The source and mechanism of aneurysm sounds has been debated for decades. It has been suggested that sounds could be caused by the aneurysm wall simply transmitting the frequency content of fluid vortex-shedding or “turbulence” [3], or that resonance of the aneurysm structure is creating the sound [4]. If we assume resonance is taking place, the dominant modes of vibration are not clear from the literature. “Breathing” mode vibration (aka “flexible Helmholtz resonator”), consisting of expansion and contraction of the aneurysm sac [4], has been considered as the only mode of vibration by most mathematical modelling studies (e.g., [5]), but recent studies have identified axisymmetric or “rocking” modes of vibration [6,8].

We have been the first to perform proof-of-concept FSI studies of aneurysm wall vibration, but only under steady [7] or ramped [6] flow conditions. In this study we performed the first pulsatile FSI simulations of vibrating intracranial aneurysms, the most detailed analysis of cerebral aneurysm vibration to date, to elucidate the mechanism of aneurysm wall vibrations.

METHODS

Three cerebral aneurysms (Cases 3, 9 and 16) previously shown by CFD to exhibit unstable flow at physiological flow rates [9] plus one stable-flow control (Case 8) were subjected to pulsatile inflow and pressure profiles (Figure 1) based on a 10% damped older-adult waveform [10]. Three cycles were run, with results shown from the

last cycle. Cycle-averaged, cross-sectional mean velocity was assumed to be 0.37 m/s [9], with a fully-developed Womersley velocity profile applied at the inlet.

Figure 1 – Inlet flow (normalized to cycle-average flow rate) and pressure applied to the inner wall as a function of time, for all cases, starting from initial conditions.

Simulations were performed using a monolithic FSI solver (“turtleFSI”) [11], with solver settings as detailed in [6]. FSI meshes were generated using the Vascular Modelling Toolkit, with ~100k tetrahedral fluid elements and ~40k solid elements in each case. The solid was constructed as two additional layers of elements, with a total uniform wall thickness of 0.25 mm and an elastic modulus of 1 MPa. To prevent over-estimation of the pressurized aneurysm geometry, an approximate zero-pressure geometry was calculated and prescribed to these meshes, as detailed in [6]. Dynamic viscosity and density of the blood were 0.0035 Pa-s and 1000 kg/m³ respectively. A zero-pressure boundary condition was applied to the fluid at the outlets, with the physiological perfusion pressure prescribed as a distributed force normal to the FSI interface. The deformable region of the aneurysm geometry was a spherical region that fully enclosed the aneurysm sac, with the proximal and distal arteries fixed in space and rigid.

For comparison with sonic and Doppler ultrasound recordings in previous studies, sac-averaged spectrograms of the fluid velocity and wall displacement were generated to demonstrate the onset and nature of flow instability and vibration, following methods detailed in [6]. Wall displacements were band-pass filtered to obtain the mode shapes.

RESULTS

The three cases known to exhibit flow instability from previous CFD-only studies exhibited flow instability under pulsatile FSI conditions, as exhibited by the high-power (green to bright yellow) regions of the spectrograms (Figure 2), while the control Case 8 did not. Cases 3, 9 and 16 all exhibited high-frequency wall vibrations that persisted into diastole, after the flow had re-laminarized, as exhibited by the return to a flat, dark indigo in the fluid spectrograms. Visualizations of the sac motion showed that these persistent frequencies corresponded to “rocking” modes of the whole aneurysm sac (e.g., Figure 3), and a modal analysis showed that these were the natural vibration modes of the structure. These frequencies were related to the size of the aneurysm, with the largest aneurysm exhibiting the lowest frequencies (120–190 Hz in Case 16) and the smallest aneurysm exhibiting the highest frequencies (360 Hz in Case 9). Case 3 exhibited the largest amplitudes of vibration, indicated by the bright yellow band at ~220 Hz in the wall spectrogram. This prominent band is visible in the fluid spectrogram as well, suggesting feedback from the structure back to the fluid.

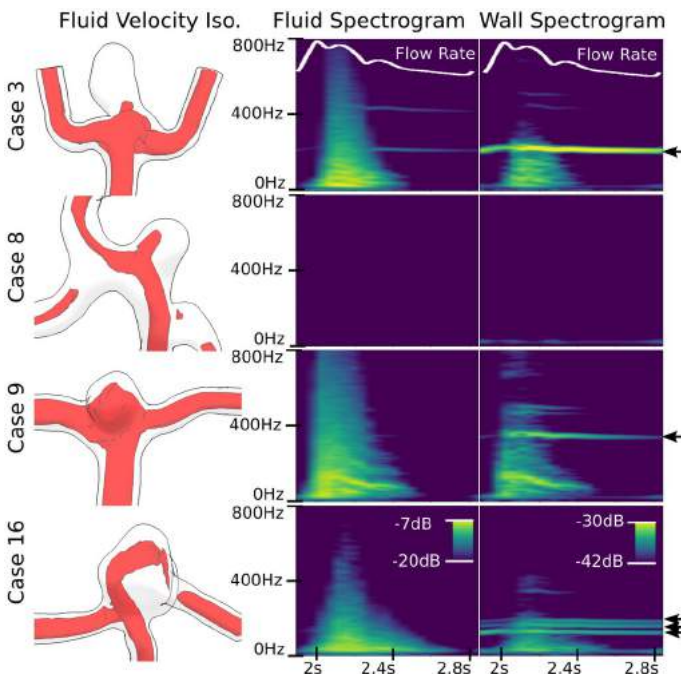

Figure 2 – (left) Peak systolic velocity isosurfaces at 0.5 m/s. (middle and right) Fluid and Wall spectrograms. The persistent bands in the wall spectrograms (indicated by arrows on the right) represent “rocking” modes of the aneurysm sac.

DISCUSSION

This study has some limitations, namely the linear elastic wall model with uniform walls, and the simplistic support method with no external damping, which may lead to some vibrations persisting longer than in a real aneurysm. However, the spectrograms do bear a striking resemblance to the Doppler ultrasound recordings of blood flow sounds from cerebral aneurysms with vasospasm reported by Aaslid and Nornes [12] (Figure 3). Those recordings consisted of a broadband systolic “bruit” with a narrowband “murmur” (or “spike”, as described by Sekhar and Wasserman [4]) superimposed; this murmur persisted until mid-diastole, after the bruit had subsided. In our results, the persistent band in the wall spectrogram (like the “murmur” in [12]) was due to vibration in a “rocking” mode of the aneurysm structure, where the sac “rocked” back and forth, while the underlying broadband wall response (like the “bruit” in [12]) mirrored the turbulent-like

fluid response. In other words, there is a resonant phenomenon taking place, with additional transitional or turbulent flow superimposed, exactly like the “turbulent” fluid bruit with superimposed resonant spikes suggested by Sekhar and Wasserman to describe their aneurysm recordings [4]. However, the “breathing mode” vibration described there [4] (and in most previous studies [5]) was not the primary source of narrow-band vibration in our study; “rocking” modes were the main cause. Similar to previous studies (for example, [5]), our results suggest that aneurysms do not self-excite in response to *stable* pulsatile flow, as shown by the control Case 8.

Figure 3 – (left) Two cycles of a Doppler ultrasound recording of cerebral vasospasm and aneurysm (from [12], with permission); (middle) wall spectrogram from Case 3 for the second and third cardiac cycle, shown in grayscale to highlight the similar broadband “turbulent” bruit and descending narrowband murmurs, the latter corresponding to “rocking” modes (right). The deformation of this mode shape was scaled by 1000x.

To explain the differences among the cases, it is thought that Case 3 vibrates most due to its oblong shape and therefore its lower resistance to bending about the neck, while Case 16 vibrates the least of the unstable-flow aneurysms, as it is the largest aneurysm and requires exposure to more prolonged flow instability to vibrate more, due to its larger mass and inertia.

Our simulations are the first to demonstrate the wall response of a cerebral aneurysm due to flow instability under pulsatile conditions. In multiple studies, it has been shown that vibration can disrupt the normal behaviour of mural cells, either by inhibition of the active force in smooth muscle cells and subsequently damaging to the passive structures [13] or damaging endothelial cells [14]. Future work aims to quantify the strains and stresses on the wall, to estimate the mechanobiological stimulus and relate this to the mechanobiological changes in the wall, and to assess the impact of more realistic wall and surrounding properties.

THE ROLE OF SKIN BIOMECHANICS IN TACTILE PERCEPTION OF ANTI-AGING FORMULATIONS

INTRODUCTION

Human skin regulates tactile perception of the world around us through interplay of the tissue's material properties and a system of mechano-sensitive cells. These mechanoreceptors transduce deformations in the skin to electro-chemical signals in the central nervous system [1]. Changes in the skin's microstructure, which could stem from UV exposure or moisturizer application, induce alterations in the skin's biomechanical state that trigger these mechanoreceptors. However, the relationship between skin biomechanics and how we perceive sensations remains unclear.

Anti-aging cosmetic formulations are associated with feelings of tightness and discomfort due to a contracting polymer film formed on the skin surface. A substantial amount of effort has been made in the development of formulations that assuage this discomfort while retaining skincare and aesthetic benefits. However, primary focus has been on optimizing chemical composition [2] and there remains no clear mechanism explaining why certain formulations outperform others.

In this work, we bolster a fundamental link between mechanical stresses in the top layer of skin, the stratum corneum (SC), and feelings of skin tightness. Furthermore, we show how careful combination of polymer films and moisturizers in anti-aging formulations can optimize both skin comfort and appearance.

METHODS

A three-pronged approach was used to connect the skin's biomechanical state to tactile perception, combining *in vitro*, *in vivo*, and *in silico* methods. First, SC from human cadaver skin was used to characterize the tissue's material properties in response to dehydration before and after application of cosmetic treatments. In particular, the substrate

curvature technique (Fig. 1) was used to measure stresses, σ_{SC} , in the thin SC ($h_{SC} \approx 20 \mu\text{m}$):

$$\sigma_{SC} = \frac{E_{sub}}{1 - \nu_{sub}} \frac{h_{sub}^2}{6h_{SC}} \kappa \quad (1)$$

E_{sub} and ν_{sub} are the elastic modulus and Poisson ratio of the substrate, h_{sub} is the thickness of the substrate ($\sim 174 \mu\text{m}$), and κ is the curvature of the substrate. Importantly, no information is needed about the elastic properties of the SC.

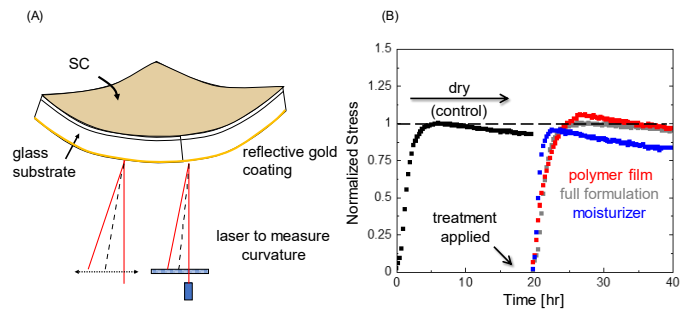

Figure 1: (A) Substrate curvature technique to measure SC stresses. The substrate's curvature increases as stress develops during dehydration. (B) Following application of either a contracting polymer film (red) or moisturizer (blue), peak stress increases or decreases. However, combining both components in the full formulation (grey) results in no peak stress change.

Stresses measured in the laboratory were used as inputs to a finite element (FE) model of a histologically accurate skin section. We used the FE model to calculate strains at mechanoreceptor locations. These strains correlate with the firing rate (number of neurological impulses sent per second) of these cells.

Complementary to the laboratory experiments and computational simulations, a consumer survey was conducted where volunteers assess the effectiveness and comfort of the full formulation.

RESULTS

The relationship between measured SC stresses and consumer perception for the full anti-aging formulation is compared with previous results for cleansers and moisturizers [3] in Fig. 2. Given the measured peak stress, we predict consumers would report tighter feeling skin for the polymer film by itself (red dashed arrow). However, these feelings could be assuaged by adding a soothing moisturizer (blue dashed arrow) in the full formulation (grey dashed arrow). In fact, 70% of consumers report the formulation combining polymer film and moisturizer feels comfortable on skin directly after application. This further establishes the connection between biomechanical state of the SC and feelings of tightness. Specifically, as SC stress increases due to application of a polymer film, increased deformation at mechanoreceptor sites leads to a higher firing rate which corresponds to augmented sensations of discomfort. However, inclusion of a moisturizer that reduces SC stress results in less deformation leading to lower firing rates and dampened feelings of tightness. Importantly, this reduction in skin discomfort had no adverse consequences on the effectiveness of the treatment.

Figure 2: Relationship between consumer perception scores and measured SC stresses. Cleansers (red) and the polymer film increase SC peak stress and lead to tighter feeling skin. Moisturizers (black) decrease SC stress and soothe skin discomfort. The full anti-aging formulation (grey) combines a specific moisturizer (blue) with the stress-increasing polymer film.

The FE model provides the capability to explore the effect of topology on perception of skin tightness. Particularly, by inputting cheek and forehead histological sections, we see that different geometries propagate strains through the full-thickness skin in different ways (Fig. 3). Differing amounts of deformation at mechanoreceptors will lead to differing sensations.

Figure 3: FE simulations of cheek and forehead histological sections after application of a polymer film, moisturizer, or full formulation that combines both. Topology as well as mechanoreceptor density and location affect the sensorial perception of our skin in response to topical treatments.

DISCUSSION

In this study, we establish a fundamental link between the SC’s biomechanical state and tactile perception, and use this to quantitatively understand the mechanism underlying sensorial perception of our skin in response to topical treatments. We demonstrate a new approach to understand and predict modifications of skin SC biomechanics by polymer films and moisturizers, and resulting consumer perception of comfort. The resulting model links SC modifications to the stimulation of mechanoreceptors well below the skin surface.

The synergistic integration of *in vivo*, *in vitro*, and *in silico* methods provides a novel framework for rapid testing of new formulations. Laboratory measurements allow for quick assessment of the SC’s biomechanical properties over time. Computational simulations can be used to explore skin regions and topographies that would be difficult in the lab. Finally, consumer surveys provide the necessary information to place computed firing rates in the appropriate neurological context.

Future studies will focus on further expanding the capabilities of the FE model to account for 1) 3D topological affects, 2) mechanoreceptor density in various body sites, and 3) precise mechanoreceptor location in full-thickness skin (e.g., higher concentrations near hair-shafts). Furthermore, the psychophysical framework developed can be extended to a full range of stimulations provided by haptic devices including wearable actuators and sensors. It also provides a novel way to study the body’s sensing system which could serve as inspiration for the design of soft robotics and stimuli responsive materials.

MECHANICAL CHANGES OF THE PREGNANT MURINE UTERUS

Emily A. Hoffmann (1), Shanmugasundaram Nallasamy (2), Kyoko Yoshida (1)

INTRODUCTION

Proper growth, remodeling, and mechanical function of the uterus are critical for a safe, term pregnancy. Abnormalities can lead to conditions like preterm birth, which can occur when the uterus contracts prematurely [1]. Preterm birth is the leading cause of infant and early childhood mortality and affects over 10% of pregnancies in the U.S. [1,2]. Mechanical and hormonal factors influence uterine contractility, but their mechanisms of action and how they influence the timing of labor is unknown. Our long-term goal is to understand the mechanisms of uterine growth, remodeling, and mechanical function during pregnancy to guide better diagnostics and treatments of preterm birth. Here, we characterize the mechanical environment that may affect uterine contractility: changes in *in situ* stretch, stiffness, and uterine material properties during pregnancy. These mechanical factors are important to understand because they result from, and drive, the growth (changes in size), remodeling (changes in material properties), and mechanical function of the uterus during gestation.

Therefore, the objectives of this study are to 1) experimentally measure biaxial *in situ* stretch and stiffness during gestation, and 2) fit a constitutive material model to our data to determine material properties and for future computational model development. In this work, we conduct biaxial stress-relaxation tests using the *in situ* stretch as a reference state to determine the most relevant mechanical properties for each gestation day. We use a mouse model for the advantages of a short gestation period, access to healthy tissue, and pregnancy-induced changes comparable to those in humans [3].

METHODS

Mouse uterine tissue was acquired at gestation days 12, 15, and 18 of a 19-day pregnancy (n=5-6 per group for *in situ* measurements; n=1 animal per group for biaxial testing). We isolated the reproductive tract, then marked a 5mm length in the longitudinal and circumferential directions on the regions around the pups (FIG. 1A). We removed the

pups to calculate the *in situ* stretch as the ratio of the lengths in the stretched and unstretched states (FIG. 1B). This measurement indicates the stretch that the uterus experiences during pregnancy and was used to calculate the stretch range for tensile testing.

Next, we cut a cruciform sample from the isolated uterus and conducted equibiaxial stress-relaxation tests (FIG. 1C). Each sample was stretched to 40%, 70%, 100%, 140%, and 180% of its *in situ* stretch and held for 30 minutes to allow stress relaxation. We calculated the maximum slope of the equilibrium stretch-force curve to assess stiffness. While previous studies have reported only longitudinal material properties of the uterus [4], our biaxial testing more closely replicates the pregnant loading condition.

To determine tissue material properties, we generated sample-specific finite element (FE) models and simulated biaxial stretching using FEBio (v. 3.6.0). We modeled two layers of tissue, one with longitudinal fibers and one with circumferential fibers, to reflect the fiber distribution of the mouse uterus [5]. We then fit a transversely isotropic Mooney-Rivlin (TIMR) material model to our equilibrium stretch versus force data by sweeping a range of values for the parameters $c1=[0.0005-0.1]$, $c3=[0.003-0.1]$, and $c4=[1.4-25]$, while fixing the parameters $c2=0$, $c5=0$, $k=100$, and $\lambda_{max}=10$ to avoid overfitting. We determined the best-fit parameter set that minimized the sum of squared error between experimental and model forces.

Figure 1: The *in situ* lengths were measured in the longitudinal and circumferential directions by comparing A) stretched versus B) unstretched lengths. C) Biaxial stretching setup.

RESULTS

In situ stretches in both the longitudinal and circumferential directions remained constant between gestation day 12 (long.: 1.06, circ.: 1.23) and day 15 (long.: 1.09, circ.: 1.19), then increased significantly by day 18 in the longitudinal direction (long.: 1.19, circ.: 1.22) (FIG. 2A, one-way ANOVA $p < 0.05$). There were no significant changes with gestation in the circumferential direction and no significant differences between the longitudinal and circumferential directions at each timepoint. These results suggest that the amount of stretch the pregnant uterus experiences is similar during mid-gestation (between days 12 and 15) and increases near term. They also indicate that that tissue experiences isotropic stretch.

In the biaxial tensile tests, maximum stiffness was higher in the circumferential direction compared to longitudinal (FIG. 2B). As pregnancy progressed, the maximum stiffness values increased. Longitudinal maximum stiffness values were 0.30, 0.62, and 0.93 [N/-] and circumferential maximum stiffnesses were 0.58, 0.84, and 1.48 [N/-] at days 12, 15, and 18, respectively. While the maximum stiffness increased, the toe region of the stretch-force curve elongated as gestation progressed (longitudinal: FIG. 2C, circumferential: FIG. 2D).

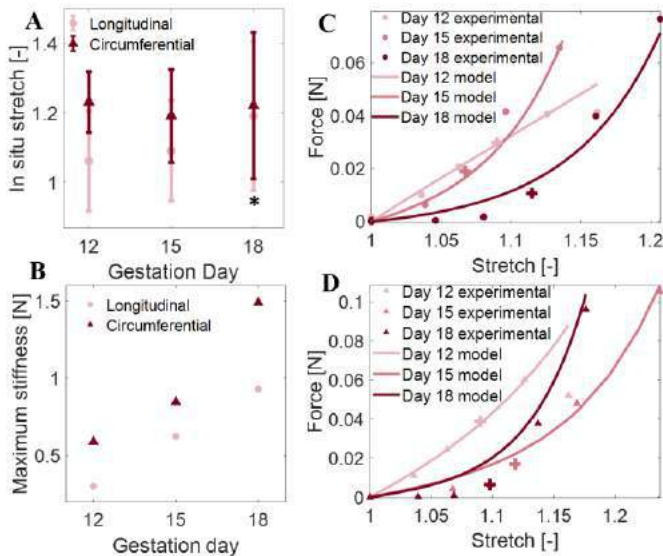

Figure 2: A) *In situ* stretch (*significant in the longitudinal direction compared to day 12 ($p < 0.05$)). B) Maximum stiffness increased with pregnancy. C) Biaxial stretch-force (dots) and model fits (lines) for the longitudinal direction and D) circumferential direction (+ indicates *in situ* stretch).

Our FE model was able to capture the material behavior on days 12, 15, and 18 of pregnancy, indicating that a TIMR material model can describe the material behavior of the pregnant mouse uterus (lines in FIG. 2C, 2D and Table 1). Over the course of gestation, the parameters $c1$ and $c3$ generally decreased, reflecting the elongated toe region, while $c4$ increased to reflect the increase in maximum stiffness (FIG. 2B).

Table 1: Best-fit TIMR material parameters.

	Longitudinal			Circumferential		
	Day12	Day15	Day18	Day12	Day15	Day18
$c1$ [Pa]	0.03	0.005	0.0005	0.02	0.006	0.003
$c3$ [Pa]	0.04	0.01	0.003	0.05	0.008	0.003
$c4$ [-]	5	21	18	11	16	24
r^2 value	0.93	0.87	0.96	0.99	0.99	0.95

DISCUSSION

The objective of this study was to characterize changes in the mechanical environment of the murine uterus during pregnancy. We report changes in biaxial *in situ* stretch and stiffness at three gestational timepoints. We conduct mechanical testing around the sample-specific *in situ* stretch measurements to determine relevant material property changes during pregnancy. Finally, we fit a TIMR material model to our experimental data and report material parameter changes of the mouse uterus throughout gestation.

Our results show that *in situ* stretch remains constant until day 15 of a 19-day gestation, suggesting that the uterus grows at a similar pace to the growing pups during this period. By day 18, *in situ* stretch increases, indicating that pup growth begins to outpace uterine growth at term. Our measurements of *in situ* stretch (FIG. 2A) agree with previous results from rabbit uteri that show a similar increase in *in vivo* length towards the end of gestation [6].

Our biaxial data show that the toe region of the stretch-force curve elongated and the maximum stiffness increased as pregnancy progressed. The toe region elongation agrees with changes seen in the pregnant murine cervix [7] and in previous uniaxial tests on uterine tissue [4,8], although the increase in maximum stiffness was not observed in these prior studies. However, our results generally agree with a recent study that demonstrated an increase in collagen fiber organization with progressing gestation in the mouse uterus [5], as increased fiber organization would suggest an increase in stiffness. Disagreements in our maximum stiffness measurements with previous mechanical data could be due to differences in the loading conditions (uniaxial vs. biaxial) or in how the reference state was defined. We are testing additional samples to further investigate these results.

Finally, we were able to capture our experimental stretch-force curves with our FE simulations using a TIMR material model, indicating that TIMR is an appropriate constitutive model to describe the mechanics of pregnant uterine tissue. We were able to describe the elongation of the toe region in our data with the decrease in the $c1$ and $c3$, while the increase in $c4$ (the exponential parameter) reflects the increase in maximum stiffness.

In conclusion, we develop and report a novel method to assess uterine material property changes during pregnancy in mice. Specifically, we connect *in situ* stretch measurements to *ex vivo*, biaxial stress-relaxation tests to determine the most relevant material property changes of the uterus during pregnancy. The main limitation of our current work is the low animal number ($n=1$) for mechanical testing and we are conducting additional tests to determine statistical significance. These data will inform our FE model of the uterus, through which we will examine how mechanical signaling controls uterine growth and remodeling during pregnancy. In the future, we aim to use this knowledge to improve prediction and prevention of preterm birth.

QUANTIFYING THE REMODELING STRAIN IN THE LAMINA CRIBROSA YEARS AFTER PRESSURE LOWERING SURGERY

Cameron A. Czerpak (1) Harry A. Quigley (2), Thao D. Nguyen (1)

(1) Mechanical Engineering, Johns Hopkins University, Baltimore, MD, United States

(2) Ophthalmology, Johns Hopkins University, Baltimore, MD, United States

INTRODUCTION

The lamina cribrosa (LC) is a collagenous tissue at the end of the optic nerve head (ONH). The cribriform plates of the LC resemble a network of beams and pores when viewed *en face*. Retinal ganglion cells (RGC) exit the eye through the LC, and the LC supports the RGCs from intraocular pressure (IOP) [1,2]. Glaucoma is a blinding disease associated with a chronic elevation in IOP, and the human LC is the primary site of RGC axon injury in glaucoma [3]. The LC also remodels with glaucoma. The LC thins and becomes more curved with axon damage [4]. The pores become smaller and the collagen and elastin composition changes [5,6]. Therefore, mechanical deformations in the LC caused by changes in IOP or remodeling may be a biomarker for developing glaucoma or glaucoma progression.

Optical coherence tomography (OCT) has recently been used to measure the motion of structural features of the ONH *in vivo* in response to changes in IOP and remodeling [7,8]. We and others have measured the change in the anterior LC depth and strain to changes in IOP using digital volume correlation (DVC) [9,10]. Our study of 29 suturelysis procedures measured the acute strain response in the LC from IOP lowering by suturelysis. Radial OCT scans were acquired of the ONH before and 20 minutes after suturelysis and DVC was applied to the before and after-lysis scans to calculate the strain field [10]. We found tensile anterior-posterior strain of $0.95 \pm 1.2\%$ and LC border movement of $1.3 \pm 6.3 \mu\text{m}$ posterior (out of the eye).

In contrast, previous studies have used only the displacement of the anterior LC border to characterize the long-term remodeling response to a change in IOP. Kadziauskienė et al. showed the largest movement of the LC border occurred 3-10 days after pressure lowering and was $37 \mu\text{m}$ anterior [11]. The LC border continued to move anterior at a slower rate up to 6 months following pressure lowering ($65 \mu\text{m}$ anterior). Krzyżanowska-Berkowska et al. found that the LC border had the largest anterior motion at 1 month following pressure lowering ($60 \mu\text{m}$ anterior), then remained at a constant depth at follow-up measurements

up to a year [12]. These results suggest there is a passive viscoelastic response shortly after IOP lowering, followed by a period of active remodeling. However, the motion of the anterior LC border may not predict the strains the LC experiences from remodeling [10]. This study aims to quantify the active biomechanics in the LC by measuring the long-term deformation response in the LC years after IOP lowering by suturelysis.

METHODS

Figure 1: A) OCT image of the optic nerve head after suturelysis, B) 1 year later, and C) the anterior-posterior strain map.

Twelve patients who previously had trabeculectomy and suturelysis surgery were reimaged 1–4 years following the suturelysis surgery. The average patient age was 65.8 ± 6.7 years and glaucoma damage, as measured by mean deviation (MD), ranged from -1.3 to $-$

27.4 dB at the time of suturelysis. IOP was measured by an iCare tonometer and applanation. IOP before the trabeculectomy surgery was calculated from the average of up to 3 applanation IOP measurements. The iCare tonometer was used to measure IOP immediately before and 20 minutes after suturelysis, and at the follow-up appointment 1-4 years after suturelysis. We also recorded the average and maximum of applanation IOP measurements taken between the suturelysis surgery and the follow-up appointment.

Heidelberg Spectralis (Heidelberg, Germany, Heidelberg Engineering) was applied to capture 24 radial scans of the ONH. Three sets of OCT images were captured 20 minutes after suturelysis, and at the follow-up appointment 1-4 years after suturelysis. Images were preprocessed to increase contrast and reduce noise by contrast-limited adaptive histogram equalization (CLAHE) and Gamma correction (Fig. 1). The Bruch's membrane opening and the anterior border of the LC were marked, and a curve was drawn 250 μm posterior to delineate the anterior portion of the LC.

DVC was applied between follow-up scans and after-lysis scans to estimate follow-up LC strains and anterior LC displacement, which include the effects of creep, IOP change over time, and tissue remodeling in response to IOP-lowering. We calculated E_{zz} , $E_{\theta\theta}$, E_{rr} , $E_{r\theta}$, $E_{\theta z}$, E_{rz} over R, θ , and Z, and calculated the maximum principal strain (E_{max}) and maximum shear strain (Γ_{max}) in the RZ plane. Baseline DVC error was calculated by measuring the strain response from subsequent image sets 20 minutes after-lysis to measure the repeatability of the strain measurements. We calculated correlation error by numerically applying a deformation to an after-lysis image and measuring the difference between the numerically applied strain and the strain measured from DVC. We used t-tests to determine the significance of the mean LC strains and to compare strain to the baseline error and correlation error. Relationships between the follow-up strain, IOP, LC border movement, and glaucoma damage (MD, and nerve fiber layer (RNFL)) were analyzed using linear regression.

RESULTS

Remodeling produced a mean tensile anterior-posterior strain (E_{zz}) $11.5 \pm 20.0\%$ in the LC ($p=0.073$) and the LC border displaced by an average of $62.7 \pm 59.8 \mu\text{m}$ anteriorly ($p=0.004$). The mean E_{zz} was borderline larger than the baseline error ($p=0.078$) and the correlation error ($p=0.085$). The follow-up strains in the radial direction ($E_{rr} = 0.36 \pm 1.14\%$) and circumferential direction ($E_{\theta\theta} = -0.61 \pm 2.35\%$) were over an order of magnitude smaller than E_{zz} and not significant. Follow-up shear strains ($E_{r\theta} = 0.48 \pm 1.28\%$), ($E_{\theta z} = -0.28 \pm 1.41\%$), ($E_{rz} = -0.58 \pm 1.41\%$) were also small and not larger than 0 or error. Maximum principal strain ($E_{max} = 15.3 \pm 18.9\%$) and maximum shear strain ($\Gamma_{max} = 9.40 \pm 9.07\%$) were both larger than 0 ($p=0.017$, 0.004 respectively).

Multiple measures of IOP were associated with $E_{\theta\theta}$ and anterior LC displacement. More tensile $E_{\theta\theta}$ was associated with higher pre-trabeculectomy IOP ($p=0.045$) and greater IOP decrease from before trabeculectomy to after suturelysis ($p=0.057$) (Fig. 2). Lower IOP measured immediately before the suturelysis was associated with greater anterior movement of the LC at follow-up ($p=0.025$).

A larger anterior movement of the LC border at follow-up was associated with tensile E_{zz} ($p=0.007$), E_{max} ($p=0.005$), and Γ_{max} ($p=0.004$). More negative MD ($p=0.052$), indicating worse damage to the visual field, and a greater decrease in MD ($p=0.015$), indicating greater worsening of the visual field, measured at the follow-up appointment were associated with greater tensile $E_{\theta\theta}$ strain. Thinner RNFL thickness, indicating worse damage, at suturelysis was associated with larger follow-up E_{zz} ($p=0.035$) and E_{max} ($p=0.045$) (Fig. 2). Eyes

with a greater after-lysis shear compliance (after-lysis $E_{\theta\theta}$ /IOP decrease from lysis) had a greater follow-up E_{zz} ($p=0.004$).

Figure 2: A) Greater tensile follow-up $E_{\theta\theta}$ was associated with greater IOP decrease from before trabeculectomy to after-lysis. B) Greater tensile follow-up E_{zz} was associated with thinner RNFL thickness.

DISCUSSION

The study suggests that the LC deformation can be reliably and accurately measured years after IOP lowering by suturelysis. The acute after-lysis deformation from IOP lowering was up to 10 times smaller than those measured years later. The anterior border movement was 47 times larger at follow-up. Remodeling increased LC thickness, reduced LC circumference and produced an anterior border movement.

LC remodeling has a complicated relationship with IOP change. We did not find that a greater IOP decrease from before trabeculectomy to after suturelysis produced greater anterior motion of the LC border nor larger tensile E_{zz} . A limitation of the method is the small sample size, and a larger sample size may be needed to determine the relationship between IOP change and ONH remodeling.

Eyes with greater glaucoma damage at suturelysis, as measured by MD and RNFL, and greater worsening of glaucoma damage, measured by MD change from suturelysis to follow-up, experienced more remodeling. Furthermore, a more compliant LC measured at suturelysis was associated with greater glaucoma damage and greater remodeling at follow-up. The structural compliance of the LC at suturelysis and LC strains at long-term follow-up may represent new potential biomarkers for early diagnosis of glaucoma and glaucoma progression.

INTRODUCTION

Each year only in America 8.2 million suffer a chronic wound arising from burns, diabetic ulcers, skin cancer surgery, or infection¹. Surgical repair of chronic wounds often requires split-thickness skin grafts in which epidermis and a thin part of the dermis from one site are harvested, cut into a meshwork, and stretched to cover a larger wound area (Fig.1A). In the process of skin grafting and as a result of skin graft stretching, cells within the skin graft experience static tensile strains. The main drawback of split-thickness skin grafting is excessive contracture of the skin graft in the wound site which is caused by the activation and transition of low-contractile fibroblasts to hyper-contractile myofibroblast cells². While a low amount of cellular contractile forces is required for wound healing, excessive contractile forces generated by hyperactivated cells can cause tightening of the skin graft, pain, scarring, and even graft failure³. On top of that, factors such as aging, obesity, and peripheral vascular disease postpone the wound healing process⁴, causing cells to remain under tension for a longer period in stretched skin grafts until new skin is produced and tension decreased.

We hypothesized that the magnitude and duration of the tensile strain that cells experience within a meshed graft regulate the activation of fibroblasts and can induce long-term mechanical memory in cells. To test the hypothesis, we first measured the strain fields that cells experience within a meshed graft and we found that the strain magnitude can significantly change by altering grafting parameters such as meshing ratio. We then evaluated the responses of human dermal fibroblasts to these strain levels within tissue constructs, and we found that cell activation and memory induction change with strain magnitude in a biphasic manner. Finally, using an integrated computational and experimental approach, we showed that the biphasic response is regulated by the time and strain-dependent behavior of the extracellular matrix (ECM).

METHODS

The human dermal fibroblasts (HDFs) at P4-8 were trypsinized, resuspended in fresh DMEM and then added to mouse rat tail-derived

type I collagen in acetic acid and 2X DMEM. After neutralizing the pH with sodium hydroxide, 1 mL of the mixture containing 1.5×10^6 cells/mL HDFs and 1.2 mg/mL collagen was poured into each cylindrical casting well and was incubated at 37 °C with 5% CO₂ for 2 d for the polymerization and compaction of the tissue. These casting wells for tissue construction were made with Teflon and have a mandrel with a diameter of 9.65 mm at the center to construct a tissue ring for the tensile test (Fig. 2A).

Figure 1: Skin graft meshing ratio can be tuned to tailor strain levels by an order of magnitude during graft stretching.

The custom-made tensile tester with sensitive isometric force transducers and stepper motors was plugged into an Arduino for applying displacement precisely (Fig. 2B). The tissue rings removed from the casting wells were hung onto the attachment bars, bathed with 25 mM HEPES buffered DMEM with 10% FBS and 1% PS at 37 °C. Then the attachment bars were separated at a 13.3 mm distance under the control of the Arduino. The initial force was measured by removing the lower attachment bars away from the samples to define the zero-force points. The samples were moved to a pre-strain setup in normal DMEM at 37 °C with 5% CO₂ for desired strain levels with 3D printed spacers with different lengths for 1h or 24h. Then the spacers were

removed to relax the tissues for another day. Then, the samples were treated with 2 μ M cytochalasin-D (cyto-D) for 1h. The cyto-D treated samples were tested with the 5% strain for 10 mins (Fig. 3A) for ECM mechanical property.

RESULTS

To test the hypothesis that the strain field within a graft varies with the meshing ratio, we evaluated how the strain field that cells experience in a skin graft is affected by altering grafting parameters such as meshing ratio (Fig. 1B). Using Holzapfel-Gasser-Ogden model, we found that the strain distribution in stretched skin grafts depends strongly on the meshing ratio (Fig. 1C). Skin meshed with higher meshing ratios has higher numbers and longer cuts, and can be stretched easily without undergoing high tensile strains. These lower macroscopic strains mean that cells within skin grafts with higher meshing ratios experience lower strain levels. Note that meshing ratios of 1 to 5 are frequently used in skin graft surgeries and our results show that the choice of meshing ratio can induce more than an order of magnitude change in the average strain level that cells experience in the skin graft with average strains of over 30% possible (Fig. 1C).

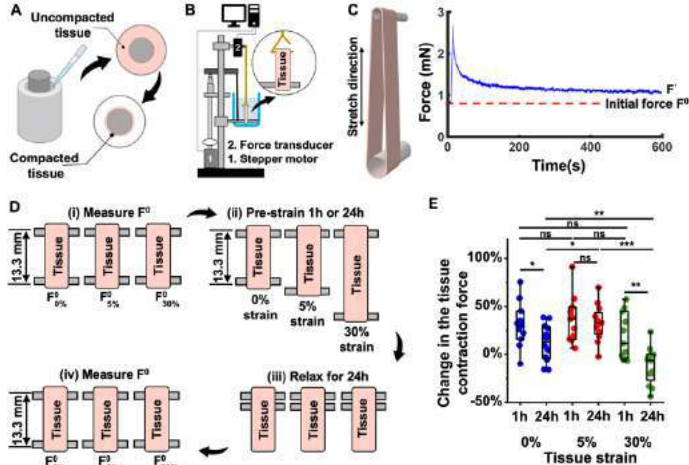

Figure 2: The strain field generated in stretched skin grafts determines the activation level of fibroblast cells.

We next studied whether the 30% change in the strain level of cells can affect their behavior by inducing a long-term increase or decrease in cell contractility level. Our results showed that the contractility level of cells and the traction force they generate depend in a biphasic manner on the magnitude of strain that they experience in their skin grafts (Fig. 2E); tissue stretching even with a small strain of 5% for 24h drove cells permanently into a higher contractile state, while very large strains significantly reduced tissue contractile force. This indicates that the level of strain that cells experience in skin grafts can cause permanent activation/deactivation of cells and therefore affect the outcome of skin graft surgeries as hypercontractility of cells can cause excessive tissue contraction, while low contractility of cells can delay and even curtail the wound healing process. Interestingly, the biphasic strain magnitude-dependent behavior was only observed in tissues loaded for 24 h, while the tissues loaded for 1h showed no significant change in contraction force. This indicates that the cell memory induction and thus permanent activation/deactivation of cells in tissues are not only a function of the strain level but also highly depend on the loading duration. As external forces are transmitted to cells through the extracellular collagen matrix^{5,6}, we next studied the role of ECM mechanical properties in cell memory induction.

To decouple the effects of cells and matrix on the total tissue contractile force F^0 , we treated the tissues with cyto-D to disrupt the actomyosin contractility of the cells. Then we tested the cyto-D treated tissues with the relaxation test to determine whether the ECM stiffness in any of the tissues has been affected by the magnitude and duration of external stretching (Fig. 3A). We found that the ECMs of the tissues loaded for 1h showed the same stiffness, independent of the strain magnitude in the tissue. They also exhibited higher stiffness than the ECMs of the tissues loaded for 24h. Interestingly, the softening in the 24h group increased with the strain magnitude in the tissue where the tissue loaded with 30% strain showed significantly lower stiffness (Fig. 3E). Note that cells in this group showed the lowest level of actomyosin contractility and activation level (Fig. 2E). This indicates that long-term loading on tissues can cause opposite permanent effects on cell behavior: long-term tissue stretching with small strain magnitudes can promote actomyosin contractility of cells and permanently transmit them to a hypercontractile phenotype, while long-term tissue stretching with large strain magnitudes can damage and soften the ECM and subsequently deactivate cells (Fig. 3F).

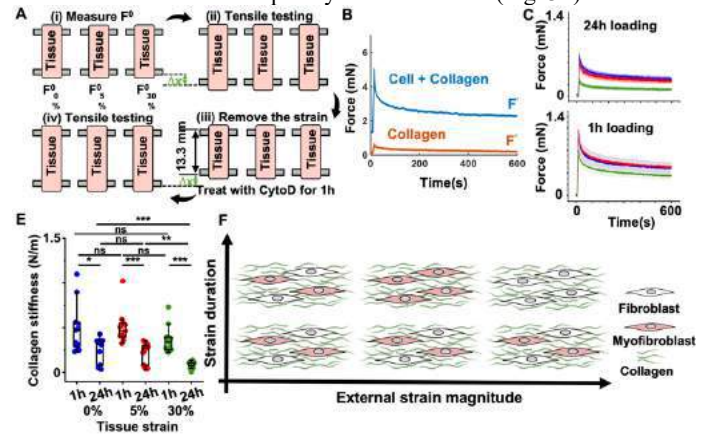

Figure 3: The long-term effect of pre-straining on tissue contractility is due to cell activation and not due to the ECM.

DISCUSSION

Cells in skin grafts undergo stresses whose magnitude depends on surgical parameters including meshing ratio, meshing orientation, skin physical properties, and wound site geometry. While current grafting protocols do not account for these mechanobiological factors, our results showed that these stresses and their durations can activate mechanosensing pathways and drive fibroblast cells to a higher or lower contractile phenotype. Using an integrated experimental and theoretical approach, we showed that by tailoring of meshing configuration, we can harness the molecular machinery of mechanotransduction to enable skin graft contracture that prevents excessive contracture while keeping the baseline contractility required for wound closure.

STRESS QUANTIFICATION ON INTACT AND TORN ROTATOR CUFF TENDONS

Nicole Tueni (1), Farid Amirouche (1,2)

- (1) University of Illinois at Chicago Department of Orthopaedic Surgery, Chicago, Illinois, USA
(2) Northshore University Department of Orthopaedic Surgery, Evanston, Illinois, USA

INTRODUCTION

The rotator cuff is a set of muscles attached to the humeral head via tendons. They surround the shoulder joint and securely retain the upper arm bone's head within the scapula's shallow socket, hence ensuring the glenohumeral joint stability. The tendon-to-bone attachment connects two very different materials: a compliant tendon and a stiff bone. It is thus prone to high-stress concentrations and an increased risk of failure. This study aims at developing a full numerical model of the glenohumeral joint, comprising cartilage, muscles, tendons, and ligaments, in order to shed light on the mechanisms of rotator cuff tears.

METHODS

From CT scans, the scapula, humerus, and clavicle bones were generated using *Materialise MIMICS* for bone segmentation. The surfaces of the four muscles were then designed using the bone surfaces and then extruded to obtain the muscle volumes in *Ansys SpaceClaim*. Each volume was then sectioned into two parts, separating the tendon from the muscle. Moreover, the muscles were sectioned into several parts representing the local orientations of the fibers (See Figure 1, Left).

Three cases were investigated: (a) an intact shoulder, (b) a shoulder with an induced partial tear of half of the subscapularis tendon width, and (c) a shoulder with an induced subscapularis tendon total transverse tear and a partial attachment to the humerus (See Figure 1, Right).

The complete assembly was then imported into *Abaqus CAE*, where the local fiber orientations were defined using the *Orientation* function.

Elastic material parameters with a Young modulus and a Poisson's ratio were assigned to the bones [1], while hyperelastic material properties were assigned to the muscles, tendons, cartilage, and ligaments. For the ligaments and cartilages, isotropic Arruda-Boyce and Neo-Hookean models were adopted respectively [2,3], and transversely isotropic Holzapfel-Ogden model parameters were assigned for the muscles and tendons [4,5].

Figure 1: Left: Complete 3D model. Yellow: bones, Red: muscles, White: tendons, Gray: ligaments, Blue: cartilage. Right: (a) Intact tendon (b) Tendon with partial transverse tear (c) Tendon with total transverse tear with partial attachment to the humerus

A tie connection was considered between the four muscles and the scapula and humerus bones, as well as between the ligaments linking the clavicle to the scapula. The glenohumeral joint was modeled using a frictionless contact, consisting of a normal and a tangential component. Furthermore, in order to mimic an abduction motion of the shoulder, the scapula was fixed, and a displacement was imposed on the humerus.

RESULTS

Figure 2 shows the stress distribution map for the three cases. The intact shoulder shows a stress concentration with a peak at mid-width of the tendon-bone attachment (Figure 2, a). We induced the partial tear on this region and observed a local increase of the stress by approximately 160% (Figure 2, b), with a peak stress on the inner edge of the tear. Interestingly, the total transverse tear (Figure 2, c), showed a 120% decrease of peak stress compared to the partial tear, implying a more homogeneous distribution of the stress in the case of a total transverse tear.

Figure 2: Stress distribution maps on the tendon-to-bone attachment for the three studied cases.

DISCUSSION

The developed model predicts the injury location in the tendon and quantifies the medically observed stress evolution in case of a tear. To improve this model, muscles should be segmented using high-definition MRI. Furthermore, the results should be validated using experimental data. In future work, different repair techniques, commonly used by orthopaedic surgeons, will be simulated and compared. Moreover, the impact of tendon tears on the glenohumeral joint stability could be analyzed.

USING A THREE-DIMENSIONAL BIVENTRICULAR MATHEMATICAL MODEL TO HELP UNDERSTAND SEX DIFFERENCES IN THE ONSET AND PROGRESSION OF PULMONARY ARTERIAL HYPERTENSION

Kristen M. Garcia (1), Becky A. Hardie (1), Jennifer Stowe (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California San Diego, La Jolla, CA, US

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a vasculopathy of the arteries of the lungs associated with vasoconstriction, stiffening, and *in-situ* thrombosis, raising the mean arterial pressure.¹ This pressure overload induces right ventricle (RV) remodeling. The RV initially maintains cardiac output by increasing muscle contractility recruitment and wall hypertrophy, however, when left untreated, RV remodeling can become maladaptive and lead to right heart failure and premature death.² Thus, RV function is an important predictor of disease severity.

PAH is four times more prevalent in women than men. Premenopausal women have a better outcome and higher survival rates than postmenopausal women and men.³ Thus, the RV remodeling process is sex dependent, where sex hormones play an important, yet unknown role. Here we study these sex-dependent differences in the sugen-hypoxia (SuHx) rat model of PAH. To study the role of sex hormones, a group of ovariectomized female rats was included.

Here we present a mathematical and experimental framework for building a three-dimensional biventricular model of the heart. By combining hemodynamic data, geometry of the heart, myocardial wall properties and fiber architecture information together, we hope to understand what factors contribute to the changes in RV mechanics that give rise to RV hypertrophy and functional changes that are sex-dependent, along with the role of sex hormones in the progression of PAH.

METHODS

All protocols were in accordance with the Institutional Animal Care and Use Committee (IACUC) at the University of California San Diego. PAH was induced in rats by a single injection of a vascular endothelial growth factor receptor inhibitor (SU5416, S8442 MilliporeSigma, CAS Number 204005-46-9, PubChemSubstance ID 24278606 Sigma-Aldrich, MO) followed by three weeks in hypoxia (10% oxygen levels). Male, female intact (OVX-), and ovariectomized

female (OVX+) Sprague-Dawley rats of four- and eight-weeks post PAH induction are studied. PAH is confirmed by invasive measurements of blood pressure at the inlet of the pulmonary artery with a mean pulmonary arterial pressure above 20 mmHg. A control group was matched to each week and referred to as week 0.

Hemodynamics and Tissue Mechanics: *In vivo* blood pressure-volume relationships are recorded during open chest surgery. The heart is harvested and a square sample from the RV free-wall aligned along the apex to the outflow-tract (AOT) is biaxed as previously described by Vélez-Rendón et. al.⁴

Cardiac magnetic resonance imaging (Cardiac MRI): Cardiac MRI was performed at three time points – weeks 0, 4 and 8 in one male, one OVX+, and one OVX- animal at the Molecular Imaging Center at Sanford Consortium (University of California San Diego) using a 11.7-T magnetic strength preclinical scanner (Bruker Biospec, Billerica, MA). Rats were anesthetized with 1-2% isoflurane in 100% oxygen while maintaining body temperature at 37 degrees Celsius. Short axis slices ranging from the apex to the base of the heart were taken every 1.5 mm. Respiration and electrocardiogram were continuously monitored which allowed for us to determine the end-systolic and end-diastolic frames. Image spatial resolution is 200 x 200 microns, with a 250 x 250 pixels image matrix, from a 50 x 50 mm field of view, acquired over a period of 318 ms per frame.

Diffusion-tensor magnetic resonance imaging (DT-MRI): Two male, one OVX- and one OVX+ rats were imaged using DT-MRI to obtain unloaded geometry of the hearts and fiber orientation. To mimic the unloaded state, the heart was fixed by an initial flush of phosphate buffer saline through the cannulated aorta, followed by a flush of 4% paraformaldehyde. The four unloaded control hearts were then sent to the Small Animal Imaging Core Facility (University of Utah) where the imaging and post-process analysis was performed. DT-MRI scans were performed at 100 μ m resolution (TR 500 ms, and TE 26.9 ms) over a period of 16 hours in a 7T horizontal bore Bruker Biospec Avance II

(Bruker Biospin, Ettlingen, Germany). Samples were placed in a custom-built 20 mm surface coil and immersed in fomblin to suppress background signal for imaging.

Image segmentation: Segmentation of the cardiac MRI and DT-MRI were performed manually to create meshes of the left ventricle, right ventricle, and epicardium using *itk-SNAP* (version 3.8.0). After outlining the two ventricles and the epicardium, the files were inputted into a graphic-based software, *Autodesk Meshmixer* (version 3.5.474), in which the segmented ventricles were smoothed out (Figure 1). Lastly, using an open-source 3D finite element generator, *Gmsh* (version 4.10.5), a 3D mesh of each ventricle and the epicardium was built. End-systolic and end-diastolic volumes were calculated using the cardiac magnetic resonance disc summation method, which includes finding the area of the ventricle at each of the slices in the heart and then adding them up and multiplying by the slice thickness.⁵ Using ImageJ (version 1.53) wall thickness measurements of each ventricle and septum were made. Based on the end-systolic and end-diastolic volumes, we computed stroke volume and ejection fraction.

Figure 1: Manual Segmentation of a Cardiac MR Image and an example of Autodesk Meshmixer used to smooth the free wall.

After creating the mesh of the full heart, *3D slicer* (version 5.0.3) was used to determine the location from which the RV sample was taken for mechanical testing.

From the DT-MRI data, we obtain a fiber orientation file (150 x 200 x 150 x 3 array) containing the pixel position of the x- and y-axis, the slice number (z-axis) and the matrix of the fiber vectors at each location (Figure 2A). The primary eigenvector for each location and the fractional anisotropy for each voxel was provided, ranging between 0.3 to 0.6 for fibrous tissues. Once the location of the RV square sample is identified in the 3D mesh (Figure 2B-C), we can assign the fiber orientation to that region.

Figure 2: Longitudinal DT-MRI slice (left, A). Vector field of fibers measured with DT-MRI of the heart (y-axis goes from apex to base and z-axis goes from posterior to anterior) (middle, B). The markers on the RV free wall represent the region where the biax sample was taken (right, C).

RESULTS

The goal is to map the fiber directions onto the geometry of the heart for male, OVX-, and OVX+ control and PAH animals, and to determine how fiber direction influences the movement of the heart. The results from this step are still in progress, however Figure 3 shows preliminary results. Here, an element model (Figure 3A) and mesh

(Figure 3B) were created to represent the portion of the tissue that is biaxed. Using *Continuity* (version 6.4), the finite element (FE) mesh will be reduced to fewer elements and the fiber angles will be interpolated using a nearest neighbor interpolation method onto the nodes of each element. Once the fiber angles are mapped onto the nodes of the mesh, *Continuity* will be used again to test the biomechanical properties of this slab, and to compare the stress-strain relationships of this biax mesh with the *ex vivo* results from harvested RV tissue from control animals.

Figure 3: Model of the biax square (left, A) and the FE Mesh that was created in MATLAB (right, B). The model will be used in Continuity to create a mesh with fewer elements that the fiber vectors will be interpolated onto.

DISCUSSION

The major goal of our work is to use different data modalities to get a more comprehensive understanding of the remodeling process of the RV during PAH. Cardiac MRI and DTI-MRI data allow us to build a realistic biventricular model of the heart with actual geometry and fiber directions. The addition of fiber directions onto the geometry of the heart allows us to determine direction of motion.

Data obtained from these computer simulations will help us discriminate the different changes undergone by the ventricle from health to disease. *In vivo* hemodynamic measurements will be used as input into the model to investigate how changes in pressure impacts RV hypertrophy and changes in mechanical properties of the RV myocardial wall during the progression of PAH. This computational framework will help guide our next set of experiments and help us understand organ level sex differences in RV remodeling.

ACKNOWLEDGEMENTS

We would like to thank Edward Hsu at the University of Utah Small Imaging Core for the Diffusion Tensor Imaging and the University of California San Diego Graduate Interfaces Program for the funding under the T32 EB 009380 training grant.

INTRODUCTION

Osteosarcoma (OS) is a rare, aggressive bone cancer that accounts for <1% of all cancers in humans. The survival rate for OS has not improved in decades due to the refractoriness of metastatic disease to therapy.¹ Non-surgical options for treating the primary tumor remain extremely limited. Recently, comparative tumor models such as canine OS have been explored for the development of effective clinical treatments. OS accounts for over 85% of bone tumors in canines, with 95% of patients presenting with spontaneous micrometastases and high levels of pain at time of diagnosis.² Current treatment options for canine OS are limited, the most common involving tumor resection via limb-salvage or limb-amputation surgery and adjuvant chemotherapy.¹⁻² Some dogs may not qualify for limb amputation, and serious complications after limb-salvage surgery such as implant failure and infection occur in 20-50% of patients. Histotripsy is a noninvasive, non-thermal ablation technique that uses ultrasound to mechanically destroy tissue.³ Previous *ex vivo* studies have demonstrated that histotripsy effectively ablates primary OS tumor tissue without causing cell death or damage to normal tissue.⁴⁻⁵ However, the relationship between histotripsy dose and bone mechanical properties has yet to be established. The objective of the current study was to explore the effects of histotripsy on OS tumor and adjacent grossly normal bone tissue by analyzing the biomechanical integrity of treated and untreated bone. We hypothesized that histotripsy does not significantly alter the biomechanical properties of treated bone and can be used as an alternative to surgery for treatment of canine OS.

METHODS

Two amputated limbs from canine patients with OS tumors undergoing standard-of-care limb amputation were acquired under an approved institutional IACUC protocol (22-091). *Ex vivo* histotripsy ablation was then applied to the OS tumor and a matching volume of grossly normal bone with a custom setup utilizing 1-2 cycle histotripsy pulses at a pulse repetition frequency of 500 Hz (**Figure 1**).

**Figure 1: Osteosarcoma tumor in the canine distal radius (left).
Ex-vivo histotripsy treatment of the tumor (right).**

Bone tissue from the ablated tumor (AT), the ablated grossly normal bone (AN), and a segment of unablated grossly normal bone (UN) were then extracted for biomechanical testing. Cubic (7.5mm x 7.5mm x 7.5 mm; n=3 per group) and rectangular beam specimens (15mm x 2mm x 1mm; n=3 per group) were tested under compressive loading and 3-point bending until failure to assess trabecular and cortical bone biomechanics, respectively. Mechanical testing was performed at a quasi-static loading rate of 1% s⁻¹. Cubic specimens were subjected to compressive loading in the three principal directions (D1, D2, and D3) until just below the yield point to assess potential differences in anisotropy, with D1 being the primary axis of loading. Compression tests were repeated (n=3) in all directions to ensure an accurate measure of the elastic properties of each tissue was achieved. A final compression test to failure in D1 was performed to determine the maximum compressive stress of the tissues. Bending mechanical testing

was performed to failure for all specimens. Compressive and bending moduli, calculated from the slope of the linear region of the stress-strain curves, and maximum stresses were determined to assess the impact of histotripsy on tissue stiffness and strength, respectively. A two-way repeated measures ANOVA was used to assess the impact of loading direction and tissue on the compressive moduli of the trabecular bone specimens. One-way ANOVAs were used to assess elastic and post-yield behavior of the cortical bone specimens and post-yield behavior of the trabecular bone specimens. If significant differences were detected, Tukey's Honest Significant Difference (HSD) tests were performed to compare data between groups if they followed a normal distribution. If data were skewed, non-parametric Mann-Whitney U tests were implemented. The alpha value was set 0.05 and p-values were adjusted for multiple comparisons.

RESULTS

Regarding anisotropy, stiffness was often higher in D1; however, no significant differences were found between the three loading directions for UN, AN or AT samples from either donor. As such, data was grouped by tissue for the remainder of the statistical analyses. No significant differences were detected in the compressive or bending mechanical properties of the trabecular or cortical bone of the AN and UN specimens (**Figures 2 & 3, Table 1**). No statistical comparison could be made between the compressive properties of the AT trabecular bone and those of the UN and AN tissue, as only one cube could be extracted from the ablated tumor tissue of either donor. Regarding the cortical bone, the bending modulus of the AT tissue was not significantly different from the UN and AN tissue. In contrast, max bending strength was significantly lower in the AT (192 ± 66.6 MPa) compared to UN (304 ± 42.5 MPa, $p=0.010$) and AN (327 ± 64.6 MPa, $p=0.002$) cortical bone.

Table 1: Biomechanical properties of UN, AN, and AT bone tissue, measured via compression and 3-point bending testing. Data reported as mean ± standard deviation or median (IQR).

	Property	Condition		
		UN	AN	AT
Compression	Maximum stress (MPa)	8.56 ± 3.51	11.2 ± 6.39	1.31
	Elastic modulus (MPa)	116 (70.6)	200 (58.7)	60.6 (60.3)
Bending	Maximum stress (MPa)	304 ± 42.5	327 ± 64.6	192 ± 66.6
	Elastic modulus (GPa)	32.5 ± 4.94	30.4 ± 10.7	23.3 ± 10.9

Figure 3: Stress vs strain 3-point bending test results for UN, AN, and AT cortical bone.

DISCUSSION

The similarities between the biomechanical properties of UN and AN tissue shown in **Figures 2 and 3** support our hypothesis that histotripsy tumor ablation does not detrimentally affect the biomechanical properties of treated OS bone. Despite the limited dataset, our results also indicate that the compressive and flexural properties of cortical and trabecular tumor tissue are compromised even before histotripsy treatment is applied; however, further analysis must be done to verify these results. Although our current sample size and number of trabecular AT tissue samples were limited in the current work, the study is ongoing. To fully power our statistical analysis, additional limbs and sample preparation are in process to gain a clearer understanding of the biomechanical effects of histotripsy treatment on OS bone tissue. The clinical nature of this pilot study prevented complete control over key variables such as tissue donor characteristics (age, weight, breed, etc.), the anatomical location from which sample tissue was extracted (i.e., radius, ulna, tibia, femur), and sample size. As such, the detected differences between groups may have been influenced by the anatomical location of each of the samples as well as donor demographics. To address these limitations, future controlled studies on the biomechanical effects of histotripsy dose on healthy and OS tissue should be performed to establish treatment guidelines. Ultimately, the results of the current work will aid in the development and advancement of effective, non-invasive treatments for clinical OS patients.

INTRODUCTION

Numerous organs in the bodies of animals consist of branched networks of epithelial tubes, which arise during development via a process known as branching morphogenesis. In many of these organs, changes in tissue mechanics have been shown to affect the formation of new branches, but this work has often relied on experimental techniques, such as microfluidic control of luminal fluid pressure or pharmacological modulation of epithelial fluid secretion, which macroscopically alter the mechanical environment in the entire branched network [1, 2]. As a consequence, it is not well understood how local changes in mechanics impact the formation of new branches or the patterns of proliferation associated with incipient buds. Recent experiments, however, have shown that small, functionalized fluid droplets can be microinjected within the mesenchyme of mechanically accessible embryonic tissues (like the developing limb bud or the presomitic mesoderm) and can be used to quantify the mechanical forces exerted by either individual cells or cell-clusters [3]. Here, we modified this technique to locally perturb the mechanical environment within cultured epithelial organs. Small fluid droplets were microinjected into the luminal space of embryonic lungs to locally alter epithelial tension in the developing airway. These microinjected explants were then cultured *ex vivo* to dynamically assess how local changes in mechanics influence branching morphogenesis and proliferation during embryonic lung development.

METHODS

A pulled glass micropipette was filled with a bioinert fluorocarbon oil (Fluorinert Electronic Liquid FC-70; 3M, St. Paul, MN) and then manually inserted into the luminal space of the developing airway in either embryonic day (E) 5 chicken lung explants or E12.5 mouse lung explants. Using a pneumatic pump, a small volume of oil was injected into the luminal space to create a local dilation within the primary bronchus. The microinjected explants were then cultured for 24-48 hr

on Nucleopore filter membranes at the air/fluid interface in DMEM/F12 medium supplemented with 5% fetal bovine serum (FBS) and antibiotics. Bright-field and epifluorescence images were captured at either discrete time-points (e.g., at 0 and 24 hr) or at 30 min intervals during time-lapse culture. In some experiments, Confetti^{+/+} female mice were crossed with ShhCreEGFP^{+/+} male mice to generate transgenic embryos that randomly express one of four fluorescent reporters within cells along the airway epithelium. At the end of each experiment, explants were fixed in 4% paraformaldehyde and stained for E-cadherin immunofluorescence, EdU incorporation, and DAPI. (The explants were pulsed with EdU for 20 min prior to fixation.) The fixed explants were then optically cleared, mounted in custom imaging chambers, and imaged as whole mounts using a laser scanning confocal microscope. Quantitative image analysis of bright-field and epifluorescence images was performed in ImageJ.

RESULTS

To locally perturb the mechanical environment within the embryonic airway, we injected a small volume of bioinert oil into the lumen of the primary bronchus in E5 chicken lung explants. The

Figure 1: Microinjected oil droplets locally dilate the embryonic airway and disrupt branching morphogenesis.
Scale bar, 200 μ m.

microinjected droplet rounded up over 24 hr of ex vivo culture and created a local distension of the airway (Fig. 1). This local dilation inhibited the formation of new epithelial buds, as compared to uninjected controls (Fig. 1). Smaller volumes of microinjected oil, however, did not dilate the airway, were morpho-logically similar to controls, and did not disrupt branching morphogenesis (Fig. 2), suggesting that a local distension of the airway – and thereby an increase in epithelial tension – is needed to suppress bud formation.

Figure 2: Smaller volumes of microinjected oil do not affect normal branching morphogenesis. Scale bar, 150 μ m.

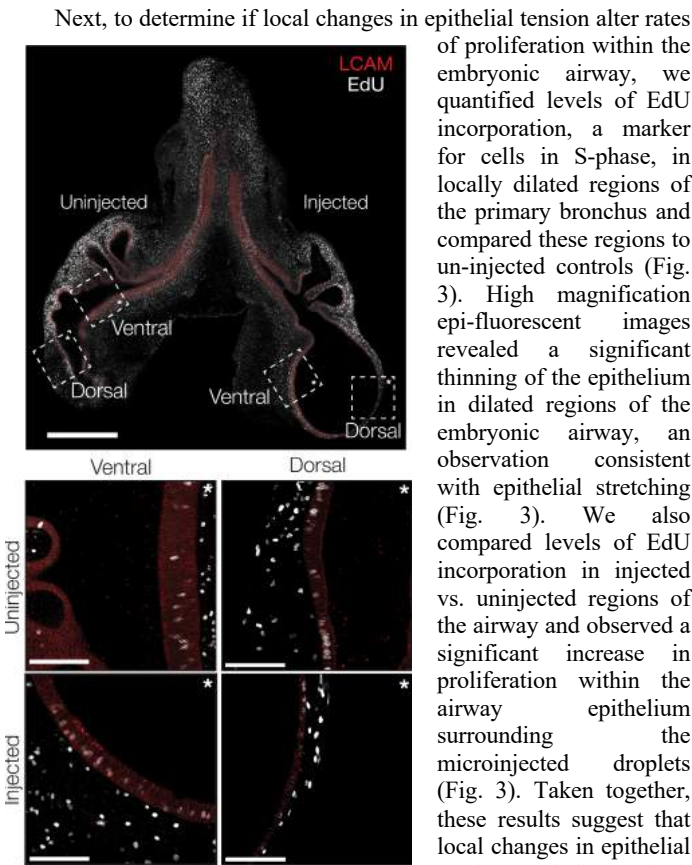

Figure 3: Epithelial proliferation is elevated within injected regions of cultured embryonic lungs. Scale bar, 200 μ m (inset scale bars, 50 μ m).

Next, to determine if local changes in epithelial tension alter rates of proliferation within the embryonic airway, we quantified levels of EdU incorporation, a marker for cells in S-phase, in locally dilated regions of the primary bronchus and compared these regions to un-injected controls (Fig. 3). High magnification epi-fluorescent images revealed a significant thinning of the epithelium in dilated regions of the embryonic airway, an observation consistent with epithelial stretching (Fig. 3). We also compared levels of EdU incorporation in injected vs. uninjected regions of the airway and observed a significant increase in proliferation within the airway epithelium surrounding the microinjected droplets (Fig. 3). Taken together, these results suggest that local changes in epithelial tension can influence both branching morphogenesis and proliferation in cultured embryonic lungs.

Next, to observe cellular dynamics within locally dilated regions of the airway epithelium, and to determine if similar results were observed in the developing mammalian lung, we repeated these experiments using

transgenic mouse embryos, which express dynamic fluorescent reporters within the airway epithelium. Time-lapse epi-fluorescent images revealed a similar local dilation of the embryonic airway (Fig. 4). In this case, however, branching morphogenesis was not completely suppressed. Instead, cells within the airway epithelium moved distally around the microinjected fluid droplet and accumulated within the distal tip of the dilated embryonic airway before forming new epithelial buds (Fig. 4). The branching pattern and dynamics within these dilated regions, however, were significantly different than uninjected regions of the cultured lungs. Taken together, these results indicate local changes in mechanics alter epithelial morphogenesis in cultured avian and mammalian lungs.

Figure 4: Injection of oil droplets within the epithelium of transgenic mice allows for dynamic evaluation of branching. Scale bar, 200 μ m.

DISCUSSION

Although biophysical cues have been shown to regulate embryonic development [4], few experimental tools exist to locally alter epithelial mechanics in cultured embryonic organs [5]. Here, we have shown how microinjected fluid droplets can be used to create a local dilation within the luminal space of the embryonic airways to focally modulate epithelial tension in developing lung explants. The microinjected droplets disrupted normal branching morphogenesis and altered patterns of proliferation along the embryonic airway epithelium. Our technique can be readily adapted to other developing epithelial organs, such as the embryonic kidney [6], intestine [7], or salivary gland [8], in which mechanical forces are thought to influence epithelial morphogenesis. In addition, going forward, our microinjection experiments can be combined with time-lapse imaging and quantitative cell tracking to determine how changes in the mechanical environment influence the epithelial deformations that sculpt incipient branches. The bioinert oil can also be substituted for ferrofluid droplets, which would enable them to be used as mechanical actuators to apply time-varying forces during ex vivo culture, as has been reported during the axial elongation of developing zebrafish embryos [9].

INTRODUCTION

Cartilage tissue engineering (TE) is a promising osteoarthritis (OA) treatment strategy where neocartilage is generated with chondrogenic cell-seeded scaffolds. Transforming growth factor beta (TGF- β) is widely utilized due to its ability to enhance the biosynthesis of cartilaginous extracellular matrix (ECM). Conventionally, tissue constructs are exposed to highly supraphysiologic doses of TGF- β (10-100 ng/mL) supplemented in culture medium, representing activity levels that are 10-1,000-fold higher than those present during native development. While accelerating ECM biosynthesis, conventional TGF- β doses are associated with promoting features detrimental to hyaline cartilage function, including the induction of cellular hyperplasia ^[1], hypertrophy ^[1], and fibrocartilage ^[2]. Further, media-supplemented TGF- β exhibits severe penetration limitations into engineered cartilage, inducing undesirable ECM heterogeneities ^[1]. Together these detrimental outcomes can compromise the clinical survival of tissues post-implantation.

In contrast to conventional TE delivery methods, the natural process of TGF- β delivery in native cartilage occurs differently, whereby chondrocytes are surrounded by TGF- β in an inactive complex, termed latent TGF- β (LTGF- β). LTGF- β is highly concentrated throughout the cartilage ECM (100-300 ng/mL ^[3]) but is activated by chondrocytes at a low, tightly controlled rate (0.1-0.7 ng/mL ^[4]), giving rise to an advantageous, need-based and spatially uniform activity throughout the cartilage tissue. This regulatory mechanism functions to maintain requisite ECM biosynthesis, while avoiding pathological tissue formation from TGF- β excesses.

Inspired by native TGF- β regulatory mechanisms, we explore the novel hypothesis that the delivery of moderated, physiologic TGF- β doses can improve neocartilage formation, marked by achieving native-matched functional mechanical properties, while reducing detrimental features of development: hyperplasia-induced cell clusters, cell hypertrophy, and fibrocartilage-associated type-I collagen. This

hypothesis is examined in two studies. In study 1, we directly examine the effect of physiologic-range TGF- β doses on neocartilage development by exposing small-size constructs to varying doses of media-supplemented TGF- β . These small-size constructs exhibit mitigated TGF- β gradients, allowing for a better assessment of the intrinsic effect of TGF- β doses on tissue development. In study 2, we directly examine the ability of a bio-inspired LTGF- β conjugated scaffold to improve the mechanical properties, composition, cell morphology, and cell phenotype in conventional sized constructs. Here, LTGF- β is conjugated to a methacrylate agarose (MeAgr) hydrogel scaffold, providing a stable LTGF- β reservoir for seeded chondrocytes, allowing for controlled cell-mediated activation to promote sustained, and spatially uniform levels of physiologic TGF- β activity.

METHODS

Tissue Constructs: For both studies, constructs were fabricated with immature bovine primary chondrocytes (30×10^6 cells/mL) and 2% w/v agarose and cultivated in chondrogenic medium. **Study 1: Intrinsic effect of physiologic TGF- β doses.** Small-size constructs ($\varnothing 2 \times 2$ mm) were exposed to a range of physiologic (0.1, 0.3, 1 ng/mL) and conventional supraphysiologic (3, 10 ng/mL) active TGF- β 3 doses supplemented in media for the initial two weeks of culture, or maintained TGF- β free continuously. Compressive Young's modulus (E_y) was analyzed at day 56 ($n=5$) ^[2]. Cell morphology was analyzed at day 30 ($n=3$) via confocal microscopy (Live/Dead) and the fraction of cells in a clustered versus isolated morphology was measured (cluster area fraction [CAF]) ^[5]. Deposition of type-I and type-II collagen were assessed at day 56 via immunostaining ($n=2$). **Study 2: Delivery via LTGF- β conjugated scaffolds.** LTGF- β 1 (R&D) was covalently conjugated to methacrylate agarose ^[6] (MeAgr) by incubating at 37°C overnight with high (3000 ng/mL), medium (1500 ng/mL), and low (600 ng/mL) doses prior to cell encapsulation. Constructs were fabricated at $\varnothing 5 \times 2$ mm. LTGF- β construct development was compared to unconjugated control constructs exposed to media supplemented

(MS) active TGF- β 3 for the initial 2 weeks of culture at a physiologic dose (0.3 ng/mL; MS-0.3), supraphysiologic dose (10 ng/mL; MS-10), or no added TGF- β (TGF- β free). LTGF- β conjugation yields were measured via ELISA. Constructs were analyzed for E γ (n=5) at day 28 and 56. GAG distribution were assessed at day 56 via Safranin O/Fast Green staining (n=1). Spatial strain distributions were analyzed at day 56 via digital image correlation [7] (n=5) with 10% platen-to-platen axial compression, strain profiles were discretized into 6 evenly spaced domains through the tissue depth and used to characterize the degree of heterogeneity in tissue stiffness, determined by a strain ratio (SR)—the ratio of mean strain in each domain to mean strain in the top first domain. CAF was assessed at day 42 (n=3). Type X collagen expression levels were analyzed at day 56 via qPCR (n=3).

RESULTS

Study 1: Intrinsic effect of TGF- β Doses. Small-size constructs (\varnothing 2 \times 2 mm) exhibited increases in both E γ and hyperplasia cell clusters with TGF- β dose. At low TGF- β doses (\leq 0.1 ng/mL), clusters were mitigated, but construct E γ remained low (Fig. 1A). At supraphysiologic doses ($>$ 1 ng/mL), constructs yielded native-matched mechanical properties (E γ ~590 kPa) but exhibited type-I collagen deposition (Fig. 1C) and a pronounced degree of cell clustering—at 10 ng/mL 58% of cells presented as clusters (Fig. 1A-B). However, for physiologic TGF- β doses (0.1-1 ng/mL), constructs exhibited native-matched mechanical properties while maintaining low clustered cellularity and low type-I collagen (Fig. 1), thus representing an optimal dosing regimen for neocartilage development.

Fig 1: (A) E γ and CAF vs. TGF- β dose. Dashed line represents native cartilage E γ level. (B) Cell morphology images depicting clustered (yellow) and isolated (green) cell regions. (C) immunostaining of type-I and type-II collagen in constructs.

Fig 2: (A) E γ , (B) Safranin O staining (* indicates tissue crack region) and strain color maps, and (C) SR of large-size constructs subjected to active TGF- β media-supplementation and LTGF- β conjugation. Dashed line represents native cartilage E γ level. * #p<0.05: significantly above the TGF- β free and MS-10 levels, respectively

Study 2: LTGF- β conjugated scaffolds. LTGF- β conjugation levels increased with incubation dose, reaching native cartilage levels (290 \pm 19 ng/mL) with the high dose. At day 56, all LTGF- β groups exhibited significant enhancement in E γ relative to TGF- β free (p<0.005) and MS-10 (p<0.05) groups, approaching native cartilage E γ (Fig. 2A). GAG gradients were observed in MS-0.3, but not in LTGF- β constructs (Fig. 2B; only high LTGF- β construct depicted). Severe cracks were present near the surface of the MS-10 constructs. At day 56, MS-0.3 and MS-10 groups exhibited large stiffness heterogeneities with SR values of 6.03 \pm 2.99 and 4.00 \pm 1.62, respectively (Fig. 2B-C). In contrast, strain heterogeneities were reduced for LTGF- β groups to an average value of

2.23 \pm 0.68. Minimal cell clusters were present for TGF- β free and MS-0.3 groups (CAF<0.21; Fig. 3A-B), but increased significantly for MS-10 (CAF=0.56 \pm 0.08). For all LTGF- β groups, CAF was significantly reduced below MS-10 levels (p<0.05) (Fig. 3A-B). The expression level of a chondrocyte hypertrophy biomarker, type X collagen was also reduced for LTGF- β groups relative to MS-10 (p<0.05; Fig. 3C).

Fig 3: (A) Cell morphology images depicting clustered (yellow) and isolated (green) cell regions, (B) CAF, and (C) type X collagen expression in constructs from TGF- β media supplementation and LTGF- β conjugation groups. *p<0.05.

DISCUSSION

These results offer a new perspective in cartilage tissue engineering, demonstrating that the administration of moderated, physiologic doses of TGF- β can improve the quality of regenerating neocartilage. In our first study, through our small construct model, we observe that, in the absence of concentration gradients, physiologic doses can yield neocartilage with native-matched functional properties while mitigating the emergence of hyperplasia-induced cell clusters and fibrocartilage-associated type-I collagen. However, due to transport limitations, the delivery of physiologic TGF- β doses to larger, clinical-sized constructs remains a significant challenge. In our second study, we address this hurdle by establishing the benefit of achieving uniform delivery of moderated, physiologic TGF- β doses in large-size constructs via LTGF- β conjugated scaffolds. Results first highlight the limitations of conventional media supplemented delivery approaches. The administration of a supraphysiologic 10 ng/mL TGF- β dose leads to tissue quality deficits in the form of cell clusters and ECM heterogeneities. The administration of a physiologic 0.3 ng/mL TGF- β dose reduces cell clustering but leads to more pronounced heterogeneities, due to TGF- β transport limitations [5]. It is reasonable to surmise that these deficits may compromise the clinical longevity of constructs—heterogeneities can lead to failure of soft tissue regions when subjected to physiologic loading and cell clusters, a hallmark of OA, can lead to propagation of excessive cellular strains under loading due to a lack of sufficient ECM buttressing. The use of LTGF- β conjugation doses that match those present in native cartilage allows for an examination of the regenerative potential of this bio-inspired delivery platform. LTGF- β -conjugated scaffolds appear to create an optimal dynamic where cell-mediated activation of LTGF- β leads to the generation of moderated and uniform TGF- β activity, akin to that present during native development. Here, we observe that this moderated activity promotes requisite ECM biosynthetic enhancements while mitigating cell hyperplasia and cell hypertrophy, leading to engineered cartilage with native-matched mechanical properties, reduced heterogeneities, and improved cell morphology.

INTRODUCTION

Osteoarthritis (OA) is a disease of the joint characterized by the degeneration of articular cartilage. Previously, we have shown the primary wear mechanism in immature bovine articular cartilage is caused by fatigue failure [1]. While cartilage wear is often assumed to occur in conjunction with frictional sliding, recent results suggest that fatigue failure in articular cartilage is specifically due to cyclical compression and not reciprocal frictional sliding [2,3]. Pure reciprocal frictional sliding did not produce damage in human articular cartilage when articulated against stainless steel [2]. However, when slid against glass in a migrating contact configuration (MCA), immature bovine tissue that was cyclical compressive loading during sliding cycles consistently delaminated between the superficial and middle zones of the cartilage tissue. In contrast, tissue that was subjected to a static compressive load during frictional sliding in a stationary contact configuration (SCA) did not result in visual or sub-surface damage [3].

In the aforementioned studies, articular cartilage was submerged in phosphate buffered saline (PBS) for the duration of the experiment. While PBS allows proper hydration of the tissue and can maintain the native osmotic environment, a more physiologic testing bath should be considered. Synovial fluid (SF), the fluid found within each joint space, is known to lower the friction coefficient relative to PBS in cartilage sliding [1,4]. However, the friction coefficient appears not to be a direct indicator of wear. Caligaris et al. found no statistical differences in the friction coefficient between human cartilage with more or less arthritis [4]. Similarly, Durney et al. reported no difference in average friction coefficient between damaged and undamaged immature bovine samples after MCA sliding tests [1]. In our most recent study, we showed that damage occurred in immature bovine cartilage samples in the low-friction MCA test configuration, but not in the high-friction SCA configuration [3]. Though SF reduces the friction coefficient in cartilage sliding, the above outcomes suggest that friction alone is not driving cartilage damage.

The purpose of this study was to investigate how SF affects wear propagation in immature bovine articular cartilage in both the MCA and SCA configurations, and whether it provides a protective effect against damage. We also investigated potential mechanisms for SF to impart protection against damage progression, such as the role of viscosity, molecular diffusion, or friction.

METHODS

Frictional Tests: Full thickness cartilage tibial plateaus were harvested from immature bovine knee joints (2-3 months old), and microtomed to an average thickness of 1.41 ± 0.05 mm. Paired strips were cut from each tibial plateau for the MCA in SF (MCA-SF) test group (10 mm \times 30 mm, $n = 5$) and SCA in SF (SCA-SF) test group (10 mm \times 10 mm, $n = 5$). Samples were mounted onto petri dishes, submerged in mature bovine SF, and placed on a custom frictional testing device equipped with a multiaxial load cell and motorized stage which recorded position and load data during testing. The MCA-SF testing configuration consisted of a hemispherical glass lens ($\varnothing 25$ mm) under a compressive load of 4.45 N, and the SCA-SF configuration consisted of a flat glass lens ($\varnothing 25$ mm) with a compressive load of 44.5 N. Compressive loads were selected to produce equal average contact stress for both configurations. Sliding was prescribed at 1 mm/s across a distance of $U_x = \pm 4$ mm for 24 h (5,400 cycles).

Quantitatively, pressure sensitive Fuji film was used to measure the contact area between each platen-sample pair. Laser scans were taken of the sample surfaces to produce a dense point cloud (50,000 points/cm²). Root-mean-square surface deviation (R_q) of the samples from a plane were quantified to detect the presence and degree of cartilage surface damage. Qualitatively, photographs were taken of the sample before and after testing, and histology was performed on the sample after complete relaxation.

Mechanical Tests: A second set of experiments was conducted to investigate how SF affects fluid exudation from articular cartilage boundaries. Cylindrical plugs (1.4 mm \times $\varnothing 3$ mm, $n = 8$) were harvested

from the femoral condyle of immature bovine knee joints. Biphasic material properties were assessed by fitting transient unconfined compression data assessed using a custom mechanical testing device with a creep tare load (0.1 N, 600 s) and a stress-relaxation test to 10% strain (0.5 $\mu\text{m/s}$ ramp, 1800 s). Samples were mechanically tested in PBS, allowed to recover, and then tested again in SF.

RESULTS

The friction coefficient for the MCA-SF group (0.014 ± 0.0032) was significantly lower than that previously reported in the MCA-PBS group (0.025 ± 0.009 , $p < 0.05$, Fig. 1) [3]. The average friction coefficient for the MCA-SF group was significantly lower than the friction coefficient in the SCA-SF group (0.056 ± 0.027 , $p < 0.01$). Surface deviation measurements showed no statistical difference between the MCA-SF and SCA-SF groups either before ($R_{q\text{-MCA}} = 0.034 \pm 0.006$ mm, $R_{q\text{-SCA}} = 0.046 \pm 0.031$ mm) or after ($R_{q\text{-MCA}} = 0.051 \pm 0.025$ mm, $R_{q\text{-SCA}} = 0.041 \pm 0.013$ mm) testing ($p > 0.3$). Average contact stresses, σ , were similar among SF groups ($\sigma_{\text{MCA-SF}} = 0.74 \pm 0.13$ MPa, $\sigma_{\text{SCA-SF}} = 0.63 \pm 0.14$ MPa, $p > 0.2$). Contact stresses in SF tests were not statistically different from those previously reported in PBS tests ($p > 0.5$) [3].

Fig. 1: Friction coefficient for one representative sample set.

One of the five samples in the MCA-SF group exhibited surface damage after testing, in the form of delamination resulting in tearing of the superficial zone (Fig. 2a,d). An additional sample exhibited

initiation of superficial zone delamination in the form of a blister (Fig. 2b,e), while the remaining three exhibited no evidence of delamination (Fig. 2c,f). The SCA-SF group showed no evidence of delamination.

Fig. 2: Cartilage histological cross-sections (left) and surface scans (right) for samples with a torn superficial zone (top), initial delamination (middle), and no damage (bottom).

The stress-relaxation tests showed similar equilibrium moduli and relaxation times between samples tested in SF and PBS (Fig. 3).

The stress-relaxation tests showed similar equilibrium moduli and relaxation times between samples tested in SF and PBS (Fig. 3).

DISCUSSION

Our results indicate SF delays fatigue failure due to compressive loading in the MCA testing configuration. Only one out of the five samples tested in the MCA-SF test group exhibited superficial zone tearing and one showed initial sub-surface damage, while the remaining three samples exhibited no indication of damage. Additionally, the lack of change in surface deviation of MCA-SF samples before and after testing suggests minimal fatigue failure, even when delamination occurred. In contrast, previously reported results in an identical testing configuration in PBS found that all five samples tested in that study exhibited gross visual damage in the form of superficial zone tearing, producing a significant increase in R_q after testing [3]. The results

presented here show that SF reduces, or even prevents, damage when compared to PBS, indicating that SF provided a protective effect against fatigue failure during frictional sliding.

One hypothesis to explain why samples tested in SF resulted in less damage than those tested in PBS could be that the more-viscous SF prevented the interstitial fluid from escaping from the cartilage tissue as quickly. However, examining the creep in the cartilage tissue during the first 30 minutes of sliding showed nearly identical creep deformation in both SF and PBS tests (results not shown). This result was further supported by the unconfined compression mechanical tests performed on the articular cartilage cylindrical plugs which showed identical stress-relaxation responses when tested in either SF or PBS (Fig. 3).

Taken together, these results suggest that SF viscosity does not impede the exudation of interstitial fluid from cartilage, thus it plays no role in reducing tissue damage by extending the duration of elevated fluid load support.

Fig. 3: Representative stress-relaxation curves for a sample tested in PBS and SF.

Another explanation could be the diffusion into the articular cartilage of SF molecules such as hyaluronic acid (HA) or lubricin which may protect the tissue against fatigue damage. Lubricin is known to play an important role in cartilage integrity and HA has been suggested to potentially protect cartilage against wear [5]. We estimated that these SF constituents can diffuse from the cartilage surface to the site of initial delamination in as little as ~12 hours, based on their molecular weights [6]. Further investigations are necessary to determine if these molecules indeed provide protection against fatigue damage.

While the primary lubrication of articular cartilage surfaces has often been attributed to boundary or fluid film lubrication due to SF and its constituents [5], several studies have shown that a more significant mode of lubrication in articular cartilage is the interstitial fluid load support [3,7,8]. The results reported here support this finding: while SF reduces the friction coefficient relative to PBS, maintaining the fluid load support has a more significant effect on the friction coefficient (Fig. 1). However, perhaps the reduced friction coefficient observed in SF tests compared to PBS tests results in an overall reduction of damage by reducing the likelihood that subsurface fatigue damage (Fig. 2b) can propagate to the articular surface (Fig. 2a). The friction coefficient is not the primary predictor of damage, as shown previously [1,3,4] as well as in the present study, with damage occurring in a low-friction MCA environment but not in a high-friction SCA environment. However, once fatigue failure has been initiated, the friction coefficient may play a role in the extent of damage observed. Damage progression due to friction may be conducted using computational models in future investigations, to help resolve differences between PBS and SF.

INTRODUCTION

Maturing developments in understanding the mechanical properties of cells has led to developing cell stiffness as novel biomarkers for understanding pathogenesis and pathophysiology¹ because the mechanical stiffness of cells is well known to correlate with cellular function and state in basic biology and disease modeling. Cell monolayers play a critical role in most of the physiological functions where cells interact collectively with neighboring cells and surrounding extracellular matrix (ECM) through biochemical exchange and mechanotransduction^{2,3}. Measurement of mechanical properties of cell monolayers is beneficial to the development of disease-specific biomarkers. Current techniques are often difficult to scale and operationally complex, due to their reliance on optical or microscope-based characterization methods. In addition, they are usually limited by low repeatability, low throughput, fragility, and few of them achieve *in-situ* measurement of mechanical properties.

To access the mechanical stiffness of cell monolayers, we presented a microfluidic-based platform which relies on the principle of elastohydrodynamics as measured through piezoresistive metal-nanoisland-on-graphene strain sensors. Therefore, throughput is improved by relying on relatively simple voltage measurements, which can be performed in parallel. The platform is capable of non-invasive stiffness measurements within conventional cell culturing conditions, without the need for optical design considerations. Our toolkit provides a new facile route for investigating dynamic cellular mechanics at the multicellular level.

METHODS

Standard soft lithographic techniques were used to fabricate microfluidic devices. A rectangular piece of metallic nanoisland-bearing graphene strain sensor (12 mm × 4 mm, GrollTex Inc.) was embedded which spans the short axis of the channel.

The platform is based on the fluid-induced deformation of soft elastic walls, or elastohydrodynamics. Under a constant flow rate, the

relationship between the flow rate and the pressure and the channel deformation are given by⁴:

$$Q = \frac{h_0^4 E}{48 c_2 \mu (L-z)} \left[\left(1 + c_2 \frac{p(z)W}{E h_0} \right)^4 - 1 \right] \quad (1)$$

$$\frac{\Delta h}{h_0} = 2^4 \sqrt{\frac{3 Q \mu (L-z)}{E h_0^4} + 1} - 2 \quad (2)$$

where Q is the flow rate, h_0 is the initial channel height, E is the elastic modulus of the channel walls, L is the length of the channel, z is the axial position along the channel, μ is the fluid viscosity, W is the width of the channel, $p(z)$ is the pressure distribution along the channel.

If a constant stress is applied to a Kelvin-Voigt material and then released at time t_1 , the relaxation obeys the following equation:

$$\varepsilon(t > t_1) = \varepsilon(t_1) e^{-\frac{t-t_1}{\tau}} \quad (3)$$

where E is the modulus of elasticity, η is the viscosity.

A brief stress is applied by flowing fluid droplet in the channel and the wall deformation relaxes over finite time due to its viscoelastic properties⁵. As the sensor resistance signal is proportional to wall deformation, the voltage change can be described in terms of the viscoelastic relaxation as:

$$V(t) = V_0 - V(t_1) e^{-\lambda t} \quad (4)$$

where $\lambda = \frac{1}{\tau} = \frac{E}{\eta}$ is the relaxation time constant. To fit the viscoelastic relaxation curve, the equation is linearized as:

$$\ln \left(1 - \frac{V(t)}{V_0} \right) = -\lambda t + \ln \left(\frac{V(t_1)}{V_0} \right) \quad (5)$$

where the negative slope of the function is the relaxation time constant. A MATLAB (The MathWorks, Inc.) program is used to do the linear fitting.

RESULTS

The relationship between channel deformation and water flow rates and voltage signal is linear (**Fig. 1b**).

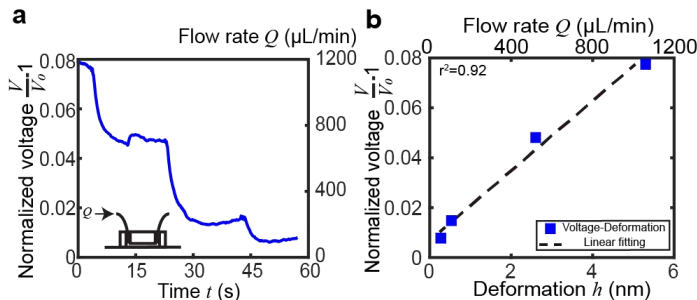

Figure 1: Calibration of microfluidic devices through elastohydrodynamics

We demonstrated measurements of dynamic *in-situ* stiffness changes of the Madin-Darby canine kidney (MDCK) cell monolayer. We observed a continuous decrease in relaxation time constant over treatment time. The treatment sequence was shown in Fig. 2a.

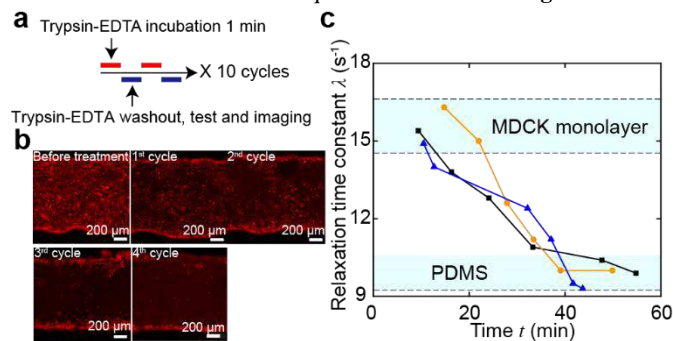

Figure 2: In-situ measurement of trypsinization process of MDCK cells.

Hepatocyte growth factor (HGF) treated MDCK cells showed lower relaxation time constant than the untreated group (Fig. 3b).

Figure 3: Epithelial-to-mesenchymal transition (EMT) induced by HGF.

DISCUSSION

A normalized electrical voltage signal from the strain sensor with different flow rates is shown in Fig. 1a. Pressure drop changes linearly with the imposed flow rate at low pressures in a rigid channel⁴. In Fig. 1b, the relationship between channel deformation and voltage signal is linear. This demonstrates that strain sensor is sensing deformation due to elastohydrodynamics and the voltage readings are proportional to channel deformation.

We obtained a λ of $14.5 \pm 0.4 s^{-1}$ ($n=10$) for channels with a MDCK cell monolayer. This relaxation time constant is greater compared to that of the bare PDMS channel wall ($6.9 \pm 0.4 s^{-1}$, $n=10$), indicating increased stiffness upon introduction of the MDCK cell monolayer. The composite structure of PDMS with MDCK cell

monolayer is stiffer than the PDMS structure alone. The mechanical contributions of MDCK cell monolayer are provided by a combination of the MDCK cells, intercellular adhesion junctions, and extracellular matrix proteins⁶.

During trypsinization process, the loss of cells and the extracellular matrix proteins led to an expected decrease in stiffness (Fig. 2c). However, the simultaneous stiffness measurements, when compared to cell count (Fig. 2b), were better able to capture the degradation of the cellular layer. At earlier time points, cell loss preceded the loss in stiffness, while at later time points, residual basement membrane proteins had a small, but detectable contribution to the channel stiffness, even after the cells were virtually absent. Compared with the slope of overall relaxation time constant decrease, the speed of cell count loss was quicker. However, compared to the earlier decrease of relaxation time constant—which was mostly due to cell count loss—the later decrease of relaxation time constant was more gradual. This suggested that MDCK cell bodies contributed more to the monolayer stiffness relative to the ECM and basement membrane proteins. Previous studies by Sorba et al.⁷ in MDCK cell monolayers through tensile testing found that cell covered region had higher relaxation time constant ($10.09 \pm 1.42 s^{-1}$) than the bare PDMS region ($3.18 \pm 1.47 s^{-1}$). They also found that EDTA treated MDCK cell had lower Young's modulus ($6.86 \pm 3.27 kPa$) than untreated group ($23.3 \pm 6.3 kPa$) due to softening effect.

For the *in vitro* EMT experiment, immunostaining images confirmed morphological changes resulting from HGF treatment (Fig. 3a). Down regulation of E-cadherin and up regulation of vimentin were observed. With HGF treatment, MDCK cells adopted a spindle-shaped morphology and vimentin expression was significantly higher. In untreated MDCK cells, polarized cells interact with the basement membrane and are held together through the adherent junction. During EMT, the monolayer stiffness decreases due to weakened cell-cell adhesions and rearrangements in the cytoskeleton. In addition, extracellular matrix undergoes significant mechanical change. There is diminished E-cadherin staining, which is present both in the cytoplasm as punctuated dots and at the periphery of the cells, indicating the disintegration of cell-cell adhesions. Previous study showed that the presence of vimentin networks reduced the effective cytoskeletal mesh size and viscoelastic relaxation time constant of the cytoskeleton, resulting in a softer cell layer⁸.

In conclusion, our toolkit provides a new facile route for investigating dynamic cellular mechanics at the multicellular level by the demonstration of the platform utility through minute-resolution of cellular monolayer dissociation via trypsinization and through multi-day *in vitro* EMT experiment. In the future, we envision this microfluidic platform to be scalable to multi-channel for more complex cellular processes and to be applied for different cell types in the field of drug discovery and disease modeling.

INTRODUCTION

The United States has the highest maternal morbidity rate among high-income countries with 23.8 deaths per 100,000 live births in 2020 [1]. Patients who survive pregnancy have an increased risk of pelvic floor disorders like urinary and fecal incontinence, overactive bladder, and pelvic organ prolapse [2]. Studying the female reproductive organs and their remodeling during pregnancy and post-partum could help in the prevention and treatment of maternal trauma but it remains challenging due to the lack of appropriate animal models. Thus, there still are unknowns about the mechanical alterations that are associated with pregnancy and how the pelvic tissues recover after parturition.

Previous research to establish murine animal models have used terminal studies to measure anatomical and mechanical changes of the vagina throughout pregnancy or magnetic resonance imaging (MRI) for studying embryonic development [3,4,5]. There is currently no research that aims to quantify how murine vaginas change prepartum to postpartum within the pelvic floor, surrounded by other organs and tissues. Therefore, we conducted a pilot study using MRI to non-invasively quantify the changes in the murine vagina throughout pregnancy. This longitudinal study is the first to observe the anatomical changes of the entire murine reproductive tract from a non-pregnant state up to three weeks postpartum. The scans from this study provide *in vivo* images that will serve to create robust finite element models to recapitulate the effect of pregnancy on the pelvic system.

METHODS

Three sexually mature (12-16 weeks old) CD-1 mice were used for this study. These animals were imaged in a small animal bore 9.4 Tesla

BioSpec 94/20 MRI scanner (Bruker, Billerica, MA) at five different time points: virgin (V), mid-pregnancy (gestation day 9-10, MP), late pregnancy (gestation day 16-17, LP), 24-72 hours postpartum (PP), and 3 weeks PP. At each timepoint, the mouse was sedated via inhalation (Harvard Apparatus, Holliston, MA) of a dose of 1-3% isoflurane in oxygen at a flow rate of 0.6 liters per minute to immobilize the mouse during imaging. Once immobilized, the animal was transferred onto the bed of the MRI scanner equipped with a radio frequency volume coil with a 40:70 mm inner to outer diameter. A pressure sensor was placed underneath the mouse's upper chest to monitor respiration. Feedback from this probe was collected by a respiration monitoring and gating system (SAII, Stony Brook, NY) and used to trigger the MRI scanner to avoid imaging when the abdomen was in motion during respiration.

The 2D imaging sequences protocol consisted of a T1 weighted FLASH (fast low angle shot) axial, T2 weighted turboRARE (rapid acquisition with relaxation enhancement) axial, and a T1 weighted FLASH sagittal scan with a spatial resolution of 10 pixels per mm³, slice thickness of 0.8 mm, and fat suppression. The number of slices and the dimension of the slices were varied across time points to accommodate the size of each mouse ([minimum – maximum] # of axial slices: 32-56, axial slice dimensions: 280 x 280 mm²-320 x 320 mm², # of sagittal slices: 32-40, sagittal slice dimensions: 360 x 360 mm²-480 x 480 mm²). Depending on the timepoint, scans were averaged between 8 to 16 times to adjust for time and animal welfare constraints.

The acquired MRI scans were exported to a DICOM format and processed in 3D Slicer [6]. The axial and sagittal scans at each timepoint were registered using the pubic symphysis as reference to visualize the volume of the vagina in both T1 and T2 sequences (Figure 1A-1F). The

T1 scan established the external contours of the vagina, while the T2 scans provided more information on the internal structures of the tissue (e.g., vaginal rugae seen in Figure 1A, 1D). Label maps and closed surface models (without smoothing) were created by segmenting the registered T1 and T2 axial scans (Figure 1G-1I) to quantify the volume of the vagina (including the enclosed volume). Circularity (which ranges roughly from 0 to 1; where 1 marks a perfect circle) of cross sections of the vagina was calculated using parameters given by the SegmentGeometry plugin [7]. Positions of each segment cross section were defined by percentages relative to their distance with respect to the introitus and total vaginal length, with 0% representing the vaginal opening (introitus) and 100% the cervix. The longitudinal length of the vagina was measured in the sagittal scan using ImageJ (NIH).

RESULTS

Computed from segmentations of the vaginas, the virgin mice had vaginal volumes of 72.2, 56.1, and 46.6 mm³ (Figure 2A). After normalizing the volume during and after pregnancy to the virgin volume, each mouse had a fold change of 0.48, 0.73, and 1.26 by MP, 0.70, 1.26, and 2.36 by LP, 0.48, 0.96, 1.94 by PP and 0.64, 1.06, 1.28 by 3WPP. The maximum vaginal length measured at each time point was also averaged across mice and normalized to the virgin timepoint. The average fold change in vaginal length and its standard deviation were 1.18 ± 0.07 at MP, 1.35 ± 0.06 at LP, 1.35 ± 0.08 at PP, and 1.03 ± 0.10 at 3WPP. Preliminary results show the circularity of the vaginal cross sections near the introitus are increased throughout pregnancy and postpartum while near the cervix, they decreased. This can be observed in Figure 2B for one mouse where at each timepoint the maximum circularity value of the vagina with its respective position (%) was: 0.56 (at 36%) at V, 0.91 (at 30%) at MP, 0.77 (at 31%) at LP, 0.87 (at 42%) at PP, and 0.85 (at 23%) at 3WPP. The minimum circularity value and position were: 0.41 (at 55%) at V, 0.31 (at 80%) at MP, 0.36 (at 75%) at LP, 0.34 (at 100%) at PP, and 0.31 (at 77%) at 3WPP.

DISCUSSION

In this pilot study, we designed and optimized an MRI protocol to capture for the entire volume of the murine pelvic floor throughout pregnancy and the postpartum recovery period. To our knowledge, this is the first MRI study that focuses on visualizing and measuring the changes to the vagina up to 3 weeks post-delivery. The properties of the MRI scan (i.e., sequences, averages, volume coil size) had to balance animal wellbeing, signal to noise ratio (scan quality), and cost.

The vaginal volume decreased by mid-pregnancy, peaked in late pregnancy, and then decreased to a similar virgin value. The vaginal length follows this trend where length peaks at late pregnancy before decreasing by 3 weeks postpartum, suggesting that the vagina may lengthen in preparation for delivery or due to the strains imposed by the growing uterine horn. Prior results using *ex vivo* rat tissues support the trends seen here [3]. The circularity of the segmented cross sections suggests that the vagina is not uniform across its length *in vivo* and that the shape varies throughout pregnancy. By 3 weeks postpartum, the range of vaginal circularity differs from its virgin state indicating irreversible changes to the vagina due to pregnancy.

A limitation of the study is the low sample size due to high cost of the MRI scans. Additionally, data collection on set gestational and delivery days was difficult to manage, so data were grouped together within a two-day range, possibly contributing to variations between mice. The estrous cycle was not accounted for at the virgin time point and can also contribute to the variation seen since murine vaginal openings appear swollen during proestrus and estrus [3]. For quantification, image resolution and software tools impeded segmentation of the enclosed volume across the length of the vagina at

certain timepoints. Overall, this MRI study acquired the first longitudinal *in vivo* images of the murine pelvic floor throughout pregnancy and postpartum recovery. With these geometric models of the vagina detailing its longitudinal changes, we can improve previously simplified finite element models that describe the biomechanical changes of the vagina during and after pregnancy to improve the women's health field.

Figure 1: T1 (A-C) and T2 axial scans (D-F) (scale bar 2 mm) depicting vaginas (yellow overlay) at virgin (V), late pregnancy (LP) and 3-week postpartum (3W PP) timepoints for one mouse with its 3D model representation (G-I) (scale bar 5 mm).

Figure 2: (A) Volume (mm³) of each individual mouse vaginal segmentations over time. (B) Circularity of vaginal cross sections for one mouse over time. Horizontal axis describes position along the vaginal length, from 0% (introitus) to 100% (cervix). Data depicted in Figure 2B is collected from the mouse whose volume is reported using blue circle in Figure 2A and seen in Figure 1.

INTRODUCTION

Tendon injuries, such as ruptures and tendinopathies, account for nearly 46% of the 33 million reported musculoskeletal injuries per year, affecting occupational- and sports-related events (1). As load bearing structures that are primarily composed of type I collagen and connect muscle to bone, tendons play a key role in daily activities and exercise (2). Although some levels of physical activity can lead to increased tendon mechanical function, without sufficient rest periods, an imbalance in matrix proteins, such as collagen, and net degradation of the tendon's extracellular matrix, can leave the tendon susceptible to injury (2, 3). The clinical presentation of tendinopathies is limited to later stages of injuries and occur after pain and loss of function. Tendinopathy is considered to be caused by a result of accumulated fatigue damage from overuse repetitive cyclic loads, although the threshold between normal and overuse is not clearly defined (4, 5). This demonstrates the need to investigate the initiation and progression of early tendon damage. The hierarchical nature of tendons contributes to their strength, therefore, investigations of tendon damage on multiple scales is important to understand how damage propagates spatially as well as temporally. The objective of this study is to assess rat Achilles tendon's mechanical, structural, and biological temporal and spatial changes and responses to noninvasive *in vivo* repetitive cyclic fatigue loading.

METHODS

Forty-two 13-week-old Sprague Dawley female rats were anesthetized using isoflurane per IACUC approved protocols. The rats' left hindlimb was fixed in full-leg extension using a splint to isolate the Achilles tendon. The foot was attached to an ankle joint actuator that allowed for passive ankle dorsiflexion up to 40° relative to neutral and the rats were secured in a prone position in a full-body platform. The ankle was cyclically dorsiflexed to an angle that loaded the tendon to the exponential region at ~1 Hz to mimic normal gait for 500 cycles.

Mechanical measurements before and after each cyclic loading bout were performed to assess the effect of loading on tendon mechanical properties. The rats were divided into three groups, where each group was subjected to either 1, 2, or 3 bouts of 500 cycles of loading with two days of cage activity between each loading bout. Following two days after each group's final bout of loading, the rats were euthanized via CO₂ inhalation.

The loaded Achilles tendon tissue was harvested for RT-qPCR analysis of gene expression (n = 5 per group), histological assessment (n = 3 per group), and transmission electron microscopy analysis of transverse and longitudinal sections (n = 6 per group). Samples of 5µm thickness from each group were sectioned and stained with hematoxylin & eosin (H&E) to assess changes in cells shape, size, and quantity. For collagen fibril assessment, sections of 50-70 nm thickness from the midsection of the tendon were cut perpendicular to the longitudinal axis of the tendon. Ten representative images from each sample were preprocessed and quantified for collagen morphological parameters (collagen fibril radius, collagen area fraction, and specific fibril contact area) using Fiji. The hysteresis curves of the baseline measurement prior to the loading protocol and the post-measurement immediately after the last loading bout for each group were analyzed to obtain the percentage change in peak stress, hysteresis, and loading and unloading modulus of the stress-strain curves. Statistical analysis was done using GraphPad (version 9.3.0 for Windows; GraphPad Software, San Diego, CA). The Kolmogorov-Smirnov test was used to determine whether the data was normally distributed. For normally distributed data, an ordinary one-way ANOVA test was used to test significance between the three load groups on the mechanical and morphological properties, otherwise, the Kruskal-Wallis test was performed. Statistical significance was considered for p-values < 0.05.

RESULTS

Histological evaluation of loaded tendons stained with H&E revealed increased rounded cells, hypercellularity, and fiber disorganization with increased loading, specifically for 3 bouts of loading (Figure 1A). Qualitative assessment of collagen fibrils showed larger amounts of fibrils with smaller radii compared to larger radii in the 1 load group in comparison to the 2 and 3 load groups (Figure 1B).

Figure 1: Structural assessment of collagen fibers and fibrils. (A) Representative images of tendons stained with hematoxylin and eosin (H&E) staining, (B) Representative transmission electron images for the three load groups used to calculate the mean fibril radius, collagen fibril area fraction, and specific fibril surface area.

Quantitative evaluation of transmission electron images revealed significant difference between each bout of loading for mean fibril radius, with larger mean radii after 2 bouts of loading, while the collagen area fraction was considered similar for each load group. Specific fibril surface area was significantly lower for the 3 loads group compared to the 1 and 2 loads groups (Figure 2). When comparing the histograms of collagen fibril distributions between each group, there are higher number of smaller fibrils after 1 bout of loading, similar fractions of smaller and larger fibrils after 2 bouts of loading, and a closer to normal distribution after 3 bouts of loading (Figure 3).

Figure 2: Calculated morphological parameters of collagen fibrils

Overall, there was a decrease in mechanical properties with increased number of loading, with a significant difference between 1 bout of loading when compared to the 2 and 3 bouts for peak stress, hysteresis, and loading modulus. Additionally, there was a significant difference between 2 and 3 loads for hysteresis ($p < 0.05$) (Figure 4).

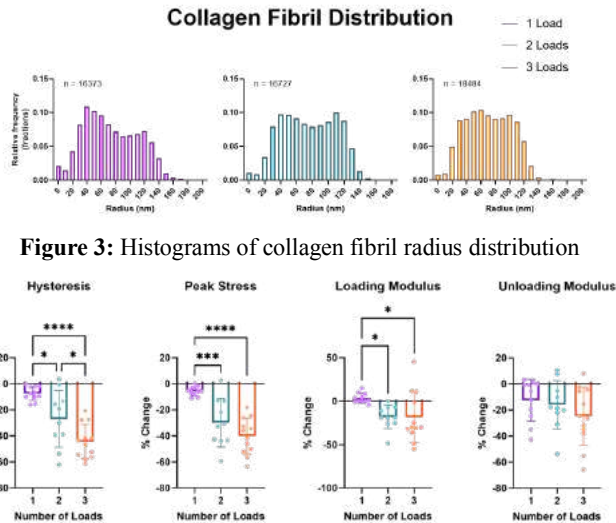

Figure 3: Histograms of collagen fibril radius distribution

Figure 4: Mechanical changes between the post-measurement of the final load and the baseline measurement before loading

DISCUSSION

These structural and mechanical results provide insight to evaluate structure-function relations of damaged tendon from repetitive fatigue loading. The decreased mechanical properties suggest loss in collagen in contributing to the overall stress of the tendon response to load. The increased cellularity and rounded cells in stained histological samples demonstrates matrix damage with increased bouts of loading. The difference in mean fibril radius shows that there are significant changes occurring in loss and formation of collagen fibrils between loads. This could be attributed either to the healing of the fibrils, the disruption of fibers and fibrils due to overuse loading, or a combination of both. Although each group has similar area fractions, the distribution of fibril radii demonstrates a shift in the formation and growth of collagen fibrils throughout the course of loading. The changes in specific fibril surface between 1 and 3 loads and 2 and 3 loads relates to fibril-fibril interactions, showing decreased interactions with more loads applied. Although macroscopically, mechanical properties reveal that the tendons become progressively more damaged with more loads, microstructurally, the change in distribution of collagen fibril radius over the course of more loads suggests growth of smaller fibrils to larger fibrils. Microscale mechanical testing can be done in future studies to understand the collagen fibril mechanical changes. Gene expression of collagen types I and III, MMPs and TIMPs, as well as inflammatory cytokines will be done to further understand and link biological changes with the quantified microstructural and mechanical changes.

We have been able to assess mechanical and multi-scale structural changes to rat Achilles tendon subjected to repetitive fatigue loading in a noninvasive, *in vivo* setting. Taken together with further analysis of remaining data of gene expression of collagen, matrix, and inflammatory markers, these results will help us understand the initiation and propagation of tendon injury and the relations between the mechanical, structural and biological healing responses to for better clinical understanding of the initiation of tendinopathy.

DYNAMICS OF SHEAR STRESS IN EMBRYONIC CHICK HEART ANATOMIES RECONSTRUCTED FROM LIGHT SHEET FLUORESCENCE MICROSCOPY IMAGING

K. Giesbrecht (1), S. Rossi (1), M. Bressan (2), B. Griffith (1)

INTRODUCTION

Congenital heart defects are the most common birth defect and are present in approximately 1% of newborns¹. Yet, only 20-30% of congenital heart defects can be traced to genetic or environmental causes²⁻⁴. Altered hemodynamic environments account for many congenital heart defects⁵⁻¹⁰. As the first functioning organ in vertebrates, the heart relies on many hemodynamic queues, such as intracardiac blood velocity, blood pressure, and shear stress, while developing. Particularly, shear stress has been shown to regulate many aspects of cardiogenesis by modulating gene expression, such as aortic and pulmonary trunk diameters¹¹. When these hemodynamic factors are altered, abnormalities may arise.

Most congenital heart defects occur in the outflow tract, a region that eventually gives rise to the pulmonary trunk and aorta¹². Outflow tract congenital heart defects are severe and have a high mortality rate¹³. However, it's unclear what role shear stress plays in outflow tract development partially due to the difficulty of obtaining shear stress measurements in the outflow tract and surrounding vasculature experimentally. Measuring shear stress in animal models is challenging due to the delicate nature and continuous pumping of the embryonic heart. Computational fluid dynamics modeling is an attractive method to simulate blood flow and the resulting shear stress throughout the heart and surrounding vasculature, capturing precise spatial and temporal patterns of shear stress.

This is the first computational fluid dynamics modeling study, to our knowledge, that uses light sheet fluorescence microscopy to image the embryonic chick heart and supporting vasculature throughout several stages of development. Light sheet fluorescence microscopy offers higher resolution than other imaging techniques for capturing embryonic heart anatomies, such as optical coherence tomography (OCT) imaging¹⁴. Shear stress is mapped throughout the outflow tract, aortic arches, and dorsal aorta of the captured anatomies. We also compare the geometric properties of aortic arches imaged by light sheet

fluorescence microscopy throughout the stages of development to areas of elevated shear stress. Together this information is critical to establishing baseline measurements of anatomical features and hemodynamic factors necessary for understanding if altered intracardiac shear stress contributes to the outflow tract and supporting vasculature abnormalities.

METHODS

Chick embryos staged at Hamburger-Hamilton (HH)16, HH18, HH19, and HH21 were imaged using light-sheet fluorescence microscopy. The imaging data were segmented and meshed. Using the finite element method, we model blood flow through the meshed anatomies described by the momentum equation (1) and the continuity equation (2):

$$\rho \frac{Du}{Dt} + \nabla p - \mu \nabla^2 u - f = 0 \quad (1)$$

$$\nabla \cdot u = 0 \quad (2)$$

The continuity equation (2) describes blood as an incompressible fluid. The blood pressure and velocity fields are p and u , respectively. Fluid density is $\rho = 1060 \text{ kg}\cdot\text{mm}^{-3}$. We model blood to have a constant viscosity of $\mu = 3.7 \cdot 10^{-3} \text{ Pa}\cdot\text{s}$ since many studies consider embryonic chick blood as a Newtonian fluid¹⁵. We impose pulsatile pressure-driven flow in the inflow modeled from previously measured pressure profiles¹⁶ and no-slip boundary conditions on intracardiac and vessel walls ($u=0$). Aortic arch diameters, curvatures, and lengths were measured for all embryos.

RESULTS

Blood velocity streamlines are plotted throughout the four examined stages (Fig. 1) during peak flow, decreasing flow, and minimum flow throughout the cardiac cycle. The streamlines reveal expected laminar flow throughout the embryonic heart, aortic arches, and dorsal aorta.

Velocity increased in narrow anatomical regions such as the aortic arches and narrow regions preceding the outflow tract.

Figure 1: Blood flow is laminar at each stage. Peak velocity occurs in aortic arches and in narrowed intracardiac luminal regions.

Shear stress is shown during peak flow, decreasing flow, and minimum flow throughout the cardiac cycle (Fig. 2). Peak shear stress is observed in many of the same regions and stages of the cardiac cycle where peak velocity is observed.

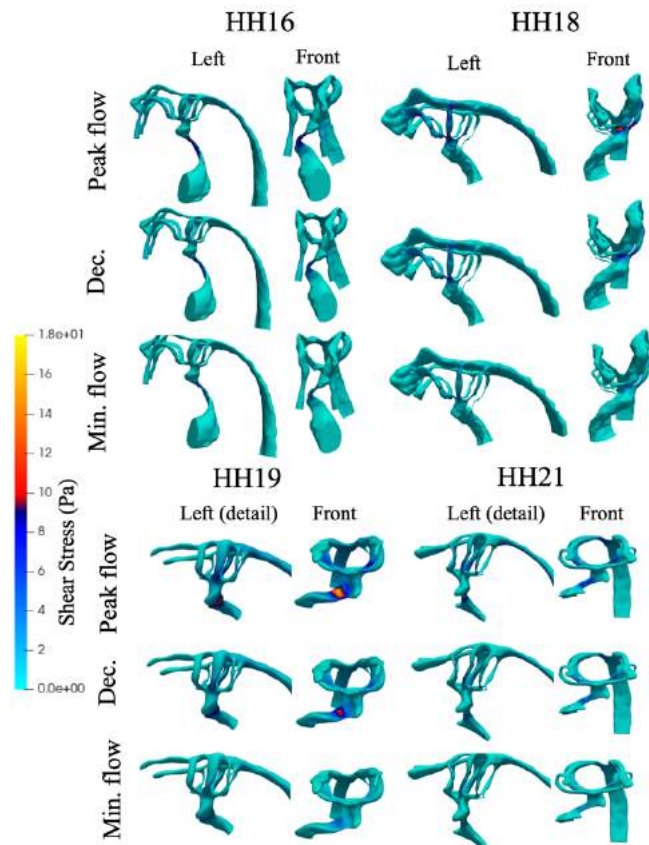

Figure 2: Shear stress is elevated in similar regions and time points where peak velocity occurs.

At the intermediate stages, HH18 and HH19, peak shear stress and velocities in the aortic arches occur in the second pair of aortic arches, which is the shortest pair of the three at these stages (Fig. 3).

Figure 3: The second pair of aortic arches is the shortest pair and experiences high shear stress.

DISCUSSION

This is the first computational study examining shear stress spanning stages HH16 through HH21 to include the heart, aortic arches, and dorsal aorta using light sheet fluorescence microscopy to reconstruct the embryonic anatomies. Light sheet fluorescence microscopy is also an excellent imaging technique to observe gene expression¹⁴. Future studies could use light sheet fluorescence microscopy to both reconstruct anatomies and indicate regions of activated shear-sensing genes to complement computational fluid dynamics modeling.

Additionally, shear stress is elevated in both the aortic arches and heart, which is typically lost on most models with smaller fluid domains, which omit either the aortic arches and dorsal aorta or ventricle. The observed velocity profiles produced expected laminar flow and are consistent with the observed shear stress throughout the stages.

We measured several geometric features of the aortic arches including the average diameter, curvature, and lengths of each aortic arch across the stages. Aortic arches undergo extensive remodeling during these stages, with some arches persisting between stages, while others disappear and new ones develop¹⁵. Yet, across all stages, the second pair of aortic arches was the shortest among the pairs. In the intermediate stages, the aortic arches that experienced the highest shear stress were the second pair arches. However, these arches were not necessarily the narrowest. Increasing the number of embryos used in the analysis is necessary to further explore this relationship between aortic arch length and hemodynamics.

DEVELOPMENT OF A REPRESENTATIVE ARTERY MODEL FOR STENT FATIGUE TESTING

(1) School of Engineering, University of Glasgow, United Kingdom, (2) Terumo Aortic, Inchinnan, United Kingdom

INTRODUCTION

Stents are devices employed in the treatment of arterial injuries including abdominal aortic aneurysms. They apply a continuous chronic outward force (COF) that resists artery-imposed hoop stresses to maintain lumen patency. Their failure conditions are difficult to predict computationally as they depend on the compliance properties of the representative (often hyperelastic) vessel. To capture arterial compliance faithfully is to select a suitable model and identify its parameter values that would yield the desired compliance. However, aleatory and epistemic uncertainties associated with parameter identification and model selection, respectively, hinder models in reproducing compliance values. Aleatory uncertainty arises from the variability in data procurement methods and subject-to-subject differences. Epistemic uncertainty is associated with the choice of a particular model [1]. To account for such uncertainties, a systematic approach to selecting hyperelastic models that outlines objective criteria for a parsimonious model in capturing arterial compliance is necessary. To this end, a Bayesian approach to hyperelastic model selection and parameter identification wall modeling is detailed and proposed. This framework employs pre- and postoperative compliance data of abdominal aortic aneurysms (AAA) patients treated with the self-expanding Nitinol stent-graft, the *Anaconda*TM, to inform the choice of a representative hyperelastic model for future 3-D computational fatigue testing.

METHODS

1. Patient sample and collected data

15 patients with abdominal aortic aneurysms underwent elective EVAR (endovascular aneurysm repair) with the *Anaconda*TM stent-graft. Anonymized collected data \mathbf{d}_{pat} of the 15 abdominal aortae are categorized into preoperative \mathbf{v}_{pre} and postoperative \mathbf{v}_{post} measures. The vector of preoperative data, $\mathbf{v}_{\text{pre}} = [r_{\text{dias,pre}} \quad p_{\text{sys}} \quad p_{\text{dias}}]$, contains the preoperative diastolic radius $r_{\text{dias,pre}}$, systolic pressure p_{sys} , and diastolic pressure p_{dias} . The vector of postoperative measures, $\mathbf{v}_{\text{post}} = [d \quad \varepsilon]$, contains the postoperative arterial compliance d_{post} and expansion ε

$$d_{\text{post}} = \frac{r_{\text{sys,post}} - r_{\text{dias,post}}}{r_{\text{dias,post}}} \frac{1}{p_{\text{sys}} - p_{\text{dias}}} \quad \varepsilon = \frac{r_{\text{dias,post}} - r_{\text{dias,pre}}}{r_{\text{dias,pre}}} \quad (1)$$

A statistical model of \mathbf{v}_{pre} and \mathbf{v}_{post} , formulated as a multivariate normal distribution, was used to construct the conditional distribution $p(\mathbf{v}_{\text{post}} | \mathbf{v}_{\text{pre}}) \sim \mathcal{N}(\mu_c, \Sigma_c)$, defined by the conditional mean μ_c and covariance Σ_c .

2. Vascular mechanics: Kinematics

The abdominal aorta is modeled as a hyperelastic tube subject to axisymmetric deformation. The tube begins at a reference configuration Ω_0 , and is subjected to arterial pressure and a chronic outward force in the deformed configuration Ω_L . The coordinates of the map $\Omega_0 \mapsto \Omega_L$ are

$$\begin{aligned} \Omega_0 : R_i \leq R \leq R_o, \quad 0 \leq \Theta \leq 2\pi, \quad 0 \leq Z \leq L, \\ \Omega_L : r_i \leq r \leq r_o, \quad 0 \leq \theta \leq 2\pi, \quad 0 \leq z \leq l, \end{aligned} \quad (2)$$

where R_i is the inner radius in the reference configuration, r_o is the outer radius in the deformed configuration, and L and l are the tube lengths in Ω_0 and Ω_L , respectively. Assuming axisymmetric deformation along the length of the tube and the incompressibility of the tube wall, the aortic radius after loading is obtained as

$$\Omega_0 \mapsto \Omega_L : r(R) = \sqrt{\frac{R^2 - R_i^2}{\lambda_z} + r_i^2}. \quad (3)$$

In cylindrical coordinates, the components of $\mathbf{F} = \text{diag}[\lambda_r, \lambda_\theta, \lambda_z] = \text{diag}\left[\frac{R}{r\lambda_z}, \frac{r}{R}, \lambda_z\right]$ map a point in Ω_0 to Ω_L , where λ_r , λ_θ , and λ_z are the principal stretches. The hyperelastic response of the aortic wall is quantified by a strain energy density function Ψ , which is related to the Cauchy stress via $\boldsymbol{\sigma} = 2\mathbf{F} \frac{\partial \Psi}{\partial \mathbf{C}} \mathbf{F}^T - p\mathbf{I}$, where $\mathbf{C} = \mathbf{F}^T \mathbf{F}$ is the right Cauchy-Green tensor. The principal stresses

$$\sigma_{rr} = -p + \lambda_r \frac{\partial \Psi}{\partial \lambda_r}, \quad \sigma_{\theta\theta} = -p + \lambda_\theta \frac{\partial \Psi}{\partial \lambda_\theta}, \quad \sigma_{zz} = -p + \lambda_z \frac{\partial \Psi}{\partial \lambda_z} \quad (4)$$

follow from the assumptions of axisymmetric loading and arterial tube incompressibility. The equilibrium condition $\text{div } \boldsymbol{\sigma} = \mathbf{0}$ holds in the absence of body forces, where $\text{div}(\bullet)$ is the spatial divergence operator. Assuming constant λ_z and thus the dependence of the inflation problem solely on r , the equilibrium equations reduce to

$$\frac{d\sigma_{rr}}{dr} + \frac{1}{r}(\sigma_{rr} - \sigma_{\theta\theta}) = 0. \quad \text{SB}^3\text{C2023-229}$$

Integrating Eq. (5) and imposing boundary conditions $\sigma_{rr}(r_i) = -p_i$ and $\sigma_{rr}(r_o) = 0$, the equation for the pressure at r_i is deduced as

$$p_i = \int_{r_i}^{r_o} \left(\lambda_\theta \frac{\partial \Psi}{\partial \lambda_\theta} - \lambda_r \frac{\partial \Psi}{\partial \lambda_r} \right) \frac{dr}{r}. \quad (6)$$

The *Anaconda*TM is modeled as a locally linear spring. The force F exerted by the spring is

$$F = k(r_{\text{dias,post}} - r_{\text{dias,pre}}) + f_0, \quad (7)$$

where k is the stent stiffness from radial force testing, and f_0 is the COF exerted by the stent graft. To calculate the expansion ε , Eq. (6) is solved by calculating the radius $r_{\text{dias,post}}$ due to the chronic outward pressure resulting from f_0 . After setting $R_i = r_{\text{dias,post}}$, $r_{\text{sys,post}}$ due to $p_i = p_{\text{sys}} - p_{\text{dias}}$ is calculated, and d_{post} is acquired.

3. Bayesian model selection framework

The proposed Bayesian approach to hyperelastic model selection and corresponding parameter identification is now detailed. Bayes' theorem is used to update prior distributions $p(\theta_k | m_k)$ of parameters θ_k given patient data \mathbf{d} and the choice of the k^{th} model m_k to give the posterior distribution of parameters $p(\theta_k | \mathbf{d}, m_k)$,

$$p(\theta_k | \mathbf{d}, m_k) = \frac{p(\mathbf{d} | \theta_k, m_k) p(\theta_k | m_k)}{p(\mathbf{d} | m_k)}. \quad (8)$$

$p(\theta_k | m_k)$ is uniformly distributed in the absence of knowledge regarding values of θ_k . $p(\mathbf{d} | \theta_k, m_k)$ is the likelihood of observing patient data $\mathbf{d} = \mathbf{d}_{\text{pat}}$ given model m_k and corresponding θ_k . The candidate models m_k include the 4-term Yeoh and Neo-Hookean isotropic models for rubber elasticity, and the GOH, Holzapfel, and HGO anisotropic models for arterial walls [2]. The evidence $p(\mathbf{d} | m_k) = \int p(\mathbf{d} | \theta_k, m_k) p(\theta_k | m_k)$ may be interpreted as the probability mass contained under the posterior distribution over the parameter space for a given model. The Monte Carlo integral $p(\mathbf{d} | m_k) \approx \frac{1}{S} \sum_{s=1}^S p(\mathbf{d} | \theta_k^s, m_k)$ is used to approximate the evidence for $n_s = 2^{17}$ samples of S . The likelihood, $p(\mathbf{d} | \theta_k, m_k)$, for a sample parameter vector θ_k^s assumes the Gaussian form

$$p(\mathbf{d} | \theta_k^s, m_k) = \frac{1}{\sqrt{2\pi} \det \Sigma_c} \exp \left(-\frac{1}{2} (\mathbf{v}_{\text{post}}^s - \mu_c)^T \Sigma_c^{-1} (\mathbf{v}_{\text{post}}^s - \mu_c) \right). \quad (9)$$

To calculate $p(\mathbf{d} | \theta_k^s, m_k)$, $\mathbf{v}_{\text{post}}^s$ is evaluated using the kinematics described in Section 2 for a given m_k and θ_k^s , and is substituted into Eq. (9).

Preoperative compliance was not measured for the patient cohort, and is incorporated as an output of the framework. Compliance data from literature, \mathbf{d}_{lit} , for subjects within the same age group [3], is compiled to form the independent distribution $p(d_{\text{pre}}) \sim \mathcal{N}(\mu_{d_{\text{pre}}}, \sigma_{d_{\text{pre}}}^2)$. Given the independence of datasets \mathbf{d}_{pat} and \mathbf{d}_{lit} , the likelihood of reproducing d_{post} and ε from \mathbf{d}_{pat} and d_{pre} from \mathbf{d}_{lit} is the product of their individual likelihoods

$$p(\mathbf{d} | \theta_k, m_k) = p(\mathbf{d}_{\text{pat}} | \theta_k, m_k) \times p(\mathbf{d}_{\text{lit}} | \theta_k, m_k). \quad (10)$$

The expected values of d_{post} and ε from $\mathbf{d} = \mathbf{d}_{\text{pat}}$ and d_{pre} from $\mathbf{d} = \mathbf{d}_{\text{lit}}$ for given m_k are

$$\mathbb{E}(\mathbf{v}_{\text{post}}) = \int \mathbf{v}_{\text{post}}(\theta) p(\theta | \mathbf{d}) d\theta = \frac{1}{n_s} \sum_{i=1}^{n_s} \mathbf{v}_{\text{post}}(\theta_i) p(\theta_i | \mathbf{d}), \quad (11)$$

with expected variance $\text{Var}(\mathbf{v}_{\text{post}}) = \mathbb{E}((\mathbf{v}_{\text{post}} - \mathbb{E}(\mathbf{v}_{\text{post}}))^2)$.

RESULTS

Figure 1 presents the predicted expected value of d_{pre} , d_{post} , and ε from various models to that of \mathbf{d}_{pat} and \mathbf{d}_{lit} . For all models, the compliance of the artery decreases after stenting. Table 1 presents the normalized model evidence values as well as parameter values that maximize the likelihood of the respective models in representing the data, also known as maximum likelihood estimates (MLEs). The models with the highest evidence values are the Neo-Hookean, GOH, and Holzapfel models.

Figure 1: Expected values of (a) pre- and postoperative compliance d_{pre} and d_{post} , and (b) expansion ε compared to \mathbf{d}_{pat} and \mathbf{d}_{lit} ("Data").

