = 8$ samples/group and evaluating USLs at 4 weeks postpartum and USLs from older nulliparous and retired breeders to characterize the effects of pregnancy, parturition, and age on the murine USL. In combination with proteomics and histology, this work will lend insight into the role of pregnancy in USL injury and POP.

IDENTIFYING COMMONALITIES OF HARMONIC BRAIN DEFORMATION INDUCED BY MAGNETIC RESONANCE ELASTOGRAPHY IN VIVO

INTRODUCTION

Traumatic brain injury (TBI) is widespread and associated with the possibility of debilitating emotional and cognitive deficits. TBIs are caused by rapid brain deformations that arise from skull acceleration. The mechanics of TBI are incompletely understood; improved insight and ability to simulate injury could help reduce, diagnose, and treat TBI.

To bridge the gap in knowledge surrounding the mechanics of TBI, both physical experiments and computational measures can be used to better understand the relationship between skull motion and brain deformation. One technique to study low-amplitude, dynamic, brain deformation in human subjects in vivo is magnetic resonance elastography (MRE). In MRE, harmonic acceleration of the skull induces shear waves in the brain, which are then imaged and analyzed.

In previous work [1, 2] we showed that shear waves induced in the brain via MRE propagate differently depending on the frequency and direction of actuation. Different regions of the brain (i.e. cerebrum and cerebellum) show different levels of deformation. Intriguingly, qualitatively similar patterns appeared in different subjects; we speculate that these common patterns of deformation may illuminate common injury mechanisms. The objective of this study is to quantitatively compare strain fields from different subjects at each frequency and brain region to characterize the similarity of brain deformation patterns between several human subjects.

METHODS

MRE was used to image dynamic brain deformation in 4 different human subjects (2M, 2F, 27-28 yrs.) undergoing harmonic skull motion at 10, 20, 30, and 50 Hz. Skull motion was driven by an inflatable silicone actuator pre-loaded against the side of a subject's head. Harmonic pressure waves were delivered to the actuator by a pneumatic driver (Resoundant, Rochester, MN) for 20-50 Hz or customized PL-300 sub-woofer, (BIC America, Anaheim CA) for 10 Hz. A custom MRE sequence [3] was used to obtain all components of 3D harmonic

displacement in 3×3×3 mm voxels at eight time points. Displacement fields were Fourier-transformed in time and numerically differentiated in space to estimate complex-valued, 3D strain tensors at each voxel. Strain amplitude was quantified by octahedral shear strain (OSS, Eq. 1).

$$\epsilon_{OSS} = \frac{2}{3} \sqrt{(E_1 - E_2)^2 + (E_2 - E_3)^2 + (E_3 - E_1)^2} \quad (1)$$

To compare harmonic strain fields from MRE in different subjects, we performed a series of spatial transformations to register the brains to a common space. Anatomical T1-weighted images were used to rigidly register each subject's brain to a standard structural template (MNI152 T1-weighted 0.8 mm brain atlas) using Advanced Normalization Tools (ANTs) [4]. T1- and T2-weighted images were rigidly registered to the MNI-152 space [5] using ANTs, and resampled to 0.8 mm isotropic resolution. Strain tensor components were re-computed in the rigidly-registered space based on the rotation matrix associated with the rigid registration.

The nonlinear transform from each subject's T1 volume to the MNI152 template was calculated using the cross-correlation standard symmetric normalization (SyN) model in ANTs. Then the SyN transformation was applied to each 2D strain tensor (ϵ_{xx} , ϵ_{yy} , ϵ_{xy}) and OSS strain field calculated from MRE data.

Each subject's MNI registered T1-weighted images were segmented using the SLANT algorithm [6] to extract the whole brain falx and tentorium. Custom segmentation tools (MaCRUISE [6, 7] and SLANT) were used to segment each brain into three binary masks: the cerebrum (~85% vol.), the brainstem (~1.5% vol.), and the cerebellum (11% vol.). These subject-specific brain region masks were then transformed to the MNI atlas using the same transformation matrices.

Comparisons between strain fields were visualized using volume-normalized, strain cross-correlation fields $\hat{\epsilon}_V$ (Eq. 2a-b) and quantified by the scalar tensor product (STP) correlation values C_V (Eq. 3). $\hat{\epsilon}_V$ is a

qualitative representation showing similarity between regions of the brain. The STP correlation C_V is a quantitative metric which defines similarity over an image volume by a value between 0 and 1 ($C_V = 1$ for two identical strain fields).

$$\varepsilon_n^{(p)} = \sqrt{\sum (\varepsilon_V^{(p)} \cdot \bar{\varepsilon}_V^{(p)})} \quad (2a) \quad \hat{\varepsilon}_V = \left(\frac{\varepsilon_V^{(p)}}{\varepsilon_n^{(p)}} \cdot \frac{\bar{\varepsilon}_V^{(q)}}{\varepsilon_n^{(q)}} \right) \quad (2b)$$

$$C_V = |\sum \hat{\varepsilon}_V| \quad (3)$$

Strain fields in four subjects were compared for each pair of subjects (a total of 6 comparisons) for four frequencies and three brain regions for a total of 72 comparisons. A two-way analysis of variance with repeated measures (ANOVA; Prism 9, GraphPad, San Diego, CA) was used to compare the effects of the interaction between excitation frequency and brain region, the effects of excitation frequency alone, and the effects of brain region alone on the mean STP correlations (Fig. 2). Mean OSS for each subject was computed for each combination of frequency and brain region to describe the magnitude of shear deformation (Fig. 3).

RESULTS

Volume-normalized 3D strain cross-correlation fields (Fig. 1) were plotted to identify regions of the brain that shared consistent, large deformations. We found high cross-correlations across the entire cerebrum at lower frequencies (10-20 Hz). At higher frequencies (30-50 Hz) cross-correlation values increased around the posterior of the cerebrum and the cerebellum.

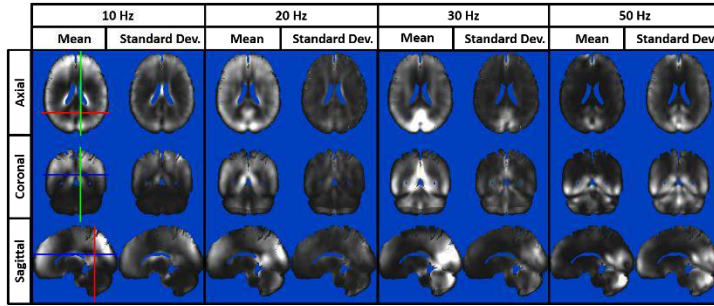

Figure 1: Cross-correlation strain field $\hat{\varepsilon}_V$ visualization. Each column represents the arithmetic mean and standard deviation across 6 strain field comparisons at a single frequency. Rows indicate each 3D anatomical plane with red, blue, and green lines to indicate slice locations. Lighter regions indicate high similarity and dark regions indicate low similarity.

The highest OSS (largest deformations) occurred at 10 Hz in all subjects and brain regions, and decreased with frequency (Fig. 2). The cerebrum and brainstem exhibited higher OSS than the cerebellum at 10 Hz, but at other frequencies deformations were similar in all regions.

Volumetric STP correlations C_V (Fig. 2) were higher in the cerebrum than both other regions at 10 Hz (Fig. 2). At higher frequencies the average correlation values in the cerebellum did not differ significantly from those in the cerebrum. The correlation values in the brainstem remained significantly lower than those in the cerebrum at all frequencies. The individual effects of frequency ($P = 0.0007$) and brain region ($P < 0.0001$) were both statistically significant, as was the interaction between frequency and brain region ($P = 0.0021$).

DISCUSSION

Strain cross-correlations between harmonic brain motion at 10, 20, 30, and 50 Hz in different subjects reveal common patterns of deformation in the cerebellum, brainstem, and cerebrum. The magnitudes of correlation differ by frequency and brain region.

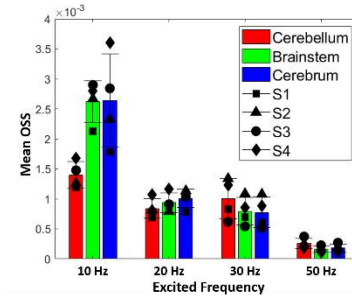

Figure 2: Mean OSS averaged across subjects and brain region. Larger values of mean OSS indicate higher amounts of shear deformation during MRE. Each symbol present on the bar plot represents the mean OSS for that subject in that brain region.

Figure 3: Volumetric STP comparisons C_V averaged across frequency and brain region. Each star indicates a comparison was found to be significantly different.

To perform these comparisons between strain fields in four different human subjects it was necessary to register and transform strain fields to the MNI-152 atlas.

We acknowledge some limitations. Data from only four subjects of similar age were used. The brains of older subjects (50+) may exhibit more differences as the brains tend to shrink and the ventricle size increase with age. These changes may exacerbate the challenges of registering images to a common template. In future studies we plan to incorporate more human subjects over a larger range of ages and both sexes. We also plan to introduce other frequencies and directions of skull motion. Nevertheless this study shows clear patterns of cross-correlation between strain fields in different subjects, which may correspond to regions likely to experience higher strains (and injury) at higher skull accelerations.

INTRODUCTION

Fibrosis contributes to one third of natural deaths worldwide and currently has no cure [1]. A critical step in the pathway to fibrosis in all organs is the fibroblast-to-myofibroblast transition (FMT), a largely irreversible event in which mechanical stimuli trigger tissue resident fibroblasts to express a subset of smooth muscle genes that enhance stress fiber formation and contractility [2]. Understanding the mechanisms behind FMT will be impactful for efforts to slow fibrosis or potentially restore organ function.

The mechanical environment of cells, including stress and substrate or ECM stiffness, can induce FMT in both 2D and 3D culture settings [3,4], but the role of stress directionality and isotropy is not clear [5]. Our specific objective was therefore to study how directionality of loading regulates FMT phenotype.

To achieve this, we tested the hypothesis that tension isotropy attenuates fibroblast contractility and FMT. To test the hypothesis, we developed a mathematical model of the effects of tension anisotropy on FMT, and tested predictions of the model against 3D platforms with geometries predicted to induce either isotropic or anisotropic contraction in collagen-encapsulated high-density fibroblasts. Results suggest that tension isotropy attenuates FMT, even in the presence of TGF- β , a well known agonists of FMT.

METHODS

Tissue constructs comprised of NIH-3T3 fibroblasts and rat-tail collagen type I were formed around micro-posts in microwells. Cells were provided anisotropic stress states using 4-post devices, and isotropic stress states using 8-post devices (Fig. 1).

Modeling: Our multiscale continuum computational model was used to design and interpret experiments on how cells respond to the polarity of extracellular mechanical signals. In this model [5], tissues are treated as a continuum of representative volume elements composed of an active contractile cell in collagen matrix. Equations

were solved using the Abaqus (Dassault Systemes) finite element software with finite strain hyperelasticity for the posts and a user-written constitutive law for the cells. Because simulations showed the evolution of tissue shape in 4-post and 8-post tissue designs to produce regions of strong anisotropic and isotropic stress fields, respectively (Fig. 1), we tested our hypothesis on tissues in these configurations.

Device Design & Fabrication: Devices had wells (3.26 mm diameter, 1.25 mm depth) with posts (200 μ m diameter, with wider caps. Master molds were 3D printed, then replicated using the HASTE technique [6] to produce PDMS devices with pillars of known stiffness. These enabled testing of the hypothesis by providing microtissues with controlled stress fields.

3D Microtissues: 8 μ L of mixture (2x10⁷ cells/ml, 1.5 mg/ml collagen, 0.5 mM Hepes, 12.5 mM NaOH, 1X DMEM) was seeded in each well. Devices were centrifuged at 4°C, 300 g for 3 min. Collagen gels set for 20 minutes at 37°C before adding media. In some specimens, TGF- β (10 ng/ml) was added.

Imaging: To test whether TGF- β induces higher compaction in the devices, we compared the morphology of the control versus treatment. Bright field images were taken 3 hours and 4 days post-seeding (Fig. 1), and side-view fluorescence images at 4 days post-seeding (Fig. 2) using a Nikon eclipse TsR microscope.

Immunofluorescence Microscopy: The microtissues were fixed and immuno-stained for α -SMA, actin (phalloidin), and DNA (Hoechst), then imaged (Olympus IX83 confocal microscope). Maximum intensity projection images from the z-stacks were analyzed using a custom-built MATLAB code to calculate mean fluorescence intensity at specific regions and test model predictions and the hypothesis.

Statistical Analysis: Two-way ANOVA with Holm-Sidak mean comparison test was used. P value < 0.05 was considered statistically significant difference. * = p < 0.05; ** = p < 0.005; *** = p < 0.0005; **** = p < 0.0001.

Figure 1: Tissue-generated compaction and collagen remodeling in (a) 4-posts devices and (b,c) 8-posts devices with predicted high tensional anisotropy (red) and low tensional anisotropy at the central region [C], respectively. Scale bar = 1 mm

RESULTS

Three significant results emerged. First, TGF- β condition promotes higher volumetric compaction (Figure 2). After 4 days of compaction, in 4-posts tissues, the 2D-projected areas of control and TGF- β treated tissues were 27.6% versus 21.5% of initially seeded area ($p < 10^{-4}$). On the 8-posts tissues, the 2D-projected area was 47.34 and 44.64 (p-value: 0.0198) of control and TGF- β , respectively.

Figure 2: Addition of TGF- β enhanced the 3D tissue-generated compaction. Scale bar = 1 mm

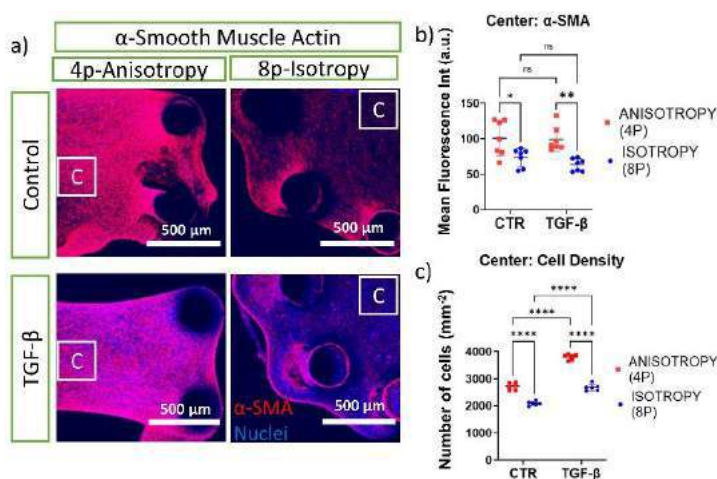

Figure 3: TGF- β conditioning does not enhance myofibroblast marker expression as strongly as tensional anisotropy in the 3D tissues. (a) α -SMA and nuclei protein expression (fluorescence); Quantitative data on (b) α -SMA intensity and (c) cell density of central regions of each tissue. Scale bar = 500 μ m

Second, across different designs (Figure 3a), we observed significantly higher α -SMA within the central region of geometrically anisotropic 4-posts tissues as compared to within geometrically isotropic 8-posts tissues. Treatment with TGF- β increased the impact of anisotropy on α -SMA expression (Fig. 3b). Observations of stress fiber density via F-actin staining were similar to observations from α -SMA visualization. These data are consistent with our hypothesis and as predicted by computational model.

Surprisingly, we observed that the effect size of anisotropy was more pronounced than the effect size of TGF- β at inducing α -SMA (Figure 3b) and stress fibers (data not shown). Nevertheless, TGF- β exposure increased cell density within micro-tissues, as gauged by overall nuclear intensity (Hoechst staining) and direct quantification of nuclear density in tissues with either geometry (Fig. 3c). TGF- β treatment also led to higher individual cellular polarization, as gauged by nuclear shape and alignment, regardless of tissue geometry. These results suggest a model in which tissue and cellular mechanical anisotropy, which may themselves be influenced by chemical cues like TGF- β , play a central role in promoting FMT.

DISCUSSION

Several new, interesting results emerged. Key facets of FMT, including expression of smooth-muscle associated contractile proteins, are more strongly regulated by tensional anisotropy than the addition of exogenous TGF- β . This discrepancy was not strongly linked to changes in individual cell geometry, as TGF- β still induced higher cellular alignment and nuclear elongation regardless of predicted overall tissue-level tension anisotropy. This trend is contradicted with another study in 3D system, in which TGF- β induced higher myofibroblast marker expression but not necessarily proliferation [1,4]. Insensitivity to exogenous of TGF- β in driving FMT in this study is potentially linked with some factors, including cell-contraction driven changes in mechanical liberation of latent TGF- β stored in extracellular matrix [7], and/or mechanically-driven changes in endogenous TGF- β secreted by the fibroblasts themselves [8]. Indeed, others have observed that localized changes in matrix stiffness induce TGF- β receptor dependent changes in α -SMA expression that were insensitive to the addition of exogenous TGF- β [3].

These results are significant. Results revealed that stress directionality is a central determinant to FMT, which further can induce fibrotic response, suggesting that while chemical cues are necessary for these processes, they may require a mechanically permissive environment for their action.

These results are potentially impactful, highlighting the importance of microenvironment, especially loading directionality of organs in attenuating FMT leading to fibrosis.

ENZYMATIC DEGRADATION DOES NOT COMPROMISE SLIDING-MEDIATED CARTILAGE LUBRICATION

INTRODUCTION

Articular cartilage serves as the near-frictionless bearing material of synovial joints. In osteoarthritis (OA), degeneration reduces cartilage's compressive modulus and increases its permeability. According to classical tribological theory, these changes should drastically impair lubrication by increasing load-induced interstitial fluid exudation and diminishing fluid load support (FLS) [1-2]. Although reduced stiffness is associated with high strains and frictions in fully depressurized cartilage interrogated under boundary lubrication conditions (sliding speeds $\leq 1\text{mm/s}$), new evidence suggests such relationships may not hold under more biofidelic sliding conditions. Recently, we demonstrated that the introduction of hydrodynamic pressurization, which occurs with high-speed ($>40\text{mm/s}$) sliding in convergent stationary contact area (cSCA) explants having curved cartilage surfaces, replenishes interstitial fluid lost to compressive loading via tribological rehydration. In healthy cartilage, tribological rehydration recovers and sustains high FLS and near-physiological friction coefficients ($\mu \leq 0.01$) in PBS-lubricated contacts with little sensitivity to variation in cartilage stiffness or permeability [3-4]. Here, we investigated whether OA-associated changes to cartilage mechanical properties, modeled via enzymatic digestion, impair cartilage lubrication under biofidelic articulation conditions.

METHODS

Osteochondral explants ($\varnothing 19\text{mm}$; $n=51$) were extracted from mature bovine femoral condyles. Specimens were indented with a $\varnothing 4\text{mm}$ spherical probe at $50\mu\text{m/s}$ to a target force of 150mN , then allowed to equilibrate under creep relaxation (Fig. 1A). The time-dependent normal force and indentation depth were fit to Hertz biphasic theory (HBT) to determine the compressive modulus (E_y), tensile modulus (E_{y+}), and permeability (k_0) [3]. Tribological characterization comprised ramp loading to a target of 7N , followed by 30min static compression and 15min reciprocal sliding against a glass counterface

(Fig. 1B). Two sliding speeds were investigated (10 vs. 80mm/s), corresponding to speeds that facilitate high and low tribological rehydration and FLS recovery, respectively. Explants were lubricated with 1X PBS or bovine synovial fluid (SF), which synergizes with tribological rehydration to enhance lubricity in the cSCA ($\mu \sim 0.003$) [4]. Following characterization in the naive state, explants were digested with 0.1U/mL chondroitinase-ABC (chABC) or 1U/mg wet weight bacterial collagenase-IV. Indentation and tribological testing were repeated after 40min , 4h , and 12h of digestion. SF-lubricated explants were characterized after 2h of digestion. Differences between groups were assessed via two-way ANOVA (significance at $p < 0.05$).

Fig. 1. Representative indentation tests (A) and high-speed cSCA tribological characterization (B) for naive and chABC-digested cartilage in PBS (note: initial ramp loading not shown).

RESULTS

Brief exposure ($\leq 4\text{h}$) to chABC or collagenase produced mechanical properties consistent with human OA samples (ICRS 1-2) as reported previously by our group [5]. After 4h , E_y decreased from 0.57 ± 0.20 to $0.41 \pm 0.18\text{MPa}$ and 0.68 ± 0.19 to $0.37 \pm 0.15\text{MPa}$ for chABC- and collagenase-treated samples, respectively ($p < 0.0005$, Fig. 2A). k_0 increased from 0.0038 ± 0.0012 to $0.0056 \pm 0.0020\text{mm}^4/\text{Ns}$ and 0.0029 ± 0.0007 to $0.0053 \pm 0.0012\text{mm}^4/\text{Ns}$ in chABC- and collagenase-treated explants, respectively ($p < 0.005$, Fig. 2B). After 12h , tissue compromise exceeded that observed in ICRS 1-2 human samples [5].

Fig. 2. Compressive moduli decreased (A) and permeability increased (B) following digestion. Data as mean \pm SD (* p <0.05, ** p <0.005, *** p <0.0005 vs. naïve). Grey shaded regions indicate the properties of human OA cartilage from Graham *et al.* [5].

Elastic strain during the initial ramp loading phase of cSCA testing increased significantly following ≥ 4 h of digestion ($p \leq 0.001$ vs. naïve, **Fig. 3A**). Nonetheless, exudative strain during 30min of subsequent static compression did not vary between naïve and digested cartilage ($p > 0.15$, **Fig. 3B**). This can be attributed to decreased contact stresses experienced following ≥ 4 h digestion (**Fig. 3C**). Furthermore, we found no evidence of altered tribological rehydration in digested cartilage. When slid at 80mm/s, strain recoveries of $6.83 \pm 1.46\%$ were seen in naïve cartilage and $6.60 \pm 1.47\%$ after 12h digestion, respectively ($p = 0.50$, **Fig. 3D**). Similarly, all explants exhibited negative strain recovery (*i.e.*, net fluid exudation) of -1.0 to -2.5% when slid at 10mm/s ($p > 0.2$ vs. naïve, **Fig. 3D**).

Remarkably, digestion had little to no influence on cartilage lubricity in the cSCA. Under conditions of low FLS (10mm/s), end-of-sliding friction coefficients were elevated (~ 0.3) but not different among naïve and digested tissue ($p > 0.2$). Importantly, under conditions of high FLS, driven by high-speed cSCA sliding (80mm/s), consistently low end-of-sliding friction coefficients of $\mu < 0.1$ were observed in both naïve and digested cartilage ($p > 0.15$, **Fig. 4A**).

Next, we examined if digestion alters lubrication synergy fostered by tribological rehydration and synovial fluid presence [4]. At 80mm/s, strain recoveries of $7.08 \pm 1.68\%$ and $7.84 \pm 2.05\%$ were observed in the naïve state and following 2h digestion, respectively ($p > 0.12$). Furthermore, indistinguishable, and physiologically consistent friction coefficients (0.003-0.006) were observed for both naïve and digested explants at the end-of-sliding in SF ($p = 0.25$, **Fig. 4B**).

DISCUSSION

Our results demonstrate that OA-like articular cartilage retains the strain recovery and lubricity of healthy cartilage under biofidelic articulation conditions (*i.e.*, high-speed sliding at high FLS). In human OA samples (ICRS 1-2), E_y decreased by 0.056MPa (12%) and k_0 increased by $0.0005 \text{ mm}^4/\text{Ns}$ (20%) for each increase in ICRS score [6]. Here, just brief chABC or collagenase exposure replicated similar OA-like mechanical properties: 40min and 4h of digestion reduced E_y by 13% and 36%, respectively. The cartilage tribology field has typically relied on exposure of cartilage to degradative enzymes or inflammatory cytokines for much longer durations to model tissue degeneration (7-48h) [1-2, 6]. Predictably, this results in more extreme degeneration ($>80\%$ decrease in modulus and $>200\%$ increase in permeability), exceeding the ranges reported for ICRS 1-2 cartilage in our work [5] and by Kleemann ($<70\%$ reduction in modulus for severe OA; ICRS 3) [7]. Thus, we demonstrate that relatively minor, but clinically aligned OA-like changes in cartilage mechanical properties can be achieved with <4 h enzymatic digestion.

As expected, digested cartilage experienced elevated axial elastic strains during load application compared to naïve cartilage. Digestion also increased contact dilatation, as quantified by *in situ* optical measurements of cSCA contact area. For example, cSCA contact areas

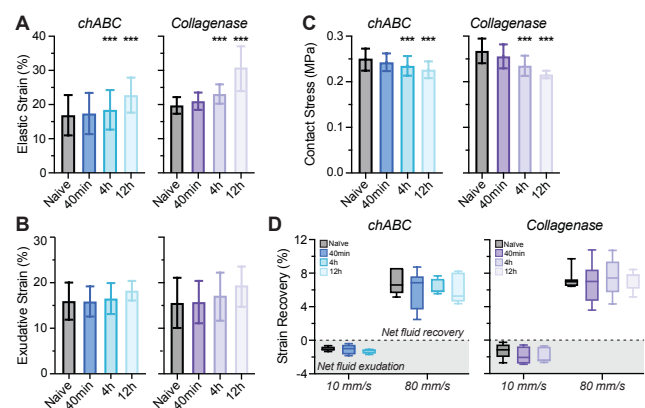

Fig. 3. (A) Elastic strain during ramp loading to 7N increased following enzymatic digestion. (B) Exudative strain during static compression did not differ among groups. (C) Contact stress at 7N decreased with ≥ 4 h digestion (D) Strain recovery at low- and high-FLS was not significantly affected by digestion. Data as mean \pm SD (A-C) and median \pm IQR (D), *** p <0.001.