Table 1: Normalized evidence and maximum likelihood estimates of θ_k for models three models with greatest evidence values.

	Neo-Hookean	GOH	Holzapfel
Evidence	1.00	0.61	0.35
θ_1 (kPa)	$\mu = 30.3$	$k_1 = 14.1$	$k_1 = 47.4$
θ_2	—	$k_2 = 29.0$	$k_2 = 13.5$
θ_3	—	$\kappa = 0.11$	$\kappa = 0.98$
θ_4 (kPa)	—	$\mu = 98.4$	$\mu = 98.1$

DISCUSSION

The decrease in arterial compliance for all m_k in Figure 1 is consistent with reported data, and is a function of the compliance mismatch between the artery and the stent [4]. Moreover, the primacy of the Neo-Hookean model indicates that evidence-based model selection intrinsically favors parsimonious models, as more complex models yielded no improvement in predictive capacity. This is corroborated by the work of [1], who show an inverse relationship between model evidence and increasing order of the Ogden in the reproduction of bovine liver compression data. In addition, the Neo-Hookean provides the poorest match for \mathbf{d}_{lit} , as its formulation is unable to capture the characteristic stiffening of compliant arteries at large strains. Nevertheless, informed prior distributions may ameliorate current predictions of d_{post} and ε . [1] also recommend the inclusion of parameter identifiability and goodness of fit via the log-likelihood (LLH) function landscape and maximum LLH values, respectively, as model selection criteria. Such improvements would render the current framework an assistive tool in the construction of representative arterial models.

INTRODUCTION

The number of Veterans and Service members (SMs) with transtibial limb loss (TLL) is growing due to the aging population with dysvascular disease and diabetes, as well as from U.S. military involvements abroad [1,2]. With high associated healthcare costs [3], it is expected that conclusive research is available to clinicians for proper prosthetic prescription. However, most research is noncommittal and lacks guidance for clinical practice [4]. Metabolic and biomechanical parameters, the primary outcomes traditionally used to determine effectiveness of prosthetic devices, indicate mixed results, limiting evidentiary support for optimal prescription guidelines [5]. Conversely, continuous measures of coordination and stability, evaluated using Relative Phase (RP) analysis, provide superior sensitivity over traditional spatiotemporal measures and detect changes at a greater resolution [6]. The first aim of this study was to quantify levels of continuous inter-limb gait coordination and stability among Veterans and SMs with TLL. It was hypothesized that individuals with vs. without TLL will walk with lower levels of inter-limb coordination and stability. The second aim was to determine the extent to which gait coordination and stability of Veterans and SMs with TLL are influenced by different Energy Storing and Returning (ESR) ankle-foot devices (i.e., ESR, articulating ESR (ART), and powered ESR (PWR)). It was hypothesized that the PWR device will indicate greater levels of coordination and stability compared to the other devices.

METHODS

Thirty individuals with unilateral TLL were fit and evaluated with 3 different prosthetic ankle-foot devices: ESR, ART, and PWR. Participants separately utilized each prosthetic foot for 1 week at home. After each 1-week trial, participants with TLL underwent biomechanical gait analysis. Ten

individuals without TLL performed a single gait analysis session. All participants walked at 1.3 m/s across a 10-meter instrumented walkway until at least 15 steps per foot were recorded. RP analysis calculated continuous measures of coordination, Mean Absolute Relative Phase (MARP), and stability, Deviation Phase (DP), between limbs.

MARP is calculated using the following equation:

$$\text{MARP} = \Sigma(|\Phi_{\text{Rel.}}|/N) \quad (1)$$

where Φ_{relative} is the relative phasing relationship between the two segments and N is the number of points in the RP mean ensemble curve.

A low MARP value (closer to 0°) indicates a more in-phase relationship, while a high MARP value (closer to 180°) indicates a more anti-phase relationship.

DP is calculated using the following equation:

$$\text{DP} = (\Sigma|\text{SD}_i|)/N \quad (2)$$

where N is the number of points in the RP mean ensemble curve and SD is the SD of the mean ensemble curve at the i th point.

A low DP value (closer to 0°) indicates a more stable organization of the neuromuscular system and a high DP value (closer to 180°) indicates less stability.

Two sample T-tests determined differences between the Control participants and each device (PWR, ESR, ART) for MARP and DP separately. Linear mixed effect models compared MARP and DP between devices, while accounting for repeated observations. Pairwise comparisons were conducted using estimated marginal means. Significance was set at $p < 0.05$.

RESULTS

Aim 1: Veterans and SMs with vs. without TLL experience deficits in coordination and stability (Table 1).

Table 1. Differences in coordination (MARF) and stability (DP) in Veterans and SMs with TLL compared to intact individuals.

	MARP	t-value	p-value
Arm to Arm			
Control	157.6	-3.1	0.004
ART	162.6		
Prosthetic-side Arm to Intact-Side Ankle			
Control	17.3	-2.1	0.03
ART	22.8		
	DP	t-value	p-value
Leg to Leg			
Control	2.9	-2.2	0.03
PWR	3.6		
Control	2.9	-2.3	0.03
ART	3.5		
Prosthetic-Side Wrist to Intact-Side Ankle			
Control	5.5	-2.0	0.04
PWR	7.8		
Control	5.5	-2.1	0.04
ART	7.4		

Aim 2: The PWR device indicates a less coordinated gait pattern than the ART device between the prosthetic-side arm and leg, and lesser coordination than both the ESR and ART devices between the prosthetic-side arm and intact-side leg (Figure 1). However, the PWR device indicates a more stable gait pattern than the ESR device between the intact-side arm and leg and is more stable than the ART and ESR devices between the intact-side arm and prosthetic-side leg (Figure 2).

Figure 1. Inter-limb coordination as Mean Absolute Relative Phase (MARF) between groups and devices (only significant differences illustrated).

Figure 2. Inter-limb stability as Deviation Phase (DP) between groups and devices (only significant differences illustrated).

DISCUSSION

Preliminary analysis of this dataset indicates that RP analysis is sensitive enough to identify differences between individuals with vs. without TLL and between the PWR, ART, and ESR devices. As expected, individuals with vs. without TLL experience deficits in both coordination and stability.

Interestingly, the PWR device was associated with both greater levels of stability and lower levels of coordination compared to the ESR and ART devices. This discrepancy may be due to the novelty of the device for some individuals with TLL (notwithstanding the 1-week acclimation). It is possible that the active push-off provided by the PWR device disrupts the coordinative pattern the individual is accustomed to with a non-powered device, while the new pattern associated with the device allows for greater consistency of the motor pattern compared to the other devices. However, it should be noted that this device is also associated with large outliers in the coordination measure. It is possible that removal of such outliers may eliminate the significant coordination deficits observed between the PWR device and both the Control group and the other devices. If so, a clear advantage of the PWR device would become evident, as it provides the greatest stability advantage to individuals with TLL. Though, device acclimation is an important consideration for future work.

Given the identified deficits in gait coordination and stability among Veteran and SMs with TLL, particularly across different types of prosthetic ankle-foot devices, such findings can help support development of rehabilitation programs focused on improving these parameters. Importantly, findings can directly influence prescription guidelines to optimize healthcare for all Veterans and SMs with TLL, helping them to live high quality, active lives.

NUCLEAR DEFORMATION OF THE TRICUSPID VALVE INTERSTITIAL CELLS: THE EFFECTS OF NUCLEAR ORIENTATION AND EXTRACELLULAR MATRIX STRUCTURE

Mina Pakzadmanesh (1), Samuel D. Salinas (2), Vineet S. Thomas (2), Rouzbeh Amini (1,2)

INTRODUCTION

The micro-scale mechanical environment of the heart valves is comprised of individual components that make up the extracellular matrix (ECM) and the residing valve interstitial cells (VICs) [1]. The VICs have an important role in maintaining the mechanical integrity of the valve [2]. In the tricuspid valve (TV), proper leaflet coaptation is required for normal valvular function. Any change in the mechanical integrity of the ECM constituents, such as collagen and/or elastin, may cause improper valve coaptation and lead to a variety of cardiac diseases [3]. For example, Marfan Syndrome (MFS) is a connective tissue disorder, in which fragmented elastin fibers are present in the ECM. Valvular diseases are more frequent in MFS patients and other connective tissue disorders.

Among different functions, the VICs contribute to ECM protein synthesis and maintain a structurally competent leaflet. As such, it is important to identify changes in the biomechanical micro-environment of the TV interstitial cells in response to the ECM structural changes. For example, previous experiments have shown that alignment of cells with the ECM affects ECM protein production [4]. While existing computational models can capture the overall responses of the TV, they fail to accurately predict cellular deformation in response to the changes of the ECM. Our multi-scale framework has the potential to bridge this gap and help us identify the interplay between macro-scale and micro-scale alterations in the TV complex.

The objective of this study was to identify how deformation of VICs changes when they are aligned in different angles relative to ECM fibers. For this purpose, a computational framework was used to analyze the cellular deformation and orientation of cells within the ECM. This computational model was also validated using experimental measurements using microscopy.

METHODS

An analysis using a multi-scale finite element model was conducted to predict alteration in the micro-structure of the ECM under equibiaxial tension (Fig. 2). This method was applied to data sourced from two groups that had been the subject of previous experimental studies: (1)

native leaflets (control) and (2) leaflets treated with elastase to remove native elastin [5]. The dimensions of the models were $7 \times 7 \times 0.406$ mm and $7 \times 7 \times 0.313$ mm for the native and elastin-digested group, respectively. Both groups were discretized into 2352 macro-scale elements and approximately 450 micro-scale elements per each ECM representative volume element with a total of $\sim 10^8$ degrees of freedom, as described previously [6].

Figure 1: Schematic of the model. An ellipsoid located in the micro-scale representative volume element was used to quantify nuclear aspect ratio (NAR) at different macro-scale loading levels.

The nuclear deformation was chosen as a measure of cellular deformation under mechanical loading. To model VIC nuclei, an ellipsoid was chosen in each representative volume element at the undeformed configuration. The nuclear deformation was quantified via alteration of the aspect ratio of the ellipsoid, referred to as the nuclear aspect ratio (NAR) [7]. The initial undeformed NAR in the control group and the elastin-digested group were 2.57 and 2.72, respectively, based on preliminary experimental findings. Initially, the nuclei were aligned with the mean fiber direction of each network in both groups.

The points of intersection of the ellipsoid and surrounding fibers represent the ECM integrins. These intersections were tracked throughout a series of simulated loading levels, and the associated NAR was measured at each point. The average NAR under different levels of stress were computed for approximately 50 elements in each group. The results of the elastin-digested and control groups were compared to experimental results obtained from microscopy.

To investigate the impact of nuclear alignment, the NAR was calculated under load-controlled conditions for a representative fiber network in three different orientations relative to the mean fiber direction. In particular, the following case studies were performed: (1) the largest axis of the nucleus was aligned with the main fiber direction, (2) the largest axis of the nucleus had a 45° angle with the main fiber direction, and (3) the largest axis of the nucleus had a 90° angle with the main fiber direction.

Figure 2: Nuclear aspect ratio (NAR) alteration under different levels of macro-scale stress.

RESULTS

Figure 2 shows the alteration of NAR under different stress levels in the control and elastin-digested group. In Fig. 1A, the NAR of the control group model went up from 2.57 to 3.75 under the stresses from 0 to 130 kPa. In the elastin-digested group (Fig. 1B), the NAR increased from 2.72 to 3.28 under the stresses from 0 to 130 kPa. In both groups, the changes were consistent with values measured experimentally via microscopy.

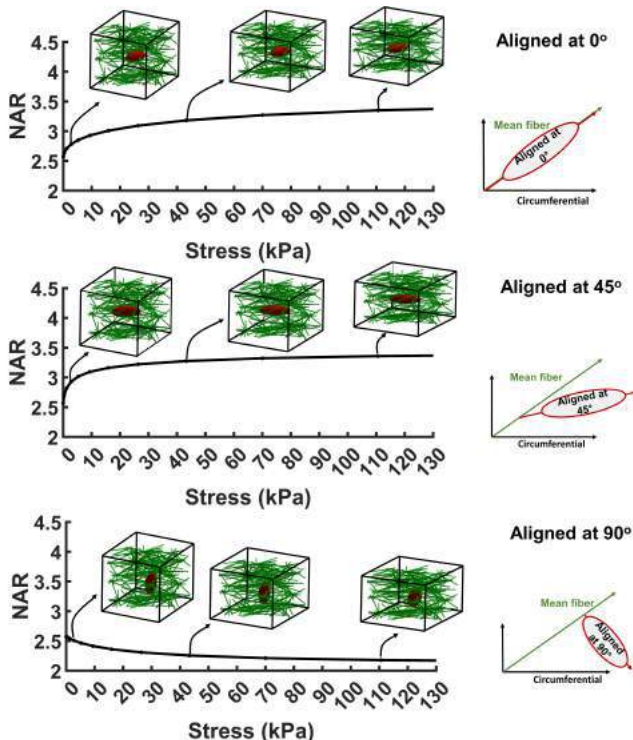

Figure 3: Changes in the nuclear aspect ratio (NAR) with stress in different orientation case studies.

Figure 3 illustrates changes in NAR that occur at various loading levels when the nucleus is oriented at three different angles relative to the mean fiber direction. The NAR increased with loading when the nucleus was aligned with the ECM fiber direction. In contrast, when the nucleus was oriented perpendicular to the main fiber direction at the undeformed configuration, the NAR decreased with increasing stress.

DISCUSSION

Both control and elastase-digested groups exhibited a rapid initial increase in NAR, followed by a plateau. This increase was due to a reduction in the undulation of ECM fibers, which plateaued once the collagen was fully recruited. As such, we hypothesized that the NAR in the elastin-digested group would plateau earlier than the control group. The simulation that we conducted had results that were similar to those found in earlier experimental studies.

Given the assumptions made in the simulation, this model can be utilized to predict the cellular deformation of the TV anterior leaflet when nuclei are oriented at various angles relative to the ECM fibers. We investigated alignment of cells with mean fibers direction in both control and elastin-digested groups and compared the results with the average orientations of VICs to a concurrent experimental study conducted in our lab. Our simulation results showed more similarity in cell orientation in the control group, while the elastin-digested group showed a slightly wider span in mean orientation.

Figure 3 displays how the initial configuration of nuclei may affect how the NAR changes under different levels of equibiaxial load. When the cell is aligned with 45° to the mean fiber direction, NAR plateaued later than when cell was aligned parallel to the mean fiber direction. Also, when the nuclei are perpendicular to the ECM fibers, NAR decreased with increasing load levels.

In the simulation, we assumed that the nuclei deform affinely with the positional changes of the integrins of the ECM in each representative volume element. Our model can be improved upon by addition of the non-affine deformation of the intra-cellular structure such as actin microfilaments, microtubules, and/or intermediate filaments.

In summary, comparing the average nuclei deformation of designated elements in two groups, we observed that elastin degradation and mechanical loading affected the shape of the nuclei. Although in MFS elastin is not compromised in the same manner as in this research, some differences in collagen structure were observed that may lead to the change of NAR with different loads. As changes in NAR can lead to deviations in gene expression and protein synthesis, it may consequently affect the mechanobiology and function of the TV. Future work will focus on computing more numbers of networks among the TV leaflet with different orientations to the ECM and comparing with the results obtained from our concurrent experimental study to statistically analyze how the orientation of cells and alignment with the ECM impact nuclear deformation.

INTRODUCTION

Within the human body, tissues are in a continuous state of remodelling. From development to disease, cell-generated forces play a key role in this remodelling, contributing to tissue shape, structure, and function. While bulk measurements are useful, they provide little insight into how local stresses arise and evolve within tissues over time, as they provide either an end-point snapshot of stress state or a global measurement of tissue-generated stress [1]–[3]. Cell-sized microspheres have recently emerged as a powerful technique to probe tissue mechanobiology at the cellular scale, as they can be sufficiently soft as to deform within remodelling tissues, and optically imaged to measure internal stresses. Oil microdroplets can be used to measure anisotropic forces [4], [5] while hydrogel-based approaches can measure isotropic stresses like tension and compression [6], [7].

However, measuring stresses with dispersible hydrogel sensors requires ultrasoft, low-polymer content gel formulations to create measurable stress sensor deformations at the ~10s of Pa stress loading conditions expected within tumors. Such low-polymer content materials are challenging to label with sufficiently fluorescent materials to support repeated measurements without photobleaching, particularly in optically dense tissues over 100 μm thick, as required in cancer tumor models [7]. Here, we leverage thermodynamic partitioning of hydrogel components to create “edge-labelled” ultrasoft hydrogel microdroplets, in a single polymerization step. Bright and stable fluorescent nanoparticles preferentially polymerize at the hydrogel droplet interface, and can be used to repeatedly track sensor surfaces over long-term experiments, even when embedded deep in light-scattering tissues. We use these edge-labelled microspherical stress gauges (eMSGs), in inducible breast cancer tumor models of invasion, and demonstrate distinctive internal stress patterns that arise from cell-matrix interactions at different stages of breast cancer progression.

METHODS

High-throughput fabrication of eMSGs was performed via water-in-oil emulsion with incorporation of fluorescein (green; polymer backbone) and interface-partitioning fluorescent microspheres (red) that preferentially polymerize at the sensor edges. eMSGs were functionalized for cell adhesion, mechanically characterized via osmotic compression [7], and imaged using fluorescence microscopy to monitor shape dimensions (Fig. 1).

Figure 1: Fluorescent microspheres enhance microspherical stress gauge visibility (scale bar = 100 μm)

We then embedded eMSGs to monitor internal tissue stress evolution within multiple engineered tumor models that recreate stages of breast cancer progression (Fig. 2). eMSGs were incorporated into collagen-embedded spheroids formed from either non-invasive T-47D, inherently invasive MDA-MB-231, or MCF7 with an inducible Src oncogene or green fluorescent protein (EGFP) expression as a control. eMSGs were imaged prior to spheroid formation (day 0) for stress-free dimensions, and finite element modelling was used to calculate radial and circumferential stresses based on deformed bead dimensions.

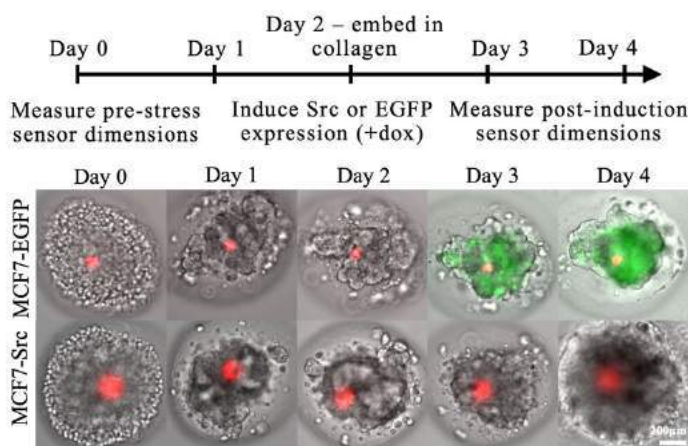

Figure 2: Inducible breast cancer model with embedded eMSGs

RESULTS

We found homogeneously low stresses within invasive MDA cell lines, compared to non-invasive T-47Ds which showed relatively high and heterogenous internal stress patterns (Fig. 3). We also demonstrate that although tissues are measurably compacted once encapsulated within a matrix, internal tumor stresses only increase in the short term, as non-invasive tumors rapidly make small internal reorganizations that reduce the mechanical stress to baseline levels (data not shown).

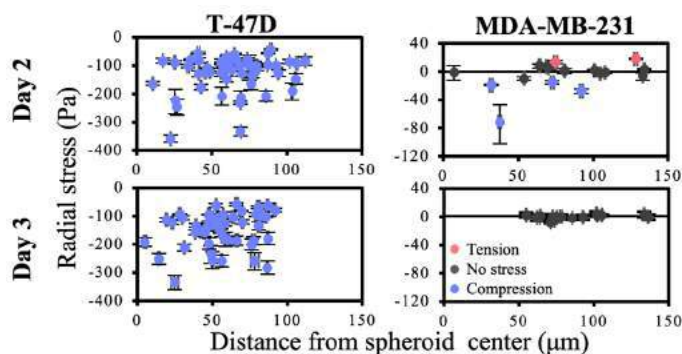

Figure 3: Non-invasive T-47D spheroids remain compressive while invasive MDA-MB-231 spheroids lose internal stress with invasion

Similarly, models induced to overexpress Src, which triggers growth and migration programs, exhibited a significant reduction in stress, while control EGFP-expressing spheroids changed internal stress levels minimally in both radial and circumferential directions. (Fig. 4).

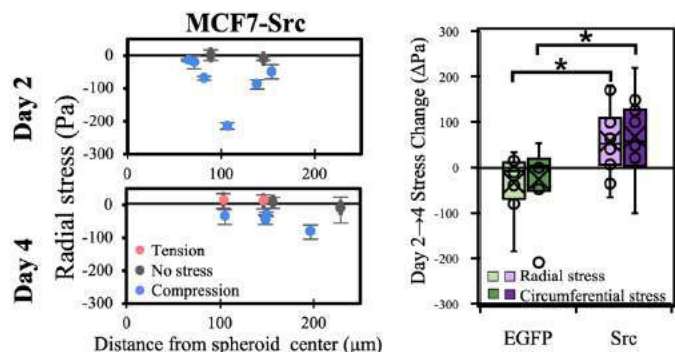

Figure 4: Breast cancer spheroids exhibit loss of internal stress with invasion triggered by Src overexpression

DISCUSSION

The eMSGs developed in this study enable enhanced visualization and long-term monitoring of cell-generated stresses within multicellular aggregates, through their engineered compliance and surface-localized fluorescent labelling. Their resistance to photobleaching even after repeated measurements at high-power excitations uniquely allowed us to characterize the heterogenous time-evolution of internal tumor stress states within breast cancer models, while simultaneously activating and monitoring gene-inducible tissue invasion.

In all cases, significant internal tumor stress heterogeneity was observed in these model systems; an emerging picture that is also supported by a recent study in our lab demonstrating that invasive tumors have highly heterogenous internal stiffnesses [10], which must correlate with local stress-generating cell behaviours. Internal stresses were also generally greater in non-invasive models, while invasive models including MDA-MB-231 and induced MCF7-Src cells consistently form relatively loose aggregates [8], [9] with low internal stresses. Speculatively, this transition to a low-stress architecture is consistent with the transition of tumor cells towards low-levels of cell-to-cell adhesion during invasion. Interestingly however, although the internal stresses are highly heterogenous, our ability to track individual sensors during a non-invasive to invasive transition in the same inducible cell system allows us to conclude that internal stresses within the tumor are collectively reduced once invasion is triggered. This finding is particularly important in potentially explaining widely varying clinical observations of tumor stress under metastatic and non-metastatic conditions; and also suggests a potential biophysical marker to determine whether a metastatic event has occurred.

More broadly, this work demonstrates that mapping internal mechanical stress in tumors may have utility in understanding the fundamental tumor microenvironment and in understanding the highly dynamic and local mechanical processes of disease and development.

SYNAPTOPODIN ENABLES FOCAL ADHESIONS TO RESIST PERPENDICULAR FORCE

INTRODUCTION

Focal adhesions resist shear forces in nearly all cell types. Kidney podocytes are unusual in that they must resist stresses perpendicular to their basement membrane arising from fluid shear stress as pressurized fluid from capillaries passes through glomerular slit diaphragms [1]. Kidney podocyte cells are lost daily and never regenerated. As the spare supply from birth is lost, a process that is accelerated dramatically in kidney injury and disease, kidney failure and chronic kidney disease arise [2-5]. Our objective was thus to identify the protein structures responsible for enabling kidney podocyte focal adhesions to resist forces perpendicular to their basement membrane.

A search of the literature turned up several candidate proteins near the basement membrane. Of these, the protein synaptopodin arose as a likely target. Synaptopodin, a unique actin-associated protein that is highly expressed in podocytes. Synaptopodin is implicated as a protective factor for kidney function following in acute kidney injury [1]. Compared with wild type mouse models, synaptopodin knockout mice have significantly decreased numbers of podocytes and significantly impaired kidney function; however, the mechanism of this disease exacerbation is not known [2].

We therefore hypothesized that that synaptopodin serves as a linker to enable focal adhesions to resist perpendicular forces.

METHODS

Normal force loading system: We developed an *in vitro* system to study the effect of perpendicular forces on cells cultured on hydrogels of defined stiffness, coated with defined extracellular matrix (ECM) proteins. Cells were cultured on substrates that were linked to a centrifuge, in swinging buckets that enabled the cells to face outwards (force perpendicular to and away from the substrate) while still staying submerged in culture medium. Accelerations of 400 m/s² (500 RPM) were applied for 1-2 minutes, producing forces at the upper extreme of what a cell might experience in an injury setting [7]. By varying

stiffness, surface proteins, culture conditions, and the mechanical loading/centrifugal forces applied, this setup allowed us to simulate perpendicular forces that podocytes experience in their native glomerular microenvironment.

Mouse models: We used primary podocytes taken from control (WT) mice as well as mice lacking synaptopodin (Synpo KO). We compared these cells to osteosarcoma cells (U2OS) as well as NIH 3T3 cells (no synaptopodin) cultured in both undifferentiated and differentiated conditions. Animal studies were approved by Wash. Univ. IACUC.

Histology: We tested our hypothesis by assessing the cellular responses to centrifugal forces using morphological analysis as well immunostaining for integrins, synaptopodin, α -actinin-4, myosin II and actin. We predicted that cells with synaptopodin would exhibit improved stability against perpendicular force.

Figure 1: Centrifugal loading apparatus.

Quantitative microscopy: We also used a quantitative scoring system for showing the degree of phenotypic change in response to perpendicular force. Confocal immunofluorescence staining and confocal microscopy at 60X showed that cell morphology changed in response to perpendicular force. Cells that had clean and continuous integrin at the periphery, were scored as 1, and cells that had integrin spreading over the whole cell were scored as 0.

RESULTS

Consistent with expectations for standard models of focal adhesions [8], NIH 3T3 cells, which do not express synaptopodin, elongated into spindle shapes or detached in response to perpendicular forces (Fig. 2). However, wild type (WT) primary podocytes spread and formed a continuous skirt of integrins at their periphery, staying largely stable. Synaptopodin (Synpo) KO primary podocytes did not show this continuous integrin $\beta 1$ pattern at the cell periphery but rather showed a diffuse pattern and were more likely to detach.

For the wild-type primary podocytes, when bearing normal forces, the $\beta 1$ -integrin relocated to the periphery of the cells and accumulated to form a continuous adhesive structure, rather than the discrete focal adhesions observed at baseline.

For the *Synpo*^{-/-} primary podocytes, integrin accumulation at the periphery of the podocytes was diminished when bearing normal force. This phenotype suggests a role for synaptopodin in mechanotransduction and integrin regulation.

For the osteosarcoma cells (U2OS), the integrin was stronger in the wild-type than in the *Synpo*^{-/-} U2OS. The myosin structure was clearer in the wild-type; however, it became cloudy in the *Synpo*^{-/-} U2OS. These phenotypes suggested that synaptopodin in U2OS had similar function as it had in primary podocytes. In addition, the absence of synaptopodin also caused the deconstruction of myosin protein.

Figure 2: Immunostaining of wild-type primary podocytes. Synpo (green), integrin (red) and synaptopodin + integrin (merged). Immunostaining of *Synpo*^{-/-} primary podocytes. α -Actinin-4 (green), integrin (red) and α -Actinin-4 + integrin (merged). Immunostaining of 3T3 cells. Integrin (red) and actin (blue). Immunostaining of osteosarcoma cells and *Synpo*^{-/-} osteosarcoma cells. Synpo (green), integrin (red) and myosin (purple). (A) No normal (perpendicular) force. (B) 500 RPM for 1min. (C) *Synpo*^{-/-} primary podocyte, no normal force. (D) *Synpo*^{-/-} primary podocyte, 500 RPM for 1min. (E) 3T3, no normal force. (F) 3T3, 500 RPM 1min.

For the wild-type primary podocyte, when we increased the time of bearing perpendicular force, the shape score significantly increased, which indicated a more resistant phenotype. For the *Synpo*^{-/-} primary podocyte, the score did not change when the time of force applied increased and is similar to the control in wild-type primary podocytes, indicating that after synaptopodin was knocked out, the primary podocytes did not have phenotype.

Figure 3: Shape index of cells following perpendicular force.

DISCUSSION

Results suggest that synaptopodin may have a mechano-resistance role in podocytes, enabling podocytes to respond adaptively to normal forces. The mechanism underlying this was relocation of focal adhesions to resist acute normal forces. This buffering process could be a characteristic of healthy podocytes *in vivo* for maintaining adhesion to the GBM after injury.

Results suggest a mechanistic, mechanobiological explanation for why synaptopodin is protective and predictive of improved prognosis following kidney injury. These results motivate further study exploring synaptopodin targeted therapies could be protective after kidney injury.

Epithelial Monolayers Develop Density and Effective Temperature Differentials to Migrate across Confined Matrices

W.J. Lin (1), A. Pathak (1)

(1) Mechanical Engineering, Washington University, St. Louis, MO, USA

INTRODUCTION

Collective migration of epithelial cells across physically heterogeneous environments regulates vital physiological and pathological processes, such as embryogenesis, wound healing, tissue regeneration, and cancer metastasis. In response to matrix stiffness and topography, epithelial cell monolayers undergo jamming-unjamming transitions. Although previous studies have shown different migration phenotypes separately in confined and unconfined environments, physical transitions required for collective cell populations to negotiate confined regions remain unclear. To address this question, we fabricated polydimethylsiloxane (PDMS) substrates with contiguous microchannels and studied collective migration of MCF10A (10A) human mammary epithelial cell line epithelial cells.

We found that cells develop a density differential in wide regions, relative to narrow channels, which could generate enough pressure for their eventual migration into confinement. To understand whether cell-cell cohesivity alters this requirement of a density differential, we used cells with constitutively-active RhoA (+RhoA) for higher cohesivity and overexpressed ErbB2 (+ErbB2) for cancer-like reduced cohesion. We found that more cohesive cells (+RhoA) developed a higher density differential relative to less cohesive cells for migration across confinement. While confined channels allowed for faster migration in WT cells, this confinement sensitivity was diminished for both alternations in cell cohesivity. With migration into confinement, cells deformed their shape and increased their effective temperature, calculated by treating cells as a granular thermodynamic system. Further, more cohesive cells (+RhoA) and those in confined regions were effectively 'warmer'.

Overall, our results show that collective cell populations build a pressure differential between narrow and wide matrices to enter confined environments and these differentials vary for cell types of varying cohesivity. These findings show that collective cell migration across confinements can be interpreted in terms of basic physical

principles of pressure and temperature of granular matter, which could inform our understanding of more complex living systems.

METHODS

We cultured MCF10A (10A) monolayers on PDMS substrates and allowed cells to migrate through rectangular PDMS microchannels of varied widths. Microchannels were fabricated following standard soft lithography with 10:1 mixing ratio. Wide and narrow channels of widths 200 μ m and 50 μ m (with 70 μ m height), respectively, were used.

We tracked cell dynamics within the monolayers for 2-3 days as 10A cell monolayers expanded and entered microchannels (Fig. 1A.) Migration of 10A cells was compared with their 10A+ErbB2 and 10A+RhoA variants. We used the ImageJ plugin TrackMate for cell velocity and density analyses. After imaging, the monolayers were fixed and stained with F-actin (phalloidin) and p120 (antibody for δ -catenin to label cell-cell junctions) for cell segmentation. The statistics of cell morphologies including distribution of cell areas (A), shape indices ($SI = P/\sqrt{A}$, P : cell perimeter), and aspect ratios (AR) were calculated from cell outlines generated by the Python program SeedWaterSegmenter with custom MATLAB scripts. Metformin (MFM; 2 mM) was used for enhancing cell-cell junctions and reversing EMT in 10A+ErbB2 cells.

RESULTS

We found that epithelial monolayers developed density differentials when cells went across confined matrices across various cell lines (Fig. 1A.) The 10A (Fig. 1B i) and 10A+RhoA (Fig. 1B ii) monolayers built up more cell densities outside the narrow channels while 10A+ErbB2 (Fig. 1B iii) monolayers maintained smaller density difference outside narrow channels. Comparing root-mean-square velocities (v_{rms}) of cell clusters outside and inside the microchannels [1], we found that there was a v_{rms} difference between 10A cells in wide and narrow channels (Fig. 1C i,v.) For 10A+RhoA cell clusters (Fig. 1C ii, vi), the

difference in v_{rms} between outside and inside the wide channels was larger compared to narrow channels. In comparison, 10A+ErbB2 cells showed some v_{rms} outside-inside difference in wide channels (Fig. 1C iii) but not in narrow (Fig. 1C vii.)

To understand whether cell spreading responds to confinement and cell cohesivity, we calculated cell areas. We found that cell spreading was the highest in 10A+ErbB2 cells in narrow channels (Fig. 1D.) By analyzing and visualizing cell aspect ratio and shape index, we found that 10A and 10A+RhoA cells were slightly jammed (Fig. 1D i, ii, dark blue) when cell monolayers were crowded against channel walls, with some unjamming in open areas (Figure 1D, light purple). The less cohesive 10A+ErbB2 cells showed unjamming when

going through narrow channels (Figure 1D iii, light pink and light purple) [2]. Treatment with Metformin (reinforces epithelial phenotype) shifted the phenotype of 10A+ErbB2 monolayers from unjamming to slightly higher jamming (Fig. 1D, darker blue and fragmented).

By utilizing our measurements of cell shapes, we calculated effective temperatures of cell colonies from distribution of aspect ratio of cells within a region: $PDF(x; k) = k^k x^{k-1} e^{-kx} / \Gamma(k)$ and $T_{eff} = s.d.(AR) / \sqrt{k}$ [3]. We found that correlation between effective temperature (T_{eff}) and local cell density was higher in narrow channels (Fig. 1E ii) compared to wide channels (Fig. 1E i.)

DISCUSSION

Through biophysical analyses of collective cell migration on substrates with contiguous microchannels of narrow and wide regions, we discovered that cell colonies develop density and migration differentials to enter confined environments. Since microchannels either warm or cool cell monolayers according to cellular cohesivity and matrix confinement, this could be interpreted as a thermal circuit that could induce tissue liquefaction or solidification [4],[5]. The narrow microchannels significantly lower effective temperature (T_{eff}) of 10A+RhoA monolayers, shifting them from a liquid-like state to a jammed state. This is consistent with their innate properties because RhoA GTPases are known to increase cell contractility and enable mechanosensing.

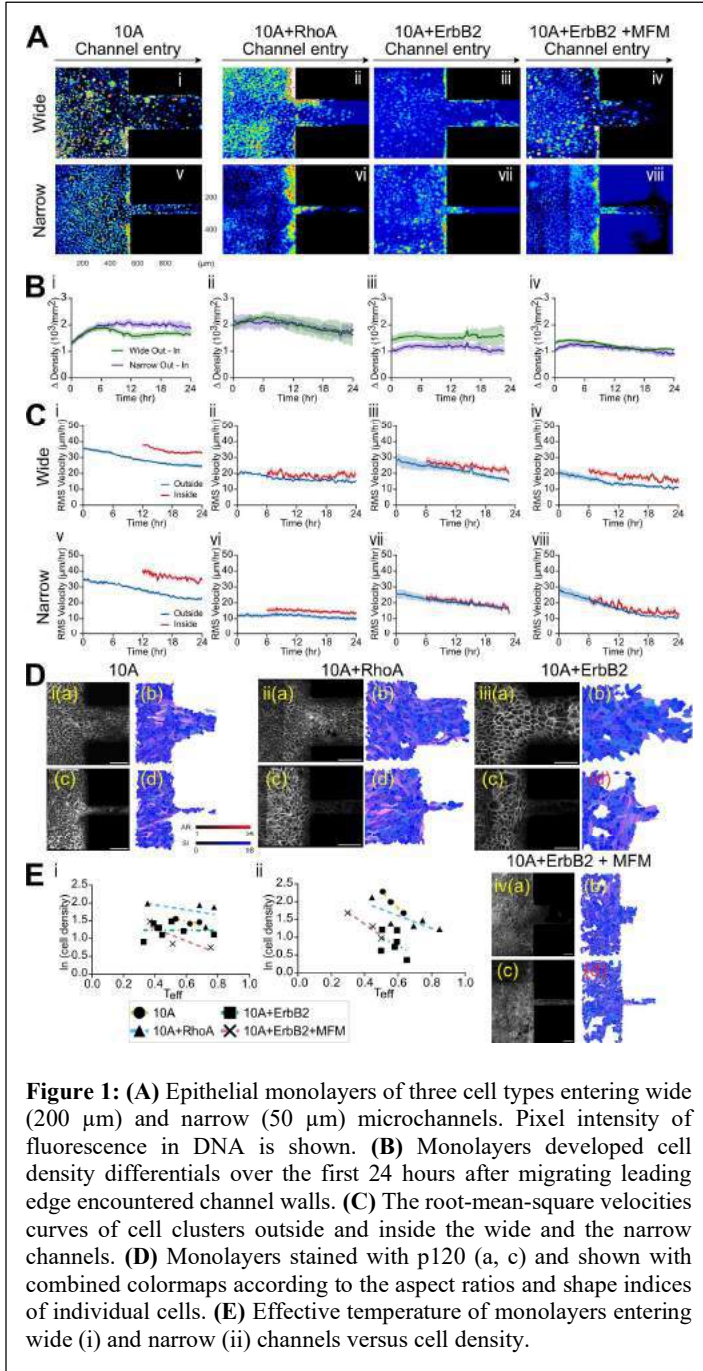

As proposed by Recho *et al.* [6], bulk stresses within an expanding monolayer are spatially constant and equal to a homeostatic stress: $\sigma_h = -E \log \frac{\rho_d}{\rho_e}$, where E, ρ_e are constants. We suppose cell surface density is a measure of effective pressure experienced by monolayers near channel walls and inside channels. Effective temperature (T_{eff}) reflects elongated and protrusive cell shape, which could indicate migration potential. When the more cohesive 10A+RhoA cells enter narrow microchannels, their effective temperature varies in concert with local cell density, which is not the case in other cell types or wider channels. By contrast, when the less cohesive 10A+ErbB2 cells enter confinement, their migration, temperature and density are weakly correlated. These difference across cellular properties indicate that cells with innately healthy and diseased phenotypes negotiate confinement environment differently, dictated by their ability to adapt cell shape, manage rise in cell density, and migratory potential.

INTRODUCTION

Materials advances can lead to breakthroughs in novel applications. Recently, Janus nanoparticles (JNPs) with heterogeneous compositions and multiple interfacial physical properties can lead to directional heating and bring new possibilities for novel nanotechnology and biomedical applications^[1-2]. The critical issue for JNP heating is thermal transport and temperature management. Wilson et al. have systematically investigated interfacial thermal resistance (ITR), and they found that the interfacial curvature and the wettability play important roles in the thermal transport across the interface^[3]. Rajabpour et al. analyzed the directional heating with JNPs with heterogeneous coating and ITRs and demonstrated a temperature difference (~10K) with octanethiolate/mercaptohexanol-coated JNPs^[4]. While these seminal works have advanced our understanding of directional heating with JNP, a comprehensive analysis of directional heating with JNP under steady-state and transient conditions is missing.

In this work, we developed a numerical framework to analyze the thermal transport induced by JNP heating with heterogeneous interfacial thermal resistance. By introducing a dimensionless parameter (ζ) to characterize the temperature contrast, we systematically investigated the key factors that affect the temperature contrast under both steady-state and transient heating scenarios. We found strong size dependence and polar angle dependence of the temperature contrast. Furthermore, we discovered a significant enhancement of the temperature contrast during the pulsed JNP heating. We expect that this work can bring new insights into the thermal responses of JNP heating and can guide future applications.

METHODS

We first constructed and validated the numerical model. Here we consider a plasmonic JNP with a gold core and asymmetric coating on its surface and thus heterogeneous ITR (Fig. 1) along the interface, and the governing equation for temperature is given by:

$$\begin{cases} \frac{\partial^2 T_{JNP}}{\partial r^2} + \frac{2}{r} \frac{\partial T_{JNP}}{\partial r} + \frac{g}{k_{JNP}} = \frac{1}{D_{JNP}} \frac{\partial T_{JNP}}{\partial t}, & r \leq r_{1D} \\ \frac{\partial^2 T_{JNP}}{\partial r^2} + \frac{2}{r} \frac{\partial T_{JNP}}{\partial r} + \frac{\cot(\theta)}{r^2} \frac{\partial T_{JNP}}{\partial \theta} + \frac{1}{r} \frac{\partial^2 T_{JNP}}{\partial \theta^2} + \frac{g}{k_{JNP}} = \frac{1}{D_{JNP}} \frac{\partial T_{JNP}}{\partial t}, & r_{1D} < r \leq r_{JNP} \\ \frac{\partial^2 T_w}{\partial r^2} + \frac{2}{r} \frac{\partial T_w}{\partial r} + \frac{\cot(\theta)}{r^2} \frac{\partial T_w}{\partial \theta} + \frac{1}{r} \frac{\partial^2 T_w}{\partial \theta^2} = \frac{1}{D_w} \frac{\partial T_w}{\partial t}, & r > r_{JNP} \end{cases} \quad (1)$$

And it's subjected to the boundary and initial conditions:

$$\begin{aligned} \frac{T_{JNP} - T_w}{R} &= -k_{JNP} \frac{\partial T_{JNP}}{\partial r} = -k_w \frac{\partial T_w}{\partial r}, \quad r = r_{JNP} \\ T_w &= 0, \quad r = r_{boundary}; \quad T_{JNP} = 0, \quad T_w = 0, t = 0 \end{aligned} \quad (2)$$

$$R = \begin{cases} R_1, & 0 \leq \theta \leq \theta_0 \\ R_2, & \theta_0 < \theta \leq \pi \end{cases}$$

Here we discretized the Equation (1&2) with a Crank-Nicolson scheme and all solutions were calculated in Matlab 2019b software. To quantify the temperature contrast, we developed a dimensionless parameter ζ which is defined as the ratio between the temperature rise in water at north pole (ΔT_1) and south pole (ΔT_2) (Fig. 1).

RESULTS

Figure 1. Schematic illustration of the modeling of JNP heating and temperature contrast.

Several factors can affect the thermal transport and temperature profile with JNP heating. We first focus on the directional heating under steady-state scenarios and start with the symmetric JNP with a $\theta_0 = \pi/2$ (Fig. 1). Nonuniform ITR can stem from the heterogeneous coating and can lead to heterogeneous thermal transport. Fig. 2A shows that for a JNP with $R_1 = 1 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$ and $R_2 = 100 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$, the temperature increase (ΔT) near the north pole is significantly higher than ΔT near the south pole due to the ITR contrast. This heterogeneous thermal transport

and temperature contrast is known as directional heating. For more generalized cases with various combinations of R_1 and R_2 , we plotted the 2D map of $\zeta_{s.s.}$ as functions of R_1 and R_2 (Fig. 2B). On this map, we can readily read the relative temperature contrast with arbitrary combinations of R_1 and R_2 . For instance, $R_1 = 1 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$ and $R_2 = 100 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$ gives $\zeta_{s.s.} = 2.5$, indicates significant directional heating with the temperature rise near the north pole is 2.5 times higher than that near the south pole.

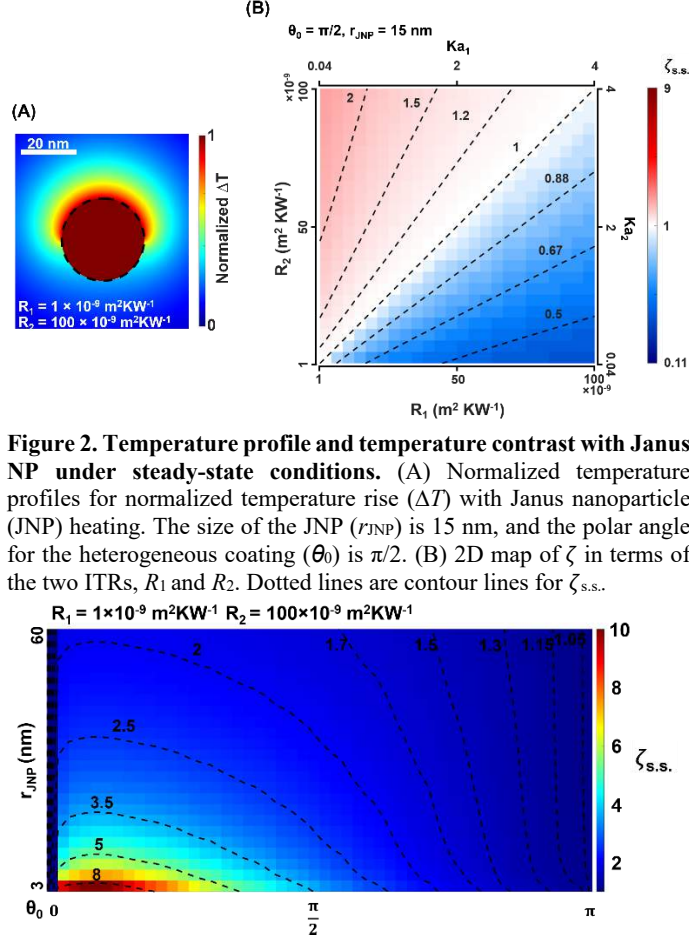

Figure 2. Temperature profile and temperature contrast with Janus NP under steady-state conditions. (A) Normalized temperature profiles for normalized temperature rise (ΔT) with Janus nanoparticle (JNP) heating. The size of the JNP (r_{JNP}) is 15 nm, and the polar angle for the heterogeneous coating (θ_0) is $\pi/2$. (B) 2D map of ζ in terms of the two ITRs, R_1 and R_2 . Dotted lines are contour lines for $\zeta_{s.s.}$.

Figure 3. $\zeta_{s.s.}$ map in terms of r_{JNP} and θ_0 under steady-state.

Next, we studied the effect of the polar angle (θ_0) and the size of the JNP (r_{JNP}) on temperature contrast under steady-state heating. Here we demonstrate this combined effect by plotting the map of $\zeta_{s.s.}$ in terms of r_{JNP} and θ_0 with a given ITR contrast under steady-state (Fig. 3). Fig. 3 demonstrates a strong size dependence of temperature contrast with JNP heating, increasing r_{JNP} will end up with less temperature contrast. This size dependence agrees with Kaptiza number analysis, where for larger NP, the ITR has an insignificant effect on heat conduction across the interface^[5]. Additionally, we found that θ_0 has a significant impact on the temperature profile and on $\zeta_{s.s.}$ when $\theta_0 = 0$ & π , the JNP is homogeneously coated, leading to $\zeta_{s.s.} = 1$. As we slightly increase θ_0 above 0, $\zeta_{s.s.}$ rises drastically and reaches its peak value at $\theta_0 \sim \pi/12$. Within the range of our parameter scanning, a greatest temperature contrast ($\zeta_{s.s.} = 10$) under-steady state is observed for a 3 nm JNP with $\theta_0 \sim \pi/12$ ($R_2/R_1 = 100$).

Finally, we analyzed the evolution of temperature contrast with JNP heating during the transient process. Here we imposed 100 ns pulsed constant heating on a 30 nm JNP with $R_1 = 1 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$, R_2

$= 100 \times 10^{-9} \text{ m}^2\text{KW}^{-1}$, and $\theta_0 = \pi/2$. Fig. 4A illustrates the temperature profiles during the transient heating process. We can observe a greater temperature contrast as no obvious heating is observed near the southern hemisphere at $t = 1 \text{ ns}$ & 10 ns , leading to a much-enhanced ζ for pulsed heating (Fig. 4B). As heating continues, thermal energy continuously diffuses, ending up with ζ asymptotically reducing to steady state level (Fig. 4B, $\zeta_{s.s.} = 2.5$). Moreover, we expand our investigation into more generalized cases and discuss the combined effects of geometric parameters (r_{JNP} and θ_0) on temperature contrast during the transient heating process. Fig. 4C&D show a strong geometry dependence of the temperature contrast during the transient heating process. Smaller JNP and moderate polar angle can lead to greater enhancement of temperature contrast for pulsed JNP heating.

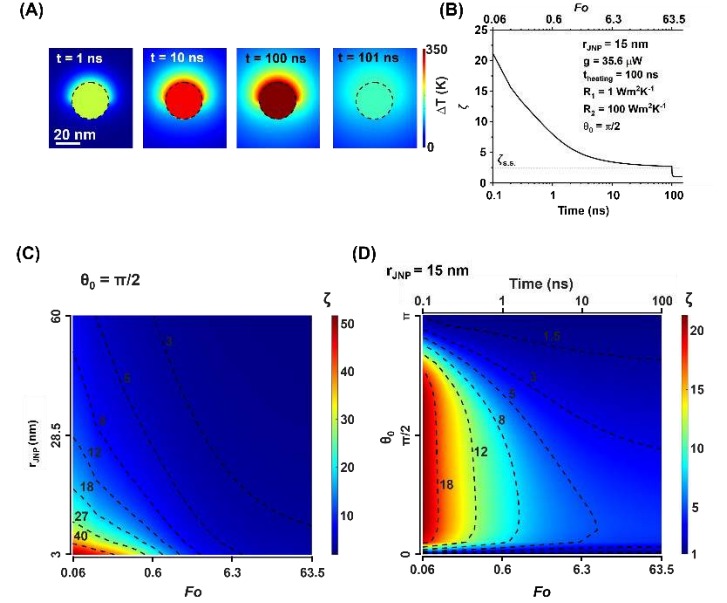

Figure 4. The temperature evolution during the transient heating. (A) ΔT profiles during the transient heating process with JNP. (B) The evolution of ζ during the transient heating process. (C) ζ map in terms of r_{JNP} and Fo . (D) ζ map in terms of θ_0 and t .

DISCUSSION

In this work, we found that shorter heating time can lead to drastic enhancement of ζ . Therefore, it is reasonable to speculate further enhancement of temperature contrast with picosecond heating. However, our numerical model is limited in estimating the thermal transport during the picosecond range as it is too short for electron-phonon energy transfer^[6]. In our future work, a two-temperature model can be a starting point to reveal the JNP heating during the picosecond pulsed energy excitation.

INTRODUCTION

The tricuspid valve (TV) maintains unidirectional blood flow in the pulmonary side of the heart through precise and complex interactions of the TV leaflets and sub-valvular components. Proper function of these sub-valvular components is critical to overall TV function. Alterations to sub-valvular anatomy or function can result in tricuspid regurgitation (TR) and reduced RV function. Specifically, the TV chordae tendineae prevent prolapse of the leaflet cusps or edges into the right atrium when the ventricle is pressurized during systole [1]. Alterations or lesions on the chordae may lead to primary TR. Complete chordae tendineae rupture (CTR) may cause TV leaflet flail into the right atrium, increasing the severity of regurgitation.

Though a majority of TV regurgitation is associated with left-sided heart disease, an estimated 8-10% of TR occurs in the presence of primary TV pathology (primary TR) [2]. Primary TR resulting from chordae abnormalities may occur due to both congenital and acquired causes. Congenital causes include Ebstein's anomaly and Marfan syndrome, while acquired causes include endocarditis, rheumatic disease, blunt force trauma (e.g., vehicular accidents), and most commonly, iatrogenic injury (e.g., endomyocardial biopsy, interference from pacing or defibrillator leads) [3, 4]. However, the mechanics of TR development following CTR are not well understood, especially for acquired causes of TR.

To address this knowledge gap, we experimentally modeled CTR in whole porcine hearts using our ex-vivo beating heart simulator to assess the mechanical impact of CTR on TV leaflet deformation [5]. TV septal leaflet strains were quantified to gain insight into acute TR development following CTR. We hypothesized that CTR further disturbs normal deformation of the TV leaflets, leading to insufficient leaflet coaptation and acute TR.

METHODS

Fresh porcine hearts were obtained from a local slaughterhouse (3D meats, Dalton, OH) for investigation using a previously developed ex-vivo beating heart system [5]. The positive displacement pump's standard

70 bpm waveform was used to circulate phosphate buffered saline (PBS) through intact porcine hearts at physiological pressures and flow rates, in accordance with the International Standard Organization (ISO 5840) guidelines for heart valve testing. The circulating fluid generates a transvalvular pressure gradient that causes the TV leaflets to open and close, mimicking native leaflet deformation.

Eight porcine hearts ($n = 8$) were evaluated in the native state (chordae intact) and then after simulating CTR. Chordae rupture was modeled by severing one of the septal chordae adjacent to the posteroseptal commissure, closest to sonocrystal 1 (Fig. 1). Sonomicrometry techniques were used to obtain displacements of the TV septal leaflet, consistent with our previous publications [5, 6]. Eight sonocrystals (Sonometrics Co., London, ON, Canada) were sutured onto septal leaflet in a predefined arrangement, with sonocrystals 6 – 8 placed along the TV annulus (Fig. 1).

Right atrial pressure (RAP), right ventricular pressure (RVP), pulmonary artery pressure (PAP) and mean flow rate were recorded throughout the cardiac cycle for all experiments. Leaflet coaptation was visually assessed using an endoscopic camera prior to data collection. The pressure signals and sonocrystal displacements were recorded for 20 seconds for both the intact and post-chordae rupture (PCR) conditions.

Figure 1: Arrangement of eight sonocrystals on the surface of the septal leaflet, with surface triangulation outlined in red. SB³C2023-227

Positional data were extracted from sonocrystal signals to determine the deformation of the septal leaflet surface with respect to the reference configuration at minimum RAP. A custom Matlab code was used to calculate strains over the septal leaflet surface throughout the cardiac cycle for intact and post-rupture conditions. Details on the triangulation and strain calculation can be found in our previous publication [5].

RESULTS

Following CTR, the maximum RVP dropped from 31 to 25 mmHg, and the flow rate decreased by 26%, indicating that regurgitation occurred immediately after CTR. The observed delay in opening and closing of the pulmonary valve (PV) further indicated regurgitation following chordae rupture (PCR) (Fig. 2). Comparison of the pressures with principal strain values calculated throughout the cardiac cycle revealed that the maximum strains occurred at peak RVP (approximately 0.4 s). After this peak, strains rapidly dropped towards the end of the systole and remained closed to zero during diastole.

Chordae rupture notably altered the strain distribution across the septal leaflet surface (Fig. 3a). A significant increase in peak principle strain was observed after rupture at the distal edge of the septal leaflet, near sonocrystal 1 (Fig. 3b). However, no significant difference was observed in maximum principal strains (mean \pm standard error) averaged across the septal leaflet between intact (14.6 \pm 3.0%) and PCR (18.2 \pm 3.4%) conditions.

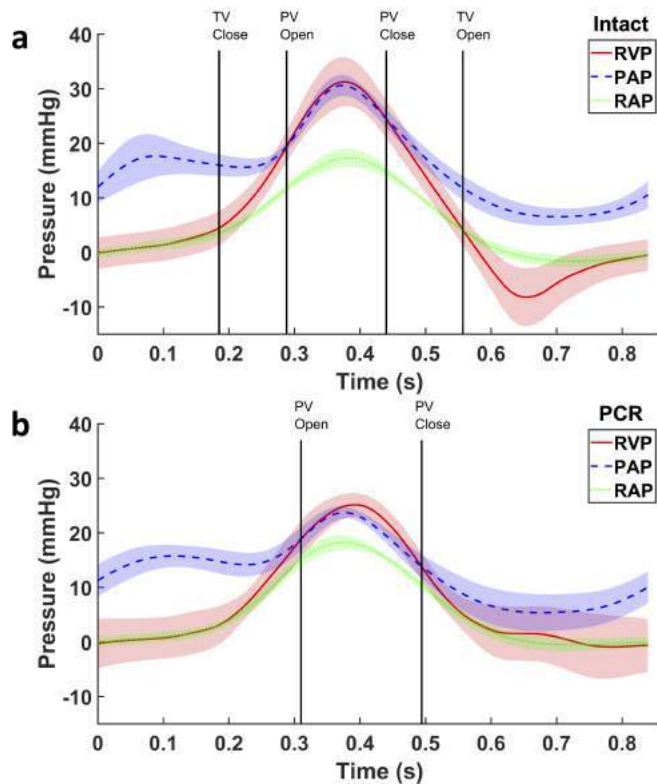

Figure 2: Mean right atrial pressure (RAP), right ventricular pressure (RVP), and pulmonary artery pressure (PAP) during the cardiac cycle for (a) intact and (b) post chordae rupture (PCR) conditions ($n=8$, paired samples), where shaded regions represent standard error. Vertical lines indicate opening and closing of the tricuspid valve (TV) and pulmonary valve (PV).

DISCUSSION

Chordae rupture was observed to prevent proper TV leaflet coaptation which caused acute primary TR, confirmed by the changes in hemodynamic pressures, flow rates and time of PV opening and closure (Fig. 2). Septal leaflet regional strains were immediately altered in PCR conditions, with a significant increase in peak principal strain occurring along the leaflet free edge, nearest the ruptured chordae (Fig. 3). Such results support our hypothesis that CTR disturbs native TV leaflet deformation and coaptation, leading to acute TR.

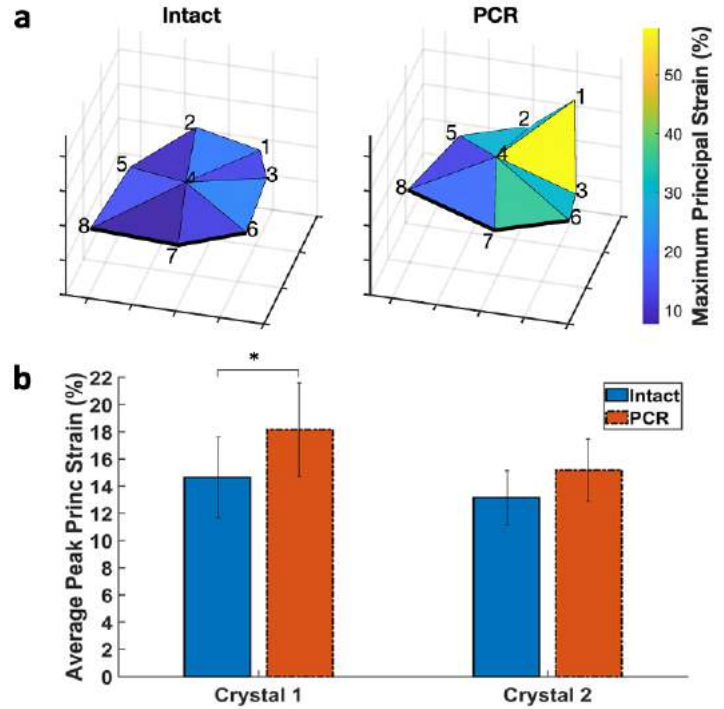

Figure 3: (a) Maximum principal strain on the TV septal leaflet calculated at maximum RVP (approximately 0.4 s) for intact and ruptured (PCR) conditions, shown for a representative sample. (b) Average peak principal strains between intact and PCR conditions for Crystals 1 and 2. Error bars show standard error and an asterisk (*) indicates significance ($p < 0.05$).

The observed changes in septal leaflet strain distribution post-CTR shows that the TV's biomechanical environment is immediately altered by chordae rupture. While we can only directly quantify acute mechanical changes with our experimental system, the presence of altered mechanical strains is indicative of potential long-term effects. Specifically, alterations in mechanical strains may elicit tissue remodeling responses that affect TV function, potentially exacerbating existing TR or accelerating its development. However, further investigation is required to determine the exact tissue remodeling mechanisms.

It is important to note that while our ex-vivo porcine model provides detailed mechanical data that cannot be readily obtained in a clinical setting, conclusions from ex-vivo animal studies do not directly translate to humans. These limitations, however, do not invalidate the overall findings of this study.

In summary, our work provides insight into the mechanics of tricuspid regurgitation development following chordae tendineae rupture. The significant alterations in leaflet strain resulting from chordae rupture highlight a need to further investigate potential maladaptive remodeling responses that may be detrimental to long-term cardiac function. Such investigations are critical to improve treatment strategies and timing of intervention for primary TR, which is currently associated with a high risk of surgical mortality for valve repair and a poor prognosis if left untreated [2, 4].

INTRODUCTION

Collagen plays a crucial mechanical role in most biological tissues and some biomaterials. Inhomogeneity and anisotropy of the individual constituents, e.g., collagen, within tissues affect mechanics at all scales. Type I collagen ($\varnothing \sim 350 \text{ nm} - 1 \mu\text{m}$) is both the most prevalent type in the mammalian world and the most studied [1]. Type II collagen ($\varnothing \sim 20 - 200 \text{ nm}$) is next in prevalence and is the primary source of tensile stiffness in some load-bearing soft tissues yet is relatively understudied.

Continuum-level constitutive models of soft tissues often use an exponential function to model the tensile response of type II collagen but these models rely primarily on untested assumptions or phenomenological fits to macroscale experimental data. In this study we aim to: 1) directly measure the stress-stretch response of networked type II collagen, 2) establish a data-driven constitutive model for individual collagen fibers in tension, 3) similarly establish a failure model for individual collagen fibers in tension, and 4) validate the final constitutive model against data from independent mechanical tests.

METHODS

Tensile Testing. We employed our previously established methods to measure the stress-stretch responses of isolated networks of type II collagen to failure [2]. We sourced bovine cartilage from the patellofemoral groove and produced dumbbell-shaped specimens (thickness of 140-160 μm) oriented along the primary fiber orientation (Fig. 1a). We performed quasi-static uniaxial tension tests to failure and converted force-displacement data to Cauchy stress σ and stretch λ .

Figure 1. (a) Mechanical test. (b) SERVEs with statistically equivalent orientation, dispersion, and volume fraction of fibers [7].

Constitutive Modeling and Inverse Finite Element Analysis. We created three $1 \mu\text{m}^3$ cubic statistically equivalent representative volume elements (SERVEs) of the superficial zone of healthy, human articular cartilage (Fig. 1b) using previously quantified data on the morphology of collagen networks in the superficial zone, specifically matching the orientation, dispersion, and volume fraction of fibers [3]. We modeled each collagen fiber as a 1-D spring element with one of ten constitutive models (Table 1, subscript c denotes critical). We filled the remaining volume with four-node linear tetrahedra using a biphasic neo-Hookean.

Table 1. Candidate models for individual collagen fibers.

Stress (σ) – Stretch (λ) $\lambda > 1$	<i>polyI1</i>	$\sigma = 4\lambda^2 c_1 (\lambda^2 - 1)$
	<i>polyI2</i>	$\sigma = 2\lambda^2 [2c_1 (\lambda^2 - 1) + 3c_2 (\lambda^2 - 1)^2]$
	<i>polyI3</i>	$\sigma = 6\lambda^2 c_2 (\lambda^2 - 1)^2$
	<i>polyS1</i>	$\sigma = 2\lambda c_1 (\lambda - 1)$
	<i>polyS2</i>	$\sigma = \lambda [2c_1 (\lambda - 1) + 3c_2 (\lambda - 1)^2]$
	<i>polyS3</i>	$\sigma = 3\lambda c_2 (\lambda - 1)^2$
	<i>expI1</i>	$\sigma = 2\lambda^2 c_1 (\lambda^2 - 1) [\exp(c_3 (\lambda^2 - 1)^2)]$
	<i>expS1</i>	$\sigma = 2\lambda c_1 (\lambda - 1) [\exp(c_3 (\lambda - 1)^2)]$
	<i>powI1</i>	$\sigma = 2\lambda^2 c_1 c_3 (\lambda^2 - 1)^{c_3 - 1}$
	<i>powS1</i>	$\sigma = \lambda c_1 c_3 (\lambda - 1)^{c_3 - 1}$
Failure $\lambda > \lambda_c$	<i>Failure stretch</i>	$\sigma = 0$
	<i>Failure stress</i>	$\sigma = 0, \text{ for } \sigma > \sigma_c$
	<i>Fiber damage</i> [4]	$\sigma = [1 - (\lambda - \lambda_f)/(\lambda_c - \lambda_f)]\sigma$
	<i>Fiber softening</i> [5]	$\sigma = \exp[-(\psi_{fib}(\lambda^2) - \psi_{fib}(\lambda_c^2))/m]\sigma$

We applied boundary conditions to the SERVEs to match the tensile experiments on isolated collagen networks. Leveraging the SERVEs we used an inverse finite element scheme (with the Constrained Levenberg-Marquardt method) to fit the candidate stress-stretch models (Table 1) to the experimental data prior to bulk softening. We repeated this process with the complete experimental data, i.e., to failure, to fit the failure models (Table 1). We determined the best fit model using $n=6$ experiments and then fit this model to all $n=27$ experiments. We completed all modeling using FEBio (R3.7.0, University of Utah) [6].

Independent Validation. We created finite element (FE) models, i.e., SERVEs, of pristine, healthy human cartilage from the superficial zone and simulated both uniaxial tensile testing [7] and large-strain shear testing [8] to exercise our best-fit fiber model including failure. We modeled intact proteoglycan as a biphasic neo-Hookean (shear stiffness 0.23 MPa and permeability $1 \times 10^{-14} \text{ } \mu\text{m}^4/\text{Ns}$ [9]). We compared our model predictions in uniaxial tension and shear to experimental measurements from these two independent studies.

Statistical Analyses. We used two-way ANOVAs to assess the variance due to both network models (SERVEs) and experiments, with $p=0.05$ for significance. We established the best models (stress-stretch and failure) by ranking R^2 regression values for each fit, and by considering the number of model parameters (i.e., penalizing additional parameters). We used the root-mean-squared-error to assess model performance in validation.

RESULTS

Tensile Testing. We performed 27 uniaxial tension tests of networks of collagen to failure. The median failure stretch was 1.51 and the median failure stress was 7.71 MPa.

Constitutive Model. We fit ten individual fiber models with three SERVEs to $n=6$ experimental bulk responses (Fig. 2a) and found the best-fit parameters for each model (Table 2). Fitting the model to all experiments, we propose the first data-driven constitutive model for individual type II collagen fibers as

$$\sigma = \lambda c_1 c_3 (\lambda - 1)^{c_3 - 1}, \quad (1)$$

with $c_1 = 0.48$, $c_3 = 4.09$ for $\lambda \geq 1$. We also established that the differences in SERVEs had no effect on the resulting fitted parameters.

Table 2. Best-fit model parameters for individual collagen fibers.

Fiber Model	c_1 [MPa]	c_2 [MPa]	c_3 [-]	R^2	Rank
<i>polyI1</i>	0.011	-	-	0.902	8
<i>polyI2</i>	0*	0.024	-	0.970	4
<i>polyI3</i>	-	0.015	-	0.983	1
<i>polyS1</i>	0.076	-	-	0.836	10
<i>polyS2</i>	0*	0.258	-	0.963	7
<i>polyS3</i>	-	0.255	-	0.961	5
<i>expI1</i>	0.010	-	1.21	0.974	5
<i>expS1</i>	0.048	-	6.59	0.934	8
<i>powI1</i>	0.017	-	3.50	0.992	3
<i>powS1</i>	0.857	-	4.09	0.994	1

* optimization process found the best fit at the lower limit, interpreted as 0

Failure Model. We fit four fiber failure models with one SERVE to $n=6$ experimental bulk responses (Fig. 2b). We established the best failure/damage model as

$$\sigma = \begin{cases} \sigma, & \lambda < \lambda_c \\ \exp\left[-\frac{\psi_{fib}(\lambda^2) - \psi_{fib}(\lambda_c^2)}{m}\right] \sigma, & \lambda \geq \lambda_c \end{cases}, \quad (2)$$

with $\lambda_c = 1.39$ and $m = 0.178$, and $\psi_{fib}(\lambda^2) = c_1(\lambda - 1)^{c_3}$.

Figure 2. Representative best fits of (a) elastic and (b) failure models to experimental data from a network of type II collagen.

Model Validation. We successfully predicted data from two independent modes of mechanical testing on healthy human cartilage (Fig. 3). Predicted tensile and shear stresses generally lie within one standard deviation of the experiments with a root mean squared error of 0.251 MPa and 40.0 kPa, respectively.

Figure 3. Validation of fitted constitutive model against independent tests on human cartilage: (a) tension [7], (b) shear [8].

DISCUSSION

We established a new validated, data-driven model for networked, type II collagen fibers within cartilage, and potentially within other soft tissues containing type II collagen. Our power-law model for single fibers presents comparable toe and linear regions to those seen in tension testing of soft tissues containing highly aligned networks of collagen. Many of the candidate stress-stretch response models performed equally well at small strains (e.g., *expI1*, *expS1*), but at large strains these models were not able to fit the experimental data. While we tested and modeled tension to rupture, physiological stretches are generally much less extreme, possibly explaining the usability of such models. Introducing fiber failure into our constitutive model, while increasing complexity and computational cost, improved the fit of our model to the gradual bulk softening present in the experimental data.

The data used for validation derived from independent experiments on human cartilage, while our tensile experiments used bovine cartilage. Thus, some discrepancy likely derives from differences in species and location. Our model produced a more non-linear response than the tensile experiments [7]. Our model also predicted higher stresses in the superficial zone under large-strain shear, potentially due to overestimation of the recruitment within the superficial zone [8].

Limitations and Outlook. We assumed that collagen was undamaged in the experimental preparation and was only type II, when collagen within cartilage is heterotypic with small quantities of types IX and XI. We assumed that there was no cross-linking between fibers in our SERVEs and that fibers had no stiffness in bending. We established constitutive models for the stress-stretch and failure responses of individual type II collagen fibers. This novel and fundamental understanding may inform the experimental study and computational modeling of tissues containing type II collagen.

MODELING CARDIAC FIBROSIS: UNDERSTANDING THE EFFECTS OF EXOGENOUS EXTRACELLULAR MATRIX ON 3D CARDIAC TISSUES

Natalie Weiss-Pachter (1), Kristen Allen (1), Tracy Hookway, PhD (1)

(1) Department of Biomedical Engineering, Binghamton University, Binghamton, NY, USA

INTRODUCTION

Cardiac injury results in the death of many cardiomyocytes (CMs), which have a very limited regenerative capacity. Following injury, cardiac fibroblasts (CFs) infiltrate the heart and attempt to repair the wound by depositing large amounts of extracellular matrix (ECM), mostly collagen I. However, this excess ECM forms scar tissue with a greater stiffness than native tissue, impairing the heart's ability to contract. This stiffening is termed cardiac fibrosis and has very few treatment options, motivating the development of accurate tissue engineered heart models for screening new therapeutics.

Current fibrosis models lack multiple human cardiac cell types, a defined ECM environment, or a 3D environment to enable better cell-cell communication^{1,2}. Because cardiac fibrosis is so dependent on both ECM composition and contractile function, we have designed a model incorporating both CMs, the contractile cells of the heart, and CFs, which produce and resorb ECM, along with exogenous ECM to provide a more defined ECM environment. Most current models induce fibrosis with a compound such as transforming growth factor- β , but few have modeled fibrosis by modulating the cellular environment as opposed to cellular signaling. By changing the amount of ECM in the system, we hypothesize that we will be able to model environments corresponding to varying degrees of fibrosis.

Our goal is to create a physiologically relevant cardiac tissue model which can be used to understand the heart's response to various fibrotic factors and to develop new therapeutics for cardiac fibrosis.

METHODS

2 different types of 3D cardiac tissues were generated- spherical aggregates and tissue rings³. Human induced pluripotent stem cells (iPSCs) were encoded with a GCaMP calcium reporter to enable calcium flux analysis in differentiated CMs (Gladstone Institutes). CMs were differentiated from iPSCs via modulation of the Wnt pathway using GSK3 inhibitor CHIR99021 followed by Wnt pathway inhibitor

IWP2⁴. For each tissue, CMs and primary human adult ventricular CFs (Cell Applications) (3 : 1) were combined with collagen I, laminin 221, a collagen-laminin mix, or Matrigel/Geltrex at concentrations of 0.1-0.5 mg/mL. The ratio of collagen I to laminin (1 : 0.86) in rings containing both ECM types together was based on physiologically relevant *in vivo* ratios of collagen and laminin reported in literature⁵. Aggregates were formed in round bottom, ultra-low attachment 96 well plates. Tissue rings were formed in custom agarose molds.

Bright field microscopy was used to assess tissue phenotype and formation. High frame rate calcium flux videos were assessed with MuscleMotion in ImageJ to measure contractile parameters⁶.

Figure 1: 3D cardiac tissue formation. Schematic of experimental design showing production of spherical aggregates and tissue rings.

RESULTS

Both spherical aggregates and tissue rings were able to form in the absence of exogenous extracellular matrix (Fig. 2). However, the

addition of collagen I, either independently or together with laminin, resulted in less robust formation of both tissue types. Aggregates with no ECM compacted efficiently and formed with an average diameter of 400 μm , but those containing collagen had inferior compaction and less defined edges (Fig. 2a). Aggregates with no ECM had 100% tissue formation as opposed to 7% formation in aggregates with collagen I alone and 0% formation when collagen I and laminin were combined (Fig. 3). Tissue rings with no ECM formed uniformly with an average thickness of 500 μm , but rings containing collagen had inconsistent thickness and highly irregular formation (Fig. 2b).

Figure 2: Morphology of aggregates and tissue rings. (a) Representative images of aggregates containing no exogenous ECM, collagen I + laminin, and collagen I alone. (b) Representative images of rings containing no ECM and collagen I. Scale bars = 250 μm .

Figure 3: Percent aggregate formation. Quantitative aggregate formation data under various ECM conditions. Figure 2 shows examples of formed (top left) and unformed (top right and bottom) aggregates.

Tissue rings showed robust beating, as shown by calcium flux (Fig. 4a-b). Calcium flux analysis also showed decreased contraction duration in rings containing both collagen I and laminin, comparable to that of rings containing no ECM and significantly lower than all other ECM groups (Fig. 4c). No significant differences in contractile parameters were found between different ECM concentrations.

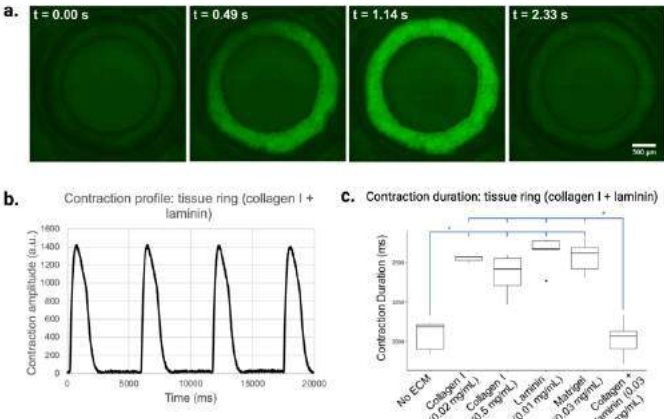

Figure 4: Calcium flux analysis of tissue ring. (a) Calcium flux time lapse of beating ring containing collagen I and laminin. Scale bar = 500 μm . (b) Contraction profile of beating ring. Obtained by analyzing calcium flux video in MuscleMotion for ImageJ. (c) Statistical analysis of contraction duration between different ECM groups. *p < 0.05.

DISCUSSION

We have shown that the addition of collagen I negatively impacts tissue formation across multiple 3D cardiac tissue platforms (Fig. 2). This indicates that exogenous ECM can modulate the environment of these tissues. Notably, rings containing collagen still showed robust beating, and the presence of collagen I and laminin together resulted in decreased contraction duration, which is a characteristic of more mature contractile function (Fig. 4). This decreased contraction duration was similar to that of rings containing no ECM, whereas all other ECM groups had a higher contraction duration. Though more studies are required, this may suggest that the presence of multiple ECM types combined in physiologically relevant ratios encourages more robust beating.

Interestingly, no major differences in either formation or contractile efficiency were seen between different concentrations of ECM. This may suggest that not all the exogenous ECM was incorporated into the tissues during formation, or that CMs were not in contact with ECM for long enough to induce functional change in tissue stiffness and/or beating.

Additionally, the robust formation of both aggregates and rings in the absence of exogenous ECM may suggest that the CFs provide a level of endogenous ECM sufficient to support the formation of these tissues. As such, the “no-ECM” conditions may instead be more reflective of a healthy heart’s ECM environment, and the addition of collagen to the system may reflect a more fibrotic-like environment that inhibits tissue formation and remodeling. Future studies will measure endogenous ECM to determine the CFs’ role in shaping our model’s ECM environment.

One limitation of our study is that CFs are cultured on tissue culture plastic prior to their use in 3D tissues. The stiffness of these plates may induce a fibroblast to myofibroblast transition, causing CFs to deposit more ECM than if they were cultured on a softer substrate⁷. Our model also lacks immune cells such as resident macrophages, which have been shown to inhibit fibrosis and mitigate adverse tissue remodeling⁸.

In addition to measuring endogenous ECM, future studies will measure tissue stiffness using atomic force microscopy to determine whether increased ECM in the system affects the stiffness of the overall tissue. These measurements will help determine the level of fibrosis represented by this model, and further optimization will enable screening of compounds for new potential therapeutics.

FOCAL ADHESION KINASE REGULATES MECHANOSENSITIVE GENE TRANSCRIPTION AND TENDON MATURATION

INTRODUCTION

Throughout development and postnatal growth, resident tendon cells respond to mechanical cues from the nascent tendon extracellular matrix (ECM) to regulate tissue properties. Focal adhesion kinase (FAK, gene: *Ptk2*) is an intracellular protein kinase that regulates the actin cytoskeleton and cell-ECM adhesions. In *in vitro* tendon cell culture, FAK inhibition alters cell morphology and attenuates the cell's tenogenic gene expression response to growth factor stimulation and mechanical stretching.¹⁻⁴ In addition, FAK inhibitor treatment of explanted tendons attenuates ECM to nuclei strain transmission, indicating that FAK plays an active role in regulating cell-ECM attachment within the native tendon ECM.⁵ Finally, tendon-targeted FAK conditional knockout mice demonstrate altered development of tendon structure compared to wildtype (WT) mice at 30 days of age (P30), specifically exhibiting reduced cross-sectional area (CSA) yet mostly normal mechanical properties.⁴ Despite these known roles for FAK in tendon, the degree to which FAK regulates mechanotransduction within the native tendon ECM as well as the regulatory role of FAK-dependent mechanotransduction in maintaining tendon homeostasis throughout postnatal growth remain unknown. Therefore, the objectives of this study were to define the role of FAK in (1) regulating mechanotransductive gene expression in response to de-tensioned free-floating explant conditions and (2) regulating tendon homeostasis during postnatal growth. We hypothesized that (1) FAK inhibition will attenuate the tendon gene expression response to free-floating explant conditions and that (2) tendon-targeted FAK conditional knockout will negatively impact tendon maturation and maintenance of homeostasis during postnatal growth, specifically by eliciting a reduction in tendon CSA and mechanical properties.

METHODS

Free-Floating Tendon Explant: Flexor digitorum longus (FDL) tendons from male and female P30 WT mice were freshly dissected and randomized to receive FAK-inhibitor (FAK-I; 10 μ M PF-573228;

Tocris; Minneapolis, MN) or control (DMSO) media (DMEM supplemented with 5% FBS and 25 mM HEPES). Tendons were maintained in explant culture conditions at 37°C for 1.5, 4, or 12 hours to assess the initial mechano-response to acute de-tensioning (n=5/treatment group/timepoint). **Gene Expression:** Following explant treatment, RNA was immediately isolated from all tendons to quantify mechanotransductive gene expression using Taqman assays (*Acta2*, *Cyr61*, *Mmp3*, *Mmp13*, *Ptk2*; Housekeeper control: *Abl1*).

In Vivo Mouse Model: We utilized tendon-targeted FAK knockout (Scx-Cre;FAK^{F/F}; FAK-KO) mice,⁶ in which we validated reduced *Ptk2* expression.⁴ Achilles tendons (ATs), FDL tendons, and patellar tendons (PTs) from P60 FAK-KO and WT littermate controls were used for viscoelastic mechanical testing (males only) and histology (males and females). **Viscoelastic Mechanics:** Tendon CSAs were measured (n=11-13/genotype), and tendons were subjected to a viscoelastic mechanical testing protocol (preconditioning, viscoelastic stress relaxation and dynamic frequency sweep, and a quasi-static ramp to failure). **Histology:** Whole ankle and knee joints were fixed, decalcified, paraffin embedded, and sectioned in the sagittal plane (n=3-5/genotype). Additional knee joints were sectioned in the transverse plane to visualize the PT cross-section (n=4-7/genotype). Overall tissue morphology was visualized via toluidine blue staining.

RESULTS

Free-Floating Tendon Explant: In DMSO-treated tendons, we observed substantial increases in *Mmp3* (~90-fold) and *Mmp13* (~15-fold) gene expression with time under de-tensioned free-loading conditions, while expression of genes involved in cell contractility (*Acta2*, the Yap/Taz target gene *Cyr61*, and *Ptk2*) were not dramatically affected at these timepoints (Fig. 1A-C). Strikingly, FAK-I treatment resulted in differences in mechanotransductive gene expression at all timepoints evaluated. Specifically, compared to DMSO treated tendons, FAK-I treated tendons demonstrated reduced *Mmp3* expression at all timepoints and reduced *Mmp13* expression at the 12 hour-timepoint

(Fig. 1A-C). In addition, FAK-I treatment modulated the expression levels of *Acta2* and *Cyr61* throughout the experiment (Fig. 1A-C).

Figure 1: Mechanotransductive gene expression response to de-tensioning was significantly affected by FAK-I treatment. Gene expression levels (represented as ΔC_t) for **DMSO** and **FAK-I** treated tendons following A) 1.5, B) 4, and C) 12 hours of free-floating explant conditions. Data represented as mean \pm standard deviation with plotted individual datapoints. Connected datapoints indicate contralateral FDLs. Bars indicate significant differences (t-test: * $p<0.05$; ** $p<0.01$; *** $p<0.001$).

In Vivo Mouse Model: For tendon viscoelastic mechanical properties, we observed reduced CSA in all FAK-KO tendons, with the greatest effects in the ATs and PTs (Fig. 2A). Structurally, FAK-KO resulted in reduced stiffness in the ATs (Fig. 2B) and reduced maximum load in the FDLs (Fig. 2C) compared to WT tendons. Interestingly, material properties including modulus and maximum stress were increased in FAK-KO ATs and PTs (Fig. 2D-E). Finally, dynamic moduli were increased in the FAK-KO ATs and PTs at all frequencies evaluated (Fig. 2F).

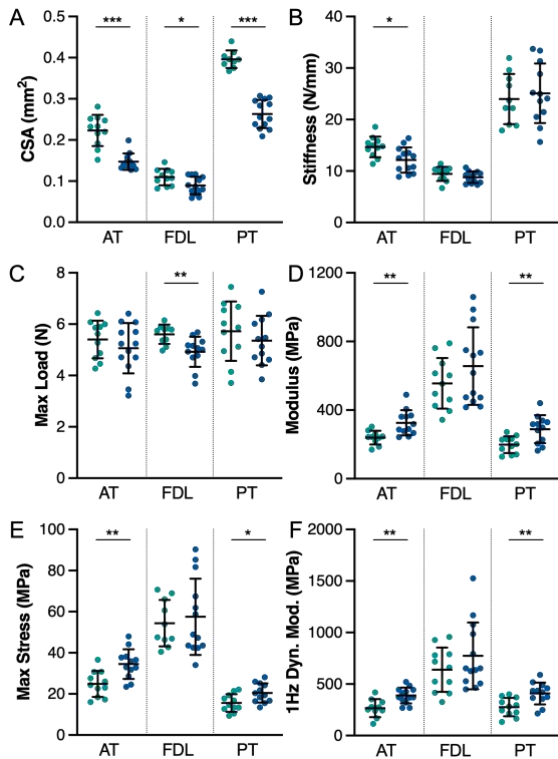

Figure 2. FAK-KO tendons demonstrated reduced size yet increased material properties at P60. A) CSA, B) stiffness, C) max load, D) modulus, E) max stress, and F) 1 Hz (shown as representative of all frequencies) dynamic modulus values for **WT** and **FAK-KO** tendons. Data represented as mean \pm standard deviation with plotted individual datapoints. Bars indicate significant differences (t-test: * $p<0.05$; ** $p<0.01$; *** $p<0.001$).

In sagittal sections, FAK-KO tendons were generally thinner than WT controls as expected (Fig. 3A; PT sections shown as an example). Transverse knee sections further illustrated the reduced CSA of FAK-KO PTs compared to WT PTs (Fig. 3B).

Figure 3. Paraffin histology confirmed the reduced size of FAK-KO tendons at P60. A) Sagittal and B) transverse sections of patellar tendons from **WT** and **FAK-KO** mice.

DISCUSSION

This study investigated the regulatory roles of FAK on cell mechanotransduction within the native tendon ECM and on maintaining tendon homeostasis during postnatal growth. Consistent with our first hypothesis, FAK inhibition affected mechanotransductive gene expression levels in response to de-tensioned, free-floating explant conditions. Previous experiments demonstrated that tendons respond to de-tensioning by increasing expression of matrix remodeling genes such as *Mmp3* and *Mmp13* and decreasing expression of mechanotransductive genes such as *Acta2* and *Cyr61*.⁷⁻¹⁰ In the present study, we observed similar severe increases in *Mmp3* and *Mmp13* with increased duration of explant treatment. Interestingly, FAK-I treatment suppressed this catabolic response to de-tensioning. In addition, we observed that FAK-I alters *Acta2* and *Cyr61* expression throughout our experimental timepoints. Taken together, these results indicate that FAK regulates the sensation of and response to changes in mechanical tension in the tendon *in situ* ECM.

Consistent with our second hypothesis, we observed substantially reduced CSA with FAK-KO in all tendons evaluated. Interestingly, despite their reduced size, FAK-KO tendons generally demonstrated increased material properties compared to WT tendons. Collectively, these results indicate that FAK regulates tendon size throughout postnatal development and that FAK-KO ultimately yields a tendon with increased material properties. Ongoing work will define the mechanism by which FAK regulates tendon size during development and postnatal growth. Specifically, we will investigate the regulatory role of FAK on tendon cell proliferation and ECM deposition. In addition, future work will investigate how mechanical loading regulates FAK-dependent mechanotransduction and tendon response *in vivo*.

INTRODUCTION

Menisci are semi-lunar wedge shaped discs that aid in load transfer in the knee.¹ Menisci are able to distribute these loads due to a complex collagen organization dominated by circumferentially aligned fibers.^{1,2} With age, menisci have increased injuries with reduced healing (Fig 1A),^{2,3} resulting in progressive osteoarthritis (OA) and total knee replacements.¹ Generally, injuries are thought to increase with age in musculoskeletal tissues due to cells remodeling collagen less as they become less active or senescent.¹ However, previous work has shown that adult tenocytes isolated from their aged ECM regain the ability to form aligned collagen fibrils *in vitro*,⁴ suggesting reduced healing with age may be due to changes in the ECM rather than aged cells. We and others have reported that meniscus ECM changes with age.¹⁻³ In particular, we have found significant increases in glycosaminoglycans (GAGs) and advanced glycation end product (AGEs) with age (Fig 1B), both of which can alter ECM mechanics, contributing to increased inflammation and injury.³ There is a need to better understand the aging process in order to regenerate collagen fibers after injury and reduce degeneration. Our long-term goal is to develop a model system to dissect the aging process so to better develop therapeutic interventions.

Previously, we developed a novel cell-seeded culture device that guides neonatal bovine cells in high density collagen gels to produce native-sized hierarchically organized collagen fibers over 6 weeks.⁵ Specifically, mechanical restrains (clamps) at the edge of constructs

restricts contraction and guides neonatal cells to produce aligned collagen fibrils by 2 weeks, which develop into native-sized fibers and fascicles by 4 and 6 weeks (Fig 1C).⁵ The objective of this work is to evaluate whether human cells isolated from aged OA menisci maintain an ability to form organized collagen fibers in our culture system, similar to neonatal cells. We hypothesize aged meniscal cells will produce fibers similar to neonatal cells by 6 weeks in culture.

METHODS

Meniscal cells were isolated from 5 deidentified human OA menisci ranging from 57 to 87 years old (IRB exempt, HM20019726). Each human donor was seeded individually into high density collagen gels as previously described,⁵ with cells being cast into 1.5 mm thick sheet gels and gelled at 37°C for 1 hour to obtain 20 mg/ml collagen gels at 5x10⁶ cells/ml.⁵ Rectangles (8x30mm) were cut from gels and cultured for up to 6 weeks either unclamped as a negative control or clamped in our culture device to guide cellular development of hierarchical collagen fibers (Fig 1C).⁵ The aged human constructs were compared to constructs seeded with cells isolated from bovine neonatal menisci (1-3 days old, 3 donors pooled). Timepoints were taken at 0, 2, 4, and 6 weeks to assess differences in organization, composition and mechanics with time in culture. Once removed from culture, constructs were photographed and weighed to assess differences in contraction. Collagen organization was assessed using confocal reflectance microscopy. DNA, GAG, and collagen were determined via PicoGreen, DMMB, and hydroxyproline (Hyp) assays.⁵ Tensile properties were determined by ramping to failure at 0.5% strain/sec.⁶ Significance was calculated using 2-way ANOVAs with Tukey post-hoc ($p < 0.05$).

RESULTS

Collectively, neonatal constructs seeded with cells from 1-3 day old bovine mirrored results previously obtained with more mature cells isolated from 2-6 week old bovine menisci.⁵ Specifically, unclamped neonatal constructs had significant contraction with time in culture and no change in collagen organization, while clamped neonatal constructs developed aligned collagen fibrils by 2 weeks, fibers by 4 weeks, and larger fascicle bundles by 6 weeks (Fig 2). Aged human constructs also contracted with time in culture, however less than neonatal cells (Fig 2A), suggesting aged cells are less contractile than neonatal cells. Specifically, unclamped neonatal constructs were ~6% their original weight by 6 weeks, while unclamped aged constructs were ~24% their

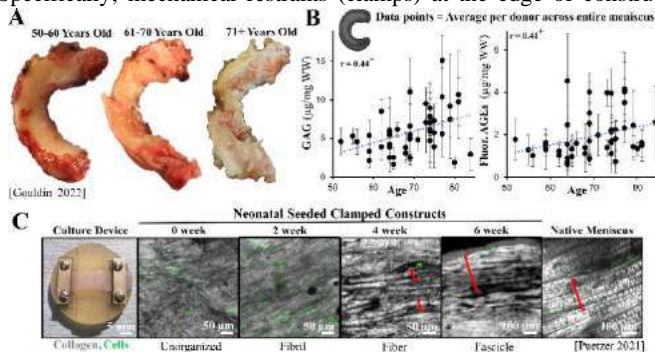

Fig 1: A) Human menisci showing increased degeneration with age.³ B) GAG & AGE accumulation normalized to wet weight in OA human menisci with age. +Significant correlation with age.³ C) Culture device that guides cells to form aligned hierarchical collagen fibers by 6 weeks.⁵ Brackets denote fibers & fascicles.

original weight by 6 weeks (not shown). Despite reduced contraction, confocal reflectance revealed clamped aged constructs were able to develop aligned collagen fibrils by 2 weeks, which matured into fibers by 4 and 6 weeks (Fig 2B). Clamped aged constructs produced similar fiber organization as neonatal constructs; however lacked larger collagen bundles observed in neonatal constructs at 6 weeks (Fig 2B).

Fig 2: A) Gross morphology & B) confocal of collagen organization in constructs seeded with neonatal bovine or aged human cells

Compositionally, clamped neonatal constructs had a significant increase in DNA and GAG with time in culture, and no change in collagen (hypro) content (Fig 3), while unclamped neonatal constructs largely maintained consistent composition throughout culture. Clamped and unclamped aged constructs had no significant differences in composition, but aged cells isolated from OA menisci were able to maintain DNA, GAG, and collagen content throughout culture, suggesting a possible shift in OA cells becoming less inflammatory (Fig 3). Interestingly, while aged constructs did not reach GAG levels of 6 week clamped neonatal constructs, several individual younger donors did accumulate higher concentrations closer to neonatal levels, demonstrating donor variability. Also, aged constructs matched clamped neonatal GAG levels at 4 weeks, suggesting more time in culture might be needed to further increase GAG accumulation (Fig 3).

Mirroring collagen organization, clamped neonatal constructs had significant increases in toe modulus (not shown), elastic tensile modulus, and ultimate tensile strength (UTS) with time in culture (Fig 4). Aged human constructs had no significant differences between unclamped and clamped constructs mechanically (Fig 4), however clamped aged constructs had an increasing trend in tensile modulus and UTS with time in culture, mirroring increased collagen organization. Further, while clamped aged constructs did not match the mechanical properties of clamped neonatal constructs, they did have similar tensile

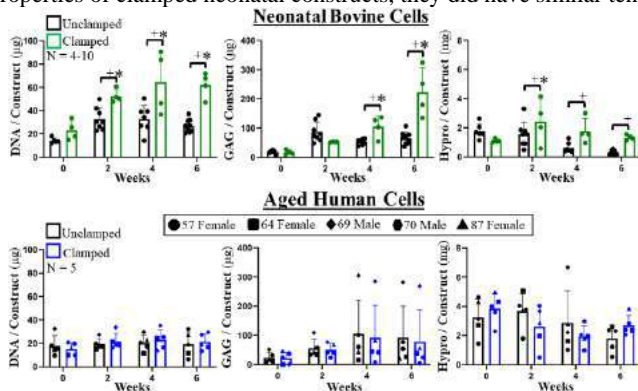

Fig 3: DNA, GAG, & collagen (represented by hypro) per construct for neonatal and aged constructs. Significance to *day 0 or + bracketed group.

moduli and UTS as previously reported clamped constructs seeded with cells isolated from immature bovine menisci (2-6 wks old, Fig 4 line).⁵

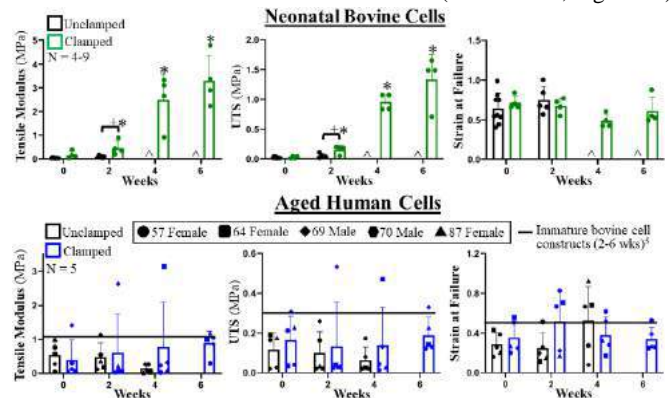

Fig 4: Tensile elastic modulus, UTS, and strain at failure for neonatal and aged constructs. Significance to *day 0 or + bracketed group. ^ denotes too small to test.

DISCUSSION

This data illustrates that human OA meniscal cells, isolated from their aged matrix, are capable of remodeling their surrounding matrix when presented with correct mechanical cues. Specifically, aged human cells cultured with boundary conditions in high density collagen gels were capable of producing aligned collagen fibrils by 2 weeks which matured into larger fibers by 6 weeks. Despite aged cells having reduced contraction compared to neonatal bovine cells, they appeared to produce aligned collagen fibrils and fibers in the same time-frame as neonatal cells (Fig 2B). However, aged constructs did lack larger collagen bundles at 6 weeks, possibly due to reduced cellular contraction.

While collectively composition and mechanics did not significantly change in clamped aged constructs, individual donors did match GAG concentrations and mechanics of neonatal constructs. Specifically, the younger human donors (age 57-69) tended to have greater contraction, increased fiber formation (data not shown), increased GAG production (Fig 3), and greater tissue mechanics (Fig 4) than the older human donors (age 79 & 87). This data suggests that within the older donors there is a shift in cellular contractility or activity with age, with the younger cells being able to organize the matrix a bit quicker. Older donors may need extended culture or the addition of chemical or mechanical stimulation to produce similar changes.⁴ However, despite these differences between the aged constructs, they did still produce mechanical properties similar to clamped constructs seeded with immature meniscal cells (2-6 wks old),⁵ suggesting differences between juvenile and aged cells may not be so extreme.

Overall, we have developed a model system to better understand how collagen regeneration is impacted with age and disease. These findings suggest that reduced healing with age may be less cell driven and more environmentally driven, which could point to future therapies targeting the matrix rather than cells to treat age-related degeneration. Ongoing work is evaluating gene expression with time in culture to elucidate whether aged cells become less inflammatory once removed from their aged matrix, as well as inducing AGEs into the system to evaluate their impact on cell function and fiber regeneration.

ROTATIONAL IMPACT-INDUCED BRAIN INJURY, A BIOMIMETIC STUDY

INTRODUCTION

Each year, millions of people worldwide suffer from traumatic brain injury (TBI) [1-3], a serious health issue that can result from falls, collisions, and other accidents [4, 5]. While the causes of TBI can vary, impacts on the head are a common mechanism of injury and can be divided into two categories: translational and rotational [6-8]. In this study, we focus on rotational impacts and use a novel experimental setup to investigate their effects on the brain.

The cerebrospinal fluid (CSF) around the brain may result in the difference between translational and rotational impacts. The CSF is a thin layer (1 to 5 mm) of water-like fluid that fills the gap between the arachnoid and pia mater, which is an important constituent of the head [9-11]. The CSF acts as a dampening buffer when the brain suffers translational impacts [12]. On the other hand, when the head experiences rotational impacts, the CSF acts as a slippery layer, which increases the relative motion between the brain and the skull.

While TBI has attracted wide attention, the brain response under rotational impacts is still unclear. Studies to investigate TBI can be categorized into two sections: experiment and numerical modeling. From the experiment side, animal tests were performed, including sheep [13], monkeys [14], rabbits [15], etc. These animal investigations all obtained satisfactory conclusions from the post-impact observations. Also, cadavers were mounted with sensors to investigate the movement of the head during the rotational impacts [16-18]. However, animal and cadaver tests can only obtain limited results due to the opaque skull. The motion of the brain can not be captured during the impact process. From the numerical modeling side, the finite element (FE) modeling has received more attention [19, 20]. However, validating the numerical model is difficult because the dataset from the experiments is limited. For example, the stress and strain data during the brain impact process are not available for numerical modeling comparison [21, 22]. Furthermore, the TBI process involves large brain deformation, highly

transient CSF flow, and intense fluid-solid interaction, which is still tricky for numerical simulation.

In this study, we develop a novel methodology to treat these challenges. An artificial transparent surrogate with biomimetic brain matter and CSF was built to reveal the response of brain matter under rotational impact. This included displacement between the skull and the brain, the stress, and the strain distributions.

METHODS

Figure 1 (A-C) shows that rotational impacts can be categorized into three directions: horizontal, sagittal, and coronal impacts. A novel experimental setup was developed to produce these three directional brain impacts. Figure 1 (D-F) shows that the experimental setup consists of an artificial head surrogate, a spring-controlled spinner, an impacting apparatus, and an accelerometer. The head surrogate was originally built based on previous work [23]. It consists of a transparent skull filled with distilled water and an artificial soft brain. On one side of the head surrogate, there is a spring-based spinner. This spinner provides a constant initial force to rotate the head surrogate. The whole setup can be adjusted to simulate the three directional impacts by changing the impacting apparatus. The accelerometer is mounted on the frame to measure the acceleration of the head surrogate.

Figure 1: The schematic of rotational impact from three directions: (A) horizontal, (B) sagittal, (C) coronal.

RESULTS

Figure 2 shows the brain response under a horizontal impact. Each subplot represents a time frame since the impact. The red line, which is the centerline of the brain, indicates the rotation and the deformation of the brain matter. As the spinner drove the head surrogate to rotate in an anti-clockwise direction, the first three subplots suggest that the brain kept moving after the skull was stopped. Then, the brain began to rotate back and slowly stopped. This relative motion between the brain matter and the skull is caused by the inertia of the brain and the slippery effect of the CSF. This motion was restricted by the geometry of both the brain and skull, which would cause scratches on the surface and further deformation of the brain. This response may lead to diffusive brain injury near the surface and blood vessel damage inside the brain.

Figure 2: Photography of the brain response after the head surrogate was horizontally stopped by the pillar.

Figure 3 shows the transient strain distribution under horizontal impact. The first row of the pictures shows the minimum principal strain (ϵ_{min}) map at different time frames. The dark blue color represents that this region has been severely compressed. From the time 0 ms to 200 ms, the ϵ_{min} at the coup region (the impact side, right bottom in the figures) and the left side show significant dark blue regions. This indicates that these two regions suffer stronger compression during the horizontal impact. The compression of the coup region is due to the brain inertia and the skull restriction. The compression of the left side is due to the bounce-back effect of the brain, where the brain bounces back from the right-bottom side and compresses to the left side. On the other hand, the second row of figure 3 shows the maximum principal strain (ϵ_{max}), indicating the material extension degree at different time frames. These figures state that the countercoup region (the far end from the impact point) has been stretched more seriously. The reason is that the negative pressure causes the extension at the far end, which impedes the brain from moving.

Figure 3: The first row shows the minimum principal strain distribution, and the second row shows the maximum principal strain distribution. The yellow icon on the left bottom represents the impact position.

DISCUSSION

In this study, we employed a novel experimental setup to elucidate the biomechanics of rotational impacts on the brain. Our findings reveal that under rotational impacts, the brain undergoes significant motion and deformation within the skull, which is modulated by the brain's material properties, the skull's geometry, and the slippery effect of cerebrospinal fluid (CSF). The CSF's slippery effect facilitates brain

rotation within the skull, leading to friction between the brain and the skull, which affects most areas of the brain surface, as observed in diffuse brain damage. The brain's motion also generates positive and negative pressure responses in the CSF, compressing and stretching the brain tissue and introducing positive and negative principal strains. Principal strains are a reliable indicator of tissue and vessel damage during a concussion. The skull's geometry also affects the brain's response to rotational impacts, with the least restriction in the horizontal direction and the highest restriction in the sagittal direction. Our experimental findings strongly suggest that rotational impacts can cause significant brain damage and could inform the development of advanced concussion diagnostic tools and protective devices.

INTRODUCTION

Glioblastoma (GBM) is an incurable and highly aggressive brain cancer with a median survival rate of only 15-months. [1] GBM progression is coupled with a molecular event known as proneural-to-mesenchymal transition (PMT) that consists of a phenotypic shift that heightens cell invasion and spread. Interestingly, this increase in cell invasion occurs despite the dense parenchyma, which contain tight pores that act as physical barriers to cell migration. Recent studies have suggested that highly invasive cells display enhanced cell deformability to bypass these barriers [3]; however, the underlying mechanisms permitting these cellular changes remain unclear. Here, we examine these mechanisms through a biophysical lens by investigating the relationship between mesenchymal transitions in GBM and mechanical changes that facilitate efficient confined migration.

We hypothesize that TGF- β 1 promotes increased confined migration by inducing PMT-dependent mechanical softening, which enables efficient navigation of the tight, natural barriers in the brain microenvironment. Further, we hypothesize that PMT specifically softens the nucleus as it represents a critical limiting factor for confined migration. In this study, we induced mesenchymal transitions via TGF- β 1 and assessed changes in structural protein expression and organization, cellular mechanical rigidity, functional confined migration, and the impact of nuclear mechanics on confined migration. Our data suggests an important role for nuclear mechanics in facilitating confined migration and spread of GBM. These data reveal the biophysical alterations that arise from mesenchymal transitions and provide insight into the mechanical features that underlie GBM aggressiveness.

METHODS

GBM cells were cultured in 1X DMEM (Corning: 10-017-CV) supplemented with 10% FBS, 1% NEAA, and 1% PenStrep at 5 % CO₂ and 37°C and treated with 10 ng/mL TGF- β 1 for 72 h to induce

mesenchymal transitions. Western blots were used to verify mesenchymal pathway activation (pSMAD2, pSTAT3, ZEB1), and evaluate nuclear and cytoskeletal protein expressions (pLamin, Lamin A/C, F-Actin/G-Actin). Confocal imaging was used to qualify organizational patterns of lamin A/C and actin before and after TGF- β 1 treatment. To assess nuclear and cytoskeletal mechanics, AFM was employed following induction of mesenchymal transitions. Confined migration was examined using PDMS microchannel platforms consisting of 1D channels at varied levels of confinement (5 μ m, 10 μ m, 20 μ m, and 50 μ m) and were imaged via time lapse microscopy on a Nikon Eclipse TE2000-U. To assess the role of nuclear mechanics in confined migration, cells were treated with 10 uM of CDK1 inhibitor (RO-3306) to increase nuclear stiffness and then plated on microchannel platforms.

RESULTS

TGF- β 1 was sufficient for inducing mesenchymal transitions in the GBM cell lines. First, TGF- β 1 activation was verified via Smad2 phosphorylation (Figure 1A). Next, we evaluated the mesenchymal marker Stat3 and the mesenchymal transcription factor ZEB1. As expected, TGF- β 1 led to significant increases in both Stat3 phosphorylation and ZEB1 expression (Figure 1B, C), indicating a mesenchymal phenotype. We wondered how structural proteins in the nucleus and the cytoskeleton might be affected by mesenchymal transitions, so we evaluated Lamin A/C expression and the ratio of F-actin to G-actin. Both Lamin A/C and F-actin/G-actin decreased with TGF- β 1 treatment at varied levels of significance (2A,B). Interestingly, we also observed significantly more irregularly shaped and porous nuclei in the TGF- β 1 treated cells (2C,D) as well as decreased F-actin across the cell (2B), indicating dysregulation among the different structural proteins.

Figure 1: TGF-β1 activates canonical signaling (A) and STAT3 signaling (B), leading to increased ZEB1, a mesenchymal transcription factor (C).

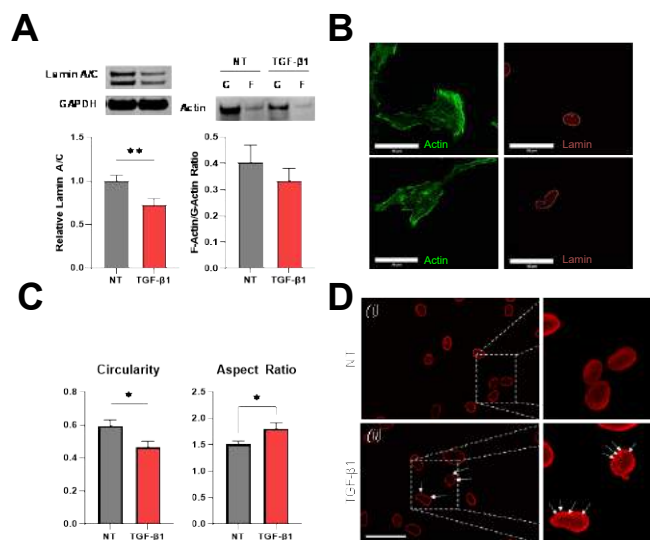

Figure 2: Both lamin A/C and F-actin/G-actin saw reductions in expression levels (A), but lamin A/C saw more pronounced dysregulation with TGF-β1 causing increased shape irregularity (B,C) as well as the formation of pores in the nuclear envelope (D).

Next, we employed AFM to determine how the protein level changes of the nucleus and cytoskeleton might affect cell rigidity. We discovered that TGF-β1 treatment led to reduced cell stiffness in both the nucleus and the cytoskeleton (3A,B). Interestingly, the nuclear stiffness was softest in both treatment groups (3A). Histograms show a narrower distribution of stiffness values were obtained following TGF-β1 treatment. Next, we evaluated the functional changes in the cells using 2D motility assays and microchannel platforms. Notably, 2D cell speed and persistence did not change significantly with TGF-β1 addition; however, microchannel platforms revealed that while NT cells struggled to migrate under tight confinement ($< 5\mu\text{m}$), TGF-β1 cells migrated more rapidly through the same channels. Ongoing work suggests that stiffening the nucleus of TGF-β1 treated cells may be sufficient to limit confined migration.

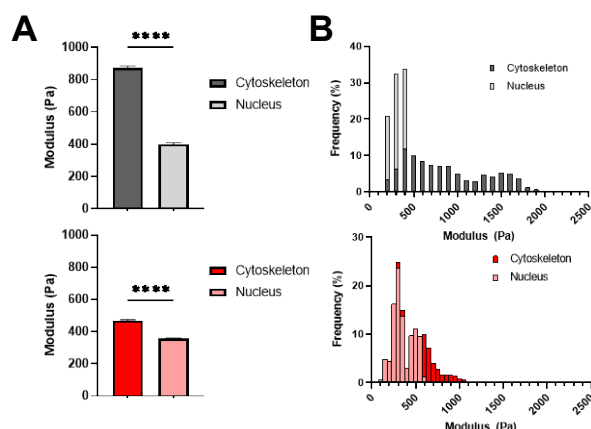

Figure 3: AFM analysis reveals that TGF-β1 treatment significantly reduces nuclear and cytoskeletal stiffnesses (A). Histograms illustrate a shift in moduli values with $> 90\%$ of the scan area exhibiting a stiffness of $< 1\text{ kPa}$ after being exposed to TGF-β1 (B).

Figure 4: Traditional 2D motility assays show minimal differences between the NT and TGF-β1 treated cells (A,B). When exposed to confinement via microchannel platforms, TGF-β1 treated cells exhibit a significant increase in speed as compared to the NT cells (C).

DISCUSSION

In this study, we demonstrate that TGF-β1 induced mesenchymal transitions are accompanied by reductions in Lamin A/C expression and F-actin G-actin ratios. Further, we show that these reductions change the organization and porosity of the nuclear lamins. Moreover, we demonstrate via AFM mapping that TGF-β1 treatment reduces cell rigidity in both the nucleus and cytoskeleton. With the increase in nuclear compliance, TGF-β1 cells navigated the constricted environment more quickly, suggesting that nuclear mechanics and organization may provide a basis for efficient confined migration.

This study uncovers a novel relationship between mesenchymal transitions and mechanical rigidity. Further, it adds to the growing appreciation for the impact of cell mechanics on cancer aggression and disease progression. Further investigations of this relationship may aid in the development of novel diagnostic tools and help identify new targets for pharmacological intervention.

ECTOPIC CHANGES IN TISSUE STIFFNESS DISRUPT EPITHELIAL BUCKLING AND FGF-10-INDUCED BUDDING MORPHOGENESIS IN CULTURED EMBRYONIC LUNGS

INTRODUCTION

Ramified networks form the basic architecture for many organs in the body, including the lung, kidney, and salivary gland. In the embryonic lung, these structures arise via a process known as branching morphogenesis, wherein the airway epithelium undergoes a series of branching events to build the bronchial tree [1]. Focal regions of FGF-10 expression within the pulmonary mesenchyme are thought to provide a biochemical template for the overall branching pattern, with individual sources of FGF-10 stimulating the formation of new epithelial branches. But it is still unclear how FGF-10 signaling drives the macroscopic changes in tissue form that sculpt incipient buds. In previous work, we have shown that a focal source of FGF-10 can promote epithelial buckling morphogenesis and stimulate the formation of multiple supernumerary buds [2]. Here, to investigate how FGF-10-induced buckling is impacted by changes in the mechanical properties of the tissue, we developed a new technique to locally and ectopically stiffen the pulmonary mesenchyme in explanted embryonic lungs. We then combined ex vivo explant culture experiments with microindentation testing, quantitative fluorescence microscopy, and computational modeling to determine how changes in tissue stiffness impact the formation of epithelial buds in response to a focal source of FGF-10 in the developing lung.

METHODS

Experimental methods: Fertilized White Leghorn chicken eggs were incubated at 37°C until embryonic day (E) 5, and lung explants were dissected in phosphate-buffered saline (PBS) using fine forceps and a stereomicroscope. In the presence of green (555 nm) light, treatment with Rose Bengal has been shown to photocrosslink the extracellular matrix (ECM) and to alter the measured mechanical properties of soft tissues, such as the cornea [3]. To photocrosslink cultured embryonic

lungs, agarose beads, soaked in either 100 µg/ml FGF-10 or 100 µg/ml Rose Bengal (RB) + 100 µg/ml FGF-10, were implanted into the pulmonary mesenchyme of explanted embryonic lungs. The explants were then cultured on Nucleopore membranes at the air-liquid interface in DMEM/F12 medium (without HEPES) supplemented with 5% fetal bovine serum (FBS) and antibiotics. To photoactivate RB, some explants were exposed to green (555 nm) light after 3 hr of culture to deliver an irradiance of 25 mW/cm² and a fluence of either 0.5 or 1 J/cm² (control explants were not exposed to any light). Bright-field images were captured at 0 and 24 hr to quantify changes in epithelial morphology. We also used the MicroSquisher mechanical testing system (CellScale), equipped with a custom 70 µm-diameter cylindrical microindenter, to measure the mechanical properties of the cultured explants. The Click-iT EdU Imaging Kit was used to quantify rates of cell proliferation and cleaved caspase-3 (CC3) staining was used to visualize apoptotic cells. Whole-mount explants were co-stained for E-cadherin immunofluorescence and imaged using a laser scanning confocal microscope.

Figure 1: Schematic of computational model for FGF-10-induced epithelial buckling.

Computational methods: We created a computational model of FGF-10-induced budding morphogenesis using COMSOL Multiphysics. As a first approximation, we modeled the airway epithelium as a growing hyperelastic layer supported by an underlying foundation, which represented the pulmonary mesenchyme (Fig. 1). Both tissue layers were prescribed a Blatz-Ko

strain-energy density function, and growth was included by decomposing the overall deformation gradient tensor (\mathbf{F}) into a component due to growth (\mathbf{G}) and a component due to elastic deformation (\mathbf{F}^*) via $\mathbf{F} = \mathbf{F}^* \cdot \mathbf{G}$. The growth rate within the epithelium was assumed to depend on the local concentration of FGF-10 ([FGF10]), which diffused outward from a focal source embedded in the pulmonary mesenchyme (Fig. 1). FGF-10 diffusion was assumed to follow Fick's second law, and, as a first approximation, [FGF10] was assumed to be at steady-state at each time-point. The growth rate within the epithelium \dot{G}_x was therefore defined by the growth law $\dot{G}_x/G_x = \alpha[\text{FGF10}]$, where α is a growth constant and [FGF10] represents the local concentration of FGF-10. The computed Cauchy stresses depended only on \mathbf{F}^* [4].

Figure 2: (A-B) Photocrosslinking with RB disrupts FGF-10-induced budding morphogenesis in cultured embryonic lungs.

RESULTS

We have shown previously that ectopic focal sources of FGF-10 can elicit the formation of multiple supernumerary buds within cultured embryonic lungs via a growth-induced buckling mechanism [2]. To determine how changes in the mechanical properties affect FGF-10-induced buckling morphogenesis, we developed a new technique to alter the stiffness of the pulmonary mesenchyme in cultured embryonic lung explants. Agarose beads containing either FGF-10 alone or FGF-10 + RB, a potent photocrosslinker of the ECM [3], were embedded within the pulmonary mesenchyme of explanted embryonic lungs and exposed to green light to initiate photocrosslinking. Treatment with activated RB was sufficient to suppress the formation of FGF-10-

Figure 3: (A-B) Microindentation tests indicate an increase in stiffness within RB-treated embryonic lungs.

induced epithelial buds, as compared to either contralateral controls or explants exposed to no light (Fig. 2). Microindentation experiments revealed that photocrosslinking with RB significantly increased the stiffness of the pulmonary mesenchyme (Fig. 3), without influencing levels of either proliferation or apoptosis within the tissue (data not shown).

We then created a computational model of the airway epithelium to investigate the mechanics of

FGF-10-induced buckling morphogenesis (Fig. 1). Growth within the epithelium was assumed to depend on the local concentration of FGF-10, which diffused from an individual focal source embedded within the pulmonary mesenchyme, in a manner consistent with previous experiments [2]. In our simulations, FGF-10-induced growth caused the epithelium to buckle and form multiple buds, similar to those observed in control explants (Fig. 4). Interestingly, if the stiffness of the pulmonary mesenchyme was increased in the model, FGF-10-induced buckling was substantially suppressed (Fig. 4), similar to that observed in our photocrosslinking experiments (Fig. 2). Taken together, these results suggest that ectopic sources of FGF-10 can promote the buckling morphogenesis within the embryonic airway epithelium and that FGF-10-induced bud formation depends crucially upon the mechanical properties of the tissue.

Figure 4: Computational model of buckling morphogenesis predicts that increased mesenchymal stiffness will suppress the formation of FGF-10 induced epithelial buds.

DISCUSSION

Although biophysical cues have long been known to influence tissue morphogenesis [5], there is a dearth of experimental techniques to alter the mechanical properties within intact embryonic organs [6]. Here, we used RB to photocrosslink the pulmonary mesenchyme in cultured embryonic lungs and investigated how changes in tissue stiffness influence FGF-10-induced budding morphogenesis. This assay can be readily adapted to the study of other morphogenetic processes, such as heart tube formation [7] and gut looping [8], as well as a variety of different model organisms, including frog, mouse, and zebrafish embryos. Within the context of embryonic lung development, our data indicate that the overall branching pattern, though certainly regulated by FGF-10 signaling, is also substantially influenced by the mechanical properties of the tissue. Future work will be necessary to disentangle more completely how various biochemical and biophysical cues are integrated together to properly sculpt the bronchial tree in the developing lung.

A COMPUTATIONAL MODEL OF COARCTATION OF THE AORTA IN RABBITS

Ashley A. Hiebing (1), Matthew A. Culver (1), John F. LaDisa, Jr. (2), Colleen M. Witzenburg (1)

(1) Department of Biomedical Engineering, University of Wisconsin, Madison, WI, USA

INTRODUCTION

Coarctation of the aorta (CoA) is a common congenital cardiovascular lesion that typically presents as a localized narrowing of the descending aorta just distal to the left carotid and subclavian arteries. While improvements in surgical and catheter-based techniques have increased short-term survival, long-term complications such as re-coarctation, aortic aneurysm, and hypertension frequently occur after CoA correction, leading to a reduced average lifespan [1].

Though ventricular and vascular remodeling has been implicated in many of these morbidities [2,3], it is not possible to measure these alterations *in vivo*. Computational models can be used to investigate potential mechanisms driving ventricular and arterial remodeling and to generate predictive estimations of remodeling [4].

The purpose of this study was to simulate CoA by modifying an existing computational model of the heart and circulation. To match non-invasive hemodynamic measurements from an experimental study on rabbits with CoA [2] it was necessary to simulate both ventricular and vascular remodeling.

METHODS

A previously published lumped parameter computational model [4] capable of predicting left ventricular growth in adult canines under hemodynamic overload was modified for rabbits with CoA. Briefly, the ventricles were simulated using time-varying elastances, aortic and pulmonary artery behavior was simulated by three-element Windkessels, distal vessels were represented by capacitors in line with resistors, and valves were represented by pressure-sensitive diodes. To model CoA, the systemic arterial pool was divided into ascending aorta, descending aorta, and upper body arteries compartments (Figure 1). To simulate the inertial effect of blood flow through the aortic valve, an inductor was also added.

These additional components, along with stressed blood volume, systemic characteristic resistance, and end-systolic elastance were fitted

to match sham data (see Table 1). Ventricular parameters governing the end-systolic and end-diastolic pressure-volume relationships were fitted to measured sham hemodynamics. Heart rate was input directly from measured data. All other parameters were allometrically scaled from the original values for canines [4].

Aortic coarctation was simulated in three steps, wherein model parameters were fitted to experimental data [2]. First, CoA is characterized by a stenosis in the descending aorta, therefore its associated resistance (R_{da}) was increased and its compliance (C_{da}) decreased. Second, following prolonged CoA, ventricular hypertrophy has been observed, therefore ventricular elastance and passive stiffness were increased to reflect increased left ventricular wall thickness. Third, following prolonged CoA, remodeling of the proximal aorta involving increased thickness, elastin fragmentation, and reduced smooth muscle function has been observed [4], therefore the characteristic aortic resistance (R_{cs}) and the ascending aortic resistance (R_{aa}) were increased along with a decrease in ascending aortic capacitance (C_{aa}).

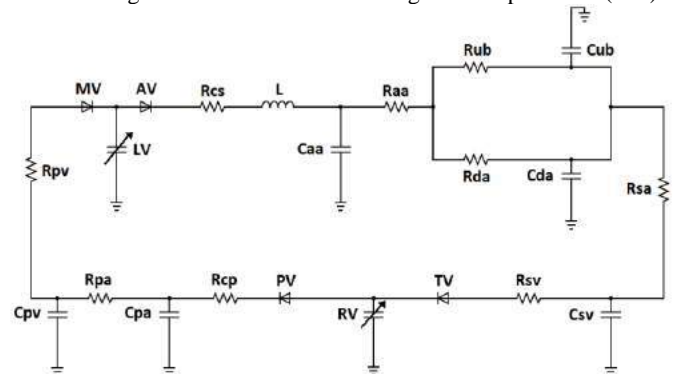

Figure 1: Schematic of the circuit model used to simulate the pressure-volume behavior of the cardiovascular system

RESULTS

To match the observed peak and mean blood pressure gradients in the CoA rabbits manyfold increases in the descending aortic parameters were required: Rda was increased 4.5x and Cda was decreased 19x. Subsequently, consistent with the significant increase in left ventricular mass observed in the CoA rabbits, to match left ventricular stroke volume (SV) and ejection fraction (EF), ventricular elastance and passive stiffness were increased 1.8x. Finally, to match reported ascending aortic pressures and flow, Raa was increased 8x, Rcs was increased 3.3x, and Caa was decreased 2.1x.

Model results agreed well with experimental data, as shown in Figures 2-3 and Table 1. Outputs for mean and peak blood pressure gradients (BPG) between the ascending and descending aorta, left ventricular SV and EF, as well as maximum flow, systemic blood pressure (SBP) and diastolic blood pressure (DBP) in the ascending aorta, and the flow split between the upper and lower body (not shown) all fell within half a standard deviation of measured data.

Figure 2: Pressure predicted in the ascending aorta throughout the cardiac cycle for sham (left) and coarctation (right) compared to measured data in rabbits [2]

Figure 3: Flow predicted in the ascending aorta throughout the cardiac cycle for sham (left) and coarctation (right) compared to measured data in rabbits [2]

Table 1: Experimental data and model outputs. Z-scores indicate the number of standard deviations model outputs are from experimental means

Index	Sham	Model	Z-score	Coarc	Model	Z-score
BPG, mean (mmHg)	3.27 ± 4.32	3.66	0.09	20.1 ± 4.75	21	0.2
BPG, peak (mmHg)	10.8 ± 7.34	10.1	0.09	31.0 ± 8.64	32.1	0.12

EF %	60.6 ± 4.82	60.7	0.02	66.4 ± 6.24	66.5	0
Maximum AA flow (mL/min)	1435 ± 110	1435	0	1445 ± 143	1446	0.01
AA SBP (mmHg)	67 ± 7.67	67	0	99 ± 17.99	95	0.22
AA DBP (mmHg)	56 ± 9.79	55	0.1	74 ± 25.93	64	0.39

DISCUSSION

Our model successfully matched reported hemodynamics in sham and CoA rabbits. To capture the ventricular behavior accurately it was necessary to simulate not just the coarctation (change in descending aortic parameters) but also ventricular hypertrophy, by increasing the ventricular parameters associated with increased thickness. Similarly, simulating coarctation and ventricular hypertrophy was insufficient to match the ascending aortic pressure and flow shown in Figures 2 and 3. A decrease in the compliance and an increase in the resistances proximal to the descending aorta was required, suggesting the rabbits with CoA underwent vascular remodeling.

Previous studies of CoA have shown an increase in the stiffness of the proximal aorta before and after corrective surgery [5,6]. Thus, the degree of vascular and ventricular remodeling—and its potential for reversal post-correction—is likely linked to the duration and severity of CoA. Future simulations will model rabbits with CoA of varying severity and corrections at various timepoints. From this, we can investigate the trade-off in severity and duration of CoA to evaluate their individual roles on the timecourse and reversibility of ventricular and vascular remodeling.

QUANTIFYING TEMPORAL DYNAMICS OF ALVEOLAR RECRUITMENT DURING MECHANICAL VENTILATION

Daniel S. Meggo (1), Edward A. Sander (1), Jacob Herrmann (1)

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, Iowa, USA

INTRODUCTION

Ventilator-induced lung injury (VILI) poses a serious risk for patients suffering from acute respiratory distress syndrome (ARDS). Protective lung ventilation strategies aim to mitigate VILI, including atelectrauma associated with repetitive alveolar recruitment and derecruitment. However, heterogeneity of alveolar dynamics in ARDS obstructs reliable bedside assessment of VILI risk and treatment efficacy. Limitations of current lung-protective strategies call for a reevaluation of our understanding of alveolar recruitment dynamics during mechanical ventilation.

In a 2011 study, Arnal et al. [1] discovered that most alveolar recruitment occurred within the first 10 seconds of a sustained inflation recruitment maneuver in ARDS patients, and that hemodynamic impairment increased significantly after 10 seconds. In another study, researchers investigating the role of time and pressure on alveolar recruitment found that 80% of alveolar recruitment was achieved in as little as 2 seconds after the application of positive pressure [2]. Although

these studies provide insights into the time dependency of alveolar recruitment, they quantified recruitment from a macroscopic perspective rather than at the level of individual alveoli. Additionally, the quasi-static conditions used in these studies may not accurately recapitulate what occurs when alveoli experience the dynamic and cyclic conditions associated with physiological or mechanical breathing. To overcome both of these challenges, we are investigating the use of a dynamic microscopic imaging modality to quantify the temporal dynamics of individual alveolar recruitment during pressure-controlled mechanical ventilation. Such data will be vital for prescribing novel ventilation strategies that can account for the heterogeneity of alveolar dynamics so that VILI can be reduced.

METHODS

Subsegmental samples of porcine lung tissue were carefully dissected to preserve airtight structure. A micro-ventilator, consisting of a microcontroller-timed solenoid valve and two adjustable pressure

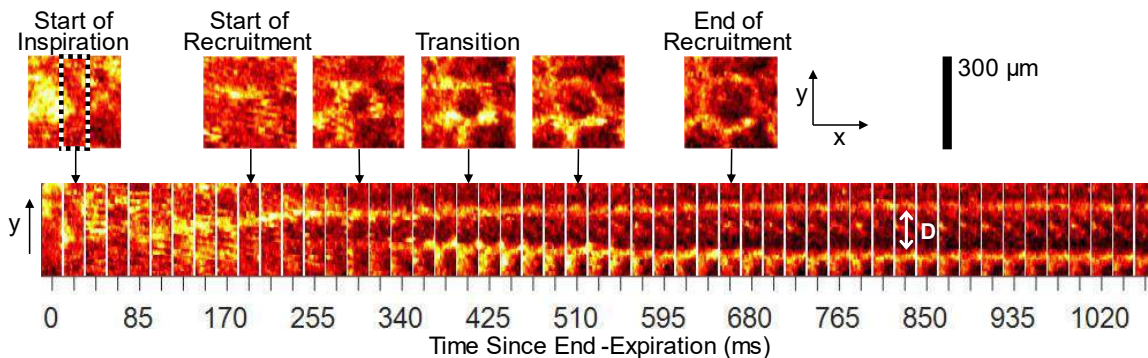

Figure 1: Top: A region of interest in the x-y plane showing a cross-section of a cyclically recruiting alveolus at selected time points during inspiration. Bottom: A time series showing a cropped region, highlighting changes in alveolar diameter (D) at each consecutive time point.