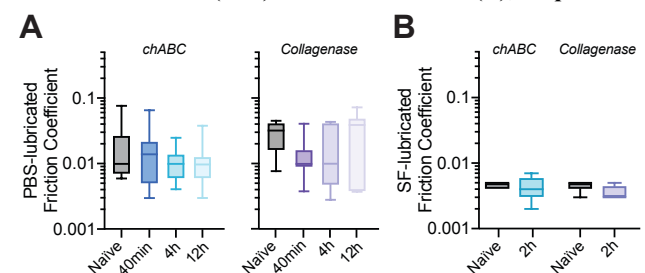

Fig. 4. Friction coefficients under high-speed sliding. (A) End-of-sliding (*i.e.*, equilibrium) friction coefficients in PBS were insensitive to digestion ($p > 0.12$) (B) In SF, end-of-sliding friction coefficients approached *in vivo*-like values in both naïve and digested cartilage ($p = 0.25$). Data as median \pm IQR.

increased from $28.4 \pm 2.5 \text{ mm}^2$ in naïve cartilage to $31.1 \pm 2.3 \text{ mm}^2$ after 12h chABC digestion, resulting in $\sim 9\%$ lower contact stress under 7N normal force. As a result, exudative strain during 30min of creep relaxation did not differ between naïve and digested cartilage, despite substantial softening (up to 85% reduction in E_y after 12h digestion). Furthermore, even extensively digested cartilage supported robust tribological rehydration when slid at 80mm/s, as evidenced by strain recovery magnitudes and PBS-lubricated friction coefficients indistinguishable from naïve cartilage. This was further confirmed in our SF-lubricated tests, which revealed that digested cartilage sustains near-physiological friction coefficients (0.003-0.006) during high-speed cSCA sliding. Together, these results suggest OA cartilage is more mechanically resilient than previously credited. Furthermore, increased elastic (or “habitual”) strain in digested tissue absent meaningful differences in “activity-mediated” (or “diurnal”) strain and friction coefficients during sliding suggest that the biomechanical consequences of OA could be mitigated through behavioral modifications that reduce total cartilage strain and promote fluid recovery (*i.e.*, weight loss and physical activity) [8].

COMPARISON OF DOMINANT MODES OF HUMAN BRAIN DEFORMATION FROM SIMULATION AND EXPERIMENT

Amir H.G. Arani (1), Jordan D. Escarcega (1), Antoine Jerusalem (2), Ruth J. Okamoto (1), Philip V. Bayly (1)

INTRODUCTION

Traumatic brain injury (TBI) affects an estimated 70 million people worldwide each year [1, 2]. Computer models of brain biomechanics are emerging as important tools to understand and develop approaches to prevent or treat TBI [3,4], however such models should be parameterized and evaluated by comparison to experiments. Magnetic resonance elastography (MRE) and tagged magnetic resonance imaging (MRI) experiments provide mechanisms to image the response of the brain to harmonic motion and mild impact to the skull, respectively. Both MRE and tagged MRI can identify dominant modes of oscillation in brain deformation [5], which can provide important insight into the mechanics of TBI.

In this study, we compare dominant modes of brain deformation predicted by a computer model to those identified by MRE and tagged MRI experiments. The results not only assess the ability of the computer model to predict actual strain fields in the intact living brain, but also illustrate common features of strain fields obtained in different subjects by the two experimental methods.

METHODS

The model used in this study is an existing model developed in ABAQUS (SIMULIA) and was used initially for the time-domain simulation of brain response to an impact (see ref. [3] for more model information). The computer model in this study uses a set of boundary conditions and excitation amplitude similar to those of the experimental setup. Two different sets of viscoelastic material properties were used to predict the first (dominant) oscillatory mode of the brain.

The head model has 792,773 hybrid tetrahedral/quadratic elements, including the brain, skull, and scalp. Material properties of all element sets can be found in ref. [3] and the brain material properties were converted to frequency-domain parameters for this study. Two constitutive models for brain tissue were considered: (1) the hyperviscoelastic (HVE) material properties in the original model [3];

(2) a linear viscoelastic (LVE) model reported in ref. [4]. In the HVE model, the deviatoric stress includes a convolution integral with respect to time, as described in ref. [6]. For the viscoelastic properties in both LVE and HVE cases, the relaxation modulus is time-dependent, defined by the Prony series with $N = 2$:

$$\bar{\mu}(t) = \bar{\mu}_{\infty} + \sum_{i=1}^N \bar{\mu}_i \exp\left(-\frac{t}{\tau_i}\right) \quad (1)$$

Here $\bar{\mu}$ is the effective relaxation modulus at time t , and $\bar{\mu}_{\infty}$ is the long-term relaxation modulus. Viscoelastic parameters are summarized in Table 1 where λ_1 and λ_2 are dimensionless forms of $\bar{\mu}_1$ and $\bar{\mu}_2$ in equation (1) with respect to the instantaneous relaxation modulus $\bar{\mu}_0$.

In MRE, dynamic deformation of brain tissue is induced by harmonic vibration of the skull; here lateral excitation at the frontal temporal bone induces left-right skull translation and rotation about the superior-inferior axis (SI-axis). Tissue displacement is measured by a phase-contrast MRI sequence and differentiated to estimate strain [7]. In tagged MRI, brain deformation is induced by a mild angular acceleration of the head, and displacement is measured by tracking “tag” lines (imposed variations of tissue magnetization) [1,4,5]. Dominant modes from tagged MRI [5] and strain fields from MRE are represented as fields of complex-valued coefficients of complex exponential (sinusoidal) functions of time. Each coefficient represents the amplitude and phase of the oscillatory strain field.

Dominant modes of deformation predicted by the computer model were compared to the modes extracted from experimental data. Strain fields from MRE during lateral harmonic excitation of the skull and from tagged MRI during rotation about the SI-axis were obtained from publicly-available datasets [8]. Frequency-domain and modal analyses were performed for the model, and modes that are excited by rotation of the brain around the SI-axis were identified.

Because brain size and anatomical features vary among human subjects, a framework is needed to register the anatomical images and strain fields of simulation and experiment to the same standard space of

MNI-152 atlas, as used in many studies (see ref. [4]), for comparison. Using the *antsRegistration* module of ANTS software [9], we applied three types of transformations (rigid, affine, and SyN transformations) to the model's image (Figure 1) in order to rotate, align, scale, shear, and nonlinearly warp the model to the MNI-152 atlas image.

The correlation value (CV) between two normalized complex strain fields $\bar{\epsilon}_1$ and $\bar{\epsilon}_2$ can be described as a complex dot product with a value close to 1 showing a high similarity:

$$0 < CV = |\bar{\epsilon}_1 \cdot \bar{\epsilon}_2| < 1 \quad (2)$$

Table 1: Viscoelastic parameters used in the computer simulation

Parameter case		λ_1	λ_2	$\tau_1(s)$	$\tau_2(s)$
1. HVE	White	0.650	0.204	3.460	735
	Gray	0.540	0.250	2.170	235
2. LVE model in [4]		0.710	0.055	0.001	0.028

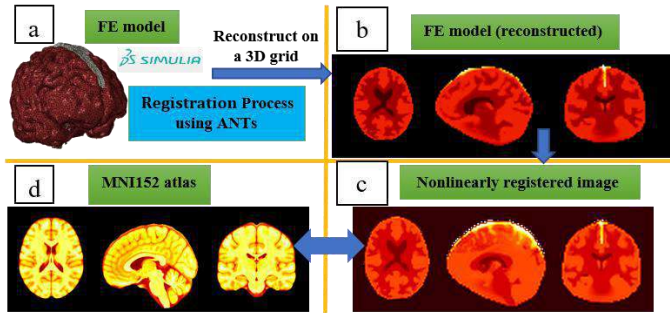

Figure 1. Registration process: (a) The Finite Element model in ABAQUS. (b) The model's reconstructed image in MATLAB R2022a. (c) The model's image fully registered to MNI-152 atlas (nonlinear registration), and (d) The fixed image in the standard space. The image array is $241 \times 286 \times 241$ with 0.8 mm voxels for panels c,d and $80 \times 80 \times 60$ with 3 mm voxels for panel b. The left to right views in each panel b-d show the axial slice (SI), the sagittal slice (RL), and the coronal slice (AP), respectively.

RESULTS

Qualitative and quantitative comparisons for two different types of simulations and two different experiments are shown in Figure 2 and Table 2. Figure 2(a,b) shows the strain fields of dominant mode of model from (i) modal analysis and (ii) harmonic response (simulated MRE), respectively. Figure 2(c,d) shows dominant modes from tagged MRI and MRE experiments for two different human subjects. Table 2 shows the average values for correlations of strain fields corresponding to two simulation cases and two imaging experiment types (each involving three different human subjects). Positive correlations are seen between experiment and simulation (case 1 slightly higher than case 2).

DISCUSSION

Dominant modes of oscillation in the brain predicted by computer simulation were quantitatively compared to modes in different human subjects when the skull is excited around the SI axis harmonically (as in MRE) or by impact (as in tagged MRI). To enable this comparison, simulated and measured fields were registered to the MNI-152 atlas. The range of values for the correlation between simulated and experimental strain fields was 0.40 to 0.56. The experimental strain fields found in MRE at low frequencies are correlated to modes excited by mild impact (from tagged MRI). The modes predicted by computer models are similar to modes identified from both MRE and tagged MRI [5], and share characteristic features of brain response to mild impact. There are inherent limitations with registering strain fields from

different subjects (as the strain fields are modified, in the process) but registration is required for quantitative comparisons. The framework developed here allows evaluation of models by comparison of predicted modes to modes observed in MRE and tagged MRI experiments. Dominant modes of brain deformation excited in a particular direction provide key information about the brain's response to mild impact.

Figure 2. Visual comparison of strain fields from simulation case 2 (see Table 1) and experiment: (a) Dominant mode of simulation from modal analysis with a frequency of 6.28 Hz. (b) MRE simulation at 10 Hz. (c) Dominant mode of tagged MRI experiment with a frequency of 5.52 Hz from a 24-year-old female subject. (d) MRE experiment at 10 Hz from a 27-year-old female subject. The slice number is 119 out of 1 to 241 in the SI direction for all panels.

IN VIVO HUMAN MRI WITH LOADING TO EVALUATE DISC MECHANICAL FUNCTION IN YOUNG AND OLDER SUBJECTS

H.R. Newman, K.D. Meadows, T.B. Elia, E.H. Williams, E.J. Vresilovic, D.M. Elliott

Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

The intervertebral disc maintains and distributes large multiaxial loads as a part of regular activity. We and others recently measured disc mechanics in young subjects using MRI^{1,2}. However, the disc undergoes large degenerative changes with age that are difficult to distinguish from pathology. Therefore, the purpose of this study was to non-invasively measure disc mechanical function in Young and Older pain-free subjects using our recently developed methods¹. To this end, magnetic resonance imaging (MRI) was used at four loading conditions to evaluate the differences in healthy disc function and spine behavior.

METHODS

Sixteen healthy women were divided evenly between Young (23-27 years old) and Older (63-77 years old) groups. Subjects were all asymptomatic, having no significant or chronic back pain, never had back surgery, scored less than 5 on the Oswestry Index low back pain disability questionnaire, and a back VAS pain score of less than 10/100.

Subjects underwent MRI in four loading states (Fig 1)¹. Loading states were achieved by postural changes and diurnal loading. Subjects were imaged first thing in the morning, following an hour of laying down to unload their spine. The supine scan was conducted first, followed by the extension and flexion positions (Fig 1). The postural positions were within the subjects' normal range of motion. The subject then conducted their daily routine and returned in the evening for a repeat supine scan.

Figure 1: Schematic of postural loading for supine, extension, and flexion positions for MRI scanning.

At each position, established MRI protocols (Table 1) were used to evaluate MRI variables and determine changes between loading states. The Supine AM, Extension, and Flexion scans were all within an hour of each other and therefore no measurable change in T2 relaxation time occurred between them, so the T2 scan was only done for Supine scans. Additionally, the gross health of the disc did not change within an hour, so the Pfirrmann TSE scan was only taken for the Supine scans.

All morning scans (Supine AM, Extension, Flexion) are taken within an hour of each other, which is insufficient time for significant fluid changes in the discs, therefore the T2-weighted scans are completed for the Supine AM and Supine PM states; while only the T1-weighted FLASH was conducted for the extension and flexion positions to assess disc geometry changes.

Table 1: MRI sequence protocol and scan details.

Sequence	Scan Time	Resolution (mm)	Slices	Imaging Parameters (ms)	Outcomes
T1-w FLASH	10.3 mins	0.5 x 0.5 x 3	20	TE=3.65, TR=9.6	Disc Geometry
T2 Map CPMG	15.9 mins	0.5 x 0.5 x 5	1	TE=13.6, ... 81.6, TR=3000	T2 Relax Time
T2-w TSE	6 mins	0.5 x 0.5 x 5	17	TE=124, TR=4540	Pfirrmann Grade

The 3D T1-weighted (T1-w) FLASH sequence provided detailed anatomic images of the disc which were used to evaluate disc geometry (Fig 2). From the mid-sagittal slice, spine cobb angle was determined as the total angle of the lumbar spine in the AM supine scan (Fig 2A). Disc height was calculated as the disc area divided by the anterior-posterior width (Fig 2A). The disc volume was evaluated by manual segmentation of the disc in all slices of the image sequence which were extruded based on the 3mm slice thickness to create a 3D volume of the disc (Fig 2B).

A T2 map sequence was used to quantify T2 relaxation time which is highly correlated with water content^{3,4} and we and others have shown that T2 time correlates with disc degeneration^{3,5-7}. To calculate T2 time, the image intensity decay in the nucleus pulposus was fit to a

noise-corrected exponential (Fig 2C)³. Lastly, a T2-weighted TSE sequence was used to determine the discs' degeneration grade by using the Pfirrmann scale (Fig 2)⁸. The grade is a disc health ranking from one to five where one is healthiest; the homogeneity of disc intensity and disc height largely determine the disc's score.

Figure 2: FLASH sequence with (A) yellow lines indicating Cobb angle, red lines showing disc area and width measures and (B) colored segmentations. (C) T2 map with regions of interest shown. (D) TSE sequence used for Pfirrmann grading discs.

For all evaluations, the Supine AM scan served as the baseline such that changes with diurnal loading and extension/flexion are the difference between Supine AM and Supine PM, extension, and flexion, respectively. A mixed model with fixed effect of age group and random effect of subject and disc level was used to evaluate differences between age groups ($p < 0.05$). A mixed model with fixed effect of Group and Loading and random effect of Subject and Disc Level was used to evaluate changes between loading conditions ($p < 0.05$).

RESULTS

Subject Data: There was no significant difference between the groups' BMI or physical activity on the day of scanning (steps taken between AM and PM scanning). The Young group had significantly lower Pfirrmann grades than the Older group (Fig 3A).

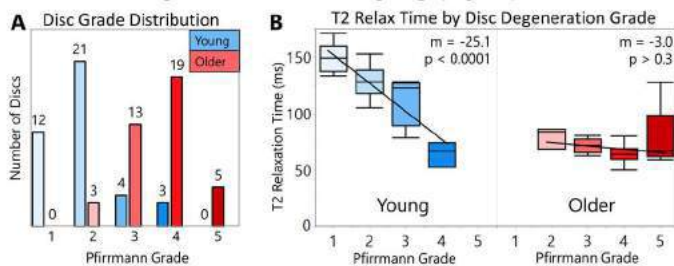

Figure 3: (A) Distribution of Pfirrmann grade by age group, where the Older group had significantly higher disc grades. (B) Correlation between grade and T2 relaxation time by age group, where the Young group had a significant correlation, and the Older group did not.

Supine AM Baseline: For comparing between age groups, the baseline disc T2 time (Fig 3B) and disc height were significantly reduced in the Older group but there was no significant difference in disc volume or baseline Cobb angle between age groups. The Young group had a significant correlation between T2 time and Pfirrmann grade, but the Older group did not.

Postural Loading: Both groups had significant differences in Cobb angle with the imposed postural changes to extension and flexion (Fig 4A). The Young group achieved 28% greater flexion than the Older group (Fig 4A), but there were no significant differences in achieved

extension. The change in disc height, change in volume, and change in T2 time were not significantly different between age groups in extension or flexion.

Diurnal Loading: With diurnal loading, there was no significant difference in Cobb angle as the result of diurnal loading both within and between age groups (Fig 4A). There was a significant decrease in disc height (Fig 4B), disc volume, and T2 relaxation time in both groups. The change in disc height (Fig 4B), change in volume, and change in T2 time were not significantly different between age groups.

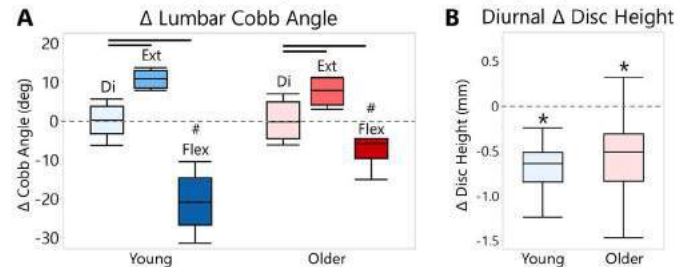

Figure 4: (A) Spine Cobb Angle was not impacted by diurnal loading (Di) but was significantly different in the extension (Ext) and flexion (Flex) positions. Flexion Cobb angle was significantly different between age groups (#), the Young group achieved greater flexion. (B) There was a significant decrease in disc height diurnally (*) for both age groups; they were not significantly different from each other.

DISCUSSION

We found that the disc exhibited age-dependent traits measurable with multi-positional MRI acquisition. The age groups had expected differences in Pfirrmann grade, where Young discs tended to have lower degeneration scores. The Young discs also had a strong correlation between the Pfirrmann grade and baseline T2, this is expected as a primary criterion of the Pfirrmann grading is nucleus visual intensity which coincides with higher T2 times. Interestingly, the Older discs had no correlation, despite a distribution of Pfirrmann grades. This suggests a potential limitation in using the Pfirrmann grading scheme, whereby intensity of a single image slice could be insufficient for assessing disc fluid content and subsequently disc health. The reduced T2 times in the Older cohort were expected, as aging discs tend to lose proteoglycans and subsequently water; there is also potential for changes in matrix composition reducing matrix integrity.

Importantly, while the groups had different baseline disc heights and T2 times, the Older group experienced diurnal changes similar to those of the Young group indicating that the geometric changes and water loss experienced throughout the day is maintained with varying age. Furthermore, Cobb angle changes confirmed postural positions were successfully achieved and did not change diurnally, as expected. The Older group achieved 28% less flexion than the Young group, this could be due to reduced flexibility in the spinal muscles. We found that disc health (degeneration) and flexion capacity were significantly impacted by age and provide valuable insights for changes to expect with age in the healthy disc.

INTRODUCTION

In fundamental biological processes of development, disease, and regeneration, cells move to and from mechanically distinct environments. For example, neural crest cells move throughout the embryo to lay the foundation for structurally complex organs [1], and cancer cells escape stiff tumors and invade through softer healthy tissue to initiate metastasis [2,3]. In any given environment, cells sense and respond to stiffness of their extracellular matrix (ECM) through actin-myosin force generation and focal adhesion signaling [4,5]. However, it remains unknown how grouped cells negotiate such mechanically dissimilar interfaces in fibrous three-dimensional (3D) environments. Further complicating this cross-environment mechanical heterogeneity, cells not only sense their current environment but also remember their past environments by retaining activated expression of mechanosensitive genes. In the context of collective cell migration, as epithelial cells move from stiff to soft 2D surfaces, adequate stiff-priming enhances their migration on future soft surfaces due to a YAP-based mechanical memory [6]. However, it is not yet clear whether such memory of cellular mechanical priming can be imparted to 3D collagen microenvironments, and whether this remodeled collagen can alter future cell invasion strategies into new, mechanically distinct environments. Here, we investigate these questions through an *in vitro* system to capture this cross-environment behavior by spatiotemporal invasion measurements and collagen remodeling done by primed cells implanted in collagen.

METHODS

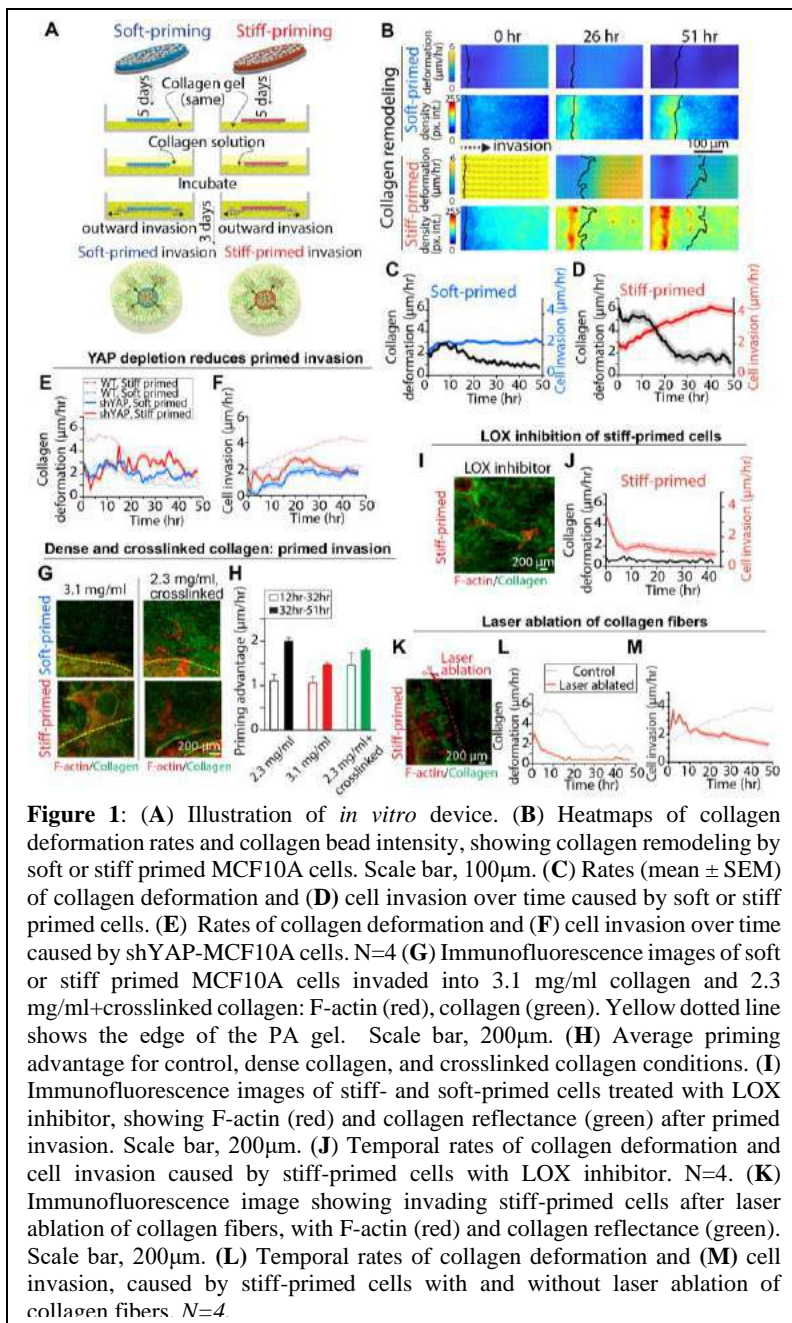

To combine two mechanically distinct environments for cellular mechanical priming and future invasion within one assay, we developed a dual-matrix scaffold with synthetic hydrogels and 3D collagen type I (Figure 1A). We first cultured MCF10A human breast epithelial cells on soft (0.08kPa) or stiff (16kPa) hydrogel substrates. Next, we implanted these hydrogel discs with adhered cells within 3D collagen (2.3 mg/ml) to allow spontaneous invasion of soft- or stiff-primed cells

into a new and mechanically different environment without intermediate detachment. We analyzed the cellular invasion by tracking the invasion front using an ROI (387 μm x 213 μm). Collagen deformation was tracked using embedded fluorescent beads and quantified using particle image velocimetry (PIVLab) and fixed images were visualized using a reflectance microscopy through confocal microscopy. To test the memory-independent invasion in case of an unstable priming, we depleted YAP in MCF10A cells.

RESULTS

Given the known importance cell-matrix engagement in cell migration, the differential collagen remodeling caused by soft versus stiff primed cells could also result in different outcomes for 3D cell invasion. In our measurements, stiff priming led to almost double the invaded distance and higher number of invaded cells, compared to soft priming (Figure 1, B-C). Notably, these differences in the number of invaded cells grew larger as the invasive front moved farther away from the priming environment (Figure 1B). When tracked over time and distance from the PA gel, stiff-primed cells pull and accumulate collagen behind the invasive front (Figure 1B-D). These high-density collagen 'anchors', shown as red band in the collagen intensity plots (Figure 1B), remain stable over the duration of observed invasion. After the initial ~12 hours period of rapid matrix remodeling, collagen deformation rate reduced, which could indicate establishment of pretension within the collagen matrix (Figure 1B).

As a result of memory-dependent collagen remodeling, invasion speed of stiff-primed cells almost doubled compared to their soft-primed counterparts. By plotting spatial maps of collagen bead density over time (Figure 1B, bottom row), we show that regions of high-density collagen accumulation are larger and more pronounced in case of stiff primed cells; and once formed, these regions do not dissolve over time. Here, collagen deformation rate around soft-primed cells remained too low (Figure 1C) to cause collagen accumulation or tension generation (Figure 1B, top row).

To test the memory-independent invasion in case of unstable priming, we used MCF10A-shYAP that were depleted YAP, a known regulator of cellular mechanical memory [6,7] and repeated the experiments of primed cell invasion. As cells invade their surrounding matrix, the resulting collagen deformation was priming-independent, somewhat temporally uncoordinated, and lower compared to the control case (Figure 4E). In addition, this lower collagen deformation by shYAP cells coincided with their slower invasion speeds (Figure 4F), regardless of soft or stiff priming.