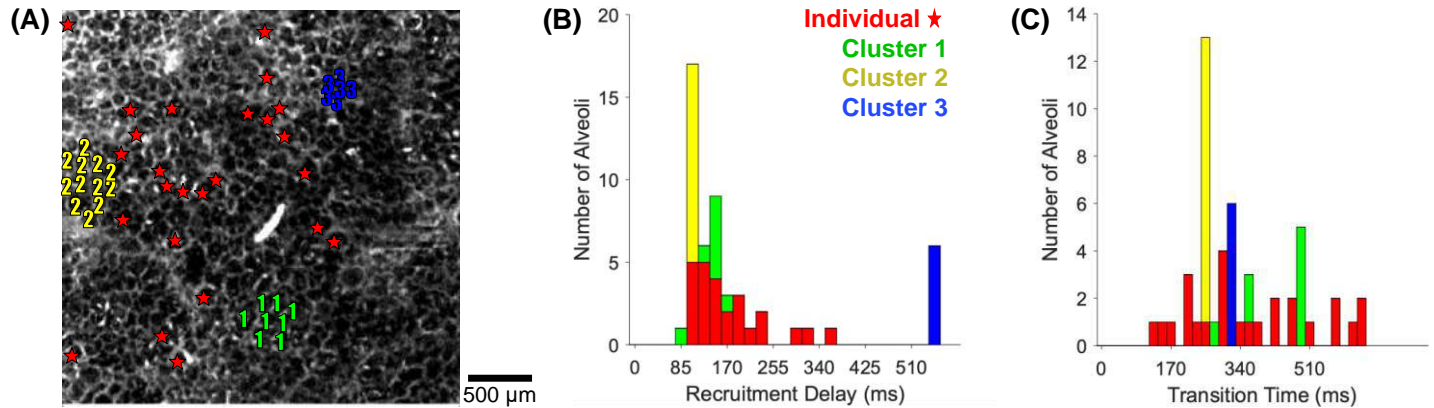

Figure 2: (A) Image at end-inspiration with 51 recruiting alveoli labeled as individuals (red ★), or in clusters 1 (green), 2 (yellow), and 3 (blue). (B) Delay times between end-expiration and start of recruitment. (C) Transition times between start of recruitment and end of recruitment.

relief valves, was connected to the airway opening of the samples to simulate pressure-controlled mechanical ventilation with an inspiratory pressure of 25 cmH₂O and expiratory pressures between 0 to 15 cmH₂O. The respiratory rate was 14 min⁻¹ with 1:1.3 inspiratory:expiratory ratio.

During uninterrupted mechanical ventilation, a series of images was acquired continuously with a Nikon A1+ laser scanning confocal microscope using 561 nm excitation and 595/50 nm emission over a 3.18-mm field of view. Assuming periodic motion of the sample during ventilation, retrospectively gated image reconstruction was performed according to the respiratory rate [3]. The respiratory cycle was partitioned into N phase bins, and each acquired pixel was associated with one of the N phases based on acquisition timing. Pixels belonging to the same phase of ventilation were assembled into a frame. After reconstruction, a sequence of N phase-binned frames was generated with each frame capturing the alveolar structure at one phase of the periodic ventilation cycle.

Alveoli exhibiting cyclic recruitment were identified in the subset of frames corresponding to inspiration (Figure 1). The spatial trajectory of each recruiting alveolus was annotated across frames. For each alveolus, frames associated with the start of recruitment (SOR) and the end of recruitment (EOR) were used to calculate the time delay from end-expiration to SOR and the transition time from SOR to EOR.

RESULTS

Alveolar recruitment was only apparent during ventilation with zero end-expiratory pressure. The 4.27-s ventilation cycle was reconstructed with 201 phase-binned frames, yielding a temporal resolution of 21 ms. Cyclic recruitment was observed in 51 alveoli, including 3 clusters defined as multiple adjacent recruiting alveoli (Figure 2A). Clusters 1, 2, and 3 comprised 8, 12, and 6 alveoli, respectively. After end-expiration, the delay before SOR was 197 ± 143 ms (mean \pm SD) (Figure 2B). After SOR, transition times to EOR were 345 ± 129 ms (Figure 2C). Relative to end-expiration, the shortest total time for an alveolus to reach EOR was 319 ms, while the longest observed time was 871 ms. Total inspiratory time was 1874 ms. A correlation between the delay to SOR and transition time to EOR was nearly nonexistent ($R^2 = 0.0001$). For clusters 2 and 3, alveoli within each cluster exhibited identical SOR and EOR timing. By contrast, heterogeneity of recruitment timing was observed in cluster 1.

DISCUSSION

In this study, the temporal dynamics of intratidal recruitment of individual alveolar structures during *ex vivo* mechanical ventilation were investigated. The absence of cyclic recruitment and derecruitment

events observed with positive end-expiratory pressure (PEEP) supports the efficacy of PEEP in clinical settings. Without PEEP, all cyclically recruiting alveoli were fully inflated within 900 ms of inspiration. This differs from the studies of Albert et al. [2] and Arnal et al. [1] who found that the majority of alveoli become recruited up to 2 s and 10 s after applying positive pressure, respectively. These differences could be attributed to the *ex vivo* preparation; however, it is also likely that intratidal alveolar recruitment behavior is different during the dynamic conditions of ventilation as opposed to the quasi-static conditions used in other studies. Individual alveolar transition times in Figure 2C are consistent with 250-ms recruitment events observed in just two alveoli during quasi-static inflation of healthy mouse lungs [4], but generally, injured lungs exhibit a wide distribution of critical opening pressures and transition times extending over seconds to minutes [5].

Observations of cyclic recruitment in alveoli indicate that cyclic derecruitment must also occur in those same alveoli. However, derecruitment events were not reliably detected. One possible explanation is that the 21-ms temporal resolution was insufficient, which would imply that derecruitment occurs much more rapidly than recruitment, and with almost no delay following end-inspiration. This explanation contradicts data reported in experimental lung injury [5]. Alternatively, the inability to identify cyclic derecruitment could imply that derecruitment occurs aperiodically, such that it cannot be reliably reconstructed using assumptions of motion periodicity, despite consistent periodic recruitment in the same alveoli. If true, the latter explanation supports the notion that reducing the time allowed for exhalation may benefit alveoli that can collapse with irregular or unpredictable timing. These results may support the development of lung-protective strategies that target dynamic recruitment based on inspiratory and expiratory timing.

INTRODUCTION

Duchenne muscular dystrophy (DMD) is the most common inherited muscle disease, affecting ~1 in 10,000 male children [1-3]. Loss of functional dystrophin protein results in progressive skeletal muscle weakness loss of ambulation, and eventually DMD-associated cardiomyopathy (DMDAC) [3,4]. With the advent of effective respiratory support, left ventricular (LV) dysfunction is the most common cause of morbidity and mortality in DMD [2,3].

Although cardiomyopathy is inexorably progressive, markers of myocardial dysfunction are necessary for starting therapies and monitoring therapeutic efficacy. LV stroke work (SW) is an established parameter proven as a marker of myocardial health in other diseases. It may be helpful in the risk stratification of DMD patients with DMD. As the line integral of intracardiac pressure and volume, simultaneous pressure, and volume measurements are required. Intracardiac pressure measurement is invasive and requires cardiac catheterization [5]. Noninvasive techniques have been established to measure stroke work indirectly. They can detect subclinical signs of LV dysfunction. Cardiac magnetic resonance (CMR) is a routine modality for cardiac evaluation in DMD [3,5]. Ejection fraction (EF) is the most commonly measured parameter. However, a decline in EF is a late finding in the temporal dynamics of heart failure [7]. Consequently, earlier measures of cardiac function are needed. Seeman et al. [7] developed a noninvasive method to compute left ventricular PV loops using CMR data, ventricular elastance curves, and non-invasive blood pressure. They showed agreement with *in vivo* PV loop measurements.

This study aims to measure non-invasive LV stroke work in DMD patients and investigate the correlation of LV SW.

METHODS

We performed a retrospective case-control study of Duchenne muscular dystrophy (DMD) patients who underwent serial CMR from 2014 to 2022. Patients were divided into two groups: those who

maintained an LV ejection fraction $\geq 55\%$ on serial CMR studies were grouped into controls (-DMDAC) and those who had a decrease of LVEF $< 55\%$. We compared the LV SW with EF for all subjects. Also, the SW of the +DMDAC group was compared with the control groups.

Study Population. Human data from 7 controls (-DMDAC) and seven patients with +DMDAC were included. Brachial systolic and diastolic blood pressures from cuff sphygmomanometer and CMR short axis steady-state free-precession images covering the LV were acquired and analyzed (Figure 1). Our Institutional Review Board approved the study, and informed consent was not required.

Figure 1. Schematic of pressure-volume loop acquisition. A) Biventricular segmentations are performed in Segment. Brachial pressure is used as input; B) Using Elastance model, pressure and volume curves are obtained in segment; and C) Pressure-volume loops are generated.

CMR protocol. CMR studies were performed on a 1.5 Tesla magnetic resonance scanner (Ingenia; Philips Healthcare; Best, The Netherlands). Study parameters: temporal resolution of 30 to 40 ms, slice thickness 8 mm, and pixels 1.5x1.5 mm. The cine images were obtained during end-expiratory breath-holds. Images were acquired in the vertical and horizontal ventricular long-axis planes and a stack of slices in a ventricular short-axis plane from the atrioventricular junction

through the cardiac apex. The imaging plane was aligned perpendicular to the aorta.

Data Analysis. Images were analyzed using Segment v3.2 R9074. LV was automatically delineated over the entire cardiac circle (usually 30-time frames), and manual corrections were performed when necessary. Our study used LV stroke work to predict cardiac dysfunction. Student t-tests were used to compare two groups of parametric variables. Paired t-tests were used to compare the LV stroke work measures with $p < 0.05$ considered statistically significant. Variation between distributed variables was estimated using the Pearson correlation coefficient.

RESULTS

Figure 2 shows the relationship of LV SW with LV EF for all subjects. A moderate negative correlation existed between LV SW and LV EF for all subjects ($r = -0.46$, $p < 0.0001$).

Figure 3 shows the correlation between the change in LV SW variation and with change in EF. Interestingly, a reasonable positive correlation was observed between LV SW and LV EF for all subjects ($r = 0.53$, $p = 0.34$).

Figure 4 shows the LV SW for the +DMDAC and control groups. The left ventricular SW of the +DMDAC group (0.77 ± 0.23 J) was higher by 50.98% ($p = 0.00093$) than that of the control group (0.51 ± 0.14 J).

DISCUSSION

This study found that SW mildly correlated with EF, which suggests that SW contains other information that the EF in the subjects may not capture. This may provide additional information on global cardiac function compared to EF in the DMDAC population. However, a better correlation was observed between the change in SW and the change in EF. A positive correlation shows that the change in SW agrees well with the change in EF. Although some patients did not follow the same trend, future extensive studies are required to validate the observation.

This study also shows that the SW of +DMDAC patients (0.77 ± 0.23 J) was higher (50.98%, $p = 0.00093$) than that of the controls (0.51 ± 0.14 J). In addition, the +DMDAC group had significantly lower EF (39.90 \pm 8.15%, $p < 0.0001$) than the control group (60.25 \pm 3.73%).

Figure 2. a Correlation of LV SW with left ventricular ejection fraction. LV SW had a moderate negative correlation with LV EF in the DMD group.

Figure 3. a Correlation of change in ejection fraction with change in left ventricular stroke work. Change in EF showed a moderately positive correlation with change in LV SW in the DMD group.

Figure 4. Comparison of left ventricular stroke work (LV SW) between the +DMDAC and control groups. The +DMDAC group had a higher LV than the control (-DMDAC) group.

INTRODUCTION

Human brain development begins with dynamic morphological changes, such as cortical folding, starting *in utero* and extending through childhood [1]. Additional changes continue to occur through to adulthood in a period of maturation. The role of internal forces and stresses in driving early brain development is commonly studied; however, the role that forces play in driving structural remodeling during maturation is unknown [1]. Measurement of internal forces *in vivo* is limited due to the invasive nature of these techniques. A non-invasive alternative is magnetic resonance elastography (MRE), which allows for *in vivo* quantification of tissue mechanical properties and has previously been shown to be sensitive to microstructural changes in brain tissue [2], but application of MRE to brain maturation has been limited. Current work has shown large scale changes in mechanical properties in regional brain structures, as well as marked differences in mechanical properties of interior and exterior brain structures [3]. We hypothesize that spatial variation of these tissue properties could create imbalances in internal force distribution creating stress concentrations, which in turn may influence maturational remodeling, such as localized synaptic pruning and myelination, through mechanotransduction processes. This study aims to quantify shear stiffness gradients in the brain and how this measure varies during maturation through extended aging. This expands on previous work that developed this measure only in the frontal lobe during a limited time period.

METHODS

MRE data from a total of 358 participants with ages ranging from 5-82 years (145M/213F, Age: 32.7 +/- 22.4 years) were included in this study. MRE scans were pooled from multiple sites to create this database, all scans were performed on a Siemens 3T Scanner including Prisma, Trio, and Verio models. The MRE portion of the protocol used a custom high-resolution 3D multiband, multishot spiral sequence [4,5]. Vibrations were applied at 50 Hz to the back of the head to induce shear

displacements. A T₁-weighted MPRAGE (resolution: 0.9 x 0.9 x 0.9 mm³) was also completed for anatomical segmentation. Displacement data was converted to shear stiffness using a nonlinear inversion algorithm (NLI) [6]. Complex shear modulus (G) is calculated using the storage (G') and loss (G'') moduli. From complex shear modulus, shear stiffness (μ) can be calculated using Equation 1.

$$\mu = 2 |G|^2 / (G' + |G|) \quad (1)$$

For each subject, shear stiffness maps were converted into standard space for comparison across the age range and between multiple studies, shown in Figure 1. The boundaries of each lobe were defined using the WFU-Pick Atlas and the average lobe stiffness was calculated. To determine gradients in stiffness from the interior to the exterior of the lobe, sequential 3D volume erosions were completed. The average stiffness of voxels removed with each erosion was calculated, with the gradient quantifying the change in this measure over the distance. Since average brain stiffness also changes with age, and thus could influence the magnitude of the stiffness gradient, we normalized the gradient measure by dividing by the average lobe stiffness.

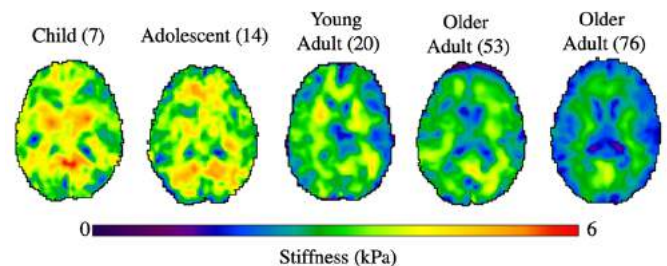

Figure 1: Representative stiffness maps of a single slice for participants across the age range with specific ages given in parentheses. The gradient can be seen as stiffer interior tissue, shown in red, transitions to softer exterior tissue, shown in blue.

Change in the normalized gradient measures during maturation was examined using partial correlations controlling for sex in MATLAB, with separate analyses for each of the four lobes. To test the hypothesis that changes in gradient occur during maturation, but plateau in adulthood, we fit a piecewise function with two slopes using a nonlinear least squares model and calculated the inflection point, using Equation 2, where IP is the inflection point where the slope with age, A , switches from being defined by m_1 to $m_1 + m_2$.

$$F(A) = b + m_1 A + m_2 (A - IP) \quad (2)$$

RESULTS

Normalized gradients changed significantly across all lobes from childhood to young adulthood (< 32 years) as shown in Figure 2. The gradient measure was negative for all participants across the cerebrum indicating greater tissue stiffness in the interior of the brain compared to the exterior.

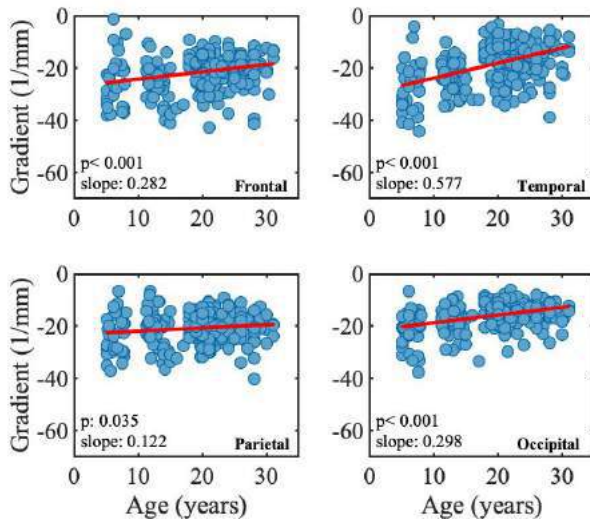

Figure 2: Average normalized gradient change, shown in red, for each cerebral lobe calculated cross sectionally from childhood to young adulthood.

Partial correlations seen in Figure 2 show consistent increase in average stiffness gradient with age, indicating less of a difference between interior and exterior mechanical properties. The greatest changes were observed in the temporal lobe, while the smallest were in the parietal lobe.

Table 1 shows the change in normalized gradient with age both before and after the inflection point. When two slopes are used to model normalized gradient change with age, the increase in gradient is seen again from childhood to the beginning of young adulthood. The inflection points shown in Figure 3 range from 18 to 22 years and mark

the start of only slight decreases in the gradient measure during adulthood, indicating that spatial gradients in mechanical stiffness, appear to reach an equilibrium in young adulthood.

Figure 3: Average normalized gradient for each cerebral lobe fit to a piecewise function with two slopes, shown in red, that change at the marked inflection point shown in green.

DISCUSSION

This study examined the spatial variation of shear stiffness across the brain during development by calculating gradients in stiffness in each lobe of the brain. Significant age-related increases in gradient (i.e. decreasing magnitude becoming less negative) are found from childhood to young adulthood. The change in gradient shows that interior and exterior stiffness of the brain become more similar with age during maturation. Significant changes in this measure were found despite normalization by average lobe stiffness for each individual, thus the gradient measure is not biased by overall average stiffness changes but by spatial distribution of mechanical properties.

To confirm if the gradient measure captures age-related changes due to maturation, we continued to track this measure cross-sectionally through adulthood. In each of the four lobes, the increase in the gradient measure stopped between 18 and 22 years old – the beginning of young adulthood. The gradient measure then plateaus through adulthood, indicating a stabilization in the spatial distribution of properties (despite continued average softening into old age), potentially indicating a mechanical equilibrium achieved. This may mean that reduction of internal stresses reaches a desired threshold and is sustained throughout adulthood even as the tissue begins to atrophy. Future work will include longitudinally assessing these gradients to understand if individual maturation confirms age-related changes and if the magnitude of the gradient present impacts structural development across the brain.

INTRODUCTION

Tendon injuries are a leading cause of morbidity with ~50% of musculoskeletal injuries involving tendons.¹ Tendinopathy is characterized by changes in tendon matrix composition and structure as well as changes to tenocyte protein and gene expression.^{2,3} The mechanisms of tendinopathy formation at the single cell-matrix level remain unclear.² *In vitro* models are promising for studying tendon pathology as they provide a controlled environment for single cell investigation.⁴ Direct-write, near field electrospinning (DWNFE) can be used to fabricate scaffolds with precise placement of physiologically relevant fibers.⁵ These scaffolds provide an effective framework for constructing *in vitro* models with control over the structure, composition, orientation, stiffness, and mechanical stimulation; which are all needed to understand how cells respond to specific changes to their environment.⁴ Prior work with DWNFE has produced gelatin fibers that mimic native tendon collagen fiber diameters.⁵ Beyond mimicking orientation, structure, and size, gelatin fiber stiffness can be controlled through crosslinking. This is important as the stiffness of a substrate has been shown to alter cell gene expression.⁶ The objective of this research was to analyze how varying stiffness of direct-written gelatin fibers can influence tenocyte phenotype and gene expression.

METHODS

Type A, 300 bloom gelatin was mixed at 625mg/mL in 70% acetic acid and direct-written in aligned fibrous patterns following an established protocol⁵ (Fig. 1A). Scaffolds were crosslinked with 1-ethyl-3-(3-dimethylamino propyl) carbodiimide hydrochloride (EDC) and N-hydroxy-succinimide (NHS) in 90% EtOH at a 10:1 ratio for 1, 6, or 24 hours (Low, Mid, and High stiffness, respectively). The stiffness of fibers (n=16 per crosslinking group) was determined via contact force mapping mode of atomic force microscopy (AFM) with a silicon nitride pyramidal tip (0.32N/m spring constant). Fiber diameter was measured from brightfield images (0, 1, 2, and 3 weeks

of culture in 1X PBS). Tenocytes isolated from an equine superficial digital flexor tendon were seeded onto scaffolds (one week after scaffold fabrication) or neutrally-charged slides at 75,000 cells/sample and cultured for 2 weeks. Cell viability was determined via a commercial cell viability kit (Invitrogen). Nuclear aspect ratio, cytoskeletal and nuclear peak orientation, and orientation index (OI) were determined via phalloidin and DAPI staining. Image processing was accomplished with ImageJ (NIH). Multiplex gene expression of matrix mechanotransduction-associated, and remodeling proteins (COL1A2, COL2A1, COL3A1, DCN, MMP1, MMP3, and PIEZO1; ACTB, GAPDH, and HPRT1 served as housekeeping genes) was determined via Nanostring (nCounter MAX system) from RNA isolated at 1 and 2 weeks. Samples were run in triplicate for analysis. Outliers were removed (ROUT 5%), and one-way ANOVA with Tukey's test ($\alpha=0.05$) was used for statistical analysis. One sample t-tests were used for statistical analysis of peak direction from the hypothetical value of 90°. Two-tailed t-tests was used for analyzing statistical significance in gene expression.

RESULTS

Fiber stiffness decreased from 0 to 1 week, then remained consistent to 3 weeks for all groups (Fig. 1B). Stiffness increased with increasing crosslinking time (High and Mid groups were 10- and 6-fold higher than Low group at 1 week) while maintaining similar fiber diameters (Fig. 1B and C). Cellular viability remained >94% for all groups at 1 and 2 weeks. Cytoskeletal and nuclear peak orientation was not different from the direction of the fibers (90°) for all groups except glass at 1 week (mean: 51°). Nuclear OI was 45-60% lower for all scaffolds vs. glass both 1 and 2 weeks (Fig. 2B). Cytoskeletal OI was 63-78% lower for all scaffolds vs. glass at 1 and 2 weeks (Fig. 2B). Nuclear aspect ratio was 71%, 59%, and 53% higher for the Low, Mid, and High groups respectively compared to neutral glass slides (1.7±0.1) at 1 week. At 2 weeks, the nuclear aspect ratio for the Low and Mid groups were 70% and 74% higher than neutral glass slides,

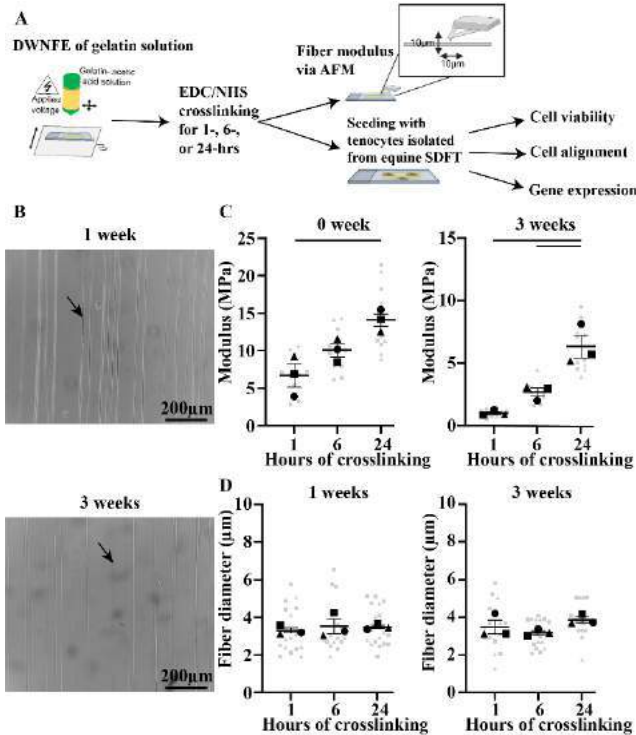

Figure 1: A) Schematic of the study design. B) Representative images of 1- and 3-weeks fibers. Black arrow indicates one fiber. C) Stiffness of EDC/NHS crosslinked gelatin fibers increased with time. Modulus of fibers crosslinked for 1-, 6-, or 24-hrs. Top 0 week to bottom 3 weeks. D) Fiber diameter did not change with time. Top 1 week to bottom 3 weeks. Bars represent statistical significance between connected groups.

while the High group was not significantly different from neutral glass slides. Multiplex gene expression showed no differences between stiffness groups at 1 week except for MMP1 which was upregulated for the High vs. Low groups. However, at 2 weeks upregulation of COL1A2, COL3A1, DCN, MMP3, and PIEZO1 was found for the High vs. Low groups (Table 1). Fewer changes were found between High and Mid as well as Mid and Low groups. Comparing changes in gene expression from 1 to 2 weeks, these same five genes (COL1A2, COL3A1, DCN, MMP3, and PIEZO1) along with MMP1 were upregulated with time for all groups. MMP1 and MMP3 showed the greatest fold change for all groups with time. The Low group showed upregulation of COL2A1 with time, while the Mid and High groups did not.

DISCUSSION

Gelatin scaffolds with similar fiber orientation and size, but varied stiffness caused similar cellular orientation but different levels of expression of genes related to matrix proteins, remodeling, and mechanotransduction. This follows previous work that has shown tenocytes aligning along the direction of fibers.⁷ Increased expression of COL1A2, COL3A1, DCN, and PIEZO1 in the High stiffness group compared to the Low stiffness group shows tenocytes are sensitive to changes in stiffness between 1 and 10 MPa. The changes over this range may be relevant for mimicking the decreased stiffness of a tendon with the onset of tendinopathy.⁸ PIEZO1 especially has been shown to be a positive marker for tendon development specifically for mechanotransduction.⁹ The increased MMP1 and MMP3 expression in all scaffold groups may represent the desire of the cells to remodel the collagenous fibers. Changes in COL2A1 and COL3A1 are relevant to

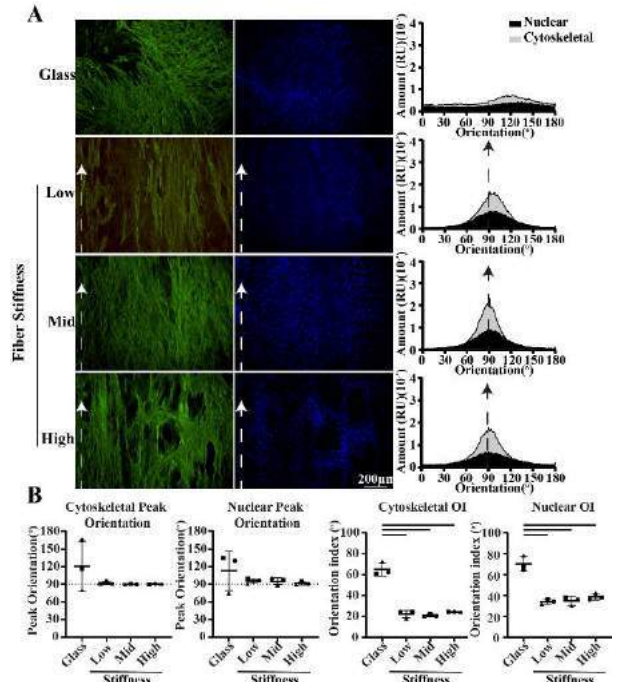

Figure 2: Tenocytes seeded on scaffolds or neutral glass slides at 2 weeks. A) Fluorescent images stained with phalloidin (green) left column and DAPI (blue) middle column. Histograms of the orientation distribution (grey=cytoskeletal; black=nuclear) right column. Arrow indicates direction of fiber orientation. RU= arbitrary relative units. B) Cytoskeletal and nuclear peak orientation and index are improved with fibers. Bar indicates statistical significance between groups.

PIEZO1	1.2 (p=0.04)	1.19 (p=0.08)	1.01 (p=0.88)	1.49 (p=0.06)	1.48 (p=0.01)	1.59 (p=0.003)

changes seen with tendinopathy with transition to a fibrotic or cartilage-like behavior. Further analysis is needed to understand how differences in gene expression translate to changes in protein expression. Additionally, it is unclear how changes to the fiber composition or external mechanical stimulation, often altered in tendinopathy, may alter these responses. In conclusion, DWNFE gelatin fibers represent an effective platform for studying the response of tenocytes to fibrous matrix properties, such as stiffness.

REPEATABILITY AND BACKLASH MEASUREMENTS OF MICRONEEDLES DISPLACED USING A NOVEL ACTUATION BLOCK

Brianna E. Morales (1) and Christopher G. Rylander (2)

INTRODUCTION

The Central Brain Tumor Registry of the United States estimated that there would be over 13,000 new diagnoses of glioblastomas (GBM) in 2022 [1]. Given that the current standards of treatment (surgery, radiation, and chemotherapy) have not effectively cured this grade IV glioma, the number of new diagnoses will continue to increase. There is a pressing need to develop an improved method of treatment delivery for GBMs.

An experimental method of improved treatment is convection-enhanced delivery (CED) of drugs using a minimally-invasive catheter. CED has shown promise and there are currently several clinical studies that are recruiting patients [2]. Our lab has designed an arborizing catheter known as the Convection Enhanced Thermochemotherapy Catheter System (CETCS), as shown in Figure 1 [3].

Figure 1: CETCS; main cannula (top) and actuation block (bottom).

The CETCS consists of a main cannula connected to the actuation block, and six microneedles capable of extending past the main cannula. Once the main cannula is deployed and secured using a conventional neuronavigational positioning system, the novel CETCS actuation block provides the ability to deploy the CETCS microneedles

individually, up to 4.5 cm from the main cannula tip into the target regions surrounding the tumor. Microneedle movement is driven by the actuation block using a lead screw that allows for unidirectional positioning. A retaining clip is used to ensure the microneedles are secured to the lead screw mechanism. Based on the fixed pitch of the lead screw, for each complete revolution, the microneedle is displaced 0.72 mm. The current mode of operation is manual, but later iterations of CETCS will have remote controlled capability. Control will be provided to the neurosurgeon user through the implementation of a software interface which will drive individual stepper motors and rotating rods which will deploy or retract the microneedles from the main cannula. Figure 2 shows a representation of the microneedles in a deployed state from the end of the main cannula.

Figure 2: Main cannula with deployed microneedles.

The end goal for the CETCS device is to be used clinically for the treatment of GBM. To reach this goal, we have been advised to apply for and receive 510(k) FDA clearance. For this process it is imperative to demonstrate the device is as safe and effective as the identified predicate device, in this case the Cleveland Multiport Catheter (CMC). The CMC design includes a sheath that can be retracted from a stylet to reveal four microcatheters, as described by Vogelbaum et al. [4]. The indication of use of the device is to gain access to the ventricles of the brain for the removal of cerebrospinal fluid (CSF) or to inject

Cytarabine. Safety and efficacy can be evaluated by conducting similar performance tests on the CETCS device that were done on the CMC.

This paper discusses a method to identify the repeatability and backlash distances produced using the manual operation of the CETCS actuation block. The repeatability is a measure of how precise the actuation block is at moving the microneedles a specified distance. The backlash in the system can be characterized as the movement lost in changing direction: deployment to retraction or retraction to deployment. Understanding and identifying these metrics will help determine the amount of compensation we need to account for in the calibration of the system. Our current goal is to stay within 1 mm of the ideal movement.

METHODS

The following experiments evaluated the ability of the actuation block to control the movement of the microneedles as they were deployed and retracted from the main cannula. Measurements of the actual length of a side microneedle and the center microneedle were taken using a caliper, as shown in Figure 3.

Figure 3: Side and center microneedle deployment distance from the main cannula controlled by the actuation block, not pictured.

Repeatability

The sequence of microneedle movements included setting an initial placement of the microneedle and then four subsequent changes in position in increments of 5 mm deployment. Then four additional changes in position were conducted in increments of 5 mm retraction. Measurements were taken at each step and the displacement was noted as: x_j . The displacement was then used to evaluate the repeatability (RP_x) of the microneedle, using equations below:

$$\bar{x} = \frac{1}{n} \sum_{j=1}^n x_j \quad (1)$$

$$l_{x_j} = |x_j - \bar{x}| \quad (2)$$

$$\bar{l}_x = \frac{1}{n} \sum_{j=1}^n l_{x_j} \quad (3)$$

$$S_x = \sqrt{\frac{\sum_{j=1}^n (l_{x_j} - \bar{l}_x)^2}{n-1}} \quad (4)$$

$$RP_x = \bar{l}_x + 3S_x \quad (5)$$

First solving for the sample mean (\bar{x}), n is the number of values in the sample and determine how much the measurements deviate from the average (l_{x_j}). Then we determine the average deviation (\bar{l}_x), which is used to solve for our sample variance among the measurements (S_x). This was used to determine the repeatability (RP_x) of the measurement.

Backlash

For this experiment, we evaluated the displacement of the microneedle, where the direction of motion of the microneedle was either changed from deployment to retraction or retraction to deployment.

RESULTS

Repeatability

Measurements were taken at each position change and recorded. The results were evaluated using Equations 1-5. The average repeatability for the center needles was lower (better) than the side needle.

	Repeatability (mm, n = 6)
Center Deployment	0.33 ± 0.09
Center Retraction	0.33 ± 0.07
Side Needle Deployment	0.59 ± 0.34
Side Needle Retraction	0.98 ± 0.63

Table 1: Average repeatability found in microneedle positioning.

Backlash

For the center and side needle the change in position from deployment to retraction or retraction to deployment did not affect the overall backlash measured. The side needle did experience a higher amount of backlash when there was a change in position than the center needle.

Needle (n = 3)	Deployment to Retraction (mm)	Retraction to Deployment (mm)
Center	0.43 ± 0.02	0.47 ± 0.02
Side	0.94 ± 0.1	0.97 ± 0.16

Table 2: Average backlash results for retraction to deployment and deployment to retraction.

DISCUSSION

We observed a higher mean and variability in the repeatability and backlash measurements that were taken for the side needle versus the center needle. These results indicate that the actuation block has an error of about 1 mm for the side needles and an error of 0.33 mm for the center needle. This could be explained by the greater bend angle and resulting friction of the side needle within the main cannula versus the center needle. Fortunately, the CETCS device can be calibrated to compensate for known backlash of center and side microneedle when there is a change in direction.

INTRODUCTION

Many biological tissues comprise a fibrous microstructure with a particular organization optimized for a physiological function. This architecture modulates the physical properties of the tissues, including the conduction of electrical signals, diffusion of water and soluble molecules, and mechanical properties. Thus, microstructural information has increasingly been incorporated into computational models of biological tissues [1].

The orientation of the microstructural fibrils is particularly important for the explanation of the anisotropic functions of tissues. This has been extensively shown for a variety of tissues including skin [1], ligaments and tendons [2], myocardium [1], arteries [3] and cartilage [4]. Explicit incorporation of 3D fiber orientation distribution functions (ODFs) such as ellipsoidal or Von-Mises is often used in finite element (FE) modeling of biological tissues [5,6]. These approaches assume a parametric form for the ODF to simplify the representation.

Recently we developed a nonparametric approach to efficiently extract and represent ODFs from 3D image data [7]. The approach is based on the Fourier transform and the Q-ball algorithm. In this work, we developed methods to measure ODFs from image subvolumes and map them onto FE mesh. We developed a user interface in FEBio Studio [8] and extended the finite element software [9] to enable the use of inhomogeneous ODFs in constitutive models. The resulting framework provides a powerful and general approach to represent anisotropy and inhomogeneity in models of fibrous tissues directly from image data.

METHODS

Characterization of fiber orientations: Fibril ODFs were directly extracted from volumetric image with our previously established approach [9]. Briefly, the fast-Fourier transform was applied to the image volume followed by the qball algorithm to the power spectrum. This resulted in an ODF that quantifies the probability density of fibrils along every orientation in space. The ODF was represented by a series

of spherical harmonics (SHs) with a maximum order, L , that allows concise representation of the function using $(L+1)(L+2)/2$ terms.

Implementation in FEBio: Our approach to extracting 3D ODFs from image data was implemented in the FEBio Studio software and further developed for use in constitutive modeling. The Matlab (MathWorks Inc.) code previously developed was ported to C++, replacing the proprietary software with open-source packages and enabling faster speeds. We implemented routines for the import of volumetric image data, and added capabilities for volume rendering and image analysis. The UI allowed the user to specify subvolumes for ODF calculation, with each represented by a separate SH series (Fig 2A).

The ODFs can be mapped to FE discretization within FEBio Studio. The FEBio solver interpolated ODFs to assign to each to a finite element, based on a previously developed Riemannian framework [10]. The resulting ODFs can define the distribution associated with fiber families using a variety of constitutive models available in FEBio [9].

Example applications: The new framework was evaluated using two volumetric image datasets of a collagenous hydrogel. A type I collagen hydrogel was synthesized according to previous experiments [11]. The first dataset was collected with a multiphoton microscope, containing axial slices at $0.5 \mu\text{m}$ apart with lateral resolution of $0.53 \mu\text{m}/\text{pixel}$ encompassing a total volume of $540.0 \times 540.0 \times 351.0 \mu\text{m}^3$. The dataset was median filtered and resampled to an isotropic voxel resolution of $0.75 \mu\text{m}^3$ (Fig. 1). The image demonstrates directional preference along the x-axis in highly noisy data.

The second dataset was collected using focused ion beam scanning electron microscopy (FIB-SEM). The data constituted similar collagen hydrogel at a higher resolution and magnification. This provided a clear example to illustrate the correspondence between the image data and the position-dependent ODFs.

RESULTS

User Interface (UI): The analysis framework was constructed with a UI to facilitate easy use and access to broader research community

(Fig. 2). Image data is directly imported to the modeling pipeline and visualized. The user can add an ODF analysis to the imaging data, revealing the properties dialogue containing parameters of the analysis. That includes the maximum SH order of approximation, the frequency cutoffs of the power spectrum, the number of divisions to image subvolumes, and graphical display settings (Fig. 2Left).

Discretization into image subvolumes and visualization on the image domain: The image analysis resulted in measured fiber ODFs that correspond to each subvolumes, and can be directly visualized in FEBio Studio (Fig. 3). This analysis can be done at various subvolume sizes, and represents increasing specificity of the spatial material inhomogeneity. The ODFs can be visualized as either an intensity colormap over the unit sphere (Fig 3A, B), or additionally as each orientation mapped by probability as radial distance (Fig 3D).

Local ODFs on FIB-SEM dataset: The correspondence between the measured ODFs and the image data can be gleaned from the high resolution FIB-SEM data (Fig 4). The image data, rendered in white, provides high contrast fibrillar structures with varying orientations. The measured ODFs directly correspond with the orientation of collagen fibrils in their subvolume region.

DISCUSSION

This work provides the ability to incorporate inhomogeneous structural information of biological tissues from image data directly into computational models. The fiber ODFs are nonparametric distributions, and thus do not make any prior assumptions about the fiber architecture. The ability to measure this information regionally further provides a high spatial resolution of material properties that is grounded on measures directly from experiments.

The computational framework of analysis was constructed with a UI and integrated into an established modelling software [11]. The need to characterize and analyze fibrous tissues is fundamental to biomechanics. This framework enables others researchers to rapidly adapt this microstructural information into constitutive models. While some of the image analysis was previously published, it was largely inaccessible because of its format and integration into computational models was difficult.

Additional developments are required to enable the effective use of this framework towards the characterization of soft tissues. For instance, nonparametric ODFs introduce increased degrees of freedom to constitutive modeling. Thus, the space of material constants that could fit to constitutive relations is larger. One solution could be to accompany mechanical results with image data, increasing the outcome parameters to regress against and the information about mechanical deformation.

STRUCTURAL AND FUNCTIONAL HETEROGENEITY OF THE UTEROSACRAL LIGAMENTS IN THE RAT

INTRODUCTION

The uterosacral ligaments (USLs) are the main supportive structures of the upper vagina and uterus within the pelvic floor. Structural changes of the USLs have been shown to contribute to the development of pelvic organ prolapse (POP). Given their anatomical function, the USLs are used as anchoring tissues in the surgical treatment of POP such as the uterosacral ligament vaginal vault suspension [1]. Thus, characterizing the mechanical function of the USLs is a crucial step in identifying the etiology of POP as well as improving corrective surgeries that rely on the USLs to restore the support of prolapsed organs [2]. Animal models can help in studying the functional role of the USLs in POP through *ex vivo* mechanical testing, without the challenges associated with the collection of human tissues [3]. In our lab, we have developed new methods for isolating and mechanically testing rat USLs [4] since rat USLs are relatively easy to acquire and histologically similar to human USLs [5]. We have also observed that rat USLs fail by delamination making the measurement of deformation fields using the digital image correlation method very challenging.

In this study, we propose the use of optical coherence tomography (OCT) during uniaxial testing to obtain volumetric images of the USLs by depth-resolving backscattered light from the tissues [6]. This optical imaging technique allow us to determine the relationship between the mechanical function of rat USLs and through-thickness micro-structural changes that cause delamination and tissue failure. This work serves as a springboard for future developments of OCT-based probes that measure the mechanical integrity of USLs *in vivo* for the prevention, diagnosis, and treatment of POP.

METHODS

Six virgin Sprague-Dawley rat USLs were dissected following recently developed dissection procedures that isolate the ligaments from other pelvic floor organs while maintaining the integrity of the entire ligaments [4]. Ligaments were secured to the linear actuators of a custom-made uniaxial machine by clamping one end of the USLs at the spine and piercing the other end with three needles spaced 3.5 mm at the vaginal attachments. The USLs were preloaded to 5 mN then displaced along their main

in vivo loading directions at a constant rate of 10 $\mu\text{m/s}$ until the stroke limits of the actuators were reached or total tissue failure occurred. Load data were recorded using a 8.9 N-capacity, 0.1% accuracy load cell (FSH00092, Futek Advanced Sensor Technology, Inc., Irvine, CA). A spectral domain optical coherence tomography system (SD-OCT) was assembled with a superluminescent diode (SLD; Superlum, Cork, Ireland; $\lambda = 837 \text{ nm}$, $\Delta\lambda = 54 \text{ nm}$) and a custom spectrometer using a linescan camera (AViVA EM1; Teledyne, Milpitas, CA; 1024 pixel, 78 kHz). The system was mounted above the specimen at a 150 mm working distance with a focused beam of diameter of 60 μm . For volume acquisition, the beam was raster scanned in two lateral dimensions across a 15 mm \times 7.5 mm area on the specimen for 512 \times 512 image pixels in the transverse and loading directions, respectively. The vertical field-of-view (FOV) of the OCT images was approximately 3 mm of optical depth in 513 image pixels. For each specimen, 30 to 40 OCT volumes and color images were recorded with a CMOS camera. Figure 1 shows the color image of the entire USL with the corresponding OCT maximum intensity projection (MIP) image overlaid.

Figure 1: Picture of one rat USL during uniaxial testing with an OCT MIP image overlay.

The typical load-displacement curve of the USL was characterized by the presence of the toe, linear, and failure regions. For one representative specimen, isometric MIP OCT images are displayed for values of the load and displacement in these three regions in Figure 2.

Figure 2: Isometric OCT MIP images at displacements (ΔX) and loads (L) that fall within the toe (orange), linear (green), failure (lilac) regions of the load-displacement curve.

RESULTS

A scalar parameter was extracted from each collected OCT image to describe the bulk tissue structural heterogeneity during mechanical testing. Figure 3 (top) shows depth-coded maps of the highest optical backscatter from *en face* MIP images acquired in the three regions of the load-displacement curve for one specimen. To derive a scalar parameter that represents the heterogeneity of the bulk tissue, a histogram of these MIP depths was computed for each depth-coded image, as shown in Figure 3 (bottom). A mask was used to exclude off-tissue positions in the images from these calculations. The depth-variation parameter, σ , was computed as the standard deviation of MIP depths within all *en face* area of the tissue. To account for inter-specimen variation, the depth variation change relative to each specimen's initial depth-variation parameter, σ_0 , was computed.

Figure 3: Top: Depth map of optical backscatter from maximum intensity projections. Bottom: Distribution of depths of maximum backscatter. The depth-variation at zero displacement for this specimen was $\sigma_0 = 0.636$ mm

Load versus displacement data measured during tensile testing are presented in Figure 4(a) for the $n=6$ specimens. The depth-variation parameter was also computed for each image during tensile testing, plotted versus displacement in Figure 4(b). The three regions of the load-displacement curve are color-coded. As the displacement increased, the load increased non-linearly in the toe region (orange) while the tissue depth-variation decreased. In the linear region (green), where the load increased linearly with the displacement, the depth-variation remained roughly constant. In the failure region (lilac), following the point of maximum load, a significant increase in depth-variation was recorded as individual micro-structural components of the USLs fail and the load gradually decreased.

Figure 4: (a) Load-displacement data for USLs ($n=6$) and (b) corresponding depth-variation change data.

DISCUSSION

OCT imaging of the USLs under uniaxial testing allowed for visualization of the complex 3D deformations of the ligaments. The depth-resolving capability of OCT imaging provided new data on the highly heterogeneous structure of the USLs in the rat model. The image-derived depth-variation parameter and the directly-measured load data in all three regions of the load-displacement curves were found to be correlated (Figure 4). In the toe region, the monotonic decrease of the depth-variation parameter was determined by the straightening and alignment of the collagen fibers of the USLs. In the linear region, the depth-variation parameter did not change as the displacement increased; the deformation was homogeneous across the tissue as no major structural changes occurred. In the failure region, individual structural components such as collagen bundles were observed to fail as also reflected in the abrupt decreases in the load/displacement curves. The depth-variation parameter captured these structural changes consistently as it increased significantly in this region.

In summary, the extracted depth-variation parameter serves as a useful parameter to characterize the material heterogeneity of the USLs in the three regions of the load-displacement curve. The correlation between the invasive and contact-based examination of tissue function (i.e., measurement of load and displacement) and the non-invasive and non-contact optical characterization of tissue structure (i.e., measurement of depth-variation parameter) shows promises for the development of OCT-based probes that perform non-contact *in vivo* evaluation of the mechanical integrity of USLs in humans.

INTRODUCTION

Kidney glomerular diseases result in damage to the kidney's filtration apparatus and often cause chronic kidney disease and kidney failure with no cure [1]. One main reason for them is that the podocyte attachment, especially that of podocyte foot processes, could be disturbed during these diseases [2], and lead to the loss of filtration function of the glomerulus (Figure 1A-C) [3].

The cytoskeleton of the podocytes is well organized to maintain this critical, yet complex structure (Figure 1D) [4], and to maintain the attachment against the changing mechanical environment of these cells. Understanding the force balance inside this environment then became important in fundamental mechanobiology perspective as well as in therapeutic application level.

Based on mathematical model we developed, we hypothesize that stresses on the integrin bonds of these podocytes were the key to their attachment, and it was balanced mainly based on the fluid shear due to the filtration and the actomyosin contraction inside of the cells.

A mouse injury model modulating their blood pressure and contractility is established in the end to verify our prediction about their kidney filtration function which illustrated the potential role of adjusting this balance in the therapy of chronic kidney diseases.

METHODS

The development of the mathematical model first includes the key mechanotransduction components like the contractile actin filaments form the podocyte cell body, the focal adhesion with integrin bonds and the slit diaphragm connecting neighboring foot process (Figure 1E). During the simulation, the force equilibrium is ensured (Figure 2A), and the stability of the integrin bonds can be determined through calibrated relationship with the force on the integrin [5], while a Monte Carlo simulation is carried out to calculate the displacements of each component until a balance is reached.

To test our model results in a mouse injury model. Two sets of techniques were used. Firstly, the sub-cellular structures inside of the podocytes and the foot processes is enables with super-resolution imaging techniques like STORM to check our predictions on cell morphological changes. Then, the filtration function of the mice is evaluated through albumin to creatinine test in the urine, where more albumin in the urine indicates worse kidney diseases, while the mechanical cues were adjusted through blood pressure controlling or myosin function inhibition.

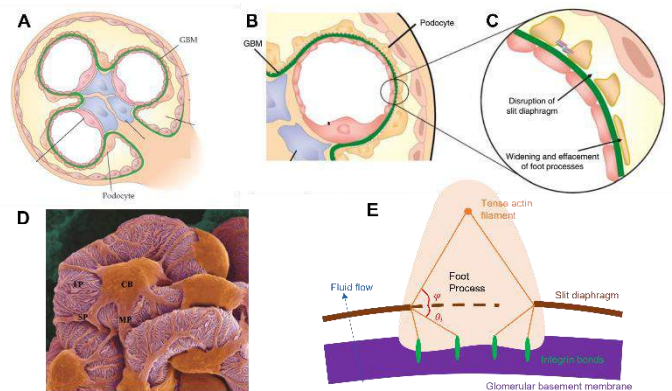

Figure 1: (A-C) Podocytes and their foot processes function in glomerular filtration [3], (D) Scanning electron microscope of healthy podocytes and their foot processes [4], (E) Our simplified model for mechanical transduction in a foot process.

RESULTS

Firstly, our models suggest the existence of linkage between the contractile actin cable, the slit diaphragm and the integrin bonds for the stable attachment of the foot processes (Figure 1E). While this

connection was never observed specifically before, we managed to visualize them using super-resolution imaging of the foot processes, where most actin staining concentrated on the upper side of each foot process, that is the contractile actin cable from the cell body, there are also actin positive signal between the nephrin-labeled slit diaphragm and the integrin on the lower side of the foot process, which we proposed to be responsible for the mechanotransduction and balance between these components (Figure 3A-B).

Then, our simulation results highlight the mechano-responsiveness of the integrin distribution in the foot processes and suggest a potential pathway for changes of the GBM's stiffness (Figure 2B) and changes to blood pressure and fluid flow (Figure 2C) to affect podocyte attachment and function. And the results can be summarized in two predictions that firstly integrins would accumulate on the edges of foot processes to maintain the stable attachment of themselves and that they would move while the foot processes would become narrower due to the increase of either GBM stiffness or fluid shear (Figure 2D). Secondly, it is predicted that the balance of attachment would be broken if fluid shear and cytoskeleton contraction increased beyond a critical point while the foot processes would also be destabilized in the absence of both fluid shear and cytoskeletal contraction at the same time (Figure 2E).

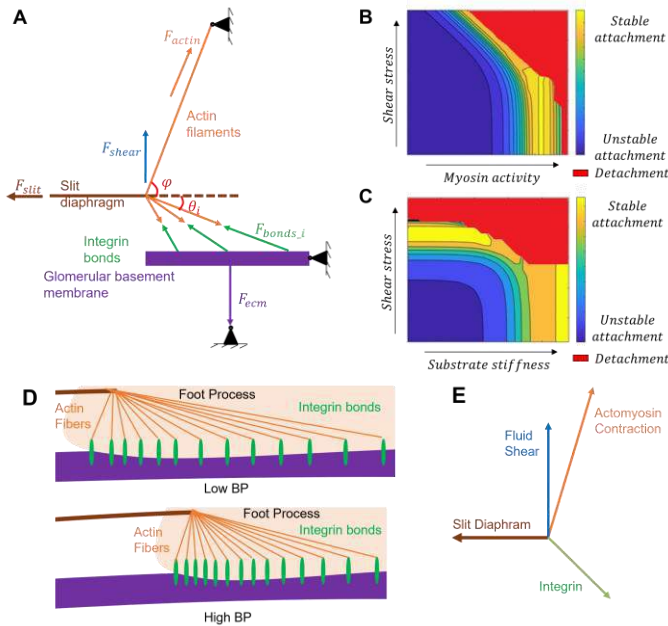

Figure 2: (A-C) Simulation of force balances inside of a foot process, (D-E) prediction of podocyte attachment.

Finally, to verify our predictions from the simulation, we looked into the integrin distribution through super-resolution techniques, and through integrin b1 staining, it is clear that we could notice the concentrated integrin be at the edge of the foot processes (Figure 3A-B) which have also been shown in previous studies [6]. Furthermore, the effect of blood pressure controlling is evaluated to show significant difference (Figure 3C), while proteinuria results reveal the progression of more severe albuminuria in the mice with decreased blood pressure after myosin inhibition, indicating the loss of contractility and fluid shear at the same time did aid the disease progression (Figure 3D).

DISCUSSION

In this project, we successfully modeled the podocyte attachment under varied mechanical properties that simulate physiological and

pathological microenvironment of the glomerulus. And made predictions to podocyte stability and kidney function accordingly. This opened new insight of how mechanical cues could aid or lead to glomerular diseases that have becoming more and more important nowadays.

This work helps us understand the complex interplay between mechanical parameters and the changes during pathological situation that could lead to the effacement and detachment of the podocyte foot processes. The fact that we have coordinated data from the mathematical model and the mouse injury model also highlights the importance of mechanical cues in the development of chronic kidney diseases.

It has potential impact on all kidney disease therapy strategies nowadays, since no mechanical cues were considered before while establishing these therapeutic methods. According to our modeling and experimental results though, the restore of mechanical environments inside of the glomerulus is also needed to achieve the complete cure of chronic kidney diseases. Moreover, different types of disease may have distinct or even opposite mechanical changes so may be beneficial from different regulating strategies.

There's even more to considering as mechanical regulations in the kidney glomerulus as next step: The expansion of capillaries with blood pressure changes, the stable connections between nearby foot processes and more [8]. They may also play an important role in stabilizing the filtration barrier and the filtration function. With increasing understanding of the mechanical cues inside of the glomerulus, we may realize the complete cure of chronic kidney diseases in the future.

INTRODUCTION

Head impact exposure in contact sports has been reported in the literature for years. Head impact sensors characterize both frequency and magnitude of exposure in many studies and are used especially in athlete and military populations. Mouthguard- or retainer-style sensors have become increasingly popular because of their potential to couple directly to the upper dentition and hence the skull [1]. Some sensors perform well in the lab under ideal conditions, for example, a tight fit with the lower dentition clamping the mouthguard in place, but their use by volunteers in the field may differ. This study aimed to determine the effect of introducing small gaps between a boil-and-bite mouthguard-style head impact sensor and the lower dentition of a headform on the sensor outputs compared to a ground truth measurement. The hypothesis was that the mouthguard would become less accurate with increasing gap size due to increased mouthguard movement relative to the headform.

METHODS

A single Prevent Biometrics (Edina, MN) boil-and-bite mouthguard was fit to a 3-D printed dentition according to the manufacturer's instructions for fitting to a typical athlete. Spring clamps provided force for forming the mouthguard to the dentition immediately following boiling. After drying, the mouthguard underwent 96 impacts. A modified medium National Operating Committee on Standards for Athletic Equipment (NOCSAE) headform attached to a Hybrid-III 50th Percentile Male ATD neck was mounted atop a linear slide table; the dentition was attached to the headform in its anatomical location. The tests were conducted at locations and severities described in [2] and [3] using a padded impactor face. Three gap conditions were tested for each combination of location and severity. The gap conditions were created by tightening the bottom dentition to the lower face of zero, one, or three 1.6mm shims stacked on top of one another, resulting in gaps of either

0mm (tight), 1.6mm, or 4.8mm (Figure 1). The mouthguard stayed attached to the upper dentition until the time of impact in all tests. Each test condition included two trials.

Raw data output by the mouthguard sensors were filtered using a custom second-order Butterworth phaseless dual-pass filter and transformed to the headform center of gravity (CG) using rigid body dynamics equations. Based on previous analyses, cutoff frequencies best matching laboratory data for linear accelerometers (350 Hz) and angular rate sensors (250 Hz) were employed to reprocess the mouthguard data. Data collected at the headform CG were filtered at SAE J211 recommended filter cutoff frequencies (1650 Hz for linear accelerometers and 259 Hz for angular rate sensors [4]) and were considered to be ground truth.

Figure 1: Lower dentition to mouthguard gap conditions from left to right: 0mm, 1.6mm, and 4.8mm.

Headform data collected at the CG were also transformed to the headform teeth location using rigid body dynamics equations. This enabled calculating the relative motion of the mouthguard with respect to the headform. Laboratory data were down-sampled to align with the

mouthguard sampling rate of 3.2kHz. Mouthguard and laboratory signals were shifted such that the first point at or above 4g resultant linear acceleration corresponded to time zero for both measurement sources. Relative resultant linear acceleration was calculated as the difference between mouthguard and headform measurements, as measured at the headform teeth location.

RESULTS

A difference in error between gap conditions was observed (Figure 2). Error relative to headform measurements in peak linear acceleration reported by the mouthguard was as high as 500% in the most extreme cases with the largest gap condition. Impact location also appeared to have an effect, with angled rear (Rearboss) impacts generating lower errors than front and angled front (Frontboss) conditions, even with the largest lower dentition gap.

Figure 2: Error in peak linear acceleration reported by the instrumented mouthguard (MG) increased with lower dentition gap size. Differences in performance by impact location were observed. Reference line drawn at a slope of one.

Relative motion artifacts were increasingly recognizable in the mouthguard measurements as impact severity and lower dentition gap increased (Figure 3). These artifacts were observed in both linear and angular measurements.

Figure 3: Exemplar traces of resultant linear acceleration at the Front location (100g severity). Relative acceleration (black curves) of the mouthguard increased as lower dentition gap size increased. Lab measurements are shown in gray for reference.

Qualitatively, a majority of the motion artifacts (10-40ms) appeared to have occurred after the true peaks in linear acceleration caused by the

impact (0-10ms), which were easily discernable from the headform measurements. Limiting the peak value output to the first 10ms post-trigger reduced the error in peak linear acceleration reported by the mouthguard (Figure 4).

Figure 4: Error in peak linear acceleration reported by the instrumented mouthguard decreased when analyzing peaks occurring only during the time of force applied to the headform (0-10ms post-trigger). Reference line drawn at a slope of one.

DISCUSSION

The fit and retention of instrumented mouthpieces are important to the accuracy of these sensors, and the amount of error introduced into their measurements will vary depending on how they are used on-field. A gap between the lower dentition and mouthguard as small as 1.6mm can affect readings in a laboratory environment. Larger gaps lead to greater errors. Gaps between dentition and mouthguard, representing an impact where an athlete has not clenched his or her jaw, may be present in a number of real-world impacts measured by these sensors and should be considered in mouthguard development and in the interpretation of any studies using these devices.

Error and relative motion differed with impact location, which suggests there may be a directional dependence of the mouthguard for retention when a gap exists. Frontal impacts fared worse, which can be explained by the headform being accelerated away from the inertial position of the mouthguard; rear impacts benefit for the opposite reason.

The mouthguard used in this study performed well during the impact event, even in the highest gap condition; however, the secondary peaks due to mouthguard motion occurred within the data collection window for the mouthguard, which caused erroneously high peak values to be reported. When considering only the 0mm gap condition, this study agrees with previous laboratory analyses of instrumented mouthguard accuracy.

INTRODUCTION

The blood-brain barrier (BBB), which is formed by the compact brain capillary endothelial cells (ECs) and junctional protein complexes, prevents the brain's uptake of therapeutic agents from the blood [1]. To overcome this problem, BBB opening by focused ultrasound (FUS) associated microbubbles (MBs) has become an effective method to deliver various therapeutic agents to the brain [2]. It has the advantages of noninvasive, repeatable, and local gene delivery to the brain. However, high acoustic pressure and high concentration of MBs will lead to BBB disruption, which induces an acute sterile inflammatory response in brain tissue [3]. A recent study has reported delivering plasmid DNA to the brain ECs without opening the BBB, called sonoporation [4]. Sonoporation is based on the microbubble cavitation induced by FUS and eventually pore formation on the cell membrane. Non-viral gene delivery to the BBB is a promising approach for brain therapeutics for two reasons. First, BBB dysfunction has been indicated in various neurodegenerative diseases and restoring functional BBB has been shown to restore brain function [5]. Second, gene delivery to BBB offers new opportunities to modify BBB function without opening the BBB and associated side effects.

In this study, we investigated how sonoporation parameters, especially acoustic pressure and microbubble concentration, affect gene transfection and BBB integrity. We found the parameters for gene transfection without opening the BBB. Our results provide guidance for high-efficiency gene delivery into the brain.

METHODS

Cationic MBs are fabricated following reference [4]. Male C57BL/6 mice (8-week-old) purchased from Charles River were anesthetized with isoflurane. A tail-vein catheter was inserted to permit intravenous (i.v.) injections of MBs, plasmids (pcDNA3-luciferase) and fluorescent dye (fluorescein). The heads of the mice were shaved and depilated, and the animals were then placed in a supine position over a

degassed water bath coupled to an MR-compatible small animal FUS system (RK-50; FUS Instruments). Mice received an injection of the conjugated MBs and luciferase plasmid (500 µg per mouse). Sonication applied to the right hippocampus region began immediately after the injection (1.46 MHz, 100 ms burst duration, 1000 ms burst period, 300 bursts).

One day later, to visualize the luciferase expression, the mice were injected with 200 µl D-Luciferin solution (15 mg/ml in PBS) intraperitoneally (i.p.) and were imaged with an IVIS imaging system (Lumina, Series III) after 15 minutes. To assess biodistribution of the gene transfection, mice were sacrificed and their organs (brain, lungs, heart, kidneys, spleen, and liver) were harvested and placed in the solution of D-Luciferin (150 µg/ml) in PBS for 5 minutes. The organs were then imaged using the IVIS imaging system.

To assess BBB integrity after FUS sonoporation, mice received an injection of 100 µl fluorescein dye (330 Da) after the sonication and were perfused with PBS followed by 4% paraformaldehyde after 30 minutes. The brains were fixed in 4% paraformaldehyde for 24 hours at 4 °C, followed by flash freezing and storage at -80 °C. The brains were then mounted with OCT and sectioned using a cryostat into 10 µm thick sections. Sections were imaged on an Olympus slide scanner microscope equipped with a 10x objective.

RESULTS

High acoustic pressure (above 0.3 MPa) has been proven to open the BBB [4]. On the other hand, low acoustic pressure with low MB concentration may not be able to transfect gene plasmids due to weak cavitation. To study how sonoporation parameters affect transfection, we investigated FUS acoustic pressure ranging from 0.1 to 0.6 MPa and the number of MBs ranging from 1×10^8 to 5×10^8 . Data points are represented as black dots in Figure 1A. FUS is applied in the right hippocampus region (red circle in Figure 1B). With extremely high acoustic pressure (0.6 MPa) and a large number of MBs (5×10^8), clear

brain injury was found at the sonication region. With low acoustic pressure (0.1 MPa) and a small number of MBs (1×10^8), there is no luciferase expression in the brain (Figure 1C). Data points with parameter values between these two cases provide results of seeing expression (Figure 1D). Additionally, live imaging shows that there exists a strong luciferase expression signal in the right hemisphere of the brain corresponding to the sonication region (Figure 1B). After harvesting the organs, there is no luciferase expression signal in the organs except the brain. This shows highly specific gene delivery and expression in the brain.

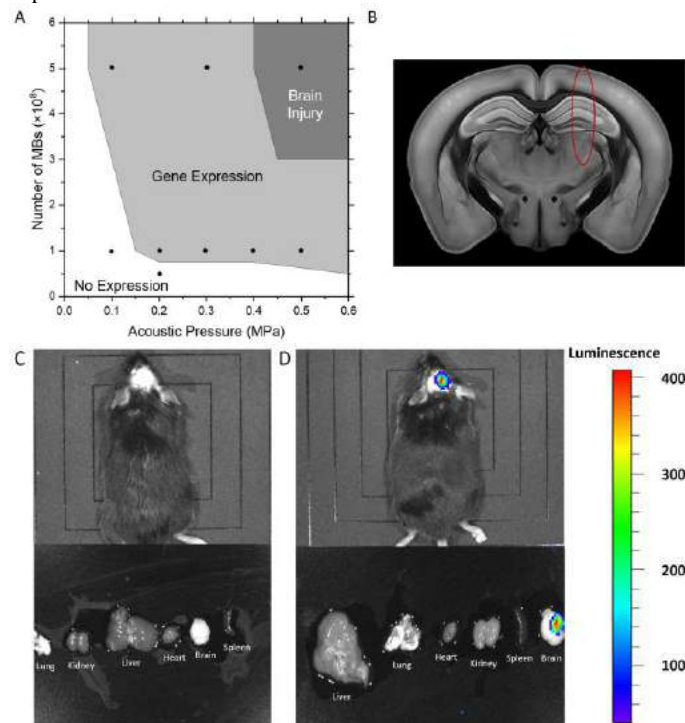

Figure 1: FUS-mediated luciferase plasmid transfection in the brain. (A) Expression efficacy with respect to acoustic pressure and number of MBs. (B) FUS application region. (C) *In vivo* bioluminescent imaging with luciferase expression signal (0.1 MPa, 1×10^8 of MBs). (D) *In vivo* bioluminescent imaging without luciferase expression signal (0.4 MPa, 1×10^8 of MBs)

To test how sonoporation parameters affect BBB integrity, we selected a small molecular dye, fluorescein (330 Da), as a tracer to examine BBB disruption. Figure 2A-B shows that with 0.2 MPa of acoustic pressure and 5×10^8 of MBs, there is an obvious dye leakage in the right hippocampus region with sonication (white arrows). However, when the acoustic pressure or the number of MBs is reduced, we observed no dye leakage, indicating no BBB disruption.

Combining Figure 1A and Figure 2B, there exists an overlap region where the gene is transfected without BBB disruption (Figure 3). In the cases of 0.2 MPa - 1×10^8 and 0.1 MPa - 5×10^8 , the luciferase plasmid is delivered to the brain without opening the BBB. Our ongoing work is to examine whether the plasmid is delivered to brain ECs.

Figure 3: Combination pattern of luciferase plasmid transfection and BBB opening test

DISCUSSION

The development of novel non-invasive gene therapy that modulates brain ECs could significantly improve clinical outcomes for numerous brain disorders. The idea of using MB activation with FUS for local gene delivery to the brain has recently gained traction. Here, we demonstrate that FUS sonoporation can deliver gene plasmid to the brain, and the transfection efficacy depends on sonoporation parameters such as acoustic pressure and MB concentration. Particularly, at optimized conditions (i.e., 0.2 MPa - 1×10^8 or 0.1 MPa - 5×10^8), there is gene expression without BBB disruption. Since BBB integrity is preserved, we will further test the hypothesis that the plasmid is delivered to the brain EC.

VASCULAR REMODELING DURING LATE-GESTATION PREGNANCY: AN *IN-VITRO* ASSESSMENT OF THE MURINE THORACIC AORTA

Ana I. Vargas (1), Samar Tarraf (1), Chiara Bellini (1), Rouzbeh Amini (1,2)

INTRODUCTION

During the nine months of gestation, the maternal body undergoes significant hemodynamic alterations. Such changes are believed to induce structural remodeling of the cardiovascular system [1–3]. During a normotensive human pregnancy, Blood pressure (BP) remains constant, while cardiac output increases (CO), and blood viscosity and peripheral resistance decrease. Combined with the drastic hemodynamic changes, the forces the growing fetus apply on the maternal body cause a burden on the maternal cardiovascular system which can reveal previously undiagnosed cardiovascular problems. Globally, cardiovascular disease (CVD) complicates about 4% of pregnancies [4].

While maternal hemodynamic changes throughout pregnancy have been investigated previously, the changes in the central vasculature during gestation are still unclear. Such a knowledge gap has limited our understanding of the etiology of pregnancy-induced CVD. Towards bridging this knowledge gap, in this study, we aimed to identify biaxial mechanical responses of the murine descending thoracic aorta (DTA) during a normotensive late-gestation pregnancy.

Given the constant BP throughout gestation despite the increase in CO, one could postulate the central vasculature undergoes a remodelling process, while maintaining a homeostatic stress state to accommodate for an increase in blood flow. As such, we hypothesized that DTA wall stress remains unchanged during late-gestation normotensive pregnancies. We also examined whether a murine model mimics clinically measured human data.

METHODS

Pregnant C57BL/6 mice (n=9) at gestation day 18 ± 1 were assigned to the late-gestation group. Nulligravida female mice (n=9) served as the non-pregnant, age-matched controls (10 ± 1 weeks of age). BP measurements were taken using a non-invasive tail cuff system (CODA; Kent Scientific). Mice were euthanized, and the DTA was excised. Samples were mounted onto a custom-made biaxial mechanical testing system, and the passive material properties were measured by performing cyclic pressure-diameter and force-length tests [5]. A four-fiber family constitutive model was fit to

the experimental data via non-linear regression to estimate the constitutive parameters and predict mechanical metrics under *in-vivo* conditions [6]. Additional mice (n=3 for both groups) underwent cardiac echocardiography at the Cardiovascular and Surgical Core, UMass Medical School. Left ventricular volumes at end-diastole and end-systole were derived from m-mode scans. Stroke volume (SV) and heart rate (HR) measurements were used to calculate the CO of each mouse such that

$$CO = \frac{(SV)(HR)}{1000} \quad (1)$$

Data is reported as mean \pm SEM. Unless specified otherwise, Student's t-test was performed to determine statistical significance ($p \leq 0.05$).

RESULTS

In-vivo echo cardiac measurements confirmed up to a 50% increase in CO in late-gestation mice (Fig. 1A). From peripheral BP measurements (Fig. 1B), we did not detect any difference between groups ($p = 0.106$), with systolic and diastolic average values of 118 ± 3 and 89 ± 6 mmHg for control mice and 113 ± 8 and 82 ± 9 mmHg for pregnant mice, respectively.

Figure 1: Hemodynamics measurements of late-gestation pregnant mice and age-matched control mice. (A) CO calculated as seen in equation 1. Statistical significance was assessed by Mann-Whitney-Wilcoxon unpaired sample test ($P \leq 0.05$). (B) Systolic Pressure.

As seen in Figure 2, pregnancy was associated with a rightward shift of the stress-stretch curve in both circumferential (Fig. 2A) and axial (Fig. 2B) directions. This shift suggests that DTA tissues in the pregnant group experience a larger stretch at the same amount of applied stress, indicating material softening.

Overall, material softening, without a significant change in BP, led to a larger circumferential stretch at systolic pressure in the pregnant group (data not shown). Concurrently, at group-specific systolic BP, the pregnant aorta was observed to have a greater luminal diameter (Fig. 3A). The increase in diameter accommodates for the significant increase in the CO observed in Fig. 1A.

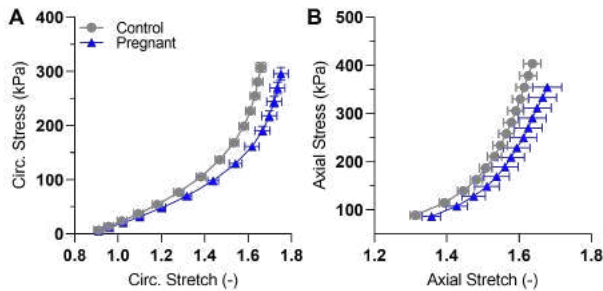

Figure 2: Stress-stretch curves of the DTA of pregnant and control mice for (A) circumferential (Circ.) and (B) axial directions.

At group-specific systolic BP, the intrinsic stiffness of the pregnant aorta was lower than the control aorta in both directions (data not shown. $p = 0.0428$ and $p = 0.0028$, for circumferential and axial directions, respectively). An increase in wall thickness was also observed in the pregnant group (Fig. 3B). However, given the larger luminal diameter at systole in the pregnant aorta (Fig. 3A) and despite no change in pressure observed, aortic distensibility increased during late-gestation (Fig. 3C). Such an increase was coupled by lower structural stiffness of the pregnant tissue. The wall stress, both in the axial and in the circumferential directions, was lower in the pregnant group (Fig. 4).

Figure 3: Geometry of the tissue. (A) Luminal diameter and (B) wall thickness were measured at group-specific systolic BP. (C) Distensibility was calculated throughout the cardiac cycle. *For a significant difference of ≤ 0.05

Figure 4: (A) Circumferential and (B) axial wall stress of pregnant and control DTA tissue. *For a significant difference of ≤ 0.05 .

DISCUSSION

With CVD being the leading cause of maternal death in the US, and maternal mortality rates continuing to rise over the years [7, 8], it is crucial to understand the aortic remodeling process that occurs throughout gestation. Herein, for the first time, we report the functional assessment of the DTA from wild-type mice in the late-gestation period, to characterize changes in the intrinsic wall mechanical properties.

Our first important observation was from the non-invasive measurements of BP and CO in the murine model. The pregnancy-induced increases in the murine CO and the lack of change in the pressure are similar to what occurs in normotensive human pregnancies [9]. As such, wild-type mice were deemed appropriate for studying vascular biomechanics during pregnancy.

With no significant changes in the BP during pregnancy, one would intuitively expect that the $\sim 50\%$ increase in CO is caused by an increase in the luminal diameter of the vessel, which is validated by our measurements. Further, we initially hypothesized that the tissue stress would remain unchanged during pregnancy. With an unchanged pressure and increased diameter, for the stress to remain constant, the vessel has to become thicker (the law of Laplace). We also observed such an increase in the wall thickness. In addition, our findings suggest that the DTA experienced material softening both in the axial and in the circumferential directions (Fig. 2). Such softening occurs potentially to accommodate a larger diameter at similar pressure levels during the late-gestation period.

Surprisingly, despite our initial hypothesis, the aortic wall stress did not remain constant — it decreased significantly — in the pregnant group (Fig. 4). Without further analysis of the micro-structure of the tissue, we can only speculate how the remodeling process led to a decrease in the tissue stress. If the remodeling was to avoid excessive stresses, perhaps the lower stress was an “overshoot” response during the shorter period of late-gestation. We did not conduct any test to examine BP or vascular tissue properties during labor and delivery or during the post-partum period. During labor, an increase in BP caused by excessive pain is possible. The reduced stress and the softening of the tissues could also be a mechanism to prevent vascular damage during labor and delivery and/or during the post-partum period. Finally, we did not examine any of the potential changes in the vascular smooth muscle responses during pregnancy. Our observations were limited, as they only pertain to the *passive* response of the tissue, both for the pregnant group and the nulligravida control group.

Our ongoing research is focused on microstructural changes in the vascular tissues during pregnancy. We aim to combine our biaxial mechanical data, with *ex vivo* multi-photon microscopy imaging to investigate the layer-specific micro-structural parameters of both groups. In addition, we will conduct mechanical testing to identify the active properties of vascular smooth muscle between groups.

MATHEMATICAL DYNAMIC MODELING (MADYMO) OF THE MATERNAL PELVIS AND NEONATE FOR SIMULATING SHOULDER DYSTOCIA AND DELIVERY MANEUVERS

INTRODUCTION

Shoulder dystocia (SD) is an obstetric emergency that occurs when the neonatal anterior shoulder is impacted behind the maternal symphysis pubis [1, 2]. It affects between 0.2 and 3.0% of vaginal deliveries in the United States [3, 4]. Neonatal brachial plexus palsy (NBPP) is caused by stretching the brachial plexus (BP) beyond its elastic limit and can result in loss of arm function [5]. The BP is a network of nerves that span from the C5-T1 vertebrae and throughout the arms, responsible for sensory and motor function of the arms and hands [6].

During SD, sequential maneuvers are performed by the clinician to alleviate the obstruction with minimal injury to the neonatal BP. The mother starts in the supine position and her legs are in stirrups, which is referred to as the lithotomy position. This is treated as the baseline for the purpose of this study. When SD occurs, the first maneuver attempted by the clinician is suprapubic pressure (SPP), in which force is applied to the soft tissue immediately superior to the symphysis pubis bone [7]. This is in effort to compress the neonatal shoulders under the obstruction.

Forces exerted by the mother and clinician, as well as delivery maneuvers performed to manage SD, contribute to BP stretch. Since these injuries are ethically and technically challenging to study in the clinical setting, computational modeling can be utilized. Previous MADYMO studies have laid a foundation for the application to SD and delivery, however the current study aims to fill the gap by enhancing the biofidelity of existing models.

METHODS

To analyze the BP stretch resulting from various delivery maneuvers used to manage SD, Mathematical Dynamic Models (MADYMO, Siemens, version 2020.2) were developed. The models consisted of a series of rigid body ellipsoids to represent the bony

structures of the 90th percentile neonate and 50th percentile maternal pelvis [8]. The maternal pelvis model is shown in Figure 1 as depicted by the grey ellipsoids and the neonate model is shown in the yellow ellipsoids from the MADYMO geometric viewer.

Figure 1: Maternal pelvis (grey) and neonate (yellow) models created from rigid body ellipsoids in MADYMO geometry viewer.

Force-displacement values from an *in vitro* study on neonatal piglet BP were applied to the BP in the model, represented as a 7.5 cm nonlinear spring [9]. The lithotomy position and SPP application were simulated. Endogenous maternal force was measured as the minimum amount of force required to deliver the neonate [10]. Maternal delivery force was applied to the torso of the neonate to simulate contractions and/or Valsalva forces of the uterus. This force was measured by incrementing the force value by 5 N starting at 0 N and observing when the neonate anterior shoulder passes the symphysis pubis. This force value was recorded as the minimum force required by the mother to achieve delivery. BP stretch was measured by the change in length over the original length, as shown in Equation 1, corresponding to the required maternal force in the simulation.

$$\epsilon = \frac{\Delta l}{l_i} * 100 \quad (1)$$

RESULTS

Table 1 shows the results of the baseline lithotomy position with varying magnitudes of SPP. As SPP increased, both required delivery force and BP stretch decreased. This shows a direct relationship between maternal delivery force and BP stretch.

Table 1: Minimum force required by the mother to achieve delivery and brachial plexus (BP) stretch as a result of the lithotomy and suprapubic pressure (SPP) simulations.

Maneuver	Applied SPP Force (N)	Maternal Required Delivery Force (N)	BP Stretch (%)
Lithotomy	0	140	21.52
SPP	40	90	17.97
	100	85	15.74
	140	80	11.26

DISCUSSION

The current study investigates the effects of a SD maneuver, SPP, on the required maternal force and neonate BP. Using models adapted from previous MADYMO studies, SD was simulated, and various forces and maneuvers were applied. The simulated results suggest that increasing SPP force decreases both the required delivery force and BP stretch. SPP is performed to depress and adduct the neonatal shoulders to reduce the obstruction [11].

When 40 N of SPP was applied to the soft tissue of the mother, the required delivery force decreased by 35.7% from the baseline (lithotomy) and BP stretch decreased by 16.5%. With 140 N of SPP, required delivery force further decreased by 42.9% and BP stretch by 47.7%. This shows an inverse relationship between SPP and the required delivery force. Greater expulsive forces acting on the neonate increase the reaction force at the anterior shoulder, therefore increasing BP stretch. In this study, the expulsive forces are the forces generated by the mother, representing contraction or Valsava force. Therefore, there was a direct relationship between the expulsive force and BP stretch observed by the simulations. The observed results align with clinical observation, supporting the biofidelity of the models [12, 13].

The created MADYMO models can allow obstetricians to understand the mechanical effects of various maternal and fetal manipulations on BP stretch and associated injury risk. Future directions include simulating additional delivery maneuvers and utilizing Finite Element models to further advance the computational capabilities [14].

INTRODUCTION

Cardiovascular disease remains the number one cause of death worldwide. Globally, 1 in 4 deaths in 2020 were attributed to cardiovascular disease. [1] A common complication of heart disease is cardiac dyssynchrony caused by left bundle branch block (LBBB). LBBB initiates adverse cardiac remodeling manifested as left ventricular (LV) free wall dilation and hypertrophy. This can lead to progressive cardiac dysfunction and increased mortality [2]. Cardiac resynchronization therapy (CRT) is a groundbreaking pacing treatment typically offered to patients with LBBB and heart failure to improve LV function. CRT uses biventricular pacing to resynchronize the right ventricle (RV) and LV for more efficient pump function. This process can result in favorable (reverse) LV remodeling, thus lowering LV end-diastolic volume (EDV) [3] and resulting in regression in hypertrophy. However, CRT yields suboptimal results in 30-50% of patients, who then continue to experience the adverse effects of cardiac dysfunction and require additional treatments. [4]

Fortunately, CRT response rates can be improved through patient-centered implementation strategies. In fact, there are several crucial elements that can be optimized for each patient, such as the LV pacing lead location, presence of ischemia, pacing mode, and timing of electrical pacing. The abundance of options make it challenging to identify the optimal CRT configuration during the implantation procedure, even though identification of the best option could improve response to the therapy. Moreover, only short-term outcomes, such as QRS duration and ejection fraction, can be measured during the procedure, even though long-term remodeling is of particular interest.

Based on these considerations, we therefore aimed to develop a patient-specific rapid computational model that can predict strain-based reverse cardiac remodeling following CRT. This model has recently been proven to successfully capture the growth caused by volume overload, pressure overload, LBBB, and CRT in canines [5]. In this study, we demonstrate the feasibility of our novel virtual CRT

simulation framework to predict and optimize long-term remodeling outcome for individual human patients using routine clinical data.

METHODS

Rapid electromechanical model of the heart and circulation

The mechanics of the heart and circulation were modeled using our recently published electromechanical model [5]. In brief, a lumped parameter model was used to model the circulation [6] and the TriSeg method was used to model atrioventricular mechanics [7]. The full-field electrical activation timing estimated by the electrical model was averaged into the 16 AHA segment model for the LV and 5 segments for the RV to link it to the mechanical model. (Fig. 1)

Strain-based growth model

Cardiac growth was modeled using a strain-driven volumetric isotropic growth relationship. Using an evolving growth setpoint, the

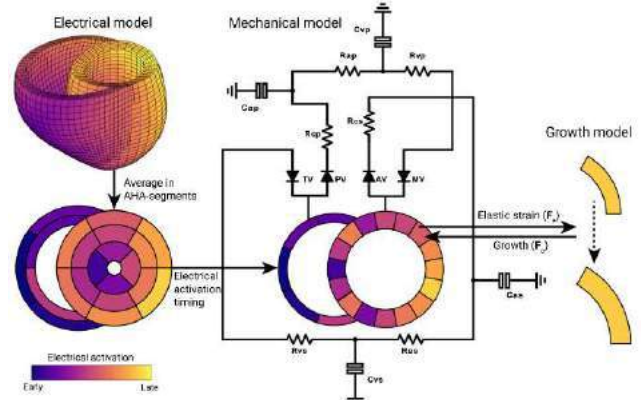

Figure 1: Schematic of the electromechanical framework used to simulate strain-driven cardiac growth following CRT.

Figure 2: Clinical and simulated LV volumes for the calibration patient (responder) and the validation patient (non-responder).

growth stimulus of each segment was calculated individually. The growth stimulus was defined as the deviation of the maximum elastic circumferential strain throughout the current cardiac cycle ($E_{cc,max}^i$) from the current growth setpoint. The initial setpoint was the maximum circumferential strain at the pre-CRT baseline $E_{cc,max}^{i=0}$, then the setpoint was allowed to evolve based on a moving-average time window of 90 days. The growth stimulus was then entered into a standardized sigmoid growth curve to calculate the incremental growth of each individual segment throughout the simulation.

Model personalization

We personalized our model to two patients treated with CRT (one responder and one non-responder) using routine clinical data. Both patients were female and had non-ischemic heart failure and LBBB. Allometric scaling laws based on body surface area were used to set arterial and venous resistances and capacitances [8]. Heart geometry was derived from cardiac MRI data, and electrical activation timing from 12-lead ECG data. Active and passive constitutive properties were held constant across all simulations, derived from a previous study using canine data [9]. Heart rate was set to directly match the daily heart rate measured by the patients' CRT device.

Calibration and validation of the growth model

The growth model was calibrated for the CRT responder and then validated using the non-responder. The strain-based growth model was calibrated by simulating 6 months of post-CRT cardiac growth and iteratively adjusting the sigmoid parameters to match LV end-diastolic (LVEDV) and end-systolic volume (LVESV). Subsequently, the growth model was validated by simulating 6 months of post-CRT growth for the non-responder using the fitted growth parameters.

RESULTS

We successfully personalized our model to match the pre-CRT states for the two non-ischemic LBBB patients. These two baseline patient models were then used to capture the overall remodeling response to 6 months of CRT pacing, simulated in under 30 seconds on a laptop computer. The calibration growth simulation was able to adequately capture the reduction in LVESV and LVEDV for the responder (Fig. 2). The calibrated model was then able to correctly predict non-response in the other patient, i.e., absence of substantial reduction in LVESV and LVEDV. Post-CRT stroke volumes for both patients were overestimated.

Additionally, we predicted the change in LVEDV (Fig. 3) and LVESV that would occur for each patient with varying lead locations. Interestingly, our model predicted that both patients could have had a

Figure 3: Change in EDV during 6 months of CRT pacing with varying lead locations throughout the 16-segment left ventricle. *Actual lead location selected during implantation

more beneficial degree of reverse remodeling with a different lead location selected. Most importantly, the non-responding patient could have achieved up to a 28% reduction in EDV when pacing from either the mid inferolateral or mid anterolateral segment, thus resulting in a beneficial CRT response.

DISCUSSION

The goal of this study was to create a patient-specific, rapid computational model that can simulate reverse remodeling during CRT. The model was successfully calibrated to data from one patient and able to predict remodeling response for another patient. Moreover, we demonstrated the potential of the model to identify the optimal lead location for individual patients. Most excitingly, our model indicated that a positive response would have been possible for the clinically non-responding patient if a different lead location had been chosen.

The current study has two main limitations. First, hemodynamics, such as blood volume and vascular resistance, were only matched at baseline and held constant throughout the growth simulation. With evolving hemodynamics that match clinical data, the predicted stroke volumes could potentially be more accurate. Second, currently only two case studies were used. We will continue training and testing our model to a larger population of ischemic and non-ischemic LBBB patients to further increase our confidence that this model can predict the reverse remodeling that occurs during CRT, while also potentially determining how ischemia affects prediction accuracy.

By calibrating and validating this framework [5] with data from two non-ischemic CRT patients, we were able to demonstrate the feasibility of our model to predict patient-specific CRT response. This is an important step in creating a valuable clinical tool to identify the best CRT treatment strategy for each patient before clinicians reach the operating room.

INTRODUCTION

As the bearing material of diarthrodial joints, the primary function of cartilage is to support varying loads while sustaining joint lubrication in order to mitigate adhesion and maintain low friction. However, the sound one commonly hears in ‘joint cracking’ is a result of interfacial tension between joint surfaces with sufficient strength to produce an audible noise during contact separation¹. This leads to a contradiction: *low friction* and *high adhesion*. How can cartilage simultaneously exhibit high-lubricity and high-adhesion? Cartilage lubrication has been studied extensively over the past several decades. Yet, there remains a lack of research on cartilage adhesion. The presence of these inherent contradictory mechanisms begs the question: *what is the fundamental role of adhesion in cartilage?* Using instruments unique to this lab, the aim of this experimental study is to quantify these adhesive effects during cartilage contact separation and elucidate the possible implications of adhesion on lubrication and joint biomechanics.

METHODS

Using a coring drill N = 5 full thickness 19mm diameter osteochondral plugs were extracted from the femoral condyles of mature bovine stifles obtained from a local abattoir. Samples were rinsed and stored in 1X PBS containing 1X protease inhibitor at 4°C and tested within 24 hours of extraction. Each sample was subjected to two series of indentation experiments. The first series of measurements focused on retaining interstitial tissue hydration by eliminating dwell times that lead to tissue depressurization. Using a cantilever beam outfitted with a ϕ 6.35mm

borosilicate glass probe, cartilage samples were indented to six randomized indentation depths between 20 and 200 μm , at a 10 $\mu\text{m/s}$ constant indentation rate. After the target deformation was reached the probe immediately retracted at 10 $\mu\text{m/s}$. The second series of measurements focused on systematically varying fluid exudation. Using the same probe, samples were indented to five randomized indentation depths between 20 and 200 μm , at a 10 $\mu\text{m/s}$ constant indentation rate and held for dwell times of 0 s (fully hydrated), 10, 50, 100, 300, 600, and 900s (equilibrium). After each dwell time period, the probe was immediately retracted at 10 $\mu\text{m/s}$. The first series of measurements (effects of indentation depth) were repeated with dry and hydrated silicone on glass, as a measurement of strong adhesion. Data Analysis: The force produced at the cartilage interface is attributed to the culmination of adhesive forces (F_a), solid forces (F_s) and fluid forces (F_f):

$$F_n = (-1.5\pi \cdot R \cdot \Delta\gamma) + \left(\frac{4}{3} \cdot E_{c0} \cdot R^{0.5} \cdot \delta^{1.5}\right) + \left(\frac{4}{3} \cdot \frac{\dot{\delta} \cdot R^{1.5} \cdot \delta^{1.5}}{k}\right) \quad (1)$$

The probe radius (R) and deformation rate ($\dot{\delta}$) are known variables, while deformation (δ) and pull-off force (F_n) are measured, and work of adhesion ($\Delta\gamma$) and interfacial permeability (k) are fit to Eq. 1. Furthermore, the maximum interfacial tensile stress (σ_{max}) was calculated as a function of the interfacial force (F_n) and the Hertzian contact area (A_c):

$$\sigma = \frac{F_n}{A_c} = \frac{F_n}{\pi \cdot \delta \cdot R} \quad (2)$$

RESULTS

Raw force-deformation data from a representative sample from the first series of measurements is plotted in Fig. 1A. The pull-off force necessary for separation *increased* with indentation depth. The loading curve from the first measurement series was fit to Eqs. 1 and 2 and gave values of 0 mJ/m², 0.074 MPa and 0.012 mm⁴/Ns, for the work of adhesion ($\Delta\gamma$), max interfacial stress (σ_{max}) and

compressive permeability (k_c), respectively (Fig. 1A).

Figure 1: The effects of indentation depth on pull-off force. (A) The loading response was fit to Equation 1 in order to quantify work of adhesion ($\Delta\gamma$) and permeability (k). The work of adhesion and permeability during loading was calculated to be 0 mJ/m² and 0.012 mm⁴/Ns, respectively. Using Equation 2, the maximum interfacial tensile stress (σ_{max}) was calculated to be 0.074 MPa. **(B)** The unloading response was also fit to Equations 1 and 2, and gave work of adhesion, permeability and interfacial tensile stress values of 0 mJ/m², 0.034 mm⁴/Ns and 0.010 MPa, respectively.

The unloading data re-illustrated in terms of positive values (Fig. 1B), was fit and gave values of the work of adhesion ($\Delta\gamma$), max interfacial tensile stress (σ_{max}) and tensile permeability (k_t) as 0 mJ/m², 0.010 MPa and 0.034 mm⁴/Ns, respectively.

Similarly, in the second series of measurements varying dwell time, the pull-off force increased with deformation. The loading curve from the second measurement series, looking at the effects of dwell time, was fit to Eqs. 1 and 2 and gave values of 0 mJ/m², 0.26 MPa and 0.0021 mm⁴/Ns, for the work of adhesion ($\Delta\gamma$), max interfacial stress (σ_{max}) and compressive permeability (k_c), respectively (Fig. 2A). The unloading data re-illustrated in terms of positive values (Fig. 2B), was fit and gave values of the work of adhesion ($\Delta\gamma$), max interfacial tensile stress (σ_{max}) and tensile permeability (k_t) as 0 mJ/m², 0.058 MPa and 0.061 mm⁴/Ns, respectively.

Figure 2: (A) The effects of dwell time on pull-off force. **(A)** The loading response was fit to Equation 1 in order to quantify work of adhesion ($\Delta\gamma$) and permeability (k). The work of adhesion and permeability during loading was calculated to be 0 mJ/m² and 0.0026 mm⁴/Ns, respectively. Using Equation 2, the

maximum interfacial tensile stress (σ_{max}) was calculated to be 0.26 MPa. **(B)** The unloading response was also fit to Equations 1 and 2, and gave work of adhesion, permeability and interfacial tensile stress values of 0 mJ/m², 0.061 mm⁴/Ns and 0.058 MPa, respectively.

Within the silicone on glass contacts, the dry glass on silicone contact resulted in consistent pull-off forces of ~0.0007 N across all deformations. This corresponded to a work of adhesion of ~42 mJ/m², which is consistent with what has been reported in the literature. When the silicone was hydrated, the interface produced zero pull-off forces and zero work of adhesion, which is expected of classically adhesive materials. Comparing the trend of the cartilage to the silicone contacts, it is visually clear that there is a deviation in the behavior of the materials (Fig. 3).

Figure 3: Pull-off forces as a function of deformation. Representative data from the indentation depth and dwell time experimental conditions is plotted with representative glass on silicone datasets under dry and hydrated conditions.

DISCUSSION

This study demonstrates that cartilage exhibits significant interfacial tension. While protected by maximal interstitial hydration (0 sec dwell), cartilage still adhered to the glass probe with appreciable strength to generate detectable pull-off forces. The increased pull-off forces with the increased dwell times indicates that the tissue is exuding fluid, and thus closing the interfacial gaps and increasing contact area. In addition to the zero works of adhesion, the relative permeability observed during the loading and unloading responses also indicate that suction, rather than adhesion, is a dominating force. For both experimental conditions, within each sample, the permeability during loading was comparable, however slightly smaller, than the permeability during unloading. The magnitude of these relative permeabilities suggests that interstitial flow within the tissue was a major contributor to this response. In other words, this suggests that the interface was well-sealed—a requirement for suction. Additionally, the slightly higher effective permeability during unloading is also consistent with the fact that tension expands interfacial and interstitial gaps. This data suggests that suction is driving interfacial tension, creating an interfacial seal and increasing interfacial pressurization needed to drive flow for lubrication.

INTRODUCTION

Characterizing the mechanical properties of cells and biological tissues is of critical importance as the mechanical properties reflect the physiological state and integrity of tissues and may serve as hallmarks of diseases such as cancer, calcification, and atherosclerosis (1,2). While most biological tissues and many cell types are highly mechanically anisotropic, many studies, especially studies in microscale and mesoscale, assume samples to be mechanically isotropic often due to the technical difficulties in measuring anisotropic stiffness of cells and microtissues. This oversimplification does not accurately reflect the mechanical properties of cells and micro tissues and may bias the interpretation in tissue mechanics and mechanobiology.

Indentation is one of the most common methods for measuring mechanical properties of biological tissues and cells. Conventional indenters are equipped with spherical, conical, or pyramidal probes which do not yield information related to mechanical anisotropy. Several recent studies have proposed solutions to this problem. However, these methods require complicated image analysis or samples to be prepared into specific shapes (3,4,5). Moreover, most studies are focused on macro level tissue properties; studies on the mesoscale and cell level are limited. A straight-forward indentation method for the measurement of anisotropic mechanical properties is needed.

Here, we propose a method to measure anisotropic stiffness of microtissues and cells by two indentations in orthogonal directions using our novel toroidal probe. Our preliminary results indicate that this approach is applicable in measuring anisotropic stiffness of aligned tissues and cells. This method will provide researchers with a simple and cost-effective means for measuring mechanical anisotropy of micro-scale samples.

METHODS

The mesoscale toroidal probe tip was designed to be 20 μm in cross-section radius and 100 μm in ring radius, the microscale probe tip

Figure 1. A schematic brief procedure of manufacturing the toroidal probe tip

was designed to be 2 μm in cross-section radius and 10 μm in ring radius. The tip was manufactured using a Naonoscribe GT two-photon 3D printer (Fig. 1). Briefly, the probe tip with supporting stage and base was created in CAD then translated to executable codes with printing parameters optimized for smoothness of the tip surface. A drop of negative photoresist resin was applied onto the cleaned substrate mounted on the device. In the printing, the two-photon laser scans over 3D space according to the code to polymerize the resin at the focal point. After printing, the base was detached from the substrate using a fine tweezer and flipped over under the microscope. A tipless probe was mounted to the nanoindenter (Optics11, Amsterdam), dabbed with UV-curing glue at the end of the cantilever, then lightly touched the bottom of the base. The glue was cured under the UV light for 30 minutes (Fig. 1). The probe was visually inspected using optical and scanning electron microscopy (Fig. 2).

Chicken breast was used for meso-scale indentation study. The sample was dissected and transferred to a 100 mm-petri dish filled with PBS (Fig.3, left). Porcine aortic valvular interstitial cells (PAVICs) were used in cell indentation study. To grow aligned cell monolayers, parallel scratches were made in 35-mm petri dishes, 100,000 cells were seeded. And the cells were cultured for 6 days to form an anisotropic monolayer (Fig.3, right).

Figure 2. Optical and scanning electron microscopy images of microscale probe and its toroidal tip. The probes were manufactured in accurate size, shape, and smooth surface.

Before indentation, the chicken breast was lightly pressed by a tweezer to avoid floating. Indentation speed was set to be 10 $\mu\text{m/s}$ until 50 μm max indentation depth. For the cell sample, the cell culture media was changed to complete L-15 medium to maintain a stable pH. The cells were aligned to the probe under a Nikon TS-100 inverted microscope. Indentation speed was set to 1 $\mu\text{m/s}$, with 500 nm maximum indentation depth. The force-indentation curves were recorded and fit to the Hertzian model for elliptical contact, in which the effective Young's modulus (E^*) is calculated by

$$E^* = \frac{3F}{4d^{3/2}R_e^{1/2}}f_2^{3/2}(e) \quad (1)$$

where d is indentation, F is force; $R_e = \sqrt{R_1 R_2}$ is the equivalent radius of the probe tip; $f_2(e)$ is an empirical function of the eccentricity of the ellipse (~ 1 for an aspect ratio of 5) (6). Two chicken breasts and one PAVIC monolayer were indented at multiple sites along (0°) and across (90°) the fiber direction. For PAVICs, the indentation data of top 50% stiffness was filtered to rule out the samples affected by substrate effect. Statistical comparisons were made using t-test, $p < 0.05$ is considered significant.

Figure 3. Anisotropic biological materials tested. Left: chicken breast shows clear fiber orientation. Right: PAVICs align in the direction of the scratches (arrowheads) to form an aligned monolayer.

RESULTS

As predicted, chicken breast samples have a higher effective Young's modulus when the long axis of probe is perpendicular to the fiber direction of the chicken breast (90°) compared to the indentation in parallel direction (0°) on both samples ($p < 0.05$). In the two samples, the moduli across the fiber direction were 3.45 ± 2.12 kPa, and 3.70 ± 2.17 kPa, while the moduli at 0° were 2.35 ± 1.27 kPa and 2.17 ± 1.28 kPa (Fig. 4, left).

Similarly, for the indentation test on PAVICs, we found a trend toward higher modulus at 90° (7.22 ± 2.01 kPa) than at 0° (5.84 ± 1.86 kPa) ($p = 0.07$, n.s.) (Fig. 4, right).

DISCUSSION

Measuring the anisotropic properties of biological materials is not readily possible with indentation testing, especially at the cell level. Previous studies trying to resolve this problem are mostly limited to

macro samples, and commonly require high-resolution live imaging to measure the non-uniform strain field or samples of specific shapes (3-5). The one study to date reporting a measure of cell anisotropy using indentation requires live confocal microscopy and inverse finite element analysis (4). Here, we present a method to measure the mechanical anisotropy of cells and tissues by two orthogonal indentations without the need for microscopy or sample of specific shapes which allows for rapid measurement of samples *in vivo*. Importantly, our method can be performed by most of the existing indenters and AFMs at a low cost. The cost of each probe tip is less than \$5 for the mesoscale probe, and \$40 for the micro probe.

Figure 4. Effective Young's modulus of a chicken breast (left) PAVICs (right) measured in two orthogonal directions (* $p < 0.05$).

In this study, we used chicken breast and PAVICs as the samples. Both samples show higher effective Young's modulus across the fiber direction than along the fiber direction. This result is consistent with previous studies (4,7). While indentation on chicken breast shows significant difference in two directions, the difference is not significant in the case of PAVICs. This may reflect a different degree of anisotropy of PAVICs and chicken breast or simply the low sample size in these pilot tests. Probes of higher anisotropy ratio may be needed for samples with lower degree of anisotropy.

One limitation of this study is that the modulus is calculated based on Hertzian contact theory which assumes materials isotropy and linear elasticity. To our knowledge, there is no analytical solution for the indentation problem on anisotropic materials. In the next step of the study, we plan to apply FE modeling to extract the mechanical parameters based on the indentation curves either with inverse methods or with forward modeling and machine learning.

In conclusion, we created a novel method for measuring anisotropic stiffness of biological samples. This method is simple, cost-effective, and can measure small samples down to the cell level. We expect this method will be of use to researchers in biomechanics, biophysics, and mechanobiology.

A MACHINE LEARNING APPROACH TO ESTIMATE SIZE AND LOCATION OF MYOCARDIAL INFARCTION

RR. Mehdi (1), EA. Mendiola (1), R. Avazmohammadi (1,2)

(1) Department of Biomedical Engineering, Texas A&M University, College Station, TX, USA
(2) Department of Mechanical Engineering, Texas A&M University, College Station, TX, USA

INTRODUCTION

Myocardial infarction (MI), due to the blockage of coronary arteries, is a leading cause of death in the US and worldwide [1]. The size of chronic scar in MI adversely affects cardiac function; however, several studies have pointed out that chronic scar formation in MI may remain undiagnosed in a large part of MI incidences [2]. Cardiac scar size and location in MI can be identified using cine cardiac magnetic resonance imaging (CMR) with late gadolinium enhancement (LGE) [3]. LGE imaging based on a gadolinium-based contrast agent identifies matured infarcted regions by bright image intensity. However, LGE has some limitations including accumulation of gadolinium in tissues and prolonged scanning time which limit its scope and safety in time-sensitive clinical applications. Furthermore, the gadolinium-based imaging process may be dangerous to chronic end-stage kidney patients and approximately 20% of the patients who suffer from acute MI also have chronic kidney disease [4]. And, perhaps more importantly, LGE requires CMR which is not a feasible imaging modality at all health centers even in developed countries. Therefore, a less invasive and more feasible method to identify infarct region characteristics will assist in reducing undiagnosed MI cases.

In this work, we developed a machine learning (ML) model to identify the location and extent of infarcted myocardium by employing cardiac strains that are feasibly obtainable from routine CMR scans and very possibly from echocardiography. We implemented a pipeline that takes raw CMR scans and calculates 4D (3D space plus time) strains. The 4D strains were used in the ML as inputs to predict the location and extent of infarct regions. Our results suggest that our framework can learn the relationship between the strains and labeling of infarcts and be used as an efficient and reliable tool to identify infarct regions.

METHODS

The 3-D reconstructed heart geometry from CMR scans was truncated under the valve plane and meshed using quadratic tetrahedral

elements as shown in Fig. 1a. An inverse problem was set up for a biventricular finite element (FE) model to estimate the passive material properties of the infarct and remote regions from the biaxial test result. Organ-level inverse simulations were performed to estimate animal-specific active tension by replicating pressure-volume measurements using inverse modeling. Details of estimating active and passive material properties are described in [5]. We developed a large database of semi-synthetically finite-element heart models covering numerous possibilities of MI region location and shape (Fig 1b). The endocardium surface was pressurized with a pressure wave of maximum amplitude of 7.5 mmHg. The average Green strains were computed at each segment according to American heart association (AHA) segmentation (Fig 1c) in circumferential, longitudinal, and radial directions.

Fig 1 (a) Biventricular FE model (b) Examples of randomly generated infarcts (c) AHA segmentation of the left ventricle.

A 17×3 image was constructed using 17 AHA segments and three anatomical strains (circumferential, longitudinal, and radial) for each segment. This image was provided to the convolutional neural network (CNN) ML model to identify size and location of infarct regions (Fig 2). We built a binary array with the same size of the number of segments

as labels in which 1 is infarct and 0 is non-infarct. Hundred examples with different sizes and locations of infarcts were generated to train the model. Leave-one-out cross-validation technique was utilized to reduce the variance with a limited number of examples. As the number of non-infarct regions was higher than the infarcted regions, the weights imbalance classification was applied, and weights were calculated and distributed at the time of training the CNN model.

Fig 2: Convolutional neural network model architecture.

The performance of our CNN ML model was evaluated by the following parameters:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN}$$

$$Sensitivity = \frac{TP}{TP + FN}$$

$$Precision = \frac{TP}{TP + FP}$$

$$F1 - score = \frac{2 \cdot TP}{2 \cdot TP + FP + FN}$$

Here TP (True Positive) means correctly detected infarct, TN (True Negative) is being identified as correctly detected non-infarct, FN (False Negative) identified infarct when the infarct was present and model did not detect, and FP (False Positive), means infarct was not present, but ML model detected infarct.

RESULTS

The inverse modeling with estimated active and passive parameters and appropriate fiber architecture provided the end-systolic strain as shown in Fig. 3. The ML model utilized these cardiac end-systolic strains in the left ventricle (LV) to locate infarct in the LV. The performance of the ML classifier was demonstrated in the form of a confusion matrix. Our approach accurately classified the infarcted regions from the normal tissues (Fig. 4). We achieved 94.59% accuracy, 0.98, 0.96, and 0.97 sensitivity, precision, and F1-score, respectively.

Fig 3: Examples of (a) Circumferential (b) Radial (c) Longitudinal strains.

VALIDATION

We validated our proposed model by comparing the ML predictions with ground-truth measurements by LGE imaging in MI human patients (Fig 5). We used our in-house diffeomorphic image registration to

calculate 4D strains (3D + time) using only short-axis slices. End-systolic strains at each segment of AHA segmentation were provided to the ML model to classify the infarcted region which is compared with the LGE imaging to obtain the accuracy of our model. Our results suggest that ML model can delineate the MI using cardiac strains (from cine CMR or echocardiography) without using a contrast agent which shows the ability of the ML model to provide timely interpretations for clinical follow-up.

Fig 4: Confusion matrix to locate infarct.

Fig 5: LGE CMR of an MI patient.

DISCUSSION

In this work, we developed a CNN-based ML model to accurately delineate the infarct regions in the LV. For this purpose, the FE simulation-based pipeline was created to mimic the function of the heart (representing the virtual twin of the in-vivo heart) and end-systolic strains were used to train the model. Once the model is trained from the FE simulations at different infarct sizes and locations, it can estimate the infarct regions with high accuracy directly from common imaging modalities, including CMR and echocardiography. Furthermore, we did not use the large dataset of human CMR to train the ML model in contrast to other existing methods that rely on a large CMR database to train the ML. Instead, we used synthetically obtained FE simulations. To the best of our knowledge, this is the first time a ML model to locate infarct location is trained using affordable FE simulations and directly applied to the human images slices. We are currently extending our model to accurately locate infarcts in very small segments and determine their transmural depth.

A THERMODYNAMIC FRAMEWORK FOR SARCOMERE FORMATION IN CARDIOMYOCYTES SPREAD ON MICRO-PATTERNED SUBSTRATES

Ryan J. Coleman (1), Vikram S. Deshpande (2), Patrick McGarry (1)

(1) Department of Biomedical Engineering, University of Galway, Galway, Ireland
(2) Department of Engineering, University of Cambridge, Cambridge, UK

INTRODUCTION

Identification of in-vitro protocols to develop mature cardiomyocytes (CMs) with ordered sarcomeric structures and aligned myofibrils remains a key challenge in the field of cell and tissue engineering [1,2]. An experimental study by Ribeiro et al. [3] reports that human pluripotent stem cells (hPSCs) develop highly aligned sarcomeres when spread on high aspect ratio (7:1) rectangular micro-patterned ligand patches. However, cells spread on square patches do not develop sarcomeres, instead developing unaligned stress fibers (SFs). The mechanism underlying the differentiation of hPSCs to mature CMs as a function of cell aspect ratio is not understood. This deficiency in fundamental understanding presents a significant barrier to the development of robust strategies for cardiac tissue engineering.

We propose a novel thermodynamically based theoretical model for sarcomere and SF formation within a cell. We develop a statistical mechanics framework to simulate the spreading of cells on square and rectangular adhesive patches and quantitatively compare our model predictions to experimentally measured levels of sarcomere formation.

METHODS

We consider that cytoskeletal proteins can exist in three states within a CM: they can be (i) bound as part of a SF, (ii) bound as part of a structured sarcomere, or (iii) unbound within the cytoplasm. Figure 1 shows the corresponding energy landscape; highly structured sarcomeres have a higher ground-state enthalpy than loosely structured SFs. However, sarcomeres generate higher levels of active contractility than SFs.

At steady-state conditions the chemical potentials of all three states are in equilibrium. We derive the chemical potentials to have the following forms: unbound proteins $\chi_U = \frac{\mu_U}{n^R} - T \frac{\partial \Delta S_U}{\partial \hat{N}_U}$, bound SFs

$$\chi_{BF} = \frac{\mu_B}{n^R} - T \frac{\partial (\Delta S_{BF} + \Delta S_U)}{\partial \hat{N}_{BF}}, \text{ and bound sarcomeres } \chi_{BS} = \frac{\mu_H}{n^R} -$$

$T \frac{\partial (\Delta S_{BS} + \Delta S_U)}{\partial \hat{N}_{BS}}$. Change in organizational entropies are computed as ΔS_U , ΔS_{BF} and ΔS_{BS} . n^R is the number of contractile units within a representative volume element (RVE) and T is the cell temperature. Conservation of cytoskeletal proteins within the CM enforces that $\hat{N}_U + \hat{N}_{BF} + \hat{N}_{BS} = 1$, where \hat{N}_{BF} and \hat{N}_{BS} are the fraction of proteins bound in SFs and sarcomeres, respectively, and \hat{N}_U is the fraction of unbound proteins. The areal density of sarcomeres at any point within the cell is given as

$$\hat{n}_S = \frac{\frac{1}{\hat{n}_S} (\xi_1 - \hat{N}_{BF}) (\hat{N}_U + \hat{N}_{BF}) \exp \left(-\hat{n}_S \frac{\mu_H - \mu_U}{k_B T} \right)}{\xi_1 + (\hat{N}_U + \hat{N}_{BF}) \exp \left(-\hat{n}_S \frac{\mu_H - \mu_U}{k_B T} \right)}, \quad (1)$$

where \hat{n}_S is number of sarcomeres in series within a myofibril and ξ_1 is the maximum local concentration of sarcomeres. A similar expression is derived for the concentration of SFs within the cell.

Figure 1: Energy landscape for unbound cytoskeletal proteins, SFs and sarcomeres.

In our statistical mechanics finite element framework, we simulate a cell spreading on a micro-patterned ligand patch by analyzing over two million spread states with incremental deformations between states tested through MCMC walks [4]. For each potential new cell state we calculate the Gibbs free energy, which consists of contributions from sarcomeres, SFs, and the deformed passive cell cytoplasm. Importantly, as the cell spreads and elongates, sarcomere formation results in a reduction in Gibbs free energy. However, such cell elongation results in stretching of the passive hyperelastic cell cytoplasm, resulting in an increase in Gibbs free energy. The potential new spread state is accepted if this energetic competition leads to an overall reduction in Gibbs free energy relative to a reference state. We develop a nested sampling framework to impose a homeostatic constraint such that the mean Gibbs free energy of the ensemble of spread states is equal to the reference state of a suspended cell [5]. Simulations are performed on rectangular ligand patches of aspect ratios 1:1, 3:1, 5:1 and 7:1 for direct comparison with in vitro experiments [3]. Each simulation requires 24 hours using 40 processors using a high-performance machine at the Irish Centre for High-end Computing (ICHEC).

RESULTS

A sample of computed spread cell states are shown in Figure 2 for CMs spread on rectangular ligand patches. Highly aligned dense sarcomere structures are predicted for a cell spread on a 7:1 rectangular patch. In contrast, for a cell spread on a square patch our model predicts a low-density of sarcomeres with low levels of myofibril alignment. Experimental images of Ribeiro et al. [3] are shown for comparison, exhibiting a similar trend to our model predictions.

Figure 2: Sample of predicted CM spread states on rectangular ligand patches. All computed states shown are within one standard deviation of the homeostatic free energy. Predicted sarcomere orientations shown by red quivers (thickness of quiver scales with computed sarcomere density). Experimental results adapted from Ribeiro et al. [3] are shown for comparison.

Figure 3A shows that the computed level of sarcomere formation increases with aspect ratio, in agreement with experimental measurements. Figure 3B shows the computed distribution of sarcomere orientations as a function of patch aspect ratio. Again, strong agreement with experiments is observed, with elongated CMs exhibiting higher levels of alignment. Our model uncovers the following mechanism: Gibbs free energy decreases with increasing sarcomere density. Sarcomere areal density exponentially increases with in series units (equation 1), driving an increase in sarcomere length. Such an increase

in sarcomere length is facilitated by elongated cells (e.g. 7:1 rectangle), but not facilitated by isotropically spread cells (e.g. 1:1 square) of a similar spread area.

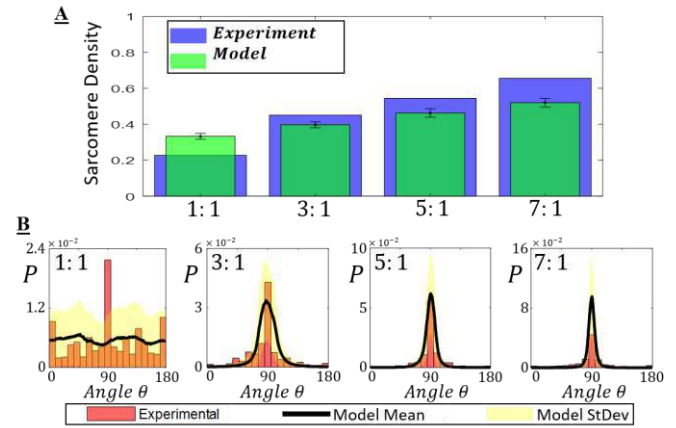

Figure 3: (A) Computed sarcomere density (mean±SD) as a function of ligand-patch aspect ratio. (B) Computed sarcomere distribution (alignment) as a function of ligand-patch aspect ratio. Experimental results (Ribeiro et al. [3]) shown for comparison.

DISCUSSION

We present the first thermodynamically based theoretical model for sarcomere formation in CMs, and we implement this model in a novel statistical mechanics framework to simulate cells spreading on micro-patterned ligand patches. Decreased Gibbs free energy is driven by sarcomere formation as cells spread into highly elongated states. Our model predictions are in strong agreement with the experimental observations of Ribeiro et al. [3]. The mechanism of sarcomere formation uncovered by our model can be used to guide in-vitro strategies to generate mature contractile CMs. As an example, high aspect ratio tissue constructs and electro-spun collagen scaffolds could be designed using our modelling framework to optimize sarcomere formation [6]. Additionally, our model can be used to simulate multi-axial dynamic loading of CMs and cardiac tissue. Optimal dynamic loading regimes to promote sarcomere formation can potentially be identified using our model [7]. Finally, our framework can be implemented into finite element models of a beating heart to predict the influence of a range of pathologies (e.g. hypertension) on remodeling of sarcomeres in vivo [8].

TOWARDS ENHANCED NON-INVASIVE ASSESSMENT OF BLADDER URODYNAMICS - VALIDATION OF DYNAMIC 3D MRI IN A PATIENT-SPECIFIC IN VITRO MODEL OF THE BLADDER

INTRODUCTION

Lower urinary tract symptoms (LUTS) and changes in bladder function occur as individuals age¹⁻³. Patients with LUTS are evaluated through multi-channel urodynamic studies to determine bladder flow and pressure during voiding and filling to gain insight into the progression and severity of symptoms²⁻³. However, these tests are invasive, time-consuming and provide limited flow visualization or insight into anatomical changes as the bladder contracts or expands. To combat this, recent efforts have focused around utilizing MRI to determine bladder volume and flow. Information obtained from MRI can be used to drive computational fluid dynamics (CFD) to analyze flow, pressure, and wall motion³. In either case, validation of these techniques in a bladder-mimicking in-vitro model remains an unmet need. In-vitro flow studies are recognized as the gold standard for flow-based MRI and CFD validation⁴. Using in-vitro models, systematic control of anatomy and flow conditions can be reached. Models can also be evaluated with higher resolution optical imaging techniques, such as particle image velocimetry (PIV).

The aim of this study was to develop an MRI- and PIV-compatible patient-specific, in vitro model of the bladder to validate a real-time volumetric MRI protocol. 3D volumes of the bladder were acquired during voiding and filling tests. Simultaneous acquisition of pressure data at the bladder outlet was obtained. Finally, fluid velocity was measured using 2D phase-contrast (2D-PC) MRI at the bladder outlet to validate the flow rate calculated from 3D dynamic MRI, demonstrating this study as an effective first step towards enhanced validation of novel 3D MRI urodynamics.

METHODS

In this IRB-approved, HIPPA compliant study, a healthy, 37-year-old subject was recruited to void in the scanner during a 3D MRI acquisition. A flexible, transparent in-vitro patient-specific model of the bladder was constructed using a hybrid additive manufacturing process.

The full bladder was segmented from the 3D MRI dataset to produce a stereolithography (STL) model. Using the model, a negative mold was generated representing a larger version of the bladder and printed in two halves using a desktop stereolithography printer (Formlabs, Somerville, MA). A positive bladder “core” was 3D-printed in water-soluble polyvinyl alcohol (PVA) (Ultimaker, Utrecht, Netherlands). The core was placed in the mold where it was cast in silicone and cured. The mold was designed so that the mean thickness of the model wall was 4mm, representing the thickness of the bladder wall⁵. Once the silicone cured, the bladder core was dissolved, leaving an anatomically realistic hollow bladder (Figure 1).

The transparent model was connected to a syringe pump (Chemyx, Stafford, TX). 6.35 mm tubing was connected to the outlet of the bladder representing a urethra. Water was injected or withdrawn from the system at various flow rates to simulate bladder voiding and filling like bladder cystometry⁶. The bladder was placed in a 3.0T MRI scanner (GE Healthcare, Waukesha, WI) where real-time volumetric, and 2DPC, MRI data were acquired. An MRI-compatible, fiber-optic pressure transducer (OPP-M200, Opsens Inc., Québec, CA) was fed into the bladder during MRI acquisitions to obtain pressure measurements during each event (filling and voiding).

MRI and pressure data were analyzed using a custom Matlab script to calculate bladder volumes, pressure, outlet velocity, flow rate and bladder work. 100 sets of images were acquired using volumetric MRI during tests with a time resolution of 1.65 seconds and spatial resolution of 1.0 mm. A semi-automatic segmentation process was used to determine bladder volume. 2DPC MRI data were reconstructed with a time resolution of 1.35 seconds and 1.0 mm spatial resolution. Pressure measurements were acquired at 100Hz, smoothed using a low-pass filter, and resampled to match the time resolution of the volumetric MRI data. The difference in volume at each time was used to approximate volume flow rate and compared to the imposed flow rates.

Figure 1: (A) Schematic of in-vitro fabrication method used to make physical model. (B) Silicone model before dissolving bladder core. (C) MRI- and PIV-compatible hollow bladder flow model (note the model in the anatomical standing position).

RESULTS

Figure 2 depicts in vitro model volumes over time during a voiding (A) and filling (B) event, as well as velocity contours (C) at the outlet of the model during the fastest voiding test. MRI-derived volumes and flow rates agreed within 10% of the flow rates imposed by the pump (Table 1). Flow rate obtained from 2DPC-MRI was 5.58 cm/s, differing from the imposed flow rate by 4.31%.

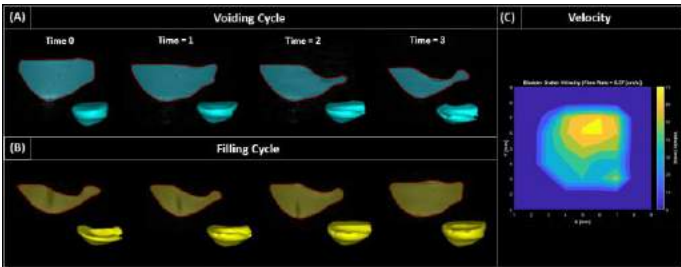

Figure 2: MRI-derived bladder volumes during (A) voiding and (B) filling events. (C) Velocity contours at the bladder outlet derived from 2DPC MRI.

Test	Imposed Volume Change [cc]	Imposed Flow Rate [cc/s]	3D MRI Flow Rate [cc/s]	MRI Volume Change [cc]	Flow Rate Error [%]	Volume Error [%]
Void	150	5.37	5.24	147.7	2.58	1.57
		2.50	2.63	148.6	5.39	0.94
		0.83	0.89	138.7	6.72	7.56
Fill	150	1.67	1.78	154.3	7.34	2.88
		0.83	0.90	140.3	8.00	6.44

Table 1: MRI-derived volume measurements and volumetric flow rates compared to those imposed by the pump during testing.

Figure 3 shows pressure-volume (PV) curves obtained for each voiding and filling test. A pressure drop is seen during voiding while pressure increases are observed during filling. Filling pressure curves exhibited more discrepancy between repeated tests at different flow rates. The work associated with bladder emptying and filling is computed as the integral of the PV-curve. More work output was associated with increased flow rate for both voiding and filling events. Calculated work for each test is summarized in Table 2.

Test	Flow Rate [cc/s]	Calculated Work [millijoule]
Void	5.37	71.75
	2.50	64.82
	0.83	49.70
Fill	1.67	99.72
	0.83	54.24

Table 2: Calculated work output for each voiding and filling event.

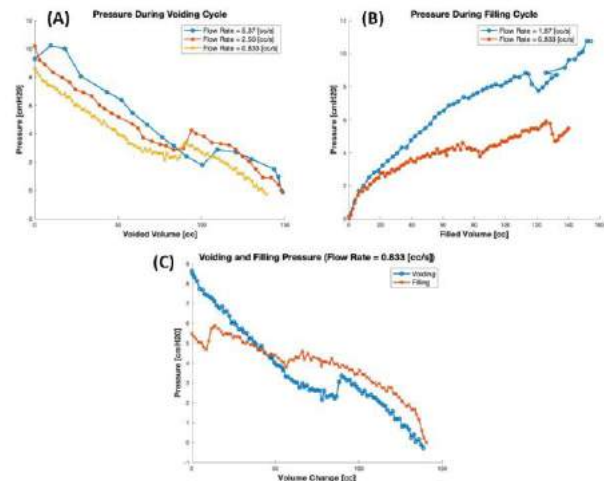

Figure 3: Pressure-volume curves obtained for (A) voiding (B) filling events. (C) Pressure-volume curve for both voiding and filling tests at the same flow rate (0.833 cc/s).

DISCUSSION

Bladder volume during three voiding and two filling tests were successfully calculated from 3D MRI data and used to estimate volumetric flow rate. MRI-derived flow rates agreed with pump flow rate within 10%. As flow rate was decreased, errors between pump and MRI-derived volume and flow rate increased. At lower flow rates there are smaller spatial changes in the model, so distinguishing between true spatial variations becomes difficult near the MRI resolution limit.

Voiding pressure was relatively insensitive to volume flow rate, suggesting that the in vitro bladder may deform similarly regardless of flow rate during emptying. However, this behavior is not seen in filling pressure curves. Higher pressures were associated with higher flow rates, suggesting it takes more effort to deform the model as flow rate increases. Differences between voiding and filling behavior are also observed at the same flow rate (Figure 3c). One explanation may be that the silicone exhibits viscoelastic behavior in response to increased strain rate (i.e higher flow rate). Further experimentation to better understand this behavior is needed.

This modeling pipeline represents a novel technique to systematically assess the validity of experimental MRI in the bladder. MRI-derived volumes can be used to drive CFD simulations to quantify velocity and pressures in 3D. Additionally, this model was designed to be PIV-compatible, and future efforts will focus on its utilization to quantify and validate velocity throughout the bladder, in addition to the localized measurements in the bladder neck reported here. A similar experimental setup can be employed in ex-vivo bladder flow studies, which may represent a more physiologically realistic replication of the bladder and lower urinary tract.

A SLIM, PULSE-DRIVEN MICROFLUIDIC DEVICE FOR INSULIN DELIVERY

INTRODUCTION

Diabetes mellitus is an extremely common condition that affects approximately 500 million people worldwide.¹ Currently, most insulin-dependent diabetic patients rely on syringes or pens that deliver insulin into the subcutaneous fat layer through a macrobore cannula, while others use battery-powered insulin pumps (Figure 1).^{2,3} According to users, both of these treatments can be painful due to the insertion of cannulas.⁴⁻⁸ In addition, insulin pumps are bulky and can interfere with

the tracheal system.¹⁷ Similarly, we have designed our devices in such a way that when gentle physiological pulses are applied, an elastomeric membrane rhythmically collapses and re-expands, changing the flow channel volume, which drives a fluid flow.

METHODS

To fabricate the devices, we have adapted a stereolithographic 3D printing technique to make master molds, which provides higher resolution and reduces time and cost needed to produce each mold as compared to traditional photolithography techniques.¹⁸⁻²¹ Briefly, we design the master mold geometry using CAD software and then print the mold for the pump (flow channel) and reservoir layers using a Formlabs 3B+ 3D printer. We then replica cast a layer of polydimethylsiloxane (PDMS) onto the master molds to make the pump and reservoir layers. For the elastomeric membrane, we spin a thin layer of PDMS onto a silicon wafer using a spin coater. The device layers are bonded together into a multi-layer device with a plasma cleaner. Hollow microneedle arrays with various geometries are fabricated using a Formlabs3B+ 3D printer, following the protocol of Yeung et al. (2019)²² using biocompatible 3D printing resins (Formlabs Clear, Rigid 4000, Surgical Guide, and Tough 2000 resins).

To test the performance of the devices, we have developed a pressurized air-driven apparatus to simulate human pulse. It contains a tunable pressurized air line, a vacuum pump, a 12 V and 1 Amp (?) DC power supply, an Arduino Uno microcontroller, an Arduino control board, a fine-resolution pressure regulator, and a solenoid valve. For the purpose of testing the devices using the pulse simulator, we add an additional device layer made of PDMS containing a pressurized air-filled actuation chamber. The pressure in the chamber is controlled by the pulse simulator. The additional layer is applied over the elastomeric membrane so that fluctuations in the actuation pressure collapse the membrane and drive a flow through the device. Clear Tygon tubing is

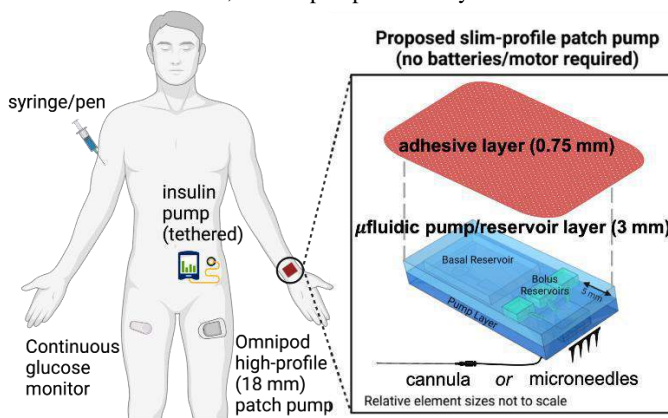

Figure 1. Current insulin delivery methods. Insets: Schematic of our device design (top), and a prototype patch-pump (bottom).

daily activity.^{9,10} These limitations result in reduced patient adherence to prescribed insulin therapy regimens, contributing to diabetes-related hospitalizations.¹¹⁻¹⁶

To remove barriers to insulin adherence, we have developed slim, unpowered microfluidic devices based on principles of insect respiratory systems. Some insects contract their abdomens periodically, which rhythmically collapses tracheal walls and pumps air throughout

connected to the flow channel inlet and outlet, as well as to the actuation channel inlet. To start the testing, a laptop with a simple “blink” Arduino program is connected to the Arduino Uno, which is connected to the DC power supply. The compressed air line and the pressure regulator are gently turned on until the reading on the pressure regulator oscillates between 0 and the desired blood pressure. The vacuum pump is connected to the solenoid valve, which rhythmically switches between the pressurized air and vacuum inlets. The modeled heart rate, or the frequency of the pulse signal, is adjusted in the “blink” program. To start the testing process, the vacuum pump is turned on, and a video is taken to record the time it takes for the fluid-air interface in the inlet tube to travel a predefined distance along the tube.

Devices were tested at 12 physiologically relevant heart rates ranging from 30 to 180 bpm and 7 blood pressures ranging from 75 to 225 mmHg. Devices integrated with reservoirs were tested using the aforementioned pulse simulator at a heart rate of 60 bpm and 100 mmHg, and initial flow rate were measured when the reservoir was fully filled and minimally filled to determine whether the device flow rate would change as the reservoir was emptied.

Additional tests were carried out using a single human subject. Prototype devices were placed on the left radial artery of a seated, X kg, 20-year-old male subject.

RESULTS

A limited number (4) of human subject tests demonstrated the feasibility of pulse-powered flow actuation in prototype devices. (Figure 2D, E). Testing the flow rate produced by the pressurized air pulse simulator, we found that the flow rate across most devices was positively related to the blood pressure (Figure 2B). However, the correlation between the flow rate and the heart rate was not consistent and depended on the device design (Figure 2A). For the integrated device, we have found no statistical difference in the initial flow rate when the reservoir was fully filled and when it was minimally filled (Figure 2C).