To understand how differentially primed cells behave in dense or stiffened collagen matrices, we repeated experiments in two collagen compositions: higher collagen density of 3.1 mg/ml, and second with crosslinking to increase stiffness but maintain density by mixing 2.3 mg/ml collagen with the photo-crosslinker Riboflavin followed by UV

exposure. We found that in these challenging matrices of higher density and crosslinking, the priming advantage, a term we defined as the difference in the invasion speeds of soft and stiff primed cells, was preserved and persisted over time (Figure 1G-H). Overall, our experiments show that prior mechanical priming continues to be advantageous in denser and stiffened collagen matrices (Figure 1H).

To experimentally test the role of stable collagen remodeling in primed invasion, we used β -aminopropionitrile (BAPN) to inhibit lysyl oxidase (LOX) that crosslinks collagen. After soft or stiff priming of cells, BAPN was added, and cells were allowed to invade into collagen (Figure 1I). When tracked over time (~2 days), both collagen deformation and invasion rates of stiff-primed cells remained low (Figure 1J).

We next asked whether cellular forces are necessary only near the invasive front, or whether they need to be propagated over long distances into the matrix to enable collagen remodeling (Figure 1K). To implement an analogous spatial disruption of force-based collagen remodeling in experiments, after the stiff-primed cells invaded into the collagen and at the onset of invasion, we performed laser-based ablation of collagen fibers ahead of the invasive front. Collagen deformation was substantially reduced within a few hours after laser ablation of fibers and remained in a low net deformation state over time (Figure 1L). This depleted effect of ablated matrix indicates the importance of long-distance force propagation within collagen for its bulk remodeling. Similarly, although the invasion rate of stiff-primed cells started at a high level, it subsided within 6-8 hours and remained low over two days of tracking (Figure 1M).

DISCUSSION

Here, we developed a novel hydrogel-collagen device to combine mechanical priming and cross-environment invasion. Using this system, we show that cells previously primed by stiff environments continue to invade through softer 3D collagen matrices – a multifaceted process mediated by collagen fiber remodeling. We show that priming-based cellular forces and matrix remodeling are such intimately coupled processes that any disruptions in collagen crosslinking or force propagation disrupt the connection between past cellular priming and future invasion. These basic mechanisms of priming-dependent matrix remodeling and invasion hold true for multiple cell types and collagen compositions. Overall, our results show that past ‘stiff-priming’ provides cells a previously unappreciated advantage in navigating new challenging environments. This memory-dependent cell-matrix coupling could apply to wide-ranging biological processes wherever cells remodel their environments over time and distance, e.g., fibrosis, cancer, and aging.

INTRODUCTION

Preterm birth (PTB) rates in the United States have remained largely unchanged since the first year when definitive national data were available, with the 2007 PTB rate being 10.44% and the 2021 PTB rate being 10.48% [1]. PTB is delivery before 37 weeks gestation, and babies born prematurely are at an increased risk of death and disability [2]. The current gold standard for PTB prediction is the sonographic measurement of cervical length, with a typical cutoff of 25mm or less placing a pregnant patient at increased risk of PTB [3]. However, this method of PTB prediction is only 30-60% sensitive, depending on other patient risk factors [3]. The structural integrity of maternal reproductive tissues is essential to a successful pregnancy. Thus, a better knowledge of maternal reproductive tissue loading on an individual basis will improve PTB prediction and provide a rationale for PTB prevention.

Because pregnancy is a protected environment, we use computational modeling to study pregnancy biomechanics. We have developed a method to create parametric patient-specific solid models of the maternal uterus and cervix from 2D ultrasound images [4,5]. These solid models have been utilized in finite element analysis to calculate cervical loading in the early second trimester in patients considered at low- and high-risk for PTB. In addition, we have explored the repeatability of these ultrasonic measurements by calculating the inter-class correlation coefficient (ICC) for each dimension, which were rated as ‘excellent’, ‘good’, ‘fair’, and ‘poor’ using the Cicchetti guideline [5]. This research aims to study the sensitivity of proximal cervical loading to variations in maternal anatomy measured via ultrasound. These measurements will lay the foundation for PTB prediction related to the mechanical overloading of the cervix.

METHODS

Previously collected sonographic measurements from the early second trimester (14-16 weeks gestation) were used in this study from a cohort of 29 patients who delivered at-term [5]. A “normal” early

second-trimester maternal anatomy was determined by finding the median value for each of the 15 ultrasonic measurements collected and a parametric 3D model built of the “normal” uterus and cervix in Solidworks (Dassault Systemes, Vélizy-Villacoublay, France). Four additional 3D solid models were built for each parametric ultrasonic measurement by varying the median value by $\pm 10\%$ and $\pm 20\%$, covering most maternal dimension values observed, and holding all other parametric values at the median. One measurement, the lower uterine segment thickness (UT4), was varied to $\pm 50\%$ and $+100\%$ to cover the range of values found in the patient cohort. In addition to the cervix and uterus, a fetal membrane and supporting abdomen was included in each geometry. The left half of each geometry was used for computational efficiency and discretized into elements using Hypermesh (Altair Engineering Inc., Troy, MI). FEBio Studio (v1.3.0) was used for finite element analysis (FEA), and the meshed geometry was imported into it [6].

Within FEBio, the material properties, boundary conditions, and contacts were defined. The same material properties were assigned to each geometry. Material properties used were based on existing mechanical tests. The cervix and uterus were modeled as passive fiber composite materials and the fetal membrane as a transversely isotropic fiber-based material with a compressible neo-Hookean ground substance [7-9]. Cervical fiber stiffness was assumed to be normal for the gestational age based on existing cervical aspiration data [10]. The boundary conditions applied were as follows: fetal membranes tied to the intrauterine wall and sliding on the cervix, the uterus sliding on the abdomen, the proximal cervix tied to the abdomen and the distal cervix sliding on the abdomen, and the model fixed in the normal direction at the superior, inferior, posterior, and sagittal plane surfaces. A gestationally appropriate intrauterine pressure was applied to the inner membrane surface [11]. Heat maps of stretch in the proximal cervix were compared between models with varying measurement values and cylindrical stretches at points in the anterior, left, and posterior cervical

midstroma plotted against percentage change in measurement value. Changes of 1% or more stretch at these points were deemed notable. This limit was used to ensure notability in results is due to changes in the maternal anatomy and not variances that may arise from the computation.

RESULTS

The measurements with reported excellent ICCs that affected proximal cervix loading are inferior-superior intrauterine diameter (UD1), left-right intrauterine diameter (UD4), and lower uterine segment thickness (UT4), with table 1 summarizing which parameters had notable effects in proximal cervical loading. An example of how the proximal cervix heat maps change is shown for the lower uterine segment thickness (Fig. 1).

Table 1: Percent change in stretch from lowest to highest dimension value dimensions with noticeable changes. Stretches at (Pos)itions in the (Ant)erior, Left, and (Post)erior cervical midstroma are reported in the (R)adial, (C)ircumferential, and (L)ongitudinal (Dir)ections. Percent change in stretch $\geq 1\%$ are bolded.

ICC Rating		Excellent			Good		Fair
Dimension		UD1	UD4	UT4	UD3b	AUCA	CD1
Pos.	Dir.						
Ant.	R	-0.2%	0.6%	0.5%	1.5%	-0.6%	-0.3%
	C	-0.5%	1.8%	1.4%	0.8%	0.3%	-0.3%
	L	0.2%	-1.3%	-1.0%	0.7%	1.0%	-0.6%
Left	R	-0.6%	2.5%	1.0%	0.5%	0.0%	0.4%
	C	0.2%	0.2%	0.2%	1.3%	0.7%	-0.7%
	L	0.7%	-2.2%	-0.7%	0.3%	-1.4%	-1.1%
Post.	R	1.0%	0.6%	0.1%	0.8%	0.8%	0.2%
	C	-0.3%	1.9%	0.4%	0.7%	-0.4%	0.0%
	L	0.0%	-1.5%	0.2%	0.5%	-0.5%	-1.8%

Figure 1: (A) Varying one measurement, the lower uterine segment thickness (UT4), while holding all other dimensions at the median value changes stretch in the proximal cervix. (B) First principal stretch decreases in the proximal cervix as UT4 increases. Anatomical directions are provided.

Ultrasonic measurements with reported good ICCs that affect loading in the proximal cervix are the anterior uterocervical angle (AUCA, angle between cervical canal and lower uterine segment) and the posterior intrauterine diameter in the inferior uterus (UD3b, controls curvature of posterior uterine wall in the inferior uterus). Only one measurement with a reported good ICC had a notable effect on proximal

cervical loading, the outer cervical diameter (CD1). No measurements with reported poor ICC values had notable effects on proximal cervix loading. Cervical length, which has a reported good ICC, did not have notable effects on proximal cervical loading.

DISCUSSION

Dimension measurements that had the largest effects on cervical loading were those that dictate the overall width of the uterus (UD4), the shape of the posterior intrauterine wall near the cervix (UD3b), and the thickness of the lower uterine segment (UT4). The overall length of the uterus (UD1) along with the width (CD1) and angle (AUCA) of the cervix were also important to cervical loading. Given the criteria of 1% change in stretch or greater, only 6 of the 15 investigated parametric ultrasonic measurements have a notable effect on loading results in the proximal cervix when varied, and none of them have reported poor ICCs. Our ongoing clinical studies have shown that patients with large radial stretches tend to deliver extremely preterm, so dimensions that change radial stretch (UD1, UD4, UT4, and UD3b) are likely highly important to capture. Several clinical studies have investigated using the anterior uterocervical angle to predict preterm birth [12,13]. It is known that the stiffness of the cervix also affects cervical loading, so in the future we will repeat this study with varying cervical fiber stiffness [4]. Additionally, an investigation of how these parameters affect stretch in other cervical locations and the uterus and fetal membranes is warranted. More methods of analysis will also be undertaken in the future, such as stretch comparisons across the entire proximal cervix rather than at select points.

Limitations to this work are non-trivial. The measurements used in this study are from pregnant anatomy, so the configurations used are inherently not in a stress-free state. Additionally, the dataset from which the dimension measurements were taken was only patients who ended up delivering at term, so measurements reflective of maternal anatomy who deliver preterm may not be covered by the range of values investigated in this work. Also, the analysis was only done in the contact condition where the fetal membrane was tied to the intrauterine wall and allowed to slide on the cervix, which may have artificially increased the degree to which the outer cervical diameter (CD1) affected proximal cervix loading.

INTRODUCTION

Tissue engineering (TE) is an emerging treatment strategy for an assortment of trauma/degenerative pathologies (e.g., cardiac/skeletal muscle, musculoskeletal connective tissue), consisting of the fabrication and clinical implantation of cellularized replacement tissues [1]. Cell-seeded tissue constructs are initially cultivated *in vitro* with an array of anabolic biomolecules, consisting of nutrients, vitamins, hormones, and growth factors (GFs), to accelerate tissue growth. In contrast to native developmental processes—whereby biomolecule transport is aided through delivery via dense vascular networks—in TE applications, biomolecules are supplemented in culture medium and expected to transport sizable diffusion distances through thick avascular constructs to reach their cell targets [2,3]. Consequentially, growth-stimulating biomolecules can encounter significant transport limitations in constructs, giving rise to sustained, steady-state spatial concentration gradients, which in turn, can lead to detrimental non-uniformity in the viability and composition of developing tissues [2,3]. As such, the development of novel TE platforms to improve the delivery of transport-limited biomolecules may considerably improve clinical treatment outcomes.

The identification of transport-limited biomolecules constitutes a significant challenge. On a theoretical basis, steady-state concentration gradients of biomolecules arise when the rate of cell-mediated chemical degradation/consumption of a biomolecule (via membrane transporters or receptor-mediated endocytosis) exceeds its rate of diffusive transport through the construct [3,4]. Accordingly, more pronounced gradients are observed for a higher biomolecule consumption rate and/or lower biomolecule diffusivity. Generally, for small nutrients (e.g., glucose, oxygen) gradients can arise as a result of their characteristic high rates of cellular consumption, but are also mitigated due to their high diffusivity. In contrast, large protein biomolecules (e.g., GFs) are

expected to exhibit lower consumption rates but also possess far reduced diffusivities. As such, it remains challenging to predict how these parametric variations for different types of biomolecules manifest into differential concentration gradients in engineered tissues.

Non-dimensional parametric ratios have traditionally been used in the field of thermofluids to provide insights into mass/energy distributions in response to complex transport phenomena. The non-dimensional Damkohler number, derived from the 1D reaction-diffusion equation, has classically been used to relate chemical reaction rates to mass transfer rates, providing an analytical estimate of the steady-state spatial distribution of reactants in a chemical system [5]. In this work, we explore the utility of adopting the Damkohler number to serve as a novel analytical tool for evaluating the steady-state gradients that arise for specific biomolecules in engineered tissues. Here, we utilize a cartilage TE model system, consisting of chondrocyte-seeded agarose constructs to examine: 1) the ability of the Damkohler number to quantitatively predict the 1D steady-state distribution of biomolecules in TE cartilage, and 2) the variation of Damkohler number and accompanied steady state concentration gradients in TE cartilage for a range of different classes of growth-stimulating biomolecules: nutrients (glucose), vitamins (ascorbic acid 2-phosphate (AAP)), protein hormones (insulin), and GFs (TGF- β 3, IGF-1, BMP-2).

METHODS

Reaction-diffusion equation analytical solution:

The steady-state 1D reaction-diffusion equation reduces to:

$$D \frac{d^2 C}{dx^2} - R_i C = 0 \quad (1)$$

where D : diffusivity, C : biomolecule concentration, R_i : consumption rate constant. The non-dimensional form of Eq. (1) reduces to:

$$\frac{d^2 \bar{C}}{d\bar{x}^2} - \pi \bar{C} = 0 \quad (2)$$

where $\bar{C} = \frac{C}{C_s}$; C_s : construct surface conc.; $\bar{x} = \frac{x}{L}$; L : tissue thickness;

Damkohler number (π) = $\frac{R_i L^2}{D}$. Solving for the boundary conditions (BC) to Eq. (2), where

BC1: $\bar{C} = 1$ when evaluated at $\bar{x} = 0$ and

BC2: $\frac{d\bar{C}}{d\bar{x}} = 0$ when evaluated at $\bar{x} = 1$, results:

$$C = C_s \frac{1}{1 + e^{2\sqrt{\pi}}} \left(e^{2\sqrt{\pi} - \sqrt{\pi} \frac{x}{L}} + e^{\sqrt{\pi} \frac{x}{L}} \right) \quad (3)$$

Damkohler number for growth stimulating biomolecules:

The Damkohler number (π) for each biomolecule in chondrocyte-seeded cartilage constructs was computed based on measures of diffusivity, chondrocyte-mediated consumption rate constant (R_i), and tissue thickness (prescribed at a conventional 3mm). Diffusivity values of biomolecules in 2% agarose scaffolds were adopted from the literature (glucose and AAP [4] and others [6]). R_i values were experimentally measured for cartilage constructs fabricated via immature bovine chondrocytes (30×10^6 cells/mL) seeded in 2% agarose. Here, small-size constructs ($\varnothing \times 1$ mm) were exposed to chondrogenic medium, consisting of glucose [4.5mg/mL], AAP [0.45mg/mL], and insulin [6 μ g/mL], and supplemented with either IGF-1 (10ng/mL), TGF- β 3 (10ng/mL), or BMP-2 (10ng/mL). The transient concentration decrease of each biomolecule in medium was monitored over 48h and curve-fit for R_i using a reaction-diffusion model and finite element model solver, as previously described [3].

Analytical model validation: Large-size constructs ($\varnothing \times 3$ mm) were exposed to CM supplemented with TGF- β 3 (10 ng/mL) for 5 days to reach steady-state conditions, as determined by FE analysis (not shown). Constructs were sub-punched, axially sectioned. Biomolecules in each section were buffer extracted and subjected to glucose assay or TGF- β 3 ELISA, yielding depth-dependent concentration profiles. Analytical model computed spatial gradients of glucose and TGF- β 3 were determined (Eq. (3)) using the diffusivity (D) and consumption rate constant (R_i) values given in Fig 2B.

RESULTS

Biomolecule gradient with respect to Damkohler number: The normalized biomolecule concentration \bar{C} versus normalized tissue depth \bar{x} in a TE construct was plotted for a wide range of Damkohler numbers ($\pi = 0.01$ -1000; Fig 1). Steady state gradient severity increases with π . For $\pi \leq 0.2$ gradients were largely absent. For $\pi > 10$, severe gradients were observed where the concentration at the construct bottom decays to a near zero value.

Damkohler number for growth stimulating biomolecules: Measured R_i for biomolecules varied by four orders of magnitude, ranging from $2.8 \times 10^{-7} \text{ s}^{-1}$ for insulin to $1.8 \times 10^{-3} \text{ s}^{-1}$ for BMP-2 (Fig 2A). Calculated Damkohler numbers also varied by four orders of magnitude, ranging from $\pi = 0.02$ to $\pi = 725$ (Fig 2B). Predicted steady-state gradients reflected these Damkohler numbers—modest gradients were observed for insulin and glucose, intermediate gradients for AAP and IGF-1, and severe gradients for TGF- β 3 and BMP-2 (Fig 2C).

Analytical model validation: Analytical model predictions of steady-state gradients of glucose and TGF- β 3 exhibited strong agreement with the experiment measures ($R^2=0.67$, $R^2=0.89$ respectively, Fig. 3).

DISCUSSION

This work advances the use of the nondimensional Damkohler number as a novel tool for estimating biomolecule concentration gradients in engineered tissues. Here we demonstrate that Damkohler number analysis can accurately predict the steady-state distribution of biomolecules in TE cartilage, allowing for a parametric analysis of concentration gradients of different classes of growth-stimulating biomolecules. An intriguing outcome of this analysis is the substantially elevated Damkohler number observed for TGF- β 3 ($\pi=53$) and BMP-2

($\pi=723$) GFs relative to glucose ($\pi=0.42$). Physically, this disparity arises from the combination of the significantly higher consumption rates and lower diffusivity of GFs relative to glucose—ultimately, these GFs are consumed by cells at a faster rate and replenished from the medium bath more slowly. This observation suggests that GF transport limitations may constitute the dominant contributor to heterogeneities of developing engineered tissues. This represents an unanticipated outcome given the primary focus of small nutrients in prior transport analysis investigations [4,7].

Damkohler number analysis can serve as an easy-to-implement analytical framework for identifying the dominant transport-limited biomolecules in a wide range of TE applications. This analysis requires measures of two easy-to-measure biomolecule parameters: D and R_i . D can be readily determined via transport characterizations of size-matched fluorescent tracers or estimated from prior literature characterizations in TE scaffolds. R_i can be determined by monitoring biomolecule depletion in culture media for small-sized, gradient mitigated constructs, as performed in this study. It is worth noting that curve-fitting of R_i was performed using an FE model to account for residual biomolecule gradients of GFs in small-sized tissues. However, future R_i measures can be performed on tissues with further reduced gradients (i.e., thinner tissues or cell monolayers), thus enabling curve-fitting with analytical models, thus avoiding need for FE models entirely. In the future, we envision that Damkohler analysis will guide the development of novel TE cultivation systems to optimize growth-stimulating biomolecule delivery, leading to control of engineered tissue composition and mechanics in order to improve their performance after clinical implantation.

VASCULAR CROSS-SECTION MORPHOMETRICS CAN PREDICT FIRST PASS OUTCOME OF MECHANICAL THROMBECTOMY FOR ISCHEMIC STROKE

INTRODUCTION

Large vessel occlusions (LVO) are associated with increased mortality and morbidity among stroke patients, bearing a high incidence rate of ~30% [1]. Mechanical thrombectomy has become a standard of care for LVOs [1]. In this method, a device (stent retrievers, aspiration catheters, or their combination) is navigated through a network of arteries to access the occlusion site in the neurovasculature and physically remove a blood clot. The primary goal of mechanical thrombectomy is to establish near-perfect reperfusion (indicated by an extended Thrombolysis in Cerebral Infarction, eTICI, score of $\geq 2c$) in one treatment pass, referred to as first pass effect (FPE) [1]. However, studies have demonstrated that mechanical thrombectomy only achieves FPE in ~29-40% of cases. When FPE cannot be not achieved, the treatment requires additional passes, and poses greater mortality and morbidity risks [1]. To improve thrombectomy outcomes, the underlying causes of first pass failure must be studied.

Several publications have demonstrated that the vascular morphology plays a critical role in procedural outcomes. Tortuosity and angulation have been the most studied characteristics to date, as reports have shown that it is difficult to maneuver stent delivery devices or to place aspiration catheters adjacent to (or in contact with) clots in tortuous vessels. Mokin et.al. measured the 3D tortuosity and angulation of vessels from the aortic arch to the terminal internal carotid artery (ICA), found that greater angulation was associated with longer procedure times due to difficulty in navigation. More recently, several studies have examined ICA tortuosity and its impact on thrombectomy outcome. While some studies identified an association between ICA tortuosity and reduced likelihood of FPE, none tested whether predictive models could be developed to predict FPE based on tortuosity alone. The existing literature tends to be either overly simplistic (only evaluating 2D morphology), limited in scope (only evaluating macro-scale characteristics like tortuosity), or limited in location (not investigating the vessels distal to the ICA). Moreover, most of the prior

work hasn't tested if morphological parameters could predict first pass outcome or if one treatment approach exhibited a greater success rate in tortuous vessels over another.

To our knowledge, no study has investigated quantitative measures other than tortuosity and angulation when analyzing 3D geometry of thrombectomy vascular pathways. In several medical specialties (e.g., congenital disorders), geometric morphometric analysis and feature engineering have demonstrated success in pinpointing subtle and highly informative anatomical differences that aid in disease assessment. Therefore, in this study, we aimed to investigate whether GMM could be used to more precisely identify regions associated with first pass failure, and if so, design new features that quantified informative vessel characteristics at cross-sections corresponding to these regions. Specifically, we also sought to test the predictive power of engineered cross-sectional features, relative to traditional measures (like tortuosity and angulation), through development and evaluation of machine learning (ML) models for classification of FPE and first pass failure.

METHODS

This study was approved by the institutional review board at the University at Buffalo (study 00005640). All methods were performed in accordance with the approved protocol. Pre-MT computed tomography (CT) angiography (CTA) and noncontrast CT (nCCT) images were retrospectively collected from patients undergoing MT by either stent retriever, aspiration, or a combined therapy between November 2018 and November 2019 at the Gates Vascular Institute in Buffalo, New York. Pre-MT and post-MT digital subtraction angiography were also collected. Patients considered for this study met the following inclusion criteria: (1) they had undergone MT for AIS because of an occlusive clot in the intracranial vasculature, (2) they had pretreatment (pre-MT) CT available with sufficient image quality and an identifiable clot, and (3) they had complete treatment outcome data. In total, 56 cases were considered; however, 6 were removed from

analysis, as portions of the ICA region could not be properly segmented.

We analyzed CTA and non-contrast CT (nCCT) from 50 anterior circulation stroke thrombectomy patients. A summary of our image processing and feature engineering pipeline is provided in **Figure 1**. As previously described, vessels and clots were segmented together and the vessel region about the occlusion was reconstructed [3]. Geometries were trimmed to the device path, from the base of the ICA through to the proximal portion of the M2 segment, and centerlines were extracted. All analysis was completed in *3d Slicer*. After segmentation, traditional metrics (vessel tortuosity, and angulation) were calculated from vessel centerlines that were transformed into the same coordinate system and same ROI through mirror reflection of vessels for cases featuring right-sided occlusions to align with left-sided cases. Univariate statistical analysis and geometric morphometrics (GMM) were used to explore differences in geometry between cases that did and did not achieve FPE, which traditional metrics could not discern. To describe these differences complex cross-section features were engineered and quantified using a semi-automatic pipeline. These features were preliminarily ranked using univariate statistics and correction for multiple testing based on their ability to differentiate between cases that did and did not achieve FPE.

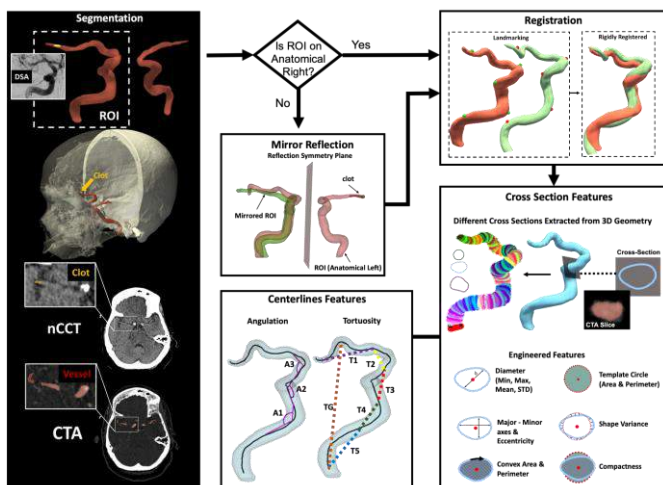

Figure 1: Image processing and feature engineering pipeline for quantification of vascular cross-sections from pre-treatment CT.
Figure adapted from Sarayi and Santo et al. SVIN, 2022.

ML was used to train predictive models of FPE based on significant cross-section features. Feature selection was completed using recursive feature elimination (RFE), while hyperparameter tuning and model evaluation were completed using stratified, 5-fold cross-validation over 50 randomizations. Evaluated classifiers included support vector machine (SVM), logistic regression (LR), extreme gradient boosting (XGB), and artificial neural network (ANN). Classification performance was summarized as accuracy, area under the receiver operating characteristic curve (AUC), and F1-Score.

RESULTS

Our data set was balanced across demographic, treatment, and stroke presentation. Overall, 48% of patients were women (n=24) and the mean age of the population was 71.1 years (SD=13.1 years). Average National Institutes of Health stroke scale at presentation was 16.1 (SD=7.6), and the thrombectomy techniques used included stent retriever (n=9, 18%), aspiration (n=9, 18%), and Solubra (n=32, 64%). A total of 54% (n=27) of occlusions occurred on the left and were

primarily located at M1 (n=27, 54%), the ICA/M1 junction (n=5, 10%), and M2 (n=18, 36%). The frequency of FPE was 42% (n=21).