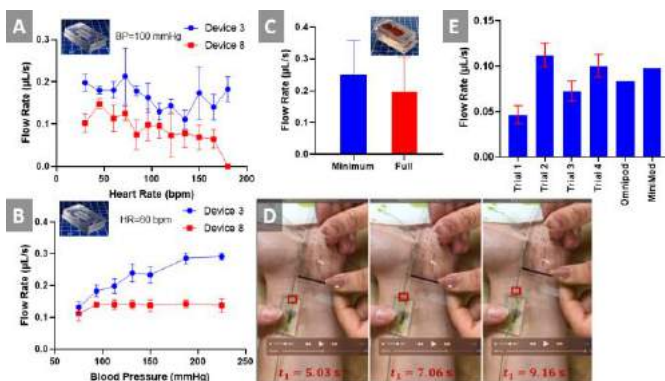

Figure 2: (A,B) Pulse simulator-produced flow rate versus heart rate and blood pressure for two prototype devices. (C) Initial flow rate of integrated device with minimally filled and fully filled reservoirs. (D,E) Human subjects test on the radial artery demonstrated proof of concept.

DISCUSSION

For ideal insulin delivery, we aim to achieve a negative correlation between the flow rate and the heart rate because the user would typically be in vigorous exercise and thus has a reduced glucose level when they are experiencing elevated heart rates.²³ This ideal relationship was achieved by some of our devices (Figure 2A), yet there was significant

variability in the flow rate produced in the same prototype designs for the same conditions. To reduce the variability and further reduce the device profile, we plan to redesign the master mold geometry and fabricate a second generation of devices. For the integrated devices, we have demonstrated that the flow rate does not significantly change as the reservoir is emptied, but we are yet to do further characterizations on these devices.

In conclusion, we have fabricated novel, insect-mimetic microfluidic insulin delivery pumps using stereolithographic 3D printing and soft lithography techniques. We have tested the flow across individual prototype devices using pulse-mimicking pressurized air and a human arterial pulse and shown the feasibility of these devices.

In the future, we plan to integrate more components into the microfluidic pump device, including the microneedle arrays and bolus insulin dose reservoirs, to make a slim, all-in-one patch-pump (as shown in the schematic in Figure 1). To tailor the devices towards specific patients, we will use computational methods including feature extraction and genetic algorithms to optimize the device design.

MULTIFIBER COMPUTATIONAL MODELING OF HOLLOW-FIBER HEMODIALYZERS

Ruhit Sinha (1), Anne E. Staples (1,2)

(1) Department of Biomedical Engineering and Mechanics, Virginia Tech, Blacksburg, VA, USA
(2) Virginia Tech - Wake Forest School of Biomedical Engineering and Sciences, Virginia Tech, Blacksburg, VA, USA

INTRODUCTION

The median life expectancy for patients on hemodialysis is just 5 years because of the poor performance of artificial kidneys, or hemodialyzers, at clearing uremic toxins from the bloodstream, compared to healthy kidneys. Remarkably, the basic design of hemodialyzers, and their prescribed operating regimens, haven't changed significantly since the hollow fiber dialyzer was introduced in the 1960s. Growing evidence suggests that current dialyzer designs and operating regimens are not optimized for toxin removal¹. But optimizing the clearance performance of hemodialyzers would require a complete understanding of the physics of clearance in hollow fiber hemodialyzer units. Efforts to do so are hampered by the difficulty of modeling flow and transport processes in units that typically contain tens of thousands of fibers. Current models of hemodialyzers either extrapolate the performance of a single hollow fiber² to the entire dialyzer unit or model the unit as a porous medium³. Both approaches neglect critical inter-fiber flow and transport physics.

Here, we develop multifiber 3D finite element (FE) models of hollow-fiber hemodialyzers that capture inter-fiber flow physics for the first time. We use the models to test whether current single-fiber models accurately capture clearance performance for 6 commercially available hemodialyzers.

METHODS

Hemodialyzers are cylindrical units containing thousands of parallel hollow fibers with semi-permeable membranes. Blood flows through the fibers and the dialyzer fluid (dialysate) flows around them in the opposite direction (Figure 1). Toxins are cleared from the blood via diffusion and convection across the fiber membranes. Hemodialyzer performance is expressed in terms of clearance (CL) as defined below.

$$CL = Q_b \frac{c_{in} - c_{out}}{c_{in}} + Q_F \frac{c_{out}}{c_{in}} \quad (1)$$

where Q_b is the blood flow rate, c_{in} and c_{out} are the concentrations of a

toxin in the blood at the inlet and outlet of the fibers, respectively, and Q_F is the ultrafiltration (flow of blood plasma across the membrane into the dialysate) rate.

Figure 1: A human kidney and a hollow-fiber hemodialyzer.

We employed a cylindrical-layer domain scaling approach to model clearance in progressively larger 3D FE dialyzer models (Figure 2), developing 1-, 7-, 19-, 37-, 61-, 91-, and 127-fiber models.

Figure 2: Cross sections of 1-, 7-, 19-fiber hemodialyzer models.

Due to the axisymmetric geometries, we were able to carry out simulations using a one-twelfth section of the models (Figure 3).

Figure 3: One-twelfth geometry sections used in computations.

For each n-fiber model (n=1, 7, 19, 37, 61, 91, 127), we used the geometric parameters for six different hemodialyzer modules currently available on the market: The Asahi Kasei APS-15S and APS-25SA, Baxter Healthcare CT190G and Syntra 160, and Fresenius Medical Care F60 and Optiflux 180NR modules. The module diameters (D), hollow fiber inner diameter (d), fiber membrane thickness (t), and fiber packing densities (ϕ), defined in Equation (2), where N is the number of hollow fibers in the actual module, are listed in Table 1.

$$\phi = \frac{N(d+2t)^2}{D^2} \quad (2)$$

Table 1: Hemodialyzer module geometries used in the study.

Module	N	D (mm)	d (μ m)	t (μ m)	ϕ (%)
APS-15S	8980	33.5	200	45	68
APS-25SA	16200	45.8	185	45	59
CT190G	12100	35	200	15	53.7
Syntra 160	11580	39	200	30	51.5
F60	9100	40	200	40	44
Optiflux 180NR	11700	48	185	36	34

We used clinically relevant blood (100-500 mL/min) and dialysate flow rates (200-800 mL/min) and solved the 3D Navier-Stokes and convection-diffusion equations, assigning zero-pressure outlet boundary conditions for both the blood and dialysate flows. We neglected ultrafiltration in this study, considering only the diffusive clearance of urea (diffusion coefficients in blood, dialyzer membrane, and dialysate are $[1.75, 0.39, 1.9] \times 10^{-9} \text{ m}^2\text{s}^{-1}$, respectively).

RESULTS

For each of the dialyzer modules considered, the relative clearance of urea (relative to that of the 1-fiber model) decreased as the number

Figure 4: Relative clearances of the 6 commercial dialyzers at $Q_b = 300 \text{ mL/min}$, $Q_d = 500 \text{ mL/min}$.

of fibers in the computational domain increased, saturating at around 127 fibers. The decrease in relative clearance was more pronounced for the modules with higher packing densities, as is evident in Figure 4. Furthermore, the dialysate flow inlet pressure increased with the dialysate flowrate, with the flow becoming turbulent for some values (Figure 5).

Figure 5: Inlet pressure versus dialysate flow rate.

DISCUSSION

The stabilization of the relative clearance values as a function of the number of fibers in the computational model, for each of the commercially available dialyzers, at around 100 fibers indicates that important features of the inter-fiber dialysate flow and diffusive clearance physics are not captured by less complex models containing fewer fibers. For commercial modules with lower packing densities (the Fresenius Medical F60 and Optiflux 180NR models), the difference in the relative clearances predicted by the 1-fiber and 127-fiber models was relatively minor, less than 10%. This indicates that using standard single-fiber models (e.g., the Krogh cylinder model) to predict the diffusive clearance performance of these modules will give relatively accurate results. But the models with higher fiber packing densities displayed significant differences in the predicted values of urea clearance for the 1- and 127-fibers models, differences of up to 32%. Single-fiber models should be avoided for these models.

The pressure versus dialysate flow rate behavior of the 19-fiber model of the APS-15S dialyzer shown in Figure 5 indicates the presence of turbulence effects. Some of the dialysate streamlines traverse the domain in the radial direction, thus decreasing the average dialysate velocity, and ultimately the clearance, as observed experimentally by Costello et al.⁴ These effects have not been captured by any previous computational model of hemodialyzer.

Because of their ability to capture previously unmodeled features of dialyzer clearance physics, the multifiber hemodialyzer models developed here could be used to improve the designs of hemodialyzers, ultimately impacting millions of patients worldwide. The models could be further improved in the future by including convective clearance physics, and by validation via *in vitro* studies.

INTRODUCTION

There is a lack of burn studies using *in vitro* and *in vivo* models that quantify both time-temperature history and tissue response for short-duration, high-temperature burns, both of which are needed to elucidate mechanisms of burn injury and to develop predictive models [1, 2]. The influence of vasculature embedded within skin on resulting burn injuries has not been adequately investigated. Engineered *in vitro* tissue platforms provide a great system for evaluating burn injury mechanisms [1, 3]. Some previous studies have created skin platforms with embedded vascular networks, however to the best of our knowledge none have been used as models for burn or wound healing research [4]. This paper presents a multilayer vascularized *in vitro* human skin platform to conduct quantitative burn experiments for investigation into the influence of vasculature on burn injuries.

$$\Omega(\tau) = \ln\left(\frac{C(0)}{C(\tau)}\right) = \int_0^\tau A e^{\left(\frac{-Ea}{RT(t)}\right)} dt \quad (1)$$

The Arrhenius model (equation 1) has been widely used for modelling burn injuries to account for the temperature-dependence of damage rates, with the common form assuming irreversible first-order kinetics [cc]. Use of this model allows tissue damage and cell response to be predicted from time/temperature data, assisting heat-based therapies to achieve successful outcomes while minimizing complications due to damage to surrounding tissue [2]. $C(0)/C(\tau)$ is the ratio of the initial cell concentration or tissue strength over that at time τ , the logarithm of which gives the damage parameter Ω . Two process coefficients determine the behavior of the common form of the Arrhenius model (Equation 1), frequency factor A (Hz) and activation energy Ea

(kJ/mol). Each type of tissue damage and cell response is modelled by its own set of coefficients, which must be determined for the temperature range of interest due to the domination of different mechanisms at different temperatures [5].

METHODS

In vitro skin tissue platforms were created by casting collagen I hydrogels bearing human dermal keratinocytes and fibroblasts into a layered structure. Silicone sample holders were made with an open top and a glass slide adhered to the bottom using plasma treatment. A pair of 22 gauge needles were inserted into the holder parallel to each other 5 mm apart. The dermis layer containing fibroblasts was cast into the holder, polymerized in an incubator, then the epidermis layer containing keratinocytes was cast on top. After polymerization of the collagen, removing the needles left well-formed cylindrical channels through the platforms, forming the vasculature. This vasculature was gradually perfused with a suspension of microvascular endothelial cells in a ramping flow scheme, forming a monolayer lining the interiors of the channels

Platforms were subjected to contact burn injury to create to characterize both extracellular matrix damage and the response of cells to thermal stress. A contact burn apparatus was made with a 3 mm diameter cylindrical copper burn tip and a motor with a microcontroller for consistent control of tip position and contact duration. Burn tests were performed with the burn tip heated to 50-100 °C for 3 seconds of contact with the platforms. Cell culture media was perfused through the model vasculature using syringe pumps, configured to impart 2 dyn/cm² of wall shear stress, in both parallel and countercurrent regimes for at least 3 seconds before, during, and 5 seconds after contact burn exposure.

Platforms were treated with a variety of fluorescent stains and imaged with z-stack confocal microscopy 24 hours after exposure. The resulting 3D images show the spatial distribution of this damage throughout the platforms and were used to measure the volumes of damaged regions.

Temperature distributions within platforms during contact burns were modelled computationally in Comsol Multiphysics (5.4a) to obtain a much higher temporal and spatial resolution than could be directly measured. Experimentally determined thermal characteristics of skin platforms and perfused media were used as inputs for this model. The resulting time/temperature histories were correlated with the experimentally determined distributions of tissue damage and cell response to determine which temperature conditions caused which level of damage. Arrhenius process coefficients A and E_a were determined for cell death and collagen ablation that closely predict the experimentally observed tissue damage using the computational temperature model.

RESULTS

Vascularized skin platforms were successfully created, with cells stratified within their respective layers. Endothelial cells form monolayers adhered to the channel walls similar to *in vivo* vessels.

Figure 1 – (Left) Vascularized skin platform in holder (Right) Fluorescent cross-section image down length of channel 48 hours after creation, with minimal deformation

Contact burn injuries resulted in consistent injury to the skin platforms, which were quantified by the volume of damaged regions. Close to the contact point collagen was completely ablated, whereas further out the damage is progressively less severe as evaluated by different stains. The different measurements taken show a range of severities of cell response, and provide a potential means to study how cell fate is determined after burn exposure. Further work is in progress to collect burn injury data with different levels of tissue damage and to determine their governing Arrhenius parameters.

Figure 3 – (Left) Vascularized skin platform in holder after 75 °C contact burn. The edges of the ablated region may make small breaches in channels, 100 °C destroy significant parts of channels (Right) Live/dead (green/red) staining of skin platform 24 hours after 75 °C contact burn, showing cross section of burned region. Intact channels are visible, cell death contained in the center

DISCUSSION

The *in vitro* multilayer vascularized skin tissue platforms created in this project provide a means of quantitatively evaluating the as-of-yet unknown influence of vasculature on burn injury response. Platforms can be created in large quantities with minimal specialized equipment and maintained with minimal labor due to the perfusion of media – essential for the large sample sizes required to determine mechanisms of burn injury. Knowledge of these parameters is needed to elucidate mechanisms of burn injuries and to help drive the parameters of predictive therapeutic models.

INTRODUCTION

Pulmonary fibrosis is a hallmark and final consequence of several acute and chronic lung diseases including ventilator induced lung injury and idiopathic pulmonary fibrosis. Although these diseases have distinct etiologies, the outcome is fibrogenesis that leads to impaired pulmonary function. Fibrotic lesions and scarring of the lung connective tissue are a result of alterations in extracellular matrix (ECM) composition and biochemistry. In fibrotic lung tissue, the ECM was found to stiffen from 1-2kPa to ~16.5kPa¹ and contained increased collagen, hyaluronan (HA), and fibronectin.² Cells have various receptors for these ECM molecules that relay mechanical and chemical signals and therefore regulate fibrosis.

Mechanosensing pathways can potentially mitigate lung fibrosis. However, animal models do not allow for isolated study of mechanical or chemical cues. Reductionist cell culture systems are essential for unraveling the molecular mechanisms of the fibroproliferative response and resolution of fibrosis. However, the lung is a dynamic environment in which cells experience cyclic mechanical loading in addition to biochemical and static mechanical cues from the extracellular matrix (ECM). Thus, engineered *in vitro* systems that allows for precise manipulation of mechanical and biochemical cues is needed to advance our understanding of how changes in the ECM influence fibrotic lung disease progression, so that better therapies can be developed.

In this study, photopolymerized hydrogels are used as substrates for the study of cellular responses to ECM alterations. Non-methacrylated monomers can be included in pre-polymer solution to reduce hydrogel stiffness while maintaining relative number of cell binding sites. The composition and concentration of pre-polymer mixtures can also be tuned to yield desired hydrogel biochemistries and stiffnesses, respectively. These hydrogels are also attached to a bioreactor that applies dynamic mechanical loading. The objective is to observe how combinations of cyclic strain, stiffness and biochemical composition differentially modulates fibroproliferative response compared to each stimulus alone.

METHODS

Fabrication of hydrogels: Methacrylated gelatin (GelMA), methacrylated hyaluronan (HAMA) and non-methacrylated gelatin (Gel) were mixed in various concentrations as base materials. Hydrogels were formed via ultraviolet light (1W/cm²), with Irgacure-2959 used at 1% vol as a photoinitiator.

Photo-rheology: Rheology was performed during the photo-crosslinking process using Kinexus Ultra+ (Malvern Panalytical) fitted with an Omnicure S2000 UV light source. Storage modulus during polymerization (G') was fitted to **Equation 1** to determine final storage modulus (G'_{∞}) and polymerization time. Crossover point (t_c) was defined as the point in which storage modulus is greater than loss modulus (G''). Compressive modulus is calculated using the slope of stress-strain curves.

$$G' = G'_{\infty}(1 - \exp[-\alpha(\frac{t}{t_c-1})^{\beta}]) \quad (1)$$

Mechanical Loading: Pre-polymer mixtures were applied to attachments designed for a force bioreactor (ADMET Inc.). Photopolymerization was then performed at pre-determined times, resulting in solid hydrogels attached to bioreactor. These hydrogels were then deformed at 0.2 Hz and 50% strain.

Cell Culture: Normal human lung fibroblasts at low passage number (<P7) were cultured in EMEM + 10% FBS. Cells were allowed to attach on hydrogels overnight before downstream analysis.

Gene expression analysis: RNA extraction was performed using TRIzol lysis followed by ethanol precipitation of aqueous phase and Zymo RNA Clean and Concentrator column. cDNA was then synthesized using Superscript VILO cDNA synthesis kit. qPCR for 30 genes related to mechanosensing and fibrogenesis was then performed using Power SYBR green with primers sequences from Primer Bank.

RESULTS

Compressive moduli were measured after pre-polymers were fully polymerized using polymerization times obtained through photo-

reology. Non-methacrylated gelatin can be added to methacrylated gelatin (GelMA) to decrease hydrogel compressive modulus (**Fig. 1A**). The addition of methacrylated hyaluronan (HA) significantly increased hydrogel modulus (**Fig. 1B**) due to inherent material stiffness.

Figure 1: Precise control of hydrogel stiffness
 Mechanosensing and fibrogenesis transcriptomics (**Fig. 2**) suggest that stiffer hydrogel resulted in increased ECM synthesis and turnover and upregulation of fibrotic growth factors and cytokines. However, fibroblasts on a stiff hydrogel with 10% HA and 90% GelMA produced gene expression profile more similar to a softer hydrogel.

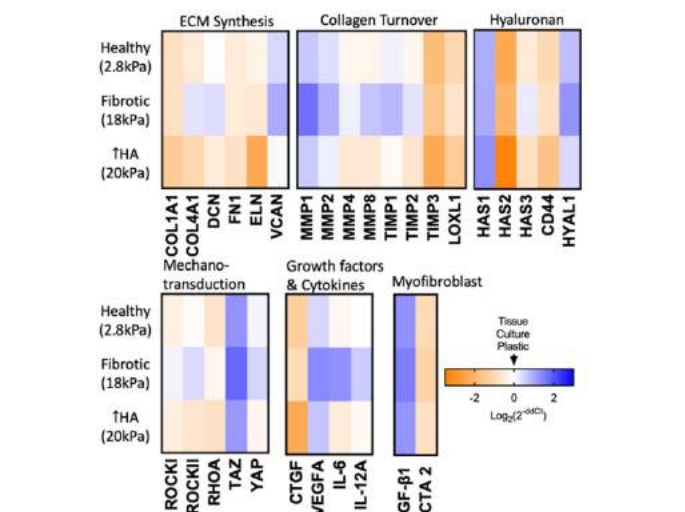

Figure 2: Heatmap of RT-qPCR analysis of lung fibroblasts on static photopolymerized hydrogels. (n=1)
 Cyclical strain was applied to lung fibroblasts seeded on stiff (50 mg/ml GelMA, 13 kPa) hydrogels for 45 minutes or 1 hr. Gene expression analysis (**Fig. 3**) showed that cyclical strain decreased expression of collagen type III (COL3A1), decorin (DCN), and fibronectin-1 (FN1) but increased the expression of elastin (ELN). In addition, there was an increase in matrix metalloproteinase 1 (MMP1) and hyaluronan synthase 2 (HAS2). There was also a decrease in TAZ expression, but a relatively constant expression of YAP compared to cells on static GelMA hydrogels.

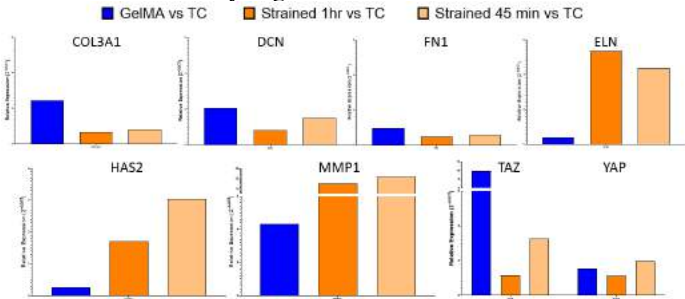

Figure 3: Gene expression of lung fibroblasts on strained GelMA hydrogels. (n=2, y-axis represents relative expression)

DISCUSSION

Our results demonstrate that photopolymerized hydrogel stiffness and biochemistry can be easily controlled. The range of stiffnesses obtained by GelMA, HAMA and Gelatin were within the range of lung tissue stiffness seen in healthy and fibrotic lungs. Inherent cytocompatibility of these hydrogels is also an advantage for this application. Photopolymerized hydrogels composed of GelMA allows for direct cell attachment, an advantage over bulk materials coated with proteins. The addition of gelatin facilitates a wider range of hydrogel stiffnesses than GelMA alone while enabling constant quantity of Arg-Gly-Asp (RGD) binding sites.

Physiologic mechanotransduction throughout the ECM involves a variety of binding sites and proteins with differential effects. For example, vascular smooth muscle cells exhibited opposing responses to substrate stiffening that were dependent on ECM chemistry (laminin, fibronectin or collagen)³. Our results indicate that despite the similar stiffness of hydrogels with HA to “fibrotic” gel, the gene expression profiles of these cells are more similar to those cultured on “healthy” substrates. However, the effects of photopolymerized HAMA on cells needs further investigation as low and high molecular weight HA have differential effects in inflammatory and fibrotic cell response.

Physiologically, lung cells undergo continuous mechanical stimulation, and in some instances, the mechanical stimuli can promote fibrogenesis.⁴ When we applied cyclical strain to lung fibroblasts, ECM deposition, turnover and mechanotransduction gene expression were altered. Interestingly MMP1, which is responsible for degrading collagen I and III, was upregulated, but we also observed a decrease in COL3A1 expression. Increase in type I and type III collagen turnover biomarkers were associated with a greater risk of disease progression in patients with idiopathic pulmonary fibrosis⁵, thus changes in COL3A1 and MMP1 expression prompts further investigation. Decorin has an inhibitory effect on fibrosis, thus decreased expression of DCN indicates a potential profibrotic effect of cyclical strain⁶. In addition, the interaction of fibronectin extra domain A and latent TGF-β1 has been implicated in fibrotic response⁷. Thus, changes we observed in FN1 expression with cyclical strain also suggest further research into fibronectin alternative splicing. Increased elastin has been observed in lungs of bleomycin injured mice and our result is consistent with this observation⁸. HAS2 is responsible for majority of hyaluronan synthesis, and its increased expression suggests cells have increased HA synthesis under cyclical strain. ECM stiffness has also been shown to mechanoactivate YAP/TAZ and promote profibrotic mediators, while decreased TAZ can attenuate fibrotic response⁹. Thus, the decreased expression of TAZ we observed with cyclical strain could potentially indicate a protective effect of strain in fibrogenesis. Inclusion of protein expression studies in the future will help confirm our gene expression results and could help resolve some apparent contradictions. Together, these experiments will address many questions regarding the relative contributions of ECM stiffness, composition, and cyclic mechanical loading to lung fibrosis progression.

MECHANICAL MODELS OF COLLAGEN NETWORKS FOR UNDERSTANDING CHANGES IN THE FAILURE PROPERTIES OF AGING MOUSE SKIN

Nathan J. Witt (1), Alan E. Woessner (2), Jacob Herrmann (1), Kyle P. Quinn (2), Edward A. Sander (1)

(1) Biomedical Engineering, University of Iowa, Iowa City, IA, USA
(2) Biomedical Engineering, University of Arkansas, Fayetteville, AR, USA

INTRODUCTION

Skin is a heterogeneous, anisotropic, and non-linear tissue whose composition, structure, and mechanical behavior changes with age [1]. With age, nonenzymatic collagen crosslinks accumulate within the dermis, which stiffens collagen fibers and decreases interfibrillar sliding [2]. These crosslinks also interfere with the normal turnover of collagen that occurs over the lifetime of the tissue, such that the dermis weakens as it evolves into a fragmented collagen network [3].

We have been investigating the influence of aging in mouse skin and found an increase in non-enzymatic crosslinking within the dermis. Although crosslinking is generally associated with fiber stiffening, we found that the mechanical response of aged skin during uniaxial stretch was softer, the peak force was lower, and the failure displacements were larger compared to young skin (Fig. 1). In this study, we used computational models of collagen fiber networks to explore how changes in fiber properties and network connectivity might explain our experimental observations of softer mechanical response despite increased crosslinking. Ultimately, we envision that these models will contribute to a better understanding of how to improve skin health with aging.

METHODS

Experiment: Young (16 wk, n=6) and aged (23 mos, n=6) dog-bone-shaped murine skin was mechanically tested in an ADMET bioreactor mounted on a multiphoton microscope (MPM). Samples were preconditioned and then stretched to failure at a rate of 0.2 mm/min while being imaged. MPM image stacks of microstructural collagen were acquired in the center of the gauge region at each mm of displacement. Microstructural measurements of collagen properties, including non-enzymatic collagen crosslinking were also obtained.

Simulation: To better understand age-related differences in the mechanical response of mouse skin, we modeled dermal collagen as crosslinked growth networks that matched the experimental fiber

Fig 1. Mechanical responses of mouse skin demonstrate a softer response, lower peak force, and greater displacement with aging.

alignment (i.e., directional variance = 0.77) and fiber volume fraction (25%). We then explored the ramifications of three alterations to the model: (1) introducing age-dependent plastic deformation prior to fiber failure; (2) applying stretch- versus force-based fiber failure rules; and (3) decreasing network connectivity. In these models, the fiber mechanical response is implemented with an exponential force equation [4]. Once a fiber's stretch ratio (λ_{fiber}) exceeds 1.33, plasticity is introduced by incrementally increasing the fiber's reference length. To simulate progressive crosslinking and a reduction in interfibrillar sliding with age, the plastic modulus was increased by two-, three-, or fourfold [2, 5, 6]. Stretch- and force-based failure were implemented by removing fibers that exceeded a stretch ratio of 1.43 or a force of 70 μN , respectively. A decrease in network connectivity was performed by removing 25% or 50% of fibers prior to the simulation. All simulations were conducted in MATLAB under constrained uniaxial stretch to $\lambda_{\text{network}} = 2.0$.

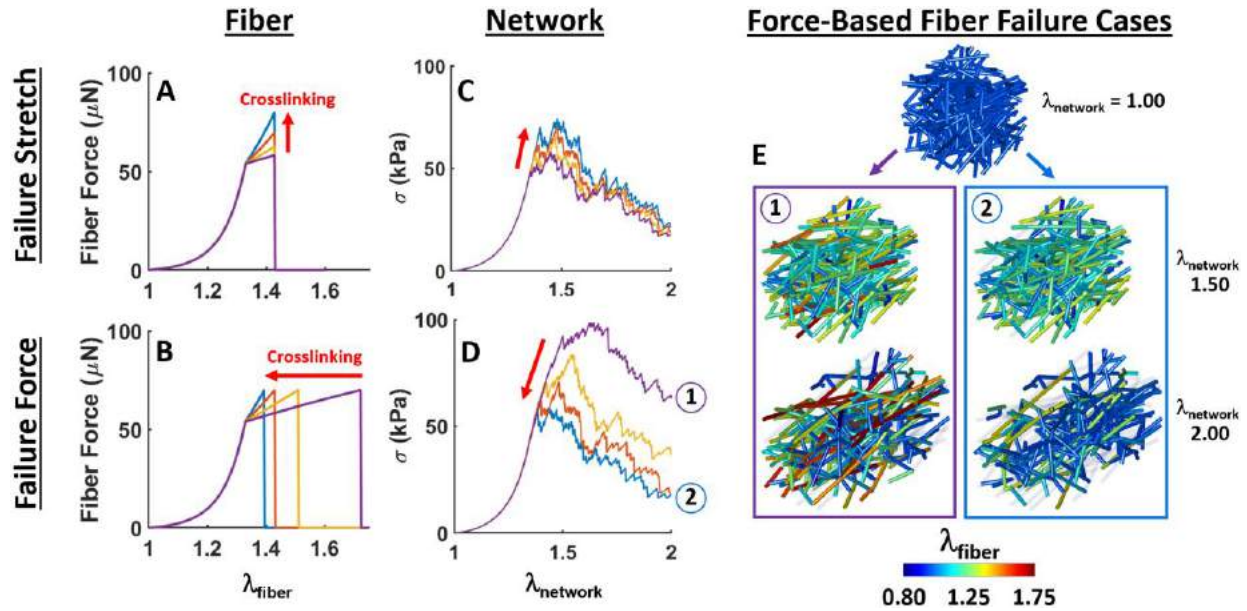

Fig 2. (A) Stretch- and (B) force-based failure rules were investigated in combination with progressively stiffer plastic responses to simulate increased crosslinking. (C) With a stretch-based failure rule, increased crosslinking resulted in higher failure stresses. (D) With a force-based failure rule, increased crosslinking resulted in reduced failure stresses. (E) The network under force-based failure rules demonstrated fewer failed fibers (transparent fibers) with (1) less crosslinking than (2) with more.

RESULTS

Modelling an increase in crosslinking combined with a stretch-based failure rule (Fig 2A) resulted in larger stresses prior to failure (Fig 2C) but did not appreciably alter the stretch at which it occurred. Increased crosslinking with a force-based failure rule (Fig 2B) reduced network stresses and the stretch at failure. (Fig 2D). Additionally, networks with increased crosslinking and a failure force rule experienced fiber breakage earlier in the simulation (Fig 2E2) while younger fibers demonstrated sustained recruitment and elongation (Fig 2E1). In both fiber failure cases, neither method strongly impacted the network's fiber reorganization results (data not shown).

Fig 3. (A) A reduction in network connectivity softened the stress responses and decreased the maximum stresses. (B) Decreasing network connectivity results in a lower percentage of fiber failure. The vertical dashed line indicates the stretch ratio at which fiber failure occurs ($\lambda_{\text{fiber}} = 1.43$). Interestingly, some fibers fail well before the network stretch ratio approaches λ_{fiber} .

Decreasing network connectivity limited the number of stress-bearing pathways, resulting in a softer stress response (Fig 3A) and fewer failed fibers (Fig 3B).

DISCUSSION

Aging within biological tissues, including skin, is a complex process that involves multilayer compositional and functional changes [3]. Our initial investigation explored the counterintuitive experimental results suggesting murine skin mechanically softens with age despite an assumed increase in collagen stiffness. Our results suggest that: (1) increased crosslinking alone does not stiffen networks responses; (2) stretch-based failure increased network stresses with crosslinking while a force-based failure rule elicited a reduction in stresses, but not stiffness; (3) decreasing network connectivity limited stress bearing pathways in the network and lessened the percentage of fiber failure, resulting in a softer stress response. Future work will include progressive aging mechanisms, consideration toward hydrating matrix proteins, and a multiscale perspective on age-dependent fiber-tissue interactions and biomechanics.

INTRODUCTION

Repetitive shaking head accelerations are considered to be a central mechanism responsible for traumatic brain injury (TBI) in some cases of abusive head trauma (AHT) in young children.^{1,2} Finite element (FE) head models have been developed to assist with understanding and predicting TBI in pediatric and other populations, but most FE models drastically simplify the structures and mechanics of the pia-arachnoid complex (PAC), a thin layer between the brain and the skull containing connective tissues, vasculature, and cerebrospinal fluid (CSF). Accurately modeling the mechanics of the PAC has been shown to significantly improve the accuracy of FE head model predictions.³ But directly computing the mechanics of the complex structures and CSF in the PAC is often prohibitively computationally expensive.

Here, we implement a new constitutive model of the forces developed in the PAC from cyclic sagittal head rotations in an FE model of the neonatal piglet brain, resulting in a reduced order, multiscale FE neonatal piglet head model. The model allows us to carry out FE simulations of the brain only, and represents the forces the skull and PAC impose on the surface of the brain at a low computational cost. The aim of this study is to carry out a qualitative comparison between the cortical stresses and displacements predicted by the new model and an existing FE head model of the neonatal piglet that uses sophisticated three-dimensional models of the PAC and skull, and to thereby determine the feasibility of this modeling approach.

METHODS

The FE brain model was constructed from a stereolithography geometry file assembled from MRI images of a Göttingen minipig brain.⁴ We added a falx cerebri structure between the hemispheres of the brain in order to capture the correct gross strain behavior. The brain tissue was modeled as a time-dependent Ogden hyperelastic material, following Prange et al.⁵ and using the materials property values from

their Table 2 for 5-day-old porcine tissue. The falx was modeled as a linearly elastic material, following Scott et al.,³ and using the material property values from their Table 7. Following Scott et al.,³ in order to accurately model the mechanics of the PAC, we defined 12 regions on top surface of the brain with different average densities of arachnoid trabeculae (AT), strands of connective fibers that extend between the dura mater lining the inner surface of the skull and the pia mater covering the brain, and used their “low-volume fraction” model distribution values (Figure 1).

Figure 1: FE model of the neonatal piglet brain. Inset: The shear force the PAC imposes on the brain surface during cyclic head rotations, calculated from the constitutive model.

The constitutive model of the forces developed in the PAC models the AT in a region as uniform strings with constant diameter and spacing. It applies a theoretical model⁶ of the response of a thin fibrous gap to oscillating shearing impacts. In the model, fibers in the gap are displaced in response to relative motion between the brain and the skull in the sagittal plane, while the flow of CSF through the fibers is governed by an effective medium approach and the Darcy-Lapwood-Brinkman model. The key dimensionless parameters that govern the

oscillating shear process are the Womersley number, representing the influence of frequency, the Brinkman number, representing the influence of the porous structure, and the Bingham number, representing the influence of the fiber stiffness.

RESULTS

We compared the predictions of our piglet head model to those of the piglet head model developed by Scott et al.³ Figure 2 shows the stress developed on the top surface of the brain during sagittal head rotations in our model and in Scott et al.'s model. While the brain geometries and rotation conditions are different (Scott et al. carry out constant sagittal plane rotation computations, while our computations are for cyclic rotations), we compare our results at 0° phase angle, which represents the same forcing conditions as constant rotation. We use an angular velocity, ω , of 156.7 rad/s, which is in the range of values that Scott et al. use in their computations. The stress maps are qualitatively similar, with the highest stresses concentrations appearing along the falx and in laterally oriented bands in the mid-anterior region.

Figure 2: Stress patterns on top surface of brain (right) match qualitative features of those from Fig. 12 of Scott et al.³ (left) for $\omega = 156.7$ rad/s. Left image modified with permission from.³

We then carried out simulations of repetitive shaking head accelerations using our model. Figure 3 shows the von Mises stresses (color map, units: N/m²) and the normalized in-plane brain tissue displacements (black arrows) that develop on the top surface of the brain for a shaking frequency of 3 Hz at 0° and 90° phase angles. The inset of Figure 3 is a close-up of in-plane brain tissue displacement vectors. The magnitudes of the displacements are represented by the lengths of

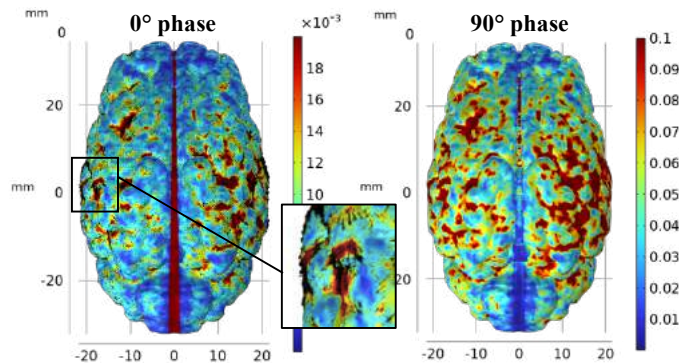

Figure 3: Stress and in-plane displacements on top surface of the brain for $\omega = 28.0$ rad/s and $f = 3$ Hz. Left: 0° phase, Right: 90°.

the arrows. Figure 4 shows the stresses and the displacements that develop for a shaking frequency of 1 Hz. Finally, Figure 5 shows the stresses and displacements that develop for a shaking frequency of 0.5

Hz. All simulations were carried for an angular velocity value of $\omega = 28$ rad/s, a typical value of angular velocity in a pediatric abusive head trauma setting.⁷

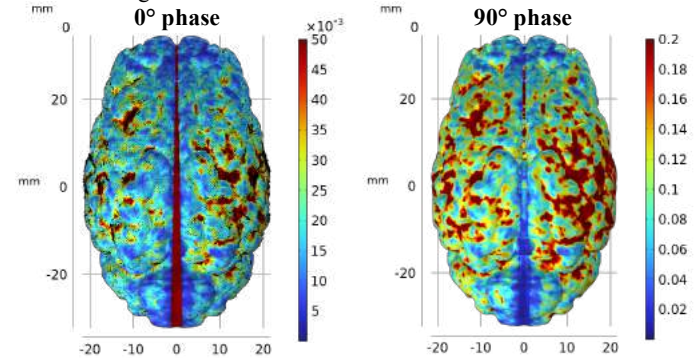

Figure 4: Stress and in-plane displacements on top surface of the brain for $\omega = 28.0$ rad/s and $f = 1$ Hz. Left: 0° phase, Right: 90°.

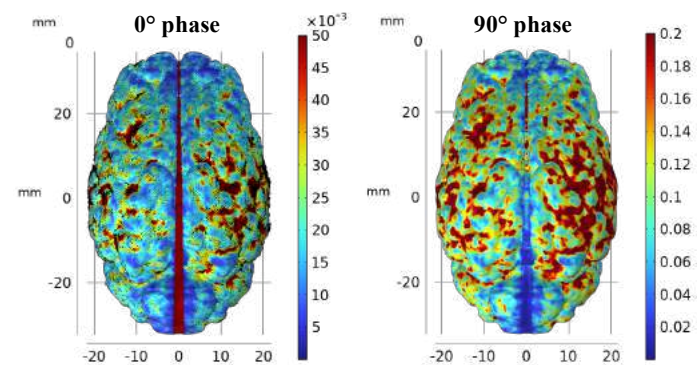

Figure 5: Stress and in-plane displacements on top surface of the brain for $\omega = 28.0$ rad/s and $f = 0.5$ Hz. Left: 0° phase, Right: 90°.

DISCUSSION

We presented a reduced order, finite element head model for the neonatal piglet that aims to accurately represent the forces from the pia-arachnoid complex (PAC) that act on the surface of the brain at a low computational cost via constitutive modeling.

Simulations of cyclic head rotations at parameter values typical of pediatric abusive head trauma predicted that the peak stress on the surface of the brain decreases with increasing shaking frequency, and that peak brain tissue displacements happen at 0° phase angle and are concentrated at the lateral edges of the brain hemispheres.

While the qualitative comparison with an existing piglet head model is promising, extensive validation studies must be carried out in order to further demonstrate the utility of the model presented here.

TECHNOLOGY FOR RAPID REWARMING OF REFRIGERATED BREAST MILK

Melika. Mehrabi Dehdezi (1), Marissa N. Rylander (1), Christopher G. Rylander (1)

(1) Walker Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United states

INTRODUCTION

Current methods for heating or cooling liquids are unsatisfactory due to the extended timeframe needed for getting a liquid to the desired temperature. For instance, existing technologies for warming breast milk and formula focus on boiling water and causing a phase change in the surrounding bath liquid and transferring heat across a plastic milk bottle to heat the target milk volume. Therefore, the heat is transferred across the insulating plastic leading to poor heat conduction and extended time to warm the milk. Furthermore, there is a need to reach the desired target temperature and maintain the temperature. Current technologies frequently overshoot the target temperature creating dangers for pediatric burns. This creates a vicious cycle of heating and cooling leading to frustration by the user and the target temperature is rarely met. Most baby bottle warmers heat milk to above 80 °C which can degrade the nutritional and immunological properties of the milk [1]. Current solutions are not able to rewarm the milk uniformly due to the lack of stirring [2]. We have developed an easy to use and inexpensive heat exchanger technology which can rapidly heat liquids to the desired temperature. Our technology decreases the heating time needed to warm an 8 ounce bottle of milk from 10-15 min with conventional bottle warmers to only 30 seconds (20 times less) which has enormous psychological benefits by reducing the crying time of a baby and stress inflicted on caregivers. Our technology leverages the on demand hot temperature and steady flow rate of a conventional household water faucet to expedite the heat transfer process when coupled with an efficient and rapid circulation of milk through a novel heat exchanger system. The technology also stirs the milk while warming it so the temperature will be uniform regardless of the bottle's geometry. A primary application for this technology is warming of breast milk which is relevant for households, child development centers, nurseries, and neonatal care facilities in hospitals. We anticipate our technology will enhance the safety and efficiency of warming bottles

for babies and create a better environment for teachers, caregivers, and families.

METHODS

We designed the device based on heat transfer and fluid flow analysis (Fig.1). The technology directly interfaces with a faucet (e.g., kitchen, bathroom, tub etc.) to harness the on-demand heating properties

Figure 1. Warming technology circulates milk via a pump from a bottle directly into a copper coil which is submerged in a bath containing hot water from the faucet. Bottle warming takes about 15 s to warm 8 oz milk bottle from refrigerator temperatures (4 °C) to body temperature (37 °C).

available from the faucet to quickly and uniformly heat a target liquid while also leveraging effective heat transfer from a heat exchanger/high thermal conductivity coil (fig.2A) submersed in a capacitive water bath at the faucet temperature. The device consists of a container housing a high thermal conductivity material heat exchanger which is submerged in a water. Water enters the container from the faucet which is continually run at a hot temperature and is continuously monitored with a temperature sensor (fig.2B). An intake tube that removes liquid to be heated (fig.2C) and circulates it by a diaphragm pump (fig.2D) at a desired flow rate (approx. 4 L/min) to be heated and send it through the previously mentioned heat exchanger coil immersed in heated water (50 °C) in the container. The container has a drain to enable continuous circulation of water by the faucet to enhance heating and enable draining during heating and cleaning. Another tube will return the heated liquid directly to the original liquid container at the desired temperature. Tubing for the intake and exit tubing is made of inert, flexible, food grade material such as silicone. The diameter of the tubing is 0.25 inch. The intake and exit tubes are coupled with the temperature sensor for monitoring temperature of the liquid to be heated so the user knows when the liquid to be heated is at the target temperature. Fluid is circulated through the heat exchanger or coil multiple times to enhance heat transfer and until desired temperature is reached. Copper material of the heat exchanger coil immersed in the water bath has a high thermal conductivity and also possesses antimicrobial properties.

Figure 2. Primary components of the system. A) Copper coil. B) Temperature probe and reader. C) Tube bundle consisting of intake and exit tubes for circulating fluid. D) Pump

RESULTS

Based on our analytical analysis using a transient heat transfer model with geometrical, material, and thermophysical properties of our design, we predict to be able to heat the milk from refrigerator temperature of 4° C to the desired temperature of 37° C in 17.3 seconds (Fig.3). Additionally, we conducted two experimental tests in which the milk was 8 fluid ounces of milk, and the water bath temperature was approximately 50 °C). The results of the experimental tests were close to the analytical results. Compared to traditional bottle warmers which require approximately 5 min to heat refrigerated milk to 37°C, our technology can warm up the breast milk in less than 20 seconds.

Figure 3. Model Predicted Milk Temperature vs. Time.

Table1. Experimentally Measured Time to Heat Milk

	Initial bath temperature (°C)	Initial milk temperature (°C)	Final milk temperature (°C)	Time (s)
Run 1	51	12	37	13
Run 2	46	3	37	16

DISCUSSION

Compared to traditional methods which rely on heat conduction through the vessel containing the fluid, our technology directly heats the target liquid (milk). Innovations of our technology includes the mixing of milk for generation of a uniform mixture. In further studies, other metals of high thermal conductivity such as aluminum and steel can be considered for the heat exchanger coil. Temperature sensors can be integrated in the system to provide continuous feedback of the temperature in the fluid in the heating container housing the coil or heat exchanger. This allows the user to determine when the faucet temperature has reached the maximum high temperature before initiating the heating process of the target liquid.

BEHAVIORAL IMPAIRMENTS IN REPETITIVE MILD TRAUMATIC BRAIN INJURY

INTRODUCTION

Mild Traumatic Brain Injury (mTBI) is a serious public health issue. There are various causes of mTBI, including blast overpressure, rapid acceleration or deceleration, penetration by a projectile, direct impact, etc. [1]. mTBI often occurs in a repeated fashion over a few minutes to a few months or years, collectively known as Repeated Mild Traumatic Brain Injury (rmTBI) and it may result in prolonged disabilities such as cognitive and motor impairments [2]. There is discrepancy between reports of the behavioral impairments in consequence of rmTBI depending on the injury model, the time of assessing the outcomes after injury, the animal species, and the severity of the injury [3].

We created a repetitive acceleration/deceleration-induced mTBI model for rats and compared sub-acute (20 days after injury) behavioral outcomes in two repetition patterns. Our goal was to see whether there is a cumulative effect in behavioral impairment over time and explore how the results depend on the repetition pattern.

METHODS

A novel rmTBI model in rats was developed based on applying Whole Body Deceleration (WBD) in the dorsal direction (Fig.1a). The anesthetized animal is positioned on a freely sliding carriage and is immobilized. The carriage is accelerated on a track at 4g to the velocity of 12 m/s and is decelerated with about 70g peak deceleration (Fig.1b) after the impact with a hydraulic shock absorber. WBD tests were either repeated 3 times in one day (WBD1) or 4 times in one day and another 4 times after 48 hours (WBD2). Each impact and retraction took about 1s. No direct impact is applied to the head and any TBI is the result of pure linear acceleration.

20 male Sprague-Dawley rats weighing approximately 300 grams were tested for this study. The Institutional Animal Care and Use Committee of Temple University approved all the experimental

protocols. We randomly grouped rats to WBD1 (n=7), WBD2 (n=5), and sham controls (n=8).

Animals were returned to standard housing for 21 days after injury to allow TBI symptoms to develop. The objective of the WBD model is to replicate mTBI in humans as in the case of repeated hits to the head in sports such as football and hockey that cause head acceleration. We used a battery of behavioral tests including Rotarod to assess motor function, Open field (OF) to evaluate anxiety, and Novel Object Recognition (NOR) for memory. These tests were conducted on days 5, 9, 15, and 20 post-injury.

Figure 1-(a) Schematic diagram of the experimental setup with linear impact carriage to study whole body deceleration TBI (WBD). (b) Three representative deceleration pulses are shown that indicate high degree of repeatability

Rotarod tests were conducted with accelerated speed from 4 to 40 rpm with maximum time of 50 s (LE8500, PanLab Harvard Apparatus). The mean latency to fall off the rotating rod and its corresponding velocity for each rat were recorded. The baseline data was recorded on three consecutive days before the injury day (day 0). The highest value for each rat normalized to the preinjury baseline is reported.

We used a large square field (82x82x35.5 cm) with solid walls for OF. The time spent in central zone of the arena was recorded by ANY-maze software for 5 minutes. The recorded times have been normalized as the percent of (time in center zone)/ (total test time).

NOR test consisted of three phases: the habituation phase, the familiarization phase, and the test phase. In the habituation phase,

animal explored the empty open field arena for 5 minutes. The OF test was used as the habituation phase in this study. In the familiarization phase, the animal explored two identical objects located in the arena for five minutes. In the test phase, one of the identical objects was replaced by a novel object and the rat was allowed to explore the familiar and novel objects for five minutes. There was at least 20 minutes between the phases. The exploration time around each object was recorded for each rat. The metric used was discrimination index (DI) defined as the difference in time spent by each rat with the novel and the familiar objects divided by the total time spent exploring both objects in the test phase.

For histological assessment, we used RT-PCR to investigate the brain inflammatory response in day 21 post-injury. We evaluated TLR4 proteins in the prefrontal cortex for both repetitive patterns.

RESULTS

Rotarod results on days 5, 9, 15, and 20 showed 15, 7, 3, and 24 percent decline in performance for WBD1, and 20.5, 27.4, 34.5, 47 percent for WBD2 (Fig.2a). There are significant differences compared to sham on day 5 ($p=0.01$) for WBD1, and days 15 ($p=0.01$) and 20 ($p=0.004$) for WBD2. WBD2 indicated significant change compared to WBD1 in rotarod performance on day 20 ($p=0.04$).

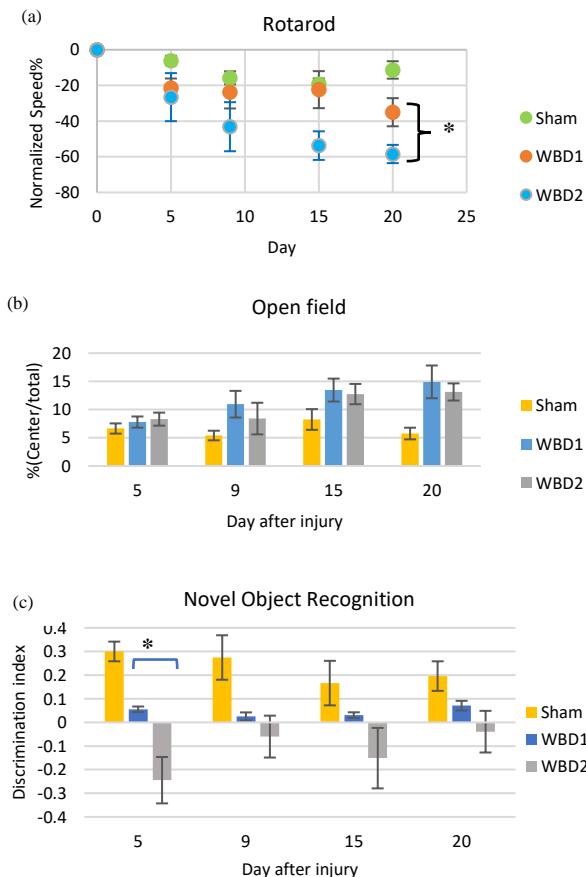

Figure 2- Behavioral test results. (a) Rotarod results show the normalized speed at fall. (b) OF results show the percentage of time spent in the center zone. (c) NOR results show the discrimination index.

OF results showed no significant difference between the two injury patterns (Fig.2b). The results demonstrated significant difference

between each injury and sham on day 20 ($p<0.05$). Injured rats spent more time in the center zone compared to shams.

NOR results detected memory deficit on days 5 ($p<0.01$) and 9 ($p<0.02$) after WBD2 and signs of recovering on day 20 (Fig.2c). For WBD1, NOR showed significant difference on day 5 ($p<0.01$) and 9 ($p=0.03$). The differences were close to significant ($p<0.1$) on day 20 for WBD1, and on days 15 and 20 for WBD2. NOR showed significant difference between WBD2 and WBD1 on day 5 ($p=0.03$).

RT-PCR showed no significant change in TLR4 following both repetition patterns compared to sham groups.

DISCUSSION

In this work, behavioral and histological outcomes were compared in two rmTBI patterns, namely WBD1 and WBD2. We used a novel injury model to replicate rmTBI in rats and evaluated motor function, anxiety and memory following rmTBI.

Rotarod showed much higher differences between WBD2 and sham compared to WBD1 that lasted for 20 days post-injury, i.e., the sub-acute phase. Motor impairment following rmTBI has been reported by some studies in the literature [4]. However, other studies reported no chronic motor deficits detected by rotarod following rmTBI [5].

OF displayed significant changes compared to sham on day 20 for both injuries. Spending less time in the center zone has been known as an indication of increased anxiety in rodents [6]. Some studies report no change [5] or increased anxiety after TBI [6], whereas others find a decreased anxiety-like behaviors [7]. In our study, injured animals compared to sham spent more time in the center zone which can be described as impulsivity or risk-taking behavior [6]. The differences were however not statistically significant.

In NOR, both WBD1 and WBD2 demonstrated significant differences in DI initially and the showed signs of recovery. There are studies that support the sub-acute memory dysfunction caused by rmTBI [5]. Also, WBD2 consistently resulted in more memory loss compared to WBD1.

Histological assessments showed that sub-acute histological changes were not significant. In contrast, in our previous work, we detected significant changes in TLR4 seven days post-injury [8].

In conclusion, the results indicate that the cumulative effect of WBD2 on motor function and memory is more severe than that of WBD1. They also suggest that rmTBI can cause sub-acute impulsivity over time. While no histological difference was found on day 20, behavioral assessments showed measurable differences at this time point. Using a greater number of samples as well as employing more than one type of behavioral test for each function can help to reach to more robust conclusions.

INTRODUCTION

Suction devices, also termed aspirators, are powered or unpowered devices employed to remove infectious materials from wounds or fluids from a patient's airway or respiratory support system [1]. It is the first equipment employed in airway management, which is itself the foremost priority when assessing a traumatically injured patient [2]. Airway compromise is the second leading cause of potentially survivable battlefield injuries among US military forces [3, 4]. Unfortunately, many of the commercial portable suction devices have not been scientifically validated for key performance measures relevant to prehospital care [5]. The current ISO 10079-1 standard for performance is for maximum free air flow rate of 20 L/min, which is confusing given the intended use of the device is to suction viscous liquids [6]. This is even more problematic as manufacturers use maximum free air flow rate as the primary reported performance metric, which misleads consumers and overestimates the real-world capability of a given device as instantaneous peak airflow rate can be manipulated to have a higher value than a unit would be able to provide in a sustained fashion. In addition, ISO 10079-1 performance requirements for portable suction devices, "equipment intended for pharyngeal suction shall evacuate 200 ml of simulated vomitus in not more than 10 s" [6]. The standards lay down the requirement for liquid flowrate but does not include requirement for avoiding backflow of liquid into patient's mouth. Suction devices are prone to the risk of having backflow during evacuation, which is a serious risk of infection to patients. Our hypothesis is that a time averaged air flowrate is a better estimate for overall device performance than peak instantaneous air flowrate. Time averaged air flowrate is a metric that provides information of device's capacity to evacuate a certain amount of fluid (liquid or air) in specific time.

To test the hypothesis four (4) portable suction devices were tested to gauge their performances based on the metrics, instantaneous air flowrate, liquid flowrate, and vacuum pressure. The metrics used to

determine the peak instantaneous air flowrate, time averaged air flowrate, real time liquid flowrate during the operation of device, and backflow. All the portable suction devices selected for the testing were the current market leaders and their weight was less than 1.5 kgs.

METHODS

The four (4) portable medical suction devices selected were subdivided into powered and unpowered categories: the Laerdal LCSU 4 & SSCOR Quickdraw were chosen as representative battery-operated suction devices, and Laerdal V-VAC & AMBU RES-QUE were chosen as the manually operated suction devices.

Air flowrate test setup utilized a microelectromechanical system (MEMS) air flow sensor (Omron MEMS Air Flow Sensor - D6F-50A61-000) which was operated against the suction devices to measure the instantaneous air flowrate. All four (4) suction devices were tested using this experimental setup. The suction devices were operated for 30 seconds, where the air flow sensor captures the air drawn by the suction device for a period of 30 seconds at 100 Hz.

The flowrate was calculated by measuring the volume of liquid (water and ISO vomit solution) evacuated by the device from a beaker filled with liquid in a certain time. Simultaneously a pressure transducer was attached to the suction tube tip to measure the vacuum pressure during the suction. The amount of liquid evacuated was measured by tracking real time the weight of the beaker filled with liquid and MATLAB timer to record the evacuation time. All the suction devices were operated until the canister capacity of the respective suction devices were filled.

All suction devices were operated at their respective peak settings. Each device was tested for 5 trials. Manual suction devices were operated by a single operator for 5 trials.

RESULTS

Figure 1 shows the comparison of peak air flowrate, total averaged air flowrate, and peak air flowrate claimed by manufacturer among all the 4 suction devices. The peak air flowrate was the maximum instantaneous air flowrate the device reaches during the operation. The time averaged air flowrate was the total air evacuated by the suction device during the operation of 60 seconds. Figure 2 shows the comparison of liquid flowrates of the 4 suction devices used against two different liquids, water ($\mu = 1$ cp) and ISO vomit solution ($\mu = 22$ cp)[3].

Figure 1: Comparison of Air Flowrate of Suction Devices

Figure 2: Comparison of Liquid Flowrates of Suction Devices

DISCUSSION

Comparison of total air flowrate and instantaneous flowrate (figure 1) for manual suction devices show that, although the manual suction devices offer high instantaneous flowrate, the time averaged air flowrate for 60 seconds were far less. Peak instantaneous air flowrate is not a meaningful or relevant specification as it cannot provide information on total amount of air drawn by the suction device, which is an implied correlation to the liquid flowrate. Time averaged air flowrate for 60 seconds, is more likely to imply liquid flowrates than peak air flowrate.

Use of the peak/maximum air flowrate metric allows the manually operated suction devices to claim comparable, or even superior, performance to their battery-powered counterparts. As per the data herein, this is untrue and misleading to purchasers and users of these portable suction systems. Based on this data, we recommend time averaged airflow rate as an improved specification for analyzing the performance of the suction device.

Figure 3: Liquid Flowrate Profile of Suction Devices

The initial observation to the liquid flowrate profiles of all suction devices in figure 3 shows that VVAC manual portable suction device exhibited backflow. As per data from liquid flowrate testing it can be incurred that the liquid evacuated from the beaker was entering back into beaker when performing suction using VVAC portable suction device. This phenomenon can be observed by the periodic increase in weight of beaker. Measured the local minima and local maxima of the peaks observed in the flowrate profile of VVAC suction device to calculate the amount of backflow. The device exhibited a backflow of 2 to 5% for every 100 ml which can lead to serious infections to the patients and it may be dangerous to use these device on patients.

RIGHT VENTRICULAR MYOCARDIUM REMODELING IN PULMONARY ARTERIAL HYPERTENSION IS SEX DEPENDENT

Becky A. Hardie (1), Jessica Huberts (1), Daniela Valdez-Jasso (1)

(1) Department of Bioengineering, University of California, San Diego, La Jolla, CA, USA

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive vasculopathy of the pulmonary arteries that frequently results in right-heart failure and death.^[1] PAH manifests as sustained elevation of pulmonary arterial pressures above 20 mmHg and irreversible vascular remodeling that leads to an overloaded right ventricle (RV).^[1,2] Previous studies with male animal models have shown that elevated RV pressures are associated with increased myocardial stiffness and tissue fibrosis.^[2]

PAH is significantly more predominant in women; modern registries suggest the incidence is 2-4 times higher in women than men.^[3] Despite the high incidence in women, they tend to fare better and survive longer.^[3] The sex-differences in PAH progression are thought to be at least in part due to the effects of sex hormones, specifically 17- β estradiol (E2), the primary female sex hormone in non-pregnant women.^[3,4] Previous studies have demonstrated that E2 improves RV function in rats with PAH and that E2 levels correlate with RV function in healthy post-menopausal women undergoing hormone replacement therapy.^[3] To investigate the tissue-level properties that may lead to a sex dependent RV remodeling, we designed a study using the well-established Sugen-hypoxia (SuHx) rat model of PAH in male, female, and ovariectomized female rats.

METHODS

Animal model. PAH was induced in male, intact-female, and ovariectomized-female (OVX) Sprague-Dawley rats by a 20 mg/kg injection of Sugen 5416, a vascular endothelial growth factor receptor blocker, followed by 3 weeks of hypoxia at 10% oxygen and a further 5 weeks of normoxia. Control animals were kept at normoxia. Hypertension was confirmed by invasive measurements of blood pressure at the inlet of the pulmonary artery with a mean pulmonary arterial pressure greater 20 mmHg.

Tissue preparation. Immediately after hemodynamic measurements, the heart was harvested, flushed, and the RV free wall

excised. A square sample aligned along the apex-to-outflow (AOT) direction was cut from the mid-wall. Side lengths and tissue thickness measurements were taken with calipers prior to testing. Five graphite markers were glued on the epicardium in the center of the tissue to track displacement. The sample was attached to a Bose Electro-Force planar biaxial testing device with 4 custom-made hooks on each side and submerged in 37°C phosphate buffered saline.

Mechanical testing. RV samples were pre-stretched with a 3 g load to ensure complete planar motion and preconditioned with two stretch series of an 8%, a 10%, and a 12% *ex vivo* lengths at 0.2 Hz. Samples were subjected to displacement-controlled biaxial testing with 7 blocks of 15 loading-unloading cycles at 0.5 Hz. The AOT:circumferential stretch ratios were 1:1, 1:0.5, 1:0.25, 1:1, 0.5:1, 0.25:1, 1:1, with a maximum stretch of 10% of the *ex vivo* side-length. The last 3 cycles of blocks 2-6 were point-wise averaged and used for analysis. Pixel positions of the markers were recorded at 200 Hz throughout the test.

Constitutive equations. The locations of the four outer pixels were used to calculate the deformation gradient tensor \mathbf{F} through isoparametric mapping. The Green strain tensor \mathbf{E} was defined with respect to the pre-loaded reference configuration β_1 , and the second Piola-Kirchhoff stress tensor \mathbf{S} was calculated with the deformation gradient tensor.

The myocardium was assumed to be a planar hyperelastic material with the loading curve described by a Fung-type exponential strain-energy function.

$$W(\mathbf{E}) = C(e^{Q(\mathbf{E})} - 1) \quad (1)$$

where

$$Q(\mathbf{E}) = a_1 \mathbf{E}_{11}^2 + a_2 \mathbf{E}_{22}^2 + a_3 \mathbf{E}_{11} \mathbf{E}_{22}. \quad (2)$$

Numerical implementation. Pre-stretches $\{f_1, f_2\}$ were estimated in terms of the experimental stretches Λ_i as:

$$f_1 = \sqrt{\frac{\mathbf{E}_{11}\Lambda_2}{\Lambda_1}} + 1, f_2 = \sqrt{\frac{\mathbf{E}_{22}\Lambda_1}{\Lambda_2}} + 1 \quad (3)$$

and used to map from the stress-free reference state β_0 to the pre-loaded configuration β_1 at the beginning of the test. Experimental data was fit to the model equations and parameter estimation was carried out using the Limited Memory BFGS algorithm with the material parameters $\{C, a_1, a_2, a_3\}$ positive in Python. A strain-energy surface was generated for each animal using the optimized set of parameters and within each group, the set of strain-energy surfaces was point-wise averaged. This averaged surface was used to generate a representative set of parameters for each group and the stress and strain relations from an equibiaxial stretch of 10% was computed.

Statistics. All values are presented as mean \pm standard error and the significance level was set at 0.05 for all statistical tests. Two-factor ANOVA was used to compare thicknesses of the RV samples, with the factors being treatment and sex or, within the female animals, treatment and ovariectomy. Stress-strain relations were compared using three-factor analysis of covariance (ANCOVA) with a log transformation in JMP, with the factors being strain, treatment, and sex when all the data was included or strain, treatment, and ovariectomy within the female animals.

RESULTS

SuHx-treated RV thickness significantly increased compared to control ($p < 0.0001$) and thickness was not dependent on sex ($p = 0.2940$) or the presence of sex hormones (ovariectomy, $p = 0.5442$) [Control-to-SuHx] (Male: 1.39 ± 0.03 mm to 1.82 ± 0.12 mm, Intact Female: 1.32 ± 0.04 mm to 1.86 ± 0.13 mm, OVX-Female: 1.21 ± 0.04 mm to 2.01 ± 0.23 mm). The biaxial mechanical data was closely fit by the Fung-type model with coefficients of determination ranging from 0.81 to 0.99. The RV myocardium was isotropic with no significant difference between the AOT and circumferential stress-strain relations within each group (Figure 1).

Figure 1: Second Piola-Kirchhoff equibiaxial stress-strain relations from control (a) and PAH (b) RV myocardium from male rats. Data are shown as the mean and standard errors.

There was a significant increase in second Piola-Kirchhoff stress with SuHx-treatment and strain (circumferential direction: treatment, strain, treatment-strain interaction: all $p < 0.0001$), but no difference between the male and female (intact-female and OVX) RV myocardium stress-strain relations ($p = 0.0519$) (Figure 2). Ovariectomized female RV samples were significantly less stiff than intact females ($p = 0.0002$) (Figure 2).

Figure 2: Averaged second Piola-Kirchhoff equibiaxial stress-strain relations for control and SuHx-treated male, intact-female, and OVX-female rats. Data are shown as mean and standard errors.

DISCUSSION

Several prior studies have examined RV remodeling due to pulmonary hypertension (PH) with male animal models, however no studies include female RVs. Prior studies from our lab and Frump *et al.*^[3] have shown sex dependent RV remodeling at the organ, cell, and molecular level. Thus, this work fills an important gap in the PH literature by providing tissue-level properties.

In the SuHx-treated PAH groups, significant RV myocardial thickening compared to normoxic controls is consistent with previous studies.^[2,3] The constitutive model used in this study was able to approximate the experimental data equally well in all the groups. The pre-stretches ranged from 0.9996 to 1.001, indicating that the pre-loaded configuration β_1 from which the tests were run was a slightly deformed version of the stress-free reference state β_0 . In all the control and SuHx-treated groups, the RV was isotropic. Most previous studies have noted that RV tissue is anisotropic, but the degree of anisotropy varies from the AOT direction being stiffer by a factor of 5:1 to the circumferential direction being stiffer by almost 2:1.^[2] Our findings of an isotropic myocardium fall within these ranges, however additional studies of RV myofiber and extracellular matrix orientations are necessary to fully understand the isotropy or anisotropy of the RV.

Although the RV has been studied from both the organ-level and the cell-level in female PAH subjects, these are the first reported tissue-level mechanical properties in intact-female and OVX-female animal models. For the normotensive animals, the stress-strain relations are similar across groups. In SuHx animals, the RV myocardium is substantially stiffer than the control myocardium in both sexes. Interestingly, there is no significant difference in the stress-strain relations when comparing the male group to a female group comprising of intact and OVX female rats. However, when accounting for the presence of sex hormones, our analysis found a significant difference between the two female subgroups. The comparative stiffening of the passive RV myocardium tissue in intact females may explain why premenopausal women are able to preserve cardiac function, such as ejection fraction, by preventing ventricular dilation.

Significant sex differences in organ-level RV function shown in patients and in Frump *et al.*'s study^[3] are not completely captured by our tissue-level RV myocardium mechanical properties. Given our previous studies in male rats where we found significant, anisotropic remodeling of the collagen extracellular matrix with SuHx treatment^[2] and Frump *et al.*'s work suggesting that the ER- α /BMP2/apelin signaling axis is linked to sex differences and RV fibrosis,^[5] in our future studies we will investigate the role played by collagen deposition and reorganization on the extracellular matrix mechanical properties in the absence or presence of estrogen.

HUMAN IPSC HYDROGEL ENCAPSULATION FOR EFFICIENT PRODUCTION OF EMBRYOID BODIES

Matthew T. Conway (1), Edward A. Sander (1), Kristan S. Worthington (1)

(1) Roy J. Carver Department of Biomedical Engineering, University of Iowa, Iowa City, Iowa, USA

INTRODUCTION

Induced pluripotent stem cells (iPSCs) are autologous, can be attained with minimal invasion, and possess the ability to differentiate into nearly any cell type [1]. Consequently, iPSCs are a popular choice for regenerative cell-based therapies and tissue engineering. Prior to directing iPSCs toward a specific cell lineage, it is a common practice to form them into 3D spheroids known as embryoid bodies (EBs). EBs contain each of the three germ layers (mesoderm, ectoderm, and endoderm) and can be formed through various methods, including spontaneous self-aggregation in suspension, settling in low adhesion round-bottomed wells, and hanging drop culture [2]. EBs can also be generated through the encapsulation of iPSCs within hydrogels, such as alginate, PEGDA, and hyaluronic acid [3-5]. During the encapsulation process, a Rho-kinase inhibitor (ROCKi), Y-27632, is often added help maintain cell viability [3]. Once the encapsulated iPSCs have grown to the desired size, the EBs can either be differentiated within the hydrogel or retrieved from the gel via decapsulation for additional processing. One potential benefit of the hydrogel encapsulation method is that it may offer a means to substantially improve EB generation efficiency over conventional methods, which could benefit pilot scale cell manufacturing or high-throughput clinical or research operations. However, iPSC stemness and differentiation can be impacted by the mechanical environment; and cell responsiveness to the mechanical environment is known to be altered by ROCKi [6]. Here, we investigated how encapsulation of human iPSCs in alginate hydrogels impacts the efficiency and yield of EB formation and whether changes in the mechano-sensing abilities of iPSCs also impacts iPSC viability, stemness, and differentiation in this context.

METHODS

Human iPSC Culture: Human iPSCs sourced from bone marrow CD34+ cells and reprogrammed using Sendai virus (ATCC) at passage 12 were grown to 80% confluency in a 6-well plate coated with cell

basement membrane (ATCC) and using E8 Flex stem cell culture medium (Thermo Fisher). The cells were gently washed with PBS and lifted by adding 1 mL of Accutase (Sigma-Aldrich) and incubated for 7 minutes.

Conventional EB Method: Dissociated iPSCs were centrifuged at 0.2 rcf for four minutes and resuspended to a cell density of 10^5 cells/mL in E8 flex medium containing 20 μ M ROCKi. 100 μ L of the cell suspension was then dispensed into each well of a 96-well low adhesion V-bottom plate (S BIO) to aggregate iPSCs into EBs. Culture medium was changed every two days without ROCKi.

Alginate Gel EB Method: Two hours prior to lifting the cells, a media change was performed with the addition of 10 μ M ROCKi (Stem Cell Technologies). Dissociated iPSCs were then collected, centrifuged, and resuspended in 1 mL of E8 flex with 10 μ M ROCKi, and mixed with 1 mL 1.2% (w/v) alginate (A2033, Sigma-Aldrich) in PBS for a final concentration of approximately 10^6 cells/mL and 0.6% (w/v) alginate. The solution was loaded into a syringe with a blunt 20G needle and added dropwise by hand into a gelling bath containing sterile 100 mM CaCl₂ (Fisher Scientific) in PBS to form 30 spherical alginate beads containing approximately 70,000 cells in each bead (Fig. 1).

Figure 1: Schematic of method used to encapsulate human iPSCs in alginate hydrogels.

The beads were allowed to fully polymerize in the gelling solution for 5-10 minutes, collected, and washed with PBS two times. Finally, the beads were transferred to a 6 cm dish with E8 flex media containing 10 μ M ROCKi. The beads were cultured for one day before being split into different groups to be grown in different ROCKi concentrations of 0, 10, and 20 μ M over the span of 8 days. Culture medium was changed after three days followed by regular media changes every two days.

Imaging and Analysis: Phase contrast images were collected from each test group on Days 2, 4, and 6 and analyzed for size using FIJI. Eight iPSC encapsulated beads were analyzed from each ROCKi concentration group along with imaging of eight wells containing conventionally generated EBs. Viability staining was performed on Day 8 using NucRed Live 647 and NucGreen 488 ReadyProbes (Invitrogen) according to the manufacturer's instructions. A one-way ANOVA with post-hoc Tukey HSD test was used to determine significance ($p < 0.05$) between test groups on Day 6.

RESULTS

Aggregates cultured in medium containing 10 or 20 μ M ROCKi quickly expanded in size compared to the 0 μ M ROCKi group and formed into EBs (Fig. 2).

Figure 2: Comparison of methods to produce EBs over 6 days. A) 0 μ M ROCKi. B) 10 μ M ROCKi. C) 20 μ M ROCKi. D) 96-well round bottom plate.

EBs formed in 96-well plates aggregated into a single large spheroid by Day 2. On average, EBs formed in a 96-well plate were approximately 4-8 times larger than those formed in hydrogels (Fig 3.).

Figure 3: Average diameter of EBs generated using alginate encapsulation method and 96-well method cultured over the span of 6 days (Error bars: \pm SD).

EBs maintained with ROCKi grew to be two times larger than those without ROCKi. Statistical testing showed significant difference in size between the 0 μ M ROCKi group and both 10 and 20 μ M ROCKi groups at Day 6 ($p < 0.0001$), while it was determined that there was no significant difference between the 10 and 20 μ M groups ($p = 0.6098$).

The number of encapsulated EBs within the 10 and 20 μ M group was estimated to contain at least 250 per bead, whereas only 37 EBs were counted within the 0 μ M ROCKi group. Compared to the conventional method, only 96 EBs could be made from the same number of starting cells, but these EBs had a much more consistent size distribution with a coefficient of variation of 11.2% on Day 6, whereas the ROCKi groups of 0, 10, and 20 μ M showed variation of 44.9%, 21.9%, and 21.3%, respectively. To determine the EB formation efficiency, the number of EBs was divided by the number of cells initially used. The encapsulation method using 0 and 20 μ M ROCKi showed an EB efficiency of 0.053% and 0.357%, respectively, whereas the 96-well method produced an efficiency of 0.0001%.

Encapsulated and conventional EBs showed similar distributions of a few dead labeled cells located at the periphery of the spheroids (Fig. 4).

Figure 4: A-B) 20x and C) 10x live (red) and dead (green) staining of EBs on Day 8. Scale Bars: 250 μ m.

DISCUSSION

Generating EBs using the alginate encapsulation method enabled the production of more EBs, but at smaller sizes. Utilizing the 96-well method allowed for the quick generation of large EBs, but at a smaller quantity. It has been shown that consistent sizing of EBs is crucial when differentiating EBs toward specific cell lineages [7]. To make use of the inconsistently sized EBs formed in alginate, precise sorting of EBs would help maximize the yield of viable EBs available to researchers. Increasing the formation efficiency of EBs using alginate encapsulation could lead to improved differentiation protocols to produce cell types with limited sources. Future work involves using a TaqMan hPSC Scorecard Assay and qPCR to determine pluripotency and lineage bias towards any of the three germ layers as a function of method parameters.

CYCLIC STRETCH RESULTS IN DIRECTIONALLY DEPENDENT RECELLULARIZATION ALIGNED WITH CELLULAR STRESS AVOIDANCE REORIENTATION

Adam W.Y. Ley (1), Eric Slaughter (2), Victor H. Barocas (1), Robert T. Tranquillo (1,2)

INTRODUCTION

Tissue recellularization is influenced by physiologic mechanical loading conditions. This is especially true for tissues that undergo constant cyclic stretch, like cardiovascular tissues [1]. This affects recellularization, as cyclic stretch impacts cell proliferation [2] and migration velocities [3], while also causing cells to reorient perpendicular to the stretch direction in a behavior known as stress avoidance (SA) [4,5]. The effects of cyclic stretch on directed single-cell migration, however, remains largely uncharacterized. In this work, we analyzed the effects of cyclical uniaxial stretch on the recellularization of an acellular “invasion” region parallel and perpendicular to the direction of stretch. We then conducted a circular statistical analysis on the morphological data to further characterize cells’ migration behavior after 24 hours of cyclic stretch.

METHODS

Glass coverslips were placed on collagen I coated FlexCell UniFlex plates in two configurations, “parallel” and “perpendicular”, (fig. 1). Human dermal fibroblasts were seeded onto the plates at 2,000 cells/mL and incubated with DMEM/F12 with 15% FBS, 100 U/mL penicillin, and 100 U/mL streptomycin at 37 °C and 5% CO₂. Coverslips were removed after 24 hr. “Static” plates were incubated another 24 hr. “Flexed” plates were incubated in a FlexCell FX-5000 tension system with 7% uniaxial tensile strain at 0.5 Hz in a sinusoidal waveform for 24 hr. This protocol resulted in 4 treatments: parallel static, perpendicular static, parallel flexed, and perpendicular flexed.

After the final incubation, cells were fixed in 4% PFA for 15 minutes, permeabilized with 0.1% Triton X-100 for 5 minutes, and stained with 500x Alexa Fluor 594 Phalloidin and 10,000x Hoescht-33342 for up to 3 hours. Imaging was conducted using a BioTek Cytation 3 with fluorescence microscopy capabilities. Fluorescence was captured using TxRed (Ex 586/15 nm, Em 647/57 nm) and DAPI (Ex 377/50 nm, Em 447/60 nm) filter cubes using a 4x objective.

Fig. 1 A. Perpendicular, and B. parallel configurations with resulting cell seeding patterns. Arrows denote stretch direction

Nuclei in the invasion region were counted using Gen5™ Data Analysis Software. The initial location of the coverslip used to identify the border between the initial cellular and acellular regions (hereafter referred to as “edges”) and identify the invasion region. Nuclear counts were normalized by the length of these edges. Single-cell morphology was characterized using a custom MATLAB script that fit ellipses to overlapping F-Actin cytoskeletons and nuclei, recording the centroid and major axis orientation for both structures. Past literature established that cells elongate in the direction of migration [6], and that the nucleus translates to the rear of migrating cells [7]. To approximate migration direction, we subtracted the nucleus centroid from the F-Actin centroid and compared the resulting vector to the major axis angle of the ellipse fitting the F-Actin cytoskeleton. If the difference was less than 90°, migration direction was approximated as the major axis angle. Otherwise, the migration direction was the major axis angle + 180°.

This data was then split based on whether cells were migrating towards or away from the edges. Rayleigh’s test tested for uniformity in the data, and non-uniform data was fit to a von Mises distribution, estimating peak angle, μ , and concentrating parameter, κ . The parameters were compared using Watson Williams and ANOVA tests respectively, grouping the data by migration direction towards or from the edge and the configuration. Finally, a Kuiper’s test was used to compare the migration direction distributions for the aggregate data.

RESULTS

First, we characterized how flexion affected the recellularization of the invasion region and determined if flexion affected parallel and perpendicular recellularization with respect to the stretched direction. Outliers were removed from the data, and the normalized counts were pooled by treatment type. 1-way ANOVA testing on the cell counts indicated significant differences ($p < 0.001$) among the treatment groups. A Tukey multiple comparison test indicated that the flexed experiments exhibited significantly ($p < 0.001$) lower cell counts than static experiments for both parallel and perpendicular configurations, suggesting that flexion results in decreased recellularization. There were also significant differences between the flexed experiments, with flexed perpendicular having lower normalized cell counts ($p < 0.05$). These results indicate that cyclic stretching's effect on recellularization is two-fold: decreasing cell recellularization of the invasion region and causing preferential recellularization orthogonal to the stretching direction. However, this data doesn't elucidate the associated migration. Specifically, the recellularization rates of the two directions could differ if the time scale for reorientation due to SA is much less than the observation time and/or if cell speed depends on orientation relative to the stretching direction. This is pertinent as cells migrating into the acellular region have perpendicular and parallel orientations relative to the stretching direction for the parallel and perpendicular configurations, respectively.

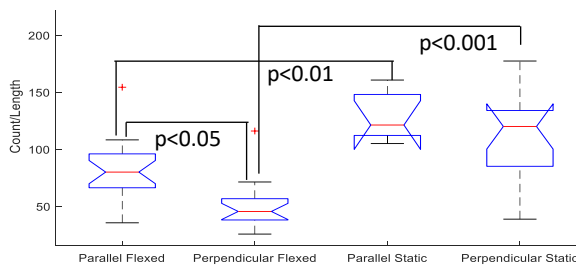

Fig 2. Normalized cell counts categorized by treatment type

Circular statistical analysis of the migration directions were used to better characterize migration behavior. As shown in fig. 3, the flexed experiments resulted in a bimodal distribution of migration directions, whereas static migration angles appeared uniform. Rayleigh's tests conducted on the split data indicated that 22 of the 24 static migration angles were uniformly distributed ($p > 0.05$) and that 23 of the 24 flexed migration distributions were non-uniform ($p < 0.05$). Von Mises fits for the flexed experiments resulted in mean angles and concentration parameters that did not differ significantly ($p > 0.05$). These results suggest after 24 hours of cyclic stretch, cells preferentially migrate nearly orthogonal to the stretch direction at 73° and 253° with $\kappa = 0.517$.

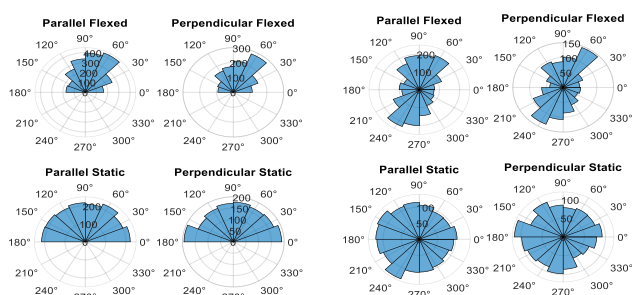

Fig 3. Polar histograms for **A.** ellipse major axis angles and **B.** approximated cell migration direction

Moreover, a Kuiper's revealed no that there were no differences in cell migration direction distributions when comparing the two orientations. However, the test did indicate that the migration direction distributions were different between flexed and static experiments.

Fig 4. Cumulative density functions for cell migration angles.

DISCUSSION

In this study, we sought to determine how cyclic stretch affects cell migration perpendicular and parallel to the stretching direction and characterize the nature of the migration. Our results indicate that cyclic stretch results both decreased recellularization and induced directionally dependent single-cell cellularization orthogonal to the stretch direction. Recent literature suggests that cyclic stretching can decrease cell proliferation and migration rates [2,3], impacting recellularization. Our results align with these interpretations, but does not separate each factor's effect on observed recellularization. Fitting the data to reaction-diffusion models Fisher-Kolmogorov equation [8] can provide further insight into the impacts of each, and is a potential future direction.

The results from the circular statistical analysis suggests that at 24 hours, migration behavior is symmetric and consistent with observed reorientation behavior due to SA [4,5]. The Rayleigh's tests of uniformity demonstrated that cell migration towards and away from the edges were effectively symmetric. Further, the results of the Kuiper test indicate that the cells undergoing flexion exhibited the same migration patterns irrespective of their initial migration past the edge. These differed from the migration angle distributions of the static tests. These data indicate that at 24 hours, the direction of cell migration closely aligns with observed SA reorientation behavior. This suggests that SA behavior might be responsible for the observed directionally dependent recellularization. Future experiments with more granular timepoints can be used to monitor the onset of this behavior to ascertain the dynamics of the observed direction-dependent recellularization.

In all, our results indicate that flexion reduces recellularization rates and results in directionally dependent recellularization rates. Circular statistical analysis indicates that after 24 hrs, cell migration orientations closely align with cellular SA reorientation behavior, resulting in preferential migration orthogonal to the direction of stretch. Ultimately, the combination of these methods allows for a more thorough analysis linking cell migration behavior with recellularization results and can lead to a better understanding of recellularization dynamics in cyclically-stretched cardiovascular tissues.

INTRODUCTION

Understanding the mechanisms by which the hemodynamic environment affects the behavior and evolution of cardiovascular structures has become increasingly central to predictive simulations. Early experiments showed that vascular cells are sensitive to their mechanical environment and seek to maintain homeostatic stress values and have been used as a basis for cardiovascular growth and remodeling (G&R) theory ever since. [1-4]

Early G&R studies treated vascular soft tissue as homogeneous when predicting vascular evolution. However, vascular tissue is made up of a complex mixture of biological constituents that each have specific biomechanical behavior. To more accurately model this behavior, the constrained mixture theory of vascular G&R was introduced to model how turnover of individual constituents drives the evolution of vessels as a whole. [5] Constrained mixture theory proved successful at modeling vascular response to a wide variety of hemodynamic and pathological conditions and has since been adapted to a myriad of applications. [6, 7]

The versatility of constrained mixture theory makes it an attractive framework to integrate into high-fidelity models of patient-specific hemodynamics. Given the ability of computational fluid dynamics to quantify hemodynamic forces in arbitrarily complex geometries, this would significantly expand the ability of constrained mixture theory to predict outcomes in clinically relevant cases. However, the complexity of constrained theory has limited its ability to be adapted to patient-specific frameworks. Previous studies have attempted to circumvent this limitation by using simplifying assumptions, either in the calculation of the hemodynamic fields or in the constrained mixture theory itself, and there has yet to be a full implementation of constrained mixture theory in fully 3D, patient-specific fluid-solid interaction (FSI) simulations.

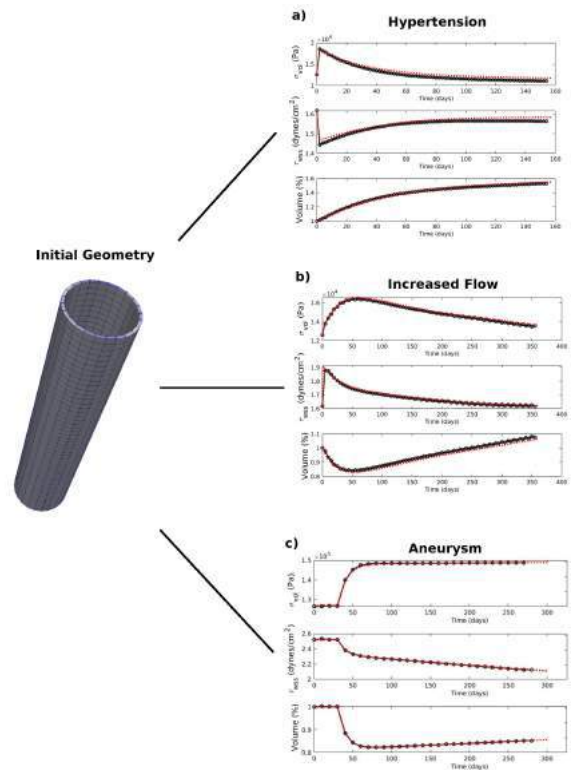

Figure 1: Validation of the FSG framework in a 3D geometry (black line) against reduced order solution (red dotted line).

This work presents the methodology for fluid-solid growth (FSG) framework that utilizes full constrained mixture theory. We validate the performance of this framework against benchmark constrained mixture theory problems and show its ability to simulate arbitrary geometries in the case of standard hypertension, increased flow, and aneurysm formation. This represents the first framework able to simulate constrained mixture theory G&R in complex, fully-3D, patient-specific anatomies.

METHODS

The evolution of the referential mass densities an individual constituents, α , is given as

$$\rho_R^\alpha(s) = \rho_R^\alpha(0)Q^\alpha(s) + \int_0^s m_R^\alpha(\tau)q^\alpha(s, \tau)d\tau \quad (1)$$

where the mass production function, $m_R^\alpha(\tau)$, and the mass survival function, $q^\alpha(s, \tau)$, are dependent on wall shear stress, τ_{wss} , and the volumetric stress, σ_{vol} . The strain energy density at any point in the tissue is postulated to be

$$W(s) = \sum_\alpha \left[\rho^\alpha(0)Q^\alpha \hat{W}^\alpha(\mathbf{F}_{n(0)}^\alpha(s)) + \int_0^s m^\alpha(\tau)q^\alpha(s, \tau)\hat{W}^\alpha(\mathbf{F}_{n(\tau)}^\alpha(s)) \right] \quad (2)$$

τ_{wss} , σ_{vol} , and the current configuration, $\mathbf{F}(s)$, are calculated using coupled fluid-solid interaction. The fluid domain is governed by the Navier-Stokes equations

$$\nabla \cdot \mathbf{v}^f = 0 \quad (3)$$

$$\dot{\mathbf{v}}^f + \mathbf{v}^f \cdot \nabla \mathbf{v}^f = \frac{1}{\rho^f} \nabla p^f + \nu^f (\nabla^2 \mathbf{v}^f + (\nabla \mathbf{v}^f)^T) + \mathbf{f}^f \quad (4)$$

and solid domain is governed by linear momentum balance

$$\text{div} \boldsymbol{\sigma} + \mathbf{f} - \rho \mathbf{a} = \mathbf{0}. \quad (5)$$

To evolve the configuration of the vessel we iterate between the fluid, solid, and *G&R* equations until convergence is reached at each timestep. To keep the evaluation of the solid governing equations tractable, we used the linearized behavior of the vascular material response at each iteration and enforce volume change via a dilation penalty framework where. The Cauchy stress then takes the form

$${}^{n+1}\boldsymbol{\sigma}(s) = -({}^n p(s) + {}^*p)\mathbf{I} + \frac{1}{{}^*J} {}^*\mathbf{F} {}^n \hat{\boldsymbol{\sigma}}(s) {}^*\mathbf{F}^T + \frac{1}{{}^*J} {}^*\mathbf{F} ({}^n \mathbf{C}(s) : {}^*\mathbf{E}) {}^*\mathbf{F}^T \quad (6)$$

$${}^*\mathbf{E} = \frac{1}{2} \left(\left(\frac{\det {}^*\mathbf{F}}{{}^*J} \right)^{2/3} {}^*\mathbf{F}^T {}^*\mathbf{F} - \mathbf{I} \right) \quad (7)$$

$${}^*p = k(\det {}^*\mathbf{F} - {}^*J) \quad (8)$$

where k is a penalty parameter that enforces the volume change to desired accuracy and ${}^n \mathbf{C}(s)$ is the linearized stress response given as

$$\begin{aligned} & {}^n \mathbf{C}(s)_{\alpha\beta kl} \\ &= \frac{4}{{}^n J(s)} {}^n F_{\alpha A}(s) {}^n F_{\beta B}(s) {}^n F_{kP}(s) {}^n F_{lQ}(s) \frac{\partial^2 W(s)}{\partial C_{AB} \partial C_{PQ}} \Big|_{{}^n \mathbf{C}(s)} \end{aligned} \quad (9)$$

RESULTS

This FSG framework was implemented in the SimVascular open-source multiphysics solver (<https://simvascular.github.io/>). Validation was done using a hypertension model where the vessel pressure was raised 40% above its homeostatic value, a increased flow model where flow was increased 20% above its homeostatic value, and an aneurysm model where elastin was degraded by 65%. We used a timestep size of 1 day, 5 days, and 10 days respectively.

In the hypertension model there was an instantaneous increase in σ_{vol} that returned to homeostatic values over the course of the simulation. In the increased flow case there was an instantaneous increase in τ_{wss} accompanied by an instantaneous increase in σ_{vol} triggered by the increased flow condition under constant outlet resistance. τ_{wss} monotonically decreased until homeostatic values were reached. σ_{vol} initially increased due to the τ_{wss} perturbation dominating the change in volume but then decreased after sufficient mediation of τ_{wss} allowed for late-stage volumetric growth. In the aneurysm case, elastin injury was initiated at $t = 30$ days after which vascular dilation progressed resulting in decreasing τ_{wss} . In all cases, the FSG framework results matched the solutions previously produced by reduced order implementations of constrained mixture theory.

DISCUSSION

This study shows that our FSG framework can accurately capture expected constrained mixture results under a variety of hemodynamic conditions, pathological conditions, and simulation timestep sizes. Unlike previous implementations of constrained mixture theory, this framework utilizes the fully 3D forms of the constrained mixture, fluid, and solid governing equations. By doing this, this framework is generalizable to arbitrary geometries including patient-specific models of cardiovascular structures. In addition, it is implemented as part of an open-source computational fluid dynamics solver, SimVascular, providing a open tool for the scientific and clinical communities. This represents a major step forward in the field of vascular simulation and will provide the basis for future studies of patient-specific vascular G&R.

INTRODUCTION

Peripheral arterial disease (PAD) can occur in various vascular beds – including the neurovasculature and the vasculature of the limbs [1]. Atherosclerosis or thrombus formation in the inner lumen of arteries can lead to significant clinical complications, including stroke, acute limb ischemia, wounds, and gangrene. To alleviate these conditions, clinicians need to be able to navigate in the arterial system, locate these areas of obstruction, and administer treatment expeditiously. Endovascular catheterization to facilitate these types of treatments requires steerable and navigating low profile catheters to the diseased arteries [1]. A major limitation of this is catheter kinking, buckling, and herniation during the process of catheter navigation within complex tortuous arteries.

To address this major limitation, our team developed a catheter (the *MultiFlex Catheter*) that can retain flexibility during navigation towards areas of disease, and then subsequently become rigid once in place to facilitate treatment of the area of disease (with stents, angioplasty balloons, or endovascular coils) without catheter herniation or buckling. The design uses a multi-lumen catheter that encases an array of wires; when space between the catheters is suctioned with a syringe, the inner and outer tubes cinch against the wire array and the catheter stiffens [2]. Our objective was to evaluate mechanisms that influence the efficacy of this mechanism. We hypothesized that including expanded polytetrafluoro-ethylene (ePTFE) tape within the outer lumen would aid this change in stiffness by holding the wire array in place during actuation.

We additionally hypothesized that the introduced wrapping styles have varying levels of effectiveness in maintaining the string array's position. Each prototype introduced a unique combination of wrapping method, ePTFE spacing, and width. Modeling the catheter as a cantilever beam with a point load placed at points along its length provides the data to find its maximum and minimum range of flexural rigidity [2]. Image analysis of this modeling allows for the

measurement of angular deflection (1) at the point load and its tangent length to the beam.

METHODS

Resonetics, an engineering and manufacturing company for the life sciences industry, created the prototypes through shaft lamination and complex catheter reflow operations. They were constructed with a reinforced coil within the inner lumen that provides support and a uniform passage for wires. The bifurcated hub located at its port end allows for access to the inner and outer lumen. The catheter without ePTFE wrap securing its string array was assigned as the control, and the remaining catheters were labeled as experimental.

The Various ePTFE tape width and spacing used in either the spiral or banded wrapping method is tabulated and differentiates each prototype based on these variables.

Catheters, which are constructed of pliable composite materials, flex significantly even under relatively light stresses. To precisely measure catheter stiffness, a non-linear formulation of Euler-Bernoulli beam theory is used as the basis for deriving flexural rigidity (2) [3].

A dunk test, which slowly injected air into the outer lumen while it was submerged to observe for leaks in the form of escaping air bubbles, was done prior to collecting data to ensure catheter viability.

Using a clamp on the bifurcation hub, the catheter is pinned horizontally to its background and placed vertically against a perpendicular, flat surface. The photos taken of each prototype in its actuated state, with the addition of a point load along its length, provides the initial imaging data for measuring the angular deflection and tangent length of the moment arm at the point load. Using ImageJ, an image analysis software, these two previously variables are measured to find the flexural rigidity, quantifying the stiffness along the catheter's length.

Angular deflection

$$\theta = \theta_f - \theta_i \quad (1)$$

Non-linear flexural rigidity

$$EI = \frac{PL^2 \sqrt{1 + \tan^2(\theta)}}{2 \tan(\theta)} \quad (2)$$

RESULTS

The ePTFE tape addition to the array successfully demonstrates its ability to secure the wires in place, increasing the stiffness range. The varying flexural rigidity range of each catheter also shows the influence of the wrapping method on actuating ability (Figure 1).

Both prototypes with the tightly wound spiral method showed the highest effectiveness in increasing flexural rigidity. Their ability to retain string array spacing during actuation attributes to this.

Plotting the stiffness range of each prototype in comparison to commercially available catheters and sheaths (Figure 2) also illustrates its potential in peripheral and neurovascular procedures. Each prototype overlaps the Catheter and LEPA Sheaths required flexural rigidity range, showing that the *Multiflex catheter's* wrapping style can be designed for an intended range.

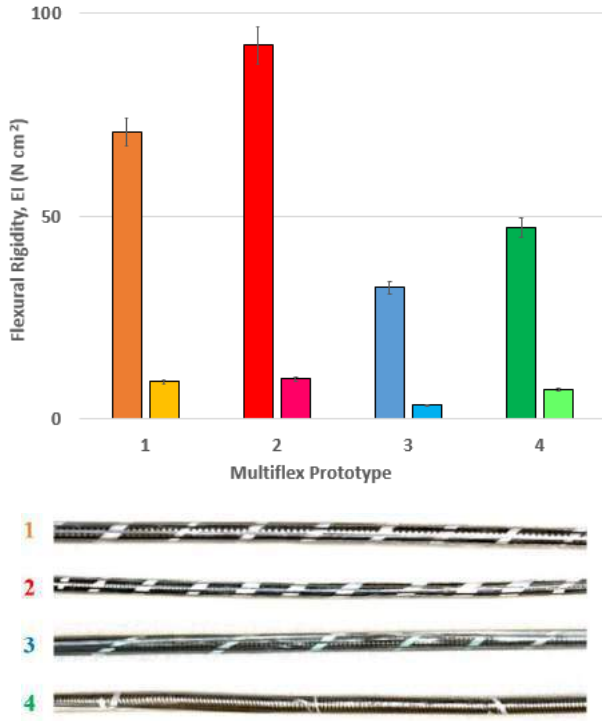

Figure 1: Flexural rigidity range of prototypes based on cantilever beam model testing. Prototype demographic displaying wrapping methods.

Figure 2: Ashy chart with the addition of prototype flexural rigidity ranges.

DISCUSSION

Overall, the results from conducting the cantilever beam modeling were within range of findings from previous prototype iterations. They also demonstrate the effectiveness of the string array tape addition and how it attributes to the variance in flexural rigidity range based on the wrapping style.

With this testing, there are flaws that allow for inconsistencies in the data. The mass per unit length is not considered in the equations and violates the previous assumption that it is negligible compared to the point load. When moving along the length, the catheter mass must be considered as well because its considerable mass does effect the deflection. The accuracy of its maximum flexural rigidity may have validity because this considerations may be disregarded when the point load is at the maximum distal end, which provided the greatest tangent length and angular deflection. Although, the minimum flexural rigidity and its measurement with respect to specific catheter segments may be inaccurate.

Setting up the experiment for each catheter also introduced a variance that may affect data accuracy. The catheter itself may have not been aligned perfectly horizontal. This influence combined with the variable, innate stiffness of each catheter based on its orientation may affect the point load location measurement and angular deflection.

The limiting factors of image quality and pixilation error during image analysis also played a role. These influences provided room for error when measuring angles and tangent point load length. The angle may not be perfect, and the length may be distorted given the set scale.

INTRODUCTION

Curative therapies are not available to greater than 80% of the patient population with hepatocellular carcinoma (HCC). There is a well-recognized need for novel methods that can intricately balance (1) treatment of the disease extent with (2) preservation of liver function and minimize the risk of recurrence and metastasis. Ablation and embolization are the two most common minimally invasive methods used in treating unresectable HCC. These are established therapies with a known survival advantage [1]. Thermally ablative therapies include radiofrequency ablation (RFA) and microwave ablation (MWA) and utilize thermal energy to destroy the disease. Embolization techniques utilize a direct injection of a chemotherapeutic agent or radiation into the hepatic artery with or without lipiodol and a procoagulant material to promote intratumoral retention. Thermoembolization (TE) provides a novel conceptual endovascular approach in which a bolus of acid chloride dissolved in an inert oily solvent delivers an exothermic chemical reaction. Recent investigations of TE indicate that it might offer unique advantages versus current techniques [2]. This approach is unique and combines the benefits of embolic and thermal- and chemical-ablative therapy modalities. The target tissue and vascular bed are subjected to simultaneous hyperthermia, ischemia, and acidic environments in a single procedure.

These complex conditions caused by the injection of acid chloride into the target tissue must be understood thoroughly in order to develop techniques to effectively destroy the intended cancerous tissue without negatively affecting the surrounding parts of the body. Accurate predictions of cell death are important towards these goals, and we have developed and calibrated preliminary mathematical models of the TE procedure using *in vitro* platforms that mimic vascularized liver. Validated cell damage models will accurately estimate the cellular damage as a function of hyperthermia, ischemia, and low pH stress that occurs during TE. The work presented in this paper focuses on the evaluation of how the conditions in the target tissue affect cells cultured

in 2D cell monolayers and 3D collagen platforms in order to develop an appropriate cell damage model.

METHODS

To understand the independent contribution of hypothermia, ischemia, and acidic environments that work in concert during TE, we first isolated the decrease in local pH and localized hyperthermia to determine their individual impact *in vitro* for computational model development. These conditions were later combined to identify any synergistic effects between them. Human hepatocellular carcinoma cell line HEPG2 was cultured in flasks and then passaged and seeded into 96-well plates for use in experiments. Cell survival ratios were determined 24 hours after exposure to hyperthermia and diminished pH using Cell-Titer blue assays. Additional unexposed control plates were measured alongside the exposed samples. The survival ratio was calculated as the ratio of absorbance between exposed and unexposed samples after subtracting the background absorbance observed from an acellular plate. The effect of heat associated with thermoembolization on representative 2D and 3D extracellular matrices was determined as follows:

2D samples: Each plate had 20-25 wells with adherent cells seeded on their bottom surfaces. Plates were placed in an incubator with desired temperature to expose cells to hyperthermia. Cell culture media was removed from cell-seeded plates, and it was replaced with only 40 μ L of media per well to reduce heating times. In order to set the exposure temperature more accurately, one cell-bearing plate was tested simultaneously with a second, acellular plate with the same fluid volumes and a thermocouple placed in the bottom of one well. Temperatures were recorded throughout the exposure. At the end of the experiment, warm media was removed rapidly, then fresh media was added, and the plates were stored in an incubator at 37 for 24 hours. Cells were exposed to temperatures of 43, 45, 47, and 50 °C for 10 to 60 minutes.

3D samples: As we have previously published [3], type I collagen was used to replicate the 3D tissue microenvironment. Collagen was mixed with HepG2 cells at a concentration of 1×10^5 cells/ml and dispensed as 50 μ L aliquots in 96 well plates and allowed to polymerize.

Phosphate-buffered saline (PBS) solutions with added glacial acetic acid were used to expose cells to acidic pH. Solutions with a pH of 6.00, 6.25, 6.50, 6.75, and 7.00 were prepared and passed through sterile filters. Media was removed from each well of a plate, then a timer was started, and 150 μ L of acidified PBS was added to each well. The plate was kept in an incubator for between 10 and 60 minutes, then the acid solutions were removed in the same order they were added. A small pH probe was used to record the pH over time in identical cell-bearing plates. Combined pH and hyperthermia testing were performed using the pH exposure protocol listed above with heated solutions, then placing the plates into cell culture incubators set to 43 or 45 $^{\circ}$ C.

Modified Arrhenius damage models are used to provide a first-order estimate of the cell death resulting from the thermal and acidic pH exposure. Cell kill as a function of exposure to temperature is known to approximately follow an Arrhenius rate process [4]. Here, parameters of the Arrhenius damage model will be considered dependent on the presence of the acid as well. Arrhenius parameters are calibrated to the pathology response observed from *in vitro* cell damage testing. The Arrhenius parameters follow a log-linear relationship [5]. Regardless of the type of damage process being examined, a plot of the activation energy versus the log of the frequency factor that defines the Arrhenius model approximately follows a straight line. This empirical relationship has been measured independently by Wright [6] and He [7] and is used to constrain the damage model under variations in temperature and acidic pH exposure. A constrained optimization formulation is numerically solved to fit model parameters to the cell viability data. The parameters corresponding to the temperature-only data are recovered first. The parameters corresponding to pH are then recovered given the known Arrhenius parameters that fit temperature.

RESULTS

Preliminary *in vitro* testing results have been applied toward the creation of cell death models based on exposure to hyperthermia and acidic solutions. As seen in Fig. 1-A, a steady decline in cell survival was observed during hyperthermia, with the rate of death increasing with higher temperature and longer exposure times.

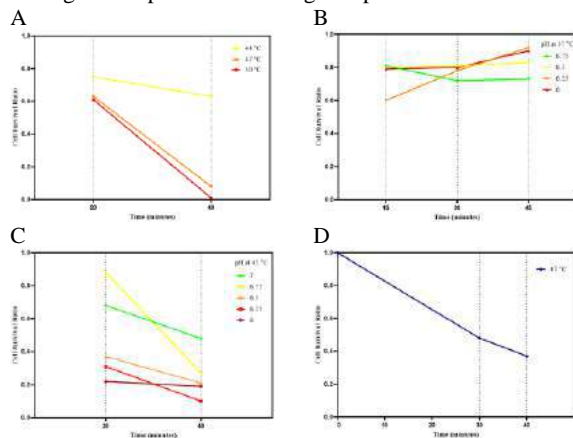

Figure 1 – Experimental viability. A – Hyperthermia exposure in 2D samples B – Acidic pH exposure in 2D samples C – Combined hyperthermia and acidic pH exposure in 2D samples D – Hyperthermia exposure in 3D samples

In the studied range, HepG2 cells in 2D samples are not sensitive to low pH (Fig. 1-B) unless exposed simultaneously to hyperthermic temperature (Fig. 1-C). These results further confirm the benefit of the combined effect of multiple mechanisms of cell injury implicitly to TE. As it is shown in Fig. 1-D, viability of HepG2 cells in 3D samples in response to hyperthermia decreases significantly while its rate decreases over time. Furthermore, it was observed that the 3D samples heat up more slowly than 2D samples and were melted almost completely at 49 $^{\circ}$ C while they had no noticeable melting at 47 $^{\circ}$ C.

A modified Arrhenius damage model was utilized to include both effects of temperature and pH to the cell viability as follows:

$$\Omega = \ln\left(\frac{1}{S}\right) = \int_0^t A \exp\left(-\frac{E_a}{RT + E_a pH}\right) dt \quad (1)$$

Two approaches of Sequential and Joint were used to curve fit the math model to the experimental data are shown in Fig. 2-A and B, respectively. These model fits of the predicted damage vs. measured damage achieve an R^2 values of 0.797831 and 0.7833556 in turn.

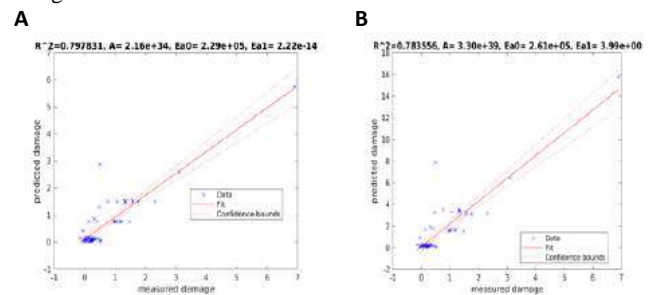

Figure 2 – Fitting of modified Arrhenius model to viability data

DISCUSSION

The work presented in this abstract has successfully broken down the conditions present in the target tissue during TE in separate and combined experiments to observe the resulting cell death. In this way, the contribution of each variable to the therapeutic effect of TE can be quantitatively studied, and the synergistic interactions between multiple conditions can be identified. Initial results demonstrate the feasibility of calibrating a temperature and pH-dependent cell damage model to the observed viability data. Further studies will cross-validate the results to study the prediction accuracy of our cell damage modeling approach.

The results from this study will enable the development and calibration of mathematical models to understand and predict the independent and synergistic effects of hyperthermia and acidic environments caused by TE. Deeper insight into effective delivery of this new therapy will provide valuable knowledge applicable to the treatment of cancers.

INTRODUCTION

The vagina is a fibromuscular organ that must undergo significant remodeling to act as a passageway during menstruation, intercourse, and vaginal delivery. The vagina is principally composed of collagen fibers, elastic fibers, and smooth muscle cells. Elastic fibers dictate compliance, constrain collagen undulation, and influence smooth muscle cell phenotypes¹⁻³. Smooth muscle cells are the primary contributor of the active mechanical properties of the vagina, which include contractility and the maintenance of the structural and functional integrity of the vaginal wall⁴. The active contribution of the postpartum rat has previously been characterized uniaxially and is thought to have an increased receptor sensitivity to agonist concentration as compared to the nulliparous vagina⁵. The vagina experiences multi-axial loading in the body, which is not reflected in the previous uniaxial testing. Biaxial extension-inflation protocols are useful tools to evaluate the multi-axial mechanical properties while maintaining the native cylindrical geometry and cell-matrix interactions^{6,7}. Such protocols have quantified the maximum contractile potential and the passive mechanical contribution of the nonpregnant murine vagina⁷. However, how the biaxial active and passive mechanical contributions change during postpartum remodeling is unknown. Therefore, the objective of this study was to determine the active and passive mechanical properties of the murine vagina through postpartum remodeling. A general agonist of potassium chloride (KCl) will be utilized to determine the dose dependent contractile response. Further, elastase digestion will be used to observe potential interactions between elastic fibers and smooth muscle cell contractility.

METHODS

Sample Size A total of n=105 nulliparous (NP) and postpartum (PP) CD-1 mice aged 2–3 months were used within this study (Tulane IACUC approved). **In Vivo Vaginal Pressure Measurements (n=5/ group)** To inform the loading environment for mechanical testing,

intravaginal pressure was quantified with a balloon catheter at the estrus stage in nulliparous mice as well as 24 hours (1D PP), 72 hours (3D PP), 1 week (7D PP), and 2 weeks (14D PP) postpartum^{7,8}. The balloon catheter was inserted into the vaginal canal and PowerLab and LabChart8 software recorded pressure (AD Instruments). **Specimen preparation** A separate cohort of CD-1 mice (n=16/ group; nulliparous at estrus, 1D PP, 3D PP, 7D PP, and 14 D PP) were euthanized via guillotine without anesthesia to preserve SMC function⁷. Immediately after euthanasia, the vaginal tissue was dissected from the cervicovaginal complex and cannulated onto a biaxial extension-inflation device (Danish MyoTechnology; DMT). **Elastase treatment (n=8/ group)** Samples were randomly allocated to either a control (n=8/ group) or elastase treatment (n=8/ group). If allocated to elastase treatment, samples were intraluminally exposed to 15 U elastase digestion for 45 minutes^{6,7}. **Dose response contractility testing** To quantify the smooth muscle contractile potential, varying doses of a general agonist, potassium chloride (KCl), induced vaginal contractions⁹. Isobaric and axially isometric vaginal contractions were first induced with 20 mM of KCl for 5 minutes. The tissue was then allowed to rest for 5 minutes in fresh active Krebs's Ringer Buffer (KRB) Solution. The protocol was then repeated with 30 mM, 40 mM, 50 mM, 60 mM, 80 mM, and 100 mM of KCl. For each KCl dose, the change in outer diameter and axial force was recorded. **Passive mechanical testing (n=16/ group; 8 control, 8 elastase)** To remove calcium from the tissue and hinder the contractile response, the media was replaced with fresh calcium free passive (KRB) solution and the vagina was subjected to 2 mM of Egtazic acid (EGTA) for 30 minutes⁷. To quantify the circumferential and axial 1st Piola-Kirchhoff stress and material stiffness, 5 cycles of pressure-inflation tests (0–15 mmHg) were performed at the physiologic length as well as $\pm 2\%$ the physiologic length⁷. **Data analysis** The axial contractile potential was defined as the difference in the maximum and minimum axial force over the 5-minute period⁹. The passive material stiffness was determined by fitting a linear function

through the 1st Piola-Kirchhoff stress-stretch curve around the physiologic region¹⁰. **Statistical analysis** To determine if concentration of KCl, elastase treatment, and postpartum timepoint influenced contractile potential, 3-way ANOVAs (dose, elastase, timepoint) evaluated changes in axial force and outer diameter, respectively. A 3-way ANOVA (direction, elastase, timepoint) evaluated differences in the circumferential and axial material stiffness.

RESULTS

For the datasets described herein, the Shapiro-Wilks test suggested that the error of the data was normally distributed ($p > 0.05$). **Dose response contractility** A 3-way ANOVA (dose, elastase, timepoint) identified significant differences in the circumferential contractile potential with respect to KCl dose (not shown) ($p < 0.001$), elastase treatment ($p < 0.001$), and postpartum timepoint ($p < 0.001$). Significant interactions were observed among dose and elastase ($p = 0.02$), dose and timepoint ($p = 0.007$), elastase and timepoint ($p = 0.006$), as well as a 3-way interaction among all three variables ($p = 0.002$). An additional 3-way ANOVA (dose, elastase, timepoint) determined significant differences in the change in axial contractile potential with regard to agonist dosage (Figure 1) ($p < 0.001$), elastase ($p < 0.001$), and postpartum timepoint ($p < 0.001$). Significant interactions were noted among dose and elastase ($p = 0.005$), dose and timepoint ($p = 0.009$), elastase and timepoint ($p < 0.001$), and a 3-way interaction among the independent variables ($p < 0.001$). **Stress-Stretch curve** Early postpartum (1D PP) resulted in a leftward shift of the stress-stretch curve, denoting decreased distensibility (not shown). Subsequent postpartum remodeling (3D, 7D, 14D PP) demonstrated increased distensibility, as indicated by a rightward shift (not shown). **Material stiffness** A 3-way ANOVA identified significant differences in the material stiffness with respect to the postpartum timepoint ($p = 0.004$), elastase treatment ($p < 0.001$), and direction ($p < 0.001$). Significant interactions were observed between the postpartum time and elastase ($p < 0.001$), the postpartum time and direction ($p = 0.003$), direction and elastase ($p < 0.001$), as well as the timepoint, elastase treatment, and direction ($p = 0.006$). Posthoc analyses was not conducted due to significant interactions.

Figure 1: The axial contractile potential in the control (filled) and elastase (outlined) samples of nulliparous mice as well as 1D, 3D, 7D, and 14D postpartum (PP) samples. The dose-dependent contractile response was quantified at 20 mM, 30 mM, 40 mM, 50 mM, 60 mM, 80 mM, 100 mM of potassium chloride (KCl). Data are reported as mean \pm standard deviation.

DISCUSSION

Dose-Dependent Contractile Potential The axial contractile potential decreased in the immediate postpartum timepoint (1D PP) and increased in subsequent timepoints (7D PP, 14D PP; Figure 1). This supported prior results obtained by testing uniaxial strips of rat vaginal

Figure 2: The circumferential (A) and axial material stiffness (B) for control (black) and elastase (blue) samples of nulliparous mice as well as 1D, 3D, 7D, and 14D postpartum (PP) samples. In both directions, the material stiffness increased early postpartum with a subsequent decrease with postpartum remodeling. Elastase increased the material stiffness in the circumferential direction. However, elastic fiber disruption had minimum effect in the axial direction. To best visualize the diminished change, the y-axis for the two directions were optimized to varying scales.

tissue⁵. Additionally, elastic fiber disruption via elastase treatment reduced the axial contractile potential, as evidenced by the decreased change in axial force, respectively compared to control (Figure 1). The demonstrated decrease may potentially be due to disrupted physical interactions between elastic fibers and smooth muscle cells. Similar decreases in vaginal contractility with elastase treatment were observed in CD-1 mice aged 2–6 months¹¹. Furthermore, the elastase induced decrease in contractile potential had a diminished effect in the 1D and 3D PP samples, as compared to the nulliparous, 7D, and 14D PP groups. In the C57BL/B mouse, decreased contractility was observed in the axial direction of the vagina at 4–6 months⁷. This decrease in axial contractility coincided with an increased area fraction of elastic fibers in the axial direction of the C57BL/6 mouse⁷. Taken together, this may suggest the potential for decreased functional elastic fibers in the early postpartum timepoints of 1D and 3D PP. **Material stiffness** In both directions, the material stiffness increased in the early postpartum groups and subsequently decreased in the later timepoints (Figure 2). Previous work in the mouse model suggests a potential burst of elastic fibers in the postpartum vagina¹². However, additional work observed an upregulation of matrix metalloproteinases¹³. These data may indicate time-dependent microstructural remodeling of the postpartum vagina. Future work is needed to better define relationships between mechanical metrics, such as material stiffness, and microstructural composition. **Limitations** Mice do not naturally sustain injuries during birth. Future work should carefully consider variations among the birth canal and fetal size. Quantifying vaginal mechanics through postpartum and with elastase treatment may provide key insights to improve the overall quality of care given postpartum patients in the clinical setting.

AUTOMATIC MODEL CONSTRUCTION FOR PATIENT-SPECIFIC AORTIC FLOW SIMULATIONS USING GEOMETRIC DEEP LEARNING

Pan Du (1), Delin An (2), Chaoli Wang (2), Jian-Xun Wang (1)

INTRODUCTION

Image-based computational fluid dynamics (CFD) modeling has great significance in facilitating clinical diagnosis and treatment planning for cardiovascular diseases (CVD) [1], where the image-segmentation, which involves characterization of cardiac geometries from image data such as computerized tomography (CT) or magnetic resonance imaging (MRI), is one of the essential steps in the process as the resulting geometry directly determines the quality of the subsequent CFD modeling. Manual segmentation has considerable artifacts and is time-consuming [2]. With the rapid development of computer vision and artificial intelligence, a large group of works emerge recently, leveraging machine learning techniques to automate the image segmentation process. Early works use conventional machine-learning methods well-developed for image processing to realize automation. For example, feature descriptors or filters are used to detect edges representing the vessel wall [3-4]. Supervised or unsupervised classifiers are utilized to classify regions according to the gray-scale intensity [5-6]. Those methods require cumbersome pre- and post-processing procedures and yield unsmooth or discontinuous reconstructed surfaces. More recently, deep neural networks (DNN) are adopted to directly map the raw image data to vessel geometry. The most popular approaches are either using 2-D CNNs for each image slice or 3-D CNN that performs 3-D convolution in the volumetric data. Usually, a deformation mechanism will be added to ensure the surface smoothness of the reconstructed geometry [7-8]. Despite the rich literature in this field, those methods are either not fully automated (e.g., require user input of the centerline, requires manual pre- or post-processing) or suffer from surface irregularity, especially for the multi-branch aorta model.

To fill the gap, we proposed an automatic-segmentation model for patient-specific multi-branch aorta which combines a 3-D CNN to encode the image data and graph deformation model where a 2-D CNN is used to extract centerline from image data and a deformation model

is used to transform the template to the 3-D label geometry. We trained and tested our model on the Vascular Model Repository (VMR) which is an open-source database of cardiovascular models [9]. The proposed model features predicting centerline and the aorta geometry simultaneously and proved to have good generalizability across different patients.

METHODS

As shown in Figure 1, the auto-segmentation model consists of two parts: an encoding-decoding 3-D CNN structure (top half of Figure 1) and a graph convolution network (GCN) based deformation module (bottom half of Figure 1).

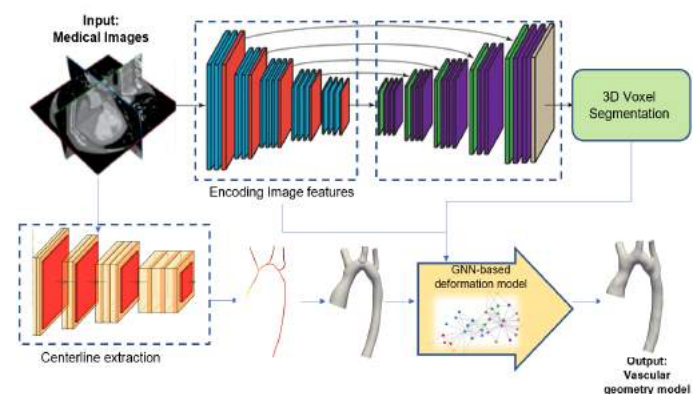

Figure 1: Diagram of the auto-segmentation model

3-D CNN: The 3-D CNN encodes the volumetric image data into the latent space and decodes them back to volumetric data with the same dimension to match the binary voxel segmentation labels (top half in Figure 2). Skip connections are added to avoid severe gradient decay. The input information is volumetric pixels with gray-scale values and

the output is a block of binary volumetric pixels where 1 represents inside the vessel and 0 otherwise.

Graph deformation model: A 2-D recurrent neural network (RNN) is used to extract the centerline of the aorta. The 2-D RNN takes in a sequence of the horizontal image slices in the image data and outputs the centerline point locations as well as the local vessel radius.

The centerline and the radius information are later used to create a synthetic aorta geometry via lofting a non-uniform rational B-spline (NURBS) surface. Then a graph convolutional network (GCNN)-based deformation model is adopted to deform the template to the 3-D label geometry with the guidance of the encoded information from the encoded information of the 3-D CNN.

Loss function

The loss function consists of two parts: the segmentation loss (from the 3-D CNN) and the deformation loss (from the graph deformation model). The segmentation loss is:

$$L_{seg}(I_i, I_o) = \sum_{x \in I_o} (I_o(x) \log(I_i(x)) + (1 - I_o(x)) \log(1 - I_i(x))) + \frac{2 \sum_{x \in I_o} I_{out}(x) I_i(x)}{\sum_{x \in I_o} I_o(x) + \sum_{x \in I_i} I_i(x)} \quad (1)$$

where the I_i and I_o denote the input image and the output binary label image. x denotes the voxel inside the image data.

The deformation loss contains four components: point loss, normal loss, edge loss, and Laplacian loss. The point loss is minimizing the point close distance between the deformed template to the label geometry, which is computed via the bidirectional chamfer distance:

$$L_{point}(G_i, G_o) = \sum_{v_i \in G_i} \min_{v_o \in G_o} \|v_i - v_o\|^2 + \sum_{v_o \in G_o} \min_{v_i \in G_i} \|v_i - v_o\|^2 \quad (2)$$

where v is the vertex of the mesh.

The normal loss promotes the surface normal similarities between the deformed template to the label geometry:

$$L_{normal}(G_i, G_o) = \sum_{v_i \in G_i; v_o \in G_o; v_o = \arg \min_{v_o \in G_o} \|v_i - v_o\|^2} \min_{v_o \in G_o} \|n_{v_i} - n_{v_o}\|^2 \quad (3)$$

where the n_v denotes the normal vector of the vertex.

The edge loss encourages the triangles mesh elements to be uniform:

$$L_{edge}(G_i, G_o) = \sum_{v_i \in G_i} \sum_{u_{v_i} \in N(v_i)} \left| \|v_i - u_{v_i}\|^2 - \mu_o^2 \right| \quad (4)$$

where the $N(v_i)$ denotes the neighborhood of the vertex v_i .

The Laplacian loss ensures the mesh smoothness:

$$L_{lap}(G_i) = \sum_{v_i \in G_i} \left\| v_i - \sum_{u_{v_i} \in N(v_i)} \frac{u_{v_i}}{\|N(v_i)\|} \right\|^2 \quad (5)$$

The total loss is calculated as:

$$L_{total} = \lambda_1 L_{seg}(I_i, I_o) + \lambda_2 L_{point}(G_i, G_o) + \lambda_3 L_{normal}(G_i, G_o) + \lambda_4 L_{edge}(G_i, G_o) + \lambda_5 L_{lap}(G_i) \quad (6)$$

RESULTS

Our model is trained for 10000 epochs on an Nvidia A6000 video GPU. The training time is about 30 minutes per case during which the Adam optimizer is used with an initial learning rate of 0.01. 30 samples are used for training and the performance of the model is evaluated over a set of 5 test samples. The prediction of the centerline extraction and the prediction of the mesh is shown in Figure 2.

The results show great consistency for the centerline. The location of the predicted centerline is very close to the center of the vessel along the streamwise direction for all branches. From the CT data, one can observe the proposed model can also predict meshes very similar to the ground truth segmentation. The average relative L2 norm loss is around 3% averaged over all 5 test samples.

Figure 2: Prediction of the multi-branch geometry and centerline

DISCUSSION

In this work, we established an auto-segmentation algorithm that reconstructs centerlines as well as geometries from raw image data for patient-specific multi-branch aorta structure. The proposed model can accurately predict the centerline of the aorta structure and reconstruct the aorta surface very close to the ground truth. This highlight of this work includes the following: Previous work usually requires manual inputs (e.g., centerline) or pre- and post-process in the segmentation process, whereas the proposed method is fully automatic. There are few work outputs centerlines and the geometry simultaneously and embedded a deformation template to ensure surface smoothness. This work fills the gap and is capable of predicting multi-branch aorta structure. Nonetheless, our model also has the following limitations: The prediction performance will worsen if the input image data has a different orientation. Furthermore, the predicted surface has smoothed out certain geometric details from the ground truth aorta surface. This can be improved by improving the graph deformation model. In general, this work demonstrates how to build a fully auto-segmentation model for multi-branch aorta structures, which massively accelerates the image-segmentation process and can be applied to further uncertainty quantification studies.

INTRODUCTION

Even though cardiovascular stenting is widely used for the treatment of coronary artery disease, there is little information in the literature on how it can affect the hematological and hemorheological profile. Stent functionality is compromised by complications at the site of implantation, including altered wall shear stresses, disordered blood flow, and device wear and biocorrosion, which may lead to thrombosis and occlusion and in-stent restenosis [1-2]. Presently, most of the work on this issue is based on simplified theoretical models and computational fluid dynamics analysis on local hemodynamics [3], lacking *in vitro* and *in vivo* experimental verification with blood samples. Several studies suggest that red blood cells (RBCs) undergo mechanical and biochemical changes during blood passage through medical devices [4]. This study aimed to evaluate, in an *in vivo* setting, the effects of time-course stenting on hematological and hemorheological parameters that could potentially compromise the device's functionality and longevity.

METHODS

Custom-made self-expanding nitinol stents (Admedes GmbH, Pforzheim, Germany), 0.7 x 3.3 mm in dimension with a closed-cell design and a diamond-shaped pattern, were implanted in male CD1 mice, weighing 40 ± 5 g (Project license: CY/EXP/PR.L9/2019). Operative procedures were performed following the experimental protocol reported by Simsekylmaz et al. 2013 [5], which describes a rapid and accessible procedure of stent implantation in mouse carotid artery. Animals were pre-treated for 48 h with aspirin (75 mg in 250 mL drinking water), which was discontinued 48 h postoperatively. General anesthesia was induced by intraperitoneal injection of 100 mg/kg b.w. ketamine and 10 mg/kg b.w. xylazine.

Whole blood (0.5 - 1.0 ml per animal) was withdrawn from control (healthy, non-stented; n=5) and stented animals at 5- and 10-weeks post-implantation (n=3 per time point). Blood collection was performed by direct cardiac puncture under anesthesia, using citrate-dextrose solution

(Sigma-Aldrich, MI, USA) prefilled syringes at a ratio of citrate-to-blood of 1:9. Hematological measurements were performed using a Sysmex XT-2000i analyzer (Sysmex, Landskrona, Sweden), within 4 hours after blood collection.

RBC aggregation and deformability and blood viscosity were estimated using standard techniques at room temperature (25 ± 0.5 °C). The RBC aggregation was evaluated through a laser-photodiode-based system, the Rheoscan A200 instrument (Rheomeditech, Seoul, Korea). An aggregation index (AI) was used, defined as the ratio between the area under the light intensity/time curve, and the sum of the areas below and above the curve in the first 10 seconds. RBC deformability measurements were performed using the Rheoscan D300 (Rheomeditech, Seoul, Korea). The instrument is based on the principle of a diffraction technique combined with microfluidic rheometry, using a disposable microfluidic chip. In this technique a very low RBC-to-medium volume is perfused through the microfluidic chip, at a varying pressure (vacuum-driven shearing of a thin layer of RBC suspension), causing the cells to deform in an ellipsoidal shape. The elongation index (EI) of the cells is calculated based on the obtained diffraction patterns over a range of shear stresses. Blood viscosity was evaluated through the Brookfield DV2T instrument (AMETEK GB LTD T/A Brookfield, Stadium Way Harlow, Essex) using a cone-plate geometry. All measurements were performed using the same predefined shear rates between 251.2 and 1.4 s^{-1} (higher to lower shear rates).

RESULTS

The effect of stenting on various hematological indices, RBC and white blood cell (WBC) counts, hematocrit (HCT), red blood cell distribution width-coefficient of variation (RDW-CV), and mean corpuscular volume (MCV), is shown in Figure 1. Results are presented as mean \pm standard deviation (SD) along with the physiological range. Even though no statistically significant differences were observed between the tested samples, notable trends were apparent. Our findings showed an increase in RBC counts and slightly elevated HCT levels at

10 weeks post-stent implantation, contrary to a reduction in MCV. These could also account for the higher RDW-CV, demonstrated at the same time point. WBC counts were used for assessing the inflammatory status of healthy (control) and stented CD1 mice. The analysis revealed a rising trend over time suggesting a gradually increasing implant-included inflammatory response. Variations were previously reported between blood sampling sites [6] and data suggest that blood cell counts and indices are found significantly lower in heart blood compared to eye and tail vein withdrawal.

RBC aggregation and deformability, expressed by the indices AI and EI_{max} respectively, are presented in Figure 2. A marked decrease in AI index is observed at 5 weeks, compared to the control case, followed by an elevation at the late stages after stent implantation. Similar behavior is also reported in other *in vivo* studies involving human subjects [7]. RBCs showed decreased deformability in the 10-week sample group, compared to the other two cases. This decreasing trend can be due to biological but also mechanical factors such as the shear stress and the period of exposure to stress, which play a role in the RBC membrane properties and deformability. It is noteworthy that the decreased RBC deformability also corresponds well with the distinct increase in RDW-CV.

The viscosity data are listed in Table 1, as normalized (η^*) with high-shear viscosity (η_∞) values ($\eta^* = \frac{\eta}{\eta_\infty}$). Measurements demonstrate the shear thinning non-Newtonian nature of blood and at shear rates of 15.82 and 44.70 s⁻¹. The results indicate a decreased blood viscosity in stented mice at the more conservative shear rate of 44.70 s⁻¹, particularly at 5 weeks post-implantation. The hemorheological results observed, are in general agreement with the literature. That is the viscosity of blood is negatively affected by increased hematocrit, RBC aggregation, and impaired RBC deformability.

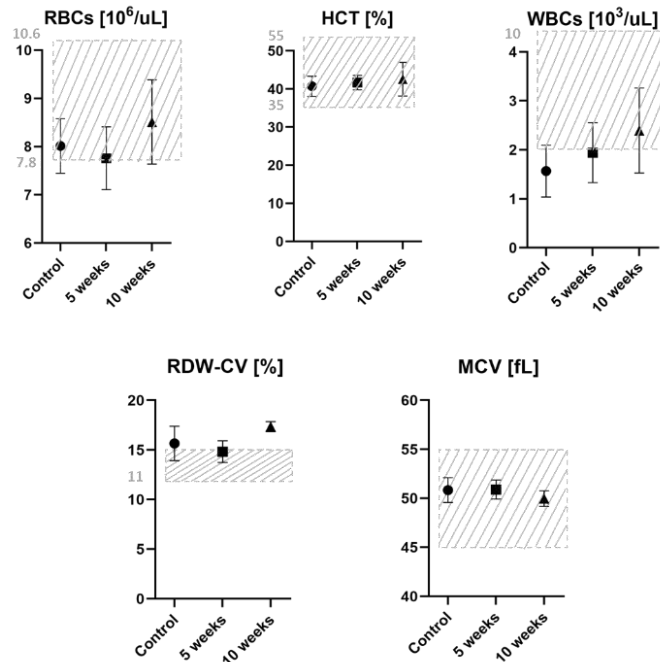

Figure 1: Effects of time-course stenting on hematological parameters. Values are expressed as mean ± SD and the physiological range is indicated with gray-lined boxes.

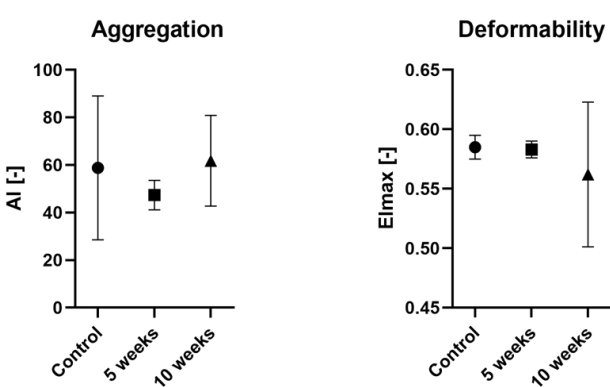

Figure 2: Stent-induced alterations in RBC aggregation and deformability.

Shear rate (s ⁻¹)	Normalized Viscosity η^*		
	Control	5 weeks	10 weeks
15.82	1.9867	2.0338	1.9505
44.70	1.5090	1.3678	1.4748

Table 1: Changes in the normalized viscosity of the samples, measured at shear rates of 15.82 s⁻¹ and 44.70 s⁻¹.

DISCUSSION

The present study showed that various hematological factors and the rheological properties of blood in mice were associated with stent implantation. The preliminary findings in this study agree with the current understanding in hemorheology that the reduction in RBC deformability results in higher viscosity and reduced RBC aggregation [8]. Although the alterations observed in the hematological parameters, and consequently on blood rheology, may be the result of inflammation caused by the stent presence, the physiological consequences in the circulation due to the stent-induced flow changes, need to be further investigated. Cells could be subjected to repeated stresses caused by the complex local flow conditions and interactions with the protruding struts in the flow. Further work on additional flow, geometry, and device parameters is warranted to establish the clinical significance of the trends apparent in the present study.

ACKNOWLEDGEMENTS

INTRODUCTION

Post-traumatic osteoarthritis (PTOA) is temporally linked to joint injuries, including intra-articular (i.a.) ligament ruptures, fractures, or meniscus tears (1). Despite PTOA representing 12% of all OA cases with incidence rates up to 50% following acute knee injuries, there are still no FDA-approved disease-modifying OA drugs designed to delay or prevent the development of PTOA (2). Absent such intervention, acute knee injuries induce diverse pathologic cascades that result in cartilage degradation (3). One of the main drivers of post-injury cartilage degradation is hemarthrosis, which occurs in 77% of acute knee injuries (4). Blood in the joint results in the rapid initiation of joint damage due to iron deposition and elevated levels of reactive oxygen species (ROS), matrix metalloproteinases (MMPs), and pro-inflammatory cytokines (5). N-acetyl cysteine (NAC) acts as an antioxidant by directly scavenging ROS and indirectly by generating intracellular glutathione (GSH), the body's most abundant antioxidant (6). Previous studies have explored NAC delivery to scavenge ROS in the context of joint injury (6–8). However, these studies focused on systemic or i.a. delivery before or at the time of joint injury, and few have investigated whether NAC administered after injury would retain its ability to delay or prevent cartilage degradation. Indeed, there is a paucity of research regarding NAC's chondroprotective nature and the “window of opportunity” for therapeutic intervention following acute knee injuries (1). Therefore, the goal of this study was to determine whether NAC can prevent chondrocyte apoptosis after oxidative stress and to identify the therapeutic “window of opportunity” for such interventions.

METHODS

An *in vitro* model was used to recapitulate the oxidative stress produced following acute knee injuries. Briefly, articular chondrocytes were harvested from juvenile bovine joints and cultured on tissue-culture-treated polystyrene at 70,000 cells/cm². After 48 h, cells were

treated with 100 μ M H₂O₂ for 0, 2, or 12 h, before NAC was added to 0.5, 2.0, 5.0, or 10.0 mM (without media replacement). Cells were cultured for an additional 12 h following NAC administration before analysis (Fig 1). The oxygen radical antioxidant capacity (ORAC) of NAC was compared to reduced GSH and a Trolox standard (Abcam; ORAC Assay Kit) with values expressed as μ M Trolox Equivalents (TE). To visualize the extent of cell death, live (calcein-AM) and dead (ethidium homodimer-1) (ThermoFisher; LIVE/DEAD™) stained cells were imaged using confocal microscopy (Nikon A1R+; 4x magnification) and cells were quantified using ImageJ. Metabolic activity was determined with a resazurin-based solution (ThermoFisher; AlamarBlue™). Messenger RNA (mRNA) was isolated at the terminal time point and expression of interleukin-1 beta (IL1B), glutathione peroxidase 1 (GPX1), inducible nitric oxide synthetase (iNOS), and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) was determined by quantitative polymerase chain reaction (qPCR), expressed as fold change relative to untreated chondrocytes. Metabolic activity and cell viability analysis was conducted with n=4 biological replicates, and ORAC and qPCR analysis was conducted with n=3 biological replicates. One-way ANOVA was used to compare values amongst groups, and two-way ANOVA was used to compare values between groups and time points. Both were followed with post-hoc Tukey HSD (GraphPad Software, Inc.). Significance was set at p<0.05.

Fig 1: Study design for *in vitro* model of oxidative stress.

RESULTS

In terms of antioxidant potential, 20.0 μ M NAC had a greater capacity to reduce oxygen radicals than 20.0 μ M GSH (had a larger area under the curve) (Fig 2A). The ORAC value for NAC was 17.6 ± 0.46 μ M TE compared to 7.70 ± 0.09 μ M TE for GSH (Fig 2B). When applied to chondrocytes, NAC at 5.0 mM showed no cytotoxicity compared to controls, as indicated by similar calcein-AM/ethidium homodimer-1 staining (Fig 2C-D) and percentage of living chondrocytes (Fig 2G). Following H₂O₂ treatment, the addition of NAC showed a dose-dependent increase in chondrocyte viability with increasing concentration, with 5.0 mM being most effective at preserving chondrocyte viability ($70.1 \pm 16.9\%$ viability with NAC treatment versus $24.6 \pm 7.50\%$ viability in H₂O₂ treated cells) (Fig 2E-G). NAC treatment in the absence of H₂O₂ significantly increased chondrocyte metabolic activity compared to the control (Fig 3A). When cells were treated with H₂O₂ alone, there was a significant reduction in metabolic activity (Fig 3A). This could be rescued with NAC treatment in a dose-dependent manner when NAC was administered at 0, 2, and 12 h (Fig 3A). When treated with 5.0 or 10.0 mM NAC at 2 h, metabolic activity was not significantly different from control cells (Fig 3A). Expression analysis showed that genes associated with oxidative stress, IL1B, GPX1, and iNOS, were all significantly increased in chondrocytes exposed to 100 μ M H₂O₂ (Fig 3B). Treatment with 5.0 mM NAC 2 h after H₂O₂ returned expression levels back to that of chondrocytes in the 5.0 mM NAC control group (Fig 3B).

DISCUSSION

Our data demonstrate that administration of NAC can rescue chondrocyte viability and metabolic activity, as well as regulate the expression of critical genes, after exposure to ROS in an *in vitro* model of oxidative stress. Our data further identify a “window of opportunity” in the therapeutic intervention with antioxidants following an oxidative insult. Specifically, we showed that treatment with NAC within 2 h of injury can reduce the severity of ROS-mediated cell death, maintain normal chondrocyte metabolic activity, and significantly reduce the expression of IL1B, GPX1, and iNOS compared to untreated conditions. While treatment with NAC at 12 h also increased chondrocyte viability and metabolic activity compared to untreated conditions, its efficacy was reduced. This suggests that the optimal “window of opportunity” is within the first 12 h period and that such early intervention with NAC following an acute knee injury may be capable of rescuing cartilage cell health and have implications for the prevention of PTOA. Ongoing studies are extending these findings to a 3-dimensional hydrogel culture model (9, 10) and exploring the delivery of NAC from mechanically-activated microcapsules (10, 11) to prolong residence time and localization following *in vivo* i.a. delivery.

DO AGE AND SEX MATTER IN A 1D SIMULATION STUDY TARGETING ARTERIAL STIFFNESS?

Friederike Schäfer, Jacob Sturdy, Leif Rune Hellevik

Department of Structural Engineering, Norwegian University of Technology (NTNU), Trondheim, Norway

INTRODUCTION

Over the past 20 years, cardiovascular diseases (CVDs) have been the leading cause of death worldwide, additionally the percentage of deaths caused by CVDs has been increasing [1]. CVDs like aneurysm formation and plaque deposition in the arterial wall alter the arteries' material properties. However, arterial material properties are not only altered by disease, but also by lifestyle, diet, and aging [2–4]. A biomarker describing cardiovascular health is local arterial stiffness. Yet, it cannot be measured directly in vivo [5]. Computational modelling approaches may allow non-invasive estimation of local arterial stiffness through inverse methods, but a key challenge are model parameter uncertainties. As some model parameters vary between age and sex groups [6–8], and certain sub-populations may have distinct distributions of these parameter values, model performance may differ between those groups. In this work, we investigated the necessity of considering sub-populations during the development of a 1D-common carotid artery (CCA) model. For each sub-population, we quantified model output uncertainty and identified the input parameters leading to the greatest output variability through a sensitivity analysis.

METHODS

To establish age and sex specific model parameter probability distributions, we identified relevant papers through a structured literature review, extracted parameter values, and computed pooled mean and standard deviations of several input parameters. The inferred distributions were then propagated through a 1D-model of the CCA. In a subsequent sensitivity analysis, we applied polynomial chaos (PC) expansion to attribute model output uncertainties to specific uncertain input parameters.

Structured literature review

The structured literature review was performed by following best practices and guidelines given in the Cochrane Handbook for Systematic Reviews and Interventions [9]. We included articles with the scope of quantifying CCA stiffness in humans. To have representative values for a cross-section of society – all ages, fitness levels, body sizes, and subjects with risk factors – we excluded only non-original studies and studies investigating rare diseases with significant changes in the cardiovascular mechanics. Mean and standard deviation of geometric parameters, pressure values, stiffness measures and the occurrence of risk factors were extracted from 94 publications. Subsequently, a pooled mean and standard deviation was computed for each age and sex group. Due to the lack of knowledge on the underlying probability distribution of each parameter, lower a and upper bound b of a uniform probability distribution were computed based on the pooled mean and standard deviation by $a, b = \mu \pm \sqrt{3} \sigma$.

1D-model of the CCA

The CCA was modelled in 1D as a straight, compliant tube with a thin, homogeneous, linear elastic wall material, shown in Fig. 1. At the inlet, a parabolic inflow with a representative CCA flow rate and waveform was

Figure 1: 1D-model of the CCA with a parabolic flow at the inlet and a three-element Windkessel model at the outlet. The eight uncertain parameters are indicated.

imposed [10]. A three-element Windkessel model was coupled to the 1D-model outlet to account for the downstream vasculature's influence on the CCA. The Windkessel model elements are arterial impedance Z , arterial compliance C , and peripheral resistance R .

With the assumption of blood as an incompressible Newtonian fluid, the conservation of mass and momentum are

$$\frac{\partial A}{\partial t} + \frac{\partial(Au)}{\partial z} = 0 \quad (1a)$$

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial z} + \frac{1}{\rho} \frac{\partial p}{\partial z} = \frac{f}{\rho A}, \quad (1b)$$

with the time t , cross-sectional area A , velocity u , fluid density ρ , spatial coordinate z , pressure p , and the frictional force term per unit length f . Fluid-structure interaction was described with the tube law [11]. Uncertain model parameters were C , total arterial resistance $R_{tot} = Z + R$, ρ , μ , Poisson ratio ν , arterial wall thickness h , lumen diameter D , and dilatancy coefficient $DC = (\Delta A/A)/\Delta p$ [2].

Uncertainty quantification and sensitivity analysis

Uncertainty and sensitivity measures were estimated by applying PC expansion [12]. The stochastic model output $Y = f(\mathbf{Z})$, which depends on a vector of independent random variables \mathbf{Z} , can be approximated with a finite number of polynomials p as

$$Y \approx Y_{PC} = \sum_{p=0}^N c_p \Phi_p(\mathbf{Z}), \quad (2)$$

where the expansion coefficients are c_p and the polynomials Φ_p . From the PC expansion, statistical moments and variance based sensitivity measures can be computed analytically.

Global sensitivity measures attribute model output variance to particular input parameters and their interactions. The main Sobol index S_i quantifies the direct contribution of a particular input parameter z_i to total model output variance $\text{Var}[Y_{PC}]$ [13]. It is computed as

$$S_i \approx \frac{1}{\text{Var}[Y_{PC}]} \sum_{p \in A_i} \text{Var}[c_p \Phi_p], \quad (3)$$

where the set A_i contains all basis functions only dependent on z_i . The total Sobol index ST_i quantifies the contribution to output variance of a parameter z_i and all its interactions with $z_{\sim i}$ as

$$ST_i \approx \frac{1}{\text{Var}[Y_{PC}]} \sum_{p \in A_{T_i}} \text{Var}[c_p \Phi_p]. \quad (4)$$

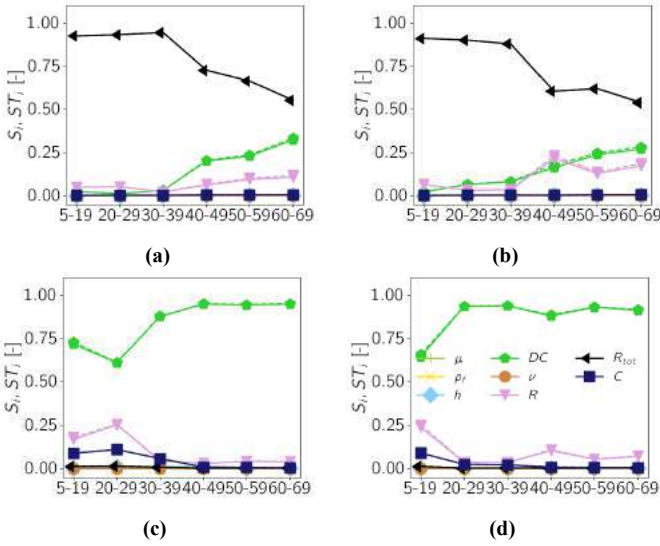

Figure 2: ST_i (dashed line) and ST_i (solid line) at the artery's mid-point and time averaged over the last cardiac cycle for (a) male pressure (b) female pressure (c) male ΔD (d) female ΔD .

RESULTS

The main and total sensitivity indices at the mid-point of the vessel for the eight uncertain parameters are shown in Fig. 2 for each age and sex group. The quantities of interest (QoI) are the pressure (a-b) and the diameter change ΔD (c-d). Values of ST_i (dashed lines) are approximately the same as S_i (solid lines). Regardless of age and sex, pressure is most sensitive to R_{tot} of the Windkessel model. Nonetheless, with increasing age changes the sensitivity structure for pressure such that DC and D contribute to the variance of the model's pressure prediction. For the two youngest age groups, ΔD is sensitive to variations in DC , D , and C , where DC 's value prevails. In the remaining age groups, all sensitivity indices except of DC are approximately zero. Fig. 3 displays the 95% prediction interval for pressure and ΔD for females in their 60s with colored area apportioned to the respective sensitivity index.

DISCUSSION

We conducted a structured literature review to evaluate pooled mean and standard deviations of geometric and material parameters for twelve groupings by age decade (7-19, 20-29, ..., 60-69) and sex. The uncertainty about input parameters based on the inferred population distributions were propagated through a 1D-model of the CCA with a PC expansion method to quantify model output variability and sensitivity.

Ranges for geometric parameters, pressures, and stiffness measures computed from the literature review were in accordance with published reference intervals for a healthy sub-population [7] and a previous summary of literature findings [8].

Since the difference between S_i and ST_i is approximately zero, parameter interactions are not significant in this model. Low sensitivity indices for fluid viscosity and density, arterial wall thickness, Poisson ratio, and Windkessel model compliance indicate that population variability within the applied distribution of these parameters does not influence model output variability. Setting these parameters to reference values will therefore not change model output variance while reducing the number of input parameters. High sensitivity of DC for ΔD suggests that it is possible to infer arterial stiffness in the inverse problem for ΔD .

The mean pressure in the arterial tree is directly determined by the total arterial resistance and mean flow as $R_{tot} = p/Q$. As such the pressure level at each time point is highly sensitive to uncertainties in R_{tot} . The magnitude of the pulse pressure depends on the total arterial compliance. In the 1D-model used in this work, total arterial compliance consists of the compliant vessel and the compliance element in the Windkessel model.

Figure 3: 95% prediction interval and expected value E with sensitivity apportioned to the QoIs of (a) pressure and (b) ΔD for females in their 60s.

DC describes the area compliance and thus, depends on the artery's D . With increasing age decreases DC , which makes the pressure more sensitive to this parameter in the systolic phase of the heart cycle, as seen in Fig 3. However, the current results suggest that the pressure is not sensitive to C . Therefore, further investigations are needed to verify the total compliance distribution between the different elements of this model and their influence on model output variance.

Differences in the sensitivity structure between age groups are apparent, whereas sex differences are not clearly evidenced. Comparison of sensitivity indices in the 20-year old group shows differences for ΔD , however, the studies investigating young males included mainly participants with a high fitness level. Thus, DC in this particular group was higher than from cross-sectional studies which confounds with any difference due to sex alone. Another difference is visible in the ranking of DC and D sensitivities for the pressure in the group aged 40-49 years. If this is due to irregularities in the data from the literature review or if this is a general trend needs to be subject to further investigation.

Summing up, we have performed a literature review to establish pooled mean and standard deviation values for geometric and material parameters of the CCA for twelve age and sex groups. Based on these values, uncertainty quantification and sensitivity analysis using PC expansion was performed on a 1D-CCA model. Results suggest that pressure is most sensitive to R_{tot} , while ΔD is most sensitive to DC . We observe that the sensitivity structure changes between age groups, whereas sex differences are not that distinct (Fig. 2). In a next step, uncertainties in the inlet boundary condition will be considered and the total compliance distribution between the 1D-artery and the Windkessel model and its implications on output variance will be examined.

INTRODUCTION

Breast cancer is one of the most prevalent cancers in women today, with approximately 287,850 new cases diagnosed yearly in the United States [1]. In recent years, breast-conserving surgery (BCS; otherwise known as lumpectomy) has replaced mastectomy (the removal of the entire breast) as the preferred standard of care for breast cancer. Illustrated in Fig. 1, BCS preserves healthy breast tissue, as surgeons only excise the tumor along with a small margin of healthy tissue, forming a cavity. The resulting tissue cavity induces inflammation, generating a cytokine gradient that induces fibroblast proliferation, collagen deposition, and scar formation. Fibroblast differentiation into myofibroblasts further promotes contraction of the cavity and adjacent tissue, which often leads to breast deformities. Patient-to-patient variability in terms of breast size, tissue composition, and tumor geometry and location affect the outcome. With current techniques, 30% of BCS patients report poor healing and cosmetic outcomes, which can potentially compromise quality of life and self-image [2].

Figure 1: Schematic of breast healing process after BCS.

To overcome these challenges, we are developing a predictive computational mechanobiology model that simulates patient-specific breast healing following BCS. The proposed model has the potential to assist surgeons with better predicting oncologic, healing, and cosmetic outcomes, allowing for a comprehensive individualized treatment plan. Previously, computational models have been developed with a focus on simulating breast cavity healing after BCS [3,4]. These models, which are often informed by patient-specific imaging data (e.g., magnetic resonance and/or surface), emphasize biochemical rather than biomechanical healing processes. The model described in the present work simulates a unique generalized breast geometry using a coupled

biochemical-biomechanical model focused on multi-scale mechanics, including cell contractility and collagen remodeling. Available human clinical data evaluating cavity contraction and data from experimental porcine lumpectomy studies were used for model calibration [5,6].

METHODS

The computational mechanobiological model is a custom C++ solver adapted from previously developed code designed to explore three-dimensional (3D) cutaneous wound healing [7,8,9]. Tissue parameter values from the cutaneous wound model were modified to be breast tissue specific. Additionally, the model was modified to express cellular diffusion as a function of fibroblast speed which is dependent on collagen density (ϕ), and cytokine concentration (c).

Two breast cavity geometries were created in COMSOL (COMSOL Multiphysics, Burlington, MA), with meshing and boundary conditions shown in Fig. 2. The porcine geometry was based on an experimental porcine lumpectomy model used to evaluate surgical outcomes with and without regenerative breast fillers [5]. The human geometry represents a generalized breast cavity based on available clinical data that analyzed cavity contraction in BCS [6].

Figure 2: The meshing and initial conditions for the (A) porcine and (B) human breast cavity geometries.

Time-dependent changes in fibroblast (ρ) and collagen densities were informed through the porcine study [5]. Hematoxylin and eosin (H&E) stained cross-sections were analyzed 1, 4, and 16 weeks after surgery in comparison to normal porcine breast tissue. Twenty-five regions ($500 \times 500 \mu\text{m}^2$) spanning each cavity domain were identified and processed in ImageJ (National Institutes of Health, Bethesda, MD), where multiple color balance filters and thresholding were applied to quantify fibroblast density. Average collagen density was measured at each time point by normalizing intensity of fibrous tissue deposition

relative to intensity of normal breast connective tissue. Cytokine decay was based on prior work in the literature [10].

To optimize model biochemical parameters, Gaussian Process (GP) was fitted to the experimental fibroblast and collagen data. To start, five uninformed biochemical parameters ($p_{p,c}$, C_{dpp} , Δ , p_ϕ , and $p_{\phi,c}$) were identified and assigned a broad range of possible values. Using the porcine geometry, the model was then run in COMSOL using parameter combinations determined through the Latin hypercube sampling algorithm. Predictive regression lines for various parameter combinations were then used to find optimum parameter combinations based on root mean square error (RMSE). Optimized parameter values from the GP were then translated directly from the porcine geometry to the human geometry. The mechanobiological model was then fit using a similar methodology. In this case, the mechanobiological model was fit to clinical post-surgical cavity contraction data in terms of the ratio between deformed and original cavity volume (V_s/V_o) [6]. Fitting was done leveraging a separate GP that focused on tuning four uninformed mechanobiological parameters (t_p , $t_{p,c}$, K_t , and $\tau_{\lambda,p}$).

RESULTS

We fitted fibroblast and collagen density data to the biochemical model using the GP and obtained profiles within the standard deviations of the experimental data. These results provided confidence in the robust selection of the biochemical parameters. We then turned our attention to the full mechanobiological model implemented with the human geometry. Using the mechanobiology GP, optimal parameters for the mechanobiological parameters were determined ($t_p = [8.5714E-6 - 1.9286E-5]$ [1/hr], $t_{p,c} = [2.14286 \cdot t_p - 5 \cdot t_p]$ [1/hr], $K_t = [0.2 - 0.328571]$, and $\tau_{\lambda,p} = [0.0388 - 0.14065]$ [hr]). Along with this fit, mechanistic parameter relationships were inferred by evaluating the cavity contraction at 4 weeks over the entire parameter range as shown in Fig. 3. Cavity contraction was heavily dependent on fibroblast force (t_p), with increasing force leading to larger contraction (lower V_s/V_o). Myofibroblast force ($t_{p,c}$) had a similar effect. The rate of plastic deformation ($\tau_{\lambda,p}$) showed larger contraction (lower V_s/V_o) for smaller values of $\tau_{\lambda,p}$ but this effect was less pronounced compared to the fibroblast and myofibroblast force. The saturation of force, parameterized by K_t , had an interesting coupling with the myofibroblast force, with lower K_t leading to more contraction as $t_{p,c}$ increased. In fact, the largest contraction (less than 20% of the initial volume) occurred at the lower end of K_t and upper end of $t_{p,c}$.

Figure 3: Plots describing the relationship between mechanobiological parameters t_p , $t_{p,c}$, K_t , and $\tau_{\lambda,p}$ on cavity contraction measured as deformed over initial volume (V_s/V_o).

The cavity contraction results from the fully informed computational model are displayed in Fig. 4. Contraction was found to

substantially increase across the first 4 weeks before reaching a steady-state, with the cavity contraction at approximately 36% of the original volume. The local metric of contraction is the plastic volume change (J^p) which decreased over time inside the cavity region while the surrounding tissue was drawn in tension ($J^p > 1$). The severity of this contraction contributed to clear deformation that was visible on the breast surface. By week 16, a visible divot had formed on the breast surface, which is a common outcome of BCS.

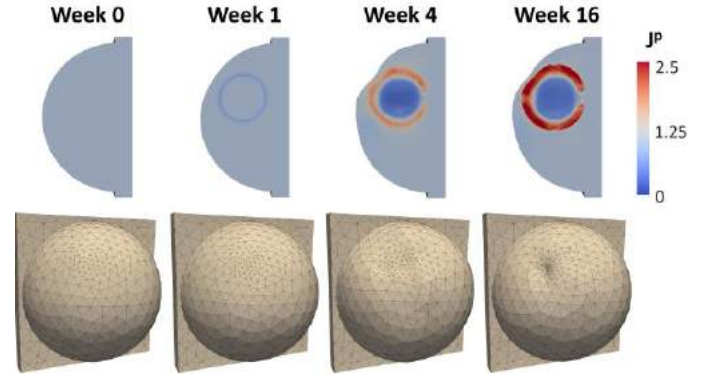

Figure 4: Mechanobiological model outcomes using optimized parameters. Permanent volume change denoted J^p .

DISCUSSION

The presented computational model proved to effectively simulate the breast healing response following BCS, including fibroblast infiltration, collagen remodeling, and breast permanent deformation. By using preclinical porcine data and human clinical data, biochemical and mechanobiology parameters were informed [5,6].

Although previous models of wound healing after BCS have been developed, we advanced these efforts by implementing a detailed mechanobiological model coupled with the nonlinear mechanics of breast tissue, including large plastic deformation and collagen remodeling. The study is not without limitations. A generalized breast geometry rather than a patient-specific geometry was used. Clinically, variables such as breast tissue composition or breast and cavity size can vary from patient to patient, which will be the focus of future model iterations. While we have some detailed data from the porcine model, the human data was more limited. Nevertheless, the mechanistic nature of the model and its fit to porcine and human data are encouraging to explore the design of therapeutic approaches (e.g., regenerative breast fillers), enabling the promise of *in silico* trials for BCS before animal or human subjects are involved.

INTRODUCTION

Scleral collagen fiber mechanics plays an important role in eye physiology and pathology and is therefore of great interest in ocular biomechanics [1]. Of particular interest is understanding how increases in intraocular pressure (IOP) affect the sclera adjacent to the optic nerve head (ONH) in the posterior pole of the eye, and the lamina cribrosa within the ONH (Fig. 1a). Sclera biomechanics has been studied extensively but the role of its three-dimensional (3D) collagen fiber organization is not well-understood. Most computational models assume sclera to be a continuum structure reinforced by fibers, rather than fundamentally a fibrous structure. These models incorporate collagen fibers empirically such that fibers are non-continuous spatially

in 3D and confined into small sub-domains of the model. Hence, current models do not represent the sclera's 3D collagen structure of long fibers that are continuous across regions. For instance, the continuity of fibers from the sclera to the pia or dura is not accounted for in current models.

We present an entirely fibrous finite element (FFE) model of sclera that incorporates scleral collagen fiber bundles, their 3D spatial organization continuous with pia and dura maters, and fiber-fiber interactions. We demonstrate that this model can predict the IOP-induced response of sclera during inflation tests and investigate the nonlinear mechanics of fibrous sclera, pia, and dura regions at the ONH under elevated IOP.

Figure 1. (a) Schematic of eye cross-section with the ONH highlighted and (b) enlarged view of the ONH with boundary conditions. (c) PLM images of coronal sections were used to determine fiber location and orientation. Shown is an example image with in-plane fiber orientation in color. (d) Example sagittal section of another eye corresponding to the region shown in (b). (e) Isometric and (f) sagittal perspective views of the FFE model. (e) shows full bundle widths. (f) shows only bundle centerlines. Longitudinal fiber bundles of the pia and dura are continuous with fibers of the sclera. The colors in (e) and (f) are intended to help compare with conventional tissue definitions.

METHODS

Model geometry: Highly detailed imaging data of a porcine eye from polarized light microscopy (PLM) was used to construct the FFE model of sclera [2]. The model included circumferential, random, and radial fiber bundles in a coronal image (Fig. 1c). The sagittal section (Fig. 1d) shows the continuation of sets of sclera fibers into lamina cribrosa, pia mater, and dura mater regions. The radial and random bundles of the sclera were constructed by tracing the bundles with PLM-matched local orientation from a stack of coronal images (Fig. 1c) and transforming them into a curved assembly using in-house algorithms [3]. Radial fibers, 100 μm away from the anterior side of the sclera along the sagittal direction, were further post-processed to mimic their transition into pia and dura maters like in the sagittal image (Fig. 1d). The circumferential bundles were included in sclera, pia, and dura regions manually with microscopy-based distributions [1,4].

FE modeling: Fibers were modeled at bundle-scale with Timoshenko beams of ellipsoidal cross-section and linear elastic material properties (E_b). The bundle widths were sampled from microscopy images and a constant thickness of 20 μm was used. The lamina cribrosa and neural tissue regions were included as linear elastic continuum structures ($E_{LC} = 0.1 \text{ MPa}$, $E_{NT} = 0.01 \text{ MPa}$) to represent the boundary conditions for the scleral canal region. A surface-based contact algorithm was used to account for the fiber-fiber interactions. The model was subjected to $IOP = 30 \text{ mmHg}$. A displacement boundary condition ($\delta = 0.1 \text{ mm}$) was applied on the periphery of the model to represent radial tension of the sclera due to IOP (Fig. 1b). The boundary of the solid regions and nearby sclera fibers were kinematically coupled. The solution was obtained using the FE solver Abaqus/Explicit.

Validation: The model response was validated against an ex-vivo inflation experiment [5] by calculating IOP-induced peripapillary sclera's (PPS) posterior displacement and scleral canal expansion. The validation was performed by inverse fitting the modulus parameter (E_b) iteratively.

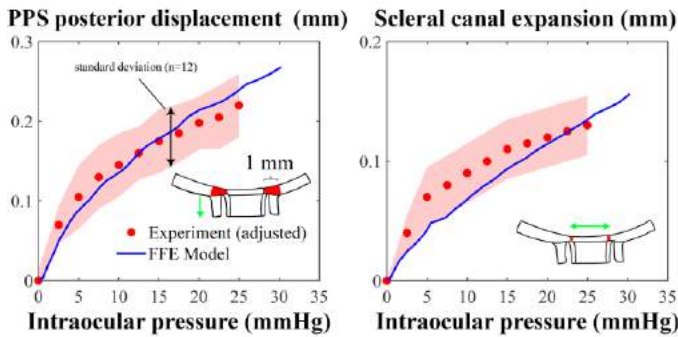

Figure 2. Intraocular pressure effect on (a) peripapillary sclera's (PPS) mean posterior displacement and (b) mean scleral canal expansion as obtained from the FFE model and experiments [5]. The insets indicate the regions used to calculate the average posterior displacement and canal expansion. Experimental data is shifted by 5 mmHg to ensure proper comparison with the model.

RESULTS

Fig. 2 compares the PPS's posterior displacement and scleral canal expansion of the model ($E_b = 8 \text{ MPa}$) with the experiment. The FFE model effectively captured the highly nonlinear variation of posterior displacement and canal expansion with IOP as observed experimentally. Note that the nonlinear response of sclera predicted by our model is a purely geometric effect of its 3D fibrous collagen structure since all the material parameters were linear elastic.

The model displacements along three directions at $IOP = 30 \text{ mmHg}$ are shown in Fig 3. Sclera, lamina cribrosa, and neural tissue

regions undergo relatively smaller in-plane displacement (along superior-inferior and nasal-temporal directions) compared to out-of-plane displacement in the posterior direction. The range of in-plane displacement was -0.1 mm to 0.175 mm whilst the range of out-of-plane displacement was $\sim 0.025 \text{ mm}$ to 0.8 mm . Posterior displacement was the dominant deformation mode of the ONH under elevated IOP [6].

Figure 3. Displacement contour plots of the model: (a) superior-inferior, (b) nasal-temporal, and (c) anterior-posterior directions at intraocular pressure ($IOP = 30 \text{ mmHg}$).

Fig. 4 shows the heterogeneous strain distribution in various fiber bundle groups of the model at $IOP = 30 \text{ mmHg}$. The axial strain varied from -1% to 5% with most fiber bundles showing tensile strains (positive) and longitudinal bundles of Pia and Dura maters showing compressive strains (negative). The circumferential bundles undergo larger strains compared to other groups of fiber bundles.

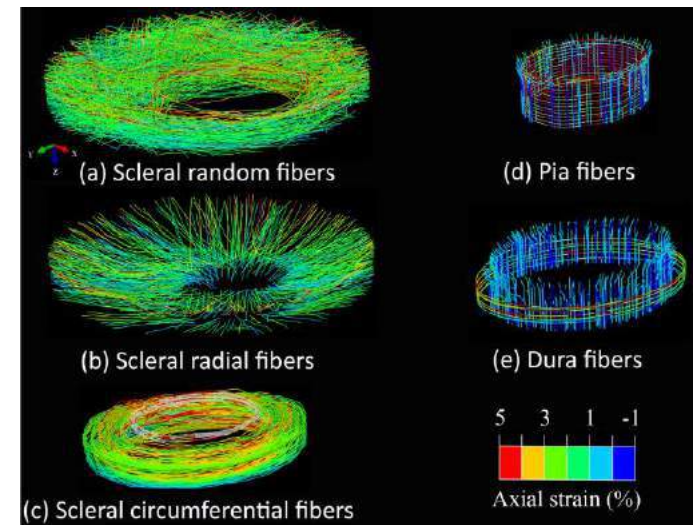

Figure 4. Axial strain contour plots for various fiber bundle groups of the FFE model at $IOP = 30 \text{ mmHg}$.

DISCUSSION

We presented a novel FFE model of sclera and demonstrated its ability to capture the nonlinear deformation of the ONH under elevated IOP entirely based on 3D fibrous collagen structure and a single material parameter. The FFE model allows for direct analysis of fiber-scale mechanics as a function of various fiber groups in sclera, which will help us understand the regional susceptibility of ONH damage in significant detail. Future work will investigate how various fiber groups independently affect ONH biomechanics under elevated IOP.

REDUCED VASCULAR SMOOTH MUSCLE CELL MECHANOADAPTATION IN AN *IN VITRO* MODEL OF CEREBRAL AMYLOID ANGIOPATHY

Samuel F. Boland (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Cerebral amyloid angiopathy (CAA) is characterized by the deposition of the 40 amino acid amyloid beta peptide ($A\beta(40)$) around cerebral blood vessels¹ and is present in more than 80% of Alzheimer's disease (AD) patients². $A\beta(40)$ is highly cytotoxic and gradually leads to vascular smooth muscle cell (VSMC) death³ and hemorrhagic stroke⁴. VSMCs extracted from CAA patients are more contractile than VSMCs from healthy patients⁵ but it is unclear whether this behavior results from exposure to $A\beta(40)$ or instead drives $A\beta(40)$ deposition. Conversely, *in vitro* models of CAA suggest chronic exposure to $A\beta(40)$ reduces contractility in VSMCs⁶, but these methods rely on measurements of cell area to make indirect claims about VSMC contractility. Here we use cellular microbiaxial stretching ($C\mu$ BS) microscopy to benchmark VSMC basal stress and mechanoadaptation in an *in vitro* model of CAA. We hypothesized that VSMCs would display reduced basal stress and reduced mechanoadaptation in an *in vitro* model of CAA and found support for this hypothesis.

METHODS

Substrate fabrication and cell culture. Human umbilical artery VSMCs were incubated at 37 °C and 5% CO₂ in supplemented Medium 199. VSMCs were micropatterned with aspect ratio 1:4 (AR4) on a fluorescent bead-doped polyacrylamide (PA) gel (Fig. 1A) with a Young's modulus of 13.5 kPa as previously described⁷. Cells were incubated in serum-free supplemented Medium 199 24 hours prior to experimentation to induce a contractile phenotype⁸.

***In vitro* cerebral amyloid angiopathy (CAA) model.** To simulate CAA, VSMCs were incubated in supplemented Medium 199 with either 100 nM or 1 μ M $A\beta(40)$ dissolved in DMSO for four days. Cells were incubated in serum-free supplemented Medium 199 with the same concentration of $A\beta(40)$ 24 hours prior to experimentation, resulting in five total days of $A\beta(40)$ exposure.

Cellular Microbiaxial Stretching ($C\mu$ BS). $C\mu$ BS experiments were performed using a custom-built microscope-mounted device (Fig.

1B) to perform traction force microscopy (TFM) on VSMCs micropatterned on a deformable substrate. VSMCs were biaxially stretched at a strain rate of 0.001 s⁻¹ to 0.2 strain in 0.05 strain increments and then returned to 0 strain in 0.05 strain increments (Fig. 2A) at the same strain rate. At each strain increment a brightfield image was acquired of the VSMC and a fluorescent image was acquired of the

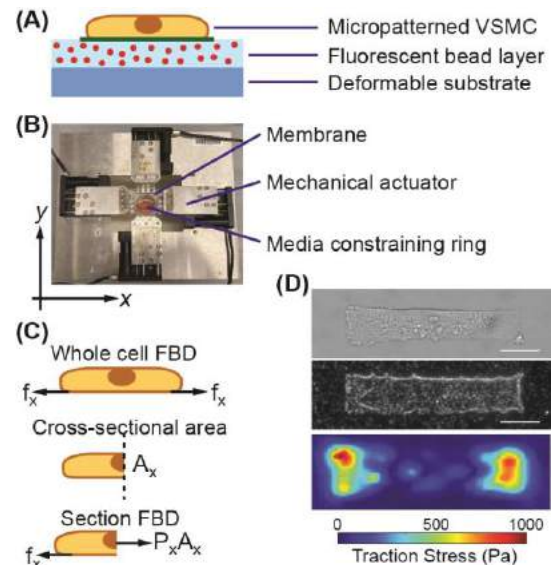

Figure 1: (A) Schematic of micropatterned VSMC. (B) Schematic of $C\mu$ BS apparatus. (C) Free body diagram (FBD) relating cell traction forces f_x to first Piola-Kirchoff stress P_x and cross-sectional area A_x . Adapted from Rothermel et al.⁷ (D) Bright field (top), bead layer (middle), and traction stress map (bottom) for a representative VSMC. Scale bar = 25 μ m.

underlying PA gel bead layer using at TRITC filter (Fig. 1D). Cells were then lysed with SDS, and the gel was imaged again using the same modalities at the location of each cell for each strain.

Traction forces at each strain were calculated using previously described methods⁷. The first Piola-Kirchoff stress, represented by $P_i = f_i/A_i$, where f_i is the total traction force acting in direction i and A_i is the undeformed cell cross-sectional area in the i -axis, was calculated at the mid-plane of the cell (Fig. 1C). Basal stress was defined as the stress produced by the cell before any deformation is applied. First Piola-Kirchoff stress was plotted against applied strain. Slope of the loading phase (0 strain up to 0.2 strain) and unloading phase (0.2 strain down to 0 strain) were calculated by taking the slope of a linear fit to the respective data. Total energy (work) and stored energy were calculated by calculating the area under the P_x vs strain plots during the loading and unloading phases, respectively. Lost energy was calculated by subtracting stored energy from total energy.

RESULTS

VSMCs were strained according to Fig. 2A. Prior to stretch, VSMCs generate a non-zero basal stress. Stress increases with each increasing strain increment up to 0.2 strain and then decreases with each successive step back to 0 strain (Fig. 2C). Stress during the unloading phases is lower than stress in the loading phase in both the x - and y -directions (Fig. 1B). Stress in the y -direction is consistently lower than stress in the x -direction. The P_x vs. strain plots for cells treated with increasing doses of $A\beta(40)$ shift downwards with a statistically significant difference between stresses in untreated VSMCs vs VSMCs treated with 1 μ M $A\beta(40)$ (Fig. 2D). There is no significant difference between the P_y calculations for each strain increment between the three treatment conditions (Fig. 2E). Slope during both loading and unloading phases of the experiment (Fig. 3A), basal stress (Fig. 3B), and both

Figure 3: (A) Slope of P_x vs. strain during loading and unloading phases of experiment (B) VSMC basal stress for untreated VSMCs (Unt) and VSMCs treated with either 100 nM $A\beta(40)$ (100nM) or 1 μ M $A\beta(40)$ (1uM). (C) Stored and lost energy for each treatment condition. (D) Lost energy normalized by total energy for each treatment. * indicates $p < 0.05$, ** indicates $p < 0.01$, *** indicates $p < 0.001$, n.s. indicates no significance.

stored and lost energy (Fig. 3C) are all significantly lower in VSMCs treated with 1 μ M $A\beta(40)$ compared to the untreated control VSMCs. When lost energy is normalized to total energy for each condition there is no significant difference across conditions.

DISCUSSION

In this study, we demonstrate that VSMCs incubated with $A\beta(40)$ in an *in vitro* model of CAA generate significantly less stress at every increment of strain when compared to untreated control VSMCs. VSMC stress decreases in a dose-dependent manner when treated with $A\beta(40)$. This finding aligns well with results from similar *in vitro* CAA models, and conflicts with the finding that VSMCs from CAA patients are hypercontractile, suggesting that VSMC hypercontractility in CAA is perhaps a driver of the condition rather than a result of amyloid deposition. Further analysis of data shows that although stored and lost energy decrease in a dose-dependent manner, when lost energy is normalized to total energy in each condition there is no significant difference. This suggests that mechanical hysteresis is conserved in an *in vitro* CAA model. We intend to develop a new predictive model of VSMC contraction in CAA based on our Hill-type active fiber model⁹. Understanding how VSMC contractile function is modified in CAA will help better understand how vascular dysfunction in AD¹⁰ leads to cognitive deficits.

VERIFICATION ERRORS IN EULERIAN POWER-LAW HEMOLYSIS MODEL PREDICTIONS IN SIMPLE FLOWS

Mohammad M. Faghih (1), Brent A. Craven (1), M. Keith Sharp (2)

INTRODUCTION

An empirical power law was originally used to correlate hemolysis with constant shear stress and exposure time in a Couette flow [1]

$$D = \frac{\Delta PfHb}{Hb} \% = C \sigma^\beta E^\alpha \quad (1)$$

where D is the percentage change in plasma free hemoglobin $PfHb$ relative to total hemoglobin Hb , σ is a representative scalar stress, E is the exposure time, and α , β and C are empirical coefficients. This power law has been extrapolated to apply to flows with varying shear and extensional stresses by using a resultant scalar stress [2]. While an improved version of the scalar stress has been proposed with increased weighting of extensional stresses [3], this paper focuses on the errors caused by Eulerian application of a linearized blood damage function with a purely convective transport equation [4]

$$\vec{v} \cdot \nabla D' = (C\sigma^\beta)^{\frac{1}{\alpha}} \quad (2)$$

where \vec{v} is the fluid velocity vector, $D' = D^{1/\alpha}$ is the exposure time-linearized damage index and $S = (C\sigma^\beta)^{1/\alpha}$ is the hemolysis generation source term.

Hemolysis is an inherently Lagrangian mechanism, since hemoglobin release fundamentally depends on the stress history applied to individual erythrocytes. Thus, a Lagrangian formulation of the power-law model analyzes fluid stresses along pathlines followed by the cells. The Reynolds transport theorem, which transforms the Lagrangian form to Eulerian, gives the full source term as $(C\sigma^\beta)^{1/\alpha} \frac{|\vec{v}|}{\bar{v}_s}$, where $|\vec{v}|$ is the local magnitude of the velocity at a specific point and \bar{v}_s is the average velocity along the streamline passing through that point [4]. Comparison with equation 2 shows that the source term in

equation 2 applies only for constant velocity along each streamline. A second issue related to integration of the linearized damage function can be addressed by raising the function to the power α before integration [4]. Therefore, the comparisons to follow will quantify the effect of the Reynolds transformation error only.

METHODS

Eulerian and Lagrangian hemolysis predictions are compared for three geometries: 1) Poiseuille flow, 2) inclined Couette flow, and 3) converging pipe with two different convergence ratios (a/b): 12 mm/4 mm and 12 mm/2 mm (Fig. 1).

The Eulerian prediction follows the common procedure of integrating the flux of hemolysis at the outlet

$$\overline{D_E} = \frac{\sum_{k=1}^l (D'_k)^\alpha Q_k}{\sum_{k=1}^l Q_k} \quad (3)$$

where Q is the flow rate through each two-dimensional element k of the outlet patch and l is the number of elements. The Lagrangian prediction at the outlet is for streamtubes in which the accumulated hemolysis along the streamline central to the streamtube is

$$D_L = \sum_{i=1}^n C \alpha \sigma_i^\beta E_i^{\alpha-1} \Delta E_i \quad (4)$$

where n is the number of exposure time steps, E_i is the exposure time from the beginning of the streamline to the end of the i th exposure step, ΔE_i is the exposure step size, and σ_i is the average scalar stress acting during that exposure step. The total blood damage is found by summing the flux of hemolysis through the outlet

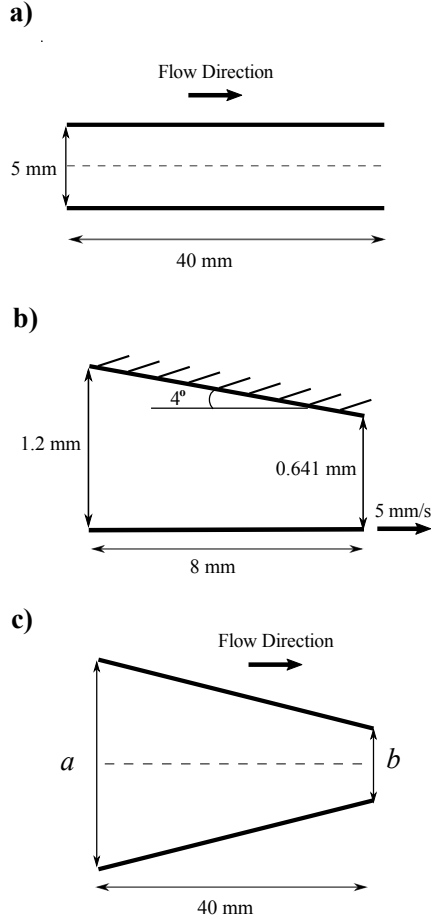

Figure 1: Schematics of the benchmark geometries; a) Poiseuille flow through a straight tube, b) two-dimensional inclined Couette flow with a gradual contraction, and c) flow through a straight, converging tube. Not drawn to scale.

$$\overline{D}_L = \frac{\sum_{j=1}^m D_{L,j} Q_j}{\sum_{j=1}^m Q_j} \quad (5)$$

where j refers to the streamtubes and m is the number of streamtubes.

Empirical coefficients from Song, et al. [5] were used. CFD computations were performed in OpenFOAM and postprocessing was done in Python. Spatial convergence of Eulerian estimates was evaluated with course, medium and fine meshes. Convergence of Lagrangian damage was obtained by increasing the number of streamlines and decreasing exposure step size along each streamline until estimates varied by less than 0.1%.

RESULTS

Results for the four cases are shown in Fig. 2, where the results are multiplied by different factors to make the differences visible on the same plot. The Poiseuille flow has no variation of velocity along streamlines, thus the Eulerian and Lagrangian hemolysis predictions are essentially the same. The inclined Couette flow has moderately increasing velocity downstream, and the Eulerian hemolysis prediction is 8% greater than Lagrangian. The converging tubes have the greatest velocity increase, yielding Eulerian predictions that exhibit 116% and

257% higher values, respectively, compared to the Lagrangian predictions.

Figure 2: Results from the Lagrangian and Eulerian hemolysis simulations for the four benchmark test cases.

DISCUSSION

These results indicate that variations in velocity cause differences in Eulerian and Lagrangian power-law model hemolysis predictions, with larger variations leading to greater differences. This trend is consistent with Hariharan, et al. [6], who found relatively small differences in Eulerian and Lagrangian predictions in Poiseuille and inclined Couette flows, but did not analyze converging channels. For more complex flows, the differences associated with the error in Reynolds transformation may be even larger.

PERISTALTSIS ALONE IS INCONSISTENT WITH MEASURED FLOW IN THE PARAVASCULAR SPACE

M. Keith Sharp (1)

(1) Department of Mechanical Engineering, University of Louisville, Louisville, KY, USA

INTRODUCTION

Diffusive or advective transport through brain tissue is important for exchange of nutrients and metabolites and for immune function, while clearance of metabolic waste requires fluid flow. Production of cerebrospinal fluid is thought to occur in the choroid plexus and interstitial fluid at the blood brain barrier of the capillaries, while a number of outflow pathways have been identified, including arachnoid villi and perineural passages in the cribriform plate [1]. It also has been proposed that fluid enters along paraarterial spaces and exits through paravenous spaces (the so-called glymphatic system [2]). Recent measurements have shown oscillatory displacement of the arterial wall and pulsatile flow around the middle cerebral arteries in rats [3]. The pulsatility of the flow logically suggests that the driver of the flow is peristalsis. However, the effectiveness of peristalsis is low for small amplitude of wall motion, as well as for oscillatory wavelength longer than the length of the channel. These recent measurements allow validation of models of paraarterial flow to evaluate the potential that it is driven by peristalsis. Comparison will also be made with alternative driving mechanisms.

METHODS

Mestre, et al. [3] reported the amplitude of normalized artery diameter displacement as 0.008, which gives a radial amplitude of $b = 0.176 \mu\text{m}$ and amplitude ratio $\phi \equiv b/a = 0.004$ in a channel with inner wall radius of $22 \mu\text{m}$ and gap between the inner and outer walls of $a = 44 \mu\text{m}$. They also measured mean flow velocity of $18.7 \mu\text{m/s}$. Ladrón-de-Guevara, et al. [4] reported the spatial root-mean-square oscillatory velocity to mean velocity ratio as 0.53. For a parabolic profile, the ratio of mean to root-mean-square is $5/4$, so the amplitude of the mean oscillatory velocity is estimated as $18.7 * 5/4 = 12.3 \mu\text{m/s}$.

Several mathematical solutions will be applied to model this flow, including peristalsis with and without a longitudinal pressure gradient in parallel-plate [5] and annulus [6] geometries. Both models assume

channel length longer than the oscillation wavelength, which likely overestimates the net flow rate, but is conservative for evaluating the plausibility of peristalsis as the primary driver of flow. Augmentation of mean flow by directional flow resistors is also evaluated in the parallel-plate geometry [7]. In this case, the resistors flex in the direction of blood flow in order to promote forward flow.

RESULTS

Fig. 1 shows the mean velocity normalized by the wavespeed (the maximum velocity that can be caused by peristalsis alone) for four different cases. For the parallel-plate model with no imposed pressure gradient (blue curve), with the measured paraarterial gap amplitude ratio of $\phi = 0.004$ (between the two purple dots on the figure), the mean flow rate is 0.000024. This value (dimensional velocity of $24 \mu\text{m/s}$) is close to the measured value of $18.7 \mu\text{m/s}$. However, the mean oscillatory velocity amplitude is too large at $4000 \mu\text{m/s}$ versus measured $12.3 \mu\text{m/s}$. For amplitude ratio $\phi = 0.00353$, at which the mean velocity is matched, the velocity amplitude is still too large at $3530 \mu\text{m/s}$. At amplitude ratio $\phi = 0.0000123$, the oscillatory velocity is matched, but the mean velocity is insignificant at $0.000227 \mu\text{m/s}$ (black square at the right-hand end of the blue curve).

Pressure has little effect on the flow for large amplitude ratio, but becomes strong as ϕ decreases. The mean and oscillatory velocities are both matched with a dimensional pressure difference of $\Delta p = 1.56 \text{ mmHg}$ at an amplitude ratio of $\phi = 0.0000123$ (black square at the right-hand end of the green curve), where the channel length is taken as $L = 2 \text{ m}$.

The effect of flexing flow resistors (red curve in Fig. 1) approaches zero as ϕ approaches its maximum value, however, the effect increases more quickly with decreasing ϕ than that of a pressure gradient. Mean velocity is matched at $\phi = 0.0000881$, but the oscillatory velocity is too large at $88.1 \mu\text{m/s}$. At a smaller $\phi = 0.0000123$ that matches the

oscillatory velocity, the mean velocity is too low at $2.61 \mu\text{m/s}$. The volume fraction of cylinders for these results is a somewhat arbitrary $\varepsilon_0 = 0.01$. The mean velocity is nearly insensitive to ε at the amplitude $\phi = 0.0000123$ that matches the oscillatory velocity, and a simultaneous match of measured mean and oscillatory velocities is not possible.

Figure 1: Mean velocity normalized by the maximum peristaltic mean velocity versus wall-amplitude-to-gap-height ratio.

The dotted blue curve in Fig. 1 presents the Wang & Olbricht [6] model for a nonporous annulus with zero pressure difference. The curve confirms that the annular model with oscillating inner wall has less potential for creating mean flow than the parallel-plate model. The purple dot again shows the mean velocity for the measured displacement. For this model, the mean velocity is $2 \mu\text{m/s}$ with an oscillatory velocity amplitude of $2000 \mu\text{m/s}$. For matched mean velocity at amplitude $\phi = 0.01223$, the oscillatory velocity is too great at $6110 \mu\text{m/s}$. For matched oscillatory velocity amplitude at $\phi = 0.0000246$, the mean velocity is only $0.0000756 \mu\text{m/s}$ (black square).

With a pressure difference of 1.54 mmHg added (dotted green curve), both the mean and oscillatory velocities can be matched to measured values (black square at the right-hand end of the curve), at an amplitude ratio of $\phi = 0.0000246$.

For the Mestre, et al. [3] measurements, the ratio of oscillatory to mean velocity is 0.66 . Fig. 2 shows that at the measured displacement of $\phi = 0.004$ (purple dots), the ratios for peristaltic flow without a pressure gradient are too large at 167 and 100 for the parallel-plate and annulus models, respectively. At the measured mean velocity (upper two green triangles), the ratios for peristaltic flow without a pressure gradient are too large at 189 and 327 for the parallel-plate and annulus models, respectively. Where the oscillatory velocity is matched to the measurements (upper two black squares), the ratios are $54,200$ and $163,000$ for the parallel-plate and annulus models, respectively. Indeed, a ratio of 0.66 is approached for the parallel-plate model only as $\phi \rightarrow 1$, and for the annulus model the smallest ratio obtainable is 6.27 for $\phi = 0.5$ (because the artery radius cannot collapse beyond its center). This fundamental characteristic of the performance of peristaltic channels reinforces that the mean flow must be driven by a different mechanism. With the appropriate pressure gradient, in both models the ratio initially rises for decreasing ϕ , but then decreases to 0.66 at smaller ϕ that simultaneously matches mean and oscillatory velocity (black squares overlaid by green triangles). The parallel-plate model with directional

resistors exhibits an asymptotic ratio for decreasing ϕ that is too high at about 4.7 .

Figure 2: Ratio of oscillatory to mean velocities versus amplitude ratio. This ratio is 0.66 for the Mestre, et al. [2018] measurements.

DISCUSSION

The Mestre, et al. [3] measurements quantified the displacement only of the inner wall of the channel. It stands to reason that the outer wall may also move, which would reduce the effective amplitude ratio. A two orders-of-magnitude reduction in amplitude ratio is necessary to match the oscillatory velocity, but this smaller amplitude ratio drives very limited mean flow. Directional flow resistors increase the mean flow, but not enough to create a simultaneous match of oscillatory and mean velocities. An added pressure difference of about 1.5 mmHg , however, is capable of producing a match of both velocities. Therefore, these models suggest that peristalsis is the driver of the oscillatory flow, but a pressure gradient is necessary to force the mean flow.

STRENGTH, STIFFNESS, AND TOUGHNESS OF TENDONS, AND THEIR VARIATION WITH TENDON FUNCTION

INTRODUCTION

Tendons throughout the body all serve to connect muscle to bone, but their function, structure, and composition vary [1]. Tissue engineering and repair strategies aim to restore function to tendons and joints, including the restoration of strength, stiffness, and toughness. However, debate persists on whether and how these properties vary over tendons throughout the body, including tendons that are sometimes categorized as predominantly energy-storing, such as the Achilles tendon, or positional, such as flexor and extensor tendons [2]. Our objective was to identify target mechanical properties for tendons across the body. Because more compliant springs are typically superior for energy storage, we hypothesized that tendons traditionally classified as energy storing tendons would be less stiff and less strong than positional tendons. We additionally hypothesized that toughness of tendons could be replicated by polymeric scaffolds.

To test these hypotheses, we conducted a comprehensive review of data in the and studied these data in the context of Ashby property charts [3]. Data falsified our first hypothesis, with properties of positional and energy-storing tendons overlapping. Data supported our second hypothesis, with strength, stiffness, and toughness of tendons all overlapping the range of existing polymers.

METHODS

Data collection

We collected tensile test data for various human tendons with the goal of establishing the ranges of their mechanical properties and comparing these properties to each other and to other engineering materials. We found 96 papers reporting data that identified a combination of elastic modulus, ultimate tensile strength, and/or data to estimate the modulus of toughness (area under the stress-strain curve to failure). From these 96 studies, a total of 236 data sets were found.

Modulus of toughness approximation

The modulus of toughness U_T was calculated as:

$$U_T = \int_0^{\varepsilon_f} \sigma(\varepsilon) d\varepsilon \approx \frac{1}{2} (\sigma_y + \sigma_u) \varepsilon_f \quad (1)$$

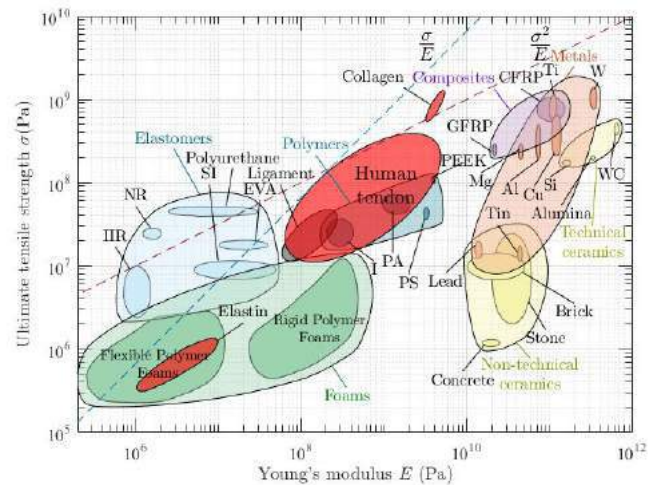

Figure 1: Strength and modulus of human tendon, elastin, and collagen compared to engineering materials. (NR=natural rubber, IIR=“butyl” rubber, SI=silicone, EVA=ethylene vinyl acetate, I=ionomers, PS=polystyrene, PEEK=polyetheretherketone, PA=polyamides, WC=tungsten carbides.)

where ε_f is the failure strain, σ_y is the stress associated with the end of the elastic range, σ_u is the ultimate stress, and the approximation on the right was used when area under the stress strain curve was unavailable, as is common for ductile materials and polymers [4, 5].

Data analysis

Data were synthesized using logarithmic property charts known as Ashby plots [3]. Two dimensional Ashby plots were made using Matlab (The Mathworks, Natick, MA), with logarithmic ellipses drawn around the ranges representing the upper and lower limits of average quantities. Data for engineering and natural materials that were used for comparison were taken from references [6], and [7].

RESULTS

Property charts were drawn for ultimate strength versus Young's modulus (Figs. 1-2) and Young's modulus versus mod-

ulus of toughness (Fig. 3). As expected for a heterogeneous, composite material, the mechanical properties of tendon fell between those of its primary constituent proteins, elastin (lower left of Fig. 1) and collagen (upper right). Energy storage at failure can be compared qualitatively by the dashed line in Fig. 1 representing the ratio σ^2/E . The σ^2/E property line intersecting tendon and ligament also intersects engineering composites and some of the strongest metals, as well as certain elastomers. Collagen fibrils outperform elastin in this metric, with tendon and ligament having values that lie between the two.

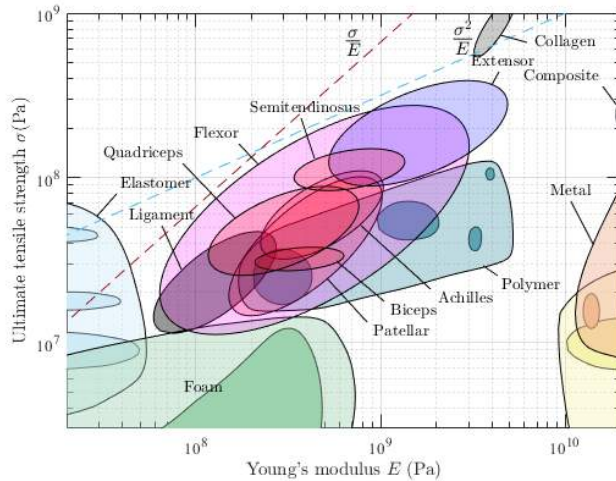

Figure 2: Property differences amongst human tendons.

Although collagen fibers are amongst the toughest of all materials (right side of Fig. 3), comparison to other materials reveals that the toughness of tendon is not remarkable for a material of its stiffness and that its stiffness is not impressive for a material of its toughness. The stiffness and toughness of the tendon are situated near the center of the material's space. Elastomers and certain metals are the toughest; non-technical ceramics such as brick are the least tough. Tendon has toughness on the order of midrange polymers.

DISCUSSION

Comparison of tendon to engineering materials

Individual collagen fibrils are as strong as the strongest metals, but tendon has a complicated composite structure that has a lower strength and stiffness than collagen. Two factors are potential contributors. The first is structure. Tendon and ligament both have a hierarchical structure of type I collagen stretching from the molecular level to the tissue, with nearly 70 percent of the weight of tendon being water [8]. This structure partly accounts for the lower stiffness and strength, but the composition also plays a role. Tendon and ligament consist primarily of type I collagen I and a small amount of elastin, as well as smaller quantities of proteoglycans, glycosaminoglycans, and minor collagens. As a composite of predominantly collagen and elastin, tendon and ligament have strength and stiffness between those of elastin and collagen. The ligament has the same hierarchical type I collagen structure as tendon but contains more elastin and thus, as expected by the rule

of mixtures, has a range of properties that lie in a region situated closer to that of elastin on the Ashby plot than does the range associated with the tendon (Fig. 2).

Figure 3: Young's modulus versus toughness Ashby chart.

Comparison of energy storing and positional tendons

A hypothesis to be found in the literature is that tendons fall into two distinct categories: positional tendons and energy storing tendons. Zooming into Fig. 1, Fig. 2 shows a spread of properties for different types of human tendons and ligaments and allows some evaluation of this hypothesis. In Fig. 2, all ligaments and tendons lie within a relatively narrow range of σ/E , indicating that nearly all of these tissues have failure strain in the same order. However, the data appear to falsify this hypothesis, with flexor and extensor tendons spanning the entire range of tendon and ligament properties. Although extensor tendons are the stiffest tendons, the range of values reported for flexor tendons exceeds the range of values reported for all other tendons.

Implications for tissue engineering

Results revealed no significant differences between the mechanical properties of positional and energy storing tendons. Results suggest that a single range of mechanical properties with elastic moduli in the hundreds of MPa range and strength in the 100 MPa range is adequate to replicate the properties of most tendons. These property ranges are achievable with existing engineering polymers, as are the toughness ranges of tendon.

IN VIVO ASSESSMENT OF PASSIVE AND ACTIVE ARTICULAR CARTILAGE STRAIN RECOVERY

Shu-Jin Kust (1), Dana Voinier (2), Kyle D. Meadows (1), Dawn M. Elliott (1), Daniel K. White (2), Axel C. Moore (1)

(1) Department of Biomedical Engineering, University of Delaware, Newark, DE, USA

(2) Department of Physical Therapy, University of Delaware, Newark, DE, USA

INTRODUCTION

Articular cartilage lines the ends of long bones in synovial joints and functions to provide load-bearing and low-friction articulation. These biomechanical functions are largely driven by the poroelastic mechanics (fluid pressurization) of the articular cartilage [1]. Unfortunately, the same poroelastic pressure that leads to load-bearing and lubrication also drives fluid exudation and concurrent tissue strain. In vivo static loading (e.g., standing) produces as much as -30% strain in 60 min. Interestingly, active loading (e.g., walking, knee bends, cycling, running) in vivo produces an initial period of fluid exudation and strain ($\sim -5\%$) [2]; after which, active loading arrests further fluid loss and tissue strain [3]. While static and active loading drive fluid exudation and cartilage strain, static unloading (e.g., lying down) provides recovery, and to date, is the only in vivo mechanism that has been shown to restore hydration and strain.

We hypothesize that active loading is actually a hydration and strain recovery mechanism that has yet to be observed. In this study, we investigate whether active loading (walking) is only an exudation and arresting mechanism or whether it is also capable of recovery. We use magnetic resonance imaging (MRI) to evaluate the in vivo strain of articular cartilage in human knees following: (1) standing (static loading), (2) lying down (static unloading), and (3) walking (active loading).

METHODS

Participants. Following IRB approval, we recruited N=8 asymptomatic young adults to participate in the study. Participant age (29 ± 3 years of age, mean \pm 95% confidence interval), biological gender (4 male, 4 female), and BMI (23 ± 2) were recorded. Up to 5 days prior to MRI scanning, participants were given a wrist worn activity monitor to track the number of steps taken each day (13 ± 5 k steps/day). Knee joint health was assessed using the self-reported Knee Injury and Osteoarthritis Outcome Score (KOOS).

MRI Scanning. Participants arrived at the MRI facility on the day of scanning and were positioned within the scanner (3T

MAGNETOM Prisma, Siemens) with a 15 channel Tx/Rx knee coil around their right knee. Participants were scanned in the following fixed order: (1) baseline, and immediately after (2) 30 min of standing, (3) walking for 10 min at 110 steps per min, (4) 30 min of standing, and (5-8) 12, 24, 36, and 48 min of lying down (**Fig 1**). A proton density weighted turbo spin echo (PD-TSE) was used to assess the morphology and thickness of the articular cartilage. The in-plane resolution and slice thickness were 0.3 and 1.5 mm respectively.

Figure 1: Order of activities (walking – green, standing – red, lying down – yellow). MRI scanning is indicated with the magnet symbol, and the numbering corresponds to the scan number, see section MRI Scanning.

Data Analysis. We calculate cartilage thickness as the tibiofemoral bone-to-bone distance within the medial and lateral compartments, measured within the region of contact. MRI scans were registered to the baseline scan to ensure the same region was measured. We calculate cartilage strain as the change in cartilage thickness divided by the baseline thickness. All values are reported as the mean \pm 95% confidence interval unless stated otherwise.

RESULTS

The average strain in the medial and lateral compartments for 8 participants are shown in **Fig 2A&B**. The baseline strain is set at 0%; we discuss the implications and rationale for this later. After 30 min of static loading (standing), there is a clear thinning of the articular

cartilage to an average -5.0 ± 0.4 and $-5.3 \pm 0.6\%$ strain in the medial and lateral compartments. Following a 10 min walk (active loading), the cartilage thickness recovers 2.3 ± 0.3 and $2.6 \pm 0.6\%$ strain, which directly agrees with our hypothesis that active loading is capable of recovery. Following another bout of static loading to approximately the same strain (-5.4 ± 0.3 medial and $-5.1 \pm 0.5\%$ lateral) the participant lies supine (static unloading), and the cartilage thickness and strain progressively recover. Following the first scan (12 min post standing), the cartilage recovered 1.5 ± 0.6 and $1.1 \pm 1.0\%$ strain in the medial and lateral compartments. Following 48 minutes of unloaded recovery the cartilage recovered 3.8 and 3.6% strain in the medial and lateral compartments.

DISCUSSION

In agreement with prior literature, static loading causes cartilage strain [4] while static unloading causes strain recovery [3]. These dynamics are driven by fluid flow out of and into the articular cartilage [5]. Counter to the existing literature, we have shown that active loading (walking) is not simply an exudative and arresting mechanism [3,6] but also a mechanism of recovery, which we hypothesize is driven by fluid flow back into the articular cartilage. In future work, we will further assess the flow of fluid back into articular cartilage using T2-w imaging.

The implication for activity driven cartilage recovery is significant. While epidemiological studies have documented the chondroprotective nature of joint activity, we have yet to identify the mechanism that provides chondroprotection. The observation that in vivo active loading recovers cartilage strain, and possibly hydration, opens new opportunities for understanding the long term biomechanical and cellular responses to active loading.

This study is not without limitations. The most notable limitation is the resolution of MRI. The PD-TSE sequence had an in-plane resolution and slice thickness of 0.3 and 1.5 mm respectively. Despite this, prior work by our group and others has shown sub-pixel sensitivity and precision when measuring tissue thickness and strain [7]. Furthermore, 0.3 mm is the typical in-plane resolution achieved for 3T MRI of cartilage. While not a limitation, it is important to note a significant deviation in our study design compared to the existing

literature. Prior studies place strict criteria on limiting a participant's activity prior to MRI and ask subjects to arrive early in the morning (e.g., 7:00 AM) and often provide wheelchair transport from the moment of their arrival [8]. The goal of this is to maximize the hydration and thickness of the cartilage. In addition, subjects typically sit or lie down for 45 minutes prior to scanning. While this gives the most realistic case for measuring 0% strain, it does not represent the typical operating strain of daily life. It has been shown that the diurnal strain for cartilage in the knee is $\sim 5\%$ and it is achieved in as little as 3 min of active loading [3]. In this study we evaluate cartilage at its 'operating strain' which we call baseline and define as 0% strain. We then drive the cartilage strain and hydration into a deficit through static loading. This deficit is what allows us to observe the recovery effect of joint activity.

In conclusion, we have shown that active loading is indeed a recovery mechanism for articular strain and has a potentially significant role in maintaining joint health. Furthermore, this finding reveals that the current view of joint activity being an exudative and arresting process (strain and hydration) is incomplete and that activity is a balance between load driven exudation and active recovery. The results of this work will help in developing evidence-based activity guidelines to promote long term cartilage health and potentially delay or prevent the development of osteoarthritis.

INTRODUCTION

Venovenous extracorporeal membrane oxygenation (VV ECMO) is a life-saving treatment for acute respiratory distress syndrome (ARDS). Blood is drained from the patient's venous network, is oxygenated in an artificial membrane, and returned. Traditionally, this drainage and return of blood from the patient has been achieved with two separate, single lumen, cannulas (SLCs). More recently dual lumen cannulas (DLCs) combining both functions into a single device have become more commonplace.

Recirculation fraction (R_f) is the proportion of oxygenated return blood which is directly drained out before passing through the tricuspid valve thus not contributing to patient oxygenation. Effective VV ECMO cannulation should achieve a low R_f . Another key design objective for ECMO cannulas is to minimize the shear stress that the blood is exposed to. High shear stress is known to increase the risk of coagulation activation (secondary thrombosis/clotting) (Casa et al. 2015) and hemolysis (red blood cell damage) (Leverett et al. 1972). Finally, VV ECMO cannulas should disrupt physiological hemodynamics as little as possible.

Whilst DLCs are thought to have superior R_f performance compared to SLCs, this has not yet been conclusively demonstrated in a direct comparison. The shear stress acting on blood when using DLCs and its impact on native hemodynamics have also not been reported in adults.

METHODS

A patient-averaged model of the adult right atrium (RA) and venae cavae from a previous study was used to model background venous flow (Parker et al. 2022c) (Figure 1). This model was based on four healthy volunteers (3 female) with mean age = 58.3 ± 3.5 yrs, weight = 77.0 ± 11.9 kg and height = 173.0 ± 2.8 cm. Two common DLC designs, the Maquet Avalon Elite® (Getinge, Rastatt, Germany) and MC3 Crescent® (Medtronic International Trading Sàrl, Tolochenaz,

Switzerland) were sectioned, measured and reconstructed, creating accurate 3D models following the same methodology as applied previously to SLCs (Parker et al. 2022b). The measured DLCs were both downscaled to 27Fr, an appropriate size for our patient model, and inserted into the model. To delineate these from the off-the-shelf products we refer to the devices with the prefix “ds” for downscaled.

Figure 1: The patient-averaged 3D model with downscaled 27Fr Avalon dual lumen cannula inserted in baseline position (left). Venous image segmentation from one of the healthy volunteers (middle + right). SVC = superior vena cava, IVC = inferior vena cava, RA = right atrium.

The computational fluid dynamics (CFD) approach followed the same setup as applied in previous investigations (Parker et al. 2022a, Parker et al. 2022c, Parker et al. 2022b). This consisted of a Large Eddy Simulation (LES) with wall-adapting local-eddy viscosity (WALE) model, simulated on a mesh of 10.5-13.3M cells. Blood was modelled as non-Newtonian using the Quemada viscosity model. All venous and cannula walls were assumed to be rigid. All simulations were run on the Tetralith Supercomputer (National Supercomputer Centre, Sweden).

The dsAvalon and dsCrescent were first placed in the optimal position with the reinfusion port directly facing the tricuspid valve location (Figure 1). These were simulated at 2, 4 and 6 L/min ECMO flow. Analyzing flow patterns, we noted a high degree of similarity between the two designs. Therefore, the impact of insertion depth (± 4 cm) and rotation ($\pm 30^\circ$ and $\pm 60^\circ$) was only assessed for the dsAvalon design.

Simulations were run for several cardiac cycles until periodicity was achieved. The velocity, wall shear stress (WSS), R_f and turbulent kinetic energy (TKE), averaged over the final cardiac cycle were analyzed. Pressure probes were also placed in the superior vena cava (SVC), inferior vena cava (IVC) and RA.

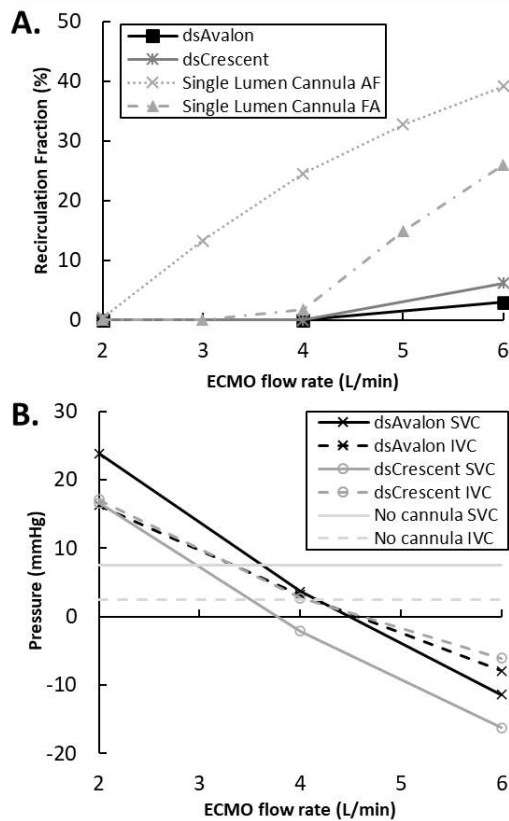

Figure 2: A. Recirculation fraction (R_f) for the downscaled (ds) Avalon and Crescent models. These are compared with previous findings for single lumen cannulas in atriofemoral (AF) and femoroatrial (FA) configuration (Parker et al. 2022b). B. Superior (SVC) and inferior vena cava (IVC) pressures using both the dsAvalon and dsCrescent compared to no cannula.

RESULTS

R_f was low for both DLCs compared to our previous findings with SLCs. Even at high ECMO flow rates R_f remained below 7% (Figure 2A). Caval pressures were abnormally high at low ECMO flow rates for

both DLCs (Figure 2B). As expected, at high ECMO flow rates caval pressures were negative (Figure 2B). Time-averaged WSS (TAWSS) was very high (>475 Pa) at the reinfusion port for both designs at all ECMO flow rates. The focused jet of return blood created regions of similarly high TAWSS (>50 Pa) at the RA wall for all flow rates. R_f did not change significantly with rotation from -60° to $+60^\circ$. Conversely, R_f was highly sensitive to insertion depth. With short insertion depth (-4 cm from baseline), R_f was $>30\%$ at all ECMO flow rates. Under long insertion depth ($+4$ cm from baseline), the increase in R_f was only significant at 6L/min ECMO flow rate (24.0%).

DISCUSSION

The results from this study confirm the widely held belief that DLCs exhibit superior R_f performance compared to SLCs under ideal conditions. The two downscaled designs assessed here both show minimal recirculation even at high ECMO flow rates. The high caval pressures at low ECMO flow rates was an unexpected finding. This likely arises from the significant obstruction caused by the large outer diameter of both DLCs. At low ECMO flow rates, caval drainage is low but return venous flow is impeded from entering the RA. This high caval pressure may provide a possible explanation for the higher incidence of intracranial hemorrhage reported when using large diameter DLCs (Mazzeffi et al. 2019). Both DLC designs feature a highly focused reinfusion port to direct flow towards the tricuspid valve. This creates high TAWSS conditions at the reinfusion port and the RA wall which may cause hemolysis and coagulation activation. Our results also provide practical clinical information. DLCs appear to be highly sensitive to insertion depth where too short an insertion depth is particularly detrimental to R_f performance. Rotation of the devices did not have any significant impact on R_f performance.

INTRODUCTION

Aortic stenosis is a prevalent disease of the aortic valve, affecting 5% of people over the age of 65 and carrying a 50% chance of mortality within two years if left untreated [1, 2]. Bioprosthetic heart valve replacements that use porcine or bovine pericardium are most commonly used to treat this disease; however, such devices typically experience premature failure within 25 years due to loss of structural integrity and calcification [3, 4]. In this research, we propose a method to develop bioinspired polymer-based materials to improve leaflet functionality while extending device lifetimes.

Glutaraldehyde-fixed bovine or porcine pericardium currently used in commercial devices does not accurately replicate the complex structure or function of the native aortic valve leaflets, which have a unique tri-layered structure and predominantly circumferentially aligned collagen fibre bundles [5]. In addition, pericardium suffers from structural valve degeneration (SVD), which is the deterioration of the tissue ultimately leading to device failure through stenosis or regurgitation [6]. SVD is known to be exacerbated by glutaraldehyde fixation, which increases tissue stiffness and promotes calcification [7]. Consequently, it is desirable to use a non-calcifying material that can withstand the complex loading environment of a heart valve for an extended period of time, which is the goal of using a polymer-based material inspired by the native aortic valve leaflets.

To better understand the material properties and structure of native leaflets in order to determine the optimum polymer material, extensive work has been performed to establish the material behaviour of individual valve leaflet layers and key microstructural characteristics. Specifically, second harmonic generation (SHG) microscopy was carried out in order to identify local collagen alignment in key locations across fresh porcine leaflets. From this, we can use finite element (FE) modelling and melt electrowriting (MEW) to define and manufacture a polymer material with an optimal, fibre-reinforcement structure that

mimics the structure of native aortic valve leaflets. We have developed an FE framework that informs this MEW fibre reinforcement structure to ultimately form the basis of an idealised polymeric valve leaflet material.

METHODS

An ACURATE neo2™ leaflet geometry was provided by industrial collaborators at Boston Scientific. This leaflet was partitioned into 28 discrete rectangular regions, all ranging from 2.5 to 3.5 mm in both height and width, see Figure 1(b). Constitutive properties of silicone rubber and PCL were informed by relevant literature and applied to a preliminary discrete fibre-reinforced model, based on a 2-layered MEW structure [8, 9]. Tensile behaviour of this PCL-reinforced silicone was then used to calibrate parameters for the anisotropic, fibre-reinforced HGO model implemented in Abaqus CAE [10]. Collagen orientation was imaged by SHG at the commissure and belly regions using a Carl Zeiss 710 NLO microscope, see Figure 1(a). With these images, fibre angles were obtained using ImageJ, defined at these locations in the model, and then extrapolated for the rest of the locations in the leaflet, see Figure 1(b). Half of the leaflet was modelled using symmetrical boundary conditions for computational efficiency, elements around the edge of the leaflet were fixed in all directions, and a pressure of 80 mmHg was applied to the face of the leaflet; see Figure 1(c). Three cases were investigated in order to probe the mechanical contribution of a MEW fibre-reinforcement structure: (i) matrix with no fibres (Neo-Hookean model: $C_{10}=0.3$ MPa), (ii) fibre-reinforced matrix with calibrated parameters (HGO model: $C_{10}=0.3$ MPa, $D=0$, $K_1=0.2$ MPa, $K_2=0.1$, $\kappa=0$), and (iii) fibre-reinforced matrix with stiffer fibres ($K_1=2$ MPa, $K_2=1$).

To assess manufacturing feasibility, MEW structures were printed using a custom-built, in-house printer [11]. One structure was embedded in Ecoflex 00-30 silicone rubber and a second implemented curved fibres in the horizontal direction.

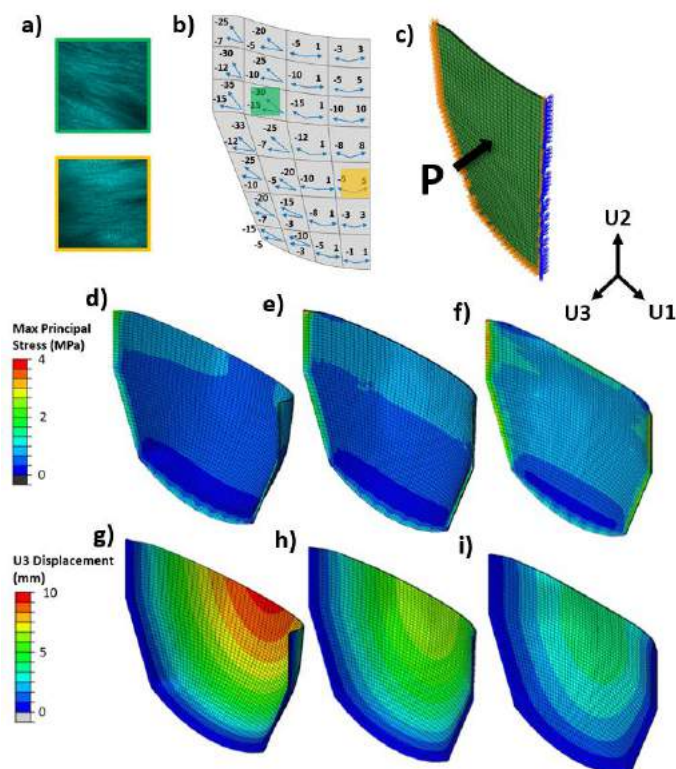

Figure 1: (a) Example SHG images for commissure and belly regions, (b) partitioned leaflet with specified fibre angles relative to the x-axis, (c) leaflet boundary and loading conditions; stress distributions for each considered case: (d) matrix only (max: 1.60 MPa), (e) calibrated fibre reinforcement (max: 1.89 MPa), and (f) stiffer fibres (max: 3.03 MPa); displacement distributions for each considered case: (g) matrix only (max: 9.77 mm), (h) calibrated fibre reinforcement (max: 6.64 mm), and (i) stiffer fibres (max: 4.13 mm)

Figure 2: (a) MEW structure embedded in silicone rubber, (b) MEW structure with curved fibres in the horizontal direction. Scale: 5 mm.

RESULTS

A partitioned polymer leaflet model with biologically inspired varying fibre orientations subjected to an applied physiological pressure was successfully simulated. Both the matrix-only and calibrated fibre-reinforced models exhibited similar stress distributions (max: 1.60 and 1.89 MPa, respectively), see Figure 1(d,e). As expected, an increase in stress magnitude was caused when increasing the fibre stiffness (max: 3.03 MPa), see Figure 1(f).

Furthermore, adding a fibre reinforcement structure and increasing fibre stiffness led to notable decreases in leaflet displacement. While the matrix-only model experienced a maximum displacement of 9.77 mm, this decreased after the addition of fibres, with the calibrated model displacing to a maximum of 6.64 mm. Increasing the stiffness of these fibres further impacted the leaflet displacement, bringing the maximum displacement down to 4.13 mm, see Figure 1(g-i).

Showing the feasibility of MEW for this application, two structures were successfully printed: one box structure that was subsequently embedded in silicone rubber, and a second with curved fibres to mimic the impact of collagen crimp, see Figure 2(a,b).

DISCUSSION

While MEW has been shown to be an effective and versatile manufacturing method for the fibre-based reinforcement of materials, there are few frameworks in place to inform MEW using modelling approaches [12]. With a comprehensive understanding of native leaflet structure and properties, computational modelling can be used to minimise the empirical mechanical assessment required during the design and fabrication of MEW constructs, and, importantly, inform an ideal material geometry.

This work has introduced a framework for using FE modelling and SHG imaging to define an optimal fibre-reinforced leaflet material manufactured using MEW for use in prosthetic aortic heart valves. We have demonstrated the impact of fibre reinforcement on an elastomeric material: by adding supporting structures at varying stiffness and orientations, the load-bearing capacity and deformation characteristics of the leaflet under applied loading can be tuned to suit the desired performance. This allows for the complete customisability of the polymer leaflets, allowing us to manufacture a material that can readily emulate native tissue.

We can validate the results of this model by conducting tensile testing of MEW-reinforced elastomeric materials, and further use this model to investigate different MEW reinforcement structures. Additionally, using the information gained from the assessment of porcine leaflets, this model can be compared to native valve tissue to evaluate its performance.

Ultimately, the objective of this work is to develop a methodology to aid with the design and development of new prosthetic heart valve leaflets, ensuring an extended lifetime for these devices. By bringing together knowledge of the native aortic valve leaflets, MEW, and FE modelling, we can define and manufacture these optimal leaflets for future commercial devices.

INTRODUCTION

Aortic coarctation has an incidence of 0.3 to 0.6 in 1000 live births, ultimately accounting for 5 to 12 % of all congenital heart disease [1,2]. Currently, neonatal coarctation is treated surgically via a thoracotomy procedure, which involves excision of the narrowed section of the aorta followed by an end-to-end anastomosis. However, for older children and adults, stenting is now the procedure of choice. Although, stenting is associated with low instances of acute complications, there is a risk of hypertension long-term [3]. Currently, due to the small patient cohort and little financial incentive for medical device companies, biliary stents are commonly used off-label in the treatment of aortic coarctation with less than optimum outcomes.

In recent years, research has been carried out into the development of 3D printed metallic stents in an attempt to overcome the disadvantages and shortfall of manufacturing stents in the conventional laser cut manner [4]. Additive manufacturing of metallic stents is a very promising method of creating bespoke stents for paediatric aortic coarctation. Recent studies by McGee et al [5] and by Demir & Previtali [6] have established the manufacturing rules for printing stents using selective laser melting (SLM). 3D printing stents provides an opportunity to create stents that are designed specifically with the patient in mind. Finite element (FE) modelling can act as this precursor to stent manufacturing by establishing what specific design is required in order to achieve maximum lumen gain and at the same time minimize the stress on the host vessel.

Therefore, the objective of this work is to develop a framework to design, experimentally and computationally evaluate 3D printed stents and individual stent units, to assess their performance and ultimately 3D print bespoke stents for patient specific treatment of aortic coarctation.

METHODS

Stent and stent unit design

The biliary Max LD Intrastent (Medtronic, United States) with a diameter = 10mm and strut thickness = 200µm was used for the initial design.

A stent repeating unit was sketched in Abaqus (SIMULIA, Dassault Systèmes) and subsequently wrapped using the wrap mesh plugin. The geometry of the full stent was assembled and then imported into ANSA Beta (BETA CAE Systems, Greece) and segmented into individual units, as shown by Fig. 1.

Figure 1: Creating initial intrastent geometry and segmentation of full stent design into individual units.

Computational setup

For the materials, 316L stainless steel was described by an elastic-plastic material model with elastic modulus of 196 GPa, Poisson’s ratio of 0.3 and a yield strength of 375 MPa [7] and printed titanium Ti6Al4V by an elastic modulus of 65.09 GPa, Poisson’s ratio of 0.3 and a yield strength of 663.519 MPa.

Crush tests were simulated by modelling two parallel rigid plates, meshed using SFM3D4 quadrilateral elements. Zero friction and hard contact was assigned between the stent and plates. The bottom plate was fixed, whilst the top plate was assigned a displacement boundary condition corresponding to half the stent diameter (5 mm).

Crimp tests were simulated by assigning a cylindrical coordinate system at the centre of the stent geometry. A radial displacement boundary condition was then applied to simulate the crimping response to a pre-set diameter.

3-point bend tests were simulated according to ASTM standard F2606-08. Three pins were modelled as rigid, with two pins fixed and separated by a span length of 30.30 mm and indented by 6.06 mm by a third centrally placed pin.

3D printing and postprocessing of stents

A Realizer SLM 50 was used to 3D print stent designs (10 mm diameter, 400 μm strut thickness) using Ti6Al4V powder using previously established parameters [5]. A scan and hatching strategy were employed to ensure continuous build-up of the structure. After printing, the stents were post-processed by sandblasting and chemical etching to achieve a strut size of 100 μm .

Crush tests, crimping & 3-point bend tests of printed stents

Each computational setup was also investigated through respective experimental methods. These are detailed as follows:

Crush tests was conducted by compressing the 3D printed stents by two parallel plates as shown by Fig. 3A. Stents were compressed to 50% of their nominal diameter at a compression rate of 3mm/min in accordance with ISO 25539-2 standard.

Crimping and balloon expansion was conducted by firstly crimping the 3D printed stents down to known diameters of 3D printed cylinders using a Machine Solutions Inc. HV 500 crimping tool. After being fully crimped, the balloon from the Express LD stent delivery system was used to expand the crimped stent to its maximum dilation.

3-point bent tests were conducted by the test method outlined in ASTM F2606-8. Like the computational setup, span length and maximum deflection was calculated and used for the test. Stents were pre-loaded to 0.1 N and deflected at a rate of 10 mm/min.

RESULTS

Changing strut dimensions can significantly alter the yield observed in individual units, see Fig. 2A, where locations above 663.519 MPa stress correspond to locations of yield in the 3D printed titanium stents. Stent units with uniform strut dimensions (100 μm) showed no yield when crushed to 50% of their diameter, demonstrating elastic behaviour and the ability to be compressed further before yielding. In our crimping simulations, yielding of the stent material is only observed when crimped to sufficiently small diameters, as shown by Fig 2B. The stent with uniform smaller strut dimensions (100 μm) could be crimped to a smaller diameter without yield. Three-point bend simulations showed Ti64Al stents to be more elastic compared to stainless steel 316L, where the latter showed yielding and consequently significant plastic deformation for the same loading, see Fig 2C.

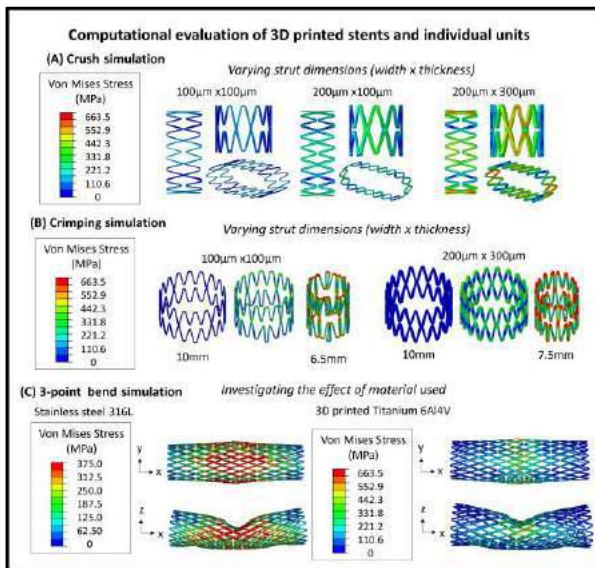

Figure 2: Computational evaluation of the stent and individual units (A) Crush testing simulation of units with different strut dimensions (B) Crimp testing simulation of units with different strut dimensions (C) 3-point bend test of stent with strut size of 200x100 μm with different material assigned

Experimental tests qualitatively validated all our computational simulations. Our post-processed stents (strut thickness = 100 μm) showed an elastic response when crushed to 50% of their diameter, as predicted by our models which showed no yield, see Fig. 2A and 3A. Radial crimping of the 3D printed stent shows the ability to crimp down to a smaller diameter, see Fig 3B(i). Interestingly, the stent shows considerable elastic recoil when crimped to set diameters, see Fig 3B(ii). Furthermore, balloon expansion shows unfolding of the stent geometry without fractures, as shown in Fig 3C. Lastly, 3-point bend experiments agreed with our computational results showing significant yield in the Intrastent and an elastic response in our 3D printed stents, see Fig. 3D

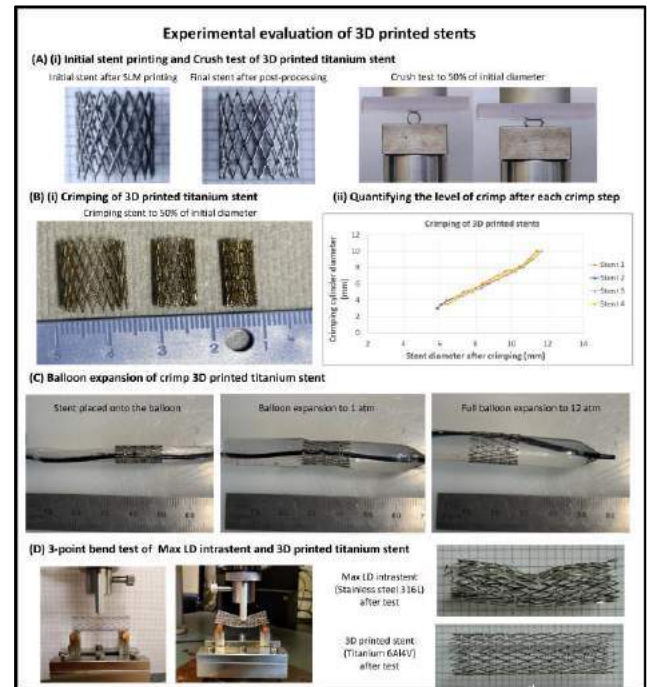

Figure 3: Experimental evaluation of the stent and individual units (A) Initial stent printing and postprocessing with subsequent crush testing (B) Crimp testing of 3D printed stent (C) Balloon expansion of crimped 3D printed stent (D) 3-point bend test of Max LD intrastent made from stainless steel 316L and 3D printed stent made from Titanium 6Al4V.

DISCUSSION

This study shows a feasible framework for creating patient specific stents for treatment of aortic coarctation. Using these virtual simulations and further validation of these using experimental methods, it is possible to estimate the geometry and material-dependent variations in radial strength, crimpability and three-point bend flexibility of the stents, enabling optimization, design, and manufacture of patient specific stents.

THE NON-AFFINE NETWORK SOLVER PLUGIN: A GENERALIZED FIBER NETWORK MATERIAL MODEL FROM VOLUME AVERAGING THEORY

Ryan R. Mahutga (1), Victor H. Barocas (1), Patrick W. Alford (1)

(1) Department of Biomedical Engineering, University of Minnesota, Minneapolis, MN, USA

INTRODUCTION

Finite element (FE) modeling is the most widely used technique for modeling the mechanical behavior of biological materials. Implicit to the use of FE modeling is the definition of a material constitutive relation describing the behavior of the microstructure of the material. There has been extensive work performed in the development of such constitutive models in the area of biological materials [1–3], with the roots of such material models tracing back to continuum mechanics. Current material models allow us to simulate the behavior of many tissues in many applications, but most material models fall short in two critical areas: failure and growth. As the biomechanics field moves toward understanding the microscopic features of biological tissues that drive failure initiation (e.g. fiber-fiber crosslinking, cell-fiber (integrin) connection, cell-cell adhesion) and growth and remodeling (e.g. cellular mechanotransduction, cellular manipulation and self-assembly of fibers), we need models that describe these features of the discrete microstructure. Thus, we propose a material model derived from the volume averaged stress within a fiber network which we call the Non-affine Network Solver (NaNS). This model allows us to simulate the discrete nature of cells and the extracellular matrix (ECM) including the non-affine nature of deformations within fiber composites and the interactions between constituents.

METHODS

In traditional FE modeling of mechanics, the application of a constitutive relation requires the stress tensor and the elasticity tensor. **The Network Stress Tensor:** Volume averaging theory gives us a convenient way to calculate the average Cauchy stress in a volume as an integral over the domain, or a summation over the fiber elements [4]

$$\begin{aligned}\sigma_{ij} &= \frac{1}{V} \int \sigma'_{ij} dv \approx \frac{1}{V} \sum_e \sigma^e_{ij} v^e \\ &= \frac{1}{V} \sum_e \left(\frac{f^e n_i^e n_j^e}{a^e} \right) (a^e l^e) = \frac{1}{V} \sum_e f^e l^e n_i^e n_j^e \quad (1)\end{aligned}$$

From this equation, we can calculate the volume averaged stress for any arbitrary shaped network provided we know the volume V , the constituent fiber forces f^e , the fiber lengths l^e , and the fiber directions n_i^e . We can also convert this Cauchy stress to the second Piola-Kirchoff using the inverse deformation gradient and the relations $J = V/V_0$ and $l^e n_i^e = L^e F_{ij} N_j^e$

$$S_{IJ} = J F_{Jk}^{-1} \sigma_{kp} F_{Ip}^{-1} = F_{Jk}^{-1} \left(\frac{1}{V_0} \sum_e f^e L^e n_k^e n_l^e \right) \quad (2)$$

where L_0^e is fiber rest length and N_j^e is the unit vector along the fiber axis in the undeformed configuration.

In the solution process for a fiber network, we only need the internal forces at all ‘nodes’ (connections between constituents) to be balanced given the deformation of the microstructural boundary. There are many ways to do this, but for this work, we choose to use a Newton iterative scheme utilizing the internal nodal Jacobian $J_{nm} = df_n/dx_m$ where f_n is the force on the node (i.e. the resultant of all fiber forces acting on the node), and x_m is the nodal coordinate.

The Network Elasticity Tensor: Let us consider the fourth-order material elasticity for our derivation given as

$$C_{IJKL} = \frac{\partial S_{IJ}}{\partial E_{KL}} = 2 \frac{\partial S_{IJ}}{\partial C_{KL}} = 2 \frac{\partial S_{IJ}}{\partial F_{pq}} \frac{\partial F_{pq}}{\partial U_{MN}} \frac{\partial U_{MN}}{\partial C_{KL}} \quad (3)$$

where polar decomposition gives us $F_{pq} = R_{pw} U_{wq}$, and the right Cauchy-Green tensor can be rewritten as $C_{KL} = U_{wK} U_{wL}$. The derivative of deformation with respect to the right stretch tensor can further be evaluated as $\frac{\partial F_{pq}}{\partial U_{MN}} = R_{pw} \frac{\partial U_{wq}}{\partial U_{MN}} = R_{pw} \delta_{qN}$, and the derivative of the right stretch tensor U with respect to the right Cauchy-Green tensor is simply $\frac{\partial U_{MN}}{\partial C_{KL}} = \left(\frac{\partial C_{KL}}{\partial U_{MN}} \right)^{-1} = (U_{MK} \delta_{LN} + U_{ML} \delta_{KN})^{-1}$. Thus, we only need the derivative of stress with respect to the deformation gradient which is given by

$$\frac{\partial S_{JJ}}{\partial F_{pQ}} = \frac{\partial F_{JJ}^{-1}}{\partial F_{pQ}} \left(\frac{1}{V_0} \sum_e f_j^e L_{0i}^e \right) + F_{JJ}^{-1} \left(\frac{1}{V_0} \sum_e \frac{\partial f_j^e}{\partial F_{pQ}} L_{0i}^e \right) \quad (4)$$

where $\partial F_{JJ}^{-1} / \partial F_{pQ} = -F_{JJ}^{-1} F_{QJ}^{-1}$.

Then the final piece is calculating how the fiber forces change with deformation, which we can do using a linear approximation of the fiber assuming that the fiber stiffness is $k = df^e / d\epsilon^e = df^e / d\lambda^e$.

$$\begin{aligned} f_j^e &= k \left(\frac{l^e}{L_0^e} - 1 \right) n_j^e = k \left(\frac{l_j^e}{L_0^e} - n_j^e \right) = k \left(\frac{F_{JJ} L_{0i}^e N_j^e}{L_0^e} - n_j^e \right) \\ &= k (F_{JJ} N_j^e - n_j^e) = k (F_{JJ} - R_{JJ}) N_j^e \end{aligned} \quad (5)$$

So that

$$\begin{aligned} \frac{\partial f_j^e}{\partial F_{pQ}} &= k \left(\frac{\partial F_{JJ}}{\partial F_{pQ}} - \frac{\partial R_{JJ}}{\partial F_{pQ}} \right) N_j^e = k \left(\delta_{jp} \delta_{jQ} - \frac{\partial R_{JJ}}{\partial (R_{pM} U_{MQ})} \right) N_j^e \\ &= k (\delta_{jp} \delta_{jQ} - U_{MQ}^{-1} \delta_{jp} \delta_{MJ}) N_j^e = k (N_Q^e - U_{JQ}^{-1} N_j^e) \delta_{jp} \end{aligned} \quad (6)$$

Dealing with Non-Affinity: The prior derivation for elasticity (Eqs. 3-6) does not account for non-affinity in the network, and is, in fact the exact formulation one would use for linear fibers deforming affinely with the macroscopic domain. To correct for non-affinity, we recalculate the fiber orientation in the undeformed configuration by remapping the fiber vector to the undeformed domain as $N_K^e = F_{Kv}^{-1} n_v^e$ after the calculation of equilibrium stress. This removes the non-affine rotations from the undeformed state to the current stress state allowing for a better approximation of the elasticity at the given deformation state. The choice of boundary behavior (fixed, sliding, periodic) while influencing the non-affine behavior, does not change the volume averaging relation, and can be entirely handled at the microscale.

RESULTS

The network stress and elasticity equations derived above were implemented as part of a material plugin in FEBio3. The non-affine network solver was adapted from [5], and utilizes periodic networks in the calculation of stress and elasticity. We combine the constitutive behavior of a Neo-Hookean solid with the network to simulate a composite fiber network (with fiber behaviors taken from [5]) embedded in a ground matrix, giving an overall stress of

$$\sigma_{ij} = \sigma_{ij}^{NH} + \sigma_{ij}^{net} \quad (7)$$

Two case-study examples for our simulation framework are given in Figs. 1 and 2. In Fig. 1a, we show the cruciform with only the neo-Hookean ground substance. In Fig. 1b, we show the cruciform with the combined neo-Hookean ground substance and a collagen network utilizing the NaNS plugin.

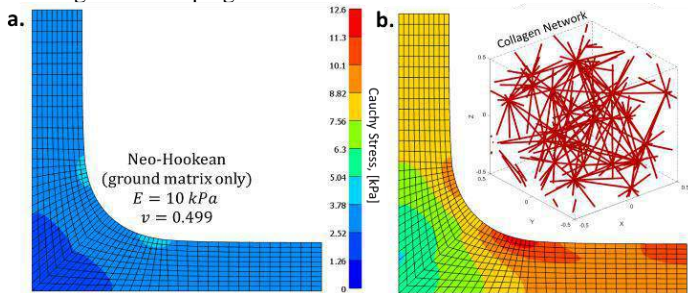

Figure 1: Biaxially stretched cruciform with neo-Hookean ground matrix only (a) and neo-Hookean ground matrix combined with collagen Delaunay networks (b).

In Fig. 2a, we show a cylinder inflation and highlight the heterogeneity present in the NaNS material model. In Fig. 2b, we show the model constituent stresses both within the neo-Hookean ground matrix and the individual fiber constituents of the model. In Fig. 2c, we show histograms of individual fiber stretches for each constituent at varying locations throughout the cylinder thickness.

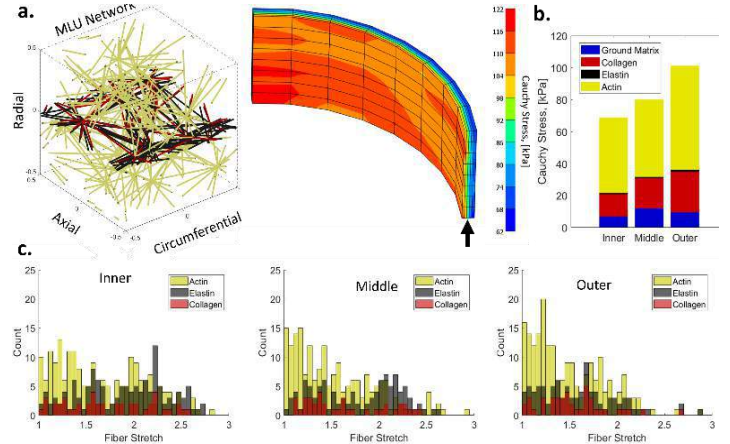

Figure 2. (a). A pressurized cylinder with composite Delaunay medial lamellar unit (MLU) networks. (b). The constituent stresses for each constituent of the MLU model at the arrow. (c). The fiber stretch histograms for each fiber constituent shown in the inner, middle, and outer element of the cylinder at the arrow.

DISCUSSION

This plugin framework is a new implementation of volume averaging theory for multiscale fiber network modeling in FEBio based on [4,5]. The mathematic description of the network elasticity and the novel method for dealing with non-affine deformations within the network are critical features that give us the ability to simulate micro-networks within our FE simulations. Further, the use of a linearized approximation allows us to use a wide variety of fiber constitutive models including structural fiber models and actively contracting fibers. This work is also a first step towards including individual fiber elements in a failure model or in an evolving growth and remodeling model.

Our simulations show heterogeneous stress fields due to the network alignments. In Fig. 1 we use a single network for all elements which has slight alignment preference in the x-direction, which is evidenced by the resulting stress field. In Fig. 2a, we use separately generated MLU networks, which on average have the same properties, but locally have small variations in stiffness and alignment as evidenced by the stress field. Our NaNS plugin not only allows us to break down stresses by constituent (Fig. 2b), but also look directly at individual fiber behaviors (Fig. 2c), which is not possible in other frameworks [1-3].

In terms of the computational resources necessary for this plugin, we examined both computational time and peak memory usage. We saw little change in memory usage, but significant increases in computational time, which is expected given the nature of the plugin. The plugin adds another force balance calculation to each element stress calculation which means it increases the computation time proportional to the number of iterations the micro network requires to converge. In the case of the cruciform, the network is close to affine and requires few iterations to converge, whereas the MLU network is heterogeneous including the structure and fiber types (including active fibers).

INTRODUCTION

Platelet adhesion to blood vessel walls and platelet-platelet aggregation in shear flow is essential in initiating the blood coagulation cascade and clot formation in vascular disease processes and prosthetic cardiovascular devices. In adhesion and aggregation, which lead to thrombus formation, platelets undergo complex and rapid receptor-ligand binding such as GPIIb α -von Willebrand factor (vWF) and α IIB β 3-fibrinogen (Fg)- α IIB β 3 bond association and breakage.

We developed a combined Dissipative Particle Dynamics (DPD) - Coarse Grained Molecular Dynamics (CGMD) multiscale model (MSM) to continuously evolve platelet structures, to describe platelet mechanotransduction processes induced by blood flow and synergistically activate platelets, aggregate, and adhere to the blood vessel wall [1]. Our multiscale adhesion model, based on in vitro platelet adhesion kinematics [2], can provide quantified flipping dynamics and comprehensive information on the GPIIb α -vWF bonds acting on the platelets. We expanded our multi-platelet model to a more realistic representation of blood clotting in blood vessel with 250 platelets (124M particles), the first of such effort to integrate multi-physics of thrombus formation at multi-scales [3].

We applied a semi-supervised learning system (SULS) [4], trained with in vitro platelet morphological changes, to overcome a major challenge of analyzing flowing in vitro platelet images and generate accurate inputs for the MSM simulations. We also developed a novel artificial intelligence (AI) inference algorithm that adaptively adjusts multiple timestep (MTS) sizes to underlying biophysical dynamics, achieving 500 \times speedup over fixed timesteps while accurately preserving diverse spatial and temporal occurrences [5].

METHODS

For platelet adhesion, we adapted our deformable CGMD multiscale platelet model to describe flipping over vWF in a channel

with DPD particles at 15-45 dyne/cm² (Fig. 1a). The platelet's bilayer membrane has a total of 67,004 particles, with 16,751 particles designated as GPIIb α receptors, which were redistributed on the membrane according to local membrane curvature (Fig. 1e). The vWF, seeded on a square-lattice 3-dimensional deformable plane with 506/ μ m² density, binds to a GPIIb α receptor and initiates adhesion. The force field between the GPIIb α and the vWF ligand is described by a parameterized hybrid force field combining Morse and Hooke potentials:

$$E_{Adhesion} = E_{Morse} + E_{Hooke} \quad (1)$$

$$E_{Morse} = D_0 \left(e^{-2\alpha(r_{ij}-r_0)} - 2e^{-\alpha(r_{ij}-r_0)} \right) \quad (2)$$

$$E_{Hooke} = k_1(r - r_b)^2 + k_2(r - r_b)^4 \quad (3)$$

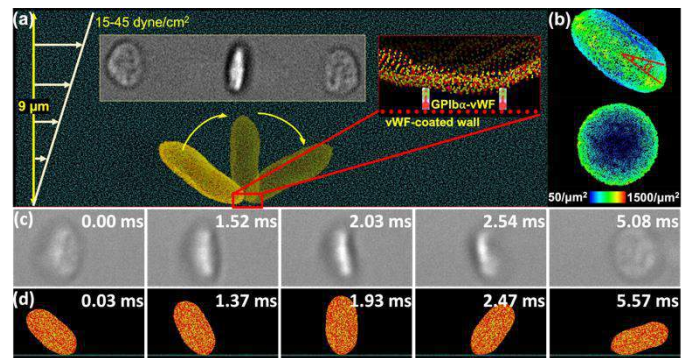

Figure 1. (a) MSM platelet adhesion model. (b) Surface GPIIb α density. (c) In vitro and (d) simulated platelet flipping at 30 dyne/cm².

We reproduced the flipping kinematics as the rotation angle θ during adhesion and validated this model by correlating with microchannel experiments [2], further expanded to 15 and 45 dyne/cm².

We also simulated a large-scale multiscale system of a shear flow-mediated forming thrombus with 250 platelets (124M particles), consisting of 70 flowing and 180 aggregating platelets, and integrated it with our AI-MSM framework (Fig. 2). A microchannel was simulated by a rectangular channel ($391.2 \times 21.3 \times 19.9 \mu\text{m}$) with periodic boundary conditions. The blood vessel walls are modeled with a no-slip boundary conditions with a pressure-driven Poiseuille blood flow between the top and bottom plates. Two blood adhered clots, each with 90 aggregated platelets, formed a $14.6 \mu\text{m}$ stenosis, with aggregation between receptors of the platelets is mediated by the membrane $\alpha\text{IIb}\beta 3$ receptors and Fg, governed by a force field [1].

Figure 2. Simulated thrombosis with 124,171,840 particles, involving 70 flowing platelets and 2 thrombi, each with 90 aggregated platelets.

Our AI-MTS algorithm splits the system into two subsystems based on the spatial scales of the underlying components [5]: the macroscopic fluid and the microscopic platelet. By collecting multiple time series properties describing platelet dynamics, we predicted the adaptive timestep sizes and number of jumps via a deep learning framework consisting of (a) 2-stage denoising by moving average and wavelet transform filters to cleanse high-frequency noise in raw data and (b) two RNN-based autoencoders to extract latent features.

RESULTS

Our multiscale model successfully described the biophysical properties for platelet adhesion and thrombus down to nm -length and ps -time scales. Angular velocity $\dot{\theta}$ during platelet flipping was quantified in vitro and in silico under at shear stresses of 15, 30, and 45 dyne/cm^2 (Fig. 3a-d). In vitro, peak $\dot{\theta}$ increases with shear stress, with $\dot{\theta}$ at 30 dyne/cm^2 ($1.618 \pm 0.206 \text{ rad/ms}$, $n=9$) and 45 dyne/cm^2 ($2.086 \pm 0.346 \text{ rad/ms}$, $n=9$) significantly higher than at 15 dyne/cm^2 ($0.688 \pm 0.102 \text{ rad/ms}$, $n=8$, $p<0.05$). The asymmetry in duration between platelet liftoff and reattachment to the vWF layer diminishes with increasing shear stress. For each shear stress level, the simulated θ curve tracks closely to in vitro data when the platelet rotational angle is $\pi/2$.

Our multiscale adhesion model can provide comprehensive information on the GPIIb α -vWF bonds acting on the platelet. At dimensionless time 0, the platelet approaches $\pi/2$ and the total bond force is 800 pN, corresponding to 200 GPIIb α -vWF bonds (Fig. 3e-f). Prior to dimensionless time 0, bond force and numbers decrease proportionally with a decrease in shear stress. Fluctuations observed in the 45 dyne/cm^2 case subsequent to dimensionless time 0 indicate that higher shear stress may be accompanied with wobbling, where bond numbers decrease in a short period, then increase again.

In the thrombus formation system, the position of individual platelets impacts the accumulation of flow-induced stresses: the closer to the blood vessels, the larger stress accumulation as expected (Fig. 2). The periphery zone of the platelets (red) experiences larger stresses than its central area (green/blue). Fluid particles approaching the stenotic section strongly accelerated downward, then redirected upwards after passing the first thrombus, slowing down downstream of the stenotic

Figure 3. Flipping angle θ from simulations (curves) and in vitro measurements (black dots) at (a) 15, (b) 30, (c) and (d) 45 dyne/cm^2 . (e) Summary of simulated θ , (f) GPIIb α -vWF bond number and (g) force.

section (Fig. 4a). Shear stresses of blood flowing in this system corresponded to its velocity profile, with the highest stresses generally observed upstream of the thrombi (Fig. 4b). We adapted a biomechanics-informed online learning framework (BIOL) to learn platelet dynamics from the ground truth generated in this platelet system and generalize the Jeffery orbit equation (L-JOE) [6]. Validation of L-JOE with platelet rotation at various shear stresses and platelet deformability is ongoing.

Figure 4. (a) Flow speed and (b) shear stress in the thrombus system

DISCUSSION

We simulated the initial adhesion process of a flowing platelets at several shear stresses, where our results converge towards high-fidelity prediction of flipping dynamics and reveal asymmetry of the adhesion process. We modeled a multi-physics MSM of flow- and platelet-mediated thrombus formation involving 124 million particles and integrated an AI-MTS algorithm for splitting the system and adapting timestep sizes to varying dynamics, with platelet dynamics learned via an online machine learning framework. This MSM approach enables computationally affordable, highly resolved, and validated granular studies of flow dynamics in stenoses, accumulated stress-induced platelet activation, platelet adhesion to vWF-coated vessels, and aggregation of flowing platelets with activated platelets adhered to the vessel walls. This approach will be expanded to simulate thrombosis processes involving several hundred platelets under pathological flow.

INTRODUCTION

Systemic hypertension is a primary risk factor for myriad cardiovascular, reno-vascular, and neuro-vascular diseases. It compromises health in women and men, and increasingly in children. Hypertension differentially affects vessels across scales – from arterioles to the aorta. Due in part to their strong myogenic capacity, elevated blood pressures lead to an inward remodeling and thickening of arterioles, which increases total peripheral resistance and thus contributes further to increasing the mean arterial pressure. Due in part to their high elasticity, elevated pressures lead to a slight dilatation and thickening of the aorta, which increases its structural stiffness and thus central pulse wave velocity, causing proximal pulse pressure augmentation. In both cases, therefore, disease progression tends to be driven by insidious positive feedback loops. There is a pressing need to understand better the vascular processes, including biomechanical, that drive hypertension.

In this work, we examine hypertensive remodeling of the aorta within the context of compromised mechanical homeostasis. The concept of homeostasis was introduced in the 1920s by the American physiologist W. Cannon and it continues to help us to understand complex biological and physiological responses. Toward this end, we sought to interpret novel data from two mouse models of hypertension within the context of mechanical homeostasis and we sought to use these data to inform a computational modeling framework that is inspired by the concept of mechanical homeostasis. In this way, we sought to discover mechanisms by which homeostasis is lost in certain cases of hypertensive remodeling.

Specifically, we contrasted hypertensive aortic remodeling in C57BL/6J and 129SvEvTac mice, both with comparable levels of induced hypertension. Biaxial data were collected after 2 weeks of hypertension and modeled biomechanically using a novel constrained mixture framework that included both mechano- and immuno-biological contributors to the remodeling.

METHODS

Animal Models. All live animal protocols were approved by the Institutional Animal Care and Use Committee of Yale University. Briefly, adult male C57BL/6J and 129SvEvTac mice were anesthetized and a mini-osmotic pump was implanted subcutaneously on the flank. This pump delivered angiotensin II (AngII) at a rate of 1000 ng/kg/min. Blood pressure was measured using a non-invasive tail cuff, without anesthesia, following 2 weeks of AngII infusion. The mice were then euthanized using an intraperitoneal injection of Beuthanasia-D and the descending thoracic aorta was harvested.

Ex vivo Experiments. The proximal thoracic aorta was cleaned of loose perivascular tissue, then secured on custom drawn glass micro-pipets and placed within a custom computer-controlled test system [1]. Following equilibration of the vessel in an oxygenated Krebs solution at body temperature, specimens were first subjected to a series of vaso-constrictors and vasodilators at a constant pressure (90 mmHg) and in vivo value of axial stretch to assess smooth muscle and endothelial function. Following replacement of the solution with a calcium-free Krebs solution, which ensured a passive mechanical response, the specimens were preconditioned via cyclic pressurization at the in vivo value of axial stretch, then subjected to a series of 7 protocols: cyclic pressurization tests at 3 different values of fixed axial stretch and cyclic extension tests at 4 different values of fixed distending pressure. Pressure, outer diameter, axial force, and axial extension were collected on-line.

Data Analysis. These biaxial data were first fit with a four-fiber family constitutive model using the unloading data from the last cycle of each of the 7 protocols. Unloading data provide information on the elastically stored energy that would be available to work on the fluid during unloading. Specifically, the 8 model parameters in this radially homogenized constitutive relation were determined using a Levenberg-Marquardt method to minimize normalized differences between

theoretically computed and experimentally measured pressures and axial loads. This approach has proven robust in describing bulk mechanical properties of the murine aorta from diverse mice [2].

Next, the data were fit using a similar model, but separately for the medial and adventitial layers. Again, this approach has proven to yield robust descriptions of the material behavior, with the added advantage that it allows one to compute values of wall stress, stiffness, and stored energy in the two primary layers of the wall [3].

Histology and Immunohistochemistry. Following mechanical testing, each vessel was fixed, paraffin-embedded, sectioned, and stained using standard methods – Movat pentachrome to identify the elastic lamellae, fibrillar collagen, glycosaminoglycans, cell cytoplasm, and fibrin, if present. Immuno-stains identified CD45+ leukocytes and CD68+ macrophages.

Computational Modeling. Finally, the associated mechanical data [4] were used to parameterize a “constrained mixture model” for aortic growth (changes in mass) and remodeling (changes in microstructure) that allows one to delineate mechano-biological and immuno-biological contributions to the adaptive or maladaptive responses of the aorta to hypertension [5].

RESULTS

Two weeks of AngII-induced hypertension resulted in similar pressure elevation in the two different mouse models and yet very different aortic remodeling. The descending thoracic aorta in the C57BL/6J mice showed excessive thickening of the wall, both medial and especially adventitial. The latter was characterized by a dramatic deposition of fibrillar collagen. By contrast, the aorta in the 129SvEvTac mice showed a nearly adaptive response to the hypertension, meaning thickening proportional to the pressure elevation. Two important observations appeared to delineate these different responses. First, the C57 aortas exhibited significantly less vasoconstrictive capacity *ex vivo* in response to exogenous AngII than did the 129 aortas, both before and after the 2 weeks of hypertension. Second, the C57 aortas had much greater accumulations of inflammatory cells than did the 129 aortas, and this accumulation was greatest in the adventitial layer wherein the collagen deposition was highest in the C57 aorta.

The bilayered model suggested that wall stress would initially increase in both the medial and adventitial layers of the hypertensive aortas under passive conditions, but that these increases could be greater in the adventitia. Noting that wall stress can be reduced at a fixed pressure during a strong vasoconstriction, the model also suggested that the potentially greater increase in wall stress in the adventitia could be attenuated by vasoconstriction. Hence, model findings were consistent with the hypothesis that a strong vasoconstrictive response of the aorta to exogenous AngII in the 129SvEvTac aortas reduced wall stresses in hypertension, especially in the adventitia, and that this lower wall stress was not sufficient to stimulate inflammatory cell infiltration. A corollary to this hypothesis, therefore, is that a weak vasoconstrictive response in the hypertensive C57BL/6J aortas led to higher wall stresses in the adventitia, which stimulated inflammatory cells.

The computational growth and remodeling model was refined to identify a data-based estimate of wall stress below which there was no inflammation but above which there was inflammation consistent with CD45 and CD68 cells. This threshold-based model was able to capture differential time-courses of change in geometric and mechanical metrics in response to hypertension in the two mouse models.

DISCUSSION

The immune system has evolved to protect against diverse threats, including bacterial, fungal, and viral. Given the importance of this

defense system, it is prioritized – that is, it can over-ride other systems, including those that promote mechanical homeostasis.

Our comparison of hypertensive aortic remodeling across two mouse models, C57BL/6J and 129SvEvTac, revealed that immunological factors tended to dominate in the former, which was characterized by maladaptive remodeling, whereas mechanical factors tended to dominate in the latter, which was characterized by near adaptive remodeling. In particular, CD45+ leukocytes and CD68+ macrophages increased significantly in the hypertensive C57BL/6J aortas but not in the 129SvEvTac aortas. The former also exhibited a gross thickening of the wall and associated reduction in wall stress well below normal. Given that wall stress appears to be a key mechano-regulated quantity in the aorta [6], this suggests that excessive inflammation contributed to the loss of mechanical homeostasis. By contrast, the lower immune cell density in the 129SvEvTac aortas associated with less thickening and a near adaptation consistent with mechanical homeostasis. Our computational growth and remodeling model suggested further that there may exist a stress threshold, above which inflammatory cells are recruited to the adventitia. Such a scenario is consistent with highly stressed fibroblasts increasing chemokine production to recruit the inflammatory cells [7]. There is a related literature suggesting that such fibroblast – immune cell communication often exists, including in AngII infusion models in mice [8].

In summary, the present results reveal a need to understand better what we refer to as immuno-mechanics wherein both infiltrating inflammatory cells and host mechano-sensitive cells play independent and interdependent roles. Single cell RNA sequencing and associated bioinformatics modeling promises to contribute further to our understanding, providing a method to test our computational model-based hypothesis on mechanical stress-mediated cell-cell interactions. Genomics information similarly promises to provide insight into possible genetic modifiers that drove the differences seen in the two different inbred strains of mice.

INTRODUCTION

Approximately 2.5 million individuals sustain pressure injuries in acute care facilities per year, resulting in an estimated annual US hospital acquired pressure injury cost exceeding \$26.8 billion [1]. The pediatric population is uniquely vulnerable to pressure injury due to immobility, underdeveloped skin, compromised perfusion, anatomical differences, sensory development status, and medical device intervention [2-4]. Pressure injury prevalence within the pediatric population has been reported as 1-8% overall and as high as 43% in critical care settings [2]. Pressure injuries result in reduced quality of life, morbidity, and increased cost. Goudie et al [5] reported for the pediatric population an average cost of \$20,000 per injury and among ages 1-4 specifically an average cost of \$86,000 per injury for advanced stage pressure injuries.

Medical device related pressure injuries (MDRPIs) are notably more prevalent than those caused by immobility within the pediatric population. Pediatric MDRPI rates range from 40%-80%, with the most common problem areas being external monitoring, oxygen delivery, and airway maintenance devices [6]. Lauderbaugh et al [7] studied the relationship between non-invasive ventilation (NIV) use and pressure injury in hospitalized pediatric patients and found a pressure injury incidence of 7.3% with high mask leak as the only significant contributing factor associated with NIV pressure injury. Masks with a high leak are likely not achieving a proper fit and as such result in a non-uniform pressure distribution over bony prominences. This is especially prevalent in the neonatal intensive care unit where NIV is the preferred intervention over mechanical ventilation.

Several approaches have been taken to evaluate the fit of NIV masks and to determine the effects of custom mask fabrication. Visscher et al [8] evaluated mask fit using 3D surface scans of the face and mask. Duong et al [9] evaluated the feasibility of custom 3D printed CPAP masks and demonstrated improved comfort. Ma et al. [10] developed a system for CPAP interface selection based on a set of anthropomorphic

data points. Most recently, Kamath et al [11] developed a workflow for custom fabrication of neonatal CPAP masks that resulted in lower interface pressures.

These approaches have demonstrated the importance of mask fit through leak and pressure measurement, 3D scanning techniques, and basic pressure distribution analysis, but have yet to incorporate the complex solid mechanics of the skin tissue at the interface. Furthermore, there is no standardization across methods making model validation difficult. The objectives of this research are two-fold: 1.) to calibrate a compressible, neo-hookean, hyperelastic material model of aggregate skin tissue in compression and 2.) to develop a global model of the contact using the resulting material properties. Effectively, a local model of skin tissue mechanics will be coupled with a global model to better elucidate the tissue-mask interaction at NIV interfaces within the neonatal population.

METHODS

Model Calibration

A three-constituent mixture theory model was developed for skin tissue in compression with solid extracellular matrix (*s*), interstitial fluid (*f*), and blood (*b*) constituents. The material properties were calibrated utilizing the *in vivo* plane ended cylindrical indentation tests of the anterior forearm from data obtained by Bader et al [12]. A hyperelastic, compressible, neo-hookean material model with a Hertzian type input was derived resulting in a total Cauchy stress of

$$T_{zz} = -p_0 + \phi^s \kappa J^s (J^s - 1) + \frac{\phi^s \mu}{J^{s/3}} \left\{ (1 + \epsilon_z)^2 - \frac{1}{3} [2(1 - \eta \epsilon_z)^2 + (1 + \epsilon_z)^2] \right\} \quad (1)$$

where κ is the bulk modulus and μ is the shear modulus.

Integration to NIV Mask Finite Element Analysis

An Artec MHT (Artec 3D) scanner was used to capture 3D scans of a Premie HAL S108.100 24-Week Preterm Newborn Skills Trainer

(Gaugard Scientific). Post processing and finite element analysis were completed in COMSOL Multiphysics 6.0 (COMSOL Group). For an initial analysis, a NIV mask was approximated as a hollow cylinder for the purposes of modeling the pressure distribution at the contact interface. The skin was modeled as a single, aggregate layer as the material properties were calibrated in this manner. The mask was modeled as a linear elastic material with a Young's modulus of 2Mpa and a poisson ratio of 0.49 consistent previous analyses of mask fit [10]. The mask approximation was aligned with the nasal bridge via visual inspection. A pressure boundary load applied at the top surface of the mask approximation was varied and von Mises stress, displacement, and contact force were the outputs of interest.