With respect to standard tortuosity and angulation measures, only one local tortuosity metric was significantly different ($q=0.019$) between FPE and first pass failure cases. The most significant Principal Component score ($q=0.012$) from GMM highlighted M1 and upper Cavernous ICA variation as morphological indicators of first pass outcome. 15 cross-section features, corresponding to ICA and MCA regions, and selected through RFE, were significantly different between cases that did and did not achieve FPE. Each of these cross-section features was mapped back to patient vessels for clinician interpretation (**Figure 2**) and were described as caliber changes at critical locations in the device path as well as the clot region itself, aligning with the theory that clot properties also affect device success. Classifiers exhibited strong prediction of FPE, with the best model (SVM) achieving an $AUC=0.98\pm0.05$. All classifiers trained using cross-section features far outperformed complementary trained using traditional tortuosity and angulation features alone.

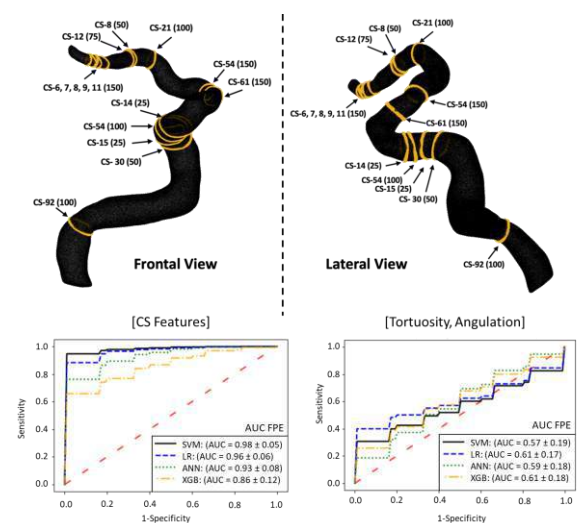

Figure 2: Models trained with cross-section features demonstrated superior performance to those trained using standard measures.
Figure adapted from Sarayi and Santo et al. SVIN, 2022.

DISCUSSION

In conclusion, computational analyses enabled us to develop and test a novel set of cross-section features that can predict FPE with high accuracy and highlighted important local changes in the thrombectomy device path. Our results not only showed that vessel cross-section features are better morphological indicators than the current standard, but also suggested that for patient-specific cross-sectional geometries, particular thrombectomy techniques are associated with greater likelihood of FPE. Anatomically-informed feature sets, such as the developed cross-sections, are clinically interpretable and may be applied in patient-specific, data-driven intervention techniques.

PULSE WAVE VELOCITY INCREASES WITH EXTENDING THE LENGTH OF VASCULAR STENT-GRAFTS

Ramin Shahbad (1), Anastasia Desyatova (1)

(1) Department of Biomechanics, University of Nebraska Omaha, Omaha, Nebraska, USA

INTRODUCTION

A vital characteristic of the aorta is elasticity. This feature of elastic arteries plays a pivotal role in maintaining blood pressure and blood flow at a stable rate [1]. Several studies on aortic hemodynamic properties have reported an increase in arterial stiffness (i.e., a decrease in elasticity) in patients with the aortic disease who have experienced endovascular aortic repair [2]. Multiple evidence accumulated from recent studies reveals a consistent association between stent-graft deployment and aortic stiffening in the long term [3]. Aortic stiffening is now accepted as one of the most critical self-reliant predictors of cardiovascular morbidities and mortalities. Therefore, understanding the effects of stent grafting on aortic compliance and cardiac hemodynamics may play a key role in either improving the design of current stent grafts or developing a new generation of stent-graft to protect the heart and aorta from these complications.

Stent-graft factors thought to be influencing aortic stiffness have been explored in several studies. However, there is a current paucity of studies focusing specifically on the contribution of stent-graft length in aortic stiffening. The present study aimed to address this discrepancy and investigate the effect of stent-graft length on vascular conduit stiffening by measuring the pulse wave velocity (PWV) in a mock flow loop.

METHODS

Mock flow loop setup. In this study, a custom-made mock flow loop has been built in conjunction with a pulsatile pump system to replicate human blood circulation. As shown in Figure 1, this mock loop consists of two main components: a pulsatile pump with a heart function emulator (HFE) and an afterload system based on a three-element Windkessel model. The pulsatile pump and heart function emulator serve as the left ventricle and supply pulsatile flow to the loop. The afterload system is a lumped model of the arterial system and imitates

the load on the heart. It includes a compliance chamber, a resistant valve, and a resistor that mimics the total arterial compliance, peripheral resistance, and characteristic impedance, respectively.

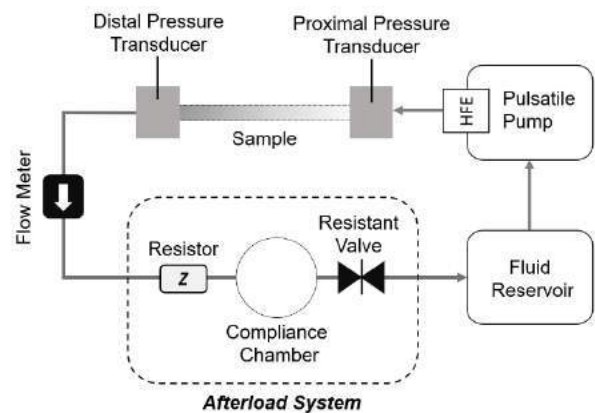

Figure 1: A schematic illustration of the developed mock loop.

Models. The human aorta was approximated as a silicone tube with tuned mechanical and geometrical properties to achieve the pulsatility of young human aortas. Four identical 320mm silicone aortas were used in this study (shore 20A). These mock vessels were connected to tee-shape connectors and placed between the pump and the afterload system. The flow and cardiac cycle rates were set at 2.5 L/min and 60 bpm, respectively, to imitate the physiological condition of the abdominal aorta. To perform all experiments at the same hemodynamics conditions, proximal pressure at baseline conditions was targeted at ~120/100/80 mmHg, representing the systolic, mean, and diastolic

pressures, respectively. Pressure data were recorded at proximal and distal locations (Figure 1) using two digital pressure transducers for about 30 continuous stable pulse waves. Upon the completion of data recording for baseline condition, a 40mm long stent graft with a diameter of 20mm was deployed in the silicone aorta. These stent grafts were made by sewing a P5010 Palmaz biliary stent and a Maquet Hemashield Platinum vascular graft. The proximal and distal pressures were recorded for 30 cycles in this condition. The stent graft was then extended with a second and a third 40mm stent grafts to 80mm and 120mm lengths. Pressure data were recorded for each of these conditions as well. When the stent grafts were deployed in each step, the pressure transducers and fluid level in the compliance chamber were calibrated and adjusted as necessary to ensure that the flow and pressure conditions of the system were the same in every situation.

Pulse wave velocity measurements. Pulse wave velocity (PWV) is an arterial hemodynamics parameter that refers to blood flow velocity through the circulatory system and provides information regarding the artery's mechanical characteristics. Since PWV is positively associated with arterial stiffness, it is commonly measured and used as an indirect quantification of arterial stiffness and risk assessments [4]. Before PWV measurement, a low pass fifth-order Butterworth filter with a cutoff frequency of 5 Hz was used to smooth out the high-frequency noises associated with pressure transducers. PWV was calculated for all four samples based on pressure pulse waves and using the intersecting tangent algorithm, which is the most reliable technique among others. In this technique, the line with the steepest slope at the systolic upstroke part of the wave was intersected with the line passing through the foot of the wave, and the intersection point was chosen as the reference point. PWV was computed as the wave traveling distance (distance between pressure transducers) divided by wave travel time (time delay between the reference points) (Figure 2).

Figure 2: A pressure wave sample at two proximal (blue) and distal (red) sites and the principle of calculating wave travel time via intersecting tangent algorithm.

RESULTS

The PWV was calculated for all four conditions of each mock aorta using the intersection tangent algorithm. The PWV was obtained at $6.81 (\pm 0.41)$ m/s for aortas without stent grafts (baseline), $7.52 (\pm 0.42)$ m/s for aortas with 40mm long stent-grafts, $8.365 (\pm 0.37)$ m/s for aortas with 80mm long stent grafts and $9.98 (\pm 0.87)$ m/s for aortas with 120mm long stent grafts (Figure 3). A single-way ANOVA was conducted to compare the effect of stent graft length on PWV. Comparisons were made among baseline, 40mm, 80mm, and 120mm

stent graft conditions. There was a significant difference in PWV among the different lengths of stent grafts at the $p < 0.05$ level for the four groups $F = 23.60$ and $p = 2.54E-05$. Tukey's HSD post hoc test results revealed that in four conditions, including baseline-80mm stent graft, baseline-120mm stent graft, 40mm-120mm stent graft, and 80mm-120mm stent graft, the latter had significantly higher PWV compared to the former. There was no significant difference in PWV between the baseline-40mm stent graft and 40mm-80mm stent graft conditions.

Figure 3: PWV values for different number of stent grafts.

DISCUSSION

Though several studies have revealed the responsibility of stent-graft factors in aortic stiffening, the effect of length is still unclear. The main result of the present study is that in the same pressure condition, PWV increased significantly by increasing the length of stent grafts. This result is in line with the previous experimental studies, which found higher PWV associated with deploying stent grafts [5]. This finding may be explained by the fact that PWV is a measurement method directly related to the modulus of elasticity of the aortic wall and aortic distensibility. The deformation range of the aorta in the circumferential direction decreases in the region where the stent graft is implanted. Increasing the length of the stent graft will reduce the distensibility of the aorta for a more extended length. The lower pulsatility of the aorta is associated with increased stiffness and impedance resulting in rapid propagation of forward waves, reflected waves, and higher PWV.

The main limitation of this study is that, instead of the actual human or porcine aorta, the project used mock vessel samples made from silicone rubber. The silicone rubber's mechanical behavior and compliance have been tested and shown to be in the range of human aorta tissue properties within the range of 60-69 years old. However, due to the high non-linearity in young aorta characteristics, it cannot cover young aorta tissue properties with lower stiffness than aged ones.

RATE EFFECTS AND MATERIAL CHARACTERIZATION OF SKIN DURING PUNCTURE

Joseph S. LeSueur (1), Frank A. Pintar (1,2)

(1) Joint Department of Biomedical Engineering, Marquette University & Medical College of Wisconsin, Milwaukee, WI, USA

(2) Department of Neurosurgery, Medical College of Wisconsin, Milwaukee, WI, USA

INTRODUCTION

As the primary mechanical barrier between the internal and external environment, skin functions to prevent puncture and penetration [1]. In military and law-enforcement environments, protective armor may reduce the likelihood of penetrating debris from blast events [2]. However, to develop effective protection, the failure thresholds of skin during penetration must be known.

The mechanical properties of skin have been thoroughly studied in indentation, suction, and tensile testing [3], but limited attention has been given to high-rate, traumatic failure of skin during puncture [4], stabbings [5], and ballistic impact [6]. Dynamic loading rates have shown to increase the stiffness response of skin in tension due to viscoelastic properties [3]. In previous puncture studies, skin simulants were used as surrogates to reduce variability but lacked representative boundary conditions of anisotropic, viscoelastic skin with natural pre-tension [4,5]. To accurately simulate the mechanical behavior of skin, hyperelastic constitutive models [1,3] and 3D digital image correlation (DIC) have been utilized for development and validation of computational models [7].

The purpose of this study was to experimentally characterize rate effects in puncture of skin and provide 3D-DIC surface strain maps for implementation and validation of computational models.

METHODS

Frozen porcine tissue was thawed at 4°C for two days. Skin samples were cut into discs of diameter 97.6 ± 6.8 mm with a smooth layer of adipose tissue ($n = 72$). A circle of diameter 25.0 ± 0.47 mm was stamped onto the center of the skin during its relaxed state. To achieve a state of natural tension determined from previous experiments, the skin was biaxially stretched with pulleys on a custom apparatus, and the circle was measured again to determine major (30.9 ± 15.3 %) and minor strain (13.4 ± 10.6 %). After testing, cutis thickness (epidermis and dermis: 2.13 ± 0.52 mm) and total sample

thickness (epidermis, dermis, and adipose: 4.55 ± 1.79 mm) were measured with digital calipers adjacent to the puncture site.

An electrohydraulic piston actuator with an attached load cell, LVDT (MTS) and a uniaxial accelerometer (DTS) provided deformation of the skin and recorded force, displacement, and acceleration at 20 kHz; acceleration was filtered with an SAE class 180 low-pass Butterworth filter. A custom tapered impactor with a 5 mm stainless steel spherical end was fixed to the load cell. With constant biaxial pre-tension, the skin was preconditioned to a displacement of 15 mm for eight trials then clamped with a custom ring clamp. Sub-failure trials were conducted to a displacement of 15 mm at 50 and 500 mm/s, allowing the sample to recover between runs. Finally, a failure trial was performed at a rate of 5, 50, 500, or 5000 mm/s.

3D digital image correlation (DIC) was performed using two high-speed cameras (NX-Air series, IDT) at sampling rates up to 4230 Hz for 13 failure runs to measure local surface strains during puncture. A black speckle pattern was randomly applied using a custom 3D-printed stamp with micro-projections to the adipose surface of the specimen. Maximum, minimum, and mean principal strains were calculated with a median spatial filter of 5 pixels (GOM Correlate Pro, Trilion).

To calculate the resistive force of skin, inertial effects were accounted for by subtracting the inertial force, derived from acceleration and load cell mass, from the total force measured by the load cell. Engineering stress and strain of the clamped skin sample were calculated from piston force and displacement measurements.

Two trials were excluded due to mechanical damage during sub-failure runs since 1) the second sub-failure run resulted in a reduction of maximum force greater than 5% of the failure force, and 2) strain energy of the second sub-failure run decreased by more than 10% from the first sub-failure run. Strain energy was calculated by computing the area under the force-displacement curve from 0 to 13 mm displacement.

Paired t-tests were performed to determine significance of loading rate for strain energy between the failure and two sub-failure runs on the

same skin sample. A generalized linear mixed model with repeated measures for pig specimen was developed to determine significant variables and predict strain energy at failure (SPSS, IBM). Utilizing a hyperelastic constitutive model, first-order Ogden coefficients were determined by curve fitting experimental stress-strain data and averaged for all trials by strain rate using Hyperfit software (Equation 1).

$$\Psi = \sum_{p=1}^N \frac{\mu_p}{\alpha_p} (\lambda_1^{\alpha_p} + \lambda_2^{\alpha_p} + \lambda_3^{\alpha_p} - 3) \quad (1)$$

where Ψ is strain energy density, λ is strain, and μ and α are constants.

RESULTS

The 500 mm/s sub-failure run resulted in significantly greater ($p < 0.001$) average strain energy (0.272 ± 0.029 J) compared to the 50 mm/s sub-failure run (0.191 ± 0.012 J). Higher loading rates between sub-failure and failure runs resulted in significantly greater strain energy at 13 mm displacement ($p < 0.001$), except for 50 mm/s sub-failure and 5 mm/s failure ($p = 0.084$). For sub-failure and failure runs at the same loading rate, two-tailed paired t-tests resulted in non-significant differences in strain energy for 50 mm/s ($p = 0.047$) and 500 mm/s ($p = 0.096$) with an alpha of 0.01. For loading at the same rate, failure trials always had greater average strain energy than sub-failure trials.

For prediction of strain energy at failure, the generalized linear mixed model resulted in significant effects ($p < 0.01$) for major tension, minor tension, cutis thickness, total sample thickness, sample mass, and failure rate. The model predicted failure strain energy values of 1.73, 1.80, 2.32, and 1.88 J for 5, 50, 500, and 5000 mm/s loading rates, respectively, with fixed average values of 32.0 %, 14.1 %, 2.1 mm, 4.6 mm, and 48.2 g for major tension, minor tension, cutis thickness, total sample thickness, and sample mass, respectively.

Average force-displacement curves were generated to show effect of loading rate (Figure 1).

Figure 1: Force-displacement during skin puncture at varying loading rates to failure

A one-term Ogden constitutive model was used to quantify the material behavior of skin subjected to puncture with all R^2 values greater than 0.97. Ogden coefficients were averaged for loading rates of 5, 50, 500, and 5000 mm/s, which represented strain rates of 0.15, 1.5, 15, and 150 s^{-1} , respectively (Table 1).

Table 1: One-term Ogden coefficients for varying strain rate

Strain Rate	μ_1	α_1	R^2
0.15 s^{-1}	0.0095 ± 0.0049	13.04 ± 2.9	0.990 ± 0.004
1.5 s^{-1}	0.0113 ± 0.0045	12.88 ± 3.37	0.990 ± 0.006
15 s^{-1}	0.0128 ± 0.0029	13.03 ± 3.37	0.990 ± 0.004
150 s^{-1}	0.0225 ± 0.0086	10.19 ± 1.31	0.978 ± 0.008

Since 3D-DIC displacement was measured on the bottom of the specimen, maximum surface displacement (13.78 ± 2.29 mm) was compared to piston displacement minus total sample thickness (13.58 ± 2.76 mm). A paired t-test determined the displacement measurements were not significantly different ($p = 0.71$) and resulted in a root-mean-square error (RMSE) of 1.80 mm. The maximum principal strain map with directional vectors was computed for each trial (Figure 2). For the 13 failure trials, the average maximum principal strain (33.71 ± 8.30), average mean principal strain (14.60 ± 4.69), and average minimum principal strain (-12.93 ± 5.99) were computed. The average engineering strain (23.29 ± 4.55) served as an approximation for the global strain of the skin, whereas maximum principal strains were localized to the area in contact with the impactor.

Figure 2: Representative 3D-DIC maximum principal strain map on the adipose surface of the specimen near puncture

DISCUSSION

Rate-dependency was shown in strain energy between sub-failure and failure puncture runs. Similarly, Ottenio et al observed an increase in strain energy and ultimate strength with increased strain rates up to 167 s^{-1} in tensile testing of cadaveric human skin [8]. Trotta et al reported increased elastic modulus, slightly increased ultimate strength, and decreased stretch at failure for dynamic tensile tests of porcine scalp up to strain rates of 100 s^{-1} [9]. Analogous to previous material characterizations of skin [10,11], an Ogden one-term constitutive model was sufficient with all R^2 values greater than 0.97.

Due to mass compensation from inertial effects, the 5000 mm/s force-displacement curves exhibited a more rounded failure region compared to a linear stiffness region in slower rates, which may have resulted in decreased ultimate strength. 3D-DIC and piston displacement measurements were not identical since the skin experienced some compression during puncture.

Rate-dependency was observed in strain energy during dynamic puncture of skin. Ogden material model coefficients and a 3D-DIC principal strain map were presented for development and validation of a computational model of skin during penetration.

INTRODUCTION

The determination of stroke etiology, which is mainly defined by the Trial of Org 10172 in Acute Stroke Treatment (TOAST) score, is critical for preventing secondary strokes, which have a recurrence rate of 11% and 26% at 1 and 5 years, respectively. Typically, secondary stroke prevention relies on mitigating the underlying cause of clot generation. For example, strokes of cardioembolic (CE) origin are treated with anticoagulation, while large artery atherosclerotic (LAA) strokes undergo revascularization surgery, and lacunar strokes can be treated with lifestyle changes and antiplatelet therapy. Unfortunately, 30-40% of all cases remain cryptogenic [1]. The increased use of mechanical thrombectomy has enabled wide-spread investigation of resected clots, and opened the door to the promise of new methods for diagnosing stroke etiology through biological analysis of the retrieved tissue. To date, many histological studies have found that clot percent composition of fibrin/platelet (FP), red blood cell (RBC), and white blood cell (WBC) components are associated with etiology [2], and thus may be biomarkers of stroke subtype. However, this body of work has been plagued with conflicting findings [3], and reports of no histologic association with etiology.

We believe that additional information is likely needed for stroke diagnosis from analysis of retrieved clots. This led us to hypothesize that the complex molecular biology and cellular architecture of the clot, rather than mere percent composition, may provide important biologic insights into stroke etiology. To this end we have begun to explore both the molecular biology and histological structure and makeup of ischemic stroke blood clots. Recently we have performed next generation RNA sequencing and gene expression analysis on clot RNA to identify expression differences between each TOAST classes and determine expression patterns that are characteristic of each etiology. Concurrently, we have developed state-of-the-art computational histopathology pipelines to quantify spatial distribution of clot components and their relation to one another. In particular, a validated

nucleotyping pipeline was implemented to characterize white blood cell (WBC) populations in each clot.

With the goal of developing etiology-specific biomarkers, we are now investigating whether paired clot transcriptomics and H&E histologic image features can be used to identify robust WBC image-omic correlates using canonical correlate analysis (CCA).

METHODS

This study was approved by the Human Research Institutional Review Board at the University at Buffalo (STUDY00002092). All methods were carried out in accordance with the approved protocol and written informed consent was obtained for all subjects. Clot samples were collected from patients receiving MT between November 2018 and December 2022 at the Gates Vascular Institute in Buffalo, NY. Clot fragments retrieved from intracranial locations were studied if they were of sufficient size and quality for histopathology (if multiple fragments were collected, the largest one was studied). Cases were excluded if they received intraarterial tissue plasminogen activator. Stroke etiology was defined using the trial of TOAST score. A combination of clinical features and results of ancillary diagnostic studies were used to classify each clot into 5 subtypes: large artery atherosclerosis (LAA), small-vessel occlusion, cardioembolic (CE), stroke of other determined etiology (OTH), and undetermined etiology or cryptogenic (CR).

We analyzed paired H&E histology and transcriptome data from 31 clots (LAA=5; CE=18; OTH=3; CR=5). A published computational pipeline for WBC segmentation and characterization was used to quantify 46 image features (e.g., textures representative of heterochromatin-euchromatin ratio) from >100,000 WBC instances. Features were used to classify WBCs into 1 of 10 validated classes and calculate clot class frequency distributions. To test associations among image features and expression data we used SparseCCA (significance defined by Pearson's $R \geq 0.4$ and $p < 0.01$). First, we tested the strength of correlation between canonical covariates (transformed WBC image and

expression features), and found that canonical covariates (e.g., histology canonical variate [CV] 1 and transcriptome CV1) were strongly and significantly correlated ($R>0.9$, $p<0.001$). Gene ontology (GO) enrichment analysis was used to identify biological process (BP) ontologies associated with positively correlated genes for each etiology.

RESULTS

In pairwise correlation analysis between CVs and original dataset features (e.g., to identify original WBC image features captured in histology CV1) we found 3 canonical covariates that were highly enriched in LAA (CV6), CE (CV14), and OTH (CV17). In LAA, WBC Class 1 was representative of cells that were primarily leukocytes. Gene ontology enrichment analysis of positively correlated genes supported this interpretation, as it indicated significantly ($q<0.05$) greater T-cell regulatory mechanisms and cytokine production. In CE, we observed granulocyte enrichment in both the histology (WBC class 9, neutrophils and other eosin-rich granular structures) and positively correlated genes. Lastly, in OTH, we found histologic enrichment of WBC Class 3 (WBCs embedded in RBC clot regions) was highly positively correlated with genes involved in heme biosynthesis. Enriched WBC classes were also found to be significantly different among TOAST groups based on a final ANOVA analysis, supporting the potential application of the WBC image and expression feature pairs as etiology biomarkers: WBC Class 1 ($p=0.035$), WBC Class 9 ($p=0.001$), and WBC Class 3 ($p=0.047$). The image-omic correlates enriched in each etiology aligned well with the results of our prior study, with T-cells enriched in LAA, Granulocytes enriched in CE, and RBC constituents enriched in OTH.

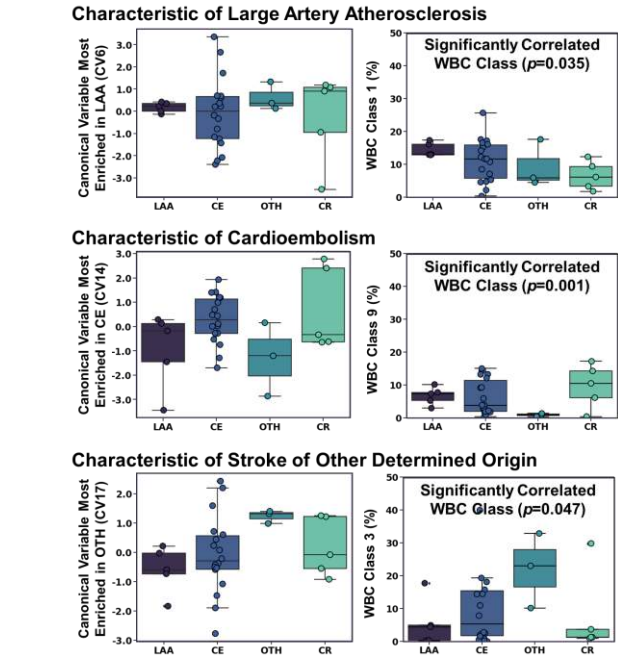

Figure 1: Enriched WBC image and expression features among TOAST classes. Top Row). Canonical covariate (CV) 6 was significantly enriched in LAA, with WBC Class 1 in histology. The frequency distribution of WBC Class 1 was significantly different among TOAST classes ($p=0.035$). Middle Row). CV14 was enriched in CE and found to represent neutrophils on histology (WBC Class 9, $p=0.001$ among TOAST groups). Bottom Row). In OTH, CV17 was significantly enriched and represented WBCs embedded in RBC-rich regions of thrombi, Class 3. Figure adapted from Tutino et al., WNS, 2022.