RESULTS

Model Calibration

The compressible, neo-hookean constitutive law with a Hertzian type input resulted in calibrated material properties of 227.7 kPa and 1.04 kPa for bulk modulus and shear modulus, respectively, with a root mean squared error of 0.209 (Figure 1A). The calibrated model was used to investigate capillary occlusion by tracking the volume fraction of blood during quasi-static compression. Assuming that complete capillary occlusion occurs at a blood volume fraction of zero, the corresponding interface pressure can be determined and compared to clinically relevant interface pressures (Figure 1B).

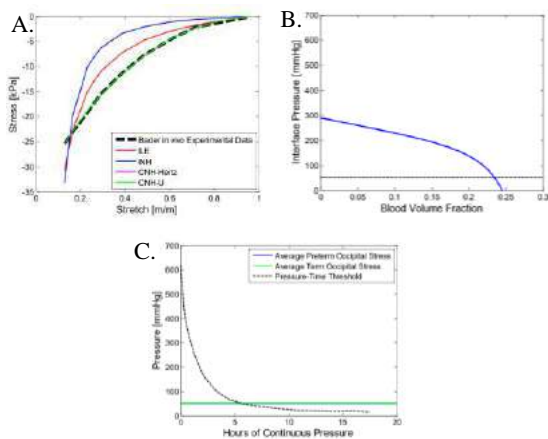

Figure 1. A) Predictive capabilities various material models of *in vivo* skin tissue compression, including compressible, neo-hookean with a Hertzian type input (CNH-Hertz). B) Tracking the volume fraction of blood across a large interface pressure range to elucidate capillary occlusion thresholds. The dashed line represents typical pressures measured at the occiput of a neonate in supine position. C) Comparison of predicted interface pressure to the classic Reswick and Rogers [13] pressure time threshold curve.

Global Model

Consistent with what is observed both clinically in existing models, the finite element analysis results show peak pressure at the nasal bridge as well as elevated pressure near the nasal septum (Figure 2). Peak values are highly dependent on the parameters of the pressure boundary condition, as well as the material model of the skin and mask; however, the results are consistent with those of previous studies [10-11].

Figure 2. The imported, repaired, and solid geometry conversion (A) of the 3D scan, the mesh (B), and a representative loading case (C) of a 6kPa boundary load resulting in a peak von Mises stress of 9.3kPa at the nasal bridge.

DISCUSSION

The ability to accurately predict the pressure distributions throughout skin tissue at both the micro- and macro-level is critical for both understanding the complex etiology of pressure injury and designing medical devices that prevent iatrogenic injury. Our results show that a triphasic mixture theory derived hyperelastic material model can be used to describe aggregate skin tissue in compression. The use of triphasic mixture theory shows promising results for the ability to track blood flow throughout the deformation of skin tissue to better elucidate capillary occlusion and tissue demise thresholds or even to revisit and refine the classic Reswick and Rogers pressure-time threshold curve [13]. However, the material model was significantly limited by lack of *in vivo* or *ex vivo* compression data, and even further limited when considering the neonatal population. This limitation is especially notable since skin tissue properties are highly dependent on age and site.

The integration of the material model into a global model of a NIV mask interface demonstrated the ability to include skin tissue mechanics at the contact boundary while applying a clinically relevant boundary load condition to the NIV mask. Previous studies have modeled the mask contact with an arbitrary prescribed displacement. This method can be used to better inform commercial and custom mask design. Limitations of this FEA effort include registering the mask placement via visual inspection, an approximation of mask geometry, and limited data on applied mask pressure (strap tension). Future work should consider developing a standardized procedure for capturing interface pressure and applied strap tension such that model validation across studies is feasible.

INTRODUCTION

Brachial artery flow mediated dilation (FMD) is a widely reported phenomenon, based on which the integrity of arterial walls, the ballast of cardiovascular health, is assessed. The appealing aspects about the FMD test are its inexpensiveness and noninvasiveness. After having a pressure cuff wrapped around a subject's upper arm while lying supine, the cuff is inflated to a certain pressure, long enough to cut off the blood flow to the lower arm, thereby collapsing the brachial artery. The cuff is then abruptly deflated, and the arterial diameter response is monitored via ultrasound imaging, until full recovery. Comparing the peak diameter throughout the response, to its baseline value, provides a dilation metric that can serve as a quantitative description for the physical state of the arterial wall. Abnormal FMD levels have been linked to smoking, renal dysfunction, and visceral obesity¹⁻⁴. BAFMD's utility for assessing cardiovascular health and diagnosing cardiovascular diseases has been further established by other studies⁵⁻⁸. Moreover, according to a recent comprehensive review⁹ dedicated to how the virus affects the heart and blood vessels, SARS-CoV-2 has been associated with leaky vessels, pointing to a compromised glycocalyx layer and endothelial function, which therefore suggests that such changes could be picked up by this test.

Based on prior experimental studies on the mechanisms tying vasodilation stimulation to Wall Shear Stress (WSS), our group hypothesized a mechanism by which mechanotransduction is manifested in the FMD response and formulated a mathematical model that successfully reproduced its rising-and-dwelling part^{10,11}. In the current study, and for the first time, a model rooted in first principles is developed to describe the entire FMD response. The parameters arising from the model, and which collectively serve as a quantitative description of the arterial state, were adjusted to produce a response that matched its experimental counterpart extracted from healthy volunteers. The new parameter among those is one that characterizes the arterial

wall's drive for recovery, thereby providing a more encompassing description of the artery's physical state.

METHODS

This paper is based on the same brachial artery FMD tests performed in the Department of Radiology at the University of Pennsylvania for our prior studies¹⁰⁻¹², where 19 data sets were obtained from the FMD response of 12 healthy volunteers aged 23-66. After 5 minutes of blood flow obstruction by means of an inflated pressure cuff wrapped around the subject's upper arm, the cuff is deflated, and the artery is monitored with an ultrasound scanner for the next 5 minutes (Fig. 1). diameter-vs-time data sets were extracted by processing the obtained ultrasound images in MATLAB.

Figure 1: BAFMD test. (a): Ischemic cuff wrapped around the arm for 5 minutes while monitoring the artery. (b) A snapshot of the monitored artery. (c) Monitoring the arterial diameter response after deflating the cuff

The system of equations governing the arterial response is:

$$\frac{\partial^2 u^*}{\partial r^{*2}} + \left(\frac{1}{E^*} \frac{\partial E^*}{\partial r^*} + \frac{1}{r^*} \right) \frac{\partial u^*}{\partial r^*} + \left(\frac{\nu}{E^* r^*} \frac{\partial E^*}{\partial r^*} - \frac{1}{r^{*2}} \right) u^* = 0 \quad (1a)$$

$$\frac{\partial E^*}{\partial t^*} + 2 \ln(10) E^* = 2 \ln(10) [(1 - E_{min}^*) e^{-Bs^*} + E_{min}^*] \quad (1b)$$

$$\frac{\partial s^*}{\partial t^*} = 2 \ln(10) \gamma \left(\frac{\partial^2 s^*}{\partial r^{*2}} + \frac{1}{r^*} \frac{\partial s^*}{\partial r^*} \right) \quad (1c)$$

$$s^*(1, t^*) = \frac{1}{(1 + \delta(t))^3} - 2 \ln(10) \zeta^* \int_0^{t^*} H(\delta(z^*) - \delta_b) \left(\frac{1}{(1 + \delta_b)^3} - \frac{1}{(1 + \delta(z^*))^3} \right) dz^* \quad (1d)$$

Eq. 1a describes the radial displacement field (u^*). Eq. 1b governs the arterial stiffness distribution (E^*) throughout the arterial wall. Eq. 1c describes the diffusion of vasodilation stimulation signal (s^*), elicited by WSS. Eq. 1d is about the modulation of the vasodilation stimulation due to the artery's expansion. E_{min}^* is a measure of the wall's sensitivity to WSS. The maximum value of 1 points to an artery that is indifferent to any sensed level of WSS. B describes the artery's resistance to softening due to an increasing WSS. A higher value signifies a lower resistance. The parameter quantifying the mechanotransduction integrity, γ , indicates how fast the dilation stimulation signal, s , diffuses throughout the arterial wall. ζ^* is the parameter characterizing the arterial propensity for recovery. A higher value results in an earlier and faster recovery.

RESULTS

The values of the parameters E_{min}^* , B , γ , p^* , and ζ^* were optimized to obtain a theoretical response $\delta(t)$ that most closely matched the complete experimental FMD response. A representative comparison is shown in Fig. 2.

Figure 2: A representative result of matching an experimental FMD response with its theoretical counterpart (solid line)

DISCUSSION

In addition to the initial curvature shift that is a hallmark of mechanotransduction, the recovery phase is also generally well captured, thereby showcasing the first complete physics-based model that can reproduce an entire typical FMD response. While the previous studies focused on the rising-and-dwelling part of the response and managed to reproduce it from more simplified models that were rooted in first principles, this one is extended to include the recovery phase. The result is a unified model that successfully reproduced an entire typical FMD response for the first time. In addition to the parameters previously introduced¹¹, a new one quantifying the artery's ability to recover, arose from the model, hence offering a more detailed description of the arterial physical state. A minimally noisy set of data (Fig. 2) highlighted the model's ability to reproduce a real FMD

response. It is anticipated that the series of studies^{10–12} concluded by the current one, will be foundational for the potential emergence of future clinical noninvasive tools that can provide a comprehensive picture describing an individual's arterial health from a simple ultrasound test.

INTRODUCTION

Current heart valve replacements are inadequate for young and active patients: mechanical prostheses require lifelong anticoagulant therapy and bioprosthetic valves are prone to structural degeneration. To overcome these limitations, in situ cardiovascular tissue engineering is a promising strategy to create living neo-valves, directly at the functional site by using the regenerative capacities of the host. Currently, inter- and intra-valve variation in tissue formation and scaffold resorption have often been reported during in situ tissue engineering [1], limiting the translation of this technique to the clinic. To overcome these challenges, a deeper understanding of growth and remodeling in (tissue-engineered) heart valves is essential [2].

So far, no studies have reported the establishment of homeostasis in in situ tissue engineered heart valves. However, it is hypothesized that mechanically regulated growth and remodeling (G&R) mechanisms are key players in this process, and similar to mechano-regulated G&R in native cardiovascular tissues to changes in hemodynamic loads [3]. In this study, we therefore developed a computational model to investigate native valvular G&R mechanisms, since more long-term experimental results are available for comparison. We specifically simulated the Ross-procedure (replacing a defective aortic valve with the autogenous pulmonary valve) to investigate if homeostasis can be re-established in these valves through mechanoregulated G&R. Since the specific mechanical homeostatic targets in valves are still unclear, we investigated both stress- and stretch-based homeostasis to determine which of these hypotheses is most likely.

METHODS

Homogenized constrained mixture models can provide valuable insights into growth and remodeling as they can efficiently predict changes in tissue composition and geometry [4]. These models utilize a constituent-specific kinematic split of the deformation gradient tensor (Fig. 1). This split ensures that each different constituent has its own

stress-free configuration and corresponding elastic deformation. Our heart valves were modeled as a mixture of collagen, glycosaminoglycans (GAGs) and elastin.

Figure 1: The deformation gradient tensor (F) is split into a inelastic deformation (F_r^i) and an elastic deformation (F_e^i) for collagen ($i=c$), glycosaminoglycans ($i=g$) and elastin ($i=e$).

The stress-free states of collagen and GAGs evolved due to their continuous turnover while elastin degradation and production were assumed to be negligible. The turnover of collagen and GAGs was assumed to be regulated by mechanical cues. When these cues were at their homeostatic level, production and breakdown were balanced. When homeostasis was disturbed, collagen and GAG production changed, which translated into in- or decreases of the constituent mass, and consequently changes in the tissue composition, stiffness and/or volume.

In this work, two different hypotheses were adopted to define this homeostasis: either stress- or stretch-based homeostasis. For stress homeostasis, the production of a constituent was modulated by the normalized differences between the current and the homeostatic stress

levels in that constituent, while for stretch homeostasis, the normalized differences in constituent stretches were used.

To describe the geometry of the leaflet a Gulbulak valve geometry [5] was adopted. First, the diastolic pulmonary pressure was applied to the outflow surface of the leaflet to determine the homeostatic stresses or stretches of the individual constituents. Subsequently, the Ross procedure was simulated by increasing the pressure to systemic diastolic values - either instantaneously or gradually over 1000 days - while the tissue was able to grow and remodel until homeostasis was re-established.

RESULTS

After an instantaneous increase in pressure, assuming stretch homeostasis (Fig. 2b) resulted in more growth in the belly region of the valve and the belly region dilating further compared to assuming stress homeostasis (Fig 2a) resulting in an average increase in thickness of 27% and 43% respectively. This difference in valve morphology can also be appreciated at the tip of the leaflets, which decreased in height more under the assumption of stretch homeostasis. This dilation was initially similar for both types of homeostasis, but valve geometry stabilized earlier in the case of stress homeostasis (Fig 2c) compared to stretch homeostasis (Fig 2e). Finally, the different homeostatic target variables resulted in different tissue compositions in the new mechanical equilibrium (Fig 2d); stress homeostasis resulted in a more collagen-dominated composition while the valve under strain-homeostasis contained more GAGs. Elastin volume fractions were greatly reduced in both valves, due to the lack of turnover and synthesis.

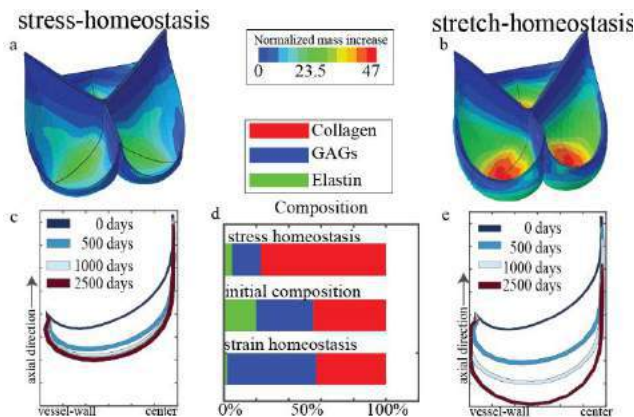

Figure 2: Homeostatic heart valves after growth and remodeling following stress (a) or stretch (b) homeostasis. Time evolution of the mid-section profile of the leaflet for stress (c) and stretch (e) homeostasis, and tissue compositions (d).

Interestingly, under the assumption of stress-homeostasis, a gradual increase in pressure (Fig. 3b) was predicted to induce a more dilated valve geometry with a smaller increase in thickness (38% vs. 43%) compared to valves subjected to instantaneous loading (Fig. 3a). Specifically, the valve dilation almost stabilized within 500 days when an immediate increase in hemodynamic load was imposed (Fig 3c). On the other hand, in the case of gradual increase in blood pressure, this dilation only stabilized after the increase in loading was complete (Fig 3e). Despite these geometrical differences caused by different rates of the blood pressure increase, the composition of the valves was predicted to be nearly identical (Fig 3d).

DISCUSSION

To better understand G&R of native and ultimately also tissue-engineered heart valves, the compositional and geometric changes of

pulmonary autografts after the Ross procedure were analyzed for either stress- or stretch-regulated G&R. An increased hemodynamic load from pulmonary to aortic diastolic blood pressure generally resulted in thickened valves with altered morphologies. The predicted increases in thickness for both stress- and stretch-based homeostasis agreed well with reported data [6,7,8]. In addition, the simulated changes in collagen content under stress-mediated growth and remodeling were more in line with findings from the literature than those under stretch homeostasis [6,7,8], suggesting that stress homeostasis might better describe heart valve growth and remodeling than stretch homeostasis.

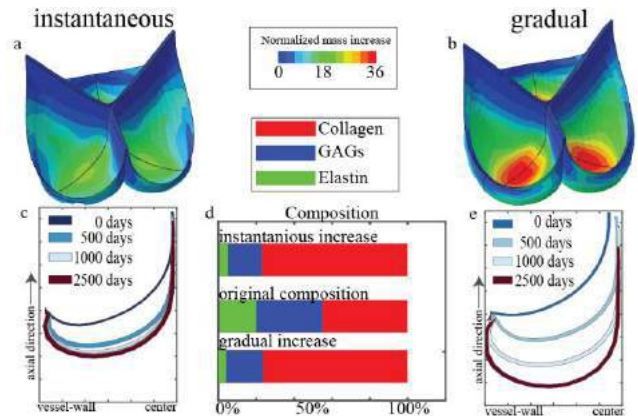

Figure 3: Homeostatic heart valves after growth and remodeling following an instantaneous (a) or gradual (b) increase in pressure. Time evolution of the mid-section profiles of the leaflet for an instantaneous (c) and gradual (e) increase in pressure, and tissue compositions (d).

A gradual increase in pressure resulted in more dilated valves compared to an instantaneous increase in pressure. This was caused by lower tissue stresses throughout the course of G&R under a gradual increase in pressure versus an instantaneous increase, due to the ongoing remodeling response. Consequently, less thickening occurred which, in turn, allowed for more elastic deformation, eventually leading to a more dilated valve morphology.

Altogether, we demonstrated that a G&R response regulated purely by mechanical cues is able to re-establish homeostasis in heart valves after an increase in hemodynamic loads. Furthermore, the predicted changes in composition suggest that stress-based homeostasis is more suitable to describe heart valve G&R in response to changes in diastolic loading. In the future, this model can be extended to understand, predict and ultimately even optimize the development and adaptation of in situ tissue engineered heart valves.

INFLUENCE OF WALL SHEAR AND MECHANICAL STRESS ON ATHEROSCLEROTIC ARTERY DISEASE IN HUMAN CORONARIES

INTRODUCTION

Atherosclerosis in coronary arteries is the main cause of coronary artery disease, also known as ischemic heart disease or myocardial ischemia [1]. The non-homogeneous distribution of atherosclerotic plaques along the coronary tree with varying components hints towards the effect of local risk factors on atherosclerosis [2]. Among such local factors, the biomechanical ones are hypothesized to influence the dynamic progression of plaques over time [3]. The two important biomechanical factors effective in arterial circulation are the wall shear stress (WSS) and the wall mechanical stress (WMS) [4]. WSS is the stress that the frictional force of the blood flow exerts on the endothelial cells on the arterial lumen surface and low WSS is known to be associated with plaque progression [5]. WMS is the structural stress caused by the blood pressure-induced arterial wall stretch and is mainly studied for plaque rupture [6], but not for plaque progression yet. In order to have a comprehensive understanding of the involvement of the biomechanical factors in atherosclerosis, we studied the individual and combined effects of WMS and WSS in healthy and atherosclerotic coronary segments.

METHODS

Study Design

The prospective patient study (IMPACT) was designed at Erasmus Medical Center to investigate the influence of biomechanical factors towards healthy and atherosclerotic plaque tissue progression in coronary arteries [7]. For the study, 40 patients with acute coronary syndrome and at least one non-stented, non-culprit atherosclerotic coronary artery were recruited. The arteries were imaged with near-infrared spectroscopy intravascular ultrasound NIRS-IVUS and optical coherence tomography (OCT) at two time points (baseline and after ~12 months (follow-up time point)) and with CT one month after the baseline imaging [7].

Wall Shear Stress and Wall Mechanical Stress

The 3D coronary lumen geometries necessary for the WSS assessment were constructed from the IVUS data. WSS was computed with Computational Fluid Dynamics (CFD) models and reported previously [7]. Briefly, blood flow was implemented as an incompressible, homogeneous, Carreau fluid. The inlet and outlet flow boundary conditions were prescribed based on the local Doppler flow measurements and the final computed WSS were averaged over a cardiac cycle to obtain the time-average-wall shear stress [7].

For the wall mechanical stress, 2D coronary cross-sectional geometries were obtained from the combined and co-registered IVUS and OCT frames every 0.5mm. IVUS data was used to delineate the lumen and the external elastic lamina (EEL) contours, and OCT data for the lipid-rich necrotic core (LRNC) [8]. A layer of a uniform thickness of 0.15 mm was added around the EEL to account for the adventitia layer [6]. Finite Element Modeling (FEM) was used to compute WMS on the arterial cross-sections due to the intraluminal blood pressure, via ABAQUS software under plane strain assumption. Isotropic, nonlinear, hyperelastic and incompressible material models were used for intima/media, adventitia and LRNC components as reported previously [3,9]. Since the imaged arteries were under blood pressure and not at zero mechanical loading, the backward incremental method [9] was applied to compute the initial stresses, already present in the arteries. Standard intraluminal pressure of 120mmHg was applied and the maximum Max Principal stress was calculated on the peri-luminal region in all forty arteries. Highly calcified regions ($> 90^\circ$) were excluded from the study as they impeded the segmentation of the EEL layer [7].

Sector Categorization and Statistical Analysis

For a local analysis of the data, the coronaries were divided into sectors, where a sector comprised an angle of 45° in the circumferential

directions and a thickness of 1.5mm in the longitudinal direction (Fig.1A). WSS and WMS results were averaged per sector. Vessel wall progression or regression was quantified as the wall thickness and plaque burden (plaque area/ total vessel area * 100%) change between baseline and follow up measurements. The sectors were also categorized as either “diseased with LRNC” (mean wall thickness >0.5mm & NIRS positive), or “diseased w/o LRNC” (mean wall thickness >0.5mm & NIRS negative), or “healthy” (mean wall thickness <0.5mm) (Fig.1B). The association of WSS and WMS on plaque progression was evaluated using Linear Mixed Model analysis in SPSS. WSS and WMS values per sector were divided into tertiles (low, mid and high) per artery for the statistical analyses [7]. A p-value < 0.05 was considered significant.

Figure 1: (A) Coronal geometries were split into sectors of 1.5mm thickness, by dividing the cross-sections into 8 sectors in the circumferential direction. (B) Sectors are categorized as healthy or diseased (with or without LRNC) based on 0.5mm thickness threshold.

RESULTS

In total, ~8k sectors were obtained and analyzed from 40 coronary arteries. At the baseline, 65% of the sectors were identified as healthy and 35% as diseased. Of the diseased sectors, 24% contained a LRNC and 76% did not. Over the ~12-month follow-up time period, 52% of the sectors demonstrated atherosclerotic disease progression while 48% showed regression. OCT measurements of the diseased sectors with LRNC revealed thinner fibrous caps in 71% of the cases resulting in supposedly more vulnerable plaque tissue.

According to the statistical analysis, low WSS was statistically significantly associated with increased plaque burden (Δ BP) (Fig.2) and wall thickness change (Δ WT) (data not shown) for all sector types (healthy, diseased w/o and with LRNC), as well as when all sectors combined. This trend was most pronounced for the diseased sectors with LRNC, where low WSS category sectors resulted in almost two-times higher disease progression than the high WSS category sectors.

Figure 2: Plaque burden change distribution based on WSS in overall, healthy, diseased with and w/o LRNC sector categories.

The association between WMS and Δ BP (Fig.3), and WMS and Δ WT (data not shown) was similar: healthy sectors with higher WMS demonstrated higher disease progression whereas the opposite was observed for diseased sectors with LRNC.

Figure 3: Plaque burden change distribution based on WMS in overall, healthy, diseased with and w/o LRNC sector categories.

The analysis of the combined effect of WSS and WMS on Δ BP and Δ WT revealed that in healthy sectors, the combination of low WSS and high WMS was associated with the highest Δ BP and Δ WT. In the diseased sectors w/o LRNC, the highest plaque progression (Δ BP and Δ WT) was observed in the category of mid WSS and high WMS and in the diseased sectors with LRNC, high and low WMS combined with low WSS were associated with plaque progression.

DISCUSSION

Our findings suggest that the local atherosclerotic disease progression in coronary arteries is not only associated with the well-known WSS, but also with WMS, which has not received enough attention yet. Moreover, our results show that the association of the disease progression with WMS depends on the existing local structural composition. Our findings indicate the importance of biomechanical analysis and local plaque composition assessment for local atherosclerotic disease progression prediction. In the future, studies with larger cohort and multiple follow-up time points are warranted in order to fully understand the association between shear and structural stress with atherosclerosis development over time.

INTRODUCTION

While myocardial motion plays an important role in driving mitral valve physiology and pathophysiology, the biomechanical interplay between them is not well understood. Hence, the goal of this work was to study how abnormal myocardial deformation induces mitral regurgitation (MR) via quantifying changes in the anterior annular perimeter (AAP), posterior annular perimeter (PAP), and myocardial circumferential strain (Ecc) in MR secondary to an inferior wall myocardial infarction (IWMI), using displacement encoding with simulated echoes (DENSE) [1]. The hypothesis is that an inferior wall MI will cause an increase in Ecc in the regions remote to the myocardial infarct, which will prevent the steep increase in the AAP that is otherwise typically seen in the PAP.

METHODS

A postero-lateral MI was induced in 4 healthy Yorkshire pigs by injecting ethanol into the left circumflex artery (LCX). ECG-gated MRI was acquired in the mid short axis (SA) to measure Ecc at baseline (pre-MI) and 3 months post-MI. The SA images were divided into 3 zones (i.e., infarcted, border, and remote), based on late Gadolinium enhancement images and the AHA 17-segment model (Figure 1). Measured strains were averaged for each zone, and their respective mean and standard deviation were calculated. Finally, the AAP and PAP were calculated at both timepoints from echocardiography, and a correlation coefficient was calculated to assess if the correlation between AAP and peak systolic Ecc in the remote zone was significant.

RESULTS

At 3 months post-MI, PAP significantly increased compared to baseline ($p = 0.037$) whereas the change in AAP was not significant. Additionally, Ecc changed over both timepoints across all three zones, where remote peak systolic Ecc increased by 0.03 ± 0.01 ($p = 0.007$).

Interestingly, AAP was found to correlate with the remote Ecc ($r = 0.91$) but less so with the infarct Ecc ($r = 0.57$).

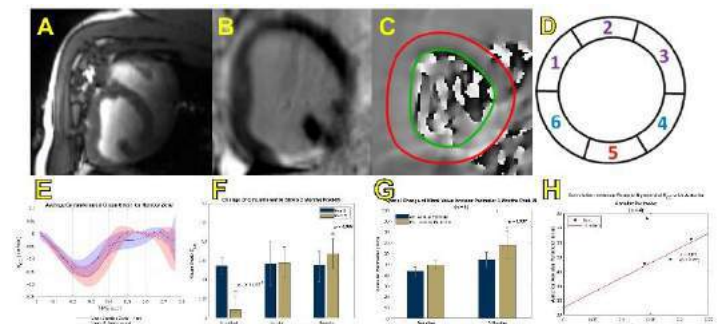

Figure 1: (A) Cine image for orientational reference. (B) Late Gadolinium enhancement image to locate the infarct. (C) Phase SA image of DENSE. (D) AHA 17-segment model for the mid SA image where 1: mid anterior; 2: mid anteroseptal; 3: mid inferoseptal; 4: Mid inferior; 5: Mid inferolateral; and 6: Mid anterolateral. Red denotes infarct zone, blue denotes border zone, and purple denotes remote zone. (E) The mean Ecc and standard deviation ($n = 4$) for the remote zone of the mid SA view; baseline strains are shown in blue whereas MI strains are shown in red. (F) The mean value of peak systolic Ecc and standard deviation for all 3 zones post-MI (left); baseline data shown in navy blue whereas MI data is shown in gold. (G) Change of mitral valve systolic anterior and posterior annular perimeters 3 months post-MI. (H) Correlation between the remote myocardial Ecc with systolic annular perimeter.

DISCUSSION

This work signifies a novel investigation for the impact of myocardial deformation on mitral valve mechanics. The results suggest that increases in remote myocardial strain prevents the increase in the AAP that is otherwise seen in the PAP of an MR. Additionally, while the severity of MR is determined by valvular dynamics, it seems to well-correlate with myocardial deformation. This provides further insights into MR heterogeneity, and thus careful consideration should be taken with respect to animal modeling as well as patient therapy as the location of the infarct will potentially dictate both myocardial and valvular mechanics.

INTRODUCTION

Marfan syndrome (MFS), affecting roughly 1 in 5000 births, is caused by mutations to the *FBN1* gene coding the glycoprotein fibrillin-1 [1]. Fibrillin-1 is primarily responsible for the long-term stability of elastic fibers in the aorta, as well as promoting mechanosensing and mechanoregulation of extracellular matrix by mural cells. A major cause of premature death in Marfan individuals is aortic dissection and rupture following the development of thoracic aortic aneurysm, resulting from progressive loss of structural integrity and function in the aorta. It is thus critical to understand the underlying mechanisms in the Marfan aorta for improved diagnosis and patient outcomes.

Experimental studies on animal models of MFS, namely *Fbn1*^{mgR/mgR} and *Fbn1*^{C1041G/+} mice, have allowed for significant advancements in our understanding of MFS. Quantifying changes in histology and biomechanics of thoracic aortas in these mice has revealed marked three-dimensional (3D) damage to elastic fibers along with strong correlations between elastin porosity and elastic energy storage, circumferential stiffness, and luminal diameter [2]. In this study, we focused on modeling aneurysm development the Marfan ascending thoracic aorta (ATA) using a constrained mixture framework [3] to capture recently published experimental data.

METHODS

Experimental characterization

Three stages of MFS disease severity were bracketed using wild-type, *Fbn1*^{C1041G/+}, and *Fbn1*^{mgR/mgR} mice at 60 days of age. Ascending thoracic aortas underwent (1) biaxial testing to compute specimen-specific material properties with a four-fiber family hyperelastic model and (2) two-photon microscopy to quantify microstructural metrics including elastin porosity and engagement of collagen fibers and cells [2]. Standard histology with Movat's pentachrome was then performed to assess fractions of elastin, collagen, and cells in each group.

Mechanobiologically equilibrated constrained mixture model

We aimed to capture experimentally observed changes in a model by investigating the individual roles of compromised elastic fiber integrity as well as lost mechanosensing and mechanoregulation of matrix. The arterial wall was modeled as a mixture of three primary load-bearing constituents that undergo changes in mass and microstructure in response to biomechanical stimuli: elastin-dominated ($\alpha = e$) and collagen-dominated ($\alpha = c$) matrix along with smooth muscle ($\alpha = m$). Each constituent α was governed by a mass density production rate $m^\alpha(\tau)$, removal function $q^\alpha(s, \tau)$, and stored energy density function $\hat{W}^\alpha(s, \tau)$, where s is the current G&R time and $\tau \leq s$ is the time of deposition. We adopted stress-mediated descriptions for production and removal given by

$$\begin{aligned} m^\alpha(\tau) &= m_o^\alpha \left(1 + K_\sigma^\alpha \Delta\sigma(\tau) - K_{\tau_w}^\alpha \Delta\tau_w(\tau) \right) \\ q^\alpha(s, \tau) &= \exp\left(-\int_\tau^s k_o^\alpha \left(1 + \omega \Delta\sigma^2(t) \right) dt\right), \end{aligned} \quad (1)$$

where m_o^α and k_o^α are basal values of production and removal, respectively, $\Delta\sigma = (1 - \delta)\sigma/\sigma_o - 1$ and $\Delta\tau_w = (1 - \xi)\tau_w/\tau_{wo} - 1$ represent normalized stress (σ and τ_w) deviations from original homeostatic targets σ_o and τ_{wo} , and gain-type parameters K_σ^α , $K_{\tau_w}^\alpha$, and ω control the sensitivity of the response. Additionally, δ and ξ model cellular mechanosensing. Material responses were described with constitutive relations

$$\begin{aligned} \hat{W}^e &= c^e (I_1^e - 3) \\ \hat{W}^{m,c} &= \frac{c_1^{m,c}}{4c_2^{m,c}} \left(\exp[c_2^{m,c} (I_4^{m,c} - 1)^2] - 1 \right), \end{aligned} \quad (2)$$

where $\{c^e, c_1^{m,c}, c_2^{m,c}\}$ are material parameters, and $\{I_1^e, I_4^{m,c}\}$ are measures of constituent-specific deformations. Material properties were

assigned from fitting to the histological and biomechanical data with a nonlinear least-squares regression routine.

Aneurysmal dilatation was modeled by prescribing heterogeneous insults ϑ onto an initially uniform cylindrical vessel with axial length l_o , varying spatially according to the expression

$$\vartheta(z_o) = \vartheta_{apex} \exp\left(-\left|\frac{z_o - l_o/2}{z_{od}}\right|^{v_z}\right), \quad (3)$$

where $z_o \in [0, l_o]$, parameters z_{od} and v_z govern the width and boundary softness of the insult region, and ϑ_{apex} is the maximum value of the insult. We modeled compromised elastic fibers by reducing the value of c^e . Dysfunctional mechanosensing was modeled with increases in $\delta = [0, 1]$. Finally, changes in mechanoregulation were modeled by modifying the collagen deposition stretch G^c from its baseline value.

Computational methods

We have previously shown in cases of TAA that the constrained mixture framework can be simplified via the assumption of mechanobiological equilibrium, resulting in a time-independent, computationally efficient approach implemented into the finite element solver FEBio [3]. We used this 3D finite element model consisting of a $1 \times 20 \times 20$ mesh of quadratic hexahedral elements, prescribing individual and combined insults of increasing severity to generate aneurysmal geometries and evaluate key biomechanical metrics related to aortic health such as stored energy and material stiffness. We determined optimal insult parameters by fitting the model-predicted to experimentally-measured quantities using a surrogate management framework algorithm [4].

RESULTS

Performance of individual insult contributors

We initially focused on characterizing the effect of insults to elastic fiber integrity alone. Simulations were run for losses in elastic fiber integrity of 0–84%, in which the stored energy and circumferential stiffness were evaluated in the insult region. We performed similar simulations for compromised mechanosensing (0–15%) and mechanoregulation (0–1.2%), shown in Fig. 1. Insults in elastic fiber integrity accurately captured the decrease in stored energy observed in experimental data. However, no insult alone achieved substantial circumferential stiffening or aneurysmal dilatation (Fig. 2).

Figure 1: Columns 1-3: individual compromises in elastic fiber integrity, mechanosensing, and mechanoregulation. Column 4: insult with all effects combined. (Top) stored energy, (middle) circumferential stiffness, and (bottom) dilatation are shown in the highlighted central insult region.

Combined insult captures geometric and mechanical properties of aortic aneurysm

In contrast, insults combining optimized values of parameters describing a loss of elastic fiber integrity with simultaneous compromises in mechanosensing and mechanoregulation maintained the desired loss of stored energy while also predicting significantly more circumferential stiffening than isolated insults (Fig. 1). Furthermore, the combined model was able to recapitulate the trends in several trends observed in the experimental data, including lost distensibility, reduced axial stiffness, and increased thickness (Fig. 2).

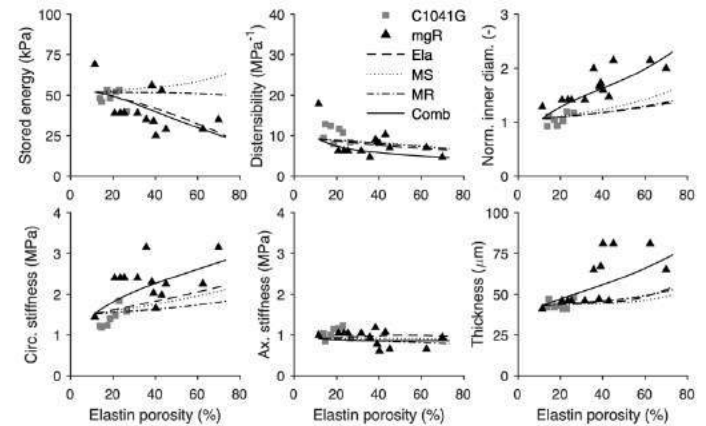

Figure 2: Performance of individual and combined insult models (lines) compared to experimental data (symbols), plotted as a function of elastin porosity measured by two-photon microscopy.

Ela = elastic fiber integrity, MS = mechanosensing, MR = mechanoregulation, comb = combined.

DISCUSSION

We found that while localized defects can give rise to progressive aortic dilatation, the model could only describe the actual data when multiple disease contributing factors co-existed. Given that fibrillin-1 microfibrils not only contribute to elastic fiber homeostasis but also promote smooth muscle cell mechanosensing and mechanoregulation of matrix. Our computational findings are thus consistent with myriad effects of compromised fibrillin-1 in the Marfan aorta. Optimal insult parameters further suggested an early loss of cellular mechanosensing in mild disease relative to loss of elastic fiber integrity, highlighting the importance of inter- and intra-lamellar elastin in the Marfan aorta, which should be further explored in future studies.

The present computational results show that aneurysmal dilatation in MFS results from multiple simultaneous contributors to progressive degeneration of the aortic wall, and mechanobiological models can help to disentangle these contributions.

Figure 2: The proposed operation (mABG) in comparison to the earlier ABG, conventional stage-1 (mBTS), and stage-2 (BDG) operations, in terms of the heart load and SVC pressure. Unshaded and shaded bars correspond to the normal and elevated PVR, respectively.

To evaluate the performance of the proposed operation, we use multi-scale CFD simulations [5]. This methodology, which has been extensively used in the past for modeling single-ventricle circulation [2–4], is capable of capturing the local and global response of the patient circulatory system to the proposed operation.

For an apple-to-apple comparison of the proposed operation against other alternatives, we consider three cases in addition to the proposed operation (mABG). Those are 1) the conventional stage-one anatomy with a 3.5 mm modified Blalock Taussig Shunt (mBTS), 2) the conventional bidirectional Glenn (BDG) anatomy with an end-to-side SVC-PA anastomosis, and 3) the original assisted bidirectional Glenn (ABG) [3]. All parameters are kept the same between these cases (including the lumped-parameter network), except for the altered anatomy associated with each operation. We additionally consider normal and elevated pulmonary vascular resistance (PVR) values to model patient response in a normal and worst-case scenario setting.

RESULTS

A comprehensive set of parameters are extracted from these simulations [6, 7], which are not reported here for the sake of space. In what follows, we only focus on the most critical parameters, which are the SVC pressure, heart load, and oxygen delivery.

As shown in Figure 2, the BDG, ABG, and mABG heart workloads are approximately half of that of the mBTS at both PVR. The mABG procedure also has the highest oxygen delivery and aortic oxygen saturation among the four procedures at both normal and high PVR. Most importantly, the present mABG lowers the SVC pressure below the PA pressure. At normal PVR, the SVC pressure in the mABG is lower than that of the BDG despite a significantly higher PA flow rate. At both normal and elevated PVR, the SVC pressure in the mABG is lower than that of the original ABG.

DISCUSSION

The simulation results confirm the advantages of the ABG circulation, including the lower heart load, which is significantly lower than the conventional mBTS operation. Even though the ABG heart load is slightly higher than the BDG due to the shunt flow, that also increases pulmonary perfusion to boost the development of pulmonary circulation in infants undergoing this operation.

As mentioned earlier, the ABG has the highest oxygen delivery among all operations as it has the highest systemic saturation. The higher systemic saturation in the ABG can be attributed to redirecting SVC flow so that it no longer mixes with the oxygenated flow in the atrium to otherwise lower systemic saturation.

The ABG has also the potential to combine the first two open-chest operations performed on single ventricles, thus reducing the total number of operations from 3 to 2. Later transition to stage-2 (i.e., BDG) circulation can simply be accomplished by blocking the shunt via a catheter.

Redundancy is built into the ABG pulmonary circulation as the PA flow is supplied through SVC and shunt. Hence, if the shunt occludes due to thrombosis, the ABG circulation reverts back to the BDG circulation. That is in contrast to stage-1 operation, where shunt blockage is a fatal incident.

The high SVC pressure was one of the major concerns in the ABG procedure that motivated this study. Both previous studies and our study shows that the ABG produces an SVC pressure that exceeds that of the mBTS and BDG at normal and high PVR to a level that may not be tolerated by infants. The proposed modifications in the mABG lowered the SVC pressure to 4.3 mmHg at normal PVR, a value that potentially avoids upper-body edema and SVC syndrome [8].

In contrast to these encouraging outcomes at normal PVR, the SVC pressure remains relatively high at high PVR. That is so since the PA pressure scales with the PVR while the ejector pump pressure recovery does not, resulting in an SVC pressure three times higher than that of a normal PVR. In practice, the PVR of newborns is elevated up to 3-6 weeks, during which a high SVC pressure could create adverse effects [9].

To identify the conditions where the ABG can be safely employed, we have generated a 2D map that allows one to look up the SVC pressure given the PVR and nozzle area (Figure 3). This 2D map, which is obtained using the combination of multidomain CFD simulations and algebraic models [7], permits one to select the right slit thickness (hence, a nozzle area) once the PVR and acceptable SVC pressure are known.

Figure 3: A master chart for selecting the nozzle size if the patient PVR and the highest tolerable SVC pressure are known. The dashed line shows the optimal nozzle area that produces the lowest P_{SVC} .

EYE-SPECIFIC MODELING OF EFFECTS OF INTRAOCULAR PRESSURE ON OPTIC NERVE HEAD OXYGENATION

INTRODUCTION

Glaucoma is characterized by progressive degeneration of retinal ganglion cells and their axons. The axon damage is believed to start within the optic nerve head (ONH) [1]. Although the mechanisms leading to axon damage remain not fully understood, a leading hypothesis is that an insufficient oxygen supply within the ONH would contribute to this process [2]. This can happen at any level of intraocular pressure (IOP), and would likely worsen if elevated IOP distorts the vasculature, affecting blood flow [3].

Our goal was a better, more comprehensive, understanding of the effects of IOP-induced deformations on the ONH hemodynamics and oxygenation. Direct examination of this process is extremely complex since measurement of ONH oxygenation in-vivo is not yet possible. Hence, we use 3D eye-specific numerical models to characterize ONH hemodynamics and oxygenation at a baseline IOP and when under subjected to experimentally-derived IOP-induced tissue distortions. Specifically, we focus on the relationship between IOP-induced vessel diameter reduction and the local decrease in oxygen.

METHODS

We reconstructed detailed 3D models of the ONH vessel networks of 3 healthy monkey eyes using histological techniques, as described elsewhere [4]. We also obtained in-vivo IOP-induced ONH deformations from a healthy monkey using optical coherence tomography images and digital volume correlation techniques while IOP was controlled, as reported before [5]. A biomechanics-based technique was used to map the experimentally-derived tissue strains to local vessel distortions. The hemodynamics and oxygenation of the three vessel networks were simulated under deformations from various IOP increases, using the methods reported before [6]. The oxygen fields adjacent to the vessels were compared to the baseline value to determine the effect of IOP-induced mechanical insult to each vessel.

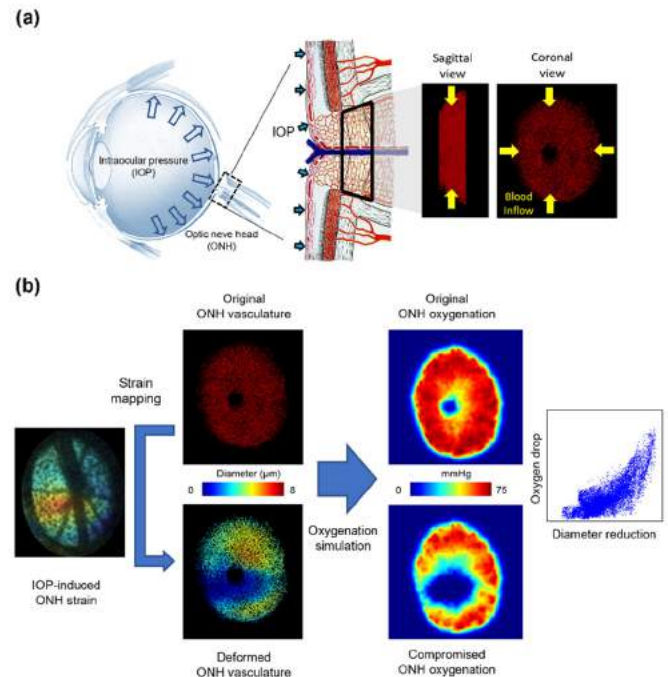

Figure 1: (a) Diagrams of the eye and ONH vasculature (left and middle). An eye-specific model of ONH vasculature (right). Blood inflow was at the periphery from the circle of Zinn-Haller [1] (yellow arrows). (b) Schematic of our analysis process, based on applying experimentally-derived deformations and computing changes in vessel diameter and oxygenation.

RESULTS

ONH oxygenations under different IOP-induced deformations are shown in **Figure 2**. As IOP increases, tissue distortions led to decreased vasculature diameters, and with this to also decreased ONH oxygenation. We analyzed the spatial association between vascular deformation and oxygenation in ONH. There was a positive, nonlinear association between the IOP-induced diameter reduction of each vessel and the decrease in oxygen in the tissues adjacent to the vessel (**Figure 3**). Overall, vessels with larger diameter reductions were more likely to have large oxygen drops. Similar patterns were observed for the two other ONH vessel networks simulated.

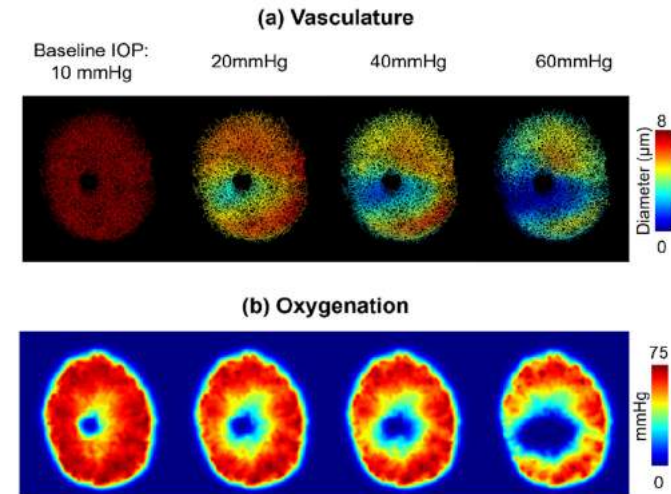

Figure 2: ONH #1 vasculature deformation and oxygenation at different IOPs. The diameters of the vasculature and the oxygenation are both decreasing with IOP elevation. Regions of low oxygenation and vessels with large diameter reduction had similar spatial distributions.

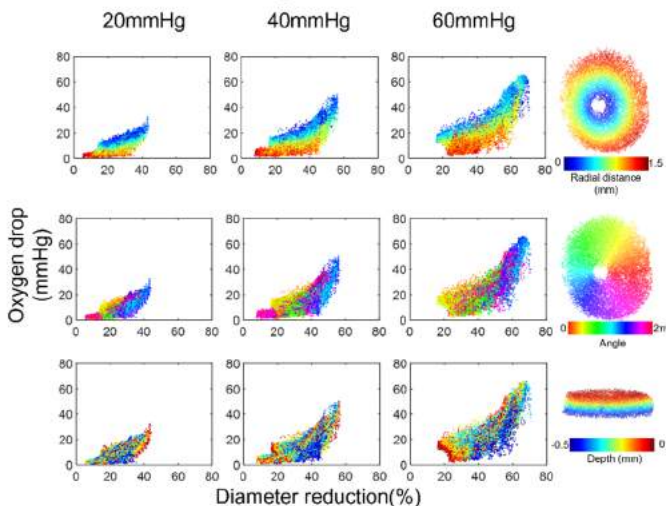

Figure 3: Scatterplots of oxygen decrease and diameter reduction at three IOPs relative to the baseline IOP=10mmHg (columns) of ONH #1. Dots corresponds to capillary segments colored according to the location by: radial distance from the central vessels (top row), clock-hour (middle-row) and anterior-posterior (bottom row). Results show larger decreases in oxygen for more central vessels for a given diameter decrease. The dependence on clock-hour and depth were more nuanced.

The spatial distribution of diameter reductions and oxygen drops relative to the baseline for each vessel are shown in **Figure 3**. For radial direction, the results show a layered structure. The periphery vessels have the smallest oxygen drop under various diameter reductions. The further away from the periphery, the more difficult it is for the vessel to maintain a small oxygen drop under deformation. For angular direction, the angular differences are mainly in the vascular compressions, which are consistent with the angular distribution of the IOP-induced deformation, as expected. For vessels at different depths, the oxygen drops and diameter reductions did not show significant differences.

DISCUSSION

We leveraged 3D eye-specific numerical models to characterize ONH hemodynamics and oxygenation under different IOP-induced deformations. Specifically, we investigated the oxygen drops and diameter reduction of ONH vessels during IOP elevation. Two main findings arise from the work: First, as IOP increases, both oxygen decreases and the diameter reduction of vessels become larger. Second, the peripheral vessels have smaller oxygen drops than the central vessels for various deformations. Below we discuss each of the main findings in detail.

As IOP increases, both the oxygen drops and the diameter reductions of vessels become larger. This can be understood as follows: Increases in IOP led to tissue deformations. The deformations, applied to the vessels result in compromised blood flow, which lead to the oxygenation reduction. This finding supports the hypothesis that elevated IOP alters the hemodynamics and oxygenations within the ONH, which, may contribute to neural tissue injury in glaucoma.

We also observed that peripheral vessels had smaller oxygen drops than central vessels under various deformations. This can be understood by recalling that ONH blood perfusion within ONH is from the periphery, draining through the central retinal vein. When interpreting these results, we must be careful to recall that the ONH vascular system is highly interconnected and therefore that capillary flows are not independent. For instance, we cannot conclude that higher oxygen decreases in more central capillaries for the same diameter reduction implies that they are more sensitive to peripheral capillaries. The results represent an integrated simulation of the whole system, in which blood flows from the periphery to the center. The diameter decreases in the periphery that cause local blood flow decreases likely contribute to the decrease in blood flow and oxygen in the central vessels downstream.

In summary, we used 3D eye-specific models to evaluate the ONH hemodynamics and oxygenations under IOP-induced deformation. Results from this study help understand the mechanisms of the IOP-induced retinal ganglion cell axon damage in glaucoma. Next steps involve expanding the analysis to IOP-induced deformations on other eyes, and eventually on the same eyes from which the vessel network was reconstructed.

SPATIAL MAPPING THE MATERIAL AND STRUCTURAL PROPERTIES OF THE UTERINE FIBROID-MYOMETRIUM BOUNDARY

Daniella M. Fodera¹, Johanna L. Lund-Jackson¹, Shuyang Fang², Arnold Advincula³, Michelle L. Oyen⁴, Kristin M. Myers²

⁴Department of Biomedical Engineering, Washington University in St. Louis, St. Louis, MO, USA.

INTRODUCTION

Uterine fibroids, also known as leiomyomas, affect 70-80% of women by age 50 and account for more than 200,000 hysterectomies in the U.S. annually [1, 2]. Characterized by the non-cancerous growth of tumors in the uterus, fibroids are a common cause of excessive bleeding, infertility, preterm labor, pelvic pain, and other obstetric conditions [3]. While fibroids have been documented to grow as large as 30 cm in diameter, all originate initially as seedling fibroids on the mm scale [4]. Relatively few studies have characterized the mechanical properties of uterine fibroids to date [4-6]. It is well established that uterine fibroids are significantly stiffer than the myometrium using bulk tissue testing approaches, exhibiting both intra- and inter-patient variability, yet no studies have investigated the transition in material properties at the fibroid-myometrium boundary [4-6]. Understanding whether a sharp or gradual change in stiffness exists at this boundary will provide key knowledge in the development of diagnostic tools for the detection and treatment of uterine fibroids. Therefore, this study aims to spatially map the time-dependent material properties of seedling uterine fibroids and their surrounding myometrium at the microscale.

METHODS

In accordance with IRB approval at Columbia University Irving Medical Center (CUIMC), human uterine tissues embedded with fibroids ($n = 13$) were collected from nonpregnant women ($n = 2$) undergoing hysterectomies. Uterine sections were collected at the anterior, fundus, and posterior regions, immediately flash-frozen, and stored at -80°C until further processing. Prior to testing, seedling uterine fibroids on the mm-scale were revealed following careful dissection of uterine tissue. A subset of samples was stained for Masson's Trichrome using standard protocols. Spherical nanoindentation (Piuma, Optics11Life, Amsterdam, NL) was utilized to map the spatial variations of time-dependent material properties of uterine fibroids and patient-matched myometrium. Samples were thawed at 4°C overnight in PBS solution and equilibrated at room temperature for 30 min prior to testing.

Figure 1: (A) Schematic of testing protocol for the fibroid-myometrium boundary. (B) Representative load relaxation curve generated from nanoindentation testing fit with the PVE model. (C) Histology (Masson's Trichrome) stains of the (i) distant myometrium and (ii) adjacent myometrium, and (iii) fibroid (blue = collagen; red = smooth muscle). Scale bar = 100 μm .

The fibroid-myometrium boundary was tested as a rectangular region shown in Fig. 1A and centered relative to the fibroid's height (F_H). The length (X) of the testing region was equivalent to the full length of the fibroid (F_L) plus a fixed 3 mm of the adjacent myometrium. The height (Y) was equal to $0.4 \cdot F_H$. The distance between indentation points was fixed at 200 μm . Distant myometrium was defined as a region of tissue greater than 5 mm from any visible fibroid; one sample per anatomic region was sampled for each patient ($n = 6$).

Using a spherical probe (50 μm radius), samples were indented to a fixed depth of 4 μm , corresponding to a 5% strain, for 15 s to achieve a load relaxation curve approaching equilibrium (Fig. 1B). Load relaxation curves were fit in Matlab with a combined poroelastic-viscoelastic (PVE) model based on established methods [7-9]. Fitted data points were excluded from the final data set if the load relaxation curve displayed (i) sharp discontinuities, (ii) increasing loads over time, and (iii) ΔP ($P_{\max} - P_{\min}$) less than 0.005. Parameters of stiffness (E), viscoelastic ratio

(E_{∞}/E_0), and intrinsic permeability (k) were determined from the PVE model. Statistical analysis was performed in GraphPad Prism 9.4.0 using a nested one-way ANOVA with significance set at $p < 0.05$.

RESULTS

Structurally, uterine fibroids exhibit increased collagen and decreased smooth muscle content compared to patient-matched myometrium (Fig. 1C). Uterine fibroids are surrounded by dense circumferentially aligned smooth muscle fibers, which is markedly distinct from the distant myometrium displaying random fiber orientation (Fig. 1C).

On the whole, uterine fibroids demonstrate increased stiffness relative to matched myometrium by nearly an order of magnitude (Fig. 2A-B). Yet, notable intra-sample variability in stiffness is exhibited across the fibroid's length without any discerning patterns, ranging from 10^1 to 10^4 Pa. The transition in stiffness values at the fibroid-myometrium boundary does not follow a singular pattern for different uterine fibroids, displaying both sharp and gradual changes in stiffness on the μm -scale (Fig. 2A). Coupled with increased stiffness, uterine fibroids exhibit decreased permeability compared to patient-matched myometrium, indicating that the tissue is less porous (Fig. 2C). On average, no differences between the distant and adjacent myometrium are observed for both stiffness and permeability parameters (Fig. 2B-C). Interestingly, no difference in viscoelastic ratio is evident across all sample groups, with median values ranging from 0.4 to 0.6 (data not shown).

DISCUSSION

Here, a novel dataset representing the time-dependent material properties of seedling uterine fibroids at small length scales is presented. Uterine fibroids are determined to be significantly stiffer and less permeable when compared to patient-matched myometrium, yet they exhibit a large degree of heterogeneity within and across different fibroids regardless of the individual patient. The transition in material properties at the fibroid-myometrium boundary also varies by sample, exhibiting both sharp and gradual changes in stiffness. Such a finding suggests multiple morphological phenotypes may in fact exist for seedling fibroids. Future work will investigate underlying changes in composition and structure for different fibroid phenotypes with immunohistological staining and second harmonic generation imaging.

Further, structural and compositional features at the fibroid-myometrium boundary suggests for the very first time that growing fibroids alter the directionality of muscle fibers for the adjacent myometrium. For this reason, we propose that uterine fibroids impart hoop stresses within the surrounding myometrium that disappear following removal of the fibroid, a hypothesis that can be confirmed with non-contacting extensometry and computational modeling.

A key limitation of this study is the singular focus on seedling uterine fibroids which are often too small to be surgically removed during a myomectomy procedure. Additionally, this study focuses almost entirely on intramural fibroids embedded in the myometrium, yet, fibroids can exist in submucosal, subserosal, and pedunculated forms. As such, future work will investigate the

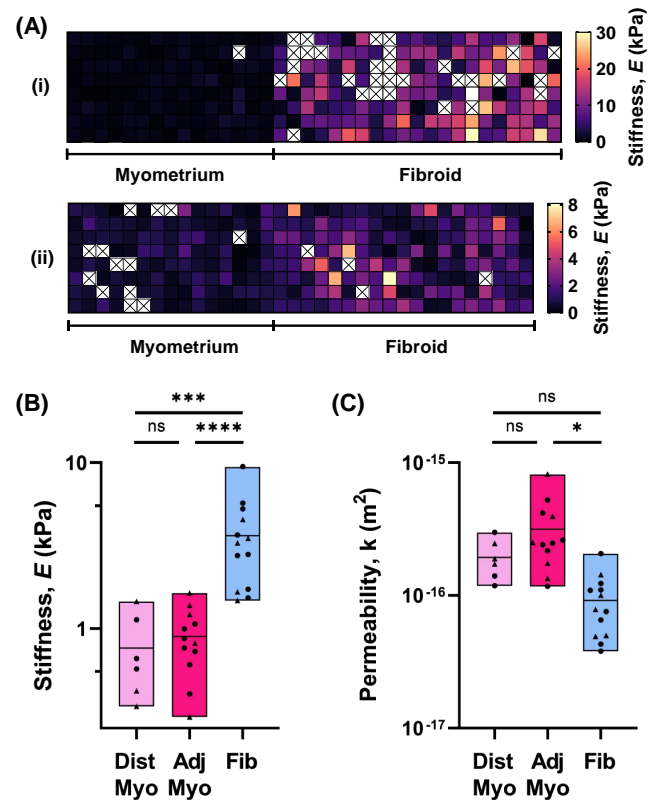

Figure 2: (A) Spatial heatmap of stiffness across the fibroid and adjacent myometrium for two representative samples (i,ii). The distance between each colored square is 200 μm . Squares marked by an [X] indicate points removed due to exclusion criteria. (B) Stiffness and (C) permeability of uterine fibroids and patient-matched myometrium (distant and adjacent). Each symbol represents the median value of all indentation points (10^1 - 10^2) for a given sample. Triangle and circle symbols denote different patients.

material properties of this boundary for larger centimeter-sized uterine fibroids found in different tissue layers of the uterus.

Yet, despite these limitations, the data presented here yield key insights into the mechanical and structural properties of uterine fibroids. Focusing exclusively on a snapshot of uterine fibroids in their seedling stage provides foundational knowledge for improved understanding of uterine fibroid nucleation and growth. In doing so, targeted therapeutic treatments for the removal and prevention of uterine fibroids may be developed.

INTRODUCTION

Transcatheter aortic valve replacement (TAVR), a minimally invasive procedure, has demonstrated superior or noninferior hemodynamic performance compared to surgical aortic valve replacement (SAVR) and became the standard procedure for high and intermediate-risk aortic stenosis patients. However, prosthetic TAVR leaflets are inherently subjected to degeneration, along with calcification and thrombosis [1]. Hence, durability remains as one of the major concerns for TAVR technology. Recently, clinical studies have found evidence of early leaflet thrombosis formation [2] that may be associated with an earlier risk of structural valve degeneration. Therefore, it is important to thoroughly investigate the thrombogenic risk of the TAVR devices with respect to patients' anatomical variability. While choosing a TAVR device, the size of the left ventricular outflow tract (LVOT) and calcium deposits on the LVOT and native leaflets get major attention. However, the sinotubular junction (STJ) size may also affect the hemodynamic performance of TAVR devices and may increase the thrombogenic risk [4]. An analysis of hemodynamic performance and thrombogenic risk of TAVR devices associated with STJ size variability may provide crucial information that can potentially aid the clinicians in optimizing device selection and reduce the risk of leaflet thrombosis and degeneration in the long run.

TAVR has recently been approved for use in low-risk patients. The increasing number of younger and low-risk TAVR recipients, and recent evidence of rapid degeneration of prosthetic valves can potentially lead to the need for another TAVR procedure on top of the first TAVR device. This procedure, known as TAV-in-TAV (transcatheter aortic valve-in-transcatheter aortic valve), is typically performed to address suboptimal outcomes such as aortic regurgitation. However, it is still unknown whether TAV-in-TAV can be a viable solution to early TAVR valve degeneration. Recently, Hoda et.al.[5] performed an in-vitro hemodynamic analysis of different TAV-in-TAV combinations deployed in an idealized geometry and suggested combination-dependent hemodynamic performance. Performance of

TAV-in-TAV may also depend upon factors including the diseased patient-specific anatomy and complex flow domain formed by the native leaflets and two TAVR device prostheses. Conducting a computational hemodynamic performance and thrombogenic risk analysis of different TAV-in-TAV combinations in a patient-specific scenario may provide important insights into the feasibility of TAV-in-TAV procedures and help identify the optimal combination.

METHODS

A patient with a 26 mm LVOT size and 30 mm STJ size was selected. The patient model was then reconstructed from a CT scan. The STJ size was later modified to 26 mm and 34 mm, while the aortic annulus size was kept unchanged (Figure 1a). An

Evolut 26 mm TAVR device was subsequently deployed in 3 virtual patient cases using Abaqus 2019 (SIMULIA, Dassault Systèmes, Providence, RI) following our previous study (Figure 1b) [6]. A 2-way coupled fluid structural interaction (FSI) using an immersed boundary method was then performed on each virtual patient case (using an in-house Multiphysics solver 'Alya', developed in Barcelona Supercomputing Center, Spain) (Figure 1c) [7]. The thrombogenic risk assessment analysis was performed following our previously developed and validated technique (Figure 1d) [8]. In this study, 2 million

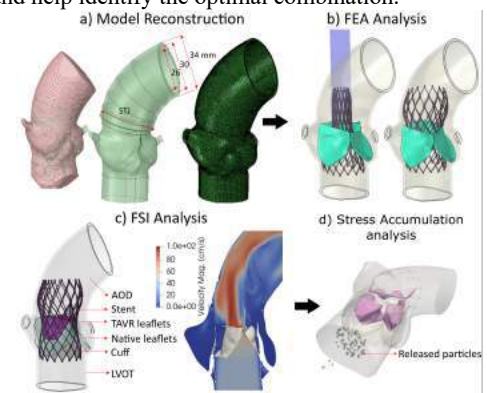

Figure 1: Schematic of the (a) model reconstruction, (b) TAVR deployment, (c) FSI simulation, and (d) particle injection for stress accumulation (SA) analysis is presented

Lagrangian particles representing platelets were injected into the flow over 10 cardiac cycles. Stress accumulation (SA) was computed along each particle trajectory and collapsed into a probability density function (PDF) to compute the “thrombogenic footprint” [8] for each virtual patient case. Additionally, Residence Time (T_R) (Figure 3), Wall Shear Stress (WSS), Transvalvular Pressure Gradient (TPG), and Geometric Orifice Area (GOA) for each model were computed.

Figure 2: Representations of the considered TAV-in-TAV combinations (SE- self expandable, BE-balloon expandable) [5]

In the second study, four TAV-in-TAV combinations were modeled using Abaqus Explicit 2019 (SIMULIA, Dassault Systèmes, Providence, RI) in a reconstructed patient model based on the two most commonly used self-expandable (SE) Evolut and balloon expandable (BE) Sapien TAVR systems. Subsequently, 2-way coupled fluid structural interaction (FSI) analysis and stress accumulation (SA) based thrombogenic risk analysis were performed for each TAV-in-TAV combinations presented in Figure 2.

RESULTS

26 mm STJ size demonstrated a smaller median GOA (9%), higher median T_R (3%), TPG (35%), WSS (11%), and a larger number of particles with high-stress accumulation (SA) (Figure 4) compared to 30 mm STJ size. 34 mm STJ size had a similar GOA and number of particles with high accumulated stress (AS), higher T_R (4.8 %), TPG (13%), and a lower WSS (12 %) compared to the 30 mm STJ size. (Table 1). However, a higher number of particles experienced SA magnitude of more than 1 Pa.s for models with larger STJ sizes in both sinus and the neo-sinus (Figure 4). Initial results demonstrate TAVR device-specific performance in TAV-in-TAV implantations in a patient-specific model (Figure 5).

DISCUSSION

TAVR subclinical leaflet thrombosis is generated following a complex process including platelet activation at high shear flow caused by a high-velocity jet either through paravalvular leaks or narrowed leaflet opening and platelets aggregation at low shear flow in pockets of space created between the native leaflets and the TAVR prosthesis that promotes blood stasis. In this study, we performed a set of computational analyses starting from finite element-based TAVR deployment in patient-specific models to FSI-based hemodynamic analysis coupled with particle stress accumulation (SA) analysis. SA accounts for the combined effect of shear stress and exposure time that drive platelets beyond their activation threshold and promotes thrombus formation.

Figure 3: a) Velocity contour, and b) Residence time during peak systole

Using these techniques, we analyzed the effect of STJ size on TAVR performance and associated thrombogenic risk. We also analyzed the feasibility and the best performing TAV-in-TAV combination, that is being considered as a solution to TAVR leaflet thrombosis and degeneration.

The patient model with a 30 mm STJ size-close to the diameter of the upper crown (32 mm) of the 26 mm Evolut device

Figure 4: Overall probability density functions (PDF) of stress accumulation (SA) for models with different STJ size in (a) sinus and (b) neo-sinus

demonstrated the best performance with the highest GOA, lowest T_R , TPG, and WSS. The model with 34 mm STJ size had a relatively inferior performance compared to the 30 mm STJ model with a higher T_R and TPG. 26 mm STJ restricted the opening of the upper crown of the TAVR device and caused the smallest GOA compared to 30 mm and 34 mm STJ models. 26 mm STJ model also had the highest TPG and WSS. However, larger room for blood recirculation causes a larger number of platelets to experience high SA for models with larger STJ size. Initial results from the TAV-in-TAV combination analysis demonstrated a device-specific performance. Further investigation is being performed to find the best-performing TAV-in-TAV device combination in a patient-specific basis.

Figure 5: (a) FSI domain of SE-in-SE combination, velocity streamline during (b) systole, and (c) diastole, leaflet opening during (d) systole and (e) diastole

This study presents a thorough computational protocol to analyze patient-specific hemodynamic performance and thrombogenic risk of TAVR devices, shedding light on mechanisms that promote TAVR leaflet thrombosis – addressing a major clinical concern and indicating on potential approaches to mitigate it by informing clinicians how to improve pre-procedural planning in order to minimize the risk of TAVR leaflet thrombosis.

CONSTITUTIVE MODELING OF MOUSE ARTERIES SUGGESTS CHANGES IN DIRECTIONAL COUPLING AND EXTRACELLULAR MATRIX REMODELING THAT DEPENDS ON ARTERY TYPE, AGE, SEX AND ELASTIN AMOUNTS

INTRODUCTION

Large artery stiffening is both a cause and consequence of cardiovascular disease and occurs during natural aging. Men and women have different susceptibilities for cardiovascular diseases related to large artery stiffening, such as hypertension and aneurysms, and also have a different timeline for arterial stiffening during aging. One cause of arterial stiffening is a shift in the amount or organization of extracellular matrix (ECM) proteins, including collagen and elastic fibers. Animal models have been used to investigate how changes in ECM proteins are related to arterial stiffening and cardiovascular disease. In particular, elastin heterozygous (*Eln*^{+/-}) mice have ~60% of normal elastin levels, increased arterial stiffness, and hypertension. We previously showed that elastin haploinsufficiency has divergent effects on arterial remodeling with aging that depends on sex [1]. However, we only investigated circumferential mechanical behavior and it is known that arteries are under biaxial loads.

Biaxial mechanical data from mouse arteries has been fitted with 2- or 4-fiber Holzapfel-Gasser-Ogden (HGO) [2] type constitutive models for biomechanical phenotyping in aging and disease. These studies provide insight into how physiological stresses and strains adapt (or not) and possible microstructural explanations for these changes. These models have a built in coupling between fiber and cross-fiber deformation. Dong and Sun (DS) [3] recently proposed a novel constitutive model that does not need a specified number of fiber families and can have varied amounts of deformation coupling. We evaluated the ability of the DS model to fit biaxial mechanical data of *Eln*^{+/-} arteries and interpret biomechanical phenotype changes as a function of age, sex, and ECM alterations in the ascending aorta (ASC) and left common carotid artery (LCC).

METHODS

Animals. Male and female *Eln*^{+/+} and *Eln*^{+/-} mice at 6 and 24 months were used [1]. All animal procedures were approved by the IACUC.

Mechanical Testing. The LCC or ASC was mounted in a pressure myograph. The artery was preconditioned and then pressurized from 0 – 175 mmHg for 3 cycles at different axial stretches and then axially stretched from about 1.0 – 1.8 at 3 different pressures. Unloaded dimensions were measured from cut rings. The experimental stresses were calculated assuming an incompressible cylinder with no shear [1]. **Constitutive Modelling.** Inflation and extension of the artery can be described by the deformation gradient (*F*) and the right Cauchy-Green (*C*) strain tensor. The total strain energy ($\bar{\Psi}$) is the sum of the matrix (*m*) and fiber (*f*) components [2], $\bar{\Psi} = \bar{\Psi}_m + \bar{\Psi}_f$. The matrix is considered an isotropic, Neo-Hookean material,

$$\bar{\Psi}_m = \frac{1}{2} c (\bar{I}_1 - 3), \quad (1)$$

where *c* is a material constant, $\bar{I}_1 = tr(\bar{C})$, $\bar{C} = J^{-\frac{2}{3}} \bar{C}$, $\bar{C} = F^T F$, $J = det F$. The DS fiber strain energy depends on the degree of deformation coupling (medium or strong) and can be described by [3],

$$\bar{\Psi}_{f-medium} = \frac{k_1}{2k_2} \{ \exp [k_2 (\delta_{\parallel} \bar{E}_{\parallel}^2 + \delta_{\perp} \bar{E}_{\perp}^2)] - 1 \}, \quad (2a)$$

$$\bar{\Psi}_{f-strong} = \frac{k_1}{2k_2} \{ \exp [k_2 (\delta_{\parallel} \bar{E}_{\parallel} + \delta_{\perp} \bar{E}_{\perp})^2] - 1 \}, \quad (2b)$$

where *k₁* and *k₂* are material parameters, $\delta_{\parallel} = H(\bar{I}_4 - 1)$, $\delta_{\perp} = H(\bar{I}_{4\perp} - 1)$, where *H* = the Heaviside step function, $\bar{I}_4 = (a_o \otimes a_o) : \bar{C}$ and $\bar{I}_{4\perp} = (a_{o\perp} \otimes a_{o\perp}) : \bar{C}$, where *a_o* and *a_{o⊥}* are unit vectors representing the symmetric mean and perpendicular fiber directions, respectively. The strain terms (\bar{E}_{\parallel} , \bar{E}_{\perp}) are,

$$\bar{E}_{\parallel} = (1 - \zeta)(\bar{I}_4 - 1) \text{ and } \bar{E}_{\perp} = (\zeta)(\bar{I}_{4\perp} - 1), \quad (3a,b)$$

where ζ is a scalar material parameter characterizing the average fiber component in the *a_{o⊥}* direction in an integral sense and ranging within [0,1] for a general planar distribution of multiple fiber families.

$\bar{\Psi}_{f-strong}$ is mathematically equivalent to the 2-fiber HGO model and strongly couples stress in one planar direction to stretch in the perpendicular planar direction. $\bar{\Psi}_{f-medium}$ has less strong deformation coupling. The theoretical Cauchy stress can be determined by,

$$\sigma = 2F \frac{\delta \bar{\Psi}}{\delta C} F^T - pI. \quad (4)$$

Material parameters for the strong and medium forms of the DS model were fitted to the mechanical testing data by minimizing the error between the experimental and theoretical stresses. Results were compared by ANOVA for age, sex, and genotype.

RESULTS

Biaxial mechanical data for the LCC, which is a muscular-elastic artery, has a better fit to $\bar{\Psi}_{f-medium}$ than $\bar{\Psi}_{f-strong}$. The ASC, which is the most elastic artery in the body, has a better fit to $\bar{\Psi}_{f-strong}$ than $\bar{\Psi}_{f-medium}$. Mean R^2 for the best fit model ranges from 0.74 - 0.80 for both arteries. Figure 1 shows material parameters for the best fit models only. For the LCC with medium deformation coupling, sex has a significant effect on all fitted material parameters except ζ , age has a significant effect on k_2 , and genotype has a significant effect on c , k_2 , and ζ (Fig. 1, left). For the ASC with strong deformation coupling, sex has a significant effect on c and k_1 , age has a significant effect on k_2 and ζ , and genotype has a significant effect on all fiber parameters (Fig. 1, right). The results show artery dependent deformation coupling and variation of the matrix and fiber material parameters that depend on artery type, age, sex, and genotype.

Using the fitted material parameters, we calculated the strain energy and biaxial stresses under physiologic loading conditions [1]. The stored strain energy decreases with age in both arteries and also with elastin amounts by genotype in the LCC (Fig. 2). In the LCC, the stresses decrease with elastin amounts and the axial stresses also decrease with age (Fig. 2, left). The stresses in the ASC are maintained across sex, age, and genotype (Fig. 2, right). The results show adaptations in the ASC to maintain stresses and partially maintain strain energy that are not observed in the LCC.

DISCUSSION

Large arteries have varying amounts of cells and ECM that depend on their location and function. Our results suggest that deformation coupling varies by artery type. As the LCC can experience large axial stretch with positioning of the head and neck, medium (as opposed to strong) deformation coupling may protect cells within the wall from excessive circumferential stress. Our results also suggest a higher capacity for remodeling to maintain homeostatic strain energy and stresses in the ASC compared to the LCC. As the ASC receives the entire cardiac output and its energy storage and pulse dampening is critical for cardiac function, this may be necessary to build flexibility into the cardiovascular system and adapt to changes in ECM amounts with aging and disease. The DS model used here allows investigation into changes in matrix and fiber mechanical contributions with artery type, age, sex, and genotype. Future work will investigate how changes in ECM amounts and organization correlate with specific material parameters for a better understanding of the remodeling process.

THERMODYNAMICS OF PHASE TRANSFORMATION OF WATER: THEORY AND EXPERIMENTS

Raphael J. Kepecs, Gerard A. Ateshian

Department of Mechanical Engineering, Columbia University, New York, NY, USA

INTRODUCTION

Phase transformations play an essential role in many bioengineering applications, such as evaporation of saliva droplets leading to aerosolization of virus loads [1], or cryo-preservation of cells for medical and research applications [2]. However, theoretical thermodynamic principles, when applied to phase transformations, are limited to reversible processes, implying that these processes undergo very slow phase changes with negligible mass fluxes. Governing equations that remain valid for irreversible phase transformations have not been reported in the standard literature.

In a recent theoretical study [3] we used the framework of reactive mixtures [4] to formulate jump conditions across a phase boundary, which remain valid for irreversible processes. Using the jump condition for the axiom of entropy inequality, we recovered the conventional result that stable phase equilibrium coincides with continuity of temperature, pressure, and free enthalpy across the phase boundary. Moreover, this jump condition led to the novel formulation of a constitutive relation for the phase transformation mass flux,

$$M\bar{\zeta} = - \left[\left[\frac{1}{T} \mathbf{q} \right] \right] \cdot \mathbf{n}^\Gamma / [s], \quad (1)$$

where \mathbf{q} is heat flux, $\left[\left[\frac{1}{T} \mathbf{q} \right] \right] \cdot \mathbf{n}^\Gamma$ is the jump in entropy flux normal to, and across the phase interface Γ , and $[s]$ is the corresponding jump in specific entropy. This relation implies that phase transformations must be accompanied by a jump in absolute temperature T across the phase boundary, consistent with experimental data for the evaporation of liquid water [5]. Recently, we reported encouraging agreement between eq.(1) and experimental data for steady-state water evaporation [3].

The objective of the current study was to validate this theoretical framework against a well-known experiment reported extensively on YouTube [6], where supercooled liquid water in a bottle suddenly freezes (turns to slush) along a rapidly moving front when the bottle is shaken or struck. The initial metastable state of the supercooled water

is explained using this novel theoretical framework. Moreover, the rapid motion of the freezing front (phase boundary) epitomizes the irreversibility of this phase transformation, thus providing an excellent illustration of a common observation which could not be explained from classical thermodynamic principles.

METHODS

The experimental method employed for producing a freezing front in a water bottle was based on various videos posted on YouTube, such as [6]. A sealed natural spring water bottle (330 mL) was placed horizontally in a household freezer for 75 minutes (-30°C). Care was taken to leave the household freezer undisturbed over this duration. The bottle was then carefully taken out, gently turned upright, and placed on a table top. The bottle cap was slowly unsealed and removed to insert a thermocouple (K type, 0.1°C resolution) and measure the temperature at various locations along the height. The bottle was also placed in front of a thermal imaging camera (FLIR ONE Pro-iOS, flir.com) to assess spatial variations in temperature, and a visible light camera as an alternative method of visualizing the moving phase boundary. Phase transformation was initiated by lifting up the bottle by a few centimeters and banging it down lightly against the table top. Thermocouple and thermal/visual imaging measurements were conducted throughout the duration of the phase transformation. In a separate experiment, two holes were drilled in the cap of a water bottle to insert thermocouples, one of which measured the water vapor (v)-air temperature above the water level while the other measured the liquid water temperature halfway along its height, as a function of time, as the bottle was kept upright in the freezer for 70 minutes.

Let the outward normal \mathbf{n}^Γ point upward on the liquid water interface Γ . Based on the axiom of mass jump across the phase boundary Γ [3], the normal velocity of Γ , v_n^Γ , is related to normal velocities v_n^ℓ and v_n^i of the liquid and ice phases, respectively, by

$$v_n^\Gamma = v_n^\ell - M\bar{\zeta}/\rho^\ell = v_n^i - M\bar{\zeta}/\rho^i \quad (2)$$

where ρ^ℓ and ρ^i are the mass densities of liquid water and ice, respectively. Since the liquid water in the bottle remained stationary, we could set $v_n^\ell = 0$ and solve for the phase transformation mass flux $M\bar{\zeta}$ from eq.(2), using measurements of v_n^Γ and knowing that $\rho^\ell \approx 1000 \text{ kg/m}^3$ near freezing temperatures.

RESULTS

When the water bottle was placed upright in the freezer, to allow placement of thermocouples in the v +air pocket, and in the liquid, through the perforated bottle cap, the temperature of v +air dropped more rapidly than that of the liquid water, as shown in Fig. 1. When the temperature of v +air dropped below -5°C , the liquid water eventually froze to a slush, reaching a nearly constant temperature of $\sim 0.2^\circ\text{C}$.

Fig. 1. Temporal temperature variation in liquid water and v +air pocket, in a bottle placed upright in a freezer.

Fig. 2: Velocity v_n^Γ of phase boundary Γ obtained from slope of position vs. time, in bottles initially placed horizontally in a freezer.

Fig. 3: Temporal evolution of T at a fixed point in bottle, as the liquid-ice phase boundary Γ traveled downward (thermocouple)

When the water bottle was placed horizontally in the freezer, then taken out carefully and banged upright on a table top, the phase boundary Γ traveled downward ($v_n^\Gamma < 0$) along the height of the bottle, with an average velocity of 1.24 cm/s as assessed from measurements on three (Fig. 2). The corresponding phase transformation mass flux, evaluated from eq.(2), would be $M\bar{\zeta} = -\rho^\ell v_n^\Gamma \approx 12.4 \text{ kg/m}^2 \cdot \text{s}$ if all the liquid water had turned into ice; however, the actual value of $M\bar{\zeta}$ is smaller since the liquid water turns into slush (liquid+ice mixture). Thermocouple measurements at $\sim 6 \text{ cm}$ above the base of the bottle was used to capture the temporal temperature variation as Γ travelled across that location (Fig. 3). In this case, the temperature of the supercooled liquid water (-3.6°C) rose to -0.2°C during the phase transformation.

A snapshot of the vertical variation of temperature across Γ in the bottle, obtained from the thermal imaging camera, is shown in Fig. 4.

Fig 4. Snapshot of vertical variation of temperature during phase transition, with phase boundary Γ at $\sim 3.4 \text{ cm}$.

DISCUSSION

As discussed in our recent theoretical study [3], metastable phase equilibria ($M\bar{\zeta} = 0$) must satisfy the entropy inequality jump

$$[[1/T]]q^\Gamma \cdot n^\Gamma \leq 0 \quad (3)$$

where $q^\Gamma \cdot n^\Gamma$ is the mean (and continuous) heat flux across and normal to the phase boundary Γ . Familiar stable phase equilibrium is the special case when temperature T is continuous across Γ , thus $[[1/T]] = 0$, satisfying eq.(3) unconditionally. In our experiments, supercooling liquid water below 0°C represents a metastable state where the interface between liquid (ℓ) and vapor water (v) + air must satisfy the above inequality. This relation is satisfied either if the air temperature is lower than the liquid and heat conducts from liquid to vapor water, or vice-versa. Experimental measurements of this study (Fig. 1) demonstrated that the v +air temperature dropped below that of liquid water, as soon as the water bottle was placed in the freezer, and until the water spontaneously froze. Thus, prior to the start of liquid-to-ice transformation, temperatures at the liquid-vapor interface satisfied $[[1/T]] = 1/T^\ell - 1/T^v \leq 0$ in eq.(3). For this upright bottle orientation, the water did not reach a supercooled state prior to freezing (Fig. 1). Nevertheless, we can assume that the temperature variation in horizontal bottles decreased similarly, with the v +air temperature dropping much faster than that of the liquid, with the latter eventually achieving a supercooled state (Fig. 2). This thermodynamic description of the metastable state of supercooled water, as per eq.(3) and experimental measurements of this study, has not been given before.

Since the specific entropy s^ℓ of liquid water is nearly zero at freezing temperatures, we have $[[s]] \approx -s^i \approx 1.22 \text{ kJ/kg} \cdot \text{K}$. Now, eq.(1) may be rewritten in the simplified form

$$M\bar{\zeta} = \frac{1}{s^i} \left(\frac{q_n^\ell}{T^\ell} - \frac{q_n^i}{T^i} \right), \quad (4)$$

where q_n^ℓ and q_n^i represent the heat fluxes normal to Γ , in liquid and ice water, respectively. Since $M\bar{\zeta} > 0$ and $s^i < 0$, this constitutive model would be valid only if $q_n^\ell/T^\ell - q_n^i/T^i < 0$ on Γ , which is indeed satisfied by the temperature gradients (Fig. 4, with $q_n^\ell \approx 0$ and $q_n^i < 0$). Therefore, experimental measurements of this study support our constitutive model in eq.(1), under irreversible conditions of rapid phase transition of water to ice.

INTRODUCTION

The use of body armor has been shown to reduce the risk of penetrating injuries among military personnel and first responders [1], [2]. While the body armor decreases the risk of penetrating injuries, ballistic energy can still be transferred through the protective layers, causing backface deformation, and result in injuries to the underlying tissues [3]. These non-penetrating injuries are referred to as Behind Armor Blunt Trauma (BABT).

The National Institute of Justice (NIJ) Standard-0101.06 is an armor test standard widely used to assess the ballistic resistance of personal body armor [4]. Tests are performed by placing the armor over Roma Plastilina No. 1 clay backing, and targeting is based on test specifications. Assuming there is no penetration of the armor, the performance of the armor is assessed by measuring the residual deformation depth of the clay behind the armor. The pass/fail criteria of the armor are solely based on the maximum allowable backface deformation depth of 44 millimeters (mm) for all test conditions. The 44 mm limit was developed in the 1970s for soft body armor applications using a limited series of ballistic impacts on live goats [5]. Although the standard was initially developed for soft body armor, it has been adopted for rigid body armor assessments. Armor plates can alter the resulting backface deformation characteristics compared to soft body armor, which could alter injury tolerance. The standard also does not account for the differing regional thoracoabdominal tolerances to injuries caused by BABT.

The overall objective of this research program was to develop thoracoabdominal regional injury risk curves by applying a hybrid approach utilizing cadaveric swine, live swine, and post-mortem human subjects to update the legacy standard. The development of new standards will aid in assessing and designing body armor and improve BABT safety against current and future threats. The present study was conducted to demonstrate a BABT experimental methodology using an

impact loading indenter to simulate backface deformation with a live swine surrogate.

METHODS

All experiments were conducted in compliance with the Institutional Animal Care and Use Committee at the Medical College of Wisconsin and the Zablocki Veterans Administration Medical Center. Prior approval was obtained from the Animal Care and Use Review Office (ACURO) of the U. S. Department of Defense.

A live swine of approximately 42 kilograms (kg) was used for the experiment. Trachea tubes and intravenous lines were placed following induction of anesthesia using telazol and xylazine. Pressure transducers were placed in each lung and aorta. One transducer was guided into each lung through the trachea tube. To place the transducer in the aorta, a small incision in the neck was made to isolate a blood vessel routing to the aorta. The blood vessel was clamped on one end to allow for a small incision to be made to insert the transducer. The transducer was sutured and secured to prevent movement and blood loss. The placement of lung and heart transducers was confirmed via C-arm radiographic imaging. The swine was connected to isoflurane ventilation for continuous anesthesia delivery for the remainder of the experiment.

A BABT indenter was designed using high-speed flash x-rays to approximate backface deformation profiles produced in body armor from military relevant ballistic rounds [6]. The indenter was launched at the target region using a gas-driven launching system. A triaxial accelerometer (Endevco 7284, Depew, NY) was mounted within the indenter and hardwired to an external data acquisition system (DTS Slice PRO, Seal Beach, CA). The mass of the instrumented indenter was 240 grams. Data from the indenter accelerometer and pressure transducers were recorded at 500 kilohertz (kHz) sample frequency and filtered at 2 kHz with a four-pole Butterworth filter.

The animal was subjected to a single impact to the left thoracic wall between the third and fourth ribs to target the left lung. The animal was placed in a supine position on a lift table so that the impact site was in line with the exit of the launching system. The animal was kept in a continuous surgical state of anesthesia, and vitals were monitored and recorded for six hours post-impact. Upon completion of the six-hour survival window, the animal was euthanized, and a necropsy was performed.

RESULTS

The animal survived the six-hour survival window post-impact. There was an increase in cardiovascular activity immediately following the impact, but vitals stabilized over the course of the survival window. The impact energy was 349 Joules (J), and the indenter peak acceleration was 3844 G. The acceleration time history of the indenter is shown in Figure 1. A contusion occurred at the impact location, but the skin remained intact.

Figure 1: Acceleration-time history of indenter filtered at 2 kHz.

There were fractures at ribs V, VI, VII, and VIII (Figure 2). Additionally, pleural lacerations occurred (not shown). Hemorrhages were seen in the left lung, and lacerations were seen on the lung adjacent to rib VI and VII fractures. Blood aspiration was observed in the right lung (Figure 3). No damage was found in the heart, stomach, liver, spleen, or kidneys.

Figure 2: Rib fractures at ribs V, VI, VII, and VIII (left to right).

Figure 3: Left lung hemorrhages and lacerations adjacent to rib VI and VII fractures.

DISCUSSION

The overall objective of this research program was to develop injury risk curves for different thoracoabdominal regions for BABT-induced injuries. It should be noted that this study focused on one sample to demonstrate the feasibility of using the experimental methodology. While studies have been conducted using live swine and different types of impactors, this study used an indenter design based on backface deformation data recorded using high-speed x-rays on a human cadaver in an earlier study [6], thus adding relevance to the BABT loading. While not reported herein, preliminary experiments were conducted at the three institutions of the authors of this study with swine cadavers and unembalmed human cadavers to add to the feasibility of using the simulated indenter on different surrogates and at different thoracoabdominal regions. In the current study, the injury severity matched a previous study by Liden et al. [3], who reported similar injuries in the left lung from using a 12-bore shotgun with U.S. No. 1 shot against 12-ply Kevlar 29 [3]. Similar injury patterns have been found in a study evaluating hard body armor [7]. Although other studies have shown similar injury patterns to the lungs, the human thoracoabdominal organs and musculoskeletal systems likely have different tolerances to BABT injuries at the same level of insult. Kunz et al. showed fatalities in swine from BABT simulated impacts to the heart at energy impact levels similar to those used in the present study (>300 J) [8]. It is necessary to perform additional tests at injurious and non-injurious impact loading levels to develop region-specific BABT injury criteria. This experimental methodology allows for targeting different thoracoabdominal regions at varying energy levels.

INTRODUCTION

Flow diverters are self-expanding braided stents used in the endovascular treatment of intracranial aneurysms [1]. Nowadays, surgeons choose the device based only on their clinical experience and measurements taken on medical volumetric images, acquired shortly before surgery. However, the configuration assumed by these devices once deployed within the parent vessel is not easily predictable. Given the tight timescale, there is a compelling need to develop computational models capable of simulating in real-time the deployment of flow diverters within patient-specific vessels to assist practitioners in the planning and interventional stages.

The mechanical behaviour of braided stents is typically assessed using a finite element (FE) model where beam elements are used to model the wires [2, 3]. However, due to the large amount of degrees of freedom (DOFs) needed to model accurately flow diverters and the necessity to solve the contact with the arterial wall, the computational time required by FE simulations is very high.

Reduced order modelling (ROM) is a family of methods that aim at reducing the computational complexity of numerical problems by approximating their solution. In practice, these techniques, such as the reduced-basis (RB) method, replace the high-fidelity (HF) model with a reduced-order model characterized by a much smaller dimension. ROM methods have been successfully used before in computer-aided surgery, e.g. to model the arterial blood flow and the heart electrophysiology [4, 5] and predict the thrombectomy procedures outcome [6].

In this study, we propose a machine learning (ML)-based ROM scheme for the prediction of the stent deployed configuration. This is achieved using a non-intrusive ROM scheme that combines the proper orthogonal decomposition (POD) algorithm and Gaussian process regression (GPR). The workflow is validated on an idealised intracranial artery with a saccular aneurysm and the effect of six geometrical and surgical parameters on the outcome of stent deployment is studied.

METHODS

Braided stent model. The braided stent is modelled as a tubular net of thin wires with circular cross-section, whose nodal positions are defined through parametric equations. A generic stent is employed in this study, with radius $R_s = 2.6$ mm, length $L = 15$ mm and composed of 48 wires.

Parametric vessel model. The Visualization Toolkit (VTK) software is employed to build the parametric model. The artery is created as a tube with constant diameter D_v around the vessel centerline. The latter is defined using a planar quadratic Bézier curve:

$$\mathbf{B}(t) = (1-t)^2 \mathbf{P}_0 + 2t(1-t) \mathbf{P}_1 + t^2 \mathbf{P}_2, \quad t \in [0, 1], \quad (1)$$

where $\mathbf{P}_0, \mathbf{P}_2$ are fixed and \mathbf{P}_1 is the control point included in the parametrisation. A spherical idealised aneurysm with diameter D_a is then added to the artery model: the sphere centre \mathbf{C}_a is positioned in the middle of the vessel centerline and the relative y -distance is parametrised.

FE simulations of stent deployment. The stent structure is discretised using beam elements and simulations are performed using EndoBeams.jl, an in-house and open-source FE solver [7]. The procedure of stent deployment within an artery is performed as follows: the braided stent is first crimped by imposing a radial displacement to all its nodes, then bent along the vessel centerline and, finally, deployed by releasing it within the artery. Since we are interested in the final deployed configuration of the stent, quasi-static simulations are performed.

HF database. For the creation of the HF dataset, we considered the following parameters:

$$\boldsymbol{\mu}_B = [y_{\mathbf{P}_1}, z_{\mathbf{P}_1}, D_v, D_a, y_{\mathbf{C}_a}, \eta] \quad (2)$$

where η is the stent deployment site along the vessel centerline. A Latin hypercube sampling method is used to generate N_s different values for $\boldsymbol{\mu}_B$; the corresponding artery models are created and a stent deployment simulation is performed within each model. If given the deployment conditions

the stent is well positioned against the vessel wall and does not land inside the aneurysm, the deployment is considered successful from a clinical perspective. Since there is no clinical need to predict the stent configuration after an unsuccessful deployment, these simulations are excluded from the training. Alternatively, the simulation parameters μ_B are substituted with μ_{cl} where, instead of the middle point of the Bézier curve (\mathbf{P}_1) and the stent deployment site (η), the y and z coordinates of N_{cl} points on the positioned stent centerline are used. The μ_{cl} vector components are calculated geometrically from the deployment conditions and no FE simulation is required.

ROM. Once the database is ready, the snapshots matrix \mathbf{S} is built by arranging the high-fidelity solutions \mathbf{u}_h , containing the nodal displacements at the end of the deployment simulation, as columns of a matrix. The POD algorithm consists in performing the singular value decomposition of \mathbf{S} and extracting, based on an optimal algorithm, the first L left-singular vectors. These column vectors represent the RBs of the model and are assembled in the matrix \mathbf{V} . To compute the projection coefficients, a GPR model is used where the predictors are the parameter values μ and the outputs are the coefficients \mathbf{u}_L , computed starting from the high-fidelity solutions as:

$$\mu \rightarrow \hat{\mathbf{u}}_L(\mu) \approx \hat{\pi}(\mu) \quad \text{trained from} \quad (\mu_i, \mathbf{V}^T \mathbf{u}_h(\mu_i)). \quad (3)$$

Once trained, the model is used to predict the projection coefficients for any desired value of the parameters μ^* , i.e., $\hat{\mathbf{u}}_L(\mu^*)$. This allows recovering the full order solution as $\mathbf{u}_p(\mu^*) = \mathbf{V} \hat{\mathbf{u}}_L(\mu^*) \approx \mathbf{u}_h(\mu^*)$.

Evaluation metrics. For the test cases, the ROM results are evaluated against the HF solutions by computing the absolute prediction error at each node of the stent mesh: $E_p = \|\mathbf{u}_p(\mu) - \mathbf{u}_h(\mu)\|$. The accuracy of a single solution can be evaluated as the average error on the mesh nodes (AE_p) while global variables can be computed by averaging these values on the test dataset (AE_p).

RESULTS

Figure 1: Sensitivity analysis on (a) the predictors used as ML input and (b) the number of training samples.

We started with a dataset with $N_s = 900$ simulations and defined three optimal subspaces with $N_s = \{150, 300, 600\}$. Then, we built four datasets with only the deployment simulations outcomes which are labelled as successful from a clinical perspective, $N_{success} = \{97, 196, 396, 555\}$. We considered a fixed number of samples for testing ($N_{test} = 50$). The spatial resolution of imaging techniques currently used for IAs detection and treatment was considered for evaluating the prediction errors: digital subtraction angiography (DSA) = 0.2 mm, 3D rotational angiography (3DRA) = 0.15 mm. Other imaging techniques show worse spatial resolution.

As visible in Figure 1, the prediction does not benefit considerably by considering a number of RBs greater than 15: in fact, the average prediction error reaches a stable plateau around $L = 15$. It can be noticed in Figure 1(a) that the prediction error is strongly reduced when using μ_{cl}

instead of μ_B : with 3 points along the stent centerline ($N_{cl} = 3$), the average prediction error is 5.65 times lower than when using μ_B . Increasing the number of considered points N_{cl} , the prediction does not improve significantly. We also analysed the influence of the number of train samples on the ROM performance (Figure 1(b)): considering $N_{train} = 146$ instead of $N_{train} = 47$, the average prediction error is 1.92 times lower. No particular improvement is observed when the training set is further expanded.

DISCUSSION

Figure 2: Examples of predicted solution from the testing database.

In summary, using this technique, simulations are achieved within a few milliseconds once the ROM is trained, compared to ~ 1 h required by traditional FE simulations, while retaining the mechanical realism and predictability of the deployed configuration. The impact of these geometrical and surgical parameters on the deployed stent configuration could be predicted accurately even with a low number of RBs (15). As can be seen in Figure 2, the prediction error is evenly distributed and the stent configuration adapts very well to the vessel curvature. The results showed that the GPR is strongly influenced by the input parameters: using the positioned stent centerline (μ_{cl}) as GPR predictors, the average prediction error could be reduced by more than 5 times. With only 47 training samples, we achieved an average prediction error more than 3 times lower than the 3DRA spatial resolution; using 147 training samples, even more than 7 times. This demonstrates the ability of ML and ROM to model the complexity of stent deployment problems.

A limitation of this workflow is the use of a parametric model that reproduces only partially the complexity of patient-specific models: the introduction of more parameters will result in a larger number of bases and thus, require a larger training database. Therefore, specific methods for constructing the training database and alternative ML algorithms need to be considered. A similar scenario could occur by introducing non-rigid arteries. Our current efforts focus on understanding the number of parameters needed to fully describe patient-specific geometries and implementing deformable-wall models within our FE framework.

INTRODUCTION

Coronary artery disease (CAD) occurs when the coronary arteries that supply blood to the heart muscle are blocked or narrowed. The combination of epicardial stenosis (ES) and microvascular disease (MVD) resistances cause sequential obstruction of blood flow to the heart muscle [1-5]. The relative contributions of these resistances must be distinguished for guiding the clinical decision-making process that leads to the selection of the most effective treatment protocol [6, 7]. The functional assessment of intermediate coronary stenosis with or without MVD remains a clinical challenge for interventional cardiologists. Current clinical practice frequently uses diagnostic variables like fractional flow reserve (FFR, the ratio of the mean distal coronary and aortic pressure at hyperemia) and coronary flow reserve (CFR; the ratio of coronary flow at hyperemia to that at rest), which are independent measures of intra coronary pressure and flow respectively. They are both susceptible to being confounded by the presence of MVD; thereby, these indices are unable to distinguish between the hemodynamic condition of concomitant ES and MVD [8, 9].

In order to simultaneously detect ES and MVD, we developed a non-dimensional parameter, the pressure drop coefficient (CDP; the ratio of pressure drop (Δp) across a stenosis to distal dynamic pressure), based on fundamental principles of fluid dynamics which combines pressure and flow measurements. The ability of the CDP to distinguish between stenosis and MVD has been examined, and the CDP cut-offs were initially evaluated to determine the various levels of ES severity using a meta-analysis [10-12].

The *objective* of this research is to determine the limiting value of CDP that can distinguish between patients with ES and MVD using patient level pressure-drop and average peak velocity (APV) data from the multicenter international ILIAS (Inclusive Invasive Physiological Assessment in Angina Syndromes) registry. We *hypothesize* that CDP, provides sufficient diagnostic accuracy for assessing the severity of coronary lesions.

METHODS

The data was extracted from ILIAS registry, which has been established on a global multicenter platform, for improved diagnosis of CAD when combined coronary pressure and flow measurements are used in clinical settings. The registry is made up of 20 reputable medical institutions from 7 different countries and all data were prospectively recorded in accordance with the protocols for individual trials. The registry consists of 2,322 patients enrolled and 3,046 assessed vessel data. Informed consent was obtained from all the study subjects who, based on the inclusion and exclusion criteria, underwent exercise testing and myocardial perfusion scans.

Using standard-of-care catheterization techniques such as coronary thermodilution and doppler flow velocity measurement, intracoronary pressure and APV measurements across the ES were obtained. Doppler flow velocity measurement was used to analyze 1,050 arteries. Patients undergoing coronary thermodilution were excluded from the present analysis, because a direct measure of velocity was unavailable for calculating the pressure drop coefficient (CDP).

FFR is defined as the ratio of the mean distal coronary pressure, p_d and aortic pressure, p_a , at hyperemia (Eq. 1).

$$FFR = \left(\frac{p_d}{p_a} \right)_{\text{hyperemia}} \quad (1)$$

CFR is defined as the ratio of coronary flow at hyperemia to that at rest.

CDP is defined as the ratio of trans stenotic pressure drop ($\Delta p = p_a - p_d$) to distal dynamic pressure, which is the product of blood density (ρ), the square of average peak flow velocity (APV) at hyperemia, and a constant value of 0.5 (Eq. 2).

$$CDP = \frac{\Delta p}{0.5 \times \rho \times APV^2}, \text{ (where } \Delta p = p_a - p_d \text{)} \quad (2)$$

The FFR and CFR were regarded as 'positive' for values of 'less than 0.80' and 'less than 2.0', respectively. The diagnostic performance of CDP with FFR and CFR was compared using a Receiver Operating Characteristic (ROC) curve analysis. The area under the curve (AUC) was calculated after the ROC curves were generated using sensitivity and specificity values with the help of R Markdown software (RStudio Team (2022); RStudio: Integrated Development Environment for R. RStudio, PBC, Boston, MA; <http://www.rstudio.com/>). For predetermined and clinically accepted cut off values of CFR = 2.00 and FFR = 0.80, the accuracy of CDP to successfully predict the outcome of FFR and CFR was calculated. For $p < 0.05$, the results were considered statistically significant.

RESULTS

Figure 1 shows the receiver operating characteristic (ROC) curve, used to determine the optimal CDP cut-off value corresponding to $FFR \leq 0.80$. A total of 464 data points satisfied the criterion for $FFR \leq 0.80$. The area under the ROC curve for CDP (Figure 1A), to predict $FFR < 0.80$, equals 0.88 (95% CI: 0.86 to 0.90, $p < 0.001$), with a sensitivity of 83.40% and specificity of 76.76%. For $FFR \leq 0.80$, the equivalent CDP cut-off value was 26.20.

Similarly, the ROC curves for the subgroups with FFR threshold of 0.8 and CFR threshold of 2.0 were plotted. The area under the ROC curve for the subgroup of $FFR \leq 0.80$ and $CFR < 2.0$ was significant at 0.75 (95% CI: 0.70 to 0.79, $p < 0.001$). Additionally, the area under the ROC curve for the subgroup of $FFR > 0.80$ and $CFR < 2.0$ was significant at 0.65 (95% CI: 0.62 to 0.70, $p < 0.001$). Also, the logarithmic correlation of CDP with combined FFR and CFR was found to be significant with $r = 0.75$, $p < 0.001$.

Figure 2 shows the schematic representation of CDP values to predict combined assessment of FFR and CFR. According to Figure 2, for FFR cut-off of 0.80, the CDP range to predict both physiologically insignificant FFR ($FFR > 0.80$) and CFR ($CFR > 2.0$) is between 0 and 15.78, whereas the CDP range to predict physiologically insignificant FFR ($FFR > 0.80$) and significant CFR ($CFR < 2.0$) is between 15.78 and 26.20. Similarly, the range of CDP to predict physiologically significant FFR ($FFR < 0.80$) and insignificant CFR ($CFR > 2.0$) is between 26.20 and 73.77, whereas the group of both physiologically significant FFR ($FFR < 0.80$) and CFR ($CFR < 2.0$) had CDP values greater than 73.77.

DISCUSSION

The CDP, developed based on fundamental principles of fluid dynamics, has the benefit of being a non-dimensional parameter. It accounts for the relationship between pressure drop and flow across the coronary artery dysfunction. As a result, it can determine the status of an ES, with or without concomitant MVD.

This study establishes the range of CDP cut-off values for distinguishing the four possible combinations of ES and MVD based on the established cut-off values of FFR 0.8 and CFR 2.0: 1) 0 to 15.78 indicating absence of both diseases; 2) 15.78 to 26.20 identifying absence of ES and presence of MVD; 3) 26.20 to 73.77 identifying presence of ES and absence of MVD, and 4) $CDP > 73.77$ indicating presence of both diseases. *Therefore, this multi-center trial further strengthens our hypothesis that CDP could be an improved diagnostic index for decision-making in the cardiac catheterization lab.*

Limitations. The outcomes of the study were presumptive as the patient-level data was extracted from a multicenter, international ILIAS registry, and all clinical decisions were made solely using the FFR, which is now the accepted gold standard. A prospective randomized clinical trial of CDP vs FFR is needed to further assess the clinical

outcome of CDP in relation to FFR and confirm the results from this multicenter trial.

POROELASTIC MODEL OF TRABECULAR STRUCTURES IN THE DEVELOPING HEART

Christine Miller Buffinton (1), James W. Baish (2)

- (1) Department of Mechanical Engineering, Bucknell University, Lewisburg, PA, USA
(2) Department of Biomedical Engineering, Bucknell University, Lewisburg, PA, USA

INTRODUCTION

Trabeculation is a dominant feature of the developing heart across organisms. Trabeculation begins at the end of the cardiac looping phase as myocardial evaginations project from the endocardium toward the jelly (mouse E9.5), progressing to a meshlike network between the central open region and the compact wall (Fig. 1), and finally coalescing with the ventricular wall (mouse E14.5) to thicken the compact myocardium. This timeline encompasses the critical chamber formation and outflow tract (OFT) septation stages. Trabeculae clearly increase ventricle mass and compliance, facilitate oxygen exchange, and increase pumping ability. Their prominence and orientation also suggest a substantial impact on flow through the heart and a role in mechanotransduction. Mechanotransduction mechanisms relating hemodynamic loading to responses at the genetic, molecular, and cellular levels are as yet unknown and likely due to a cascade of responses. Computational models can allow parametric studies and help elucidate dependencies, thus supplementing and better focusing experimental measurements.

Figure 1: Confocal microscopic image of the ventricles of a mouse heart at embryonic day 12.5 (image width = 1.4 mm)

A major challenge with modeling the trabeculated ventricles is that the pore spaces are numerous and small, but not to the extent that a continuum model averaging over countless microstructures can be naively

applied. Although the complete morphology of the trabeculated ventricles can be determined by, e.g., confocal imaging and 3D reconstruction [1, 2], inclusion of the explicit geometry in computational fluid dynamic (CFD) analysis with two-way fluid-structure interaction (FSI) is computationally-intensive, sensitive to thresholding and segmentation settings in image analysis, and does not allow parameter sensitivity studies.

The goal of this study was to provide a computational framework that can be used to study the effects of hemodynamic loading in the chamber formation and OFT septation stages of cardiac development. We analyzed detailed models of single pores and multiple pore systems to recommend and calibrate appropriate continuum models of poroelastic materials, considering alternative formulations of the continuum model to recommend the simplest model that accurately accounts for inertial and viscous effects within the pores. The continuum model is intended to be suitable for use in a whole-organ model where the explicit model would be computationally impractical. Ultimately, the aim is to provide tools for relating results obtainable from the whole-organ continuum model back to the shear and bending stresses expected in the trabecular structures, these stresses being most relevant to the mechanobiological processes guiding development.

METHODS

This study considered CFD FSI models of the trabecular region on three levels (Fig. 2). The first is an idealized single 3D pore with fluid flow through the pore modeled with the full Navier-Stokes equations and the solid structure governed by linear elasticity. Pore geometry was determined from a study of reconstructed confocal images of E12.5 mouse [2], and inlet pressure chosen to match experimentally measured ventricular blood velocity. Calculations of flow and pressure with finite element analysis (COMSOL) yielded an effective fluid permeability, and parameter studies over inlet pressure and elastic modulus assessed the contribution of poroelasticity.

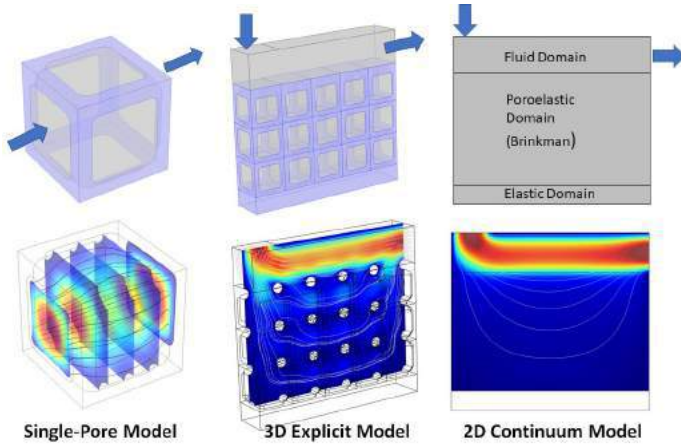

Figure 2. Three levels of model. The single-pore model represents a typical trabecular pore in the developing heart that is surrounded by identical pores (strut diameter=18 μm , pore width=65 μm). The 3D explicit multi-pore model combines several typical pores and exposes the composite structure to an impinging flow from an open domain as might occur where blood in the open center of the ventricular chambers interacts with the heart wall. The 2D continuum model shares the geometry of the multi-pore model, but the porous domain of the wall is now modeled with permeability and stiffness properties that yield the same flow and deformation as obtained from the more computationally intensive multi-pore model.

The second level is an explicit 3D model of a developing heart wall section containing layers of open channel flow, pores, and elastic wall, also analyzed using the full fluid and solid equations (Fig. 2). We examined how free-flowing fluid that impinges on the porous wall from the open chamber of the heart passes through the trabecular spaces. The third level is a 2D continuum model with the same configuration as the 3D explicit model, but replacing the explicit model of the pores with a continuum representation using the Brinkman equation [3]

$$\mu \nabla^2 \mathbf{u} - \frac{\mu}{\kappa} \mathbf{u} = \nabla p \quad (1)$$

relating the average velocity \mathbf{u} , fluid pressure p , and viscosity μ to the effective fluid permeability κ that was determined from the single pore model.

RESULTS

For a rigid structure, the permeability estimated from the single pore model was typically $9 \times 10^{-11} \text{ m}^2$ ($\pm 3\%$) over the range of velocities 4–21 mm/s. Deflection of the pore structure due to elastic effects decreased the permeability by only 17–24%. Solid stress was largest at the junction of the trailing vertical and horizontal struts, with maximum of 250x inlet fluid pressure, while wall shear stress (WSS) was largest on the curved inner cylindrical surfaces of the struts and approximately equal to inlet pressure.

The 3D explicit model showed that most fluid flow was contained in the open channel, with 21% entering the porous region. Half of this flowed through the first pore layer underneath the open channel. Maximum velocity was 1.6 mm/s in the center of the inlet for 1 Pa inlet pressure. Porous layer velocity was small, with increases when flowing through the narrowed regions between trabeculae. Solid stress was largest in the radii at the junction of horizontal and vertical struts, while WSS was largest on the top curved edges of the upper layer of pores (1.6x inlet pressure).

Flow patterns in the 2D continuum model were similar to those of the 3D model, 21% of inlet flow entering the porous region and 1.9 mm/s maximum velocity. The largest fluid velocity in the porous region was near the porous-open interface. The fluid volume entering porous could be matched with $5.4 \times 10^{-11} \text{ m}^2$ permeability. WSS was maximal at the inlet and outlet channel walls. The results were relatively insensitive to changes in Brinkman region elastic modulus and porosity within a reasonable physiological range. A tenfold increase in permeability, from 10^{-11} to 10^{-10} m^2 , caused only a small reduction in maximum stress, a 1.5x increase in maximum flow velocity, and an 18x increase in volumetric flow rate into the porous region.

Figure 3. Relative solid stress with deflection in the single pore model (left), and wall shear stress on trabecular struts in the 3D explicit model (right), with maximum values shown in red.

DISCUSSION

In general, we found that the effective fluid permeability based on porosity ϵ was well estimated by the Kozeny-Carman relationship [3]

$$\kappa = \frac{\epsilon^3}{G s_0^2 (1-\epsilon)^2}, \quad (2)$$

where G depends on the shape of the pores and s_0 is the wetted surface area to solid volume ratio. We confirmed that small differences in the estimated porosity and pillar dimensions have a dramatic effect on the effective permeability. The changes in porosity and shape due to elastic deflections, while not negligible, were relatively small and insensitive to the elastic modulus compared to the uncertainties inherent in the initial estimation of the porosity and strut diameter. We also found that the fluid velocity and inertial effects diminish rapidly away from the porous-open interface, which would allow use of the simpler Darcy's equation (Eq. 1 without the first term) deep into the wall, but that the full Brinkman equation was appropriate near the interface where fluid shear stresses are highest and likely produce the strongest mechanotransduction effects.

Results from the single pore model compared favorably to our CFD analysis of image-based reconstructions of sections (150- μm cubes) of trabecular region from E12.5 mouse. These confirm that a small change in strut diameter causes a large change in fluid permeability.

The results of the present study are being used as the basis for model of the entire developing heart where trabecular structure will be represented by an equivalent poroelastic continuum. The simplifications made possible by this study will facilitate an efficient parametric study of congenital defects in the heart flow paths and the resulting solid and fluid stresses.

DESIGN AND CHARACTERIZATION OF A SILICONE VENOUS VALVE MODEL

Matthew S. Ballard (1), Dallin Brimhall (1), Sarah Dayley (1) and Andrew Rasmussen (1)

(1) Department of Engineering, Utah Valley University, Orem, Utah, USA

INTRODUCTION

Venous valves act as a series of miniature pumps to aid blood in returning to the heart from the lower extremities against the pull of gravity. Fluid pressure oscillations from contractions of the skeletal muscles surrounding the vein cause the valves to open to allow forward flow, and to close to prevent backward flow. While venous valves are vital to proper circulation, they are also a known location of the formation of thrombi in the deep veins, a condition known as deep vein thrombosis (DVT). While DVT can lead to pain and swelling, its chief risk is that thrombi can break free and travel through the circulation to ultimately block blood flow to the lungs, giving a condition known as a pulmonary embolism (PE). PE is a leading cause of death in the United States and has been estimated to cause approximately 200,000 deaths annually, which is likely a conservative figure since PE can be difficult to detect and thus is often not recognized [1]. The presence of DVT, PE, or both is also known as venous thromboembolism (VTE). Individuals who experience an extended period of immobility, such as hospital patients and long-haul plane passengers, are especially at-risk for VTE.

Despite the severity and prevalence of VTE, the effect of valve morphology on flow conditions through venous valves has remained largely unknown. Recently, a numerical model was used to investigate the effect of morphological factors such as the stiffness, length and shape of valves on the resulting flow conditions [2]. In this work, we develop and demonstrate a physical silicone model for use in validating the numerical model and in expanding the capability of testing the effect of valve morphology on disease-conducive flow conditions. Specifically, we reproduce the geometrical features and boundary conditions used in the numerical model to compare experimental and numerical findings. We experimentally reproduce results that show how valve stiffness and three-dimensional (3-D) shape affect the ability of valves to allow forward flow and block reverse flow. Further, we introduce particles into flow through the venous valve silicone model to elucidate the effect of valve morphology on disease-conducive factors

such fluid residence time. Results of this study make progress toward providing doctors with the information needed to better identify at-risk patients for whom they should take preventative measures against VTE.

METHODS

The vein and valve geometry used in this study is a simplified venous valve region consisting of a rigid sinus vessel containing water and a flexible bi-leaflet valve taking the shape of two planes intersecting the vessel. Leaflet tips are crescent-shaped with a sinusoidal cutout of depth δ , as shown in Figure 1. A pressure gradient is applied across the vessel by attaching the open ends of the vein test section to water lines at pressures applied using a pressure controller (Elveflow OB1). The model recreates the geometry and conditions previously studied numerically [2], to directly compare to numerical results.

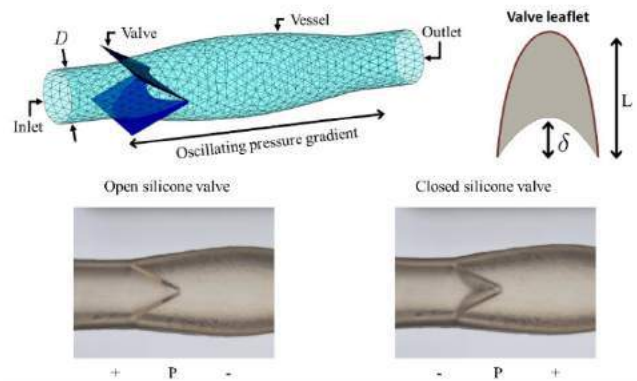

Figure 1: Simplified venous valve model. Bottom images show the silicone venous valve silicone model open (left) and closed (right) due to applied fluid pressure gradients

Parameters varied in this study are the valve length L , depth of the crescent at the valve tip δ , valve thickness, and applied pressure gradient ΔP . Relevant parameters varied in this study are characterized and reported in terms of dimensionless parameters, namely the aspect ratio $A = L/D$, the depth of cut $D_c = \delta/L$, and the dimensionless stiffness K [2,3]:

$$K = \frac{4 k_b}{\pi D^3 \Delta P} \quad (1)$$

The silicone venous valve model is created as a single piece using a molding process. A computer-aided design (CAD) model of the negative of the silicone model is created to give the desired geometry. The CAD model is sliced and then used by a stereolithography (SLA) 3-D printer (Elegoo Mars 3) to create a four-part mold (Figure 2) consisting of a two-part mold for the outer vessel wall and a two-part mold of the inner vessel wall and valve leaflet geometry. Printed molds are post-processed through cleaning with alcohol, followed by post-curing and polishing. Finished molds are coated to prevent curing inhibition of the silicone. Liquid silicone (Smooth-On Ecoflex 00-31 Near Clear) is then degassed and poured into the mold, then cured for 24 hours in a pressure pot at 10 psig.

Figure 2: CAD model of geometry used to 3-D print a mold, which is used to create silicone model of vein and valve

In this study, a numerical model is also used to compare experimental and numerical results [2]. Briefly, the numerical model is a fully-coupled 3-D fluid solid interaction (FSI) model using a lattice-Boltzmann method (LBM) [4] for the fluid mechanics, and a lattice spring method (LSM) [5] for the solid mechanics. The LBM and LSM models are fully-coupled via appropriate boundary conditions [3,6].

RESULTS

A numerical model was previously used to study the effect of valve morphology on the ability of venous valves to properly open and close to allow forward flow and block reverse flow [2]. This model showed that valves with low A , low K and high D_c are most effective at allowing forward flow and preventing backward flow, provided that they have enough material to allow for proper closure. For example as seen in Figure 3, numerical simulations showed the effect of D_c and A on the ability of fluid to flow through the valve. Figure 3a shows the resistance that a valve gives to forward flow, normalized by flow resistance in a valve-less vein section. The three curves representing various values of K demonstrate that the resistance to forward flow increases with increasing K . From this plot, it is also evident that forward flow resistance decreases with increasing D_c . Figure 3b shows the normalized conductance of reverse flow with varied D_c and K . Here, significant conductance means that the valve did not close well

enough to block reverse flow. Figure 3b shows that a valve with D_c of about 0.25 or less is predicted to adequately close over a significant range of K , while higher D_c can result in regurgitation since the crescent tip is too deep to adequately close. For $D_c > 0.25$, high K results in increased regurgitation as compared to lower K valves.

Figure 3: Numerical results to which silicone model will be compared. For constant $A = 1.25$, effect of D_c and K on a) valve resistance to forward flow and b) valve conductance of reverse flow

In this study, we use the silicone venous valve model to reproduce the conditions from the numerical model to reproduce the numerical results, including the plots from Figure 3. This provides additional validation of the numerical model, and demonstrates that the silicone model is designed and operating as expected.

DISCUSSION

Comparing the numerical and physical models not only provides the ability to ensure accuracy of both models, but also allows the two models to complement each other in providing a more complete picture of the behavior of venous valves than either could provide on its own. For example, particles are introduced to flow through the silicone model demonstrated in this study to investigate the residence time of particles in the venous valve region, as well as locations where they tend to adhere to solid surfaces. Additionally, this silicone model can be used to develop and test VTE intervention strategies such as active compression devices. Thus, the use of this silicone venous valve model can provide insight into risk factors that can alert doctors of the need of preventative measures, and can also inform the effective design of preventative technologies.

REGIONAL HETEROGENEITY IN THE BIOMECHANICS OF HUMAN AORTA

M.Kazim (1), S.Razian (1), D.Varandani (2), M.Jadidi (1)

INTRODUCTION

Aorta is the largest conduit in the human body that acts as a buffering chamber to distribute blood to the peripheral organs and tissues. It starts as the ascending thoracic aorta as it leaves the left ventricle, travels down the thorax and abdomen, and branches into common iliac arteries. Due to the structural inhomogeneity, varied blood flow, and kinematic constraints on the aortic wall from the spine, different vascular disorders are more prone to occur at certain locations than others. For instance, the aneurysm is more commonly observed at the abdominal aorta (AA) and thoracic aorta (TA). In contrast, calcification is first observed at the AA and iliofemoral artery [1]. Given the important role of arterial mechanical and structural properties on its physiologic and pathophysiologic response, a better understanding of the aorta biomechanics can help explain disease development and progression at specific locations along the aorta and develop improved vascular repair materials and devices.

Prior *in vivo* studies demonstrated that aortic stiffness is greatest at the abdominal aorta and least at the aortic arch [2]. While these studies provided valuable information about the aortic biomechanical environment, they rely on surrogate measures of stiffness and cannot reliably estimate the intrinsic arterial wall properties while accounting for the residual and physiologic deformations [3]. *Ex vivo* techniques, on the other hand, allow for determining the intrinsic anisotropic aortic stiffness and assessing its structure. Comprehensive *ex vivo* analysis of arterial properties along the aortic tree has been carried out in animal models [4]. However, animals differ from humans in many factors, and a comprehensive study of human aorta biomechanics along its length is warranted. Human studies from diverse samples have mostly been centered around one or two locations, such as the abdominal and thoracic region, or compared specimens from different subjects [5]. Our objective in this study was to determine the morphological, structural, and mechanical properties of the aorta and iliac arteries at different

anatomically important locations and study how these properties vary within the arteries of each subject.

Figure 1: (A) Aorta along the length demonstrating locations used in mechanical and structural analysis. (B) Kinematics of the aorta in the loaded configuration under axial pre-stretch and luminal pressure. (C) The arterial specimen transected from the body. (D) The residual stresses are released when the load-free specimen is cut radially. (E) schematic of planar biaxial testing.

METHODS

We obtained 108 specimens from 20 cadaveric human aortas and iliac arteries (51.8 ± 18.12 years, mean \pm SD) within 24 hours of death. Samples were tested fresh within 12 hours of procurement. First, arteries were dissected from their surrounding tissues, and visual and palpatory analysis was done on the vessels to record the extent and spread of the vascular disease. If the artery did not have significant

calcification along its circumference or blood clots, it was used for further mechanical testing and structural evaluations.

Specimens were cut from the descending thoracic aorta (TA), supraceliac aorta (SC), infrarenal aorta (IFR), distal abdominal aorta (dAA), common iliac (CI), external iliac (EI), and internal iliac (II) arteries (Figure 1). We measured the morphometric characteristics, including the thickness (h), and inner and outer radius of the load-free ring (ρ_{int}, ρ_{adv}), the thickness (H), intimal and adventitial lengths (L_{int}, L_{adv}), and the opening angle of the stress-free cut ring (α), and the opening angle of the stress-free longitudinal strip (β), using a custom-written software in Visual Studio C#.

From each anatomical location, specimens were cut from the lateral region of the wall for mechanical tests. The intrinsic passive mechanical properties of the tissues were determined by applying multi-ratio biaxial protocols using a CellScale BioTester while samples were submerged in 37°C phosphate-buffered saline (PBS).

Samples used in morphometric assessments were fixed in methacarn, dehydrated in ethanol, and embedded in paraffin for histological analysis. Slides were cut from each paraffin block and stained with Movat to assess the Extracellular Matrix (ECM) structure.

Statistical analyses were performed in Jamovi 2.2.5 to investigate the possible differences in the morphological characteristics of the seven anatomical locations. First, we assessed the normality of the data and then used Repeated Measures of Analysis of Variance (ANOVA) or Friedman's nonparametric tests to compare the locations. A p -value <0.05 was considered statistically significant.

RESULTS

We observed that in 30-50 years old aortas, soft plaques were distributed inhomogeneously at the lateral section of IFR till the dAA. In 50-60 years old aortas, we observed soft plaque localizing at the posterior TA extending to the medial and lateral quadrants of SC. Around this age, we also observed calcification at dAA. Subjects older than 60 displayed circumferential disease at the dAA, and plaques at the medial region at CI and II, while EI showed almost no sign of disease.

Figure 2: (A) Changes in the load-free ring and stress-free cut ring thickness, (B) decrease in the intimal and adventitial radius of the load-free ring, and (C) stress-free cut ring's length. Boxplots represent the 75th and 25th percentiles, with endpoints of whiskers corresponding to the 5th and 95th percentile. The size of the dots corresponds to the subject's age.

Overall, the inner and outer radius of the load-free ring and stress-free ring length decreased along the aortic length from TA to II (Figure 2). The average load-free thickness remained relatively constant until SC at 2.87 ± 0.4 mm. It remained stable in the abdominal region with a minimal decline till EI and a subsequent increase in II (2.05 ± 0.3 mm to 2.28 ± 0.61 mm). While we observed a gradual decrease in the thickness, radii, and length, statistically, the aortic locations were not different but showed a variation below the common-iliac bifurcation ($p < 0.05$). TA was the only location that differed from IFR and dAA in radius and length ($p < 0.001$). The circumferential opening angle remained

relatively constant at $228.86 \pm 86.60^\circ$, while a difference between locations was only observed after the aortoiliac bifurcation. The longitudinal opening angle, on the other hand, remained constant until IFR at $291.22 \pm 30.57^\circ$ and subsequently decreased in CI.

In terms of mechanical behavior, overall, longitudinally, in younger samples, we observed TA to be more compliant than the other locations. This was closely followed by dAA, IFR, and CI. The circumferential compliance decreased throughout the length of most arteries, and TA was more compliant than other locations (Figure 3).

Figure 3: Representative experimental equibiaxial stress-stretch response of a 71-year-old male in the (A) longitudinal and (B) circumferential direction.

Figure 4 shows representative histological images demonstrating changes in the ECM structure throughout the aorta and iliac arteries. We observed that elastin content decreased throughout the length while collagen content increased.

Figure 4: Structural changes along the aorta and iliac arteries of a 37-year-old male subject.

DISCUSSION

Our results demonstrate that there is a difference in the disease formation along different aortic locations, which may have originated from different blood flow conditions, structure, and mechanics along the vessel. The presented data can help better understand the aorta physiology and pathophysiology and inform the development of better repair materials and devices.

ACKNOWLEDGEMENTS

We wish to acknowledge LiveOn Nebraska for their help and support in collecting the blood vessels and thank donors and their families for making this study possible.

INTRODUCTION

Stroke has a high prevalence in society, affecting 1 in 4 adults over the age of 25 globally [1]. The majority (~87%) of strokes are ischemic in nature, which occur due to a thrombus obstructing blood flow in a cerebral artery. These thrombi can occur *in situ*, or more commonly as emboli [2]. The trajectories of emboli *in vivo* is hypothesized to be influenced by their size, mechanical properties, and cerebral blood pressure [3,4]. Understanding the dynamics of emboli has important implications in the treatment of Acute Ischemic Stroke (AIS), as the final occlusion location of a thrombus is directly associated with the degree of neurological severity experienced by the patient [5]. *In-vitro* simulations of embolic occlusion formation in the anterior circulation can provide critical insights to gain a better understanding of thrombus dynamics in AIS patients.

To date, limited research has been conducted investigating the trajectories of emboli *in-vitro*. Previous *in-vitro* testing has been completed in simplified models, which failed to include the geometry and characteristics of known vessel sites for stroke occurrence [6]. These models also failed to accurately recreate physiological pressure conditions [5] and or to use suitable thrombus analogues [7], limiting the translation of the results.

The deformation patterns of thrombi have been hypothesized to be associated with their composition [11]. Understanding the influence of composition on thrombus deformation may have important implications in the choice of AIS treatment, as thrombi may possess varying responses to different mechanical thrombectomy treatment approaches.

The aim of the present study is to investigate the influence of thrombus size, mechanical properties, and cerebral blood pressure on the trajectory of emboli *in vitro* in patient specific models.

METHODS

A design of experiment (DoE) response surface model, with a central composite design was conducted using Design Expert (Statease®). Three factors were identified for inclusion in the experimental design: thrombus size, mechanical properties, and systolic blood pressure (SBP). The experimental design space was created with a high and low setting, a center point, and two axial points for each factor. This resulted in five different levels for each factor: thrombus size (0.09g, 0.2g, 0.4g, 0.6g, 0.7g), mechanical properties, controlled by varying the composition of red blood cells (RBCs) in the thrombus (5%, 11%, 22.5%, 34%, 40%), and SBP (120mmHg, 130mmHg, 150mmHg, 170mmHg, 180mmHg). 40 runs were completed in total, with a minimum of 2 replicates per run.

Platelet-contracted clot (PCC) analogues with various compositions, determined by the percentage of RBCs used in clot preparation (5-40%), were assembled from ovine blood [8]. Ovine blood was selected as it has been shown to be an appropriate substitute for human blood in coagulation studies [9] and the clot analogues produced following this methodology have been shown to be histologically comparable to human clots [8,10]. The thrombus analogues had a diameter of 9 mm (± 1 mm) and were cut to a pre-defined weight (0.09-0.7g).