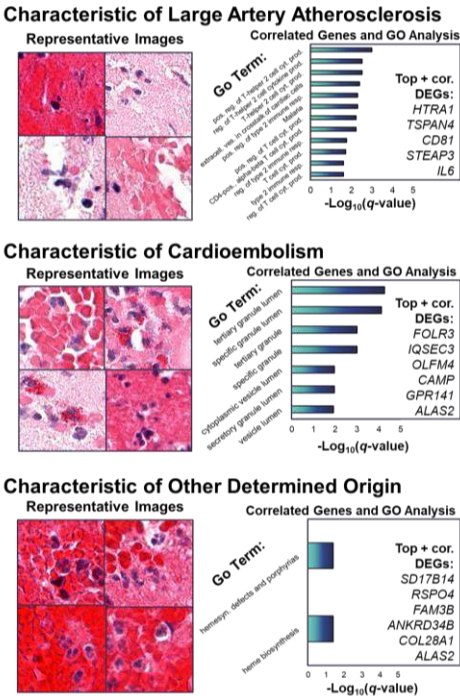

Figure 2: Enriched WBC image and expression features among TOAST classes. Top Row). For CV6, there was high correlation of histology with T-Cell GO biological processes. Middle Row). For CV14, polymorphonuclear cells corresponding to neutrophils are readily apparent among eosin-rich granular structures. These WBCs were positively correlated genes related to granule enzymes. Bottom Row). For CV17 WBC Class 3 was highly correlated with heme biosynthesis. Figure adapted from Tutino et al., WNS, 2022.

DISCUSSION

CVs were strongly and significantly correlated ($R>0.9$, $p<0.001$). Pairwise correlation of CVs and original feature sets showed the most enriched CVs in LAA (CV6, top row of Figures), CE (CV14, middle row of Figures), and OTH (CV17, bottom row of Figures). These represented distinct WBC subtypes on histology and unique GO signatures. LAA clots had enrichment of leukocytes (and greater T-cell regulation and cytokine production), while CE clots had granulocyte enrichment, and OTH clots had many WBCs embedded in RBC-rich regions with greater heme biosynthesis. Through joint analysis of clot histology and gene expression data, we engineered and validated unique structure-expression covariates that are highly correlated, biologically interpretable traits with practical application. While seldom studied, computational investigations of histomics and transcriptomics in stroke are rapidly developing. We hope our findings motivate continued research to develop biological markers of stroke etiology. Together, computational biomarkers and routine clinical data (workups and imaging) will facilitate robust identification of stroke etiology, reducing cryptogenic diagnoses and aiding secondary stroke prevention efforts.

INTRODUCTION

Cardiovascular patient-specific modelling aims to recreate vascular anatomies with the goal of improving diagnosis and optimizing clinical treatments [1]. In the study of pathologies such as thoracic aortic aneurysm, a patient-specific model should integrate the tissue material properties [2] and the zero-pressure state of the vessel [3] and should consider the interaction of the aorta with the surrounding structures, especially the spine and soft tissue [4]. The importance of including the aortic root motion and its role in increasing the wall stress has already been described in [5]. A first approach to calibrate the mechanical boundary conditions (BCs) presented in [4] exploiting multi-phase CT and a 3-parameter Windkessel model was presented in [6].

In this work, we describe a procedure to tune 4 parameters governing the mechanical BCs of a thoracic aorta (TA) model considering the displacement due to heartbeat at the level of the aortic annulus. The mechanical BCs we introduced consist in a set of visco-elastic components (Robin BCs) representing the support provided by the soft tissue and able to reproduce the interaction of the aorta with the spine. The model, which also involves the whole area of the Valsalva sinuses and includes the modeling of the aortic valve, accounts for the zero-pressure state. Exploiting information on the position of the aorta from a set of 2D cine-MRI sequences, we tune the parameters governing the BCs to obtain an improved correspondence between the displacement of the simulated model and that derived from the images.

METHODS

The procedure, here applied for a single TA geometry, consists of two steps: in the first one, we manually segmented a MRI-Angiography dataset to obtain the anatomies (Fig. 1a) and 11 cine-MRI sequences to extract the aortic boundaries during 25 different cardiac phases. We performed then a rigid-wall computational fluid-dynamic (CFD) analysis coupled with a 0D closed loop, whose lumped parameters were calibrated following what reported in [7, 8], to extract the pressure field

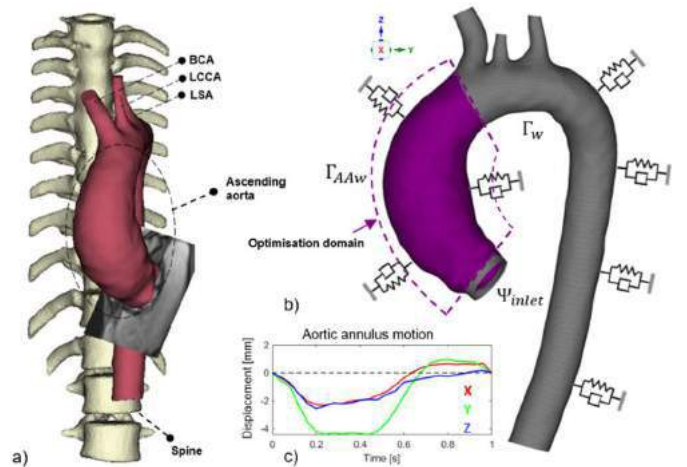

Figure 1: a) The segmented aorta and spine. b) The structural model. c) The displacements imposed at the inlet boundary.

at the aortic wall $P_w(t)$. Besides, we created the structural model (Fig. 1b) and from cine-MRI tracked the motion of the annulus deriving its displacement in space: $Dx(t)$, $Dy(t)$ and $Dz(t)$ (Fig. 1c). Concerning the mechanical BCs, we connected each i -node of the wall Γ_w to three dampers and springs, each for a j -direction of the space. The stiffness of each spring was defined as:

$$K_{ji} = K_{ST} + W_{di} W_j K_{SPINE} \quad (1)$$

where K_{ST} was the first sought parameter representing the stiffness of the soft tissue, W_j the weight to be optimised for each j -direction of the space, $K_{SPINE} = 10^6$ Pa/m the stiffness linking the aorta to the spine [9] and W_{di} the scaling factor to represent the distance to the vertebrae:

$$W_{di} = 1 - \alpha \frac{d_i}{d_{\max}} \quad (2)$$

with $\alpha = 0.95$, \mathbf{d} the vector containing the minimum Euclidean distance of each node to the spine and $d_{\max} = \max(\mathbf{d}) = 142$ mm.

In the second step, with the aim of minimising a cost function described below, we performed an iterative procedure, computing each time a new zero-pressure model and running a structural simulation with $P_w(t)$ applied at Γ_w and $D_x(t)$, $D_y(t)$ and $D_z(t)$ at the inlet boundary Ψ_{inlet} . Starting with $\mathbf{p}^0 = [W_x^0, W_y^0, W_z^0, K_{ST}] = [1, 1, 1, 10^5 \text{ Pa/m}]$ and using Levenberg-Marquardt, we minimised the following loss function:

$$f(\mathbf{p}) = \sqrt{\sum_{\varphi} \sum_{l=1}^m \sum_{k=1}^{n_l} |d_{l,k}^{\varphi}(\mathbf{p})|^2} \quad (3)$$

where $\varphi = 25$ was the number of cine-MRI frames from which we retrieved the motion of the ascending aorta wall Γ_{AAW} , $m=11$ the number of splines from the full 2D dataset, n_l the number of points for the l -spline and $d_{l,k}^{\varphi}(\mathbf{p})$ the nearest neighbour distance of each k -point belonging to the l -spline and all the points of the spline derived from the intersection between the cine-MRI plane and the deformed aortic model. Four additional initial guesses were selected to verify each time the minimum reached.

RESULTS

The calculation took 32 hours in total. The loss function $f(\mathbf{p})$ was reduced from 0.343 m to 0.227 m (34%) after 19 iterations. The value of the parameters at the end of the calibration was $\bar{\mathbf{p}} = [0.6, 0.02, 0.04, 1.5 \times 10^4 \text{ Pa/m}]$. The values of the cost function, the maximum and mean neighbour distance, normalised with the corresponding value at the first iteration, are shown in Fig. 2. In addition, the same figure shows the baseline model related to the first iteration and the final calibrated model with the splines used to compute the distance at the systolic peak. The relative displacement of the computational grid in systole compared to the configuration in late diastole is shown in Fig. 3 for the model simulated with the initial parameters from \mathbf{p}^0 and the calibrated model.

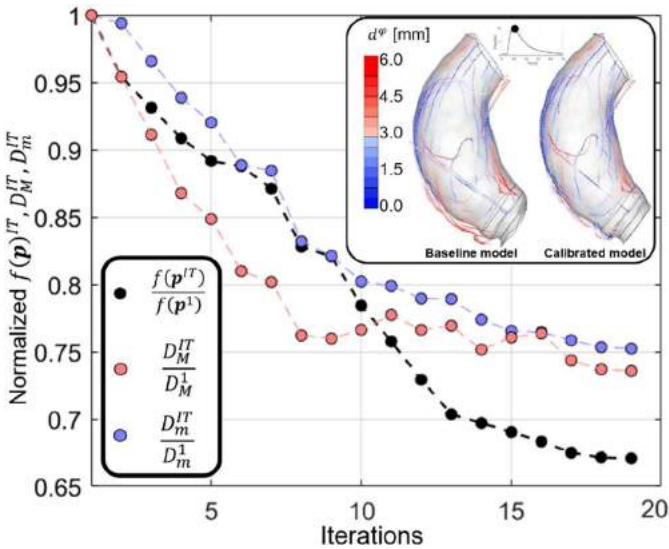

Figure 2: Normalized loss function $f(\mathbf{p}^{IT})$, maximum (D_M^{IT}) and mean (D_m^{IT}) neighbour distance for each of the iterations of the Levenberg-Marquardt optimisation. The top right-hand box shows the splines with which the calibration is performed.

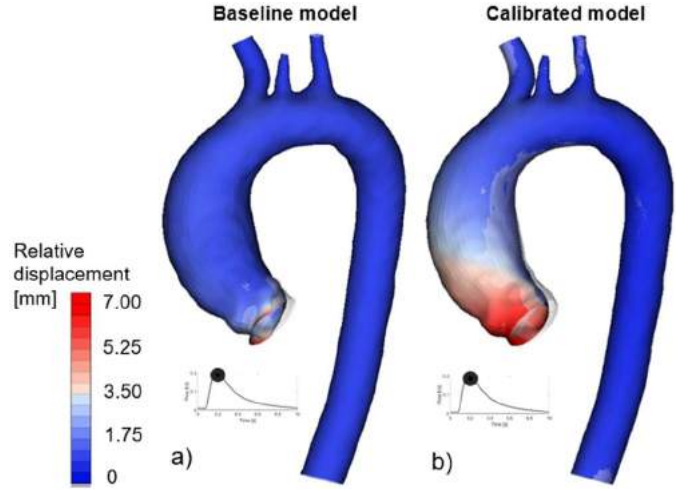

Figure 3: Relative systolic-diastolic displacement contours for a) the model with non-calibrated parameters and b) the tuned model.

DISCUSSION

In this work, we proposed a method to tune 4 parameters governing the mechanical boundary conditions of a thoracic aorta model. As shown in Fig. 2, the loss function (3) could not be reduced to 0 because the full set of mechanical BCs was controlled by only 4 variables. Fig. 3 shows how the baseline model was strongly constrained and the motion applied at the level of the annulus was propagated exclusively to the nearest elements up to the central part of the Valsalva sinuses. For the calibrated case, on the other hand, it was the entire ascending aorta that absorbed the impulse caused by the heart muscle. Although cine-MRI was here used, this workflow can be repeated with every image set that considers dynamic acquisitions during the cardiac cycle, such as multiphase-CT or even 4D-Flow MRI. To ensure the robustness of this procedure, it should certainly be extended to more patients. Combining mechanical BCs parameters with shape parameters derived from statistical shape modelling (SSM) and building reduced-order models (ROMs) could be one of the keys to exploit patient-specific models in clinical practice.

INTRODUCTION

Tissue engineering is recognized as a translational approach to replacing damaged tissue or whole organs. However, it faces challenges preventing the successful repair or replacement of biomechanically functioning tissues. Low mechanical integrity is a crucial problem faced during the clinical translation of these constructs¹. Understanding the relationship between changes in microscopic structure and macroscopic mechanical response provides insight into biological function, which can help in the design of new biomaterials and enable monitoring of changes during biomaterial fabrication and deformation^{2,3}. Within these constructs, collagen fiber and cell compaction often produce local mechanical stress, which influences the structure and mechanical behavior of the engineered tissues⁴. Since the orientation of cells and collagen fibers is essential for proper tissue functioning, several studies have focused on estimating the alignment of cells and collagen fibers. However, some of these techniques are limited in their widespread application since they are incompatible with hydrated tissue or are destructive.

To overcome the limitations of previous techniques, our research group is using a polarized Raman spectroscopy (PRS) method, which provides advantages such as label-free preparation, high molecular specificity, non-contact, non-invasive, real-time imaging of cell-laden scaffolds under normal physiological conditions, and good compatibility with hydrated tissue^{5,6}. Raman spectroscopy is a spectroscopic technique that is typically used to determine the vibration modes of molecules⁷. Since Raman spectra can be collected for a small volume of samples (less than 1 μm in diameter), are insensitive to aqueous absorption bands, and can be used on live cells, it is suitable for testing cells and proteins. In addition to identifying chemical composition, polarization effects on Raman spectra can provide information on the orientation of molecules in anisotropic materials and single crystals. In this study, we are using noninvasive polarized Raman spectroscopy combined with computational modeling to quantify the

alignment in engineered tissue constructs. Such tools can be used to non-destructively evaluate whether engineered tissue constructs approach the same structure as native tissues.

METHODS

Engineered tissue constructs: 1-mm thick polymer molds were fabricated using polydimethylsiloxane (PDMS). Selective functionalization of the surface of two anchorage wings increased the adhesion strength between the hydrogel and the PDMS mold. A microtissue precursor solution was prepared by mixing high-concentration rat tail collagen type-I (Corning) with 0.2% acetic acid (Glacial, Fisher Scientific), Matrigel (Corning), 10x DMEM (Sigma), HEPES (Gibco) solution, and phosphate buffered saline (PBS). The precursor solution contained a 4 mg/ml final concentration of Collagen I and 10% v/v of Matrigel. The precursor solution for the two parts (wings and central part) was separated. C2C12 myoblasts were gently admixed to the precursor solution for the central part until it reached a density of 5.0×10^5 cells/ml. Then, to ensure an equivalent Collagen I concentration of 4 mg/ml in the central part and wings, the volume of the wing's precursor solution was adjusted using PBS according to the volume of myoblasts added (Figure 1).

Polarized Raman spectroscopy: Two regions, 10 μm each, were scanned at a step size of 1 μm (11 points) at each location of interest (middle center, middle edge, and corner edge). For each point, a 10 s acquisition time and 12 accumulations were chosen. Measurements were performed for the sample submerged in PBS at room temperature, neglecting thermal effects. The PRS measurements were conducted with a linear polarizer. To capture the anisotropy, the tissue sample was rotated from 0° to 180° in 30° increments to measure the different polarization angles between the laser polarization direction and the sample alignment axis. After measuring the spectra of the tissue sample, the PBS background was subtracted in software. A Savitzky-Golay finite impulse response (FIR) smoothing filter to smooth the spectra.

Next, Standard Normal Variate (SNV) was performed to normalize the spectra. Principal component analysis (PCA) was used to provide Primary Principal Component (PC1) for the tissue sample using the loading coefficient for every normalized intensity at a given wavenumber⁶. The PCA converted the spectra of different polarized angles into a single score (PC1) as a function of polarized angles. By fitting a sine function to this output and comparing the Amplitude Alignment Metric (sine amplitude), the protein fiber alignment variation in one tissue sample in different regions was determined.

Computational modeling: A solid structure similar to the experimental mold was first modeled in Abaqus, including the wings (collagen gel without cells) and the center part (collagen gel including cells). A compressible, Neo-Hookean model was applied as the constitutive model. Also, uniform shrinkage was only applied to the center part to capture the deformation of the tissue structure due to cell contraction. A geometrical treatment was used to visualize the state of local deformation in the neighborhood of a point by mapping to the material points a quadratic surface ellipsoid (initially a circle). The decomposition of the calculated deformation gradient to stretch tensor (chosen as the square root of right Cauchy-Green stretch tensor) and rotation tensor was used to find the deformed ellipse at each point. The ratio of the maximum and minimum axes of the deformed ellipse (alignment factor) was used to show the ratio of fiber alignment in different locations.

Figure 1. Engineered tissue construct constructed of collagen. Cells (C2C12) are only within the central part. Three select locations (middle center, middle edge, and corner edge) were measured.

RESULTS

Tissue constructs deformed due to cell contraction (as shown in Figure 1), resulting in changes in fiber alignment as confirmed by microscopy. The PRS method was used to find the variation of alignment in different locations after 12 days. Figure 2 shows the alignment metric that was calculated by fitting the sine function $y = y_0 + A \sin\left(\frac{\pi(x-45^\circ)}{90^\circ}\right)$ at adjusted PC1 Score at each point at each select location. The corner edge was found to have a higher level of alignment. Computational models also predict higher alignment in corner regions as predicted by alignment factor. Dominant directions of fiber alignment predicted by the model also matched with image analysis of stained fibers.

DISCUSSION

We have implemented an experimental, analytical, and computational procedure to quantify the variation of alignment in engineered tissue constructs. By utilizing PCA of PRS spectra, we were able to identify peaks in the spectra that corresponded to the alignment of biological proteins. Comparing the amplitude of sine fit for select

locations shows that we have maximum alignment at the corner edge of our samples. In addition, the alignment factor of the computational model was useful for further predicting the spatial variation of alignment within the construct.

Figure 2. Alignment within test samples as determined by PRS. The Amplitude Alignment Metric was calculated by amplitude analysis of the PC1 Score at select locations.

Figure 3. Alignment factor and directions calculated from the FEA model.

INTRODUCTION

Post-traumatic osteoarthritis (PTOA), a subclassification of osteoarthritis (OA), results after a major impact or injury to the joint, such as dislocations or ligament tears. Significant clinical interventions for PTOA remain elusive. Patients with a prior history of joint injury present with OA on average more than ten years younger than OA patients without a history of joint injury¹. Because total joint replacements have limited *in-vivo* lifespans, these younger patients make poor candidates for this current gold-standard treatment. Osteochondral allografts (OCAs) provide a biologic alternative for the treatment of large cartilage defects, and may provide better long-term results for younger OA patients. While plug and shell style OCAs have so far shown promising clinical results, particularly in the knee^{2,3,4}, the challenges of size and curvature-matching between donor articular cartilage and recipient native joint anatomy currently limit their use.

Previously, our lab proposed creating bendable osteochondral allografts (BOCAs) to increase joint congruence between donor and recipient by machining grooves through the depth of the bone to the tidemark, leaving a flexible layer of articular cartilage.⁵ These BOCAs may be especially advantageous in joints such as the patellofemoral joint. Chondral lesions in the patellofemoral joint are present in >33% of patients undergoing knee arthroscopy, and these defects are considered more difficult to manage in clinical settings due to patellar malalignment in the femoral groove, lateral tilt, and attachment to the patellar tendon. Studies investigating the feasibility of using BOCAs to restore joint congruence in the patellofemoral joint (PFJ) have included computational⁵ and cadaveric analysis. Our prior finite element analyses found that patellofemoral contact in the knee with either non-grooved patellar OCAs or patellar BOCAs was maintained at a level comparable to that assessed in the native joint⁵. The encouraging outcomes of the finite element study motivated further cadaveric investigation of BOCAs in order to validate the

computational results in a more physiologically representative environment and over a greater range of flexion.

In the present study, we aimed to validate these prior computational results against our recent cadaveric experiments. In both computational and cadaveric studies, we found that BOCAs in the patellofemoral joint produce contact values equivalent to those observed in the native joint.

METHODS

Computational Analysis: Simplified finite element models of three native PFJs and 12 allograft PFJ models were employed in the finite element analyses⁶. Knee models included femur, tibia, patella, articular cartilage, patella tendon, and quadriceps muscles⁶. Active contractile forces of 178 N, 89 N, and 267 N were prescribed to represent the vastus lateralis, vastus medialis obliquus, and combined rectus femoris and vastus medialis longus, respectively⁷. To ensure numerical convergence despite the exclusion of some stabilizing capsular tissues in the PFJ, knees were articulated from 40 to 70 degrees of flexion⁸. PFJ contact area was compared between knees with either the native patella, non-bendable OCA, BOCA bent at 60 degrees flexion and fixed in that configuration through the flexion cycle, OCA shifted distally by 6 mm (SOCA), and 6 mm shifted BOCA (SBOCAs)⁶.

Cadaveric Analysis: Five fresh-frozen human cadaver knee joints obtained from the Anatomy Gift Registry were dissected to expose and separate the major muscle groups and mounted on a custom-built kinematic loading rig designed to support the knee at 15-degree increments of flexion from 15 to 90 degrees. Pressure-sensitive paper (fujifilm.com) was positioned in the PFJ space, tensile loading forces of 189 N, 44.5 N, and 133.5 N were placed on the vastus lateralis, vastus medialis obliquus, and combined rectus femoris, vastus intermedius and vastus medialis longus, respectively⁷. Additionally, to represent the contribution of the hamstring muscles, 55.5 N, 55.5 N, and 22.5 N were applied to the biceps femoris, semimembranosus, and combined

sartorius, gracilis, and semitendinosus. A further 44.5 N was loaded via the iliotibial band. These loads were applied to their respective tendons for 60 seconds at each flexion angle. Five additional cadaveric patellae were used to create non-bending OCAs by first milling a uniform planar surface on the anterior side of each patella resulting in an allograft bone depth of 12 mm. Non-bending OCAs replaced the native patellae and contact area measurements were taken using the same loading regimen. A 6 mm distal shift of the OCA (SOCA) was implemented to match the computational study, and the knee was loaded again. Finally, this loading regimen was repeated using BOCA or shifted BOCA (SBOCA), which were created from the OCA patellae by machining a set of two proximal-distal 2 mm-wide grooves through the depth of the subchondral bone. Pressure-sensitive film was used to measure contact area at each loading angle⁹. Contact measurement comparisons were calculated using the *stats* package for R Statistical Software (v4.2.2, R Core Team 2022) and the *Estimated Marginal Means* package (Length, 2022). Plots were generated using the *ggplot2* package (Wickham, 2016).

RESULTS

Statistical analyses of both the computational and cadaveric studies yielded very similar trends in the data. In both studies, the *in-silico* and *ex-vivo* results indicated that none of the treatment groups (OCA, BOCA, S-OCA, S-BOCA), showed a statistically significant difference between the respective group's average contact throughout all angles of flexion compared to the native PFJ contact area ($p > 0.05$, Figure 1). Although treatment groups did not show an overall statistically significant difference in contact area relative to the native group, there were observable differences in measured contact areas between the different treatment groups at smaller angles of flexion (Figure 2), with the most significant differences seen between the OCA and SBOCA groups. The differences observed from the cadaveric study were more modest than the results seen in the *in-silico* models of the treatment groups, as computational models of patellofemoral contact generally resulted in greater measured contact areas and smaller in-group standard deviation of contact measurements.

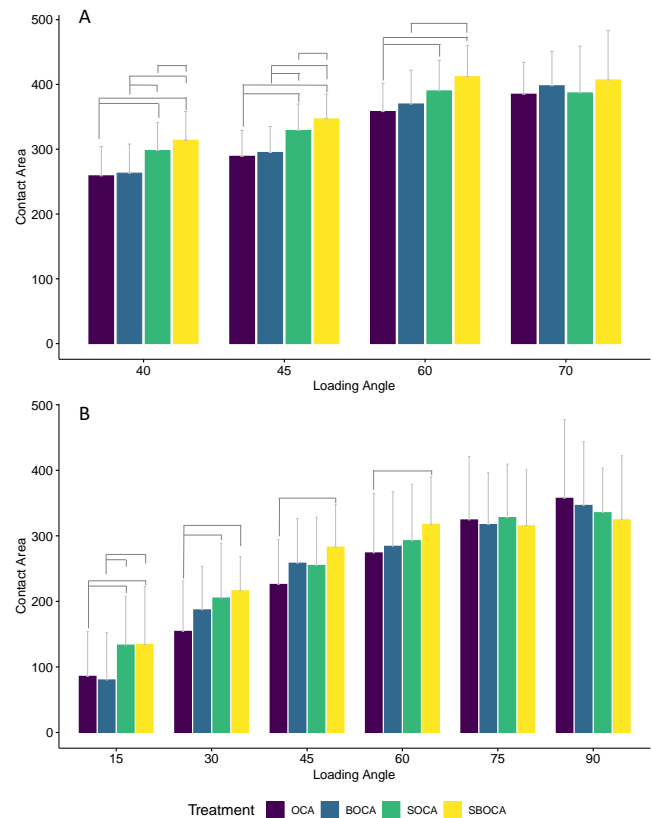

Figure 1: Measured contact areas by flexion angle for (A) computational models and (B) cadaveric models. Bars show groups for which there is a significant difference ($p < 0.05$)

computational model represented twice the load applied to the cadaveric knee models, which may account for the greater measured joint contact area *in silico*.

While the results of the cadaveric analysis of surface contact area and the computational results show similar trends, it is notable that the results from the cadaveric joints show a much higher average standard deviation in the contact area. The joint measurements from cadaveric knees likely had greater variability due to the fact that more human knee joints from a wider range of donor heights and weights were used, as donor cadaveric total knees and patellae were not initially screened for size. In summary, the cadaveric results substantially support the predictions of the computational models of bendable osteochondral allografts, showing that BOCA can match the joint contact area of native patellae.

DISCUSSION

Significant differences in applied loads and range of loading exist between the computational and cadaveric models due to the limitations of each model. The computational model could not load across the full 15-to-90-degree range of flexion due to the inability of the model to converge at low angles of flexion without additional soft tissue support. Moreover, the simulated load of the quadriceps muscle group in the

CD44 MECHANOSIGNALING MAY REGULATE DRUG RESISTANCE IN OVARIAN CANCER

INTRODUCTION

Ovarian cancer is the 5th most common and the deadliest gynecologic cancer. Despite its five-year survival rate being less than 50%, little is understood about the role of biomechanics in the tumor microenvironment (TME) on the progression of ovarian cancer [1]. The CD44 receptor is found on the surface of ovarian cancer cells and is associated with increased invasive properties and maintenance of stemness in ovarian cancer cells. CD44 regulates these processes through signaling pathways associated with cancer proliferation, migration, and drug resistance including the Ras-MAPK pathway [2]. Hyaluronic acid (HA), a ligand of CD44, is prevalent in the ovarian TME and required for metastatic invasion [3]. Furthermore, previous studies have shown that an increase in HA in the ovarian TME is associated with a worse prognosis [4]. In the clinic, ovarian cancer is commonly initially treated with chemotherapy drugs including paclitaxel; recurrent disease can occur when a patient develops a decrease in sensitivity to the drug, and this may be regulated by mechanotransductive factors in the MAPK pathway. We hypothesize that mechanosignaling in the HA-CD44 axis enhances ovarian cancer growth and metastasis and increases chemoresistance. The objective of this study was to evaluate the combinatorial effects of HA-CD44 signaling and mechanical strain on ovarian cancer cell response to paclitaxel in 2D and 3D environments.

METHODS

Studies utilized the non-serous, highly invasive OVCAR8 cell line for all experiments. Using shRNA, we previously generated genetically-modified OVCAR8 cells including a knockdown of CD44 (shCD44) and a scramble control (shSCR). The shCD44 knockdown cells exhibit a stable decrease of ~60% as measured by Western blot. In 2D studies, HA was introduced to the cells by coating the tissue culture plates with 1 μ M HA in HBSS overnight, before seeding the cells (PLT HA). No treatment (NT) controls were incubated with HBSS only. OVCAR8

wildtype (WT), shSCR, and shCD44 cells were seeded at 2x10⁵ cells per well in a 6 well plate on to the PLT HA plates or NT (no HA) controls. The cells were allowed to adhere to the plates for 24 hours before treatment with 5 μ M paclitaxel or vehicle (Veh) control. After 24 hours, the treatment was removed, and samples were incubated with Sytox (ThermoFisher, S11381) and DAPI stains. After 30 minutes, the cells were washed and imaged. Images were processed in FIJI to determine the relative number of dead cells normalized to total cell count.

To further explore the effects of mechanical tension on the cells, a Flexcell (FX-6000T) system was used for monolayer, uniaxial strain studies. Samples were exposed to 9% strain at 0.3Hz for 24h. Control samples utilized the same Flexcell plates but were not exposed to cyclic strain. OVCAR8 WT, shSCR, and shCD44 cells were seeded at 2x10⁵ cells per 6 well plate on Flexcell plates and were allowed to adhere overnight prior to strain exposure. To facilitate Sytox image analysis, the cells were trypsinized after strain treatment and re-plated at 1x10⁶ cells per well in a 24 well plate. The cells were allowed to adhere for 6h before treatment with 5 μ M paclitaxel or vehicle control. After 24h, the treatment was removed and Sytox analysis was completed as described previously.

For 3D studies, a microfluidic device consisting of 3 diamond-shaped tissue chambers connected in series was utilized [5]. The devices were loaded with fibrin only (F only) or fibrin embedded with HA (F+GEL HA, 9:1 ratio). OVCAR8 WT cells were loaded at 1x10⁶ cells/mL and cultured for 7 days, with fresh media added every day. Devices were then treated with 5 μ M paclitaxel or vehicle control. After 24 hours, the treatment was removed and Sytox and DAPI stains were added and allowed to diffuse overnight before imaging analysis. As cell growth in the microfluidic devices was denser than that observed in 2D studies, we analyzed total positive-area for Sytox and normalized to total DAPI area to quantify chemoresponse of the cells.

RESULTS

As expected, paclitaxel treatment increases cell death for all tested cell types with and without HA compared to Veh treated samples. However, WT cell death is decreased for PLT HA samples treated with the drug compared to the no HA (NT) group. (Figure 1). The shCD44 cells demonstrate no significant difference in cell death in NT groups but do have increased cell death in response to both PLT HA and paclitaxel (Figure 1).

Figure 1: a. Representative images of OVCAR8 WT cells grown in the presence of no HA (NT) or PLT HA and treated with vehicle (Veh) or 5µM paclitaxel. Sytox (dead cells) are shown in red; blue is DAPI. Scale bar = 500 µm. b. Quantification of cell death for OVCAR8 cells normalized to total cell count for each sample. Data shown are averages + SEM.

Pre-treating cells with tensile strain before treatment with paclitaxel abrogated cell death in WT and shSCR samples but not shCD44 samples (Figure 2). To expand our studies to a 3D TME model, we cultured OVCAR8 WT cells in a microfluidic device to investigate how HA in the matrix altered response to paclitaxel. In Fibrin only samples, paclitaxel treatment caused a significant increase in cell death; however this was not observed in F+GEL HA samples (Figure 3).

Figure 2: a. Representative images of OVCAR8 WT cells pretreated with strain via the Flexcell for 24h before treatment with vehicle or 5µM paclitaxel. Sytox (dead cells) are shown in red; blue is DAPI. Scale bar = 500 µm. b. Quantification of cell death for OVCAR8 cells normalized to total cell count for each sample. Data shown are averages + SEM; NT = no strained controls. N=3; ^ p > 0.05 versus WT NT Pac. * p < 0.05 versus shSCR NT Pac.

DISCUSSION

The results show that OVCAR8 cells expressing CD44 (WT and shSCR) can exhibit chemoresistance when cultured in the presence of HA before drug treatment paclitaxel in both 2D and 3D environments. Alternatively, OVCAR8 cells with CD44 knockdown (shCD44) do not exhibit the same chemoresistance shown in WT or shSCR cells. Interestingly, the absence of HA in these experiments may indicate that CD44 can be mechanically-activated without HA ligand-induced signaling. This suggests that there is a mechanotransduction phenomenon occurring through CD44 that could be affecting the drug resistance and potentially altering ovarian cancer disease progression.

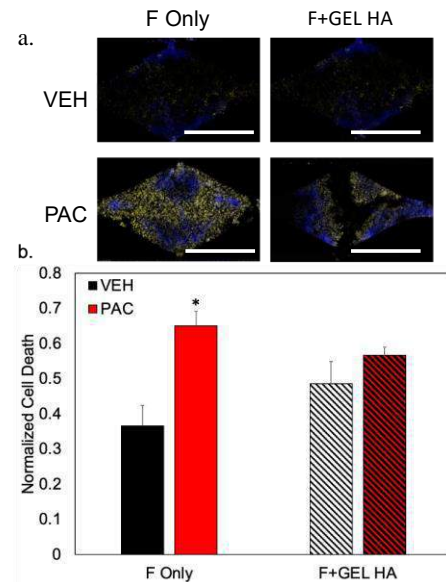

Figure 3: a. Representative images of OVCAR8 WT cells grown in F or F+GEL HA in microtissue TME models and treated with vehicle or 5µM paclitaxel. Sytox is shown in yellow; DAPI shown in blue. Scale bar = 500 µm. b. Quantified showing area of dead cells normalized to total cell area. N = 3; * p > 0.05 versus F VEH.

Future directions for this project incorporating HA into Flexcell studies to investigate crosstalk between HA-CD44 signaling and mechanical stimulation on OVCAR8 chemoresistance behaviors. We also plan to perform proliferation and migration studies in microfluidic models to determine the role of mechanosignaling via HA/CD44 in on these behaviors. These proof-of-concept studies help explain the role HA and strain plays in mechanically stimulating CD44. Ultimately, this project will help elucidate proliferation, metastasis, and drug resistance observed in ovarian cancer and open the doors for researching new diagnostics and therapeutics.

INTRODUCTION

Trapeziometacarpal (TMC) osteoarthritis (OA) is one of the most common conditions affecting middle and older aged adults¹. Given that the opposable thumb is central to activities of daily living, loss of function has a significant impact on quality of life. Patients with TMC OA are initially managed with activity modification, non-steroidal anti-inflammatory drugs, splinting, and occasionally corticosteroid injections². These conservative treatments often fail in the long term, and many patients will eventually require surgical intervention. Despite the prevalence of this disease, and the paucity of effective treatments, diagnosis largely relies on patient reported outcomes.² However, analysis of radiographs, the gold standard for OA diagnosis, shows little correlation to pain or functional deficits.^{3,4} In this study we sought to close gaps in knowledge related to the initiation and progression of TMC OA by evaluating the morphology and gross appearance, wear patterns, mechanical properties, subchondral bone morphology, and histological characteristics of the tissue across a spectrum of disease severity.

METHODS

Thirty-two human hands were acquired from fresh frozen cadaveric donors with approval from the University of Pennsylvania committee for cadaveric testing. Fluoroscopic images were recorded for each specimen in five anatomic views (posterior-anterior, lateral, oblique, stressed oblique, and Robert view). A board-certified hand surgeon used these images to assign a semiquantitative modified Eaton OA grade³ to each sample, in a blinded manner. Next, the trapezia were isolated and stained with India Ink to assess areas of cartilage wear⁵. Indentation creep testing was then performed on the cartilage at nine anatomic locations from dorsal to volar and from radial to ulnar, and the creep displacement curve was fit to a Hertzian biphasic model in order to compute the compressive and tensile moduli and tissue permeability.⁶ Locations where the cartilage was completely worn away were

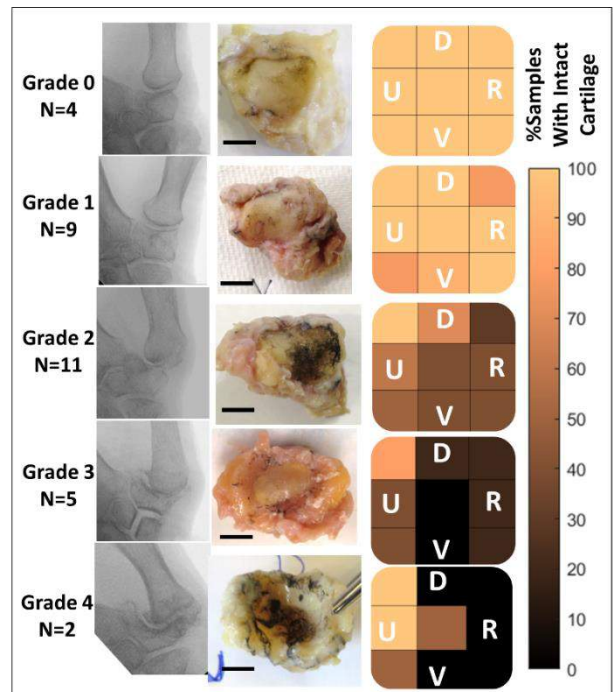

Figure 1: From left to right: Number of samples at each modified Eaton grade, with a representative Robert view radiograph for each. Representative gross images of the trapeziometacarpal surface of the trapezium with India ink staining. Scale=5mm. Regional maps showing the percent of samples with intact cartilage at each of nine anatomic regions for each grade. Photos and maps are each oriented so that Dorsal is up, Volar down, Ulnar to the left, and Radial to the right.

excluded. Each specimen was then fixed in formalin, and scanned via microCT at 70kVp, 85μA, with a voxel size of 10.3 μm. This was repeated after a 24 hour immersion in Lugols solution (10% KI, 5% I₂ in water) to increase the radiopacity of the cartilage. These contrast-enhanced images were used to compute the cartilage thickness across each sample. Specimens were then decalcified, paraffin processed, embedded, sectioned, and stained with Safranin O/Fast Green. All quantitative data were compared with one-way ANOVA followed by Tukey's post hoc tests, with significance set at p<0.05.

RESULTS

Radiographic assessment yielded a range of modified Eaton grades assigned to specimens, with grade 0 showing no evidence of OA to grade 4 representing a severely degenerated joint. (Fig. 1). One of the 32 specimens was excluded from this study due to past trapeziectomy. Macroscopically, samples with a higher Eaton grade showed a greater degree of gross degeneration, with increased cartilage eburnation, especially on the radial and volar aspects of the joint (Fig 1). Higher Eaton grades also showed greater evidence of bone abnormalities, including subchondral sclerosis and osteophyte formation, as well as a narrowing of the trapezium (Fig 2A-B). Histologically, specimens with higher Eaton scores showed evidence of major cartilage degeneration, with grade four specimens showing little if any Safranin-O positive staining for proteoglycans (Fig. 2C). Cartilage was thickest at grades 0 and 1, with thinning starting on the radial and volar edges by grade 2 (Fig 3A). Cartilage compressive modulus was significantly lower beginning at grade 1 in comparison to grade 0, with tensile moduli showing similar trends (Fig 3C-D), while cartilage permeability increased from grade 0 through grade 4 (Fig 3E). However, loss in mechanical properties did not seem to follow the same pattern of regionality as the cartilage erosion.

DISCUSSION

This study assessed the tissue and micro-scale properties of human trapezia throughout the stages of radiographically-diagnosed osteoarthritis, in order to better understand the progression of the disease. Our findings indicate that the onset of thumb OA is characterized by increased wear at the volar edge of the joint, progressing toward the dorsal side; this is well supported in the biomechanics literature^{7,8} as well as imaging studies of healthy specimens.⁹ Interestingly, loss of mechanical integrity of the cartilage preceded volumetric tissue loss, but did not follow the same pattern of regionality. Future work using this data set will include quantification of subchondral bone abnormalities, semi-quantitative scoring of osteochondral histology, and the assessment of synovium and synovial fluid harvested from these joints. As with any study involving donated human tissue, one limitation of this study is the low sample number. Another limitation is our inability to correlate any of our tissue and micro-scale outcomes to clinical measures of pain and functional deficit. Despite this, this data provides a rich data set for the evaluation of TMC OA and effectiveness of regenerative therapeutics.

INTRODUCTION

Pulmonary hypertension (PH) is defined as an elevation in mean pulmonary arterial pressure (mPAP) and is believed to affect 1% of the world population [1]. PH increases the afterload in the right ventricle (RV) leading to dysfunction and remodeling of the RV. PH also leads to the remodeling of the pulmonary artery (PA) and pulmonary vasculature following the increased resistance in the downstream capillary bed. The correlation between the severity of RV and PA remodeling is unknown. The increased stiffness and resistance in the pulmonary vasculature require a larger pressure head at the main pulmonary artery to maintain the flow rate in the capillaries. The RV contracts harder to achieve this increased pressure head leading to RV stiffening and remodeling. Our objectives in this study were to i) investigate the correlation between RV and proximal PA stiffening in rodents under mild and severe PH conditions, and ii) deconvolute the effects of increased stiffness and resistance in the pulmonary vasculature on the stress experienced by the RV free wall (RVFW).

METHODS

Two severities of PH were induced in rats for this study. The mild model of PH was developed by placing Sprague Dawley (SD) rats (n=6) in a hypoxia (Hx) chamber (10% O₂) for 3 weeks. The wild-type (WT) control rats for the Hx group (n=6) were placed in normoxia. The severe model of PH was developed by injecting a single dose of SU5416 (20 mg/kg sc) into Fischer (CDF) (n=6) and placing the animal in a hypoxia chamber for 3 weeks, followed by 1 week of normoxia (SuHx). The WT control rats for the SuHx group (n=6) were placed in normoxia and were injected with vehicle instead of SU5416. Both male and female rats were used in this study (male=12, female=12). Hemodynamic parameters were measured through echocardiography and catheterization. RVFW and right proximal PA tissues were harvested and subjected to biaxial and uniaxial loading, respectively.

To analyze the PA remodeling, the lungs of two rats (1 control and 1 SuHx) were isolated and fixed using the method described in Knutsen et al [2]. The lungs were imaged using micro-CT to obtain the morphology of the pulmonary vasculature (Fig. 2A). The images were segmented and processed to obtain the dimensions of individual vessels (slicer VMTK). This information was used to reconstruct the major vessels in the pulmonary vasculature (Fig. 2B) and the connectivity information was used for in-silico experiments. For the in-silico model, a 1-D fluid-structure interaction (FSI) model, originally developed by Colebank et al. [3], was extended to include nonlinear vessel elasticity and was integrated with our existing biventricular model [4]. The pressure at the inlet of the pulmonary vasculature was translated into the stress on the RVFW via our integrated RV-PA model. The stiffness and resistance of the PA vasculature were altered (3x stiffness and 10x resistance) to determine the contributions of narrowing and stiffening of the pulmonary vasculature on RVFW stress. In addition, the terminal resistance was also increased to determine the contribution of the increased capillary bed resistance to elevating RV afterload and increasing RVFW stress.

RESULTS

RVFW stiffness increased in both mild and severe PH, but the increase observed in the case of SuHx was significant (Fig. 1A). There was a strong correlation between the change in RVFW stiffness and change in hemodynamic parameters such as RV systolic pressure (RVSP) (Fig. 1B) and mPAP (results not shown here). In addition, there was a hyperbolic relation observed between RVFW stiffness and the ratio RVSP/TAPSE (Tricuspid annular plane systolic excursion) as a measure of RV-PA coupling (result not shown). These results indicate a strong relationship between RVFW remodeling and RV-PA uncoupling, which is the hallmark of RV maladaptation and triggers RV failure. The uniaxial testing of the PA specimen revealed that the PA stiffness increased significantly in the circumferential direction for the

SuHx rats, but remained unchanged in the Hx rats (control vs Hx: 237.6 kPa vs 216.9±12.72 kPa at 40% strain: control vs SuHx: 441.19.9±189.2 kPa vs 1139.3±309.3 kPa at 40% strain).

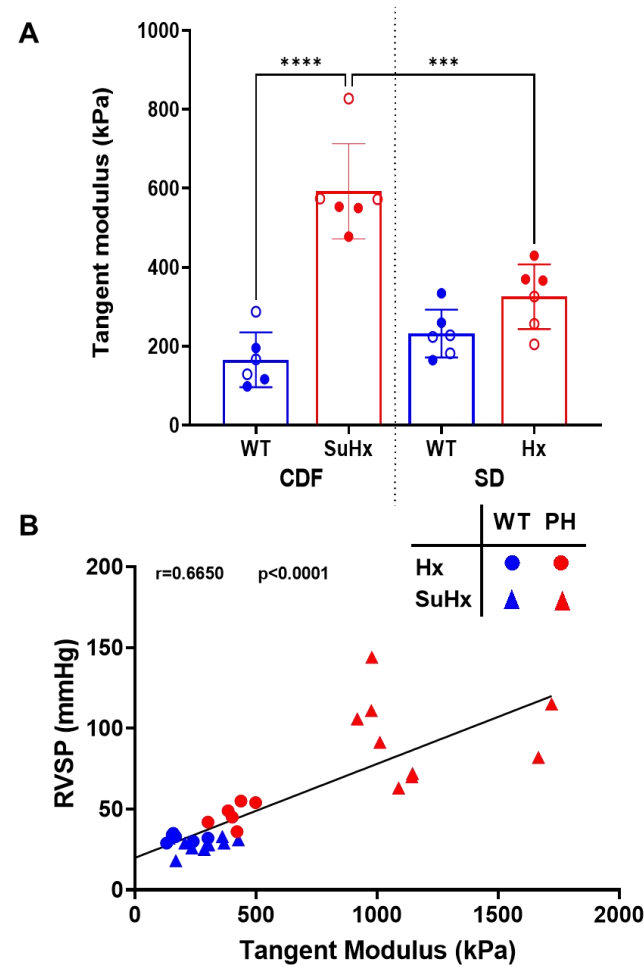

Figure 1: A) Ensemble tangent modulus of RVFW (Male - solid symbol, Female – hollow). B) Correlation of ensemble tangent modulus with RVSP.

The imaging of the pulmonary vasculature with the addition of the contrast agent allowed for the segmentation of extremely fine details such as the distal vasculature (Fig. 2A). Analysis and reconstruction of the vasculature provided morphological information of 342 vessels, which was reduced to 241 vessels after discarding extremely small features. Preliminary flow simulations were mapped onto the segmented vasculature geometry (Fig. 2B). In-silico experiments reveal that pulmonary vessel stiffness significantly affects the predicted stress in the RVFW (Fig. 2C). Simulations indicate that RVFW stress is doubled for SuHx rats based on the measured increase in pulmonary artery stiffness (PA stiffness tripled in SuHx) (Fig. 2C). Based on the measured change in pulmonary resistance (through the measurement of pulmonary vascular resistance using catheterization) and the change in pulmonary artery stiffness (through ex-vivo testing), we were able to replicate the increase in mPAP (Fig. 2D)

DISCUSSION

PH resulted in RV hypertrophy measured by increases in RV weight and RV thickness. The stiffness of the PA in the circumferential direction

increased significantly in the case of the severe PH model, but not in the mild form of PH. The RV stiffness significantly in SuHx rats, but not in Hx rats, and the result was expected according to the PH severity.

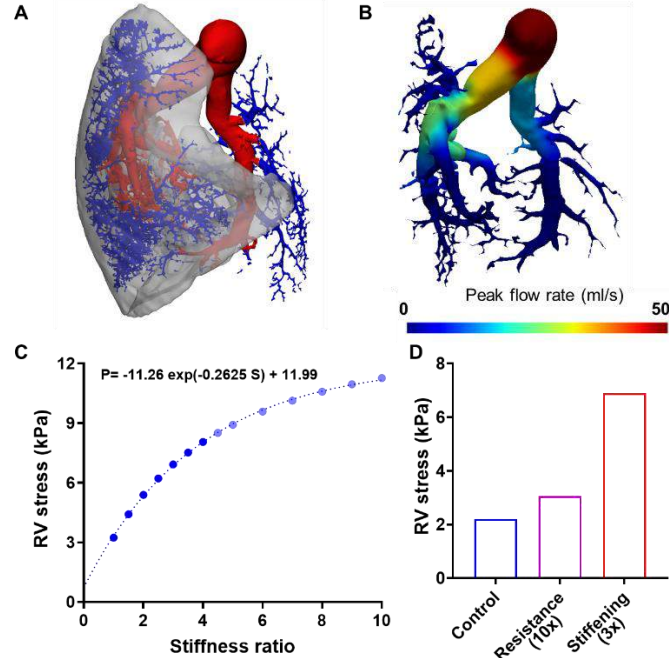

Figure 2: A) Segmented lung and pulmonary vasculature (Red – proximal, blue – distal). B) Flow rate mapped to pulmonary tree (preliminary result from rigid wall simulation). C) The effect of vessel stiffness on RV wall stress. D) Preliminary results on effects of increased resistance and stiffness on RV stress (n=1).

Preliminary results from in-silico experiments indicate the stiffening of the PA, increasing vascular resistance, and narrowing of vessels contribute to increased RV stress during PH. The results from the in-silico experiments combined with mechanical testing of the PA indicate that the SuHx rats will experience a significant increase in RV stress and RVSP, and the Hx rats will experience a mild increase (Fig. 1A). These results agree with the measured hemodynamic parameters (Fig. 1B). The combined effect of these remodeling events triples the RV stress (Fig 2D), with vessel stiffening being an important contributor. The method used in this study offers provides insights into the biomechanical coupling between the PA and RV and determines the larger contributor to RV remodeling on the PA side. Results from the study indicate that both the RVFW and pulmonary vasculature undergo significant remodeling due to PH. Distinguishing the contributions of various remodeling events of the vasculature on the function of the right heart can provide us with additional risk-stratification tools and aid in identifying optimal therapeutic targets.

ALTERED OXYGEN TRANSPORT IN INTRACRANIAL ANEURYSMS IN SICKLE CELL DISEASE

INTRODUCTION

Neurological complications are more common in patients with sickle cell disease (SCD), with subarachnoid hemorrhage (SAH) of an intracranial aneurysm (ICA) among the most common¹. Given the life-threatening risk of SAH, understanding the relationship between development and rupture of ICA with SCD is highly important.

In SCD, under moderate to low oxygen conditions, the sickle hemoglobin undergoes a polymerization process that leads to stiffer and sickle-shaped cells². The apparent viscosity of the blood increases³, most obviously affecting blood flow resistance but also potentially affecting oxygen advection, which could further reduce oxygen levels and drive a cascade contributing to ICA formation and weakening.

Our aim in this study was to investigate how the geometry and blood rheology affect oxygen transport and consequently oxygen availability in the blood of an idealized ICA, testing the hypothesis that feedback between oxygen level, blood viscosity, and oxygen transport can aggravate the reduction in available oxygen in SCD.

METHODS

Primitive geometries were used, in which an arched 4-mm diameter cylindrical tube represented the vessel, and an attached 9-mm diameter spherical bulge represented the aneurysm. Two parameters were studied: (1) the ratio between the aneurysm throat length and the aneurysm diameter (L/D^a), and (2) the vessel curvature (κ).

The Carreau-Yasuda model was used to describe the shear thinning of the blood, with parameters dependent on the level of sickle hemoglobin (HbS) in the blood stream, based on our previous study⁴. The computed flow fields were validated against published in vitro data on flow in an idealized aneurysm model⁵.

Oxygen transport in the blood was described by

$$\frac{\partial O^T}{\partial t} = D^P K \nabla^2 O^T - v \cdot \nabla O^T \quad (1)$$

where O^T is total (hemoglobin-bound and free) oxygen in the blood. $K = O^P/O^T$ is the equilibrium constant for association and disassociation

of oxygen, where O^P is the free (plasma) oxygen concentration⁶. D^P is the diffusion coefficient for oxygen in plasma, and v is blood velocity.

Oxygen level in the vessel wall (O^W) was modeled using Fickian diffusion without convection for transport and Michaelis-Menten kinetics for consumption⁶:

$$\frac{\partial O^W}{\partial t} = D^W \nabla^2 O^W - \frac{A O^W}{B + O^W} \quad (2)$$

where D^W is the diffusion coefficient of oxygen in the wall, and A and B are kinetic constants⁶. A pulsatile velocity waveform and constant oxygen concentration were imposed at the model inlet. Outlet boundary conditions were fixed pressure and no axial oxygen gradient.