An *in-vitro* patient specific silicone model was used to represent the cerebral anatomy. The model consisted of the complete intracranial circulation, including a complete Circle of Willis, anterior and posterior communicating arteries, distal circulation up to M3 segment of the middle cerebral artery, and extracranial circulation, including both carotid, basilar, and vertebral arteries, the aorta and aortic arch, and vessels to simulate femoral access. A glycerol/water blood mimic was

circulated in the model at 37°C, to simulate *in vivo* conditions. The range of SBP between 120-180mmHg was selected based on patient physiological data (n=20) provided by Hôpital Foch (Paris, France). Clots were introduced into the model via the ascending aorta, to simulate embolization from the heart. The distance from the proximal clot face to the Carotid Terminus (mm) was used as a metric to evaluate thrombus embolization after 15-minutes.

RESULTS

Each factor: thrombus size, mechanical properties, and SBP, was found to have a significant influence on the trajectories of emboli *in vitro* ($p < 0.01$). Figure 1 a) & b) shows the significant impact RBC content had on the ability of thrombi to deform and embolize distally. Figure 2 a) displays the linear relationship between SBP and the extent of embolization, independent of clot size and mechanical properties. Smaller thrombi with increased RBC content were more likely to occlude a vessel within the distal vasculature (see Figure 2b). Thrombi with higher RBC compositions, lower weight and under higher physiological pressures embolized further in the *in vitro* model.

Figure 1: a) 0.2 g clot made from a blood mix with 34% RBC under 130mmHg, b) 0.2 g clot made from a blood mixture with 11% RBC under 130mmHg. These images show the effect of RBC content on the final occlusion location of the same size thrombus.

Figure 2: a) Graph displaying linear relationship between SBP (mmHg) and thrombus distance from the Carotid Terminus (mm), b) 3D-heat map showing the effect of RBCs (%) and size (g) on thrombus embolization *in vitro*.

DISCUSSION

The composition of thrombi impacts their mechanical properties, by altering their morphology [8], and thus, their ability to deform and travel distally. Thrombi may be described in various ways based on their composition, one common approach divides thrombi into RBC-rich and fibrin-rich thrombi. In this study, we found that thrombi rich in RBCs were more likely to travel further distally in comparison to fibrin-rich thrombi (Figure 1). These results may be explained by the well reported

associations between composition and mechanical properties [8,12]; where thrombi rich in fibrin have been found to have a greater coefficient of friction, increased stiffness, and higher fracture toughness in comparison to RBC-rich thrombi, which may limit their ability to deform and embolize distally. The fibrin network in thrombi provides mechanical strength to the thrombus, reinforcing its structural integrity [8]. RBC-rich thrombi in comparison, have been shown to have higher tendencies for fragmentation due to their limited fibrin network. We only observed fragmentation during embolization (n=4) in thrombi with medium-to-high RBC content (22.5%, 34% and 40%). Interestingly, all fragmentation events occurred in the same location, the Carotid Terminus. At this location, thrombi experienced tension in two directions via the fluid flow, towards the A1 segment of the anterior cerebral artery and M1 segment of the middle cerebral artery. Overall, our findings suggest that at constant pressure, thrombi with different composition must be of different sizes to create an occlusion in the same location, as a result of their differing mechanical properties.

The deformability of thrombi is also an important factor during retrieval. In AIS treatment, thrombus retrieval is primarily performed via two techniques: stent retrieval (SR) or contact aspiration (CA). The mechanisms by which these devices interact with thrombi differ; SRs aim to achieve interaction of the whole thrombus between struts to optimize retrieval, while CA interacts with the proximal face of the thrombus only to achieve retrieval [11]. It is hypothesized that the appearance of the shape of the thrombi at the occlusion site may be a prognostic factor for the success of retrieving the thrombus with different techniques [11]. However, there is currently much debate surrounding this topic. If the shape of the thrombus can be associated with the mode of deformation during embolization, and in turn used to predict the behavior of the thrombus during retrieval, it could aid selection of the optimum procedural approach. Investigating this link between thrombus shape and mechanical properties is ongoing at our lab. Future work will examine the interaction between the mechanical properties of the thrombus, inferred by its composition, and choice of retrieval technique to better understand this relationship.

In conclusion, as visualization of thrombus embolization *in vivo* is challenging, realistic thrombus analogues combined with representative *in-vitro* models are critical to better our understanding of thrombus dynamics in AIS [12]. These results provide an important insight into the influence of thrombus size, mechanical properties, and cerebral blood pressure on thrombus occlusion dynamics *in vitro*.

INTRODUCTION

The identification of atherosclerotic plaques prone to cause myocardial infarction (MI) is a clinically relevant problem. The anatomical evaluation of coronary lesions still plays a fundamental role in clinical decision making, although a functional approach based on intravascular pressure gradients evaluation, measured in terms of fractional flow reserve (FFR), has emerged as an effective risk assessment tool [1].

Recalling the Bernoulli's principle, the presence of a lumen narrowing within the vessel is not only associated with a translesional pressure drop, but also with intravascular blood flow energy conversion/transformation involving kinetic energy. In the complex scenario of cardiovascular flows, the energy transformation process may also lead to a production of rotational energy [2]. Moreover, the blood pressure gradient caused by lumen narrowing impacts the shear forces acting at the blood-endothelium interface, i.e., the wall shear stress (WSS). In this regard, WSS has been reported to be associated with intravascular flow features [3], with plaque progression and destabilization [4], and ultimately with future MI [5].

Motivated by the fundamental fluid mechanics theory as well as by previous observations [2], here we investigate the capability of blood flow energy profiles in diseased coronary arteries to predict MI within 5 years by applying a recently proposed angiography-based computational fluid dynamics (CFD) strategy [5].

METHODS

Patient population. Patients presenting with MI were retrospectively selected according to three main inclusion criteria: (1) a previous coronary angiography performed between 1 month and 5 years before the event (baseline angiography); (2) a visually recognizable mild stenosed lesion (i.e., less than 50% diameter stenosis) culprit for future MI (FC) at the baseline angiography; (3) at least one additional lesion, non-culprit for the future MI (NFC) in the other major epicardial

vessels. This selection resulted in 80 patients and 188 diseased coronary arteries with 80 FC and 108 NFC lesions.

Vessel reconstruction and computational hemodynamics. The 3D geometry of each coronary artery was reconstructed from two angiographic projections. Then, the discretized governing equations of fluid motion were solved under unsteady-state conditions using the finite volume method, as detailed elsewhere [5].

Myocardial infarction predictors. By using a quantitative coronary angiography (QCA) approach, the lesion segment was identified as the one containing the minimum lumen area (MLA) and delimited by the proximal and distal intersection of the interpolated reference line with vessel area line (Figure 1).

Figure 1. Lesion and sections definition based on QCA.

In addition to the clinically adopted anatomical and functional quantities percentage area stenosis (%AS) and translesional virtual FFR ($\Delta vFFR$), and to the WSS-based quantity topological shear variation index (TSVI, recently emerged as a strong predictor for MI on the same dataset [5,6,7]), blood flow kinetic and rotational energy production in the converging flow segment of the lesion were tested as possible MI

predictors in coronary arteries. Technically, the amount of kinetic energy was quantified in terms of specific kinetic energy (KE_u). The amount of rotational energy was quantified in terms of enstrophy (ε):

$$\varepsilon = \frac{1}{2} |\boldsymbol{\omega}|^2 \quad (1)$$

where $\boldsymbol{\omega}$ is the vorticity vector. Then, the transformation of kinetic and rotational energy within the converging flow segment was quantified in terms of kinetic energy ratio (KER) and rotational energy ratio (RER):

$$KER = \frac{\frac{1}{S_{MLA}} \int_T \int_{S_{MLA}} KE_u dS dt}{\frac{1}{S_{Prox}} \int_T \int_{S_{Prox}} KE_u dS dt} \quad (2)$$

$$RER = \frac{\int_{S_{MLA}} \int_0^T \varepsilon dt dS}{\int_{S_{Proximal}} \int_0^T \varepsilon dt dS} \quad (3)$$

KER and RER quantify the change of kinetic and rotational energy, respectively, occurring between the narrowest section of the vessel (i.e., MLA) with respect to a healthy section (i.e., proximal section), as defined in Fig. 1.

Statistical analysis. Differences between FC and NFC lesions for continuous variables was tested using Mann-Whitney's U test. The area under the curve (AUC) of receiver operating characteristic (ROC) curves and DeLong test was used to assess the predictive power of each variable. Statistical significance was assumed for $p < 0.05$.

RESULTS

The distribution of ε and KE_u averaged over the cardiac cycle is visualized within all vessel and at MLA and proximal section for two representative cases (one FC and one NFC lesion) in Figure 2. In general, FC and NFC vessels presented comparable values of ε and KE_u on the proximal section while FC lesions exhibited markedly higher values of ε and KE_u at the MLA section, compared to NFC lesion.

Figure 2: Enstrophy (ε) and specific kinetic energy (KE_u) volume and surface (at proximal and MLA sections) visualization for two explanatory cases (one FC and one NFC lesion).

The analysis highlighted that FC lesions were characterized by significantly higher KER (5.59 [3.59-7.69] vs. 3.37 [2.58-5.13],

$p < 0.0001$) and RER (6.59 [3.92-9.63] vs. 3.67 [2.60-5.16], $p < 0.0001$) values, compared to NFC lesions. From the analysis of ROC curves (Figure 3) it emerged that RER and KER were strong predictors for MI at 5 years (AUC=0.76, 95% CI 0.70-0.83, $p < 0.0001$ and AUC=0.74, 95% CI 0.67-0.81, $p < 0.0001$, respectively). The clinical parameters %AS and $\Delta vFFR$ resulted also significant predictors of MI (AUC = 0.65 95% CI 0.56-0.72, $p = 0.0008$ and AUC = 0.63 95% CI 0.55-0.71, $p = 0.0030$, respectively) though significantly weaker than RER (DeLong test: $p = 0.0042$, $p = 0.0059$, respectively) but not KER (DeLong test: $p = 0.0620$, $p = 0.0519$, respectively). Finally, TSVI emerged as the strongest predictor of MI at 5 years (AUC=0.77, 95% CI 0.71-0.84, $p < 0.0001$), but not significantly stronger than RER and KER (DeLong test: $p = 0.8927$ and $p = 0.2982$, respectively).

Figure 3: Receiver operating characteristic (ROC) curves for myocardial infarction (MI) prediction.

DISCUSSION

This study compared the predictive power of blood flow energy-related quantity with clinically used parameters and the WSS-based descriptor TSVI, which has been identified as a strong predictor of MI. The main results can be summarized as follow: (1) RER and KER were strong predictors of MI at 5 years; (2) RER was a significantly stronger predictor of MI than clinically used parameters; (3) RER and KER presented a predictive capacity for MI comparable to TSVI.

Blood flow energy conversions/transformations was related to the geometry of the lesion: the converging flow segment imparts a transformation of pressure in kinetic energy ($KER > 1$ in all vessels) and a decrease of pressure ($\Delta vFFR > 0$ in all vessels), consistently with Bernoulli's theorem that links variation of pressure and velocity. The results on rotational energy expand recent observations of abnormal vorticity profiles in diseased coronary arteries [3], providing a direct link with clinical outcome which was previously only inferred.

In conclusion, blood flow energy conversions/transformations in coronary lesions resulted a strong predictor for future MI. These findings encourage further study on blood flow energy transformation using angiography-based CFD models, suggesting the addition of quantitative intravascular flow characterization to $vFFR$ and WSS in the next-generation clinical decision making tools available to interventional cardiologist.

INTRODUCTION

Adherent cells in several tissues and organ systems such as lungs, arteries, and cartilage undergo cyclic stretch and actively respond to changes in mechanical stimuli, which play an important role in regulating cellular form and tissue function [1]. The ability to mimic the complex, biomechanical environment experienced by cells and tissues *in vivo* is a crucial to better understand variations in tissue properties under stretch and characterize them in disease contexts such as fibrosis. Key requirements in the design of stretching devices for such applications are the abilities to independently control the amplitude and frequency of stretch in orthogonal directions mimicking deformations relevant to biological applications, maintain strain homogeneity in thin planar materials, and be compatible for high resolution optical imaging for real-time data acquisition during experimentation. Existing cell stretchers have some of these features but are limited to either equibiaxial or uniaxial stretching, use large amounts of cell media (increasing expenses), or use out-of-plane actuation that makes real-time imaging difficult [2-4]. To address these limitations, in this work, we have developed and validated a pneumatically controlled cell stretcher with independent control of strain in two directions of a membrane. In-plane actuation geometry allows real-time microscope imaging during actuation. Our biocompatible device is sized similarly to standard 60-mm petri dishes, making it compact and lightweight.

METHODS

The design of the biaxial cell stretcher is depicted in Figure 1-i). Four vacuum cavities generate two-directional stretch, with two opposing cavities connected to a single pneumatic channel to ensure uniform strain in each direction. All cavities (34-mm inner diameter, 64-mm outer diameter) and stretching membrane (0.4-mm thickness) are made of polydimethylsiloxane (PDMS) Sylgard 184 (Dow Corning, USA) with base to cross-linker ratio 17.5:1. The mechanical properties of the PDMS (17.5:1) were characterized by uniaxial testing. Vacuum pressure driven shrinkage of the inner shell of cavities stretches the membrane that is attached to the shell's bottom. Rigid stickers at the edges of the membrane guide the deformation of the membrane to enable uniform strains [2]. The base is made by stereolithography (SLA) 3D printing and cured in an oven at 70°C for 24 hours to ensure

biocompatibility. This base enable mounting on an inverted microscope stage for live-cell imaging. We used uncured PDMS to bond the individual components together. For the control system, an Arduino with MPC4725 is used to generate 0-5V analog signal that is input to an Alicat Electro-pneumatic Transducer (PCD-series) to control the pressure from 0 to 100 psi. By means of vacuum generator (Festo VAD 1/4), the pressure is transferred to vacuum pressure and then connected to the actuator to generate shrinkage of the inner shell of the cavity. The in-plane membrane strains were quantified by tracking fiducial markers on PDMS using a particle tracking algorithm [5]. All materials in contact with culture media were tested separately for biocompatibility. We also tested for biocompatibility of the entire system by performing live-dead staining on 3T3 fibroblasts cultured using DMEM +10% FBS+1% PenStrep inside the cell stretcher system for 24 hours under standard culture conditions (37°C, 95% humidity, 5% CO₂).

RESULTS

Uniaxial tensile tests on the 17.5:1 PDMS membrane measure a Young's modulus of 303.26 ± 11.56 kPa and an elongation at break of 240%. We used these parameters to predict the strain fields on the membrane under different vacuum inputs using Finite Element (FE) simulations by COMSOL (Figure 1h-1j).

We validated the actuation of the stretcher under sinusoidal loading. We compared three cases – uniaxial, equibiaxial and non-equibiaxial loading – and experimentally quantified the in-plane strains in each case. The maximum strain amplitude was maintained to be 7% in each case. From Figure 1e-1g, we observe that the device has a stable and repeatable sinusoidal response to the loading input. Figure 1e indicates the uni-directional stretching in x-axis can cause a heterophase strain change (~2.4%) in y-axis caused by the Poisson ratio of the elastomer membrane. [5] FE simulations shown in Figure 1h shows uniform strain in the middle working area with average E_{11} of 7.1% and E_{22} of 2.2%, corresponding well with experimental measurements. Figure 1f indicates that the stretcher can produce equibiaxial strains when the input air pressure is the same in both channels. Figure 1g demonstrates the stretcher can generate different strain in two directions independently, allowing the investigation of unique phenomena in

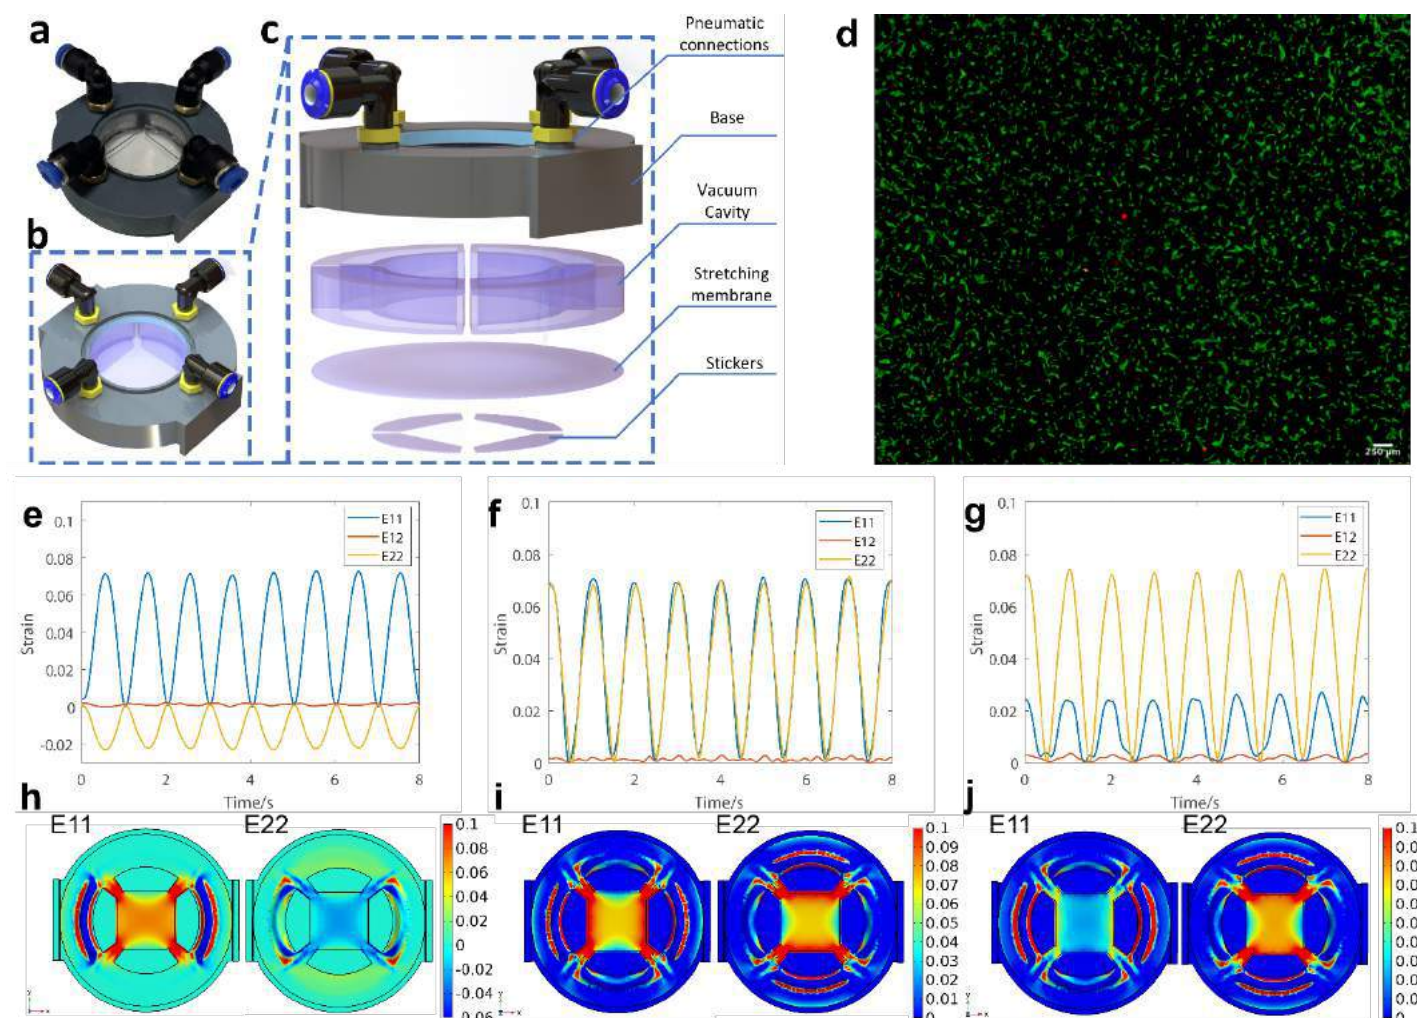

Figure 1: a)-c) Design of the pneumatic bi-axial cell stretcher. a) The practical cell stretcher. b) The 3D model of cell stretcher. c) The exploded diagram of cell stretcher. d) Live-dead assay of cells cultured on the stretcher shows 99% viability after 24 hours. All three cases employ sinusoidal loading. h), i) & i) shows the corresponding strain maps using FEA for each case.

mechanobiology. Also, Figure 1i & 1j depicts that FE simulation results that agree with their relevant experimental measurements within 5% error. Finally, 3T3 fibroblasts cultured on the membrane for 24 hours were shown to be 99% viable by live-dead assay as shown in Figure 1d.

DISCUSSION

In this work, we present a novel cell stretching system that enables independent control of orthogonal in-plane strains on a deformable membrane, through which live cell imaging is possible. Uniaxial and biaxial cell stretching devices are useful to quantify cellular response to complex microenvironment during tissue development or disease progression. These devices can provide useful insights in research on tissue engineering, cell and developmental biology, cancer, among other areas. Our strain calibration experiments show that the custom-developed stretching device can provide multiaxial mechanical stimuli. Ongoing efforts are aimed at measuring amplitude and frequency dependent cellular responses under multidirectional stretch using the custom stretching device. We have verified cell viability and biocompatibility in our cell stretching system. The device can also be mounted on a microscope stage, suggesting potential for capturing dynamic cellular responses under mechanical stretch. The controlling

set-up also enables us to simultaneously stretch up to five identical devices which allows for higher-throughput studies. Development of such customizable mechanobioreactors will be crucial in quantifying strain-dependent cell responses [6] under multiaxial cyclic stretch.

INTRODUCTION

Cerebrospinal fluid (CSF) and the brain tissue pulsate following the cardiac cycle and respiration [1]. These pulsations are caused by volume changes of cerebral arteries and veins and were previously implemented in a computational fluid dynamics (CFD) model of the CSF which, together with windkessel boundary conditions, allowed computing CSF flow and intracranial pressure in line with literature [2].

Less well understood is the impact of sudden venous volume changes, induced by physiological actions such as coughing, on the overall CSF flow. Coughing was observed to cause a rapid rise and fall of intracranial pressure and has been associated with volume variations of cerebral and epidural veins [3]. Previous experimental and computational studies have investigated the impact of sudden physiological actions on the CSF and the surrounding tissues but did only consider simplified geometries or certain parts of the CSF space such as the spinal subarachnoid space (SAS) [4, 5].

Therefore, in this study, the effects of sudden changes in venous volume on CSF pressure and flow are investigated in our CFD modeling framework of the complete cranial and upper spinal CSF circulation. After tuning the model to a newly generated and comprehensive MRI dataset, it was used to evaluate the implementation of sudden physiological actions with the aim to improve our understanding of their impact on the overall CSF circulation.

METHODS

Image acquisition: Under ethics approval, MRI brain images were obtained on a healthy subject using a 3T MRI scanner at the medical research institute Mātai (Gisborne, New Zealand)(SIGNA Premier; General Electric Healthcare, Milwaukee, WI) based in Gisborne, New Zealand. Data collection included whole-brain anatomical T1, T2, and T2 FLAIR weighted images (0.5 mm³ isotropic resolution) and PC-MRI images (axial slices at cervical level (C2) and cerebral aqueduct with

velocity encoding = 9 and 16 cm/s, respectively and 0.7 mm² in plane resolution).

Segmentation and meshing: The 3D geometry of the CSF space was extracted from the anatomical MRI images using the segmentation software Mimics (Materialise, Leuven, Belgium). An unstructured mesh was generated using ICEM (Ansys, Canonsburg, USA) containing 1,445,916 cells.

Model setup: The model was set up using the numerical software Fluent (Ansys, Canonsburg, USA) with boundary conditions based on physiological processes as presented in [2]. Figure 1A depicts the locations of the inlet and outlet boundary conditions in blue and red, respectively. Bulk flow was modeled through a source term in the lateral ventricles, resistors at the arachnoid villi and lymphatic outlets, and 2-element windkessel models at the spinal and interstitium outlet. A total compliance of 0.17 ml/mmHg was considered for all cases distributed over the interstitium (1/3) and spinal (2/3) outlet. Cardiac contraction was assumed to create a pulsatile displacement of CSF in front of the brainstem (arterial 1), which was implemented as a sinusoidal source term with an amplitude of 5.06 ml/s and a frequency of 1Hz. Moreover, brain motion was observed to show an up-and-down piston-like pumping motion in the mid-brain region following the cardiac cycle [6]. This effect was considered by imposing a sinusoidal velocity at the upper wall of the lateral ventricles (arterial 2). Starting from a maximal displacement of 0.03 mm as in [2], the value leading to the best match with subject-specific phase-contrast MRI measurements was determined (= baseline model). The phase-contrast data was analyzed using CFI42 (Circle, Calgary, Canada), across two cross-sections: the cerebral aqueduct and spinal SAS. In contrast to the model in [2], normal breathing was not considered.

Imposing sudden physiological actions: To mimic the effects of coughing, sudden flow changes are numerically introduced in the region of the occipital veins (vein) as a source term by imposing consecutively a positive and a negative gaussian curve as a time signal with an

arbitrarily chosen standard deviation of 0.05s and amplitudes of 5.3 ml (cough 1) and 10.6 ml (cough 2), and a standard deviation of 0.1 s and amplitude of 12.7 ml (cough 3). Finally, a short positive flow peak is mimicked by a positive gaussian curve with a standard deviation of 0.05s and amplitude of 5.3 ml (peak). The corresponding input flows are visualized in figure 2 (input change). The pressure gradients are calculated between a point in the spinal SAS and the lateral ventricles as depicted by Δ_{lv-sas} in figure 1A.

RESULTS

In figure 1, CFD flow rates at a cross-section of the cerebral aqueduct and the spinal SAS are visualized together with subject-specific phase-contrast MRI measurements. The maximal displacement of the ventricles was increased from 0.03 to 0.13 mm to match the measured flow amplitudes, which increased CSF flow at the aqueduct level by a factor 4.6 (figure 1B) and causes the maximal pressure gradient (not plotted here) to go up from 0.4 to 2.4 mmHg/m.

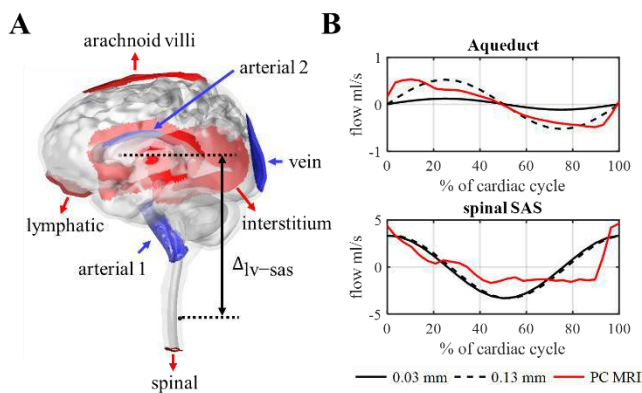

Figure 1: (A) Overview of inlet (blue) and outlet (red) boundary conditions. (B) Comparison of simulation results (maximal displacement of 0.03 and 0.13 mm) to phase-contrast MRI measurements at two cross-sections.

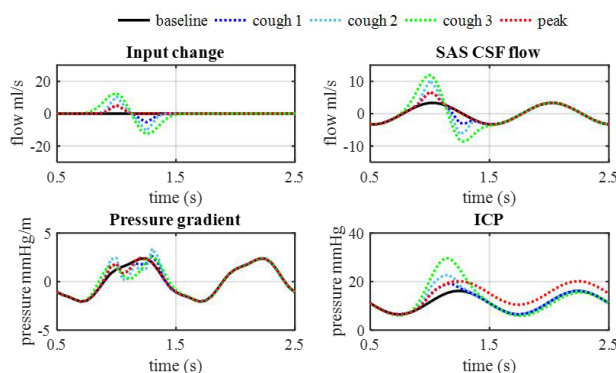

Figure 2: Input flow rates and CFD simulation results of the baseline model, cough 1, 2, 3 and peak for the CSF flow through the spinal SAS, the pressure gradient between the lateral ventricles and the spinal SAS, and the intracranial pressure (ICP).

Figure 2 shows the effects of three physiological actions against the baseline model (0.13 mm) on spinal SAS CSF flow, the pressure gradient between the lateral ventricles and spinal SAS, and the intracranial pressure (ICP). A maximal pressure gradient of 2.6, 3.4, and 2.5 mmHg/m was obtained for cough 1, 2, and 3, respectively, compared to 2.4 mmHg/m for the baseline model. Coughs 1, 2, and 3 cause a brief intracranial pressure elevation of 3.7, 7.5, and 14.2 mmHg,

respectively, above the baseline at time = 1.15s. Meanwhile, a positive peak (peak) results in a maximal pressure elevation of 4 mmHg or 25% which is sustained beyond the peak.

DISCUSSION

Comparison of CFD with in vivo CSF measurements at the level of the spinal SAS and cerebral aqueduct shows that a maximal displacement of 0.13 mm matches the in vivo CSF flow amplitudes (Figure 1). This also leads to a pressure gradient of 2.4 mmHg/m which is better in line with values 0.72 and 2.2 mmHg/m as recorded in patients with idiopathic normal pressure hydrocephalus [7].

Important differences are observed when imposing sudden flow changes (see cough 1, 2, and 3, and peak in figure 2). Simulating cough results in a brief perturbation of the CSF flow and intracranial pressure, whereafter the original conditions are directly restored, as the volume increase is directly followed by an equal volume decrease. In the model, peak pressure appears to linearly increase with input flow magnitude and standard deviation. In vivo studies reported an increase in intracranial pressure of about 35 mmHg in response to a single cough [3], which is more than two times the amplitude reported for cough 3 in this study. In contrast to [3], no decrease in pressure was found after the sudden volume changes.

Meanwhile, a short infusion of fluid results in a slightly higher and long-term elevation of intracranial pressure. Predictions based on 0D model simulations (data not shown) indicate that it might take over 15 minutes before returning to normal intracranial pressure. This delay depends on absorption and compliance parameters imposed through resistor and windkessel boundary conditions.

Importantly, the volume changes increase and disrupt the pressure gradient between the ventricles and the spinal SAS. Whereas these pressure gradients are quickly restored in healthy subjects, we speculate that a CSF flow obstruction might sustain and even increase these pressure differences. Previous studies reported larger spatial pressure gradients in patients with a spinal SAS blockage as in Chiari type 1 malformation and hypothesized that physiological actions such as coughing might drive syrinx progression in patients with Chiari type 1 malformation [4].

In this study, the effects of sudden physiological actions on CSF circulation are investigated in a CFD model of the CSF. This allowed us to evaluate the effects on both intracranial pressure and pressure gradients. Comparison with the literature indicates that accurate modeling of cough requires adequate selection of amplitude and duration of input flow. Moreover, further optimization of inlet and outlet boundary conditions in the baseline model should continue. In the future, accurate modeling of physiological actions can lead to a better understanding of their role in neuro-biomechanical disorders such as Chiari type 1 malformation.

INTRODUCTION

Erectile dysfunction (ED) is the inability to achieve or maintain erection during sexual activities, affecting approximately 52% of men in the age 40-70 [1] and increasing by 10% for each decade of age [2]. It is one of the most commonly undiagnosed and untreated diseases leading to a poor quality of life for both the sufferer and their partner. Minimally invasive treatment methods such as pharmacotherapy, intracavernous injection, low-intensity shock-wave therapy exist, yet, many men do not respond well to these treatments, often due to underlying health issues such as diabetes or vascular diseases [3]. The only real alternative in such cases is a penile implant [3, 4]. Various penile implants are commercially available, including malleable penile prostheses and, 2- or 3-piece inflatable penile prostheses (IPPs). All of these implants consist of a pair of cylinders which are placed in the corpora cavernosa (CC). The 2- and 3-piece IPPs also consist of a pump (inside the scrotal sacs) while an additional component, reservoir (inside the abdomen), is attached to the 3-piece IPP. In this study, the authors focus on the 3-piece IPP which shows a higher satisfactory rating among consumers [5]. The components of a 3-piece IPP, along with their placements inside the body, are shown in Figs. 1a, b. The pump consists of a button which helps in inflating (erect state) and deflating (flaccid state) the cylinders by passing the fluid stored in the reservoir. The positioning of the IPP cylinders results in non-physiological loading within the CC and tunica albuginea (TA), see Fig. 1b.

Penile biomechanics is a relatively unexplored topic and to-date very few research studies have been performed on mechanical testing of human penile tissues. Timm *et al.* designed an external fixator, with four indenters, which was used to record the force-displacement behaviour of the whole penis [6]. Whilst this was the first mechanical characterization of the whole penis, the indenters created only local deformation on the tissue and hence tissue characterization was limited. A recent study reported the material properties of TA but there was a limitation in the number of specimens and irregular specimen

geometries [7]. Earlier work by Gefen *et al.* [8], using finite element analysis to explore penile mechanics, represented the penis as a linear-elastic material with somewhat arbitrary tissue properties; although it is widely known that soft tissues behave as hyperelastic materials.

There is a lack of available knowledge on penile tissue properties and hence the pre-clinical testbeds (benchtop and computational models) developed to date, do not provide a realistic testing environment [8],[9]. To improve these models, mechanical characterization tests of whole penis and individual penile tissues are necessary. Individual tissue properties are needed to define or identify suitable analogue materials for pre-clinical models, whilst intact penis segment testing can validate them. Such pre-clinical testbeds will ultimately provide a means to improve IPP designs, their surgical implantation and long-term success.

METHODS

Fresh-frozen human penis (distal and proximal) was purchased from ScienceCare, USA, cleaned and segmented into 30 mm segments (Fig. 1c, d). These segments (n=4) were tested between two compression platens (Zwick Testing Machine) with a load cell of 20 N up to 30% deformation in multiple orientations to obtain the whole tissue response. The segments were labelled as S1, S2, S3, and S4, from the distal to the proximal end (see, Fig. 1d).

Following this, these segmented sections were snap frozen to -80°C and subsequently stored at -20°C. After this stage, individual components such as CC, TA and whole urethra encompassed within corpus spongiosum (Ur_CS) were segregated whilst frozen using scalpel and biopsy punches. These tissues were then cryopreserved at -80°C using a tissue freezing media (TFM) until mechanically tested.

Cylindrical specimens were obtained for CC in radial and longitudinal (n=5) directions. CC and CS along with the urethral lumen (Ur_CS) (n=5), were tested under compression up to 50% deformation using a load cell of 5 N. TA (n=5) was tested in tension along both

longitudinal (TA (Long)) and circumferential (TA (Circum)) directions and also in compression (radial direction, TA (Rad)) using a load cell of 200 N. All the tissue testing was performed in phosphate buffered saline at $37 \pm 2^\circ\text{C}$.

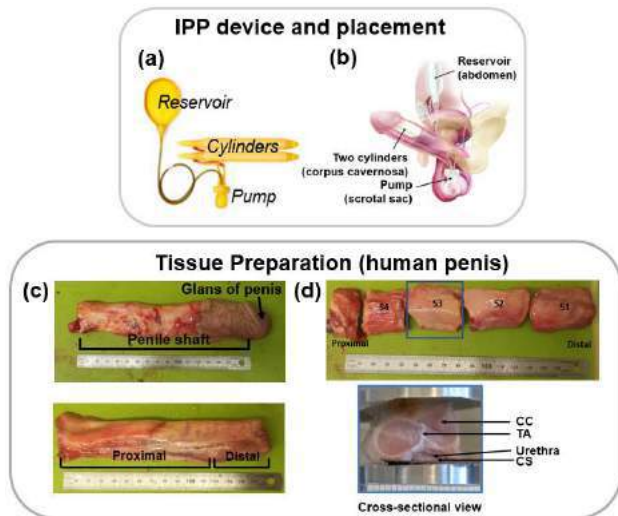

Figure 1: (a) 3-piece IPP device having a pair of cylinders, reservoir and pump [10], (b) the placement of the IPP inside the body [11], (c) Preparation of the tissue by removal of the penile glans and foreskin, (d) Segmenting the penile shaft into 30 mm segments and the cross-section showing the important features of the penis.

RESULTS

The whole penis segments ($n=4$) were tested in multiple orientations: 0-degree and 90-degree up to 30% deformation (Fig. 2a). This whole tissue response will be used to validate the pre-clinical models in future (benchtop and computational models).

The '0-degree' orientation testing was dominated by the buckling of the TA septum whilst the septum had little impact during '90-degree' compression. The levels of force generated ranged 0.15 – 0.6 N and 0.1 – 0.45 N for 0-degree and 90-degree loading, respectively, for deformation up to 30% (Fig. 2b).

Figure 2: (a) Testing of whole penis representative segment in multiple orientations, (b) Mechanical response in both orientations.

The tissues most affected during IPP inflation/deflation are the CC, TA and urethra along with CS (Ur_CS) (Fig. 3a). Individual tissues were segregated and mechanically tested. CC and Ur_CS are spongy tissues demonstrating very low stiffness initially but showing a stiffening behaviour at higher levels of deformation (Fig. 3b).

TA exhibited stress of approximately two orders of magnitude higher when compared to CC and Ur_CS in compression (at 50% strain). As expected, for tension test, TA in the transverse direction showed a stiffer mechanical response than the longitudinal direction, this could be due to the orientation of the underlying collagen fibers along the circumferential direction (Fig. 3b).

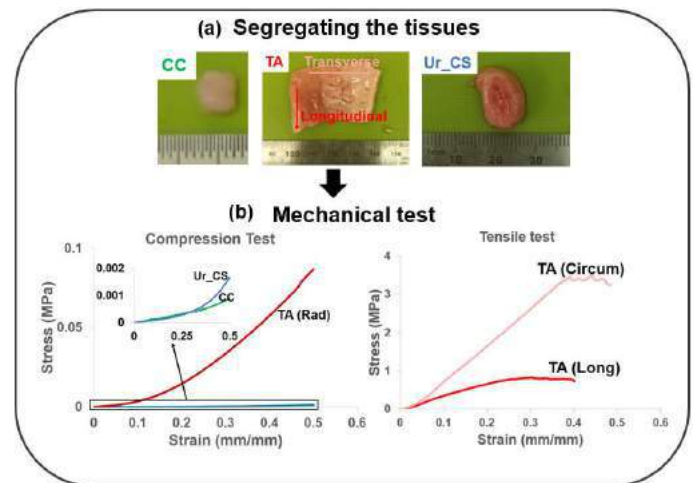

Figure 3: (a) Segregating the whole penis segments into CC, TA and urethra, (b) Mechanical testing of the individual tissues under compression and tension.

DISCUSSION

The whole tissue testing results show that the whole organ tissue is much more deformable than some of the numerical models that have previously been presented in the literature [8].

The segregated tissue results show that TA is much stiffer in tension when compared to the other penile tissues in compression. The material properties obtained from the segregated tissue tests will be used to develop benchtop and computational models in the future. These models can then be validated against the mechanical response obtained from the whole penis segments.

INTRODUCTION

The buildup of atherosclerotic plaque tissue within the carotid arteries contributes to approximately 34% of ischemic strokes and is linked to an increased risk of cardiac arrest [1]. While the vessel wall is composed of collagen, elastin, and smooth muscle cells, plaques can be composed of fat, calcium, fibrous tissue, and iron in differing quantities and microstructural arrangements [2,3]. Early identification and treatment is of the utmost importance to avoid stroke-related disability and death caused by carotid plaque. Currently, the percent stenosis, or luminal blockage, is the diagnostic criterion to determine if a patient should undergo surgical intervention [4]. If the plaque occludes the lumen by more than 50-70%, it is deemed vulnerable to rupture. However, this criterion lacks mechanical insight and is becoming more widely accepted to be insufficient [5-8]. Therefore, the implementation of a mechanically sensitive and clinically relevant biomarker is needed.

Quantitative susceptibility mapping (QSM) is a magnetic resonance imaging (MRI) method which can spatially map the magnetic susceptibility of biological tissue [9]. Recent studies have investigated QSM *in vivo* at the carotid bifurcation and showed the ability to differentiate between intraplaque hemorrhage and calcification due to their markedly different susceptibilities [10-12]. Meanwhile, previous work from our lab investigating *ex vivo* arterial tissue identified QSM susceptibility as a promising arterial tissue biomarker, with significant sensitivity to elastin and collagen, the main load bearing component in arterial tissue [13].

This work aims to further translate QSM from *ex vivo* to *in vivo* to assess the potential of this technique for diagnosis of atherosclerosis with a specific focus on mechanically sensitive microstructures like collagen. Through the optimization and implementation of a carotid QSM sequence on two different 3T clinical scanners, Siemens and Philips, the true potential of this methodology will be assessed. Novel insights from this work have the potential to change how current clinical decisions are made.

METHODS

A multi-echo gradient echo (ME-GRE) sequence was implemented at two centers on both a 3T Philips Achieva (Centre for Advanced Medical Imaging, St. James' Hospital, Dublin) and a 3T Siemens Prisma (Trinity Institute of Neuroscience, Trinity College Dublin). Table 1 outlines the sequence parameters. Voxel size, slice thickness, and the impact of a venous saturation band were investigated. One healthy volunteer (male, 29 years old) was recruited and provided written informed consent with ethical approval provided by the St. James' Hospital/Tallaght University Hospital Joint Research Ethics Committee (#2170). The volunteer was imaged at both centers on two different days.

Table 1. Sequence parameters for both scanners. Parameters marked with an asterisk were investigated.

	3T Siemens Prisma	3T Philips Achieva
Sequence	VIBE	THRIVE
Coil	(2) 4-channel special purpose coils	8-channel carotid coil
Field of view [mm]	210 x 210	258 x 258
Orientation	Transverse	Transverse
Slices	28	40
Voxel size [mm]*	0.5 x 0.5; 0.6 x 0.6	0.5 x 0.5; 0.6 x 0.6
Matrix size	448 x 448	480 x 480
Slice thickness*	1.0; 2.0 mm	1.0; 2.0 mm
TEs	2.9, 7.6, 12.3, 17 ms	2.9, 7.6, 12.3, 17 ms
Flip angle	10°	10°
TR	21 ms	21 ms
Bandwidth	580 Hz/Px	430 Hz/Px
Averages	2	2
Saturation band*	ON; Off	ON; OFF
Acquisition time	7 min 38 sec	6 min 25 sec

RESULTS

Figure 1 shows magnitude images of a healthy volunteer scanned on a 3T Siemens Prisma with (A) 0.6 and (B) 0.5 mm in-plane resolution. Figure 2 demonstrates the impact of slice thickness, from 2.0 to 1.0 mm, in a healthy volunteer on both scanners. The influence of the application of a venous saturation band on both scanners in a healthy volunteer can be seen in Figure 3. Red arrows point to (A, C) the signal in the jugular vein and (B, D) lack of signal when the saturation band is applied.

Figure 1. Magnitude images of healthy volunteer scanned on Siemens Prisma with (A) 0.6 and (B) 0.5 in-plane resolution.

Figure 2. Magnitude images with slice thickness of 2.0 mm (A, C) and 1.0 mm (B, D) for both clinical scanners.

Figure 3. Magnitude images with venous saturation band off (A, C) and on (B, D) for both clinical scanners.

DISCUSSION

A previously reported ME-GRE carotid QSM sequence which was used to investigate calcifications and hemorrhage [12], was repeated on a Siemens scanner (Fig. 1(A)). A higher resolution ME-GRE sequence, with respect to both in-plane voxel size (Fig. 1(B)) and out-of-plane slice thickness (Fig. 2), was implemented on two clinical scanners. To the authors knowledge, this is the first implementation of QSM at the carotids on a 3T Philips Achieva. The influence of a venous flow saturation band was also investigated – with no qualitative advantage or disadvantage observed (Fig. 3).

While higher resolutions are advantageous when imaging at the carotid bifurcation to avoid partial voluming effects on the vessel wall, several issues can arise. Smaller voxel sizes lead to decreased signal and increased noise which can be insufficient for further QSM analysis. This increase in noise can be seen in Fig. 2(B) when compared to Fig. 2(A). Additionally, it has been shown previously that isotropic voxels are generally required for accurate susceptibility maps [14]. Therefore, future work aims to optimize the current sequences further to achieve high resolution and isotropic voxels, while maintaining a sufficient signal-to-noise ratio.

Once the sequence is further optimized, more healthy volunteers will be imaged in both scanners to better establish a multi-center comparison. We will also need to further optimize the processing pipeline. With an optimized sequence and QSM processing pipeline, the final stages of this work will focus on patients scheduled for carotid endarterectomy surgeries. Patients will be imaged prior to surgery to obtain *in vivo* carotid plaque QSM. Their excised atherosclerotic plaques will then be imaged *ex vivo* and mechanically and histologically characterized. By linking *ex vivo* characterization of the mechanical integrity of these tissues with *in vivo* QSM, this work will assess the feasibility of this sequence to yield novel insights into carotid atherosclerosis and plaque vulnerability.

ACKNOWLEDGEMENTS

DETERMING THE GEOMETRICAL PROPERTIES OF URINARY BLADDER WALL DURING PASSIVE FILLING

F. Azari (1)

(1) Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA, U.S.A.

INTRODUCTION

Bladder is a hollow muscular organ capable of undergoing massive deformations during filling and voiding. The functionality of this organ decreases with age leading to numerous abnormalities (i.e., cancer, urinary incontinence, interstitial cystitis). Bladder wall undergoes a complex remodeling process as it experiences heterogeneous properties from dome to trigonal area. To aid surgical interventions and pharmacological treatments, a better understanding of the filling behavior is essential [2,3].

Understanding the shape of the bladder is a significant steppingstone to quantifying the deformation amount (i.e., stress vs. strain relation). Previously, biaxial and uniaxial testing of a bladder strip was studied. However, almost no study up to this date analyzed the geometrical properties of the whole bladder under applied pressure. The thickness of a rat's urinary bladder is characterized by a custom inflation setup and microcomputed tomography (micro-CT) scanner.

METHODS

The inflation setup studied the passive filling process of bladders. Each rat's bladder was mounted to a 40mm gauge needle and secured by multiple nuts at the middle of the urethra. The bladders were inflated from 0mmhg to 35mmhg by an automated syringe pump while recording the process with a high-resolution stereo imaging system. Prior to any inflation, bladders were imaged by micro-CT at 0mmhg. The n=5 bladder geometries (P=0mmhg) were reconstructed from scanned slices. After the shape reconstruction, bladder wall thickness was measured by an algorithm (Materialize-3Matics) based on the nearest distance from the luminal body to the abluminal body.

RESULTS

There were N=5 cases analyzed to understand the sharp thickness changes. It was observed that the bladder dome has the highest thickness of around 2.6mm, while the trigonal areas have the least thickness of

0.16 mm. The bladder tends to be stiffer at the initial filling pressure (Figure 1).

Figure 1: wall thickness color maps, n=5, P=0mmhg

It then expands to relatively uniform thickness, highlighting the bladder colormaps at 17.5mmhg to be very similar to 35mmhg. This is another scientific observation while characterizing the geometrical properties (Figure 2).

Figure 2: wall thickness color maps during bladder filling up to P=35mmhg, CASE 5

The filling images also demonstrate the areas with the least transparency from the dome towards the bladder body (Figure 3A).

Figure 3: Bladder filling images from stereo cameras, P=35mmhg (D), P=0mmhg (A), CASE 1

The filling process for the bladder (CASE 5) was also recorded and depicted in (Figure 4).

Figure 4: Bladder filling images from stereo cameras, P=35mmhg (D), P=0mmhg (A), CASE 5

DISCUSSION

This study shed some light on the heterogeneity of the bladder wall during the initial phases of passive filling. As depicted in the wall thickness color maps, towards the end of the inflation cycle, the bladder reaches an almost uniform wall thickness of around 0.073mm, much thinner than (p=0mmhg) lowest thickness of 0.16mm. The thickness of the bladder at higher pressures (p=35mmhg) supports the assumptions of [3] that the bladder is a vessel of constant thickness. However, the thickness of the bladder varies regionally at lower luminal volumes [2]. The microstructure of the bladder at the dome is still unknown. The study of [4] assumes types of collagen III coils sit within the extracellular matrix. Parts of the bladder microarchitecture were imaged under an SEM microscope (Figure 5); the complex vasculature highlights the tissue's ability to contract many times during filling and distension while preventing any damage to surrounding blood vessels and organs. Thus, to better understand the thickness variability, the bladder microstructure needs to be understood (Figure 5).

Figure 5: Bladder mucosal microstructure observed under SEM [1] * features the submucosa layer

The passive filling of the bladder wall was drawn from two studies [2] and [3] corresponding to (Figure 6) and (Figure 7), respectively. The pressures ranged from 2 cm H_2O to 4.5 cm H_2O and volumes of 0-50ml had the peak pressures; then they reached a stable pressure of 3.5 cm H_2O [2]. As the pressure increases, the luminal volume also increases nonlinearly (Figure 6).

Figure 6: Pressure (cm H_2O) vs volume (ml) graph during pig's bladder passive filling, N=6, [2].

The filling process for mouse bladders is also very stiff, near 200 for the green and red lines with pressure around 2.5mmhg (Figure 7), then the pressure increased to 7.5mmhg-9mmhg for the black and purple lines. The black line is the only different filling case, while the remaining five cases increase in a similar pattern (Figure 7).

Figure 7: Pressure (mmhg) vs volume (μL) graph during mouse bladder passive filling, N=6, [3]

Additionally, there is a lack of consensus on the reference volume or thickness for the measurements. The study of (Trostorff et al., 2022) [2] extrapolated the thickness between 4.6 and 7.2 mm (porcine bladders) to find the 0% luminal volume. However, in this report, the bladder with zero inflation was assumed to serve as the reference point. This study is limited to the number of samples at intermediate pressure levels (2.5mmhg-8.5mmhg). On the contrary, it clearly depicts the massive regional differences in thickness as the bladder fills. Furthermore, the images from the stereo cameras provide the opportunity to calculate the abluminal volumes of the bladder and quantitatively describe the shape of the bladder during filling.

With the extension of future detailed experiments, the filling process of intact bladder and its correlation to the thickness and luminal volume can be analyzed and compared.

MULTISCALE MODEL PREDICTS THE EFFECT OF BETA BLOCKERS ON VENTRICULAR REMODELING IN DOGS WITH EXPERIMENTAL MITRAL VALVE REGURGITATION

J. Bracamonte (1), L. Watkins (2), J. Saucerman (2), J. Holmes (1)

(1) Department of Biomedical Engineering, University of Alabama at Birmingham, Birmingham, AL, USA

INTRODUCTION

Understanding the triggers and drivers of left ventricular remodeling due to mitral valve regurgitation (MR) is key for the design of therapies for patients with mitral valve disease. This motivated several groups to develop animal models of volume overload and experimental MR, generating a rich body of literature. Consistent with the complex multiscale nature of eccentric hypertrophy, which involves an array of hormonal and mechanical changes, published studies include data on non-invasive imaging, histopathologic assays, and gene microarray analyses. Integrating the wealth of available information to better understand the progression of hypertrophy and design potential therapies requires a holistic approach that incorporates multiple aspects of cellular and organ physiology. We therefore coupled a multicompartimental model of the heart, a lumped model of the systemic vascular circulation, and a logic-based network model of relevant cell signaling pathways to generate a multiscale model of eccentric hypertrophy in the heart. The model was calibrated to reproduce short-term hormonal alterations and long-term ventricular mass increase of dogs after experimental MR by chordal rupture.

METHODS

Ventricular and circulation model

The multi compartmental model of the heart assumed the left and right ventricles to be spherical shells with time-varying elastances (Fig. 1a) and end diastolic and systolic pressure-volume functions defined as:

$$P_{ES} = E(V_{ES} - V_0) \quad (1)$$

$$P_{ED} = A(e^{B(V_{ED}-V_0)} - 1), \quad (2)$$

where E was the end-systolic elastance of the ventricle, V_0 the unloaded volume of the ventricle, and A and B were coefficients describing the exponential shape of the end-diastolic pressure-volume relationship (EDPVR). We assumed equal end-diastolic parameters for both ventricles and set the end-systolic elastance of the right ventricle to 43% of that for the left.

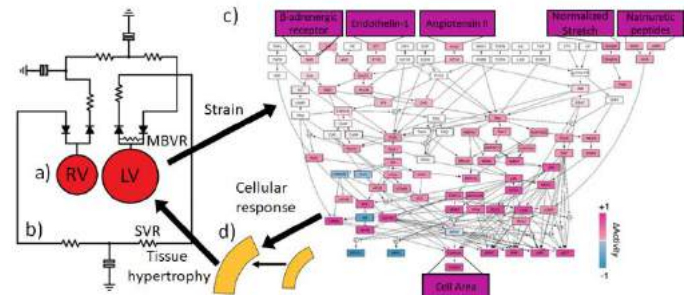

Figure 1. Coupled multiscale model. a) Compartmental model of the heart, b) Lumped model of vascular circulation, c) Network model of cellular hypertrophy pathways, d) Continuum model of tissue growth.

We set parameters for the vasculature circulation model at the values employed by Santamore and Burkhoff [1], except for the stressed blood volume (SBV), systemic vascular resistance (SVR), and mitral valve regurgitant flow resistance (MBVR) (Fig. 1b). SBV, SVR, MBVR, A , B , E and V_0 were fitted from experimental reports of baseline and acute experimental MR from dogs with body weights and regurgitant fractions (RF) ranging between 19-26 kg and 50 and 70% respectively [2,3]. A , B , E and V_0 were adjusted at each growth time-step to maintain fixed material stiffness (stress-strain function) of the myocardium [4]. MBVR was adjusted to keep RF at 60%.

Hypertrophy signaling network model

We incorporated a computational model of the hypertrophy signaling network that integrates many established pathways implicated in cardiac myocyte growth through logic-based differential equations. The network consists of 109 nodes representing hormones and intracellular molecules and 144 reactions (Fig. 1c) [5]. The baseline state was defined by setting all hormonal inputs at an activity level of 0.06 and running the network model until it reached steady state.

Coupling of the multiscale model

At each step, the multicompartamental model and lumped circulation model were solved to simulate one cardiac cycle. The calculated strains were fed to the network model and used to simulate 12 hours of cellular remodeling, producing a normalized Cell Area between 0 and 1. The Cell Area output was used to prescribe the growth of the left ventricle at the organ level. The fiber-direction strain at the baseline and acute states were linearly mapped to the normalized Stretch input of the signaling network so that baseline strain produced a Cell Area of 0.21 (no growth) and maximum strain during acute MR produced a Cell Area of 0.5 (Figure 2a). The Cell Area output was linearly mapped to the growth tensor so that the basal value produced no growth and the predicted mass fold change over 120 days was 1.2. The estimated growth was used to update ventricular properties. All growth was assumed to occur in the fiber direction (Fig. 1d).

Modeling the effect of MR+ β B

β blockade (β B) was simulated by assigning a null maximum value for the β AR network node (β -adrenergic Receptor). Additionally, we imposed decreases in heart rate (HR), systemic vascular resistance (SVR), and pulmonary vascular resistance (PVR), such that they were 95%, 90%, and 84% of their respective values for untreated MR. These were calculated by averaging the reported effect of β B in dogs [6–8].

Cell-signaling network parameter selection

A comprehensive literature review of volume overload by experimental MR and aorto-caval shunt in mammals revealed that under volume overload the renin-angiotensin system and sympathetic nervous systems are activated and circulating concentrations of natriuretic peptide, endothelin-1 and norepinephrine are elevated [6,8]. Within the Network model, these are implemented by increasing the input weights of AngII, NE, BNP, ANP, and ET1 above baseline.

RESULTS

In the coupled model, the simulated MR produced an increase in both normalized stretch network input and circulating hormone levels, triggering rapid growth. That growth reduced peak strain in the compartmental model and the normalized stretch input in the network model by increasing the unloaded volume V_0 . Sufficiently high hormonal input levels could produce enough growth to drive the normalized stretch network input level below its baseline, despite the continued presence of volume overload due to MR (Figure 1a).

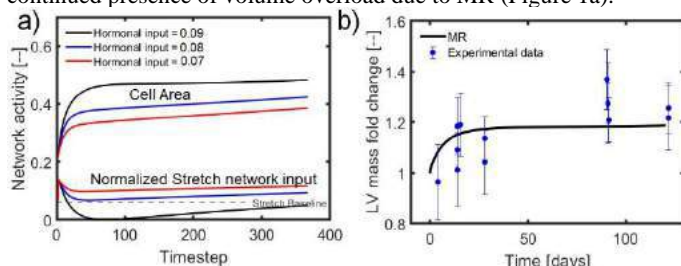

Figure 2. a) Effect of hormonal input (AngII, NE, BNP, ANP, and ET1) on normalized Stretch input and Cell Area. b) Ventricular mass fold change.

Focal adhesion kinase (FAK) is a signaling protein involved in cell adhesion, migration, and growth, which is phosphorylated in response to integrin engagement. Within the network model, FAK activity depends primarily on the normalized Stretch network input and is rather insensitive to other hormonal inputs. Sabri et al. reported that 4 weeks after experimental MR in dogs, FAK phosphorylation drops to 30% of its magnitude on healthy dogs. For the remaining simulations, we therefore chose a hormonal input level that produced similar FAK activity at 28 days as reported by Sabri, and adjusted the Cell Area to ventricular growth mapping function to match experimental data on LV

mass changes during MR in dogs (Fig 2b). When calibrated, the model predicted end-diastolic volumes consistent with experimental data at most time points (Fig 3a). The model estimated a decrease of ventricular wall thickness of 2%, slightly below the average $7 \pm 5\%$ reported in literature. The model also predicted increased activity of p38, JNK, ERK, and AKT during MR relative to control/baseline as reported by Sabri, although the modeled increases were overestimated for JNK and underestimated for AKT (Fig 3b).

Simulations of MR+ β B

In simulations of β B treatment following MR, our model predicted changes of less than 2% in ventricular mass between the MR and MR+ β B, which agrees with the observations of Sabri et al. and Trappanese et al. [7,9] (Fig 3b). In agreement with data on intracellular signaling pathways reported by Sabri et al, β B treatment reversed the depression of FAK signaling associated with MR. Our model also matched the trend of decreased activity of p38, ERK, and AKT with β B treatment but underestimated its magnitude (Fig 3b).

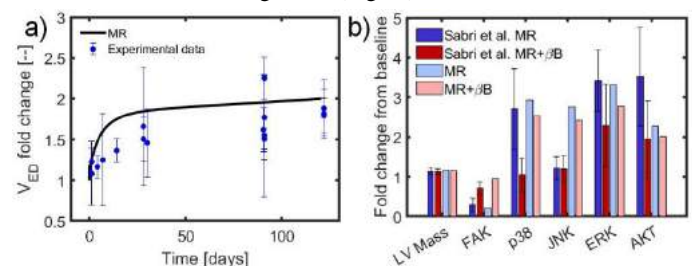

Figure 3. a) Simulated end-diastolic volume fold change vs experimental data. b) Effect of β B on LV mass and hormonal alterations at 4 weeks after experimental MR.

DISCUSSION

We developed a multiscale model of hypertrophy during experimental MR that quantitatively matched data on mass and volume changes over several months and qualitatively matched trends in the activity of several intracellular signaling nodes. Although the model was sensitive to both hormonal inputs and stretch, hormones accounted for most of the growth during simulated MR, because the growth itself reduced stretch below baseline levels after the first ten days. This model result offers a possible explanation for the otherwise paradoxical finding that activation of the stretch-sensitive kinase FAK is reduced rather than increased during experimental MR in dogs [7]. Our model reproduced both this drop in FAK during MR and its recovery following β B treatment, illustrating the promise of multiscale approaches for understanding and designing therapies to modulate hypertrophy. Further work is needed to capture changes in other signaling pathways and to account for the effects of other drugs and combinations.

BUILDING ENTREPRENEURIAL MINDSET: MOTIVATING CURIOSITY, CONNECTIONS, AND CREATING VALUE IN AN ASSISTIVE-DEVICE DESIGN PROJECT.

Joshua A. Gargac (1)

(1) Dr. Carl D. and H. Jane Clay Department of Mechanical Engineering, Ohio Northern University, Ada, Ohio, USA

INTRODUCTION

The Kern Entrepreneurial Engineering Network (KEEN) outlines the 3C's associated with the entrepreneurial mindset (EM) as Curiosity, Connections, and Creating Value. Incorporating EM into curriculum can help students understand the bigger picture, recognize opportunities, and learn from mistakes to create value [1]. Developing these 3C's can equip students with the tools to "build interfaces across tissues, disciplines, and communities." Entrepreneurship is cross-disciplinary in its nature, bringing together multiple skillsets. Students with an EM are willing to explore unfamiliar tissues, disciplines, and communities (Curiosity), identify opportunities to integrate this new knowledge with their existing ideas (Connections), and design products to address the needs of actual people (Creating Value).

Previously a rehabilitative design project was designed and incorporated into a junior-level machine design course [2]. The goal of the original project was to introduce mechanical engineering students to the field of biomechanics. The purpose of this paper is to describe additions made to incorporate entrepreneurial-minded learning (EML). Specifically, the updated project required students to 1) discover the project's motivation by connecting personal passions and everyday objects with client need, (2) build empathy for their clients and develop design ideas using the Wrong Theory Protocol [3], 3) create value by applying course content to design an assistive device, 4) communicate value propositions and design details through formal presentations and design reports, and 5.) consider aspects of curiosity, connections, and creating value through periodic reflections.

METHODS

Mechanical Design 1 is a required course for junior Mechanical Engineering students at Ohio Northern University. The 15-week course covers the theory of machine kinematics and dynamics. Four bar linkages are the focus of the course since they are the most common one degree-of-freedom mechanisms. Throughout the semester, students

applied 3D modeling and MATLAB to design and analyze these mechanisms. The 3 credit hour course had a total enrollment of 53 students across two sections and met for 50-minute lectures three times each week.

A semester-long project was updated to include EML elements during the Fall 2022 semester. The projects were completed in 14 teams with 3-4 students each. A project flow chart is shown in Figure 1.

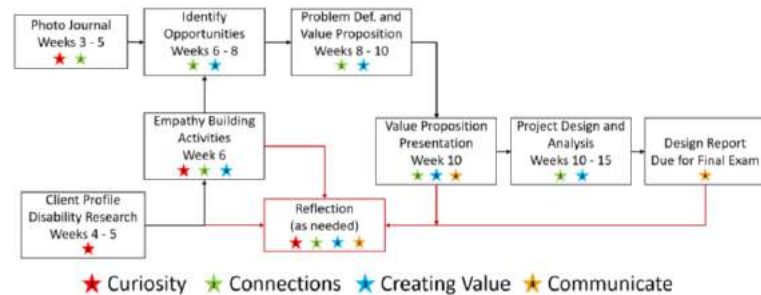

Figure 1: Project flow chart for semester long EML project. The project is not content-specific and could be adapted to any course.

Part 1: Discovery and Connections (Weeks 1 - 5)

The project was not immediately described to the students. Instead, the students discovered the project's goals and motivation over the course of several weeks. To motivate this outcome, each student was required to create a photo journal by taking pictures of 1) objects they interact with every day, 2) activities they enjoy, and 3) products that improved their life through the product's motion. They uploaded these pictures to a Google Jamboard [5] to create a photo journal.

Student groups were formed during the fourth week of the semester. Each group was provided with a client profile detailing an existing medical condition and the challenges associated with daily life

while living with the condition. Each profile was created based on interviews the instructor conducted with real people and an example can be found at this link:

https://drive.google.com/drive/folders/16Eqm_6k_Arbiv4mSrgvbYV_IWE3jY5ov?usp=sharing

Part 2: Identifying Opportunities to Create Value (Weeks 6 - 10)

At the start of the 6th week, the students were provided with the goal of their project: Design an assistive device to create value for their client, but the device must contain a mechanism that can be analyzed with the course content (typically a 4-bar or crank slider linkage).

Lecture meetings during the 6th week were dedicated to project groupwork and focused on building empathy for the client. Project teams met and compared research notes. Students shared their photo journals with their teammates. Using Jamboard, each student added "sticky notes" to the photos with objects or activities that could be good candidates for an assistive device. To address empathy, the students completed the Toronto Empathy Questionnaire [4] and discussed their scores. Finally, the Wrong Theory Protocol [3] was utilized as both an empathy-building and design ideation tool. Reflections were assigned to help the students connect the project and course content to their own passions and interests.

Part 3: Technical Design Work (Weeks 10 - 15)

The project teams were required to apply the course content to design and evaluate the assistive devices. The teams were also required to apply content from previous courses by using computer-aided design tools and completing a stress analysis on their mechanism. To build EM, each student created a concept map to visualize the connections between the client's needs, proposed value proposition, course content, and content from previous courses. The students reflected on the knowledge gaps they would have to address in order to complete the project. A final design report, peer evaluation, and project reflection were due during final exam week.

RESULTS

The project followed the paradigm from Norton's *Design of Machinery* text [6]. Performance and motion goals were defined and linkage dimensions were determined to provide that motion (linkage synthesis). A vector loop equation was used to calculate the spatial orientations of the links with respect to the input link (position analysis). Given an input motion (i.e. motor input), the first and second derivatives were taken to calculate the velocity and acceleration of each link (velocity and acceleration analysis). Joint and inertial forces were then calculated through inverse dynamics (force analysis).

Due dates were scaffolded throughout the semester. Each team presented their problem definition and value proposition during the 10th week of the semester. Next, the teams submitted a memo report describing their synthesis and position analysis during the 11th week of the semester. A velocity and acceleration analysis memo was completed for week 13. Finally, force analysis, stress analysis, and finalized design plans were due as part of the final report at the end of the semester.

Overall, student teams were able to complete the project with periodic guidance from the instructor. Example assistive devices included a wheel chair mounted table (Fig. 2A), a wheel chair lift platform (Fig. 2B), a wheel chair mounted ball launcher (Fig. 2C), and a translating painting easel (Fig. 2D). The scaffolded assignments and in-class work time ensured that each group appropriately applied the course theory to prove the efficacy of their design. The average project score was a $77\% \pm 12.8\%$ with scores varying in value created, design quality, and evaluation strength. Periodic reflections revealed student comprehension of and engagement with the EM concepts.

Figure 2: Example student designs include A) a wheel chair mounted table, B) a wheel chair lift platform, C) a wheel chair mounted ball launcher, and D) translating painting easel.

DISCUSSION

Since first described [2], this assistive device project has provided a practical application for vector-based analysis while reinforcing the engineering design process, rigid body dynamics, mechanics of materials, programming in MATLAB, and 3-D solid modeling. The described changes promoted entrepreneur thinking. Instead of a solving well-defined problem, the student teams were asked to think in terms of value creation to determine the best design. Post course surveying revealed that some students struggled with this type of open-ended assignment. However, exposure to open-ended design projects will help prepare the students for future coursework, including the senior capstone design course.

During past iterations, the students were only provided a short, general description of the client. Most recently, the students engaged with longer client profiles developed from interviews with real people. This enabled a greater sense of empathy for their clients than possible before, and anecdotally the students were more motivated to complete the project. Building upon this, the project could be further improved in the future by providing opportunities to interface with the clients and then building prototypes to demonstrate the performance of each device.

INTRODUCTION

Acute ischemic stroke is a leading cause of death and morbidity in the United States [1]. Recent studies suggest that, in addition to embolus morphology, their mechanical properties contribute to complications in clot removal procedures [2,3]. In addition, thrombus adhesion to medical devices is well documented, and computational modeling has accounted for an adhesive behavior of clot-artery interfaces [4,5,6], but the nature of the adhesion has not been characterized. Due to the fragile nature of clots, benchtop experiments that have characterized thrombus behavior have been limited to mainly tensile and compressive work. The goal of this project is to characterize the adhesive tendencies of embolus analogs (EAs) to various biomaterials and endothelial cells as a mechanism for potential complications in thrombus removal.

METHODS

EA Formation Conditions:

To study the effect of EA composition on embolus adhesion to biomaterials, EAs were created using human blood, following approved institutional IRB protocols. Briefly, extracted whole blood was anticoagulated with 0.32% wt. sodium citrate. Blood was separated into red blood cells, platelet rich plasma (PRP), and platelet poor plasma (PPP) via centrifugation. Blood was reconstituted to 214×10^6 platelets per mL. Hematocrit was controlled in EAs by addition of 40% vol. red blood cells to form clots. To counter the effects of the anticoagulant, blood was recalcified with 20 mM calcium chloride (CaCl_2), 15 NIH Unit/mL thrombin from human plasma (BioPharm, Bluffdale, UT, USA), and 100 mM ADP to initiate platelet activation in the blood. Recalcified blood was mixed and injected into custom cylindrical molds that allowed for attachment to biomaterials. Samples were coagulated on acrylic, glass cover slips, and endothelial cells. Blood was allowed to coagulate for 24 hours at 37 °C for EAs to form 14 mm diameter by 10 mm cylindrical specimens. To prepare the endothelial cell lining,

human coronary artery endothelial cells were cultured with human cell media at 37 °C and 5% CO_2 before testing.

EA mechanical testing:

Figure 1: Detachment Instron rig with a 1. syringe applying a suction through 2. a custom suction chamber fixed to 3. the Instron top grip. 4. The cylindrical specimen was fixed to 5. a bottom fixture with 6. a mirror placed at 45° to visualize the bottom of the clot as it detaches. 7. Shows an isometric projection of the clot attached to the biomaterial and 8. shows a zoomed in view of the suction mechanism.

Once EAs were formed, the samples were removed from molds and attached to the bottom plate of a custom rig on a uniaxial load frame (Instron, Norwood, MA, USA) with a 5 N load cell, see **Figure 1**. A suction fixture was used to apply a negative pressure of 200 mmHg to the top surface of the cylindrical specimens to grip the surface, using a custom syringe fixture. Once the suction was applied, the specimen was loaded at a rate of 10% strain per second (based on sample height) until

complete detachment from the bottom plate. From these data, a polynomial of degree 1 was fit to the curve prior to fracture to compute the modulus. The peak stress and strain were recorded. All samples were embedded in paraffin wax for histology and stained with a standard Carstairs protocol to visualize all major clot constituents.

Statistics:

Due to variability in coagulation, clot contraction, and other factors, multiple sources ($n = 6$) were collected with replicates ($n = 6$) tested for each source. For this reason, mean values were computed with standard deviation, and a Kruskal-Wallis analysis of variance was applied to compare means. All data analysis was carried out using MATLAB's multiple comparison function.

Hyperelastic Modeling:

To simulate the experiment, a Neo-Hookean elasticity model was applied to the interior of the clot in an axisymmetric setting. A spring foundation and a displacement-based failure criterion were applied to the bottom surface to simulate the detachment. Finally, surface traction on the bottom and top surfaces were computed. All work was done in COMSOL Multiphysics (Stockholm, SWE).

RESULTS

Preliminary, nominal stress-strain curves, as shown in **Figure 2**, show a tensile-like behavior with nearly linear elastic-like behavior in the loading portion of the curve. Measured moduli were 2.17 ± 0.34 kPa, with a linear R^2 value of 0.92. Maximum nominal stresses at failure were 0.37 ± 0.13 kPa and maximum strains were $14.74 \pm 4.06\%$, meaning the clot elongated 14% before detachment. From the COMSOL simulation in **Figure 3**, a detachment is seen to initiate from the bottom corner of the cylinder and radiate inward, due to a stress concentration near this point. Failure was initiated via a displacement criterion of 0.1 mm. Von Mises stress distribution mapping shows a stress concentration near the corners of the specimen, with fracture stresses similar to those observed in the experiments, roughly 400 Pa. Traction vectors near the fracture also show a slight decrease in the axial force before full clot detachment.

Figure 2: Nominal stress – strain curves for the detachment test with 40% HCT human blood clots on acrylic.

Figure 3: Axisymmetric center view of a hyperelastic Neo-Hookean simulation of clot detachment test with a spring foundation bottom boundary and displacement-based failure criteria at $t = 0.2$ s. The zoomed in panel shows fracture initiating from the bottom corner of the clot and radiating inward. Von Mises stresses shown in Pa, and the red arrows depict tractions on the bottom surface of the clot.

DISCUSSION

Measured moduli were 2.17 kPa, similar to work done by Sugerman et al. [5] This suggests the loading for this test prior to detachment was similar to a standard uniaxial tensile test. Pressure gauges on the aspiration rig confirmed constant pressure at the top of the clot. Nearly linear loading curves also suggest a linear elastic behavior of the material in tension. Previous work by F. Ghezelbash *et al.* has shown a highly nonlinear behavior in compression, attributing this to loading of elastic-like fibrin and viscous-like red blood [7]. In tension, EAs seem to exhibit a more elastic behavior. Furthermore, clots detached at roughly 15% strain, lower than previously reported fracture strains of roughly 40% [8].

The COMSOL hyperelastic model used a spring foundation, allowing for displacement of the bottom surface before fracture, a phenomenon not observed in the experiments. As mentioned, the fracture stresses from the computational model were similar to experimental measurements. However, in the experiments, clot detachment occurred at random from the surface, where the computations showed a constant initiation from the outer corner. The clot deformation is constrained to be incompressible, yet from the testing, fluid leakage was observed clearly. This suggests a different nature than either hyperelastic or viscoelastic, with a tendency of the clot to store fluid. Future work will focus on capturing this porous nature of clots and the uneven detachment of the clot to different surfaces. This work has shown that there exists an adhesive behavior of EAs that has been understudied, and which may play a role in complications for clot removal in thrombectomy surgeries among other scenarios.

INTRODUCTION

Global/intercultural learning is an area of interest at Northeastern University. Students are strongly encouraged to participate in activities that foster enhancing intercultural communication skills. In a global learning setup, students can benefit both from the international and transnational aspects of their discipline and from the intercultural and local nuances in the host country. The students are also able to combine critical thinking and problem-solving skills with comparative perspectives and multidisciplinary approaches. Northeastern University has highlighted the following areas as goals for the intercultural learning [1]: *(1) recognize and critically examine their own cultural influences; (2) analyze the connection between the global and the local, and understand how structures, forces, and phenomena shape culture and individual experience; (3) live, learn, and work effectively with people whose backgrounds, experiences, and perspectives are different from their own; and (4) reflect and act with an understanding of the local and global impacts of their decision.*

Dialogue of Civilization (DOC), a faculty-led program at Northeastern University, is one of the mechanisms through which these goals are sought after. During a DOC program, students spend 30 days or more of a summer semester with a faculty leader in locations outside of their main campus. For many students, DOC is an excellent short-term program to obtain international experience. Students are required to complete two courses during this program. The faculty leader(s), with help from local stakeholders, teaches the courses that require closer examination of the problems and their potential solutions in the host country.

Travelling to Paraguay and Argentina for learning Guarani or spending time in Samarkand and Bukhara to examine the history of the silk road in the central Asia seem to be no-brainer ideas for DOC programs. However, at the first look, learning computational skills for mechanical engineering and bioengineering students may not seem to be a skill requiring a global framework. Afterall, everybody can sit at

their computer and write scripts. Nevertheless, as shown in our previous work, even in computational courses, active and experiential learning positively contributes not only to the students' course-specific knowledge but also to their self-efficacy [2,3]. Herein, we have shared our experience of a DOC program in Norway. We aimed to teach important technical skills to students and to stimulate them to think and discuss the cultural and social aspects of engineering and technology in Norway.

PROGRAM DESCRIPTION

We travelled for 31 days in Norway, from mid-May to mid-June in 2022. We chose Norway because its pioneering role in the development and application of computational methods in engineering. For example, Norwegian Computing Center, established in 1952, is one of the World's leading institutions in computational research and provides service for many of the local industries. Our program focused primarily on two courses: Mechanical Engineering Computation and Design (ME 4508) and a special topics class particularly designed for this DOC program (ME4699).

In ME 4508, we introduced the theory of finite element (FE) analysis, focused mainly on the behavior of elastic materials. Heat transfer through conduction and convection was also covered. Students developed scripts in MATLAB and used available commercial FE software. At Northeastern University, ME 4508 is a required course for the Bachelor of Science in mechanical engineering, and an elective course for Bachelor of Science in bioengineering. Specifically for this DOC, we chose applications that were relevant to guest lectures and site visits in Norway. For example, students received lectures from biomechanics experts at the Norwegian University of Science and Technology and then completed a biomechanics project. In addition, they were able to visit sites and see the outcomes of the design and analysis that they learned about in the classroom (Fig. 1). Considering the importance of experiential learning, many of the site visits were

planned for the students to become more familiar as how to apply their knowledge of computational methods in practice.

Besides the industry exposure and engineering aspects of the program, this global experience gave ample opportunities of exposure to a different culture, with a rich history both as it pertains to the modern era as well as to the ancient traditions of Sámi people. The special topics course was focused on the interplay of modern technologies (e.g., green energy) and the rights and traditions of the Sámi people. Although Norway has rich crude oil resources, it has been vibrant and proactive in using other sources of energy such as hydropower, wind power, and wave power. In the realm of social policies, Norway is an interesting and progressive European country and one of the pioneering nations with supportive legislations for women's rights, minority rights, and LGBTQ rights. Nevertheless, Norway, for decades had discriminated against the Sámi people and had unjustly deprived them of owning their ancestral lands as part of the policies of Norwegianization [4]. In the special topic course, the students first learned about the general policies of governance (including education, healthcare, etc.) and the concept of a "welfare state" in Norway. Subsequently, the lectures were focused on the experience of the Sámi people (Fig. 2) and how, for decades, they were displaced from their land. The students also learned about the modern concept of "green colonialism", e.g., the expansion of the wind energy industry into the ancestral lands of the Sámi. For engineering students, who are often used to exact solutions to technical problems, posing open-ended questions in this course seemed to be thought provoking and enriching. Based on the lectures from the local experts and group discussions, students presented their final project for this course on the following topic:

Renewable energy resources (including wind) are often considered as the solution to curb global warming. However, they may have other environmental and social disadvantages. In Norway, for example, they can lead to deposition of micro-plastic beads in protected mountain lakes and/or to stressing and starving reindeer. Another example is the offshore windmills that generate vibrations, changing the marine lifestyle and affecting the fishing industry. While these problems may affect many people, some like Sámi people, who traditionally live outside of urban centers and/or are involved in farming reindeer, may suffer more than others. How can we protect the earth inhabitants (including ourselves) from climate change without marginalizing already disadvantaged groups such as Sámi people?

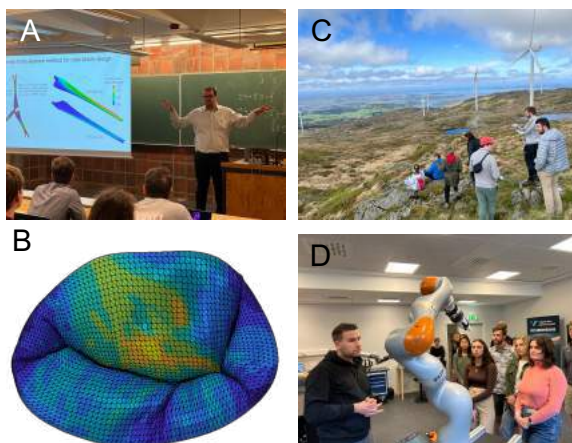

Figure 1: Guest lecturers presented applications of computational techniques in (A) mechanical and (B) biomedical engineering often accompanied by (C and D) visiting the sites where the technologies are used.

Figure 2: (A) Lectures at Arctic University of Norway (B) history of the struggles of Sámi people in handmade artwork.

STUDENT FEEDBACK AND FUTURE DIRECTION

The student anonymous feedback for this DOC program was overwhelmingly positive. The experiential component of the course was acknowledged by many students. For example, the students were fascinated to learn about heart valve structure and how FE modeling is used in *in-vivo* imaged-based approaches from experts in this field. They felt that a "real-world" example of this approach was extremely relevant and motivating for them when they conducted their own FE project for the course focusing on biomechanics of image-based shapes. They better appreciated the complexity of segmentation and generation of such models. Some of the students' comments are provided here:

- *I want you to know that this trip has had an incredibly positive effect on my life (and for a lot of other people), and I'm so happy that I had this opportunity. This was such a unique experience that I will be talking about for the rest of my life. Thank you so, so, so much for everything. I really can't thank you enough for planning and executing this trip.*
- *Wrapping up this trip, I am very happy with everything we were able to see and do over the past month in Norway. This is the most engaging trip I have ever been on and I will definitely be applying for another dialogue of civilization in the future.*
- *This program has truly been a source of great personal growth as well as great enjoyment for me, and I am so very grateful for having been given the opportunity to participate in it.*

Based on the positive feedback from the students, we intend to continue this program in the upcoming years. For better assessment of the program, we plan to conduct pre-departure and post-departure surveys including self-efficacy assessments [5].

ACKNOWLEDGEMENTS

We thank Northeastern University Global Experience Office (GEO) both for their assistance in the development of this program and for providing Rouzbeh Amini with the Global Experience Faculty Fellowship. Tireless efforts of GEO staff, particularly those of Meisha Swaby and Brigid McMahan, were essential for this program. We also thank Elise Mikkelsen, Cristian Gebhardt, Maria Brandsøy, Rune Knapstad, Guttorm Nygård, Eli Nummedal, Marcin Fojcik, Trond Strømren, and Navid Varasteh for their tremendous support.

CALCIUM SIGNALING IN IN-SITU CHONDROCYTES UNDER DYNAMIC COMPRESSIVE LOADING

Vineel Kondiboyina (1), Timothy Boyer (1), Sandra J. Shefelbine (1,2)

(1) Dept. of Bioengineering, Northeastern University, Boston, MA, USA

(2) Dept of Mechanical and Industrial Engineering, Northeastern University, Boston, MA, USA

INTRODUCTION

Physiological deformation of articular cartilage results in several mechanical, electrical, and chemical stimuli in the chondrocytes. Studies have shown that chondrocytes respond to all these signals by increasing their intracellular calcium concentration. However, the spatiotemporal characteristics of the calcium influx differ based on the cellular environment.

Chondrocytes in explanted cartilage respond relatively quickly (within 5 secs) under static load while cells in 3D hydrogel constructs respond much more slowly (~200 secs). Similarly, with increased mechanical load, about 20% of chondrocytes respond with increased calcium influx but under osmotic loads of 20mOsm, about 35% of cells respond and higher magnitudes of an osmotic shock result in a greater percentage of signaling. These studies demonstrate the importance of the matrix environment as well as the load characteristics on the intracellular calcium signaling in chondrocytes.

Previous studies on load-induced calcium signaling in in-situ chondrocytes utilized slow ramp loads with non-physiological strain rates¹. While the studies using dynamic cyclic loads were done on cells embedded in hydrogels². The response of chondrocytes in their native environment under physiologically relevant cyclic loads has not been studied yet.

In this study, we characterized the calcium signaling response of in-situ chondrocytes (explanted cartilage) under physiological cyclic compressive loads with varying frequency and strain rates. We hypothesized that chondrocytes have strain rate-dependent calcium signaling characteristics compared to no load control conditions.

METHODS

Full-thickness cartilage explants were collected from the femoral condyles of a fresh bovine knee (2-3 weeks old, Research 87, Boylston, MA) using a 6mm biopsy punch. The explants were cut into cylindrical discs of 6mm diameter and 2mm thickness from the articular surface

using a custom cutting tool. The harvested explants were incubated in culture media for three days prior to the experiment.

On the day of the experiment, the cylindrical explants were axially halved and stained with a fluorescent calcium indicator dye solution of 10 μ M CalbryteTM 520 AM (AAT Bioquest) in HBSS with 20mM HEPES for 40 mins at 37°C. The samples were then washed with fresh HBSS for 30 mins at room temperature.

The stained explants were placed in an imaging chamber filled with HBSS with the cut surface facing down. The explants were secured in a custom-built loading device. The loading device was secured on a confocal microscope (Zeiss LSM 800). A schematic of the setup along with the different loading profiles used is shown in Fig 1. A description of the loads can be found in Table 1.

Figure 1: (a-g) Different loading profiles tested (h) Schematic of the custom loading machine

The loading device consists of two linear actuators (Helix Linear Technologies, SMA-8S2.5V-C) that apply equal displacement from both directions, simultaneously during imaging. The resultant load was recorded by a load cell (Loadstar USA, REB7-005M-S). During the test, the loading platens were moved until contact was detected with the explant (threshold: 0.1N). A 10-minute resting period was allowed for the explant to recover from the agitation. Using a 20x objective and 0.8X zoom, a 400 μ m \times 400 μ m area was located along the central axis of

the explant. The imaging area was focused ~30um below the cut surface to avoid imaging damaged cells. The explants were imaged for 10-mins at a frequency of 1.5s under randomized loading conditions (Table 1). A maximum strain of 10% was applied in all conditions.

Calcium fluorescence intensities of the cells were tracked using the Trackmate® plugin in ImageJ. 150-300 cells were tracked per explant sample. A custom-built MATLAB code was used to plot the calcium intensities of the cells and identify responsive cells. A cell was regarded as responsive if it had at least one calcium peak with a prominence greater than 4 times the noise level of the signal¹ and a width of at least 20 seconds. The number of explants tested, and the total number of cells tracked in each case are listed in Table 1.

Table 1: Number of explants and cells analyzed for each loading condition							
Load Condition	Baseline	Slow ramp	Fast ramp and Hold	0.1 Hz x 1 cycle	1 Hz x 1 cycle	1 Hz x 5 cycles	1 Hz x 10 cycles
Time to Peak Strain (s)	-	600	5 (Hold for 600 s)	5	0.5	0.5	0.5
Number of Explants	3	3	3	3	3	3	3
Imaging During/After Load	During	During	During Hold	After	After	After	After
Total Cells Tracked	925	761	691	741	873	877	861

MATLAB (R2019b) Statistical Toolbox was used to perform all statistical analyses. The percentage responsive cells were compared across loading conditions using 1-way ANOVA followed by a posthoc test with Tukey correction (normal distribution and equal sample sizes). The duration of the calcium signal and the distance between consecutive peaks were analyzed using Kruskal-Wallis Test with Tukey-Kramer correction (non-normal distribution and varying sample sizes). An alpha value of 0.05 was used as the threshold for significance.

RESULTS

The percentage of cells signaling increased in all loading conditions compared to the no-load baseline (Figure 2). Further, the percentage of cells responding under 1Hz load (1,5,10 cycles) was significantly greater than the slow ramp group.

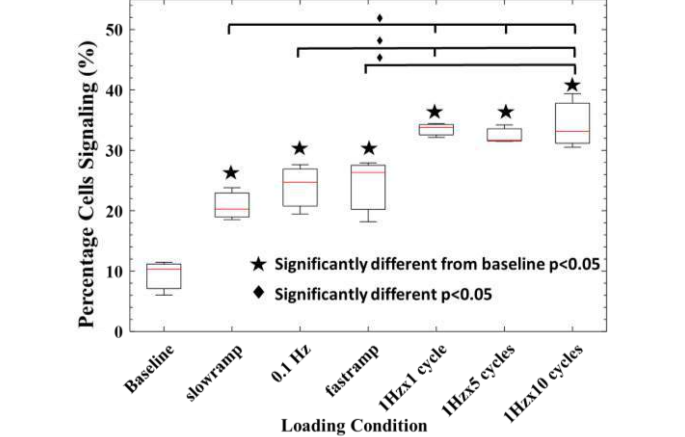

Figure 2: Percentage of cells responding to load with increased calcium fluorescence intensity. The upper and lower boundaries on the box plot represent the 25th and 75th percentile in the data respectively with the median being represented by the red mid-line. The non-outlier extremes in the data are shown by the whiskers.

Similarly, the response percentage of the 1Hz group (1, 10 cycles) was greater than the 0.1Hz group and the 1Hz x 10 cycles group had a

greater response percentage than fast ramp group. No difference in the percentage of responsive cells was found between the slow ramp, fast ramp, and 0.1Hz groups.

The width of the signal was not different between the loaded groups compared to the no-load baseline (Fig 3a). Similarly, the time between consecutive peaks was also not different between the groups compared to the baseline (Fig 3b).

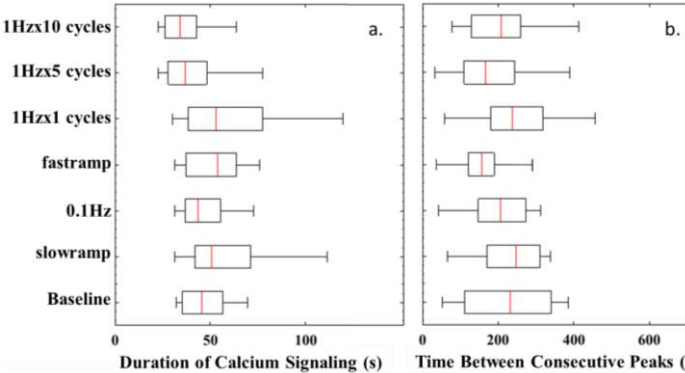

Figure 3: (a) Width of calcium peak (b) Distance between consecutive calcium peaks

DISCUSSION

In this study, the characteristics of calcium signaling in chondrocytes in their native environment were quantified under physiological dynamic compressive loads. An increase in the percentage of cells responding with increased intra-cellular calcium concentration was observed with loading. Further, the percentage response increased with strain rate.

0.1 Hz and fast ramp cases in the current study have similar strain rates during the loading phase. However, 0.1Hz case has an unloading phase preventing fluid flow while fast ramp phase experiences fluid flow induced stress-relaxation after loading. No difference in the percentage response between the groups suggests that sustained fluid flow might not be the driving factor for calcium signaling.

The increase in response between 0.1Hz and 1Hz groups suggests that hydrostatic pressure might be the stimulus that induces calcium signaling in chondrocytes in their native environment. We hypothesize that the increase in matrix hydrostatic pressure causes cell volume changes due to reverse osmosis, which in-turn activates calcium signaling in in-situ chondrocytes.

No effect of the number of cycles on the responsive rate of in-situ cells was found which is consistent with previous findings in hydrogel embedded chondrocytes³.

In conclusion, in-situ chondrocytes respond to physiological loads in a strain rate-dependent manner with an increased number of responsive cells. Signaling profiles, however, are similar across all loading profiles. Future studies will evaluate how hydrostatic pressure induced by the physiological loading of the tissue is transduced into a cellular-level signal.

ACKNOWLEDGEMENTS

This project was funded by NSF grant # 2010010. Imaging was performed at the Center for Imaging Living Systems (CILS), Northeastern University.

DETERMINING HOW VEGFR-2 INHIBITION AFFECTS PHOSPHORYLATION AND FUNCTION IN THE PRESENCE OF MECHANICAL STRAIN

Bronte Miller (1), Michael Heim (1), Bryan Mortimer (2), M.K. Sewell-Loftin (1,3)

- (1) Biomedical Engineering, University of Alabama at Birmingham, Birmingham, Alabama, USA

INTRODUCTION

Blood vessel growth is a vital part of development; however, dysregulation of vascular structures is involved in various disease states such as ischemia and cancer. New vessel growth from preexisting vasculature is known as angiogenesis, a key process in tumor progression. When small, a tumor can rely solely on diffusion to receive nutrients and oxygen, but it requires a vascular network to meet increased demand as the tumor grows [1]. Tumors induce an angiogenic signaling cascade which causes nearby vessels to grow towards the mass. Vascular endothelial growth factor (VEGF) and VEGF receptor-2 (VEGFR-2) are common targets when treating cancer due to their essential role in angiogenesis. However, notwithstanding the critical role of VEGF and VEGFR-2 in angiogenesis, these therapies are often insufficient and demonstrate little to no improvement in patient populations [2].

One reason why anti-angiogenic therapies have proven ineffective could be due to VEGFR-2 mechanoactivation, which remains understudied in cancer research. The tumor microenvironment (TME) contains altered mechanics such as increased matrix stiffness, interstitial fluid flow, and strain [1]. Cancer-associated fibroblasts (CAFs) are known to be mechanically-active, distorting the matrix surrounding cells and causing strains [3]. This cellular-induced strain likely affects VEGFR-2 expression and phosphorylation, and previous studies have shown that forces such as matrix stiffness and shear stress can alter VEGFR-2 activity [4, 5]. Different VEGFR-2 tyrosine residues have shown varied phosphorylation patterns depending on mechanical cues, with matrix-bound VEGF stimulation causing prolonged Y1214 phosphorylation [6]. VEGFR-2 inhibition through soluble factors such as SU5416, a drug previously involved in clinical trials, may be insufficient to stop mechanoactivation of the receptor and subsequent blood vessel growth. We hypothesize that endothelial cells exposed to biomechanical stimulation will express altered VEGFR-2 phosphorylation patterns and enhanced angiogenic activity even in the

presence of VEGFR-2 inhibitors. Results from these studies will help address the knowledge gap related to mechanically-driven blood vessel regulation and possibly provide novel targets for anti-angiogenic therapeutic strategies.

METHODS

To study VEGFR-2 phosphorylation patterns, human microvascular endothelial cells (HMECs) received either 3 μ M SU5416 and/or 25ng/ml VEGF in EGM-2 (Lonza) for 72hr. Western Blots analyzed resulting lysates to quantify VEGFR-2 pY1054/Y1059 or pY1214. HMECs also received 25ng/ml VEGF and/or uniaxial strain through FlexCell plates for 0, 5, or 15min. Western Blots analyzed the same VEGFR-2 tyrosine residues. Densitometry was performed using FIJI, and all expression levels were double normalized to β -actin then to total VEGFR-2.

A custom-built, multi-microtissue microfluidic platform was utilized to determine the effect that mechanical stimulation has on angiogenesis [7]. The system has three chambers that can be loaded with matrix and cells, each with its own fluidic lines to permit control over interstitial flow. Flow within devices moved outward from the center chamber to the side chambers, inhibiting soluble factors from diffusing into the center chamber. Tissue chambers were filled with 10mg/ml fibrin gels with the center chamber filled with 1:1 human umbilical vein endothelial cells (HUVECs) and normal human lung fibroblasts (NHLFs). Devices contained either control normal breast fibroblasts (NBFs) or CAFs in the side chambers and were treated with SU5416 or a vehicle controls. Additional experimental set-ups utilized thrombin-coated magnetic beads or cell-free/bead-free fibrin gels. The magnetic beads permit mechanical stimulation of the microtissues without requiring stromal cells. Half of the devices containing magnetic beads were placed above a magnet on a rotating orbital shaker inside the incubator, while the others were kept in a control incubator. Devices were fed for 7 days then were fixed and stained for VE-Cadherin, a

blood vessel marker. Devices were then imaged and processed with FIJI and AngioTool to quantify blood vessel growth.

RESULTS

HMECs show a significant decrease in pY1054/Y1059 and pY1214 with the addition of SU5416, even in the presence of VEGF (Figure 1a). Levels of pY1054/Y1059 increase at 5min with the addition of VEGF; however, the residue appears unaffected by strain (Figure 1b). pY1214 levels increase in HMECs at both 5min and 15min when exposed to strain (Figure 1c). Overall VEGFR-2 phosphorylation can increase due to mechanical strain, and SU5416 can decrease this activity in unstrained conditions.

Figure 1: VEGFR-2 phosphorylation in HMECs. (a) HMECs were treated with VEGF (V) or SU5416 (SU) for 72hr.

Western Blots quantified VEGFR-2 pY1054/Y1059 and pY1214. * $p < 0.05$ compared to NT, ^ $p < 0.05$ compared to V, # $p < 0.05$ compared to SU. (b) HMECs were treated with VEGF or strain (ε) for 0, 5, or 15min. Western blots were run on pY1054/Y1059 and (c) pY1214. + $p < 0.05$ compared to 0min NT, * $p < 0.05$ compared to NT at same time, ^ $p < 0.05$ compared to V at same time, # $p < 0.05$ compared to ε at same time. N=3, Avg+SEM.

To examine phenotypic changes due to strains in the TME, microfluidic devices were used to determine how angiogenesis is regulated by mechanical stimulation. HUVECs and NHLFs in the center chamber create a self-assembled, stable vascular network. Fluorescent images were taken showing sprouting blood vessels penetrating the side chambers (Figure 2a,c). Devices treated with SU5416 show increased angiogenesis in chambers filled with CAFs compared to control NBFs (Figure 2b). For devices with magnetic beads in one side chamber, those that experienced mechanical strain induced by the magnetic stimulation of the beads show increased angiogenesis in the bead side chambers compared to devices without the magnet (Figure 2d).

DISCUSSION

In our HMEC line, we decided to analyze Y1214 due to its link to mechanoactivation and Y1054/Y1059, which is necessary for full kinase activity [6, 8]. SU5416 limited chemical activation of both these residues in unstrained environments, and future work will determine if strain is sufficient to restore VEGFR-2 phosphorylation in the presence

of an inhibitor. Furthermore, Y1214 displayed an increase in phosphorylation when treated with strain even without exogenous VEGF, suggesting that certain tyrosine residues are more sensitive to mechanical activity than others. Further research will focus on additional residues.

In our three-chamber microfluidic devices, vessel networks treated with SU5416 grew towards chambers with mechanically-active CAFs compared to NBFs, suggesting that strain is sufficient to promote angiogenesis even with a soluble inhibitor. We also showed that there was an increase in angiogenesis in chambers containing magnetic beads and cultured above a magnetic force, producing matrix strain similar to CAFs. This magnetic bead system fully removes stromal secreted factors that could potentially affect the observed angiogenesis. Overall, this work indicates that mechanically-active environments result in increased angiogenesis, even in the presence of soluble inhibitors. The TME can produce similar mechanical forces, which may be one reason why anti-angiogenic therapies have often proven ineffective in stopping blood vessel development in tumors. Understanding how the TME regulates angiogenesis via mechanical forces and how this process is affected by inhibition is a critical area that requires further investigation to develop effective anti-angiogenic therapies.

COMPUTATIONAL ASSESSMENT OF ELASTIN IN A HYBRID MODELLING APPROACH OF ARTERIAL BIOMECHANICS

INTRODUCTION

Elastin lamellae play a key role in the load bearing function of elastic arteries, especially at lower levels of strain before collagen becomes the major load bearing component, and damage to elastin integrity is associated with diseases in human aortic tissue [1]. With genetic mouse models of aortic dilatation/dissection exhibiting elastin lamellae defects to various extents, we want to better understand the biomechanics of the elastin lamellae. In previous work, we and others assessed the straightening of lamellae as they go from a crimped, wavy configuration at zero luminal pressure, to straight, circumferentially loaded configurations [2,3]. Here, mouse carotid arteries were subjected to quasi-static intra-luminal loading at fixed axial stretches, and two different imaging modalities were used to assess the above criteria. Additionally, Yu et al. hypothesized that the gradient of waviness between the inner lamella and outer ones at an unloaded configuration correlates directly with the homogeneity of the stretch transmurally [3]. Moreover, they observed that as the artery was loaded from this stress-free configuration, lamellar stretch (and therefore load-bearing) begins even before the lamellae are fully unfolded, and that unfolding occurs at the inner lamellae more drastically in comparison to outer ones.

In this study, we propose a hybrid method of modelling the arterial microstructure, where elastin lamellae are modelled discretely as isotropic hyperelastic sheets embedded within a homogenized matrix of fiber-dominant anisotropic hyperelastic material. Data from [2,3] were used to set up the hybrid modelling approach, whereby the three lamellae (henceforth referred to as L1, L2 and L3 for the inner, middle and outer lamella respectively) are considered. Different initial configurations of crimped elastin lamellae, that reflect a waviness gradient between lamellae, are loaded *in silico*. We compare the effect of having three different waviness gradients on lamellar stretch, within each simulation and between simulations.

METHODS

An idealized axisymmetric 3D model of the artery with the initial dimensions of an inner and outer diameter of the unloaded artery reported in [2] was constructed using Matlab. A cross-section of the artery is shown in **Fig. 1** where the solid black undulating lines are the lamellae while the green represents the matrix continuum in which they are embedded. The first elastic lamella was taken to be at an average radius of $R + (\frac{1}{2} \times \text{lamella thickness})$ and with the same β (the amplitude of the undulation) and ω (the frequency of undulation) as the inner wall (R of L1, L2, and L3 is 135, 145, 155 μm). The circular length of the elastin lamella was taken as (s) and the straightness parameter (p) was

Figure 1 Five configurations of lamellae shown adjacently

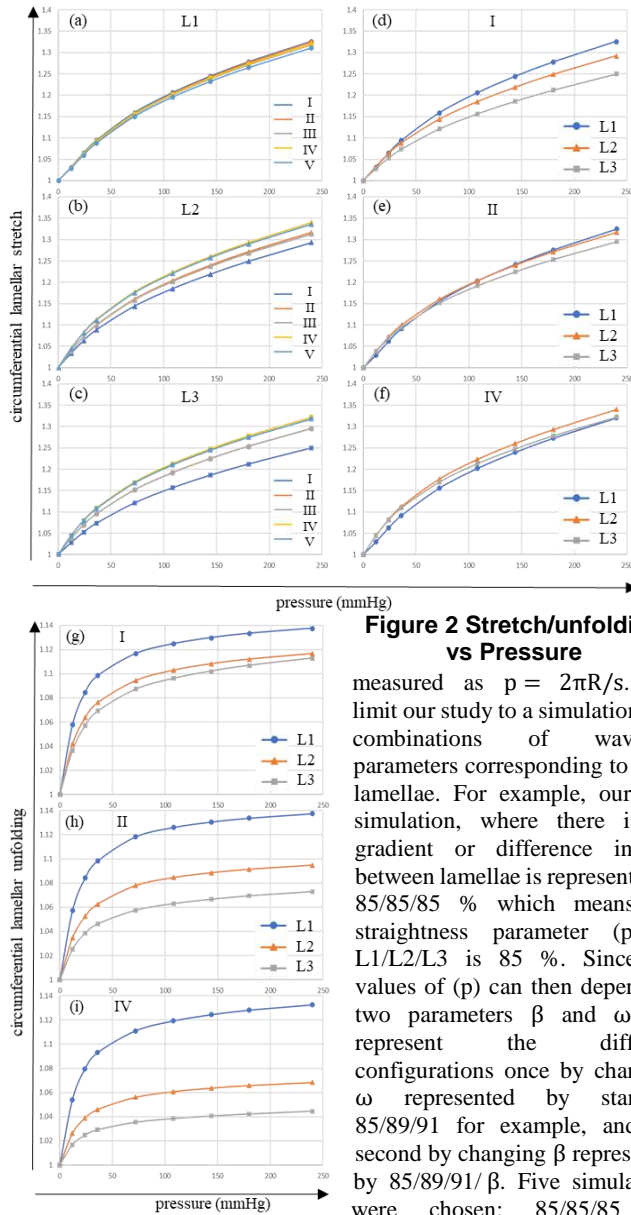

Figure 2 Stretch/unfolding vs Pressure

measured as $p = 2\pi R/s$. We limit our study to a simulation of 3 combinations of waviness parameters corresponding to the 3 lamellae. For example, our first simulation, where there is no gradient or difference in (p) between lamellae is represented as 85/85/85 % which means the straightness parameter (p) at L1/L2/L3 is 85 %. Since the values of (p) can then depend on two parameters β and ω , we represent the different configurations once by changing ω represented by standard 85/89/91 for example, and the second by changing β represented by 85/89/91/ β . Five simulations were chosen: 85/85/85 (I), 85/89/91 (II), 85/89/91/ β (III), 85/92/95 (IV), and 85/92/95/ β (V). **Fig. 1** shows the five configurations chosen, with sections shown adjacent to one another. The sections are color coded to match the plots in **Fig. 2** (a-c). The 2D geometries of the underlying matrix and the elastin lamellae are then extruded into 3D in the axial direction.

In Abaqus/Standard, the underlying matrix is discretized and modelled as C3D6 hexahedral elements in 3D, and the elastin lamellae are modelled as M3D3 triangular membrane elements formed as a sheet. The elements of the lamellae and matrix meshes are coupled using the distributing continuum coupling approach [4], with the master node coupled to nodes within a radius of influence ($3 \mu\text{m}$), and every coupling is given a cubic radial weighting function. The elastin lamellae are defined as neo-Hookean materials while the underlying matrix was defined as an anisotropic Gasser-Ogden-Holzapfel (GOH) material model with 2 fiber families [5]. The matrix was also partitioned into two sets with differing material properties, namely the Media and the Adventitia. While the material properties of the matrix were used from [6], three key assumptions had to be made:

1. Collagen/SMC fibers are defined circumferentially, where the radial directions of these local coordinates were assumed to be distributed along a linear curvature gradient between lamellae, where the circumferential directions of the fibers are biased towards the curvature of the lamella closest to it.
2. Definition of the GOH material properties of the Media in which the elastin lamellae are embedded. We assumed the neo-Hookean component of the GOH model to be zero or negligible. As such, we assume the media's isotropic response to arise from the interaction between lamellae and the underlying matrix.
3. Residual stresses are not taken into account in our model, and that the compression of elastin, along with the tension in the adventitia is not accounted for.

The analysis involves two steps: the first of which an axial stretch of 1.6 is applied, and the second is the static inflation from 0-240 mmHg. Lamellar stretch (**Fig. 2** a-f) is calculated as $(s_{\text{deformed}})/(s_{\text{initial}})$, and Lamellar unfolding (**Fig. 2** g-i) is calculated as $(p_{\text{deformed}})/(p_{\text{initial}})$.

RESULTS & DISCUSSION

A comparison of our simulations demonstrates faint difference in stretch. **Fig. 2** demonstrates two comparisons: (a-c) shows that lamellae L2 and L3 stretch more at higher gradients of (p) . The absence of a toe region confirms the hypothesis in [3] that stretch begins before lamellar unfolding is complete. Additionally, the method of defining (p) plays no role as the simulations (II) and (III) or (IV) and (V) are indistinguishable. Interestingly, a comparison of lamellae within simulations in **Fig. 2** (d-f) shows that a large gradient corresponds to a smaller difference in lamellar stretch. As we increased the gradient from **Fig. 2** (d) to (e) to (f) we see that the L2 and L3 stretch more freely at these higher (p) values. This suggests that the lamellae move somewhat independently of each other. Moreover, the difference in lamellar stretch of L2 and L3 (**Fig. 2** (b), (c)) suggests that the drastic mitigation in L3 stretch arises from its over-constraint, since it is coupled to nodes in the adventitia which are stiffer in the circumferential direction, and so at a wavier configuration, it is less likely to stretch and flatten. Finally, we comment on the similarity between results shown in **Fig. 2** (h) and Fig. 3 (d) in [3], demonstrating that unfolding occurs more drastically at L1 than at L2 and L3. Furthermore, a cursory comparison between our lamellar stretch shown in **Fig. 2** (e) which has the most similar configuration to [3], and Fig. 5 (c) in [3] shows two characteristics of note: 1- That the different lamellae in the artery have similar stretches, confirming that the gradient may play a role in that similarity. 2- The stretch in our model is lower overall. We surmise that this discrepancy can be attributed to our assumption not to incorporate residual stresses, and that the ideal figure of waviness may correspond more closely to a combination of flattened and undulating configuration rather than strictly one or the other. Future work involves reconstruction of 3D synchrotron data obtained in [2] and applying our methodology to investigate lamellar dynamics and further assessment and (experimental) validation of the hybrid approach.

INTRODUCTION

Coronary stenting has become a common technique to treat patients with atherosclerotic plaque build-up in the coronary arteries. Implantation of the stent allows for the restoration of blood flow through the previously stenotic artery. However, once implanted, the presence of the stent frame often causes several additional complications, most common of which are restenosis and thrombosis. These complications are thought to occur due to the altered hemodynamics at the microscopic scale near the stent struts and the lumen wall [1]. Wall shear stress (WSS), which is the frictional force of blood against the lumen wall, has become a critical hemodynamic metric for predicting the likelihood of such complications in patients who have undergone the stenting procedure. Specifically, WSS is known to be significantly altered at the “local” scale (the stent struts) due to the presence of the stent footprint, which may begin the process of restenosis or thrombosis.

In-silico approaches, namely computational fluid dynamics (CFD) simulations, are commonly used for quantifying WSS. When used for predicting the likelihood of stent-induced complications in individual patients, these computational models require the use of patient-specific lumen and stent geometries for the most accurate results [1]. However, many previous approaches do not include the stent footprint, thus providing information only at the “global” scale (the artery) and little information at the “local” scale (the stent struts), where the local scale information is required to accurately assess and predict flow dynamics.

Recent studies have begun including the stent footprint into the patient-specific lumen geometries as well [2]. However, in such instances, the number of cases evaluated becomes severely limited, primarily due to the level of automation required for reconstructing such high-fidelity models. Recently, we have developed a semi-automated reconstruction approach for patient-specific stented coronary arteries that is based on data assimilation techniques and computer aided design (CAD) [3]. The approach allows for a nearly operator-independent reconstruction of patient-specific coronary geometries, which is critical

for analysis of large patient cohorts, especially within the context of clinical trials, i.e., *in-silico clinical trials*.

The objective of this study is to employ the previously developed reconstruction methodology as a part of the SHEAR-STENT clinical trial. A subset of patients was taken ($n = 30$) for analysis, where we focus on the applicability of the reconstruction pipeline for efficiently generating a large cohort of patient-specific arteries for CFD analysis. In addition, we perform an analysis of the same patient cohort without the presence of the stent to evaluate the true impact the stent footprint has on the resulting WSS distribution at a large-scale statistical level. We hypothesize that the presence of the stent footprint causes a statistically significant difference in the WSS distribution, and this difference may be correlated with the vessel curvature and tortuosity.

METHODS

Patient data was obtained from the SHEAR-STENT trial in the form of optical coherence tomography (OCT), intravascular ultrasound (IVUS), and angiography imaging. The trial focuses on evaluating the effects of two drug-eluting stents, the Abbott XIENCE Xpedition and Medtronic Resolute Integrity, on regional plaque response following implantation. The subset of patient data for this study ($n = 30$) was randomly chosen from the total cohort in the clinical trial ($n = 86$).

The previously developed semi-automatic reconstruction approach can be summarized in a few steps. Angiography and OCT imaging were initially used to reconstruct the 3D lumen for each of the patients. OCT imaging was then used to identify stent strut point clouds in a semi-automatic manner, where most of the points are identified automatically with some manual input to fix any errors in the point cloud. A 3D CAD template of the two stents (XIENCE and Resolute) are deformed to the point cloud via an image registration approach [3]. The deformed stent template is then deformed to the 3D lumen via an elastic deformation process. Finally, the stent skeleton is expanded into a 3D structure with the use of Nef-polyhedra, and subsequently imprinted into the 3D lumen via a Boolean operation, resulting in the final patient-specific stented

geometries. Non-stented geometries of the same patient cases were also generated for direct comparison purposes.

All stented and non-stented models were meshed using *ICEM CFD* (ANSYS ICEM 21), with the average mesh size ranging from 2-3 million elements. Steady CFD simulations were performed with the commercial solver *Fluent* (ANSYS 21). The steady approach was used as a surrogate for the time average of the unsteady solution, as the primary objective was to compare the WSS between the stented and non-stented reconstructions using the same CFD approach. Inflow boundary conditions were prescribed with patient-specific constant velocity inlets, and percentage-based flow distributions were prescribed at the outlet. WSS data was calculated and extracted from *Fluent*.

To gain a better understanding of the local hemodynamics at the stent strut level, a series of post-processing steps were performed. Specifically, this involved thresholding the WSS data from the stented simulation such that the region of focus along the lumen geometry was only on the stented area. This was followed by a series of filtering and thresholding steps to remove all WSS data that were not embedded on the lumen wall, such that the focus of the WSS analysis would only be on the endothelium surrounding the stent struts. Finally, these steps for the stented WSS data were also repeated for the non-stented WSS data for comparison purposes. All post-processing was done using the *Visualization Toolkit* (VTK) and *Vascular Modeling Toolkit* (VMTK).

Curvature analysis was performed for the reconstructed arteries using *VMTK*. Individual centerlines were extracted for each case, from which average curvature and tortuosity values were calculated and compared against the difference in WSS between the stented and non-stented models. A slice-by-slice analysis was also performed along four randomly chosen patient cases to have a better understanding of the local average curvature against the local average differences in WSS.

RESULTS

CFD results for five sample cases following filtering of the lumen geometries are shown in Fig. 1. Comparing the WSS distribution between the stent and no-stent models, clear visual differences can be seen. The presence of the stent footprint causes regions of lower luminal WSS as compared to the same regions from the no-stent model. The average WSS was greater in the no-stent model, with an average difference of 0.293 Pa and a standard deviation of 0.086 Pa. Closer inspection of the endothelial WSS also indicates that the WSS is lower in parts of the lumen that correspond to regions of stent malapposition.

Figure 1. Comparison of WSS between stented (left) and non-stented (right) models for five sample cases (A-E).

The percentage of lumen area exposed to low (less than 0.5 Pa) and moderate (less than 1.0 Pa) WSS was also compared to gain a better understanding of the impact at the microscopic scale (Fig. 2). Both scenarios had statistically significant differences between the models, with the low WSS case showing an especially large discrepancy.

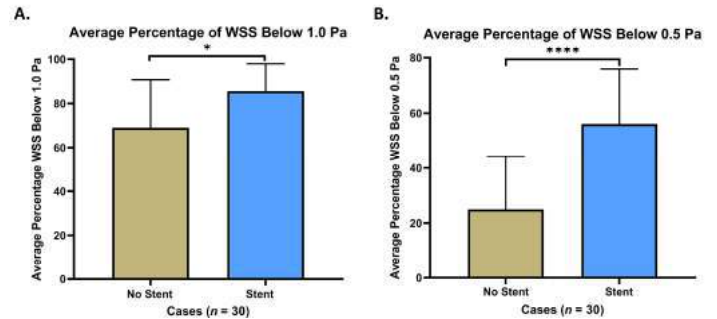

Figure 2. Comparison of the percentage of lumen area exposed to moderate (A) and low (B) WSS between the two models.

Average curvature and tortuosity values for each case are plotted against the difference in percent WSS below 0.5 Pa in Fig. 3. A negative trend is seen with R-squared values of 0.1779 and 0.06061, indicating that the greater the vessel curvature is, the less of a difference is seen in the WSS. Slice-by-slice analysis for the four patient cases also resulted in similar and stronger trends (R-squared values up to 0.6837).

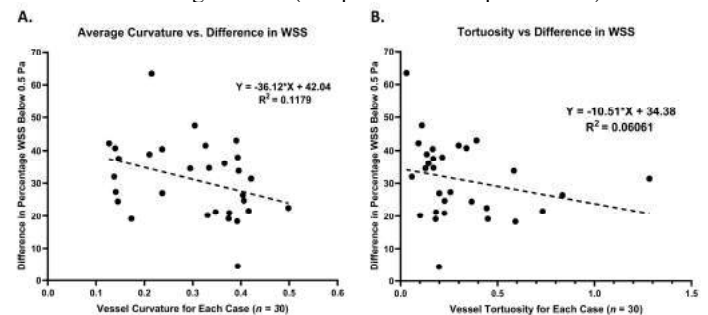

Figure 3. Curvature (A) and tortuosity (B) vs. differences in WSS.

DISCUSSION

In this study, we employ a semi-automatic reconstruction approach for patient-specific arteries to examine the impact of the coronary stent footprint on the WSS at a large-scale, statistical level, which is one of the first to focus on such a large sample size ($n = 30$). The results show that the stent footprint causes a statistically significant impact on the coronary hemodynamics, indicating that the stent footprint must be included in most traditional computational models for accurate WSS analysis. Especially large differences were seen at low WSS thresholds, which may be important in the context of restenosis as it is known to begin developing in regions of lumen wall exposed to low WSS [4]. The curvature analysis indicates that vessel curvature may help determine the need for the stent footprint in simulations, where a potential cut-off value could be determined to see when exactly the stent footprint should be included. A major limitation of the study is that only steady flow simulations were performed, which may ignore the pulsatile nature of flow through the coronaries. Future work includes performing transient, pulsatile CFD simulations for more accurate values, although we expect to see similar, and potentially more significant trends as seen here.

In conclusion, this study shows that the stent footprint causes a significant impact on the WSS. The present study also indicates the feasibility of performing large scale *in-silico* clinical trials in a patient specific manner with the use of automated reconstruction methods.

BIOMECHANICAL FOLLOW-UP AND EVALUATION OF ANEURYSM GROWTH

F. A.M. Garbou (1), O. O. M. Elnamla (1), W. A.K.A. Saber (1), K. B. Kose (1),

INTRODUCTION

Cardiovascular diseases have the highest mortality and morbidity rates. Each year, cardiovascular disease (CVD) is estimated to be the cause of 32% of all deaths worldwide[1]. During blood flow in the circulatory system, the vessel wall is constantly exposed to mechanical forces and can play a role in the development of pathologies if the arterial endothelium morphology is abnormal. In an aortic artery with an aneurysm, these changes may result in a rupture of the endothelium. An accurate pre and post-operative risk of an abdominal aortic aneurysm rupture is an important guide for planning aortic aneurysm repair surgery. Clinical studies have determined the risk with maximum aneurysmatic diameter based on medical imaging technologies. [2] However, it is known that the risk is not necessarily reflected by the maximum diameter alone [3]. Therefore, additional information is required for accurate risk assessment of an aneurysm before and after surgical repair. This study was designed to numerically evaluate the remodeling in aortic aneurysm morphologies and underlying mechanical factors. This study compared the relationship between the changes in aneurysm morphology and hemodynamic parameters in patients who were scanned at regular intervals. In flow visualizations based on virtual aortic models obtained from computed tomography datasets of three different scans, it was determined that the endothelial segments with distinctive changes in wall shear stress (WSS) distribution showed high consistency with the morphological change segments seen in the next periodic scans of the same patients.

METHODS

Five patients diagnosed with thoracic aortic aneurysms and aged between 70-75 were included in the study. Virtual aorta models were created from the CT images of the patients taken at

three-month intervals (Figure 1). Three-dimensional (3D) models were created with VTK algorithms and a model mesh for finite element analysis was created with Simmetrix libraries. Blood flow was simulated by computational fluid dynamics analysis and visualized in Ceetron Analyzer Cloud [4]-[6].

In this study, we focused on WSS visualization, a parameter that cannot be measured in the clinical setting but can be calculated by multi-physics algorithms. Blood was considered Newtonian fluid and boundary conditions were established from case-specific data obtained from the clinic [7]. The initial velocity gradient was obtained from the Doppler ultrasound reports of the patients.

Figure 1: 3D models of the aorta segmented from CT data obtained at regular intervals of the selected patient.

RESULTS

Numerical simulation results were visualized as WSS distribution on the arterial wall. The WSS in the proximal ascending aorta was reported to be up to 1800 ± 100 Pa for patients with aortic aneurysms, while it was reported to be up to 700 for healthy people in the literature. Studies have shown that WSS can alter the material properties of thoracic aortic aneurysms through arterial wall remodeling, making the aortic wall more prone to swelling as shown in the figure which represents the growth segments of the following scan (Figure 2).

Figure 2: The WSS distribution on the first scan of Patient A.

DISCUSSION

After this preliminary study, it has been observed that the most obvious effect of WSS on the change of endothelium morphology starts from the segments where dramatic decreases in WSS distribution are seen. The numerical analysis results were obtained in line with our hypothesis that shape change rates that may be encountered in the next scan could be predicted. This work was able to present significant findings on the evaluation of studies on aneurysm growth with in-silico methods and it is possible to strengthen it with more scan datasets.

INTRODUCTION

Biological sex is a significant risk factor for traumatic brain injury (TBI). However, there has been little attention to sex differences in concussion until recently. Diffuse axonal injury (DAI) is one of most prominent pathologies found in all severities of TBI. At the axonal level, there are significant sex morphological differences as observed in ultrastructure studies (e.g., smaller in microtubule (MT) density and axon cross-sectional area and with fewer MTs than male axons⁵).

To-date, studies on axonal injury are focused on injury triggering mechanisms, such as microtubules (MTs) tear¹, strain concentration around the Ranvier node,² and interaction among various axonal substructures³. These axonal injury models offer valuable insight into the potential causes of heterogenous DAI pathologies. However, no study exists to investigate sex differences in axonal substructural responses.

To facilitate a systematic investigation into sex differences in DAI at the microscale, we have developed a parameterized modeling approach for automatic and efficient generation of sex-specific axon models according to specified geometrical parameters. In this study, baseline female and male axon models in the corpus callosum with random MT gap locations are generated for model calibration and validation. We then report results of sex differences of MT and Ranvier node peak strain amplification and tau protein and neurofilament (NF) failures under a realistic dynamic input generated from a real-world impact simulation that contains both a loading and an unloading phase.

METHODS

Baseline unit female and male FE models of 8 μm in length were developed. The main cytoskeleton components of both axon models include MTs, axolemma, myelin sheath, Ranvier node, MT-associated protein (MAP), tau and NF network. Both models explicitly meshed all

major axonal substructures and adopted their respective averaged geometrical parameters according to the literature, as reported in (Table 1). To maximize geometrical radial symmetry and to facilitate meshing, 7 MTs were retained for a typical female model (1 MT in the center with 6 additional ones to form a one-layered hexagonal pattern), and 13 MTs were retained for a typical male axon (with 6 additional MTs in the second layer), respectively. They reflect the average of 8 and 12 MTs. To avoid ambiguity, they are also referred to as MT7 and MT13 models.

Table 1 | Geometrical features of axonal substructures²⁻⁴

Axolemma radius	# of MTs	MT spacing	MT inner radius	MT outer radius	g-ratio*
200/300 nm	7/13	30 \pm 2.5 nm	7.0 \pm 0.75 nm	12.5 \pm 1.5 nm	0.65 \pm 0.075
MT length	NF	Axolemma thickness	Ranvier node	MT gap length	
4.02 \pm 5.28 μm	Fill remaining space.	8 \pm 0.75 nm	1 μm	0.12 μm	

*g-ratio, the ratio of the inner axonal diameter to the total outer (myelin sheath) diameter

Most axonal substructures were assigned with linear viscoelastic material properties based on the literature. Material properties for the NF were calibrated for both MT7 and MT13 models with a hertz contact experiment to ensure their responses fall within the experimental measurement corridor. With the calibrated NF stiffness, the baseline models were then validated against in-vivo experimental tension dataset⁷ by simulating a quasi-static uniaxial tension experiment (30% peak strain at a rate of 0.17 s^{-1}). MT breakage and Axolemma rupture behaviors were simulated using a strain failure threshold of 50% and 34%, respectively. For tau and NF, a 100% failure threshold was adopted based on relevant literature, above which the corresponding elements would produce a zero-reaction force. Elements after failure

were deleted for subsequent simulation. Baseline models were then used to simulate axonal stretch from a real-world impact. Specifically, a strain history curve (Figure 1a) in the corpus callosum obtained from a previous simulation of a reconstructed real-world head impact using the anisotropic Worcester Head Injury Model V1.0.

Axon dynamic behaviors depend on MT gap configurations. They are quantified by using a bivariate probability strategy. The unit axon model length (L) was used to define a series of discrete “sampling lengths”. Starting from the shortest sampling length (L_s) chosen to be 5% of L , the entire axon model was scanned axially to identify the maximum number of MT gaps (N) falling within the specified length. The pair of parameters, (L_s , N), were then used to characterize the MT gap configuration. For each sex, ten thousand ($N=10,000$) models with baseline geometrical parameters (Table 1) were created, from which the bivariate distribution probability, (L_s , N), was calculated.

For each simulation, 5 axon models were generated for each MT gap configuration with a nonzero probability for each sex. Peak strain amplifications in MT relative to peak input strain were obtained, along with the associated tau and NF failure rates. They were then organized according to the bivariate MT gap configurations to obtain corresponding averaged responses, from which sex differences in responses were compared. All simulations were conducted in SIMULIA Abaqus with the implicit non-linear FEA solver (32 CPUs, 64GB).

RESULTS

For each simulated axon model, we consistently observed MT undulation, regardless of the sex or specific MT gap configurations. They all started near the end of the unloading phase and sustained even after the completion of unloading. The undulation behavior agreed well with TEM findings observed immediately after dynamic stretch injury. Case illustrations are shown in Figure 1.

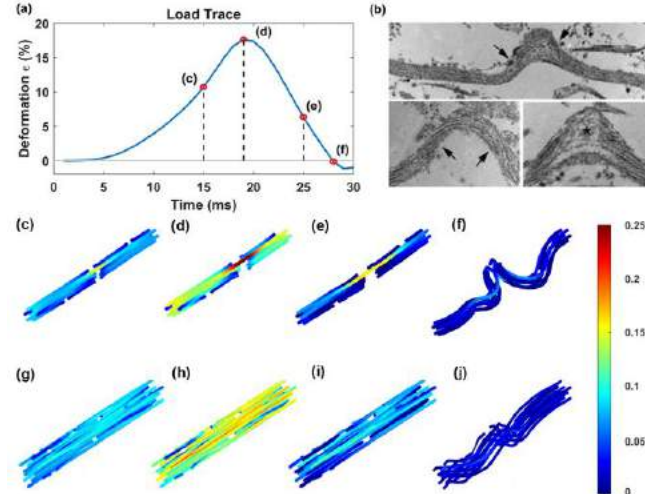

Figure 1: (a) Corpus callosum fiber strain time history as input applied to the axon models. (b) MT undulation in dynamic stretch injury test ⁶; From (c) to (j): MT strain distributions in deformed states at selected time points (as indicated in (a)) for a typical female and male axon model.

With the applied input (peak strain of 18%), none of the MTs or Ranvier nodes in any model exceeded their failure strain thresholds. In general, higher MT strain amplifications occurred when there were more MT gaps within a shorter sampling length for both female and male models. However, peak strain amplifications in the Ranvier node were mostly uniform for both models and were insensitive to the gap configuration. Figure 2a-b report tau and NF failure rate (element

length-weighted percentage of failed elements) progressions over time for a female and a male axon model with their most common MT gap configurations. The male model had a higher tau failure, but the female axon model had a much higher rate for NF failure.

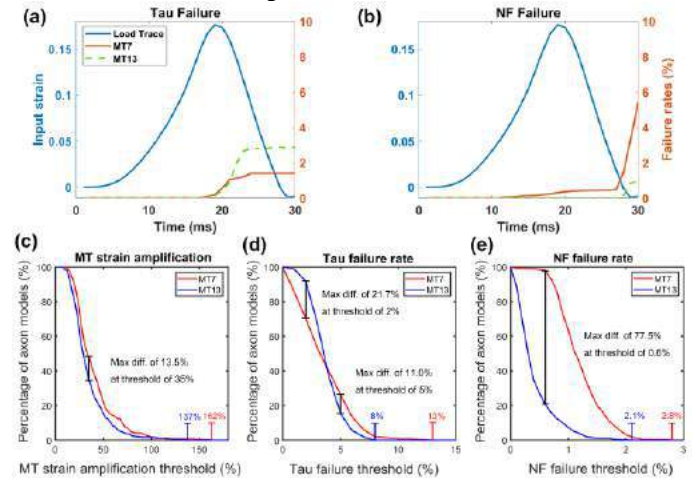

Figure 2: Tau (a) and NF (b) failure rates over time for a female and a male axon (MT7 and MT13, respectively); Percentages of female and male axon models with MT peak strain amplification (c), tau (d) and NF (e) failure rates exceeding a range of thresholds for each sex.

Using a large sample of axon models with random MT gaps for each sex, the percentages of axon models with MT peak strain amplifications exceeding a range of thresholds were compared, as well as those with tau and NF failure rates above a given threshold across their respective value ranges (Figure 2c-e). For MT strain amplification and NF failure, female axon models always had a higher percentage of above-threshold responses across the value ranges. For tau failure, however, the sex difference depended on the threshold value, itself.

DISCUSSION

We find axonal substructural responses in terms of peak strain amplifications in MTs and the Ranvier node as well as NF failure rates in female axons are considerably higher than those in male axons in dynamic tensile loading and unloading. The underlying reason are largely due to the sex-related difference in the cross-sectional number of MTs and the random nature of MT gaps. Both random MT gaps in model and the unloading phase in dynamic tension are critical to reproducing MT undulation as observed experimentally. The study may lead to an improved understanding of sex differences in injury vulnerability at the microscale as well as the biomechanical mechanism of DAI in general.