A full factorial study was done on three factors: HbS level (0, 10, 30, 50, 70, and 90%); aneurysm throat / aneurysm diameter ratio (0.07, 0.1, 0.3, 0.6, 0.8, 1.0); vessel curvature (-0.44, -0.14, -0.06, 0, 0.06, 0.14, 0.44 cm^{-1}) for a total of 36 geometries and over 140 cases. Simulations were performed at the Minnesota Supercomputing Institute.

RESULTS

Thirty-six geometries were studied, for both sickle (~90% HbS) and non-sickle (0% HbS) blood. Figure 1 shows one example geometry and the corresponding oxygen distribution during mid-systole for the non-sickle (Fig. 1A) and sickle (Fig. 1B) cases.

The average Peclet number in the aneurysm ranged from 30-4000, meaning that even for more the extreme cases, oxygen transport was dominated by advection. Figure 1C and 1F compare the normalized blood oxygen level for the non-sickle and sickle cases, respectively. Values range from 0 (no oxygen present) to 1 (oxygen level is the same as in the vessel). For throat sizes >0.7 times aneurysm size, oxygen distribution is not affected by the increased viscosity of the SCD system. However, for smaller throat sizes, there is reduced blood flow into the aneurysm, as shown by a smaller throat Reynolds number for the SCD. (Fig. 1G vs. 1D). Oxygen transport through the aneurysm wall was also lower in the sickle case (Fig. 1H vs. Fig. 1E), even for large throat sizes.

Figure 2: Normalized oxygen distribution for (A) non-sickle and (B) sickle in a plane cut for $\kappa=0.14 \text{ cm}^{-1}$ and $L/D^a=0.3$ calculated at peak of the cardiac cycle. Color maps show time average values for different curvatures (κ) and aneurysm throat diameter to vessel diameter ratio (L/D^a), for (C, F) normalized oxygen (D, G) throat Reynolds number and (E, H) Sheerwood number.

Figure 2 shows the results of the parametric study, with each column of the figure corresponding to a different aneurysm throat size (increasing left to right) and each row showing a different measured quantity. The first row (A-C) shows the normalized oxygen level in the aneurysm as a function of vessel curvature and HbS level. Increased HbS (more severe disease) decreases the oxygen level, especially for smaller throat sizes. The next three rows show the oxygen distribution (D-F), the blood viscosity (G-I), and the blood velocity (J-L) in a midplane slice through the geometry. For the small throat (A, D, G, J) in particular, oxygen is depleted in the aneurysm, leading to increased viscosity, but some effect was seen even at moderate throat sizes (B, E, H, K). The blood recirculated in the aneurysm for all cases (J-L).

The effect of curvature on oxygen transport is less consistent (Fig 2A-C). For small and large throats (Fig 2A, C), the higher curvature leads to lower oxygenation, but for intermediate throats (Fig. 2B), there was little effect or slightly increased oxygenation with curvature.

DISCUSSION

The most significant finding of this work is that oxygen availability is a potential issue in intracranial aneurysms, especially in large aneurysms with small throats. This effect was seen in all simulations, even those using healthy blood parameters, and the problem as more pronounced for SCD blood parameters. The higher viscosity of the sickle blood increases the effect of the narrow throat, and the poor oxygen transport can lead to even greater increase in blood viscosity. This sequence could create a positive feedback loop, wherein smaller throats produce less flow inside the aneurysm, leading to lower shear rates and lower levels of oxygen; the lower oxygen level could then lead to more sickling and greater viscosity, aggravating the problem.

The *geometrical* analysis showed that throat size seems to be a more important determinant of oxygen distribution than vessel

Figure 1: Normalized oxygen distribution maps for (A) $L/D^a=0.1$, (B) $L/D^a=0.3$, (C) $L/D^a=0.6$ at different level of sickle hemoglobin (HbS%) and different vessel curvatures (κ). Values are time averaged. Plan cuts show (D-F) oxygen distribution, (G-I) apparent viscosity distribution, and (J-L) velocity magnitude and direction.

curvature. For the sickle cell case, a larger throat is required to maintain full oxygenation of the aneurysm wall. Smaller throat Reynolds numbers and mass transfer coefficients measured for the SCD case suggested that less oxygen is available for the tissue in SCD patients who have aneurysms with smaller throats.

Synergizing with the geometrical effects, the *rheological* effects, in which a higher percentage of sickle cells leads to a higher apparent viscosity inside the aneurysm, also impact the oxygen distribution. The effects of the HbS% in the deoxygenation of the aneurysm site is higher for smaller throats and more curved geometries.

Finally, it is important to recognize certain considerations that were not addressed in the current study. Perhaps most importantly, this study did not address the mechanisms by which an aneurysm might form or by which a small aneurysm might grow into a larger and more fragile one. The process of intracranial aneurysm formation and growth is incredibly complex⁷ and this work focused only on fluid mechanics and oxygen transport. While oxygen's central role in SCD makes it important to study in the context of elevated ICA rates for SCD patients, the larger process of ICA formation requires more detailed and thorough study.

INTRODUCTION

Hemorrhage from traumatic injury is the leading cause of death in the United States in patients under 46 years of age [1]. Timely cessation of hemorrhage prevents hemorrhagic shock that results from severe blood loss and lack of tissue oxygenation [2]. Applying pressure to a vessel is the first line of defense in stopping hemorrhage and buys time to locate the source of the bleed, transport the patient, and prepare them for long-term treatment. However, prolonged pressure from a tourniquet or localized pressure such as a finger or clamp on the lacerated vessel occludes blood flow to surrounding tissue as well. Thus, the goal for long-term care is to repair the laceration and revascularize the vessel as soon as possible to restore oxygen-rich blood to the surrounding tissue.

One method of long-term vessel repair is the use of surgical sutures or staples, but these are associated with increased risk of infection or non-favorable wound healing outcomes [3]. Another strategy is the use of bioadhesives that come in the form of sealants, tissue adhesives, or hemostatic agents. Bioadhesives and sealants have shown advantages in ease of application and stable wound healing compared to sutures and staples [4,5]. With a wide array of bioadhesives and sealants available, it is important to consider the mechanical properties, application method, storage conditions, and biocompatibility of the sealant before choosing the one that achieves the greatest clinical efficacy. Multiple biomedical sealants and hemostatic agents have shown clinical efficacy in stopping bleeds and initiating the wound healing process, and each has its own set of advantages and limitations in terms of mechanical properties, storage conditions, and application method [5].

In this project, we investigate the use of a photo-curable, porcine-gelatin based sealant [6] in a murine venous hemorrhage model. The photo-curing extracellular matrix sealant (pcECM, Cook Biotech Inc., West Lafayette, IN) has the potential to address limitations in mechanical properties and storage conditions of currently available sealants, potentially expanding use for situations in ambulances, battlefields, and other remote settings. In this study, we tested pcECM

for its mechanical properties and use in venous hemorrhage cessation against a popular commercially available sealant (Tisseel, Baxter Healthcare, Deerfield, IL) to evaluate viability in stopping hemorrhage, promoting wound healing and revascularization of the lacerated vessel, and its effects on vessel hemodynamics and morphology.

METHODS

Sample Preparation: pcECM (low, medium, and high modified gelatin %) formulations consist of a 1mL syringe filled with 0.9mL precursor solution and 0.1mL of activator solution. Two 1mL syringes were attached with a luer lock connector and mixed back and forth 100 times. The mixture was dispensed via cannula and crosslinked with a visible light source for 1-4 minutes. Tisseel consisted of 2mL syringes in a double barrel configuration filled with human thrombin solution and human sealer protein solution. We thawed the syringes at 37°C, attached the provided mixing tip, and dispensed Tisseel via cannula allowing 2-5 minutes for crosslinking to take place.

Mechanical Properties: Low, medium, and high modified gelatin pcECM formulations and Tisseel samples (n=6-9/group) were tested for swelling, burst strength, and tensile strength. In addition, the density and viscosity of the three pcECM precursor formulations were measured.

Murine Venous Hemorrhage Model: Purdue University Institutional Animal Care and Use Committee approved all procedures under protocol #2002002016. After anesthetizing mice with 1.5-2.5% isoflurane, we made an incision in the abdomen, isolated the infrarenal portion of the vena cava (VC), and passed 2 nylon sutures around the VC. The VC was lacerated with a 27G needle, pressure was applied to the vessel with sutures immediately proximal and distal to the laceration, and the vessel was treated with either low modified gelatin percentage pcECM (n=9) or Tisseel (n=4).

Ultrasound Image Acquisition: A small animal, high frequency ultrasound system (Vevo3100, FUJIFILM VisualSonics, Toronto, CAN) was used to acquire B-mode, ECG-gated kHz video, 3-dimensional

ultrasound, and color and pulsed-wave Doppler images of the VC at baseline and days 1, 7, 14, 21, and 28 after surgery.

RESULTS

We found that varying the percentage of modified gelatin in the three pcECM formulations had significant effects on each formulation's mechanical properties, and Tisseel also had significantly different mechanical properties compared to the three pcECM formulations.

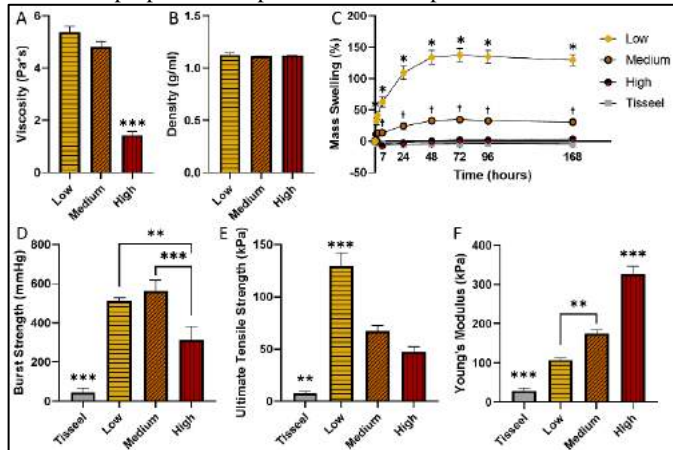

Figure 1: Mechanical properties of pcECM can be modified by adjusting the percentage of modified gelatin to fit different applications. A-D) The low and medium modified gelatin percentage pcECM formulations had significantly greater viscosity, swelling, and burst strength compared to the highly modified pcECM and Tisseel. E-F) The low modified gelatin pcECM had significantly greater tensile strength and a lower Young's modulus compared to the other pcECM formulations.

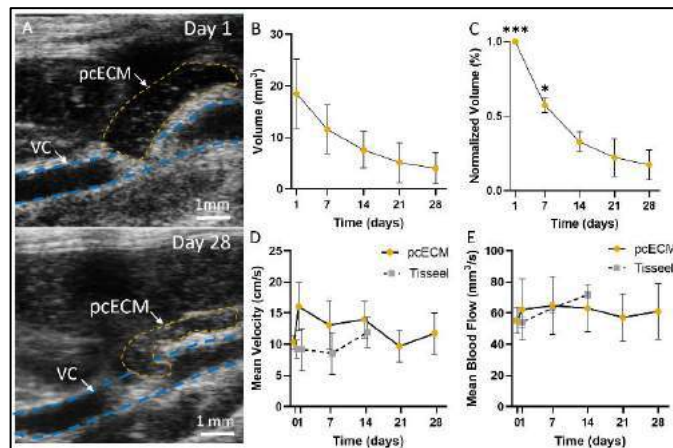

Figure 2: 3DUS volume measurements showed that pcECM degrades significantly but was robust and adhered/sealed the VC up to 28 days after surgery. A) B-mode ultrasound images show pcECM covering the laceration site on the vena cava and degradation over 28 days. B-C) Total pcECM volume degraded significantly over 28 days. D-E) The presence of pcECM or Tisseel did not significantly affect mean velocity or volumetric blood flow compared to baseline measurements.

We also found that pcECM significantly degrades over time and only small volumes of pcECM remained at the 28 day explant (Fig. 2). While pcECM compressed the VC after implant, only mild increases in

velocity (+5.7 mm/s) and volumetric flow (+7.8 mm³/s) were observed with pulsed-wave Doppler and luminal area measurements.

DISCUSSION

In this study we found pcECM to be a mechanically robust, biocompatible sealant capable of stopping venous hemorrhage without significantly altering vessel hemodynamics and morphology after application. All three pcECM formulations and Tisseel were tested to determine their respective mechanical properties, but only the low percentage modified gelatin pcECM and Tisseel were tested *in vivo*. The low modified gelatin formulation was selected due to its significantly higher viscosity that provided ease of application to the ~1.0mm diameter murine VC, as well as its high burst strength and tensile strength (Fig. 1) that make it suitable for vascular applications. However, the low formulation experienced the greatest amount of swelling which may cause it to compress veins and surrounding tissue structures depending on the volume implanted. Nevertheless, pcECM is crosslinked by a visible light source allowing the user to clear unwanted pcECM, reposition it on the tissue, or apply more before crosslinking.

Tisseel also successfully stopped venous hemorrhage in this study with little effect on mean velocity and morphology of the vessel. It is important to note that bleeding was well controlled while applying either pcECM or Tisseel to the vessel. One limitation of Tisseel is that it cannot be applied to severe or brisk bleeds as the sealant is quickly washed away before crosslinking. We observed that both sealants can be crosslinked in an aqueous environment with little or no active flow. While pcECM and Tisseel performed similarly in this venous hemorrhage application, pcECM's significantly greater burst strength, tensile strength, Young's modulus, and its crosslinking method/time make it a suitable candidate for arterial hemorrhage applications in the future. While bleeding can be controlled with pressure to a lacerated vessel in real-world cases, future experiments will also test pcECM application and crosslinking in both venous and arterial hemorrhage cases where active flow is present.

3DUS volume approximations showed pcECM degrades significantly to 17.4±8.1% of its initial implant volume 28 days after application. We were unable to visualize Tisseel with ultrasound and could not perform volume degradation analysis, but there were no traces of Tisseel present at the 14 day explant. Both sealants were significantly degraded and cleared by the body over time, and histology results showed minimal inflammatory response to pcECM or Tisseel suggesting both have a high degree of biocompatibility. pcECM can also be stored and quickly prepared at room temperature whereas Tisseel is stored at -20°C and must be thawed. Low modified gelatin pcECM's high burst strength, tensile strength, and room temperature storage and preparation conditions provide the possibility for future use in remote location emergencies and arterial bleeds, and the ability to adjust pcECM's mechanical properties by changing the percentage of modified gelatin open an array of surgical applications where a fast-curing, durable, naturally degraded sealant is needed.

INTRODUCTION

Significant cardiovascular changes occur with the metabolic demands of growing a child. Cardiac output and glomerular filtration increase, the cardiac muscle is physically remodeled, and an entirely new organ is made to regulate this demand: the placenta [1]–[4]. This complex and delicate process is upset in hypertensive disorders of pregnancy, but the etiology of these is still poorly understood. Study of preeclampsia – hypertension in pregnancy with end-organ dysfunction – focuses on placental biomarkers and associated changes in hemodynamics which explain some cases, but not the majority [5].

Conversely, the role of renal venous compression, known to occur in early- and late-term preeclampsia, is underexplored [6]. The short gestation (19-21 days) and similar placental structure of mice is ideal for evaluation of this. Herein we explore the impact of compromised renal perfusion in pregnancy through a murine model of left renal vein (LRV) stenosis with the hypothesis that renal injury occurs (such as that seen in preeclampsia) when adequate collateralization does not exist.

METHODS

This study was approved by Purdue University's Institute for Animal Care and Use Committee. Thirty-four nulliparous female mice were paired with male mice (C57Bl/6J) and imaged with high-frequency ultrasound (Vevo3100 Imaging system, FUJIFILM VisualSonics, Inc., Toronto, ON, Canada) every 3-4 days to date the gestation [7]. On gestational day 6.5 (e6.5) a proximal (PS, n=14), distal (n=15), or sham stenosis (n=5, Figure 1) was induced by placing a 30g needle parallel to the LRV, tying a suture around both, and removing the needle. Ten distal animals also underwent mini-osmotic pump implantation (Alzet, Durect) filled with angiotensin II (n=5, 1000ng/kg/min) or saline (n=5).

All distal, all sham, and a subset (n=5) of PS animals underwent blood pressure (CODA, Kent Scientific) and ultrasound imaging at pairing, e12.5, e15.5, and e18.5 using a 40MHz central frequency

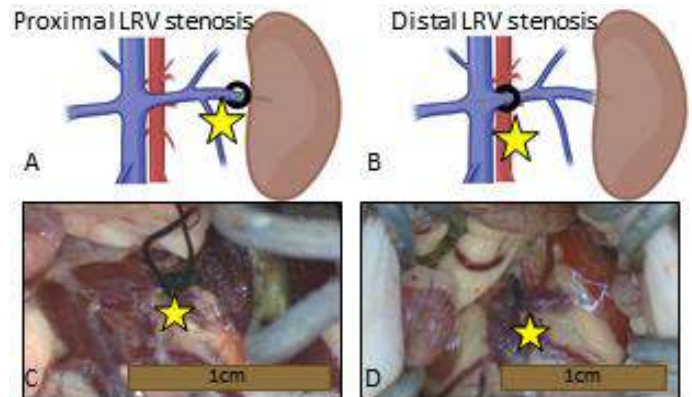

Figure 1: Proximal stenosis (A, C) provides no alternate route for blood to return to the heart. Conversely, a distal stenosis (B, D) assumes detours. A and B created with biorender.com.

transducer (Figure 2A). Renal volumes and velocities were noted. Impedance index was calculated using peak systolic velocity (PSV) and end diastolic velocity (EDV, Eq. 1). At e18.5 animals were euthanized. Maternal kidneys were weighed and fixed in 4% paraformaldehyde for histology. Renal weights were normalized to the contralateral control.

Renal impedance index

$$\text{Impedance Index} = (PSV - EDV)/PSV \quad (1)$$

Glomerular changes throughout gestation

To better assess renal injury progression, we euthanized six PS animals earlier in gestation at e12.5 and e15.5 (n=3 each). Kidneys were weighed, fixed in 2% glutaraldehyde and compared with PS animals euthanized at e18.5 (n=8, 3 of whom did not undergo ultrasound).

Figure 2: General timelines. (A) focuses on changes with differing stenosis location. (B) focuses on longitudinal changes with the PS group only. Pump implant created with biorender.com.

RESULTS

Renal weight difference (right – left) was significantly higher in the PS group compared to all other groups. (Figure 3B, 34.3 ± 21.8 mg vs. 6.1 ± 17.6 mg in the distal stenosis (DS) group, $p=0.026$). Histological and gross pathological analysis demonstrated evidence of acute infarct (Figure 3C). There was no significant difference in renal weight difference between other stenosis location groups. In the PS group left renal weight increased initially (at e12.5), then decreased until euthanasia at e18.5, with a significant difference between e12.5 and e18.5 (-30.4 ± 34.6 and 31.4 ± 24.0 respectively, $p=0.01$). Left renal venous impedance index (VII) was significantly higher in the PS group at e18.5 compared with other groups (0.76 ± 0.16 , PS, $p=0.03$) (Figure 4). There was no significant difference in left renal VII between other groups.

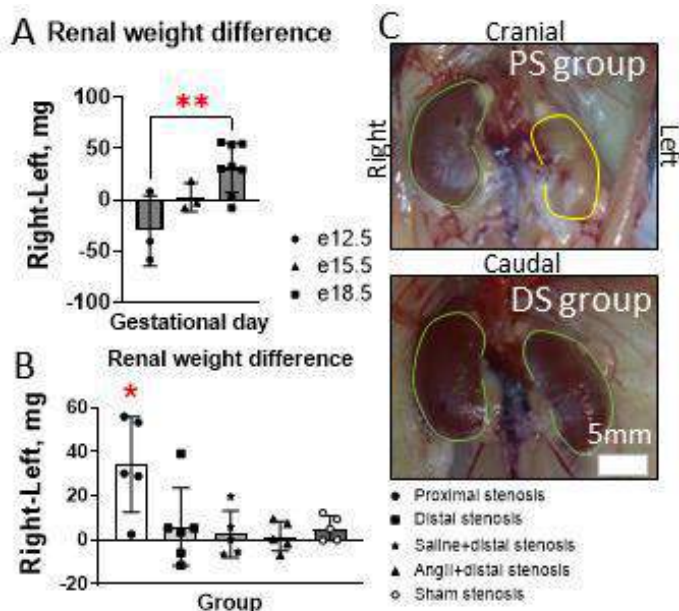

Figure 3: Difference in PS right and left renal weight as gestation progresses was significantly higher at e18.5 than e12.5 (A) and in the PS group (B). Gross pathology demonstrated necrosis (yellow outline) in the PS group compared with distal groups (C). PS, proximal stenosis; DS, distal stenosis.

Left renal venous impedance

Figure 4: Venous impedance index what significantly higher in the proximal group at e18.5, suggesting increased intrarenal pressure.

DISCUSSION

Proximal renal vein stenosis results in decreased renal weight, increased venous resistance, and acute infarct as pregnancy progresses. While not statistically significant at e15.5, changes to the difference in PS right and left renal weight throughout gestation (Figure 3A) otherwise agree with our hypothesis – an initial decrease due to left renal congestion, followed by an increase as ischemia and atrophy of the left kidney begins to occur. This surgically induced murine stenosis is likely more severe than that experienced during human pregnancy, with positional changes causing a more intermittent stenosis and anatomic variation resulting in differing degrees of collateral vascularization. In the context of preeclampsia and no collaterals to re-route blood to the heart these results demonstrate a potential link to the renal injury in these patients. Future work is needed to explore the impact on glomeruli. Scanning electron microscopy and histological analysis will provide additional insight on glomeruli integrity.

Combined, these highlight the importance of collateral vessels in the mitigation of renal injury from renal venous compression by the gravid uterus. Therapies which reduce compression (positional changes, etc.) in patients without adequate collaterals may prevent renal injury.

EFFECT OF AORTIC ROOT MOTION ON AORTIC WALL STRESSES IN THORACIC AORTIC ANEURYSMS

INTRODUCTION

Thoracic aortic aneurysms (TAA) carry the risk of potentially lethal complications such as type A aortic dissection (TAAD). Current known risk factors of TAAD are aortic dilation and hypertension [1]. Most TAAD occur a few centimeters above the sinotubular junction (STJ) and along the greater curvature of the ascending aorta [2]. In TAAD, the intimal tear is normally oriented in the circumferential direction. However, risk factors such as aortic dilation and hypertension fail to explain the strong predilection for circumferential intimal tearing.

In each cardiac cycle, the aortic annulus is displaced downward during cardiac contraction. We hypothesize that such aortic root motion may impart significant stress on the ascending aorta in the axial direction that are ultimately responsible for the direction of intimal tearing. Several studies have investigated the effect of aortic root motion on the wall stress of the ascending aorta using finite element analysis (FEA) [3,4]. These studies showed increased aortic wall stress when aortic root motion was considered in the model. However, these studies used idealized and non-aneurysmal aortic geometries or prescribed simplified, unidirectional (e.g., axial) aortic root motion. Furthermore, validation of simulation results against motion data over the cardiac cycle was also lacking.

In this study, our goal is to investigate the effect of aortic root motion on axial and circumferential stresses in patient-specific models of TAAD using 3D dynamic data on vessel motion and a novel nonlinear rotation-free shell FEA model [5].

METHODS

A patient-specific aortic model was constructed from a 69-year-old male with a history of TAA (maximum diameter: 48mm), hypertension, and mild aortic regurgitation. The blood pressure was 131/85 mmHg. Dynamic computed tomography (CTA) images were available to define systolic and diastolic aortic configurations. The configurations were segmented using a custom U-Net neural network. Subsequently, a

patient-specific aortic model for the FEA was constructed by trimming the aortic inflow and outflow branches to define flat faces (Figure 1.A). 3D root motion was then extracted using a technique recently developed by our group, termed vascular deformation mapping (VDM), which can define 3D aortic displacement (both axial and in-plane) from dynamic CTA imaging [6] (Figure 1.B).

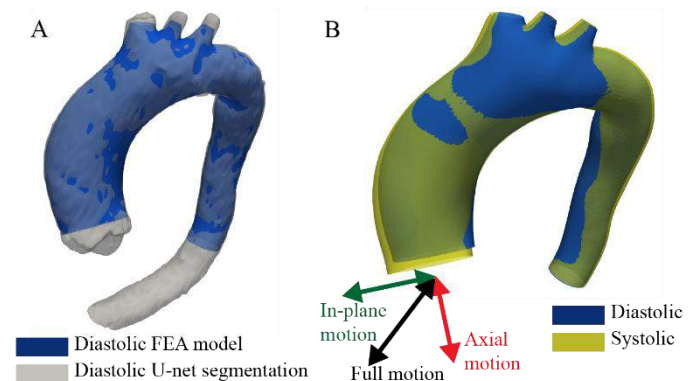

Figure 1: A: Diastolic U-net segmentation (gray) overlaid with FEA aortic model (blue). B: diastolic (blue) and systolic (yellow) patient-specific aortic models.

An incompressible Neo-Hookean constitutive model was used to characterize the aortic wall. The unloaded configuration of the aortic model was estimated using a pre-stressing technique [5]. Literature values of ascending and descending aortic material stiffness [7] were first prescribed in the analysis. Then, comparisons of systolic configurations between FEA and segmentation data were used to iteratively adjust ascending and descending aorta material stiffnesses until the difference between computed and segmentation cross-sectional areas was smaller than 5% (Figure 2).

Figure 2: Comparison of systolic configurations between segmentation and shell FEA. CSA: Cross-Sectional Area.

To understand the impact of pressure and root motion in aortic wall axial stress, a combination of the following loading scenarios was considered: no root motion, in-plane motion, axial motion, and full root motion, both under diastolic and systolic pressures. For all loading scenarios, a full 3D displacement was prescribed for the three arch branch vessel outlets, whereas a free radial, fixed axial displacement was assigned to descending aorta outlet [5]. A mesh independence study was performed. The results reported here were obtained with a 17,681 triangular element mesh.

RESULTS

Aortic root displacement magnitude was 4.3, 5.6, and 7.0 mm in the in-plane, axial, and full components (Figure 1.B), respectively. Figure 3 shows the axial stress for the different pressure and aortic root motion scenarios described above. We report representative values of axial stress in the ascending aorta 2 cm above the STJ along the greater curvature of the aorta, noted by the red star. This is the location where TAAD is more likely to occur. For the case of diastolic pressure and no aortic root motion, the axial stress was 88.5 KPa (Figure 3a). Loading the aortic to the systolic pressure without considering root motion increased the axial stress to 140.3 KPa, a 58% increase (Figure 3b). Considering both systolic pressure and full 3D root motion resulted in an axial stress of 176.7 KPa, a further 26% increase (Figure 3h). As expected, Figure 3d and f show that the axial motion has a much greater impact on axial stress than in-plane.

DISCUSSION

We used a nonlinear rotation-free shell FEA and 3D aortic root displacement data extracted via VDM to study the impact of aortic root motion and blood pressure on axial stress in a patient-specific TAA model. Our results suggest that the contribution of aortic root motion to axial stress in the ascending aorta may be just as important as the blood pressure. Therefore, aortic root motion is critically important when performing aortic stress analysis in the ascending TAA, especially in studies examining risk of TAAD. Further studies will apply these techniques to a large cohort of TAAD subjects.

INTRODUCTION

Organoids derived from human induced pluripotent stem cells (iPSCs) are a promising approach for congenital and adult disease modeling, regenerative medicine, and gaining fundamental understanding of organogenesis [1]. However, organoids are limited in their production scale, reproducibility, and physiologic function and structure [2], posing a considerable barrier to their application. Thus, an important open question is the extent to which engineering control over culture conditions guides organoids toward specific outcomes in composition and organization.

Here, we build upon a DNA ‘velcro’ approach to achieve precise control over initial iPSC-derived progenitor cell numbers and ratios in arrays of microwells, independently of well geometry. We focus on kidney organoids as a model system. We show significant control over organoid size and morphological trajectory after 15-day differentiation of nephron progenitor (NP)-derived organoids. We then create mosaic organoids by establishing precise ratios of NPs and ureteric bud (UB) tip cells, which give rise to the ureteric epithelium (UE, the urinary collection network) *in vivo*. Preliminarily, we find that transition of 2D mosaic cell patterns to 3D suspension culture facilitates cell sorting and discrete compartment formation early in organoid development, which resembles physiologic organization. Furthermore, UB tip cells and NPs synergistically upregulate the stromal cell population. Our approach achieves significant advances in organoid homogeneity relevant to disease modeling and drug screens as well as improved control over tissue interface formation crucial to engineered morphogenesis efforts.

METHODS

Derivation of kidney precursors. Prior to organoid culture, NPs and UB tip cells were derived from iPSCs using established protocols [3]. Briefly, intermediate mesoderm was induced from iPSCs by CHIR99021—a Wnt agonist—and transitioned to NPs under exposure to FGF9. For UB tip cells, NPs were fully differentiated into distalized

nephron organoids and transdifferentiated into UB tip cells by TTNPB (a retinoic acid analog), GDNF, CHIR99021, FGF2, and rock inhibitor.

Fabrication of integrated DNA-cell-patterning technology with microwell arrays. Photoactivatable polyacrylamide (PAA) gels on glass slides were patterned with single-stranded DNA (ssDNA) using UV light exposure through a photomask [4]. To create microwell walls, silicone (PDMS) through-hole sheets were replica micro-molded on 3D-printed pillar arrays and passivated with a polyacrylamide (PA) brush layer [5]. Silicone through-hole sheets were then aligned and adhered to ssDNA-patterned PAA gels. Finally, chamber walls were clamped onto PAA base gels, making 8 separate culture compartments.

Progenitor cell patterning in microwells. NPs and UB tip cells were each functionalized with unique lipid-conjugated ssDNA, which was complementary to an oligo sequence patterned on PAA substrates. During gentle mixing, the lipid moieties passively inserted into cell membranes, decorating cells with ssDNA that was accessible for base-pairing with PAA-bound ssDNA. Cells were then serially patterned by settling them in microwells and washing away excess, unadhered cells.

Kidney organoid culture. Once patterned cells had spread and formed cell junctions with adjacent neighbors, DNase was added to cleave ssDNA tethers, initiating lifting and aggregation. Organoids underwent differentiation in suspension culture for 15 days, receiving minimal medium supplements during the first 2 days. Kidney organoids were then fixed and immunostained for well-established markers of nephron, ureteric epithelium, and stromal tissues.

Image acquisition and analysis. Images of fluorescently labeled patterns of ssDNA and cells, as well as immunostained organoids, were acquired using a Nikon spinning disk confocal microscope. A subset of evenly spaced planes from each organoid z-stack was manually segmented in Fiji to measure the area of proximal tubules, distal tubules, and podocytes. The proportion of each tissue was calculated as the area of the tissue divided by the total area of all segmented tissues of interest (sum of proximal tubule, distal tubule, and podocyte areas).

RESULTS

We began by adapting cell patterning technology to a microwell format suited to long-term organoid culture (**Figure 1**). We targeted three design criteria: 1) using cell patterning to achieve precise cell number and compositional control, 2) inducing the transition of 2D patterns to self-organized 3D spheroids open to continued differentiation, and 3) sequestering individual organoids in passivated microwells throughout long-term culture. For cell patterning, we used our modified photolithographic technique [4], in which base-pairing between cell- and PAA-bound ssDNAs creates temporary cell-substrate adhesions. Nonspecific cell adhesion was reduced by grafting a PA brush layer on the PDMS microwell walls [5]. Furthermore, the addition of DNase, which enzymatically cleaved paired ssDNAs, aided in the transition of patterned cells to a single spheroid per microwell.

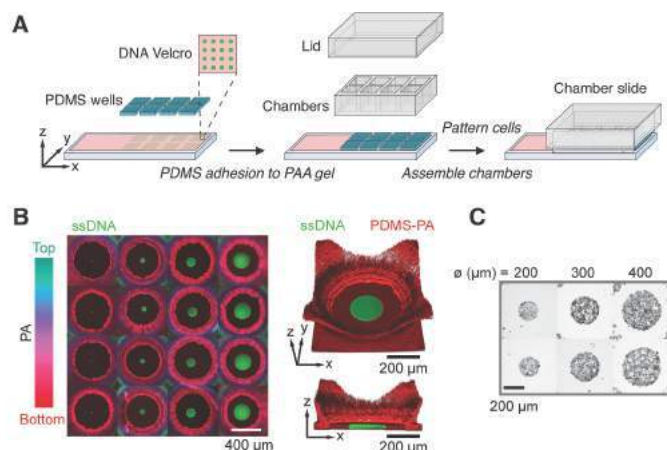

Figure 1: Integration of DNA-cell-patterning with microwells.

(A) Schematic of culture device fabrication. (B) Fluorescently probed ssDNA patterns on PAA base gels and aligned within PA-grafted PDMS microwell walls in array (left) and single-well (right) formats. (C) An example of patterned iPSC-derived NPs on ssDNA spots with variable diameters (\emptyset) in microwells.

Next, we applied our culture system to study the effect of initial NP number on organoid morphogenesis (**Figure 2A**). We discovered that throughout culture, organoid sizes directly depended on NP number, as set by the ssDNA spot sizes used to pattern them. Moreover, larger nephron organoids displayed a shift in final composition, with a significant increase in proximal tubule proportion from $40\% \pm 8.6\%$ to $61\% \pm 7.3\%$ from pattern size diameters 200 to 500 μm (\pm S.D., $n = 10$ organoids per diameter, Tukey's multiple comparisons test, $*p < 0.0332$, $**p < 0.0021$, $***p < 0.0002$, $****p < 0.0001$). These data suggest that the initial NP quantity modulates cell differentiation.

During kidney organogenesis, reciprocal interactions between NPs and UB tip cells influence nephron endowment, a major predictor of kidney disease [6]. We therefore examined how modulating NP to UB tip cell ratios affects organoid morphogenesis *in vitro* (**Figure 2B**). 24 hours post orthogonal cell patterning of UB tip cells and NPs on ssDNA patterns within microwells, we observed lifting, integration, and condensation of both populations to form early mosaic organoids. Interestingly, cells sorted to a single NP and a single UB tip cell compartment. Furthermore, regardless of starting ratio, an outer shell of NPs consistently covered UB tip cell cores, much like the wrapping of the NP cap mesenchyme around UB tips *in vivo* (**Figure 2B, 2C**). Preliminary assessment of immunostained late-stage mosaic organoids suggests an upregulation in stromal cell differentiation, as compared to NP- or UB tip cell-only organoids.

(B) Transition of UB tip cells and NPs from 2D patterns to 3D spheroids. (C) Organization and crucial interactions between NPs and UE *in vivo*.

DISCUSSION

Here, we contribute an integrated cell patterning and long-term culture platform that decouples organoid size from well geometry, enables 3D suspension culture, and maintains discrete organoid cultures. Using this technology, we first discovered a positive correlation between initial NP number, organoid size, and resulting proximal tubule proportion. In a second application, we observed the formation of NP caps around UB tip cell cores in early mosaic organoids, mimicking the organization of these cellular compartments *in vivo*. This cell sorting was likely primarily driven by differential cadherin-based cell-cell adhesion [7]. Preliminary analysis of final mosaic organoids suggests that NPs and UB tip cells synergistically upregulate stromal differentiation, an area of ongoing work.

Future studies are needed to gain mechanistic insight into our resulting organoid phenotypes. Furthermore, it may be necessary to identify, source, and incorporate additional cell types into organoids and/or engineer further control over culture conditions to achieve the structure and function needed for applications in regenerative medicine.

ACKNOWLEDGEMENTS

INTRODUCTION

The visceral pleura is a thin layer of stiff tissue on the surface of the lung, encapsulating the spongy parenchyma. Among its many roles, the visceral pleura helps seal the lung tissue which conducts air exchange. Visceral pleura injuries cause air leaks and are amongst the most common complications in thoracic surgery [1]. Patients undergoing a lobectomy have an 8% to 26% chance of experiencing a prolonged air leak (PAL), defined as air seepage into the pleural cavity persisting for more than 5 days after the procedure [2,3]; Patients experiencing PAL after a lung resection experience higher morbidity rates and lengthier hospital stays [4]. Today there are many lung sealants both on the market and in development to help reduce PAL in thoracic surgery, however, the ability of the sealants to reduce PAL are often inconclusive [5]. Sealants must adhere to and synchronously stretch with the visceral pleura at the site of injury, and therefore characterizing the mechanical properties of this biological tissue is central to understanding how to improve sealants and patient outcomes [6].

Currently, only a few studies characterize the mechanics of the visceral pleura and such studies are limited to uniaxial tests [7]. In-vivo rat and porcine lung studies focus on the rupture performance of lung sealants, not the mechanical behavior of the visceral pleura [8,9]. To date, there has been no mechanical characterization of rat visceral pleura while porcine pleura has been tested only uniaxially. Given the multi-axial loading experienced by the visceral pleura with each dynamic breath, unidirectional testing is an inadequate representation of tissue physiology. This study addresses this knowledge void in the literature by investigating the material properties of both rat and porcine visceral pleura using equibiaxial tensile tests, and considering regional and anisotropic dependencies.

METHODS

Fresh porcine (N=3) and rat (N=3) lungs were obtained from local vendors (Sierra for Medical Science, IACUC exempt). Visceral pleura

specimens were collected from both ventral and dorsal sides of the lung for both porcine and rat lungs (Figure 1). The sheets of visceral pleura tissue were carefully separated from underlying parenchyma while tracking of sample orientation to be aligned with the cranial-caudal (CC) and medial-lateral direction (ML). A total of six rat visceral pleura specimens (4x4mm test area) were collected (Figure 1A). Porcine lobes (Figure 1B) were substantially larger than the rat, allowing for additional consideration of upper (cranial) versus lower (caudal) lobe pleural mechanics. A total of 16 porcine samples (1x1cm test area) were collected.

Figure 1: (A) Rat lung and (B) pig lung single lobes where the reflective outermost layer is the intact visceral pleura. Cranial-caudal (CC) and medial-lateral (ML) orientations are shown.

Tissue thickness was measured using a digital thickness gauge for porcine specimens (Mitutoyo, Kawasaki, Japan) and a confocal microscope for rat specimens (Zeiss, Oberkochen, Germany) [10]. Each specimen was loaded onto rakes and immersed in a 1X phosphate buffered saline solution bath maintained at 37°C [11]. Samples underwent equibiaxial tension tests using a commercial planar biaxial machine (1.5N load cell, BioTester, CellScale Biomaterials Testing, Waterloo, ON, Canada). Extensive preliminary tests informed the testing parameters utilized to avoid tissue damage: 60% strain was applied simultaneously in both the CC and ML directions at a strain rate

of 0.2%/s. Two preconditioning cycles were followed by a third cycle used for data analysis [11]. All tissues were refrigerated at 4°C upon receipt and experiments were conducted within 72 hours postmortem [12].

The First Piola-Kirchhoff engineering stress was calculated and the resulting bilinear stress-strain loading curves (Figure 2) were analyzed by fitting lines through both the initial and final slopes of the curve ($R^2 > 0.95$) to determine the tissue initial and final moduli [11,13]. The maximum stress at 60% strain was noted and the strain energy was calculated as the area under the loading portion of the stress-strain curve. Each metric was explored for the CC and ML orientations, and the ventral and dorsal sides of the lung. Additionally, thickness variations in the porcine visceral pleura suggested upper ($79 \pm 12 \mu\text{m}$) versus lower ($104 \pm 25 \mu\text{m}$) regions should also be examined; the rat visceral pleura thickness was consistent ($11 \pm 1 \mu\text{m}$). No region dependent mechanics were found, and thus ventral-dorsal and upper-lower sample groups were pooled together. Data comparisons were performed using a student's t-test. Statistical significance was defined at $*p < 0.05$, where **, ***, and **** are $p < 0.01$, $p < 0.001$ and $p < 0.0001$ respectively.

RESULTS

The stress-strain response shown in Figure 2 illustrates rat and porcine CC and ML directional responses. Overall, rat visceral pleura experienced higher stresses throughout the strain range compared to porcine tissue.

Maximum stress, strain energy, initial, and ultimate moduli were compared between species. Porcine visceral pleura had an initial modulus of $1.21 \pm 0.11 \text{ kPa}$ and $0.97 \pm 0.09 \text{ kPa}$ in the CC and ML directions respectively, while rat was nearly double that of the porcine moduli (CC: $2.82 \pm 0.41 \text{ kPa}$; ML: $2.80 \pm 0.35 \text{ kPa}$). The ultimate modulus between species differed only in the CC direction (pig: $14.3 \pm 1.26 \text{ kPa}$; rat: $8.64 \pm 0.87 \text{ kPa}$). Despite the greater ultimate modulus for porcine tissue, the maximum stress was greater in rat specimens along both CC and ML directions compared to porcine counterparts. The strain energy was also significantly greater along both CC and ML orientations for the rat compared to porcine visceral pleura.

Intraspecies comparisons were also made. Regional dependencies were not found when comparing ventral and dorsal samples within each species. Despite the sizeable variation in upper versus lower lobe thicknesses of porcine samples, no regionally dependent differences were observed in the mechanical responses of porcine tissue. Anisotropic CC and ML analysis of rat visceral pleura did not exhibit any significant differences. However, porcine specimens demonstrated statistically significant greater CC values for the ultimate modulus, maximum stress, and strain energy compared to ML (Figure 3).

Figure 2: Average \pm standard deviation stress-strain behavior for rat and porcine visceral pleura tissue in both the cranial-caudal and medial-lateral orientations.

DISCUSSION

This study compares porcine and rat visceral pleura mechanical properties via equibiaxial planar testing for the first time. Intraspecies'

Figure 3: (A) Initial and (B) ultimate moduli, in addition to the (C) maximum stress and (D) strain energy values in both the cranial-caudal (CC) and medial-lateral (ML) directions.

mechanical properties demonstrate that porcine and rat visceral pleura are homogenous with no regional variation across the lung. Rat visceral pleura was observed to behave isotropically, however, porcine specimens were anisotropic. Previous literature notes potential anisotropy for canine visceral pleura but concluded isotropic behavior due to experimental errors while determining the tissue reference state [14]. This current study is the first to report biaxial species variability and directional dependency of the visceral pleura. The anisotropic response documented in this biaxially analyzed study will be further substantiated histologically in the future, to investigate the role of the underlying fiber orientation on the directional dependency observed in porcine but not rat visceral pleura.

Rat and porcine visceral pleura material properties are notably disparate and indicate variability from species to species. As such, the effects of differing visceral pleura mechanics among animal models should be considered when constructing and testing pleural sealants. The mechanical properties of modern tissue sealants are often tunable, and thus, comprehensively characterizing the mechanics of the visceral pleura can aid the optimization and effectiveness of pleural sealants [6]. Our future studies will also investigate human cadaveric visceral pleura lung tissue to assess the applicability of animal models for clinical translation.

INTRODUCTION

Rheumatic and calcified aortic heart valve disease is prevalent globally among all aged people, and the number is rapidly increasing. Minimally invasive xenograft-based transcatheter aortic heart valve replacement (TAVR) shows limited durability (<10 years)¹. Hyaluronic acid (HA) enhanced polyethylene polymeric TAVR shows excellent *in vitro* and *in vivo* anti-calcific, anti-thrombotic, and hydrodynamic performance. HA, a glycosaminoglycan, is one of the major constitutive elements of the native heart valve leaflet¹. The long dynamic chains of HA over low-density linear polyethylene (LLDPE) thin-film surface interpenetrated at the molecular level provides a robust and durable hydrophilic biomaterial. LLDPE thin film has high tear strength and excellent flexibility, making it a suitable candidate for heart valve leaflets. However, during durability testing, impact wear causes early valve failure in a consistent fashion related to TAVR assembly (figure 1. b). TAVR leaflets were assembled into a cylinder from a flat film by welding two ends together where they meet over the commissure post and the TAVRs were tested in an accelerated wear tester (AWT). The welded areas never failed and always tore at the cusp opposite the weld commissure post (figure 1. a). The weld at the commissure post is mechanically stronger than the rest of the leaflet, protecting this region. Therefore, this research investigates failure mechanisms and provides methods to increase durability by strategic strengthening of the leaflets in the region of the commissure posts.

METHODS

Fiber-reinforced valve fabrication: We fabricated polymeric heart valves by reinforcing the commissure posts with polyester fiber. One polyester fiber (0.2 mm diameter) was hand-laid upon a thin sheet of LLDPE (80 μ m) along the commissure posts **parallel** to the valve height (figure 1. c). Another thin sheet was laid on top and melt-pressed to create a composite structure. The melt press applied 500 lbs. pressure at 125 °C for 1 minute. The flat laminate was further melt-pressed (i.e.,

Figure 1 (a) Simulated polymeric TAVR assembled over cobalt chromium stent and (b) Tested in AWT. The white rectangle shows torn commissure and dark curve shows stent line and the round holes are where test samples were punched out of leaflets. (c) Fiber reinforcement at the commissure post.

welded) at the two ends to create cylindrical leaflets that were fitted over the stent to complete the valve².

Hydrodynamic Testing: This valve was tested for hydrodynamic performance in an *in-vitro* left heart simulator (LHS) under adult physiologic pressure (120/80 mmHg), heart rate (70 bpm), and cardiac output (5 L/min) using a 60/40 water/glycerin mixture to simulate blood properties. Eighty consecutive cardiac cycles of flow waveforms data were recorded at a sampling rate of 100 Hz³. The fiber-reinforced valves (n=2) were compared to an unreinforced (control) valve⁴. After averaging all cardiac cycles, we calculated the effective orifice area (EOA) and mean transvalvular pressure gradient (PG) and compared them with a control valve without any fiber reinforcement. In this study, particle image velocimetry (PIV) was also performed to measure flow velocity magnitude. Time-resolved recordings were acquired at a temporal resolution of 1000 Hz³. Later the valves (n=3) were tested for durability in an AWT according to ISO 5840¹.

Finite Element Analysis: SolidWorks was used to create a CAD model assembly of cylindrical leaflet and stent to simulate the TAVR in

ABAQUS. The internal diameter and height of the stent (cobalt chromium) were 26 mm and 18.5mm, respectively. The fiber-reinforced valve CAD file was created by thickening a 3mm width of the commissure post with a peak thickness of 0.28mm, which was tapered down to 0.08 mm of the rest of the valve thickness. The thickest region housed the fiber (0.2 mm diameter) **parallel** to the valve height (figure 1 c). In another iteration, a fiber (0.1 mm diameter and 6 mm long) was wrapped over the leaflet **perpendicular** to valve height in the CAD model and simulated in ABAQUS. The stent and the leaflet were discretized in Hypermesh 2021, and mesh convergence was achieved on the leaflet. Cobalt-Chromium alloy and fiber were modeled using the linear elastic material model: elastic modulus 210 GPa and 4 GPa, respectively, and Poisson's ratio of .33. LLDPE leaflet was modeled with 2nd order Ogden hyperelastic material properties. The model simulated the mid-diastolic or leaflet closure part of a cardiac cycle and applied a 100 mm Hg pressure load on the outer surface of the leaflet. Appropriate boundary conditions were applied to the leaflet bottom edge and the entire stent to restrict their movement completely.

RESULTS

The fiber-reinforced valves were tested in LHS and compared with the unreinforced valve. The fiber-reinforced valves had a pressure gradient of 13.2 ± 2 mmHg and EOA of 1.5 ± 0.5 cm². Reinforced valve peak velocity was 2.2 m/s (figure 3) compared to 2.2 m/s for the control group³. In AWT the reinforced valve survived for 73 million cycles compared to 4 million cycles for the control group.

Figure 2. FEA results of (a-b) control valve and (c-f) fiber-reinforced valve. Fiber running parallel to valve height shows (c) compression on the inner surface and (d) lower max principal stress on the outer surface compared to (a-b) unreinforced control group. Fiber running perpendicular to valve height shows (f) a drastic reduction of stress at the commissure post yet (e) height stress concentration at the fiber endpoint.

Max. principal stress reduced from an average of 18 MPa to 15 MPa (n=3) for parallel fiber reinforced group and had compression on the high bending region instead of tension compared to the control group. On the other hand, the valve of fiber running perpendicular to valve height tensile stress at the commissure post was replaced with compressive stress, but fiber tip had high-stress (22 MPa) concentration.

Figure 3 Velocity magnitude of fiber (parallel to valve height) reinforced valve: mid to late acceleration (a), peak (b), and mid to late deceleration (c)

DISCUSSION

The fiber-reinforced valve hydrodynamics were comparable to the previously published control group (pressure gradient 9.5 mm Hg and EOA 1.91 cm²) because the strong reinforcement was tucked behind the stent⁴. The results showed a slightly higher standard deviation, indicating inconsistent valve assembly during testing. Interestingly the fluid velocity did not significantly change, indicating the overall good performance of the valve. This parallel-to-valve-height-fiber reinforced valve showed drastic improvements in durability as the highly stressed commissure posts were strengthened and protected, confirming the initial hypothesis. However, FEA simulation results did not show significant peak stress reduction due to the parallel fiber reinforcement, although thickened commissure post-bending area had compressive stress compared to tensile stress in the control group. Which indicates that the strong composite at the post was more of a surface protection from abrasion between the leaflet and stent than stress reduction in the leaflet itself.

Tensors of the deformed valve showed high stresses perpendicular to valve height instead of parallel to valve height (figure 1 c). Therefore, a fiber with an aspect ratio 60 was placed perpendicular to valve height to transfer the maximum load from the matrix to the fiber. The FEA showed promising results where leaflet stresses near the commissure post were drastically reduced to negative tensile stress (compressive stress). The fiber was 16 times stiffer than the matrix, so showed 562 MPa stress while transferring load from matrix LLDPE. However, the perpendicular fiber placement could cause a new failure mode due to the high leaflet stresses at the fiber ends.

Critical fiber length determines the minimum length required to transfer the maximum load from matrix to fiber. The perpendicular-to-valve height fiber modeled above was longer than the estimated critical fiber length. For a thermoplastic composite like LLDPE, yield shear stress is generally below 10 MPa, and polyester fiber strength is ~400 MPa depending on braiding and diameter⁵. Therefore, the critical aspect ratio is below 50. Thus, for a 0.1 mm diameter, the critical fiber length is below 5 mm. Therefore, the perpendicular-to-valve height fiber modeled above was able to carry commissure post load and thus protect the leaflet in the region of commissure from failure. It should also provide protection from abrasive failure, as the parallel fiber did. However, the perpendicular fiber does create new areas of stress concentration in the leaflets at the ends of the fiber.

The CAD models can be readily devised into a composite valve where the fiber is embedded into the LLDPE matrix between two layers of LLDPE instead of laying over only one layer. Future simulations will compute embedded fiber in two layers of LLDPE to create a geometry contour at the fiber tip to reduce stress concentration. In addition, strategic bio-inspired fiber orientation, like collagen fiber orientation in native valves, will also be studied in computational modeling. Finally, these strategically reinforced valves will be devised using melt press technology and tested for hydrodynamic testing.

This research has shown drastic improvement in polymeric valve durability outcomes by strategic fiber placement. The fibers tucked at the back of the stent retained valve hydrodynamic performance. Therefore, this research can be considered a gateway towards improving durability outcomes using bio-inspired fiber placement strategies.

INTRODUCTION

Cerebral aneurysms are prevalent (3-5% of adults), and with high mortality and morbidity if the aneurysm ruptures. For unruptured aneurysms discovered incidentally, there is a need for more reliable indicators of rupture risk than the basic systemic and morphological characteristics currently used [1]. Some aneurysms are known to produce sound in the range of 100-800Hz [2], and the wall vibration producing this sound could be a mechanobiological stimulus for deleterious wall remodelling or rupture.