UNDERSTANDING FABRIC FRICTION TO REDUCE THE RISK OF PRESSURE INJURIES IN WHEELCHAIR USERS

Archana Lamsal and Tamara R. Bush, PhD

Mechanical Engineering, Michigan State University, East Lansing, MI, USA

INTRODUCTION

Wheelchair users spend a great deal of time seated and because of this, they have a high risk of developing pressure injuries (PIs). Wheelchair users are particularly prone to PIs on the bottom of their buttocks [1]. Infections, sepsis, and even death can result from PIs which makes PIs a serious health issue [2]. One risk factor that increases the risk of PIs are shear forces (forces parallel to person's tissue) on the buttocks [3]. Shear forces are greater when friction is higher. Lowering the coefficient of friction between the seat and the user's pants, can help reduce the shear forces that a wheelchair user experiences and as a result, decrease PI risk. To achieve this, it is essential to understand the friction at the interface between the seat cushion and the pants. It is also critical to understand how the presence of a deformable foam affects the frictional behavior of these interacting fabrics.

Thus, the goals of this study were: 1) to determine the coefficients of friction of seven commonly worn pant fabrics and two seat cover fabrics and 2) to investigate the effects of a deformable seat cushion on the coefficients of friction between fabrics.

METHODS

The materials and devices used for this research included a seat pan with the ability to tilt from zero degrees (horizontal) to 45 degrees of rearward tilt; a mechanical system called the 'sled' (Figure 1) where different fabrics were attached; a multi-camera motion capture system; and reflective markers. The sled had a cross section of 15 cm x 15 cm and thickness of one centimeter. A test weight of 110N was attached to the sled and the sled system was placed on top of the seat pan with the seat cover attached to it (Figure 1). The friction was determined through monitoring movement of the sled on the tilting seat pan. The seat pan was tilted until the sled system started sliding. Positional data of markers on the sled and the seat pan were obtained using a motion capture camera system with sampling rate of 100 Hz and accuracy < 0.5 mm.

The coefficient of static friction was determined using Newton's second law of motion. The free body diagram of the experimental setup, just before the sled started sliding on the seat pan, is shown in Figure 1 (right). The axis parallel to the inclined surface was denoted as the t-direction (tangent) and that perpendicular to the inclined surface was denoted as the n-direction (normal).

The force balances used to determine the coefficient of static friction (μ_s) are given by Equations 1 and 2.

$$\sum F_t = \mu_s mg \cos(\theta_{\max}) - mg \sin(\theta_{\max}) = 0 \quad (1)$$

$$\mu_s = \tan(\theta_{\max}) \quad (2)$$

Where, F_t was the total force in tangential direction, m was the mass of the sled system, g was the gravitational constant and θ_{\max} was the maximum angle of tilt before the sled started to slide.

Figure 1. Left: Sled system on seat pan was tilted from horizontal until sliding started. The angle of tilt is denoted by θ . Right: Free body diagram of the sled system just before the sled started to slide on the seat pan, used to calculate coefficient of static friction (μ_s).

Two different seat covers were analyzed; a vinyl seat cover commonly used in wheelchairs and a fabric type seat cover commonly

used in office chairs (referred to as ‘office cover’). Seven different pant fabrics were analyzed (Figure 2).

Figure 2. The fabric structures of all the pant fabrics and seat covers under 50x magnification.

To achieve the second goal, a piece of polyurethane foam with a density of 67 kg/m³ and thickness of 38 mm was secured underneath the seat cover to replicate the effect of an office or wheelchair seating environment. The seat cover was nailed into the wooden seat pan (along the sides) to secure the foam and the seat cover taut. All the data sets were collected for 10 repetitions.

RESULTS

The static coefficients of friction between the pant fabrics and the seat covers; both with and without the foam in the seat pan are presented in Table 1. The office seat cover produced a smaller friction coefficient than the vinyl seat cover for all the pant fabrics - both with and without the foam. With the vinyl seat cover, the women's pull on pants and women's khakis produced the lowest coefficients of friction whereas jeans and basketball shorts produced the highest coefficients of friction. With the office seat cover, the basketball shorts and women's khakis produced the lowest coefficients of friction whereas the sweatpants and jeans produced the highest coefficients of friction. For any given pair of pants and seat cover, the coefficient of friction was consistently larger with the presence of foam in the seat pan than without the foam.

Table 1 Static coefficients of friction (μ_s) between the pant fabrics and seat covers; both with and without the foam in the seat pan. Values in the parenthesis indicate the standard deviation.

Pant material	Vinyl seat cover		Office seat cover	
	Without foam	With foam	Without foam	With foam
Women's pull on pants	0.492 (0.025)	0.548 (0.032)	0.376 (0.029)	0.381 (0.016)
Women's khakis	0.502 (0.016)	0.549 (0.01)	0.343 (0.038)	0.375 (0.029)
Sweatpants	0.539 (0.015)	0.572 (0.021)	0.414 (0.037)	0.449 (0.02)
Men's khakis	0.54 (0.014)	0.555 (0.021)	0.345 (0.03)	0.379 (0.027)
Women's jeans	0.546 (0.018)	0.61 (0.016)	0.428 (0.026)	0.493 (0.039)
Men's jeans	0.585 (0.016)	0.635 (0.017)	0.422 (0.033)	0.486 (0.037)
Basketball shorts	0.59 (0.031)	0.661 (0.042)	0.281 (0.016)	0.308 (0.01)

DISCUSSION

Understanding the frictional properties of the seat interface is important, especially for wheelchair users. Since increased shear forces leads to increased risk for PI formation, identifying material pairings with lower frictional properties could help mitigate this risk.

Fabrics such as men's and women's jeans were not optimal pant choices as they had higher frictional coefficients with both seat covers. Women's khakis produced smaller friction coefficients with both the seat covers and therefore would be considered an optimal fabric choice with the seat covers tested. The lower coefficient of friction demonstrated by women's khakis could be due to the interaction of various factors such as presence of spandex in the fabric, a relatively smooth feel of the fabric (although it was difficult to quantify) and a tight fabric structure woven with a thin yarn as shown by the microscopic images.

The results of this study also documented the complexity of frictional behavior of fabrics. While the basketball shorts demonstrated the largest coefficient of friction with the vinyl seat cover, this fabric also had the lowest coefficient of friction with the office seat cover. This implies that the best fabric choice for friction reduction with a particular seat cover might not be an optimal choice with a different seat cover. Furthermore, there were large differences in the friction coefficients of basketball shorts and women's pull on pants with the vinyl seat cover despite both being made of 100% polyester. These results demonstrate that despite a similarity in the type of material (polyester), there might be differences in other properties such as yarn material, weave, surface finish etc., which also affects friction [4, 5, 6].

The larger coefficient of friction with the vinyl cover was likely attributed to the larger contact area of the vinyl surface as evident from the microscopic images (Figure 2). The vinyl surface comprised of large flat plateaus and smaller valleys which would provide a large contact surface area as opposed to the office fabric which was made of woven fabric yarns. Since vinyl is commonly used in wheelchairs, choosing an alternative seat cover that provides lower frictional coefficients would be beneficial.

The effect of foam should also be considered in regards to the friction at the seat interface as all customized wheelchairs include a foam cushion on the seat pan. The data indicated that the presence of foam underneath the seat cover increased the coefficient of friction for all materials.

The results of this study provide valuable information regarding the friction that occurs between pants and a seat surface. Replacing a traditional vinyl cover with an alternative fabric cover might be beneficial to reduce friction, and therefore reduce shear forces on wheelchair users. While some pant fabrics demonstrated consistent frictional behavior with both seat covers, some fabrics showed vastly different behavior with the two seat covers. Thus, careful considerations should be made while selecting pant fabrics for wheelchair users as well as the cushion material.

INTRODUCTION

Mitral regurgitation (MR) is a prevalent disease, present in 1.7% of the general population and 9.3% of those age 75 and older [1]. The disease occurs when the two leaflets of the mitral valve (MV) do not close properly during systole. For treatment of symptomatic moderate-to-severe or severe MR in patients deemed high-risk for surgical treatment, Abbott's MitraClip transcatheter edge-to-edge repair device may be used. MitraClip is the only FDA approved transcatheter device and one of two transcatheter devices with CE mark. The device clips the two leaflets together to reduce MR, creating a double orifice. The current G4 generation is composed of four sizes with leaflet footprints of: NT, 9x4mm; NTW, 9x6mm; XT, 12x4mm; XTW 12x6mm.

Analyzing MV pressure gradient (MVG), defined as the mean MVG by simplified Bernoulli through diastole measured by continuous wave (CW) Doppler, during the MitraClip procedure is important. Leaving patients with gradients of 5 mmHg or more is undesirable and can lead to iatrogenic mitral stenosis, worsening patient prognosis [2-3]. MitraClip size is expected to impact MVG, and the impact on MVG is especially important in patients with geometries on the border of usage guidelines. However, there is a lack of understanding relations between geometric factors and MVG after clip sizes, as current analyses require full, expansive, patient-specific simulations. The objective of this study is to assess how border-line mitral anatomies and different MitraClip sizes impact MVG.

METHODS

A parameterization method was developed and applied to simplify MV geometries based on annular commissural (CC) and anterior-posterior (AP) dimensions and anterior and posterior mitral leaflet (AML and PML) lengths.

Based on measurements from 3D echo scans of 13 MR patients and guidelines for MitraClip use, six parameterized MV geometries were created *in silico* to capture the borders of MitraClip usage while

remaining reflective of patient MVs. Key measures of the six pre-clip geometries are shown in **Table 1**.

Table 1: Pre-Clip Model Dimensions

Model	CC [mm]	AP [mm]	AML [mm]	PML [mm]
A	26.0	24.0	23.0	10.0
B	28.0	26.0	23.0	10.0
C	28.0	26.0	23.0	10.0
D	30.7	28.7	22.0	10.5
E	32.7	30.7	22.0	10.0
F	37.3	35.3	22.0	11.0

Using an in-house reduced-order clipping simulation, clip placement was simulated to produce post-clip geometries. First, NT with central placement was mimicked. An example of pre- and post-clip geometries is shown in **Figure 1**.

Figure 1: Post- and Post-Clip Mitral Geometries

The pre- and post-clip geometries were 3D printed from rigid ABS for assessment in a left-heart simulator, where the model was placed upstream a bioprosthetic MV in order to maintain proper mitral flow. The simulator was set to physiological conditions of 60 bpm heartrate, 120 mmHg left ventricular pressure, and 5 L/min cardiac output. The working fluid was a 60-40 water-glycerin mixture to mimic the kinematic viscosity (3.88 cSt) and density (1060 kg/m³) of blood. MVG was measured using CW Doppler.

Based on these results, the models with the highest post-NT MVG and the highest post-NT percent increase MVG were reassessed using the other three MitraClip G4 sizes (NTW, XT, XTW) with central clip placement.

The resultant post-clip MVGs were compared against geometric factors to find a meaningful relation.

RESULTS

Post-NT MVG and percent increase MVG are shown in **Table 2**.

Table 2: Post-NT Mitral Valve Gradient and Percent Increase

Model	MVG [mmHg]	Percent Inc MVG [pct]
A	10.8	283
B	6.3	192
C	7.8	318
D	4.5	178
E	3.2	165
F	1.7	109

Since the greatest post-NT MVG was observed with model A (10.8 mmHg) and greatest post-NT percent MVG increase was observed with model C (318%), these models were analyzed with NTW, XT, and XTW. Analyzing the MVG against geometric factors yielded the area product between MVA and MAA to have a meaningful relation. This relation for all model-clip combinations is shown in **Figure 2**.

Figure 2: Mitral Valve Gradient vs Area Product

DISCUSSION

Across all configurations assessed, there was a strong power relation between the post-clip MVG and area product, with an R² of 0.90. This relation is expected, as choking off the flow by reducing inlet area (MAA) and outlet area (MVA) area is expected to greatly increase MVG as the velocity increases.

Focusing first on the smallest clip, which is the NT, the MVG had an overall increase with smaller models. Again, this relation is expected. Model A had the greatest post-NT MVG. This is because the conditions of the left-heart simulator were maintained across all configurations assessed, and model A was the smallest model. However, model C had the greatest post-NT percent increase MVG. This may have been due to

how the annular dimensions effect stretching of the leaflet over the orifice when clipped.

Assessing the G4 generation on model A yielded overall expected results. First, the relation between MVG and area product operate on the steeper limb of the relation (**Figure 2**), which is expected since model A is the smallest. The largest clip (XTW) gave the highest MVG followed by the XT. NT and NTW had similar MVG.

Assessing the G4 generation on model C gave similar results, landing a further down the relation curve compared to model A (**Figure 2**). Again, the XTW gave highest MVG. XT and NTW had similar MVG, and NT had the smallest MVG.

One cause of similar post-clip MVG with different clip sizes may be due to how the left-heart simulator is tuned between models, as afterload may have differed in order to maintain the same cardiac output, peak LVP, and overall mitral flowrate waveform. This also serves as a limitation of the study, as keeping these parameters constant between pre- and post-clip configurations does not account for changes in forward flow that comes with MR correction. Another limitation is the rigidity of the left-heart simulator, which is likely the leading contributing factor of sharp MVG increases, especially for smaller orifice models and larger clip sizes. However, these limitations keep conditions similar in order to capture effects of MV size and clip size alone.

Future work includes assessing different clip placement, as location of MitraClip in patients depends on location of the regurgitant lesion. Similarly, multiple clips should be assessed, as well as a combinations of different clip sizes, which is also reflective of clinical practice. Lastly, these results should be compared to *in vivo* data to assess potential of translating findings to clinical practice.

Results from this study show how simplified mitral geometries with *in silico* MitraClip placement can be used to gain insight on how device size and mitral geometry effect MVG. Expanding this work can help guide clip selection to prevent suboptimal MVG outcomes.

INTRODUCTION

Stroke is one of the leading causes of death and disability worldwide, with 13.7 million strokes in 2016 alone [1]. Large vessel occlusions account for up to 46% of acute ischemic strokes [2]. More specifically, blockage of the carotid arteries accounts for 34% of all ischemic strokes [3]. The rupture of ‘vulnerable plaques’ present in the carotid artery can lead to the obstruction of downstream vessels, consequently blocking blood flow to the brain [4]. Atherosclerosis is a progressive inflammatory disease, initially occurring in the inner layer of the arterial wall. The amount of lumen blockage caused by the cascade of inflammatory events is commonly referred to as the percent stenosis. Clinical decisions for carotid atherosclerosis treatment are primarily based upon this measure [5]; however, there is a growing body of evidence highlighting that vulnerability is governed by plaque composition and morphology, and not simply percent stenosis [6].

Ultrasound imaging is a non-invasive, safe, cheap, low-cost, and fast technique that can provide valuable information on plaques. The American Society of Echocardiography recently recommended the increased use of multimodal ultrasound imaging to gather more information on plaque characteristics [7], highlighting the need to establish better clinical biomarkers for plaque risk assessment using ultrasound. The goal of this study is to investigate *ex vivo* inflation testing of fresh human atherosclerotic plaques using ultrasound imaging. This testing set up, which reproduces physiological loading, facilitates the investigation of plaque mechanical behaviour, and has the potential to yield new insights for ultrasound derived biomarkers which can be assessed *in vivo*.

METHODS

Depending on the surgical technique, excised atherosclerotic plaques can present with large incisions. To circumvent leaks and allow for watertight pressurization, highly deformable balloons were created, and their compliance investigated on native porcine carotid arteries (NPCaA). For balloon fabrication, stainless steel mandrels were dipped in a liquid latex:water solution (3:2) and after >6 hours curing at 37°C, the balloons were removed using lukewarm water. NPCaA were collected from 6-month-old large white pigs and cryopreserved to -80 °C at a controlled rate of -1 °C/min in the presence of a cryoprotectant to preserve mechanical and structural properties. Samples were thawed in a water bath at 37°C on the day of testing and connective tissue was removed prior to inflation, Fig.1(a). NPCaA (n=6) were then inflated both with (n=3) and without (n=3) a balloon inserted in the lumen.

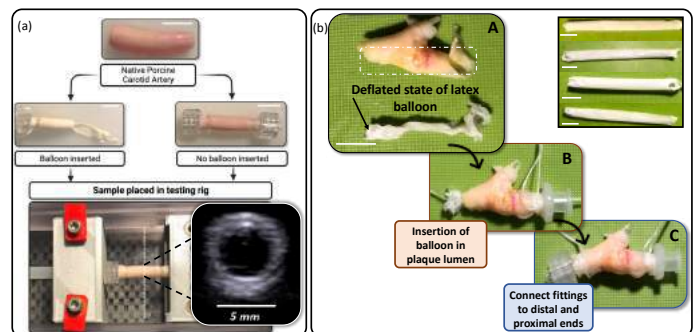

Figure 1: (a) NPCaA and (b) atherosclerotic plaque testing.

Intraluminal pressure was applied using a PID controlled syringe pump in 10 mmHg increments. An in-house inflation testing rig was developed to allow for ultrasound imaging of the pressurized samples up to 120 mmHg. Inflation occurred at room temperature in PBS. An axial stretch of 10% was applied to the NPCaA to reproduce *in vivo* pre-stretch. An ultrasound probe (9L4/12L4, SIEMENS, S2000) was placed above the sample to obtain B-mode scans for each pressure step. Outer diameters were measured using ImageJ and static compliance was calculated for each inflation [8]. For plaque testing, fresh human atherosclerotic plaques (n=6) were collected from carotid endarterectomy surgeries. Samples were cryopreserved and thawed in the same manner as NPCaA. Any lacerations or holes on the plaques were sutured closed using 6-0 polypropylene sutures followed by balloon insertion into the plaque lumen (Fig. 1(b)). After balloon insertion, both the plaques' and balloons' ends were attached to connector fittings. Statistical analysis was performed with Prism 6 statistical software (GraphPad Software Inc., San Diego, California). For compliance measurements, unpaired non-parametric t-tests were performed between the tested NPCaA groups (No Balloon, Balloon) for each sample. Significance was considered when $p < 0.05$.

RESULTS

B-mode scans of cross-sections of an inflated sample without (Fig. 2, top row) and with balloon (Fig. 2, bottom row) at 120 mmHg reveal similar wall expansion. This is further confirmed when comparing compliance measurements between inflations for each NPCaA (Fig. 2(b)). No significant differences were found. Therefore, the mechanical response of NPCaA to intraluminal pressurization is not affected when using this compliant balloon inflation approach.

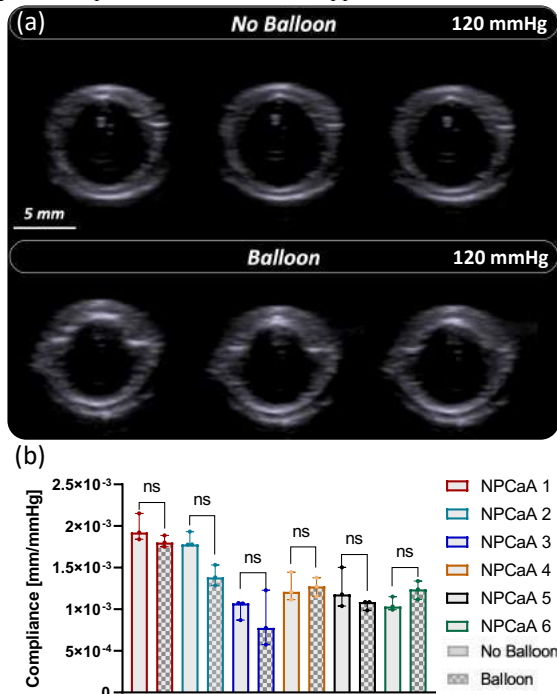

Figure 2: (a) B-mode scans of cross-sections of inflated NPCaA (n=1) without (top row) and with balloon (bottom row). (b) Median compliances of NPCaA (n=6) each inflated three consecutive times with and without balloon.

Using the method presented in Fig. 1(b), human, fresh atherosclerotic plaques were pressurized. B-mode scans of cross sections were obtained, see Fig. 3. A 9L4 probe was used for samples I to IV while a 12L4 one was used for samples V and IV. Bright hyperechoic regions

reveal areas of calcification as seen for sample I. Interestingly, sample V ruptured near the bifurcation where the balloon border can be observed out of the lumen, see Fig. 3.

Figure 3: B-mode scans and photographs of plaques (n=6) inflated using the balloon inflation methodology. Red dotted lines show cross sections imaged using ultrasound. Scale bars = 1 cm.

DISCUSSION

A methodology to perform watertight pressurization of excised human plaque samples is presented. NPCaA wall expansion was not significantly influenced by the balloons, with no significant difference between vessel compliance measurements with and without the balloons. This methodology was then used to inflate excised atherosclerotic plaques and obtain ultrasound cross-sections. This *ex vivo* testing setup facilitates *in vivo* physiological loading to be replicated; conditions which are inherently precluded when performing uniaxial or biaxial tensile testing on strips of plaque tissue. This set-up can therefore provide improved fundamental understanding of plaque mechanical behavior and, through parallel ultrasound imaging, identify features that can be translated clinically as biomarkers of vulnerability. Specifically, the potential of intraplaque neovascularization as a vulnerability indicator [9] can be investigated through this *ex vivo* testing rig. This opens the door for future quantitative analyses and investigations between mechanical indicators and plaque features, ultimately improving the clinical management of carotid atherosclerosis.

ACKNOWLEDGEMENTS

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) has become an increasingly common technique to treat patients with stenotic native aortic valves. As a part of the pre-operative planning strategy for patient-specific TAVR cases, computational modeling has become a critical tool for assessing the risk of post-TAVR complications, namely coronary obstruction and paravalvular leakage [1]. Traditionally, these models involve the use of finite element analysis (FEA) and computational fluid dynamics (CFD) techniques for visualization of the transcatheter heart valve (THV) during and after deployment [2-3]. Such analyses become extremely computationally expensive, as they involve time-dependent simulations of highly nonlinear mechanics that govern the THV stent frame and leaflets, as well as the patient-specific aortic root, native leaflets, and calcium deposits.

Reduced order models (ROM) have been readily used to introduce significant computational advantages as compared to traditional full order model (FOM) simulations (CFD or FEA). ROMs are traditionally divided into two stages, the *offline* and *online* stages. In the offline stage, several hundreds of parameterized FOM simulations are performed to generate a *snapshot* library of solutions. Using model reduction techniques such as the Proper Orthogonal Decomposition (POD) approach, this library is subsequently recycled in the online stage for new parameters of interest which results in a rapidly produced reduced order solution that comes at a fraction of the cost of the FOM [4].

The overarching objective of this study is to develop real-time predictive models of the entire TAVR deployment process with the use of ROMs, predicting both the structural and fluid dynamics of the THV during and after deployment. This involves generating separate ROMs for both the structural and fluid problems, which will then be coupled with appropriate boundary conditions at the fluid-solid interface. Specifically, the focus here is on advancing a previously developed POD-ROM for the structural deformation of the Medtronic Evolut R valve. This includes incorporating the nonlinear elastic properties of the

stent frame, as well as the time-dependent problem within the ROM framework. The goal is to use ROMs such that the computational costs of simulating the deployment of the valve are significantly reduced.

METHODS

For small local deformations, an initial linear elastic constitutive law is prescribed as follows,

$$\nabla \cdot \sigma = F \quad (1)$$

$$\sigma = \lambda(\nabla \cdot u)I + 2\mu\varepsilon \quad (2)$$

$$\varepsilon = \frac{1}{2}(\nabla u + \nabla u^T) \quad (3)$$

where, σ is the Cauchy stress tensor, ε is the strain tensor, F is the external volume force, and λ and μ are the Lamé constants. For larger deformations, nonlinear constitutive laws are required to accurately capture the deformation of the self-expandable nature of the Evolut stent frame. Specifically, a hyperelastic model is implemented, which serves as an initial approximation of the true superelastic properties of the nitinol stent. A Generalized Neo-Hookean form of the strain-energy density function in the following form is used.

$$\psi = \frac{\mu}{2}(I_c - 3) + \frac{\lambda}{2}(J - 1)^2 \quad (4)$$

Here, J is the Jacobian of the deformation gradient, and I_c is the first invariant of the right Cauchy-Green tensor. Boundary conditions (BC) in the form of zero displacement ($u = 0$) were prescribed at the upper and lower edges of the stent frame. The normal stress was also prescribed at a set of 15 points, i.e. $\sigma \cdot n(P_i) = d_i$ for $i = 1, 2, \dots, 15$. More precisely, all possible pairs among the 15 points were obtained, and the vector d_i was defined such that it was oriented along the line connecting two end points of each pair. These BCs are labeled as “force-pair” BCs which idealize the loads applied from the aortic wall on the stent frame and are used to mimic crimping and expansion of the stent (Fig. 1). The steady form of the models were initially used, followed by implementation of the time-dependent hyperelastic problem.

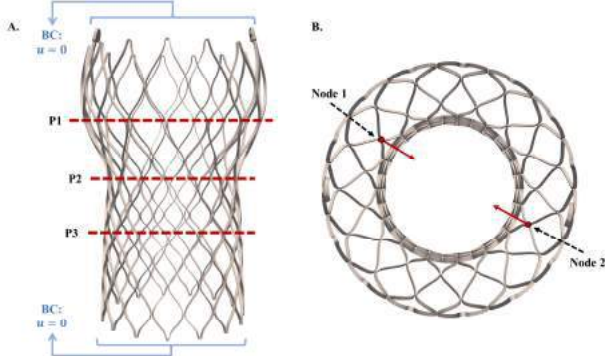

Figure 1. Boundary conditions enforced on Evolut R model.

The offline phase of the framework begins with a series of finite element (FE) simulations of Eq. (1) and (4). The 3D geometry of the Evolut R stent frame was generated in *SolidWorks*, and subsequently meshed using *Netgen* and *MmgTools* (260K elements). The stent frame was modeled with Young's modulus of 50 GPa and Poisson's ratio of 0.33. Using the 15 specified points for the parameterized BCs, a total of 105 FE simulations were performed in the offline stage. For the transient simulations, a semi-implicit approach is used. The time step was defined as 0.01 seconds, and the total time simulated was 0.3 seconds, which approximates the time taken for the stent to undergo deployment.

The online stage of the framework begins with a filtering operation to reduce the redundancy of the generated snapshot library. This is performed via the *Singular Value Decomposition* (SVD), which allows for analysis of the resulting singular values of the snapshot library. A rapid decay in the singular values indicates high redundancy, and that key features of the snapshot library can be captured by a linear combination of those left eigenvectors associated with the largest singular values. These eigenvectors form the reduced order basis, in the sense that the ROM solution reads as

$$u_{ROM} = Wc \quad (4)$$

where W is an $N \times n_{ROM}$ matrix, and c is a vector of coefficients. Following discretization of the governing problem, the FOM leads to a linear system of equations in the traditional form (i.e., $Au = b$, where A is the stiffness matrix and b is the forcing terms). With the POD technique, the ROM solution may then be substituted into the traditional discretization, resulting in the final reduced order system below.

$$W^T A W c = W^T b \quad (6)$$

Here, $W^T A W$ is a matrix that has a size in the range of tens or hundreds of rows, as compared to the traditional stiffness matrix A , which may feature a size in the range of hundreds of thousands or millions. Thus, the savings in computational costs becomes evident.

The entire ROM framework is implemented within *RBniCS*, an open-source model reduction library which is built upon *FEniCS*, an open-source FE library [4]. *RBniCS* allows for the automation of the entire process, from offline stage FE simulations to model reduction and online stage simulations. Results are all visualized in *ParaView*.

RESULTS

Stent crimping and expansion simulations were performed using a new set of force-pair BCs in the online stage. Fig. 2 visualizes the von Mises stress distribution for both linear and hyperelastic stent crimping simulations, and the ROM and FOM solutions were in strong agreement for each. In the linear elastic case, the maximum stress occurs along the same planes at which the BCs are applied (peak stress of 2344.66 Pa). In the hyperelastic case, the stress values are much greater (peak stress of 6948.72 Pa), and the maximum stress occurs adjacent to the nodes at which the BCs are applied. The stress distribution is also significantly more asymmetric in the hyperelastic case.

Figure 2. Comparison of ROM and FOM solutions for linear elastic (A) and hyperelastic (B) stent crimping simulations.

Computational details for all simulations are summarized in Table 1. The linear elastic case had a large reduction in time, with the FOM taking 14.82 and the ROM only 1.05 seconds, a 98.25% reduction. In the hyperelastic case, the reduction was from 107.99 to 10.46 seconds with the ROM, a 90.32% decrease. The transient simulations also had a slight decrease (195.50 to 132.83 seconds) with the use of the ROM.

Table 1. Computational details for all simulations.

Simulation	Mesh Size	# of Snapshots	# of FE DOF	# of RB	Wall Clock Time (s)		
					FE	ROM (Online)	ROM (Offline)
Linear Elastic	257671	105	227511	12, 13, 15	14.82	1.045	1556.32
Hyperelasticity	257671	105	227511	20	107.99	19.602	2797.79
Transient + Hyperelasticity	257671	105	227511	20	195.51	132.831	18062.44

DISCUSSION

This study introduces and advances a previously developed POD-ROM framework for rapidly simulating the structural deformation of the Evolut R valve. The ROM framework significantly reduced computational costs in both the linear and nonlinear cases while providing identical results as the FOM, highlighting the effectiveness of the POD approach for such structural problems. Although the reduction in computational time with the transient problem was not as large as the steady cases, this will be improved with the use of more advanced model reduction techniques. Namely, we will implement the discrete empirical interpolation method (DEIM), which is more effective for nonlinear transient problems and will allow for a larger reduction in costs. A major limitation is the lack of a true superelastic model, which is needed to capture the unique material properties of the nitinol stent. Future work involves implementing such a constitutive model, as well as adapting this structural ROM framework for use in real-time simulations of THV leaflet motion during the cardiac cycle. This new framework will then be coupled with a fluid-based ROM for the valve that will allow for real-time fluid-structure simulations following deployment of the THV.

In conclusion, the proposed ROM framework significantly reduces the computational costs of simulating the deformation of the Evolut R, while maintaining the accuracy from traditional FE simulations. Further refinements are underway for the framework to rapidly simulate the full fluid and structural dynamics of the THV following deployment.

THE ROLE OF ANNULOPLASTY RING SHAPE AND SIZE ON TRICUSPID VALVE REPAIR

Collin E. Haese (1), Mrudang Mathur (2), Manuel K. Rausch (1,3,4)

INTRODUCTION

Tricuspid valve disease remains a significant source of morbidity and mortality in the United States and worldwide [1]. Current estimates believe nearly 1.6 million Americans suffer from a regurgitant tricuspid valve [2]. The current gold standard surgical treatment for tricuspid valve disease, despite novel inventions in the percutaneous heart valve space, is tricuspid valve annuloplasty. Over the last 30 years of innovation in the medical device community many different annuloplasty ring sizes and geometries have been introduced. However, current clinical guidelines for selection of ring size and shape are not well defined and are primarily motivated by surgeon preference rather than quantitative scientific investigations. We have developed a high-fidelity, subject-specific finite element model of the healthy and diseased human tricuspid valve. The objective of our current work is to utilize the high-fidelity model to quantitatively compare different annuloplasty ring geometries as well as sizes. Specifically, we intend to investigate their effect on three measures of valve competence: 1) coaptation area as a primary measure of valve function, 2) opening angle as a secondary measure of tricuspid valve function, 3) leaflet stresses as a likely measure of mechanobiological stimuli for future valve disease.

METHODS

As mentioned in the introduction, we are going to use our high-fidelity finite element model of the healthy and diseased human tricuspid valve, the Texas TriValve 1.0, to quantify the effect annuloplasty ring size and shape has on valve function [3]. Please find a detailed account of all model specifics in our recent work. In brief, we built an accurate model of the human tricuspid valve from donated healthy human heart valves. To this end, we used data collected in a beating human heart that was rejected from transplantation using an organ preservation system. Thereby, we were able to record transvalvular pressure and displacement boundary conditions at the leaflet-myocardial annular interface as well as dynamic data for

validation using 2D echocardiography. After collecting hemodynamic data from the organ preservation system, we performed mechanical testing of the leaflet and chordae tendineae to derive valve-specific material properties and morphology. This data informed Holzapfel-like hyperelastic constitutive models and an Ogden material law for the leaflets and the chordae tendineae, respectively.

After assembling this valve in conjunction with knowledge from existing literature on placement of the chordae tendineae, we validated an explicit finite element simulation of the valve closure dynamics against our 2D echocardiography recordings. We use the same model to simulate a diseased valve state through asymmetric dilation of the annulus and displacement of the papillary muscles to test the impact of various annuloplasty devices.

Figure 1: a) Assembly of the healthy Texas TriValve 1.0
b) Cauchy stress of the healthy valve model at end-systole

RESULTS

In Figure 1 we see the results of a baseline simulation of our healthy Texas TriValve. The healthy valve after assembly is depicted in

Figure 1a while Figure 1b shows the valve at end-systole with Cauchy stress overlaid on the closed configuration of the valve. In Figure 2 we see the comparison between the stress state in the healthy valve and the diseased valve as well as the stress induced by five unique annuloplasty rings. For the results presented herein, the diseased annulus was asymmetrically dilated to be 60% larger than the healthy valve. The five annuloplasty rings utilized were the Edwards Lifesciences Carpentier-Edwards Physio, the Cosgrove-Edwards Classic, and the Edwards MC3, as well as the Medtronic Contour 3D and the TriAd 2.0 Adams band, which are all widely available. A uniform nominal ring size of 30 mm was used across repaired valve simulations, which were previously digitized [4]. The predicted deformation and stress state produced by the five rings is heavily dependent on the chosen ring. The Contour 3D appears to produce the lowest level of stress in the leaflets followed by the Physio ring. The Physio and MC3 rings present high levels of stress on the posterior leaflet which is likely due to chordae tethering. The stress on the other leaflets is similar between the MC3, Classic, and TriAd rings.

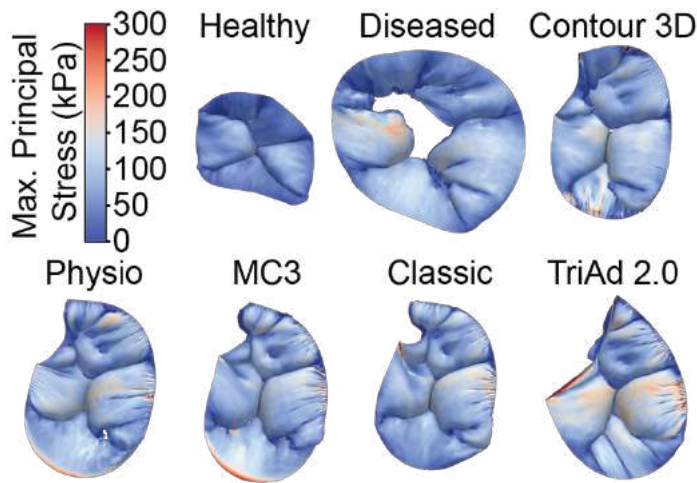

Figure 2: Comparison of the Cauchy stress exhibited by the healthy, diseased, and repaired valves

The comparison of the opening angle between the healthy, diseased, and repaired valves is detailed in Figure 3. The Contour 3D and Physio rings produce a smaller opening angle than found in the healthy valve, while the Classic ring presents a larger opening angle. The remaining rings reproduce an opening angle similar to the one found in the healthy valve. Likewise, Figure 4 illustrates the differences in coaptation area between the various valves. All repaired valves predict a larger coaptation area versus the healthy and diseased valve, suggesting all rings produce competent valve closure. However, between rings the amount of contact area varies substantially. Notably, the TriAd 2.0 generates the largest coaptation area while the MC3 develops the smallest contact area increase.

DISCUSSION

In this current work we used the Texas TriValve to investigate the impact of five different annuloplasty devices on three measures of tricuspid valve function. We found that annuloplasty ring choice impacts all measures of tricuspid valve function. Thereby, we have shown a numerical model such as ours, which is openly available, can be used to gain quantitative insight into choices which have previously been dominated by the personal experience of each surgeon. Please note we are currently working on completing identical comparisons to investigate the role of annuloplasty ring size. We anticipate to present a

total of 180 combinations of simulations to give never-before gained insight into choices of not only device type but also device size. We will apply these combinations on three different valves from three separate patients with various levels of annular disease progression to better represent the larger patient population as seen by clinicians. We are hoping our insight not only improves future device choice but also encourages others to use our open-source valve for similar investigations.

INTRODUCTION

Embedded fiber networks are ubiquitous in nature. For example, soft tissues rely on an embedded fiber network for strength and elasticity. Examples of such tissues include blood clots and myocardial tissue [1,2]. Notwithstanding their omnipresence in nature, there is little literature on the mechanics of these *embedded* fiber networks. That is, most prior work investigates networks in isolation, without considering the mechanics of the embedding matrix and the effects of their coupling. Those few works that considered embedded fiber networks have used either a confined mixture, i.e., continuum, approach (Fig. 1A) or have used discrete network and matrix models with matching discretization between the fibers and the surrounding matrix (Fig. 1C). In the former case, anisotropic, hyperelastic strain energy functions are being used to model both the network architecture and the surrounding matrix and confinement between both constituents is assumed [3]. While computationally inexpensive, this approach does not provide detailed control over the network's microstructure or the coupling between fibers and matrix. The second approach, while accurately representing

the network geometry, requires a very fine mesh, thus leading to a prohibitive computational cost [4].

A possible compromise between these two approaches is the use of a coupling scheme to embed discrete elements in an isotropic solid matrix without the requirement for matching discretizations (Fig. 1B). Thereby, we can inform our model with detailed microstructural information such as the network density, average fiber length, fiber crimp, type of crosslinking and average connectivity number, without requiring a matching mesh for the matrix material. Therefore, the matrix can be modeled with few elements, making this approach computationally highly efficient. Thus, this current study aims to use this fiber embedding approach to better understand embedded fiber networks. Specifically, we are interested in the network parameters that affect the “effective stiffness” of soft tissues.

METHODS

Network geometry. We consider Voronoi-based networks by discretizing a 3D unit domain using the Voronoi tessellation (Fig. 2A). Next, we isolate the cell edges, representing the individual fibers of the

Figure 1: Modeling approaches for embedded fibers. (A) Continuum model. (B) Beam to solid coupling. (C) Full 3D model with matching discretizations.

Figure 2: A) Voronoi tessellation of the unit cube. B) Network and fiber length distribution after applying min. length constraints.

network (Fig. 2B). Our pipeline can impose minimum fiber length constraints and generate networks with a target average connectivity $z < 4.0$, representing real semi-flexible polymer applications. To model fiber crimp, we introduce sinusoidal undulations on two normal axes of the cross-section. Finally, our pipeline iteratively removes any dangling or disconnected fibers.

Finite Element Model. We implement a mortar-type finite element method in Abaqus (SIMULIA, Providence, RI) as first described in [3]. We model individual fibers as spatial shear flexible (Timoshenko) beams and the surrounding matrix as an incompressible, hyperelastic material. We enforce the displacement coupling constraint through a Lagrange multiplier field using the penalty method.

RESULTS

To gain initial insight into how the effective stiffness depends on embedded fibers, we first investigate the simple case of a helical beam embedded in an isotropic, incompressible Neo-Hookean matrix under uniaxial extension (Fig. 3A). Note that the beam's cross-section is circular, and its material law is linearly elastic.

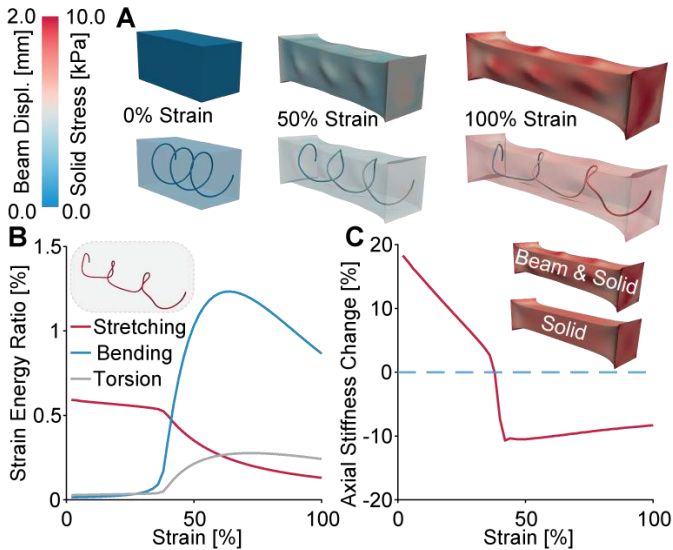

Figure 3: Embedded helical beam example. A) Beam displacement and solid stress fields. B) Beam strain energy components. C) Relative change of the axial stiffness of the embedded, coupled system with respect to the corresponding stiffness of the Neo-Hookean matrix without the embedded beam.

In particular, we examine the strain energy ratios of the beam at each strain level (Fig. 3B). Note that at approximately 40% strain, the dominant strain energy mode transitions from stretching to bending and torsional components. Fig. 3C illustrates the same transition in terms of the effective axial stiffness, as a %-relative change with respect to Neo-Hookean matrix without any embedded elements. Accordingly, even though the axial force always remains higher during the extension for the embedded/coupled model, the corresponding stiffness does not.

Fig. 4 illustrates our preliminary results of a Voronoi-based fiber network under simple shear (up to 40% shear strain), embedded in an isotropic, incompressible Neo-Hookean solid. Here, we introduced sinusoidal undulations of amplitude 5% and 10% of the straight fiber length (Fig 4A, B). In Fig. 4C & D we show that the increase in the undulation amplitude leads to a decrease in the effective shear stiffness.

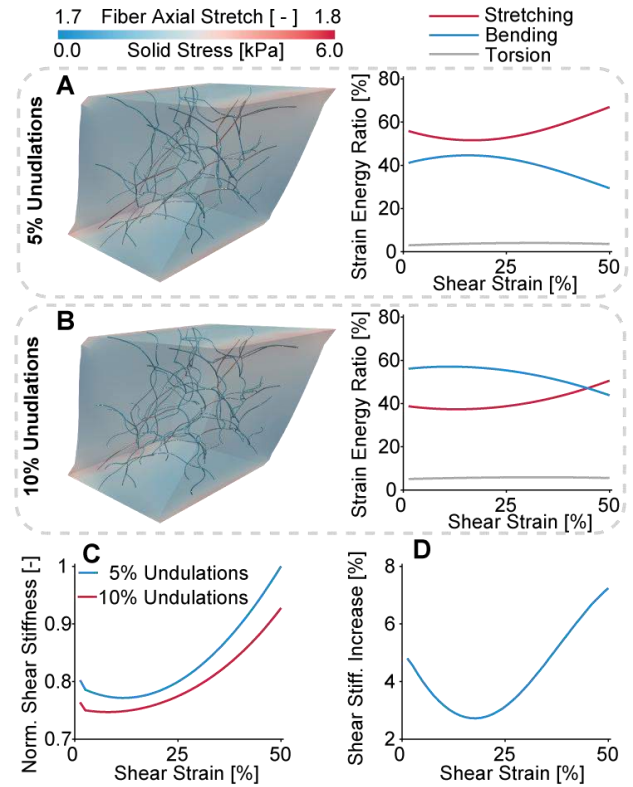

Figure 4: Embedded Voronoi-based networks. A), B) Fiber axial stretch, solid stress and beam strain energy ratios in cases of undulations with amplitude of 5% and 10% fiber length, respectively. C) Normalized shear stiffness for (A) and (B). D) Relative shear stiffness increase.

DISCUSSION

We presented a modeling approach to study the elastic behavior of embedded fiber networks. To this end, we used a coupling approach that allows embedding discrete fibers into an amorphous matrix without requiring matching discretizations. Our approach's main advantage is that we can change a microstructure's architecture without requiring the high computational cost of remeshing and solving a high-density (matching) matrix. For example, this enables investigating the effect of the fiber length, crimp, crosslinking, and fiber axial and bending stiffness on the global, effective stiffness. As we have shown in the example of the embedded helical beam, the fiber-beam kinematics and any instabilities caused by the interface forces may have a significant impact on the apparent stiffness. Furthermore, in the case of the networks, our preliminary results suggest that an increase in fiber crimp/undulations is associated with a decrease in the effective shear stiffness. The latter depends on the dominant beam strain energy component, namely the stretching energy (Fig. 4C, D).

In conclusion, our model is able to capture the effects of microstructural features on the effective stiffness of embedded networks in a computationally efficient manner.

INTRODUCTION

The Fontan surgery is a common palliative treatment operation for children born with single ventricle malformations. The operation involves an artificial connection of the inferior vena cava (IVC) directly to the pulmonary arteries (PA), resulting in a cross-shaped graft known as the total cavopulmonary connection (TCPC). The TCPC allows for unidirectional flow of oxygenated and deoxygenated blood, preventing any mixing of the two in the ventricle. However, the surgery typically provides only short-term effectiveness, and in the long-term, several complications are commonly seen in patients such as pulmonary venous malformations (PAVMs) and exercise intolerance. Optimizing the shape of the TCPC for individualized patient-specific cases has previously shown to limit the severity of these complications.

Within the pre-operative planning strategy for patient-specific Fontan surgeries, computational fluid dynamics (CFD) has often been used to visualize and predict flow dynamics in the TCPC. This analysis, commonly known as surgical planning, allows for the examination of many different TCPC morphologies for the individual patient prior to surgery. This essentially represents a shape optimization problem, where the different potential anatomical connections between the IVC and the PAs results in unique flow dynamics. Traditionally, the most optimal TCPC geometry is determined by two factors: the hepatic flow distribution (HFD), and power loss (PL). Certain thresholds for both hemodynamic factors are known to be correlated with increased risk of post-operative complications, and thus clinicians often quantify these metrics for any potential TCPC geometry to aid in decision-making.

Although surgical planning and CFD simulations are effective in helping optimize the TCPC, the computational costs associated with simulating physiologically accurate conditions (unsteady Navier-Stokes, with time-dependent boundary conditions) becomes extremely expensive. This is especially true for repetitive testing of various patient-specific TCPC options in a trial-and-error manner, which may take several weeks or months to complete for a single patient [1-2].

To this end, many new methodologies have been introduced for reducing the computational costs of fluid dynamics modeling. One such approach is the idea of reduced order models (ROMs), which are a common *model-driven paradigm* used to simplify the governing full order model (FOM). ROMs are traditionally divided into two stages, the *offline* stage, where the computationally expensive FOM simulations are performed, and the *online* stage, where these results are recycled for a rapid, reduced order solution. This approach is in contrast to *data-driven paradigms* which have been more recently popular, such as neural network or artificial intelligence techniques.

The primary objective of this study is to develop an ROM framework using the Proper Orthogonal Decomposition (POD) approach coupled with trust-region optimization methods for real-time optimization of the TCPC geometry. Specifically, the POD-ROM will allow for a significant reduction in the computational costs of simulating finite element (FE) based CFD simulations with the TCPC. This may then be leveraged in the optimization problem for determining the optimal TCPC morphology, where the optimization criteria will be determined by the HFD to the left and right PAs (LPA, RPA).

METHODS

An initial reference geometry of an idealized 2D TCPC is generated, where specific points that dictate the inlet diameters of the superior vena cava (SVC) and the IVC as well as the offset between the two were parameterized as indicated by $\mu_0 \dots \mu_5$ in Fig. 1. Parabolic velocity profiles were prescribed at the inlets for each parameterized case, with the maximum velocity prescribed to be 100 cm/s at the SVC, and 50 cm/s at the IVC. Pressure boundary conditions were employed at the LPA and RPA ($P_{RPA} = 200 \text{ Pa}$, $P_{LPA} = 1000 \text{ Pa}$). 100 FE-based CFD simulations were performed in the offline stage using the parameterized geometries, from which a *snapshot* library of solutions was generated. Both the steady and unsteady forms of the Navier-Stokes equations (NSE) were simulated in each case, each creating separate snapshot libraries.

Figure 1: Idealized 2D TCPC reference geometry.

In the online stage of the ROM framework, a filtering step is first performed to reduce the redundancy found in the snapshot library. This is done via the *Singular Value Decomposition* (SVD) technique, which calculates the singular values and eigenvectors of the snapshot matrix. If a rapid decay is seen in the singular values, this indicates that the snapshot library can be well approximated by a small number of eigenvectors that are associated with the largest singular values. These select eigenvectors are then used in the POD approach to form the reduced basis functions. When substituted into the traditional linear system of equations that results from discretization of the NSE via the FE method (i.e. $Au = b$, where A is the stiffness matrix and b is the forcing terms), the final reduced order problem below is obtained [3].

$$W^T A W c = W^T b \quad (6)$$

In this reduced problem, the matrix $W^T A W$ is in the range of tens or hundreds of rows, and when compared to the stiffness matrix A , which is in the range of thousands or millions of rows, the savings in computational costs become evident.

The ROM framework is implemented utilizing the open-source model reduction library *RBniCS*, which automates all the above steps. The framework is then leveraged for the shape optimization problem. The optimization criteria implemented depends on the HFD, such that the TCPC shape optimization problem reads as follows: find a value for μ_0 and μ_5 that minimizes the functional J_{TCPC} under the constraints of the NSE, where J_{TCPC} reads as follows.

$$J_{TCPC} = \left(\int_{LPA} u \cdot n d\gamma - \frac{x}{100} Q \right)^2 \quad (6)$$

Here, μ_0 and μ_5 are the two parameters that directly control the offset between the IVC and SVC, and Q is the inlet flow rate from the IVC, with the fraction in front indicating the desired percentage of flow split from the IVC to the LPA in the optimal TCPC geometry. Specifically, two test cases were simulated, where x was chosen to be 45 and 75, which translates to finding the optimal TCPC morphology such that the HFD_{LPA} is equal to 55% and 25%, respectively. The optimization problem was implemented using the *Py-BOBYQA* library, a Python-based derivative-free trust-region method optimizer [4]. Each iteration of the optimizer calls the online stage, which allows for the real-time calculation of the optimal TCPC geometry. Local and global optimal solutions were calculated for the steady version of the framework.

RESULTS

The local optimal TCPC geometries generated from the ROM framework are shown in Fig. 2 for an HFD_{LPA} value of 55% (left) and an HFD_{LPA} value of 25% (right). In each case, the velocity streamlines are visualized, and the hepatic flow streamlines are shown in yellow. Visualization shows that the distribution of the hepatic flow streamlines match with the intended optimal HFD_{LPA} value that was prescribed in the framework, indicating that the ROM framework was successfully able to produce the optimal offset between the IVC and SVC for the

desired HFD_{LPA} value. The ROM results shown are also identical to FOM simulations with the same offset prescribed in terms of resultant velocities, flow distributions, and pressure contours.

Figure 2: Optimal TCPC geometry for specified HFD values, with hepatic flow streamlines (yellow) from IVC.

The computational details for the optimization simulations via the ROM framework are summarized in Table 1. Both local and global optimal solutions were calculated, where the local solution differed depending on the initial guess chosen for the parameters μ_0 and μ_5 . In terms of computational time, local optimal solutions required approximately 15 minutes to compute, highlighting the real-time nature of the framework to produce the optimal TCPC morphology.

Table 1. Computational details of optimization simulations.

Optimization	Initial Guess	μ_0	μ_5	J	$\ \nabla J\ $	# of Evaluations	Wall Clock Time (min)
Local	[-0.1, -0.1]	-0.1129	-0.1041	3.93E-13	2.40E-05	32	about 15
Local	[-0.4, -0.3]	-0.275	-0.265	2.04E-16	1.70E-08	35	about 15
Global	[-0.49, -0.1]	-0.362	-0.4183	1.17E-17	2.80E-07	300	about 155

DISCUSSION

This study introduces a POD-based ROM framework that is leveraged for real-time shape optimization of an idealized 2D TCPC. The framework resulted in near real-time simulations (under 15 minutes) that were able to produce the optimal TCPC geometry for a desired HFD distribution towards the LPA, all while providing accurate and identical results as compared to traditional FOM CFD simulations. Such an approach may be able to provide critical information in terms of flow distributions and unique hemodynamics to clinicians in a rapid manner, all on local computational facilities. Although the framework shows increasingly promising results in performing this shape optimization of the TCPC, a significant limitation of this study is the use of idealized 2D TCPC geometries. To this end, we have begun adapting this framework towards 3D TCPC geometries, with the goal of eventually employing the framework for patient-specific models. To do this, more advanced shape optimization techniques will be required. Specifically, we are employing the free form deformation (FFD) and radial basis function (RBF) techniques, both of which allow for adaptive mesh morphing. Such techniques will be critical for use in the parameterization of the 3D geometry that occurs during the offline stage, as well as during the optimization problem.

In conclusion, the POD-ROM framework for shape optimization of the TCPC presented in this study allows for the identification of the optimal TCPC morphology for a given HFD value in a near real-time fashion. Further refinements are underway to translate the framework towards more physiologically accurate geometries.

INTRODUCTION

The field of biomechanics is currently suffering from a reproducibility crisis. That is, biomechanical data on the same tissues often suffer from drastic uncertainty, especially when collected from different groups [1]. This uncertainty partially stems from inherent tissue variability, i.e., inter-subject variability [2]. However, we argue that in addition, the use of differing tissue storing protocols, loading conditions, and testing devices add to the uncertainty. As a result, comparing data between studies is usually difficult, if not impossible [3]. We submit that one critical step toward overcoming the current reproducibility crisis in biomechanics would be the use of the same device among groups – in addition to agreeing on common tissue storage and testing protocols. Our goal was, therefore, to provide such a device. That is, we designed a low-cost biaxial device made of mostly off-the-shelf parts and are planning to make this device openly available. Note, this device is also designed to allow the sample to be loaded and imaged simultaneously with different imaging modalities such as optical coherence tomography (OCT) or 2-photon microscopy. Thereby, the device not only enables the use of shared hardware among research groups, but it also lends itself to new, enriched biomechanical studies in which micro- and macro-properties of tissues can be characterized simultaneously. In summary, our goal is to construct an affordable, planar biaxial device to improve the accessibility of such devices and decrease data variability among groups.

METHODS

The objective of this study is to build a planar biaxial device that is inexpensive, easy to assemble, and composed largely of off-the-shelf parts, as depicted in Figure 1. To this end, the device consists of four linearized motor stages (X-LSM025A-E03, Zaber, Inc., Vancouver, British Columbia, Canada) and two load cells (LSB200, FUTEK, Inc.,

Irvine, California, USA). It employs 3D printable goosenecks to connect the motors and load cells to a rake system (CellScale, Waterloo, ON, Canada) by which the tissues are mounted. The base of the device is 3D printed and may be customized to fit under a variety of imaging modalities and different microscopy.

Furthermore, the setup also contains a mount for a high-resolution camera for digital image correlation (DIC) (UI-308xCP-C, IDS Imaging Development Systems, Obersulm, Germany). Additionally, the device includes a clear acrylic water bath to submerge tissues. The clearness of the bath permits the simultaneous use of DIC from underneath the bath and other imaging modalities from above such as OCT, as shown in

Figure 1. Imaging stage combining a camera for DIC, and an OCT device. Also shown is the miniature biaxial device that can be transferred between this station and a 2-photon microscope.

Figure 1. To hold the device, we built a table consisting of an aluminum breadboard (MB18) held up by a frame composed of 25 mm square construction rails (XE25L24) joined by construction cubes (RM1G), T-Nuts (XE25T1) and, low-profile channel screws (SH25LP38, ThorLabs, Inc., Newton, NJ, USA).

The software is written in LabVIEW (LabVIEW Version 20.0.1, National Instruments, Austin, TX, USA) and enables various loading protocols such as cyclic loading, step loading, stress relaxation, and individual control over each motor.

To test our device, we mechanically tested and imaged two representative soft, fibrous materials: mouse skin and electrospun polymer meshes. To collect the skin samples, we adhered to NIH's Guide for Care and Use of Laboratory Animals and all animal procedures described here were approved by the Institutional Animal Care and Use Committee at the University of Texas at Austin under #AUP-2020-00054. Following the humane sacrifice of the mice via CO₂ inhalation we excised 10 mm x 10 mm square samples of skin. We then speckled the samples with graphite powder for DIC-based strain tracking. Next, we mounted the tissue in our custom biaxial device and performed 20 cycles of preconditioning to 1000 mN and then performed one final equibiaxial loading cycle to 1000 mN. During testing, we halted the displacement, let the tissue stress relax, and then imaged the collagenous microstructure of these samples under a 2-photon microscope (Ultima IV, Bruker, Billerica, MA, USA) via second harmonic generation while being mounted in the device.

To make representative fibrous polymer meshes, we dissolved PCL in an 80:20 mixture of chloroform and dimethylformamide before doping the solution with 0.1 wt% rhodamine-B to create fluorescent fibers. We then used a custom electrospinning setup to spin the solution onto a copper plate at 15 kV, 25 cm distance, and a 20-gauge needle. We then cut out two 10 mm x 10 mm square samples of the meshes and mounted them on our custom device. Next, we again performed 20 cycles of preconditioning to 4000 mN followed by one equibiaxial cycle to 4000 mN. Finally, we imaged the fibrous microstructure of the electrospun meshes using a 2-photon microscope through the fluorescence produced by rhodamine-B.

RESULTS

We built a planar biaxial device for a total cost of \$15,728 and tested its versatility by recording biaxial, DIC, and 2-photon data. Figure 2A-B depicts representative skin (left column) and electrospun mesh (right column) samples mounted in our custom device. In addition, Figure 2C-E illustrates mechanical data collected with our device on both sample types, as well as 2-photon microscope images collected *in-situ*, i.e., while the samples were mounted on our device. From our tests, we found that skin samples exhibited classic nonlinear J-shaped constitutive behavior with more compliance in the cranial direction. While difficult to see from the raw images, fiber orientation analyses of the 2-photon data highlighted a higher orientation probability of collagen in the lateral direction, explaining the observed mechanical anisotropy. Similarly to the mouse skin, the electrospun PCL samples also exhibited nonlinear J-shaped constitutive behavior. However, its behavior was more isotropic. The 2-photon images of the electrospun mesh samples explain this mechanical isotropy by revealing a random fiber orientation. Overall, the device performed flawlessly and, through its simplicity and flexibility, allowed us to test two vastly different materials, while also allowing us to adapt it for use with a 2-photon microscope and DIC.

DISCUSSION

The field of biomechanics is currently dealing with a reproducibility crisis. To address this challenge, we designed a planar biaxial device that is easy to assemble, inexpensive, and composed nearly entirely of

off-the-shelf components. We chose a biaxial device because of its applicability to many soft tissues. In addition, by omitting two motors, this device can readily become a uniaxial testing device. The device's compatibility with multiple imaging modalities will also allow others to study the microstructure of samples *in-situ*. Thereby, the device provides an avenue to investigate the structure-function relationship of a variety of soft fibrous materials. The end-result is a versatile device capable of testing many kinds of tissues under different loading and imaging modes. In addition, commercial biaxial devices cost \$100,000 or more, making them inaccessible to many smaller labs and start-ups. Designing this device for a fraction of the price increases accessibility encouraging the use of the same device among research laboratories, minimizing variability due to device selection.

CYCLIC LOADING COMPARISON BETWEEN STANDARD ULTRA-HIGH MOLECULAR WEIGHT POLYETHYLENE BLOCKS AND BIOFIDELIC SOLID RIGID POLYURETHANE BLOCKS FOR ASTM PEDICLE SCREW TESTING

Jeremy G. Loss (1), Robb W. Colbrunn (1), Kevin J. Lawson, MD (2)

INTRODUCTION

Current pedicle screw compliance tests rely on ASTM standards to determine the durability of screws. However, ASTM testing is conducted using ultra-high molecular weight polyethylene (UHMWPE), which has a significantly higher density than spinal bones. It has been noted clinically that pedicle screws fail in patients at lower cycles of loading and with different modes of failure than what is seen in the ASTM standard. Conducting ASTM testing in materials with more physiological material properties may generate loading patterns more similar to those seen *in vivo*. In this study we investigated the influence of testing block material properties used in ASTM Standard F1717. We compared four solid rigid polyurethane blocks with differing material properties to the standard UHMWPE blocks. We hypothesized that, using the same loading profile, blocks with material properties more similar to human bone will fail at lower cycles and have different modes of failure compared to the UHMWPE blocks.

METHODS

All testing was completed by Element Materials Technology (Element Materials Technology, Fairfield, OH, USA) at their Cincinnati location. Testing was conducted in two stages and followed the “fatigue test” instructions provided in ASTM Standard F1717 with a constant load ratio (R) of 10. Briefly, compressive loads were applied using a sinusoidal profile where the ratio between the peak load and valley load was 10 (i.e. a peak load of 300 N and a valley load of 30 N). All loading is applied perpendicular to the superior and posterior faces of the blocks. In the first stage, four pairs of ultra-high molecular weight polyethylene (UHMWPE) blocks were made according to Figure 13 in ASTM Standard F1717 for lumbar pedicle screw testing. Each block was instrumented with 6.5 x 40 mm lumbar pedicle screws (Spine Wave, Shelton, CT, USA), and a block set was made by joining two blocks with titanium rods (Fig. 1). Each block set underwent fatigue testing at one of four different loads (250 N, 300 N,

345 N, and 375 N) for a runout of 5,000,000 cycles. Displacement (peak and valley values), Load (peak and valley values), number of cycles before failure, and failure mode (rod fracture, screw fracture, block fracture) were recorded for each set.

Figure 1: Sample block set featuring two UHMWPE blocks.

For the second stage, four pairs of solid rigid polyurethane foam (non-UHMWPE) blocks were procured from Sawbones (Sawbones, Vashon Island, WA, USA). Three block pairs had varying densities (15 pcf, 20 pcf, and 25 pcf) to simulate different quality of bone. The fourth block pair had a density of 20 pcf with an added 2mm layer of short fiber filled epoxy laminate to simulate the cortical layer of bone. Similar to the first stage, each pair of blocks were instrumented with lumbar pedicle screws and joined with titanium rods. The loading

condition for these four block sets was determined by selecting the largest load applied in the first stage to the UHMWPE blocks that led to runout (i.e. the fatigue testing ran to completion of 5,000,000 cycles). Displacement (peak and valley values), Load (peak and valley values), number of cycles before failure, and failure mode were recorded for each block set.

RESULTS

Table 1 outlines the number of cycles achieved before failure for both the UHMWPE and non-UHMWPE blocks. Based on the results of the first stage, a maximum load of 300 N was selected for the non-UHMWPE block sets in the second stage. Failure in the non-UHMWPE blocks occurred well before failure in the UHMWPE blocks, even though the UHMWPE blocks failed under higher loads.

Table 1: Cycle achieved for each block set prior to failure.

Test Block	Test Load (N)	Cycles
UHMWPE	250	5,000,000
UHMWPE	300	5,000,000
UHMWPE	345	539,430
UHMWPE	375	319,341
25 PCF	300	5,000,000
20 PCF	300	151,501
15 PCF	300	202,610
20 PCF + 2 mm laminate	300	197,078

For all 5 block sets that did not reach runout, mode of failure was rod fracture. The two UHMWPE block sets that failed had their rods break at the head of the pedicle screw while the rod failure in all three non-UHMWPE block sets occurred closer to the middle of the rod (Fig. 2).

Figure 2. Failure location in the A.) UHMWPE and B.) Non-UHMWPE blocks.

With respect to average displacement of the blocks during fatigue testing, the three non-UHMWPE blocks with varied densities had similar average displacement (7.65 mm for 15 pcf, 7.28 mm for 20 pcf, and 7.28 mm for 25 pcf) to the UHMWPE block tested at 300 N (7.52 mm) (Fig. 3). However, the 20 pcf block with the 2mm laminate had a noticeably larger average displacement (9.34 mm) than the UHMWPE block tested at 300 N.

Figure 3. Average displacement during cyclic testing for each block set.

DISCUSSION

Our results indicate that the material properties used for the ASTM testing block influence the failure mode for pedicle screw testing. Focusing on the difference in average displacement, it is hypothesized that the laminate caused a pivot point for the pedicle screw that was not seen in either the UHMWPE or other non-UHMWPE blocks. This pivot point could account for the increased displacement seen in the laminate non-UHMWPE block and support anecdotal clinical findings of screws loosening by gaps formed at the tip of the screw in patients needing revision spine procedures. Based on clinical device failure modes and this biomechanical data, we believe that the substantial material property differences between UHMWPE and vertebral bone affects the loading characteristics and the durability of spinal fixation devices in clinical use. While UHMWPE testing can serve as a comparative measure between devices, the biofidelity may be insufficient to understand in vivo failure modes and loads.

SIGNIFICANCE

The difference in the numbers of cycles prior to failure and in average displacement between the UHMWPE blocks and the solid rigid polyurethane blocks calls into question the biofidelity of using UHMWPE blocks for ASTM pedicle screw testing. Future works can test additional non-UHMWPE blocks to increase sample size, delve deeper into alternative materials for pedicle screw testing, and advise new ASTM guidelines to better understand the strength of pedicle screws within the human body.

ACKNOWLEDGEMENTS

The authors would like to acknowledge SpineWave for supplying the pedicle screws and rods used throughout testing. Partial funding for this project was provided by the Field Neuroscience Institute.

ANATOMICAL LOCATION-SPECIFIC QUANTIFICATION OF TISSUE COMPOSITION OF PERIVASCULAR ADIPOSE TISSUE

INTRODUCTION

Remodeling of the vascular tunics has been identified as a contributing factor to increased arterial stiffness in aging and hypertension. Arterial stiffness is an independent risk factor for stroke, heart disease, and cognitive decline [1-5]. Although perivascular adipose tissue (PVAT) is recognized as an essential layer of the functioning vasculature, few studies have quantified its composition in health and disease. Here, we introduce the novel idea that the composition of load-bearing constituents in PVAT remodels in hypertension, much like that of the arterial wall.

METHODS

We analyzed the collagen composition of the thoracic aorta and its surrounding PVAT of six Dahl SS rat, half fed a control diet and half fed a high-fat diet. This is recognized as an established model of adiposity-driven hypertension [6]. A 2-photon microscope was used to image the histology samples stained with picrosirius red (PSR) for visualizing collagen. The intensity of each pixel ranged from 0 to 255, correlating with increasing collagen density. To quantify the collagen content in a reliable and reproducible way, we developed a custom algorithm in Python. To consider variations due to the anatomical location, the samples were analyzed using a polar coordinate system, i.e., considering a radial and an angular direction (Fig. 1).

Figure 1: Coordinates based on thoracic aorta geometry A) angular direction, θ B) radial direction, r

Figure 2: A) Calibration image. B) Circle detection. C) Circle selection. D) Lines for intensity profile every 2 degrees about the aortic center.

Angular zero was set at the symmetry axis of the ventral PVAT strip (Fig. 1B) and radial zero was placed at the geometric center of the aortic lumen (identified using a circle detection function in Python, shown in Fig. 2). Every two degrees about the center of the aorta (Fig. 2D), the intensity profile was recorded in the radial direction and stored in a data frame. This allows us to unravel the arterial wall and represent the data collected in a cartesian reference system (Fig. 3 and 4), representing the angle on the horizontal axis and on the vertical axis the normalized radius calculated as

$$\text{normalized radius} = \frac{\text{radius}}{\text{average lumen radius}} \quad (1)$$

For this study, pixel values equal to or above 100 were identified as collagen, while values of 25 or below were considered background noise. Thus, the lumen radius was identified at each angle as the first pixel with a value at or above 100 (represented by the bold line in **Fig. 3**). The interface between the arterial wall and PVAT at each angle was then identified by, first, taking the derivative over periods of 5 pixels in the radial direction. The derivatives of each angle were then smoothed using a convolution integral. Finally, the interface between the arterial wall and PVAT was located where the largest negative derivative occurred, signifying a large change in pixel value (represented by the bold line in **Fig. 4**).

With the arterial wall and PVAT borders identified, the fractional area of collagen was calculated as the number of pixels with values over 100, over the total of the non-background pixels in each region.

$$\text{fractional area} = \frac{\text{pixels} \geq 100}{\text{pixels} > 25} \quad (2)$$

Figure 3: Analysis of the PSR histological image of a representative control diet sample of the thoracic aorta + PVAT with lumen detection.

Figure 4: Analysis of the PSR histological image of a representative control diet sample of the thoracic aorta + PVAT with thoracic aorta-PVAT interface detection.

RESULTS

There was no statistically significant difference between the collagen content of the control and high-fat diet thoracic aortas. There was a statistically significant difference between the left dorsal strip of the PVAT between control and high-fat diet samples. These results suggest that there may be location-specific remodeling associated with hypertension in the extracellular matrix of the PVAT surrounding the thoracic aorta.

Figure 5: Average fractional area of thoracic aorta collagen and PVAT collagen for three control and three high-fat diet samples.

DISCUSSION

Through the histology image analysis of the thoracic aorta with perivascular adipose tissue, we were able to analyze the distribution of collagen in six Dahl SS samples. Comparing control and high-fat diet PVAT, there was a statistically significant difference in the collagen fractional area of the left dorsal strip. No other significant differences were found with the current small sample size for this study.

INTRODUCTION

Mesenchymal stromal/ stem cells (MSC) are one of the most promising candidates for a myriad of cell therapy applications because of their multifunctional regenerative properties. Despite showing promise for numerous preclinical studies, MSC based therapies are not yet a reality for regenerative medicine due their suboptimal outcome at the clinical endpoint. During degenerative disease and aging, the cell niche turns into a microenvironment characterized by hyperoxia produced by high amounts of reactive oxygen species (ROS). Therefore, MSC are exposed to a high amount of ROS in their natural environment in disease and aging, and post implantation in the degenerated tissue. ROS is known to cause cell damage at various cellular compartments including the DNA that can alter the functionality and viability of cells. Using isolated DNA, it was previously reported that upon exposure to the ROS, chromatin remodeling occurs which protects the chromatin over a short timeframe post ROS exposure [1]. However, it is largely unknown what the key regulators are in chromatin remodeling and what effect chromatin remodeling has on the cell phenotype and viability in the longer timeframe. Such information is relevant for understanding the cell functionality in their natural environment and upon implantation in aged and diseased tissues characterized by a high amount of hyper oxidative stress.

In this study our objective is (i) characterize what changes the chromatin of MSC undergoes upon exposure to hyperoxia, (ii) to identify a key molecular regulator of such chromatin level changes and (iii) finding a potential intervention strategy for maintaining cell viability on a longer timeframe upon the ROS exposure. We utilized an *in vitro* model of cell exposure to hydrogen peroxide and confocal microscopy imaging to accomplish the objectives. We hypothesized that the chromatin remodeling complex (CRC) SWI/SNF (SWItch/ Sucrose Non-Fermentable) is a critical component for the chromatin remodeling during the cell exposure to ROS and is a potential target to minimize the chromatin remodeling mediated damage in cells.

METHODS

Cell culture: Human bone-marrow derived passage 4 MSC (Lonza) was used for all experiments. **Characterization of chromatin remodeling:** MSC were stained with Nucblue, a live DNA stain. Cells were exposed to 500 μ M hydrogen peroxide. Subsequently, the MSC nuclei were imaged at a high-resolution using time lapse laser scanning confocal microscopy (Zeiss LSM 980) while cells were maintained in an incubation chamber. An in-house image registration algorithm was created, validated, and applied to calculate the Chromatin Remodeling Index (CRI: unit is pixels) at every pixel, thus providing a spatiotemporal map of chromatin remodeling. The CRI was further averaged over each chromatin region - euchromatin, heterochromatin, and interchromatin to quantify the spatially averaged CRI at different intranuclear domains. **Inhibition of chromatin remodeling:** GSK126 (10 μ M) was used to indirectly block ARID1A and hence, chromatin remodeling through inhibiting EZH2 methyltransferase. **Immunofluorescence:** DNA damage was assessed by an antibody targeting the DNA damage marker γ -H2AX. Cell damage was assessed through the F-actin staining by phalloidin. **Statistics:** T-tests were used for all statistical analysis. Sample sizes are reported in the figures.

RESULTS

First, we wanted to characterize the effect of ARID1A inhibition for 3 days on the MSC phenotype and proliferation. Cell proliferation was found to decrease (Figure 1A) when they were exposed to the pharmacological agent GSK126 indicating ARID1A was inhibited. SWI/SNF CRC including ARID1A is necessary for cell division, specifically during the chromatin condensation in the metaphase and anaphase periods of cell division. However, ARID1A inhibition almost doesn't have any effect on the cell and nuclear phenotype (Figure 1B) and the cell viability (data not included: found by calcein AM and Ethidium Bromide based viability assay). The cytoplasm structure was maintained (Figure 1A) and stress fiber formation was not affected.

Therefore, this data suggests that GSK126 treatment does not affect the MSC phenotype in the prophase period.

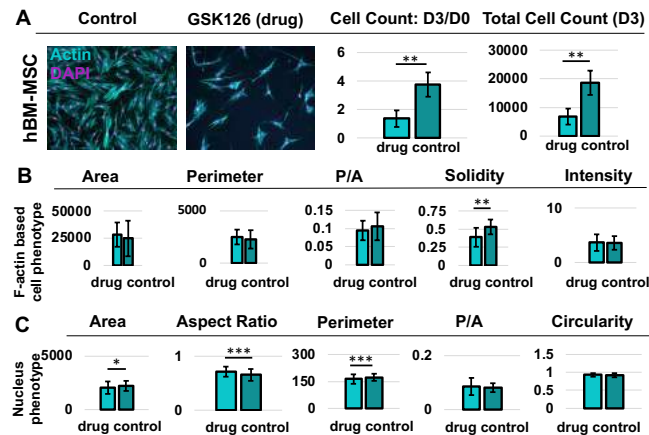

Figure 1. Characterization of cell and nuclear phenotype and the cell proliferation on the application of 10 μ M GSK126 (ARID1A inhibitor). (A) GSK126 treatment decreases cell proliferation. (B) Cell phenotype after GSK126 treatment on day 3. (C) Nuclear phenotype after GSK126 treatment on day 3. * p <0.05, ** p <0.01, *** p <0.0001. Error bars: SD. Based on n > 500 cells/ group.

Next, we visualized the effect of hydrogen peroxide treatment on the nuclear and cell shape. 500 μ M hydrogen peroxide is a physiological level of hyperoxia cells undergo *in vivo*. The Nucblue stained nuclei and time lapse images revealed that nuclei undergo rapid change in their shape and area (Figure 2). The cell shape also changes during this period (revealed from bright field images) because the nucleus is connected to the cytoskeleton through the nuclear envelope. Interestingly, the pretreatment of cells by the inhibition of ARID1A significantly decreases such drastic change in nuclear and cell shape (Figure 2).

Figure 2. Effect of hydrogen peroxide treatment and ARID1A inhibition on nuclear area change. * p <0.0001. n > 20 cells/ group.

High resolution imaging of the chromatin revealed that hyperoxia causes rapid chromatin remodeling (Figure 3) which starts at around 20 min after H₂O₂ treatment and continues until 80 min in all chromatin regions - heterochromatin (HC), euchromatin (EC) and interchromatin (IC): interface of EC and HC. ARID1A is indeed required for the chromatin remodeling as shown by the spatiotemporal CRI maps (Figure 3A) and CRI values over time in the 3 chromatin regions (Figure 3B). This data reveals that SWI/SNF CRC is required for the chromatin remodeling post exposure to hydrogen peroxide.

Previous studies with isolated DNA suggested that nanoscale chromatin reorganization occurs after DNA damage [1]. We wanted to understand how much DNA and cell damages are incurred after the MSC exposure to 500 μ M H₂O₂ treatment for 90 minutes.

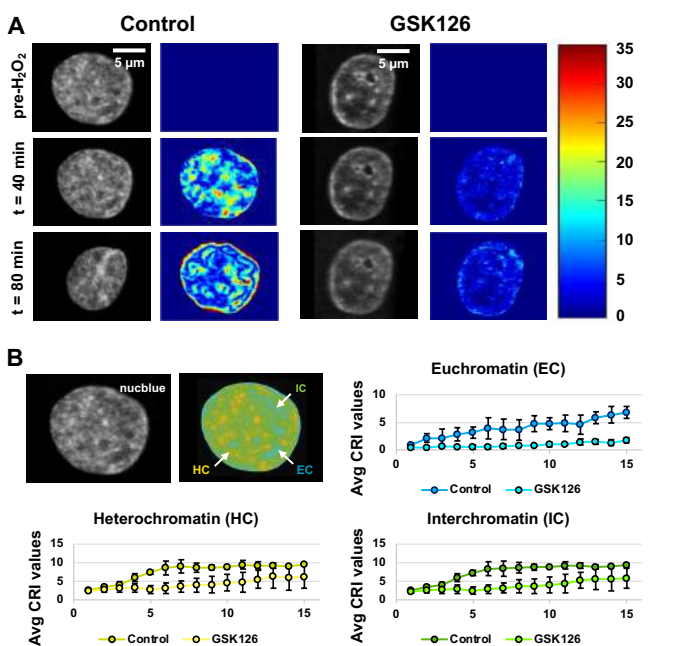

Figure 3. Time lapse visualization of chromatin remodeling and calculation of CRI. (A) MSC nuclei and CRI maps over 80 minutes on 500 μ M H₂O₂ treatment. Color bar indicated the CRI value (unit: pixel). (B) Temporal evolution of average CRI values in each intranuclear domain. Based on n > 4 cells/ group. * p <0.05, ** p <0.01

We found that GSK126 treatment only does not result in DNA damage (Figure 4: control vs GSK126 groups) after 90 minutes of H₂O₂ treatment. Treatment of MSC with H₂O₂ increases the DNA damage after 90 minutes (stronger green signal in H₂O₂ and H₂O₂+GSK126 groups). However, 24 hours after the removal of the H₂O₂ the DNA damage level is same in all groups but cytoskeleton is almost destroyed in H₂O₂ group while it is preserved in the H₂O₂+GSK126 group.

Figure 4. Effect of hydrogen peroxide and GSK126 on the DNA damage in short term (90 minutes after hydrogen peroxide treatment) and longer term (24 hours after 90 minutes treatment of hydrogen peroxide).

DISCUSSION

We identified a key regulator of chromatin remodeling upon hyperoxia using MSC. Our future work will include the pretreatment of MSC with the blocking of chromatin remodeling before the injection of MSC in the degenerated and hyperoxic tissues.

INTRODUCTION

Osteoarthritis (OA) is a degenerative joint disease characterized by aberrant changes in subchondral bone remodeling (increased subchondral thickness, density, or both) [1]. While there is not a cure for OA, pharmaceutical interventions continue to be explored including the use of rapamycin. Human and animal models of OA demonstrate increased activity of the mechanistic target of rapamycin (mTOR) [2] and inhibition of mTOR by rapamycin can attenuate OA severity in surgical mouse models [3]. However, it is unknown if rapamycin can modify features of naturally occurring OA—the most common form of OA in older humans. Marmosets are small, short-lived non-human primates that develop OA naturally—an ideal model system. The aim of this study was to determine how age and rapamycin treatment affect subchondral bone architecture of the common marmoset knee.

METHODS

Sample Preparation and Imaging: Fifty-five marmosets (31M/24F, mean age = 9.5 ± 4.2 years) were analyzed. They were housed in male-female pairs at the University of Texas Health Science Center at San Antonio and the males were vasectomized. The marmosets were divided into two groups: control ($n = 35$) and rapamycin-treated ($n = 20$). The treated group received 1mg/kg/day of eudragit-encapsulated rapamycin dissolved in yogurt and the controls received empty eudragit encapsulation in yogurt [4]. At necropsy, hind limbs were collected, fixed in 10% neutral buffered formalin, and then stored in 70% ethanol. The knees were micro-CT scanned using a Rigaku CT Lab GX130 (isotropic voxel size = $50 \mu\text{m}$). Study staff were blinded to the treatment allocation and all subject characteristics.

Image Processing: Micro-CT data were binarized using a consistent attenuation threshold and the femur and tibia were separated into individual image stacks in Amira (v2021.2). Anatomical landmarks were used to identify the subchondral regions (Fig 1).

Figure 1: A) 3D micro-CT rendering of a representative marmoset knee (four subchondral surfaces analyzed in blue). L = lateral, M = medial, F = femur, and T = tibia. B) Sagittal view of a femoral condyle (subchondral surface in blue).

The subchondral bone was segmented from the underlying trabecular bone using our previously validated algorithm [5]. Three hydroxyapatite (HA) phantoms were included in all scans and used to convert Hounsfield units to apparent HA density. Three-dimensional thickness and density maps of the subchondral surfaces were created using ImageJ (BoneJ plug-in) [6] and custom MATLAB code (R2021a). Four regions of subchondral bone were analyzed: the lateral and medial condyles of the femur and tibia (Fig 1). The subchondral surfaces were spatially normalized to account for morphological differences between subjects and visualize the average thickness and density for each group.

Statistical Analysis: Kolmogorov–Smirnov tests were used for comparisons. We calculated the median and median absolute deviation (MAD) of thickness and density per subchondral region per subject to measure the central value and variability of the data, respectively. Statistical analyses were done in R with a type one error rate of $\alpha = 0.05$.

RESULTS

Thickness: Rapamycin significantly affected subchondral thickness of the lateral tibia. Specifically, the median subchondral thickness was 11% lower ($p < 0.05$) in the rapamycin-treated marmosets (0.32 mm) than the controls (0.36 mm) (Table 1). The subchondral thickness of the lateral tibia had 38% less variability ($p < 0.01$) in the rapamycin-treated marmosets than the controls. Neither age nor sex had a significant effect on thickness. Local differences in thickness were observed with heat maps of the subchondral surface (Fig 2).

Density: Rapamycin did not affect median subchondral bone density (Table 1). However, subchondral bone density of the medial tibia had 24% more variability ($p < 0.01$) in the treated marmosets than the controls. Neither age nor sex had a significant effect on density.

Table 1: Median and MAD of the thickness and density for the control and rapamycin-treated groups (* p-value < 0.05, ** p-value < 0.01). Lat = Lateral and Med = Medial.

	Bone	Side	Thickness (mm)		Density (mg HA/cm³)	
			Control	Rapamycin	Control	Rapamycin
Median	Femur	Lat	0.39	0.37	619	633
		Med	0.40	0.38	642	665
	Tibia	Lat	0.36	0.32*	606	626
		Med	0.39	0.40	684	717
MAD	Femur	Lat	0.07	0.08	79	75
		Med	0.06	0.06	58	59
	Tibia	Lat	0.08	0.05**	83	78
		Med	0.06	0.06	70	87**

DISCUSSION

Osteoarthritis of the knee is commonly associated with subchondral sclerosis [1]. Thus, thicker and/or denser subchondral surfaces are

indicative of osteoarthritis. Here we used marmosets, a natural aging model of OA, to evaluate the effect of rapamycin on subchondral bone and found that rapamycin decreased subchondral thickness (Fig 2).

Surprisingly, rapamycin only significantly affected subchondral thickness of the lateral tibia. This may be related to the biomechanical usage of the marmoset knee. Marmosets spend much of their time squatting, unlike humans, who are primarily upright while the knee is loaded. During knee flexion, the center of pressure on the femoral condyle varies, whereas tibial loading tends to stay within the same plateau region. We hypothesize that more consistent loading of the tibia could lead to increased bone remodeling as compared to the femur.

One limitation of our study is the sample size ($N = 55$), which does not allow us to fully analyze how age and sex interact with rapamycin treatment. Also, there is some subjectivity with the identification of bony landmarks, from which the subchondral regions are defined. Nonetheless, the ability to co-register the datasets provided a unique ability to visualize the average thickness and density across the entire articular surface and gave insight into the spatial changes in response to rapamycin. Indeed, rapamycin decreased thickness in most regions of the tibial plateau, suggesting a robust response to treatment. Our results show that inhibition of mTOR by rapamycin may prevent OA-related subchondral sclerosis. Continued work using natural animal models of OA, as done here, will lead towards improvements in our understanding of the causes and treatment options for osteoarthritis.

ACKNOWLEDGEMENTS

This work was supported by funding from the National Institutes of Health (R21 AG067464). Marmoset samples were collected at the San Antonio Nathan Shock Center of Excellence in the Basic Biology of Aging in San Antonio, TX, and micro-CT scans were taken at the Beckman Institute in Urbana, IL.

IT TAKES A VILLAGE: CATALYZING CLINICALLY-DRIVEN UNDERGRADUATE DESIGN PROJECTS AT THE NEXUS OF ENGINEERING, MEDICINE AND BUSINESS

Byron D. Erath, Laurel Kuxhaus

Mechanical and Aerospace Engineering, Clarkson University, Potsdam, NY USA

INTRODUCTION

Design projects offer unparalleled opportunity for students to synthesize their classroom knowledge and wrestle with the unpredictable nature of real-world problems that often involve competing optimization criteria. In essence, design projects are a gateway to useful problem solving in the real world, while simultaneously serving as a meaningful introduction to the research process. For assistive technology concepts to become market-ready solutions, incorporation of engineering, clinical, and business perspectives is essential.

Prior literature has described tools and techniques for identifying clinically-relevant projects that need engineering solutions [1], global student collaborations [2] and the importance of design projects as a vehicle to meet ABET goals. [3]

There are substantial challenges endemic to such 3-way collaborations, particularly at the undergraduate level. For example, at Clarkson University although the graduate health sciences programs encourage (and in some cases require) participation in research, those programs run on a quarter system that is not well-aligned with the undergraduate semester. A further complication is that capstone courses in business programs (such as Engineering & Management) and health sciences have substantially different learning outcomes from those in engineering design courses. This same problem often arises even when organizing design teams from different engineering disciplines.

This abstract presents outcomes from 12 undergraduate design team projects in biomedical engineering that was implemented over 6+ years at Clarkson University. We present strategies for overcoming common obstacles such as those described above, as well effective approaches for catalyzing cross-disciplinary collaborations in undergraduate design projects.

METHODS

Our approach was to create interdisciplinary design teams including undergraduate students in engineering (primarily mechanical engineering, and mostly those enrolled in Clarkson's biomedical engineering minor), students in health sciences (those pursuing PA, PT, or OT graduate degrees), and business to tackle clinically-motivated meaningful design projects to improve quality of life for persons with disabilities. All students earned course credit for their work, whether it fulfilled a major requirement (e.g., capstone design) or an elective requirement. Given critical mass of students and faculty, our process typically ran in parallel with the Mechanical Engineering capstone design courses in which students chose teams and projects near the end of the first semester, with the bulk of project work being done in the second semester. We recruited clinical and business students through faculty networks and email advertisements, including through the University's Honors program. The development of this design strategy was supported by NSF (#1510367, Walking and Talking: Improved Quality of Life Through Enhanced Mobility and Communication; original PI Kuxhaus).

Figure 1: Idealized workflow (E=engineering; B = business; PA = PA/clinical students)

Student teams included at least one clinical student (PT, OT, or PA) and at least one business student to more realistically model the R&D process. In pursuit of the idealized workflow (Figure 1), each team

performed a needs assessment, product ideation and design, and made a prototype, while intertwining clinical relevance, human subject research, and marketing activities throughout. At least one trainee continued the research and development (including refinement) of promising projects; this often included an intensive summer period, with some continuing into the next academic year and one leading to a student's Master's thesis.

RESULTS

The 14 completed end-user identified projects engaged 72 students (at least 47 women and 10 with disclosed disabilities) in the design experience. These projects produced 12 conference publications, two journal articles, and eight provisional patent applications. Five teams were selected as finalists in the Summer Biomechanics, Bioengineering, and Biotransport Undergraduate Design Competition in Rehabilitative and Assistive Devices, with one team winning first place. Over 15 of these undergraduates went to graduate school to pursue bioengineering-related research (e.g., Georgia Tech; Michigan State).

Recurring challenges that appeared to be exacerbated by the interdisciplinary nature of the teams included:

- Scheduling challenges for meetings and work sessions, exacerbated by fluctuating class times common in health sciences curricula and others that use a cohort model (e.g., class times can flex from one week to the next);
- Necessity of IRB training and approval prior to students interacting with end users;
- Emphasis on different deliverables and timelines as required by different disciplinary courses.
- Logistics of interacting with end users, particularly if travel was involved.
- Ideation of *de novo* solutions compared to developing a solution that had previously been described but not implemented.
- Student perception of having to do 'extra' work beyond what was required by their 'own' course (e.g., a Benchtop-to-Market transition plan)
- Projects within a single semester (e.g., without a second-semester continuation) generally did not yield a useful prototype.

DISCUSSION

Our student design teams worked together and the demographic diversity within our teams was greater than that of the University's student population, as expected from [4]. We attribute this to the emphasis on improving quality of life through product design that attracted more diverse students, and that our funded projects offered students more opportunities to interact with end users, present their work, and the possibility of a national conference presentation. We explicitly observed that the SB3C Undergraduate Design Competition was a strong motivator, particularly in years when multiple teams submitted abstracts because only one team per University could be make the finals. We believe that this 'friendly competition' was particularly motivating.

The most developed products came from teams that worked for 2 semesters, and had a team member continue the work (with funded support); this led to additional publications, including two journal papers. An additional benefit of project continuation (beyond offering professional development to trainees) is that this additional product development can set the stage for patents, small business opportunities, and other commercialization (e.g., I-Corps, SBIR/STTR, or NSF PFI proposals).

In many instances, these projects served as gateways to research for students who previously professed disinterest in pursuing a graduate education. Many of the students that ultimately attended graduate

school weren't even thinking of it when they started the projects. Our gains of building confidence in research capability in students may be comparable to those seen by a summer REU program [5], yet do so within the context of the typical academic year and avoid the selection bias inherent in REU programs, which self-select for students predisposed to research pursuit. Future work could study the effect of these team design projects on developing scientific identity and fostering a sense of belonging.

Our students thrived when they established direct personal contact with the end-user (or group) to establish design goals. This helps students gain an appreciation for the challenges faced by the end users (sometimes accompanied by wide eyes during meetings, and intense fervor in group discussions about how to improve quality of life for persons with disabilities).

To optimize student success in such projects, we offer the following recommendations:

- Ensure that all students get some form of course credit for their work (e.g., Independent Study, research, or fulfill a course requirement). If students are using the project to fulfill a course requirement, ensure that deliverables are aligned with an engineering design project and at an appropriate timeline. This may necessitate direct faculty-faculty communication across disciplinary lines, or pedagogically-appropriate alternatives. (For example, we had success in pulling students out of traditional capstone design in some semesters to ensure that prototyping timelines allowed for revisions.) Simply put, over-emphasis on reports can hamper product development.
- Mitigate scheduling challenges by modeling clear expectations that cross-disciplinary meetings often occur outside of 'typical' course hours.
- A meaningful design experience in biomedical engineering requires a design assessment; end users must be involved throughout the process, and students must be coached to integrate the feedback appropriately.
- External support, even if small, can create motivating opportunities for students. (Those with an active NSF award from the Engineering Directorate may apply for Undergraduate Design Supplements, see NSF 19-078)
- Clinically-driven design groups should make IRB training and evaluation an integral part of the instruction/design process prior to project initiation. This could be a significant roadblock at larger institutions.
- "Piggy-backing" off of existing frameworks for integrated design typically lead to more developed prototypes; *de novo* projects come with additional mostly-administrative tasks that are educational for students often at the expense of prototype progress.

ACKNOWLEDGEMENTS

The authors thank their students and colleagues for the education through the years, NSF CBET-1510367 for support of many of these projects, and the SB3C Undergraduate Design Competition for serving as a strong motivator for students.

INTRODUCTION

Computer simulations of the heart valve function are an invaluable tool for research into the progression and treatment of valvular disease. Of particular interest is the potential for individualized simulations for patient-specific care, which requires solving the inverse problem to determine the soft tissue material properties based on the *in vivo* deformations. To date, inverse analysis frameworks have been developed for the aortic and mitral valves [1, 2], yet there remain issues with the clinical translation of these tools due to the computational time or the potential for inaccurate predictions. In these *in vivo* animal models or *ex vivo* beating heart apparatuses, the use of high resolution imaging, fiducial markers, or the implantation of sonocrystals allows the inverse problem to be solved with greater confidence. On the other hand, when using clinical images (e.g., echocardiography) the inverse problem is more challenging due to noise in the segmentation data caused by low resolution images, and the inability to perform a distinct mapping between the simulated and image-segmented surfaces.

As the next step in improving the inverse finite element analysis (iFEA) of the atrioventricular heart valves, we propose the use of Bayesian optimization (BO). Briefly, in the BO method the objective function is considered a "black box" fitted by a posterior distribution. For each iteration of the solver, this distribution is updated and the next query point is selected by a probabilistic selection that balances exploration and exploitation of the search space. This technique is computationally advantageous due to the pre-assessment of each query point. Evidence for the usefulness of BO in complex inverse problems can be found in the fields of fluid mechanics [3] and skeletal muscle biomechanics [4].

In this work, we demonstrate that BO can be used as an efficient solver for the iFEA of the heart valves. Specifically, we evaluate this technique by performing iFEA using medical imaging data of the tricuspid valve (TV) from newborns with hypoplastic left heart syndrome (HLHS).

METHODS

Finite Element Analysis Setup: Echocardiogram images were obtained from newborns with HLHS (IRB#14112), and the images were segmented to obtain the points along the annulus (open and closed valve) and the leaflet free edge (open valve), and a point cloud of the leaflet surfaces (closed valve) (Fig. 1(a)). The annulus and free edge points were imported to MATLAB (MathWorks, Natick, MA) and smoothed using a periodic cubic spline fit. The finite element mesh was then constructed using a "lofted surface" approach, joining the annulus and free edge curves and discretizing the surface into 4-node shell elements (i.e., S4 elements in ABAQUS) (Dassault Systèmes, Simulia Corp., Johnson, RI). The leaflets were also modeled using an isotropic Lee-Sacks material:

$$\psi_{\text{leaflet}} = \frac{c_0}{2}(I_1 - 3) + \frac{c_1}{2}(e^{c_2(I_1 - 3)^2} - 1) - \frac{p}{2}(J - 1). \quad (1)$$

In this model, $c_0=10$ kPa, c_1 and c_2 are the material parameters to be optimized, p is a penalty term to enforce tissue incompressibility (i.e., $J=\det(\mathbf{F})=1$), and I_1 is the first invariant of the right Cauchy-Green tensor ($\mathbf{C} = \mathbf{F}^T \mathbf{F}$, where \mathbf{F} is the deformation gradient).

Due to limitations of the echocardiograms, we were unable to extract the chordae tendineae or papillary muscle locations. To this end, we elected to use a generic representation, with branching chordae inserting to the center and free edges of each leaflet. All chordae were modeled as truss elements (T3D2) with a cross-sectional area of 0.1 mm^2 , and material behaviors following a hyperelastic form:

$$\psi_{\text{chordae}} = c_{10}(e^{c_{01}E_{11}} - 1), \quad (2)$$

where c_{10} and c_{01} are the optimized material parameters, and $E_{11} = (1/2)(F_{11}^2 - 1)$ is the uniaxial chordae strain. Finally, the boundary conditions applied to the model were as follows: (i) a transvalvular pressure

gradient of 30 mmHg; (ii) pinned papillary muscles; (iii) deformation of the annulus based on the segmented image data.

Bayesian Optimization: In our iFEA framework, our goal was to determine the leaflet and chordae material parameters that provide agreement between the shapes of the image-segmented point cloud and the finite element surface. Our objective function was thus formulated as the minimization of the summed Euclidean distances between each segmentation point and the corresponding element centroid (Fig. 1(c), see [1] for additional details). From our preliminary analyses, we determined that the objective function required an additional weighting parameter (w) for the residual of each leaflet (i.e., $\mathcal{F}_{\text{total}} = \sum_{i=1}^3 w_i \mathcal{F}_i$), where $w_{\text{septal}} = 20\%$ and $w_{\text{posterior}} = w_{\text{anterior}} = 40\%$.

The BO-based minimization of \mathcal{F} was implemented in MATLAB via the bayesopt function. The optimization parameters were restricted to the search domains: $c_1, c_{10} \in [0.001, 10]$ kPa, $c_2 \in [1, 20]$, and $c_{01} \in [10, 30]$. Herein, we use this technique for two demonstrations: (i) the verification of the framework using a finite element surface with a known solution with the target leaflet parameters of $c_1 = 0.209$ kPa and $c_2 = 11.65$ uniformly prescribed to all 3 leaflets; and (ii) the prediction of the *in vivo* tissue properties for a representative HLHS newborn, with the chordae and leaflet parameters unique to each leaflet, resulting in a 12-dimensional problem.

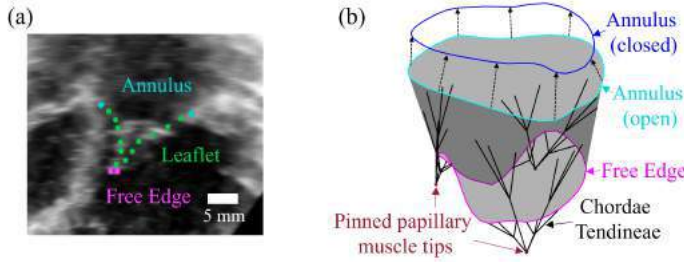

Figure 1: (a) Echocardiogram of the tricuspid valve; (b) the generated finite element mesh

RESULTS

From our verification problem, we found that the BO routine was able to successfully reconstruct the synthetic solution with reasonable accuracy within 100 iterations ($\mathcal{F} = 2.19$ mm, average error of 0.006 mm per point) (Fig. 2(a)). Specifically, the optimized parameters were $c_1 = 0.184$ kPa and $c_2 = 9.73$. Analyzing the residual search space (Fig. 2(b)), we observed that the BO successfully found the global minima despite the presence of several local minima, demonstrating an advantage of the technique.

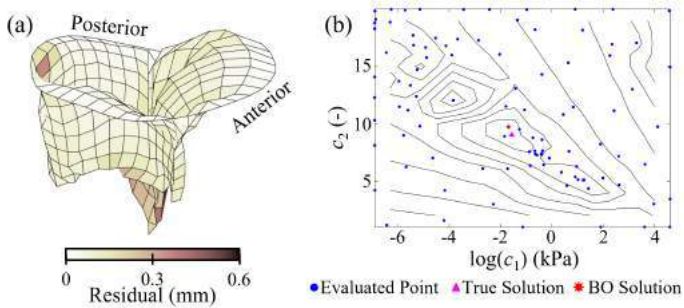

Figure 2: (a) Isometric view of the element-wise errors for the optimized solution to the synthetic problem; (b) a contour plot fitted to the residual history

For the representative patient, the optimized finite element surface yielded a total error of 29.1 mm (average error of 0.081 mm per point) after 100 iterations (Fig. 3(a)), with the final parameters provided in Table 1. With this solution, we observed the posterior leaflet as the stiffest and the septal leaflet was the most extensible, whereas for the chordae this trend was reversed (i.e., septal chordae as the stiffest). For the mechan-

ics metrics, the average von Mises stresses were found as: anterior leaflet, 35 ± 20 kPa; posterior leaflet, 50 ± 26 kPa; septal leaflet, 43 ± 27 kPa (Fig. 3(b)). We also noted minimal regurgitation in the final valve configuration, which was in agreement with the echocardiogram.

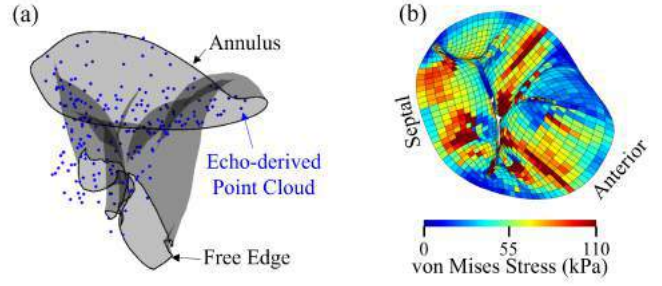

Figure 3: (a) Isometric view of the optimized solution for the representative patient; (b) superior view of the von Mises stresses

Table 1: Leaflet and chordae material parameters from the BO of the representative patient

Parameter	c_1 (kPa)	c_2 (-)	c_{10} (kPa)	c_{01} (-)
TV Septal Leaflet	0.004	19.8	99.30	20.4
TV Anterior Leaflet	0.028	11.5	1.82	11.5
TV Posterior Leaflet	0.774	13.6	0.02	11.5

DISCUSSION

From our preliminary results, we have demonstrated a novel use of BO for iFEA of the tricuspid valve. First, we have shown the method to provide minimal error in retrieving a synthetic solution. Second, the efficiency of the method was evidenced by solutions being obtained within 100 iterations and performed in under 3 hours with batch parallel processing. Third, we have also shown the usefulness of BO for solving high-dimension problems by optimizing the 12-D problem with the representative patient.

It is worth noting that in these preliminary analyses we used low-resolution models (360 leaflet elements) to reduce the computational time; however, this technique may be useful for improving processing times for iFEA while maintaining accurate predictions – a topic of future investigation. Also, we noticed a mismatch of the coaptation line in the simulated surface and the point cloud (Fig. 3(a)). This may be attributed to the inability to accurately reconstruct the chordae geometry from the medical images, which could potentially be remedied by using a functionally equivalent model [5]. While additional progress must be made in iFEA research and medical imaging resolution to address this issue, BO will be a valuable tool for making efficient predictions of the *in vivo* tissue properties.

IMPACT OF VIMENTIN INTERMEDIATE FILAMENTS ON 3D MULTICELLULAR DEVELOPMENT AND MORPHOGENESIS

Camille D. Rodriguez (1), Ming Guo (1)

(1) Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

INTRODUCTION

Vimentin intermediate filaments (VIFs) are a type III intermediate filament and the most abundant in mammalian cells. VIFs are known as markers for epithelial to mesenchymal transitions, and evidence has been shown that vimentin expression contributes to cancer metastasis. In 2D analysis, vimentin expression is shown to alter cell mechanics through reorganization of the cytoskeleton and cell-cell adhesion. While it has become increasingly clear that VIFs are important in individual cell behavior, their role in collective cell behavior remains unclear, especially in a 3D environment. A recent study examined vimentin in varying malignant breast cancer cell lines, and found without VIFs there was a decrease in proliferation and directional migration [1]. It has also been recently revealed that vimentin adjusts a collective's mechanical properties by reducing cell-substrate traction and intercellular tension while increasing stiffness in MCF-7 cells [2]. However, both studies were conducted as 2D collectives.

In this work, to elucidate vimentin's role in the development and morphogenesis of multicellular clusters in 3D, cell clusters are embedded in a Matrigel-Alginate interpenetrating gel for growth *in vitro*. Compared to 2D cultures, cells are able to remodel their surrounding matrix appropriately. MCF-7 cells are utilized in this study due to a naturally null vimentin expression, allowing vimentin to be chemically induced. A comparison of morphology, migration patterns, and invasiveness between control (uninduced) MCF-7 cell clusters and induced vimentin clusters was examined. Clusters with induced vimentin had significantly higher instances of protrusions along with an increase in mean square displacement and nuclei velocity.

METHODS

MCF-7 cells with a nuclear localized sequence (NLS) were embedded in a Matrigel-Alginate gel. Using a Matrigel-Alginate mixture for the gel allows for a tunable viscosity and other mechanical properties. The final concentration used for all samples was 4.4 mg/mL

Matrigel, 5 mg/mL Alginate, and 0.043 mM CaSO₄. 10 µL of cell suspension was mixed in when creating the gel. Vimentin expression was induced in MCF-7 cells by adding 5X concentration of Cumate in MEM media.

From single cells, clusters began expanding from roughly 3 cells around day 3 of embedding to about 10 cells around day 7. Clusters were imaged on a confocal microscope on days 3, 6, 7 and 10 to study growth progression.

Using grayscale static images, the area moment of inertia was studied along with an invadopodium count. The area moment of inertia was determined by first finding the area, A , and centroid, d_{xy} , of the cluster body (2) applied to (1).

$$I_p = \int r^2 dA = I_x + I_y \quad (1)$$

$$I_{x,y} \propto d_{x,y}^2 A \quad (2)$$

The ratio (4) compares the calculated area moment of inertia to its theoretical circle, I_{circle} . The larger this value is from 1 the greater it deviates from a perfect circle.

$$C_{2D} = \frac{I_p}{I_{circle}} \quad (3)$$

Migration analysis was conducted on day 7 over 12 hours with a 10-minute frame rate. Tracking the fluorescent nuclei, the mean squared displacement (MSD) was calculated along with velocity trajectories and average velocities. Analysis was on 8 induced and 6 uninduced clusters.

RESULTS

There are clear distinctions on day 7 when comparing induced and uninduced MCF-7 clusters of approximately the same size and cell

count. In Fig. 1A those induced with vimentin have an increase in protrusions from the bulk of the body. Uninduced cell clusters tend to be more rounded, with minimal, if any, protrusions.

Figure 1: Morphological differences between induced and uninduced cluster. A) Grayscale and fluorescent images of sample clusters. B) Number of invadopodium over increasing days. C) Area moment of inertia coefficient over increasing days. ($n_I = 16, 28, 10, 22$ and $n_U = 18, 32, 13, 17$ with days 3, 6, 7, 10 respectively).

The number of invadopodium would increase in the vimentin induced MCF-7 cells as the days progressed (Fig. 1B). Invadopodium's were classified as having a nucleus leading a protrusion, and the protrusion had a larger length than width. With this classification system the largest number of invasive tips seen in induced clusters was at 3 with an average of about 1. To better quantify the irregular shapes exhibited by the vimentin induced clusters, the area moment of inertia was calculated (Fig. 1C). As the days progressed the deviation of vimentin clusters from a perfect circle (C_{2D} of 1) increased averaging at 3.41 on day 10 whereas uninduced was 2.79 ($p = 0.0403$).

Induced cells within a cluster showed an increase in migratory behavior. While the cells were confined generally to the cluster body, induced cells had an increase in velocity trajectories compared to uninduced cells. In the induced cluster (Fig. 2A), most trajectories have a velocity of 13 μm/h or above, with more instances of velocities around 27 – 31 μm/h and 36 – 40 μm/h. The uninduced cells mainly vary between 4 – 18 μm/h.

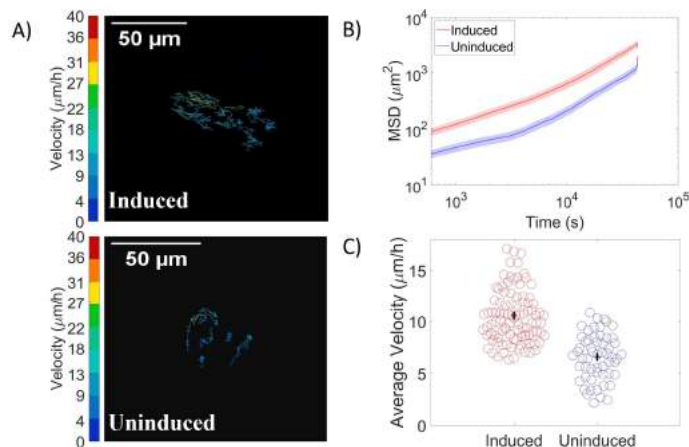

Figure 2: Dynamic differences between induced and uninduced clusters. A) Velocity map of sample clusters. B) MSD of induced clusters. C) Average velocity of induced and uninduced clusters.

and uninduced. C) Average velocities of individual cells within induced or uninduced clusters ($n_I = 98$ and $n_U = 56$).

Additionally, the MSD quantitatively expressed this larger distance covered by the induced cells (Fig. 2B) with an average velocity of 10.56 μm/h. Uninduced cells had an average of 6.59 μm/h ($p = 3.6E - 16$, Fig. 2C).

DISCUSSION

Vimentin expression in MCF-7 3D clusters alters collective behavior. Morphology of induced clusters are more irregular than uninduced. The area moment of inertia quantitatively captures these morphological differences. It considers both cases of filopodia and invadopodium (protrusions) and possible invasiveness of inducing MCF-7 cells. One difference against 2D collective behavior was that uninduced MCF-7 cells had more membrane extensions than induced cells [1]. Indicating a further need to study in a 3D softer, environment. Potentially VIFs are needed to cleave the ECM, thus making them more likely to form extensions or protrusions.

The MSD and velocity trajectories show with vimentin expression individual cells within the collective tend to migrate greater distances and with larger average velocities. Similarly, in 2D MCF-7 analysis it was found that there was weaker cell-cell adhesion thus cells can reorganize within the cluster [2]. However, one key difference is that vimentin expression reduces intracellular motion in 2D [2]. In 3D the nuclei's movement is generally confined within the cluster region but has a significantly more active motion.

The preliminary results indicate clear morphological and dynamic differences when vimentin intermediate filaments are present in clusters. When induced in individual cells, vimentin impacts the collective behavior of 3D multicellular systems. Lending some evidence to the study of vimentin as a marker for early stages EMT or hybrid EMT. With this knowledge there can be a deeper understanding of vimentin's active role in cancer progression, along with other physiological processes such as wound healing.

SUPERPOSITION TESTING ON A FUNCTIONAL SPINAL UNIT WITHIN A MULTI-LEVEL SPINE CONSTRUCT

INTRODUCTION

Robotic testing of anatomical joints involves deterministic control of a 6 degree of freedom (DOF) joint with a 6 DOF robot. However, in the case of spine testing, the number of DOF is 6 times the number of functional spinal units (FSU). If testing more than 1 FSU, the motion at every level cannot be independently controlled by a 6 DOF robot.

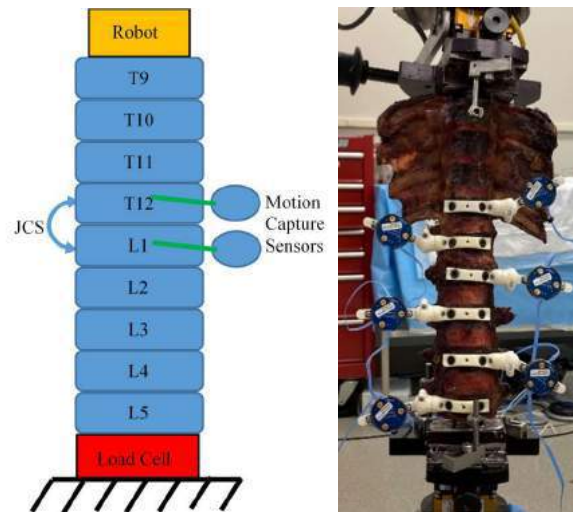

Historically this limitation has meant that robotic spine testing, is typically approached as control of the superior and inferior end points of the spine. This results in the FSU not being uniquely controlled when part of a multi-level spine construct. Consequently, applied kinetics have been limited to pure moment testing where every level of the spine experiences the same torque and all forces are commanded to 0 N.

Given these kinetic limitations, kinematic control has historically been approached in two ways. The **first method** is to align load cells and actuators with an estimate of the spine axis of rotation and use the native load cell and robot/actuator coordinate systems for measuring and controlling motions and loads [1]. This approach does not take into account local vertebra shifts in orientation or translation as a function of spine bending. The **second method**, the *static transform method*, is to control motion based on the location of the middle two vertebra in a spine construct and robot position. A joint coordinate system (JCS) that relates the superior and inferior vertebrae of the middle FSU would be constructed based off the ISB standard [2]. Static transforms are constructed based on the pose of the spine and robot during an initial digitization. These transforms will only account for local vertebra shifts in translation or rotation at the instance of digitization.

The aim of this study was to show that with a **third methodology**, called the *eXactoPOSE method*, it is possible to perform 6-DOF repetitive kinematic control (i.e. superposition testing) on a single FSU within a multi-level construct. This will serve as a stepping stone for future work that will look at how both kinetic and kinematic control of a single FSU interacts with adjacent level motions and loads.

METHODS

A thoracolumbar spine was obtained with T9-L5 intact. L5 was attached to a based mounted load cell while T9 was attached to the robot (Figure 1).

**Figure 1: Left: Schematic of Experimental Setup
Right: Representative Spine Mounted to simVITRO System**

In order to control the T12-L1 FSU within the middle of the spine, two 6-DOF motion capture markers (Optotrak Certus, Waterloo, CAN) were attached to T12 and L1 and a JCS was constructed to describe FSU kinematics. The simVITRO[®] software (Cleveland Clinic, Cleveland, OH) was used to apply 5 Nm of flexion to the spine while minimizing all other torques and forces. The kinematics of the T12-L1 FSU were

recorded during the pure moment tests, low pass filtered at 3 Hz to reduce noise from the motion capture data, and played back at 1/3 speed to improve kinematic tracking when doing superposition testing. Next, a sensor fusion algorithm in simVITRO called eXactoPOSE was used to control only the motion of the T12-L1 FSU. The eXactoPOSE algorithm closes the loop on 6-DOF positions using both the robot and motion capture data. Kinematics were again recorded during these superposition tests.

RESULTS

Figure 1 shows the T12-L1 kinematics based on the eXactoPOSE method from the pure moment vs superposition flexion test. The RMS error of the kinematics in all 6-DOF are given in Table 1, Column 1.

Figure 2: L1-T12 eXactoPOSE Pure Moment vs Superposition Kinematics (superposition kinetics have a thicker line)

It is notable that the static transform method measures different kinematics than the eXactoPOSE method. This is because the static transform method only uses robot motion and ends up being more of a global measure of spine motion rather than a local FSU measure based on motion capture sensors. Further, the static transform method was 1-2 orders of magnitude less repeatable than the eXactoPOSE method when comparing pure moment kinematics to superposition kinematics (Table 1).

Table 1: Root Mean Squared Error (RMSE) between pure moment and superposition test kinematics

Degree of Freedom	eXactoPOSE Method	Static Transform Method	Units
Anterior Translation	0.05	9.34	mm
Superior Translation	0.03	1.50	mm
Lateral Translation	0.03	2.18	mm
Right Lateral Bending	0.03	0.80	deg
Left Axial Rotation	0.04	2.11	deg
Extension	0.15	5.45	deg

Forces when performing the pure moment vs superposition tests were also different. In the pure moment tests all forces/torques are

commanded to 0 load except for flexion torque where 5 Nm is applied to the spine.

Figure 3: Force Control vs Superposition 6-DOF Kinetics (superposition kinetics have a black border)

DISCUSSION

Comparison of the 5 Nm flexion pure moment test to the T12-L1 superposition test reveals that it is possible to control the 6-DOF kinematics of a single FSU within a larger spine construct. The T12-L1 kinematics are different when looking at the static transform method's kinematics (Table 1) so kinematic reporting in manuscripts should always clarify this distinction. Since the spine has many more DOF than are actively able to be controlled by the robot, an indeterminate system will result where there can be many kinematic or kinetic poses of the superior and inferior vertebra (T9 and L5) that can produce the same pose in the middle of the spine (T12-L1). The static transform method is based on robot position and does not take into account local deformation of the spine, which means that it cannot account for multiple robot positions producing the same kinematics in the middle of the spine. These multiple solutions explain how different positions of the robot (table 1) and different forces (figure 3) can produce the same 6-DOF kinematics at the T12-L1 FSU.

The number of robot positions that could produce identical T12-L1 kinematics is indeterminate given the under-constrained system. Future work will add constraints to limit this solution space by using control laws weighting FSU forces and/or additional FSU kinematics.

Traditionally, cadaver spine testing has been focused on controlling global spine kinetics or kinematics and seeing these affect local kinematics. The authors hope that the ability to fully control an FSU in the middle of a spinal construct will allow researchers to ask meaningful questions about how FSU motion might affect motion both at adjacent levels of the spine and globally over the whole spinal construct. Additional future work will look at controlling compression and shear forces on a vertebra within a spinal construct so that clinicians can better understand the effect of combined loading scenarios on a spine construct.

EFFECT OF AGING, SEX, AND GENE (FIBULIN-5) ON THE ARTERIAL STIFFNESS OF MOUSE: 20 WEEKS ADULT MICE WITH FIBULIN-5 KNOCKOUT ARE OLDER THAN 100 WEEKS WILD-TYPE MICE

INTRODUCTION

Arterial stiffening is an independent predictor of cardiovascular risk [1]. It is also a key cause of many cardiovascular diseases. For instance, arterial/aortic stiffening could alter the hemodynamics in the aorta, increase the afterload of the left ventricle and ultimately promote myocardial remodeling, dysfunction, and failure [2].

Fibulin-5 (Fbln5) is an extracellular elastin-associated protein that connects to integrins and localizes tropoelastin to microfibrils [3, 4]. Fbln5 deficiency alters arterial microstructures by disrupting the integrity of elastic lamellae [5], which results in elongated and tortuous central arteries [3]. In addition, aging is another dominant risk factor for many cardiovascular diseases. Prior work by Wan et al. [5, 6] and Ferruzzi et al. [7, 8] documented how aging and loss of elastic fiber integrity due to Fbln5 deficiency alters material properties across the central vasculature. However, it is still not fully understood how the Fbln5 and aging influence the intrinsic material property/stiffness of arteries.

Here, we investigated how the aging, sex and Fbln5 gene affect the arterial stiffness of mice, based on a total of 128 biaxial testing samples of mouse arteries by Ferruzzi et al. [7, 8], using the recently developed unified-fiber-distribution (UFD) model for arterial tissues [9, 10].

METHODS

We assumed that arterial tissues are incompressible. The strain energy function of the unified-fiber-distribution (UFD) model can be expressed as [9, 10] $\bar{\Psi} = \frac{1}{2}c(\bar{I}_1 - 3) + \frac{k_1}{2k_2}[\exp\{k_2[\zeta^2(\bar{I}_{4\theta} - 1)^2 + (1 - \zeta)^2(\bar{I}_{4z} - 1)^2]\} - 1]$, where c, k_1, k_2 and ζ are four material parameters, representing the matrix stiffness, fiber initial stiffness, arterial stiffening factor, and circumferential fiber component, respectively. \bar{I}_1 is the 1st invariant of right Cauchy–Green tensor $\bar{\mathbf{C}}$, $\bar{I}_{4\theta} = (\mathbf{a}_{0\theta} \otimes \mathbf{a}_{0\theta}) : \bar{\mathbf{C}}$, and $\bar{I}_{4z} = (\mathbf{a}_{0z} \otimes \mathbf{a}_{0z}) : \bar{\mathbf{C}}$, where $\{\mathbf{a}_{0\theta}, \mathbf{a}_{0z}\}$ are the unit vectors in the circumferential and axial direction, respectively. The UFD model [9, 10] considers the fibers as a unified distribution,

rather than separating the fiber distribution into two/several fiber families. The consideration of a unified distribution for the fibers in the UFD model may be more physically consistent with the real fiber distribution of arterial tissues than existing fiber-family-based models.

We applied the UFD model to a total of 128 biaxial testing samples of mouse central arteries, which were obtained from Ferruzzi et al. [7, 8]. The samples were classified into three pairs (**Table 1**). The values of c, k_1, k_2 and ζ for each sample were obtained by fitting of the cylindrical biaxial testing data. Paired Student's t-tests were used to compare the parameters from different groups. A p -value less than 0.05 was considered to be statistically significant.

Table 1: three pairs of biaxial testing data of mouse arteries. M: male, F: female, 20wk/100wk: 20/100 weeks old, Fbln5^{+/+}: wild-type with fibulin-5 gene, Fbln5^{-/-}: knockout type. ATA: ascending thoracic aorta, DTA: descending thoracic aorta, SAA: suprarenal abdominal aorta, IAA: infrarenal abdominal aorta, and CCA: common carotid artery. Note that Pair-1 and Pair-3 contain a same group type (M-20wk-Fbln5^{+/+}).

Pair	Group type	Specific Location				
		ATA	DTA	SAA	IAA	CCA
Pair-1	M-20wk-Fbln5 ^{+/+}	n=5	n=5	n=5	n=5	n=5
	M-20wk-Fbln5 ^{-/-}	n=5	n=5	n=5	n=5	n=5
Pair-2	F-20wk-Fbln5 ^{+/+}	n=5	n=5	n=5	n=5	n=5
	F-20wk-Fbln5 ^{-/-}	n=5	n=5	n=5	n=5	n=5
Pair-3	M-20wk-Fbln5 ^{+/+}	n=5	n=5	n=5	n=5	n=5
	M-100wk-Fbln5 ^{+/+}	n=6	n=6	n=5	n=6	n=5

RESULTS

The UFD model obtained good fittings (Fig. 1a, b) of the experiments, with $R^2 = 0.9363 \pm 0.0032$ ($n=128$). The results show (Fig. 1c, d) that the arterial stiffening of the mouse with the knockout of the fibulin-5 gene ($Fbln5^{-/-}$) is significantly larger than that of the wild-type ($Fbln5^{+/+}$), for both male (Fig. 1c: $p<0.001$, “All Locations”) and female (Fig. 1d: $p<0.001$, “All Locations”), at each of the five locations (Fig. 1c, d: all $p<0.02$, each “Specific Location”). No statistical difference was found between the male and female groups at all five locations (all $p>0.05$ for each “Specific Location”).

The aging effect (20 vs 100 weeks old) also significantly increases the arterial stiffening of mice (Fig. 1e: $p<0.001$, “All Locations”). As to the “Specific Location”, the arterial stiffening factor of mice at 100 weeks old is notably larger than that of mice at 20 weeks old for most locations (Fig. 1e: $p<0.02$ for each “Specific Location” except ATA).

It is interesting to note that the mouse arterial stiffening of 20 weeks old with fibulin-5 knockout ($Fbln5^{-/-}$) is even larger than that of 100 weeks old with fibulin-5 ($Fbln5^{+/+}$), as shown in Fig. 1f (all $p<0.001$). This indicates that the 20 weeks old mice of $Fbln5^{-/-}$ are even much older than 100 weeks old wild-type mice of $Fbln5^{+/+}$, in the sense of arterial stiffening, based on the assumption that older mice have stiffer arteries.

Another interesting phenomenon is that the arterial stiffening follows exactly the same pattern in terms of locations for male (Fig. 1c) and female (Fig. 1d) mice. For the $Fbln5^{+/+}$ male/female groups (orange bars in Fig. 1c, d), the arterial stiffening factor increases from ATA to DTA, and then decreases to IAA to CCA. For the $Fbln5^{-/-}$ male/female groups (green bars in Fig. 1c, d), the arterial stiffening factor increases from ATA to DTA, and then keeps about the same value among DTA, SAA, IAA, and CCA.

The parameters c , k_1 and ζ also follows similar patterns in terms of locations for male and female mice (not shown here due to limited space). The parameter c decreases from ATA to SSA to CCA for $Fbln5^{+/+}$ groups, while first increases from ATA to SSA, and then decreases to CCA for $Fbln5^{-/-}$ groups. The aging significantly decreases circumferential fiber component (ζ) but has not much effect on matrix stiffness (c) or fiber initial stiffness (k_1). The parameters c , k_1 and ζ were influenced little by the $Fbln5$ gene knockout.

DISCUSSION

Comparison between Fig. 1c and Fig. 1f indicates that the knock-out of $Fbln5$ changes the location patterns but the aging effect does not, despite both aging and the $Fbln5$ knock-out increase the arterial stiffening factor. The specific location patterns may be a result of adaption to the hemodynamic, which suggests that the $Fbln5$ knock-out may also alter the blood flow profile in the arteries.

Ferruzzi et al. [7, 8] showed that the elastic fibers lose some waviness in $Fbln5^{-/-}$ mice with respect to $Fbln5^{+/+}$ controls, while medial collagen was increased in 100 weeks old mice. Therefore both loss of elastic fiber integrity and accumulation of collagen represent micro-structural mechanism for the increased arterial stiffening by $Fbln5$ knock-out and aging.

It should be noted that the 4-fiber family model was applied to the comprehensive and valuable experimental data [7, 8], however, property/stiffness differences have been seldom captured between different groups. The reason could be the overparameterization of the 4-fiber family model which has 8 material parameters, in contrast to the UFD model applied here which has only 4 material parameters but still achieves good accuracy (Fig. 1a, b).

INTRODUCTION

Extracellular vesicles (EVs) are cell-derived, membrane-bound vesicles that carry various biomolecules, such as proteins, nucleic acids, and lipids. They play important roles in cell-to-cell communications as molecular messengers. EVs are also attractive circulating biomarkers for molecular diagnosis of various diseases and carriers for therapeutics. Most published studies have investigated nanoscale EVs and focused on EV biochemical content. There is much less understanding of large microscale EV characteristics and EV mechanical properties.

EV stiffness has been measured using atomic force microscopy (AFM). AFM can differentiate natural EV populations based on stiffness [1], though only nanoscale EVs have been studied and the molecular origins of stiffness differences were not proven. However, pressure build-up inside the vesicles during AFM indentation from substrate adhesion [2] seems to have led to large variability and suspiciously high values of reported EV stiffnesses measured by AFM. We recently introduced a microfluidic technique that measures the effective stiffnesses of large EVs (L-EVs, >1 μm diameter) [3] as a higher throughput and non-contact approach to study L-EV biomechanics.

The objective of this pilot study is to probe the robustness of our microfluidic technique to distinguish between EV populations by comparing stiffness distributions of L-EVs derived from glioblastoma cell lines with expected lipid differences. Thus, this study will investigate the potential of high-throughput microfluidics to distinguish between large EV populations that differ in biomolecular composition.

METHODS

L-EVs were derived from glioblastoma multiforme cell lines (MGG, Gli36) with and without the isocitrate dehydrogenase 1 (IDH1) mutation, which occurs in many GBM cancers and affects lipid metabolism. L-EVs were isolated from collected cell culture media using differential centrifugation (300g for 10 minutes then 2,000g for

20 minutes). L-EV morphology, size distributions, and concentrations were assessed from optical microscopy images.

The microfluidic device that stretched suspended L-EVs consisted of two straight channels (width 1 mm, depth 150 μm) at right angles that generated linear planar extensional flow at the intersection (**Figure 1A**). L-EVs were suspended in a viscified aqueous solution (0.7% w/v methyl cellulose in phosphate-buffered saline, ~65 mPa·s) and injected through one inlet channel (**Figure 1B**). Fluid infusion flow rates were 500 $\mu\text{L hr}^{-1}$ to 1500 $\mu\text{L hr}^{-1}$ (equivalent strain rates ~ 2.8 – 8.3 s^{-1}). L-EV stretching was imaged with a 100 \times objective (Zeiss Axiovert 200M, Prime95B sCMOS camera, 500 frame movies at 40 fps). L-EV stretch was quantified from a strain measure based on the axes of the best-fit ellipse to the detected contour in MATLAB (**Figure 1C**).

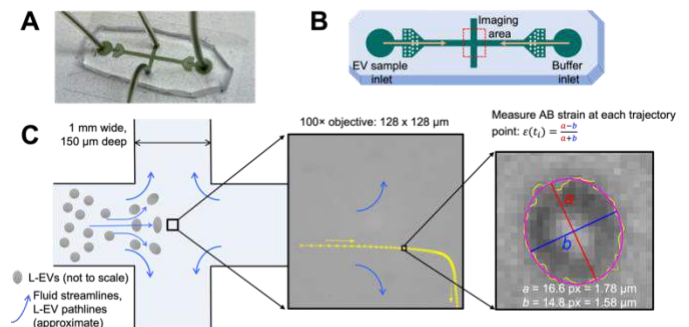

Figure 1: Non-contact microfluidic technique to measure the effective stiffness of microscale large extracellular vesicles. (A) The extensional flow microfluidic device. The channel width is 1 mm. (B) The extensional flow is created by impinging sample and buffer flows. (C) The L-EV strain measurement procedure.

An analytical linear elastic mechanical model of a sphere deforming in planar extensional flow [4] was applied to extract the L-EV's effective shear modulus G from the average strain. Stiffness distributions were statistically compared using classical (two-sided Wilcoxon) and bootstrapping (100,000 iterations) hypothesis tests. 95% confidence intervals of distribution medians and difference in medians was estimated from bootstrap resampling of the data.

Lipidomics analysis of L-EV populations was conducted to determine lipid profiles. Full scan spectra were collected on an LTQ-Orbitrap Velos mass spectrometer in both positive and negative ionization modes. Lipids were identified using the Lipid Mass Spectrum Analysis (LIMSA) v.1.0 software linear fit algorithm, in conjunction with an in-house database of hypothetical lipid compounds. For principal component analysis (PCA), all the lipid portion data was processed using the R program (version 4.0.3).

RESULTS

The diameter of all spherical L-EVs measured for stiffness ranged from 0.65 – 5.7 μm with a sample mean of 2.6 μm and a standard deviation of 0.95 μm . This is within the 1 – 5 μm size range considered for atypically large vesicles. The concentration of L-EVs that were measured for stiffness was $0.4 - 1.2 \times 10^7$ spherical L-EVs per milliliter.

L-EVs derived from Gli36 and MGG cells with the IDH1 mutation had ~20% higher medians than their wild-type counterparts (Figure 2) with a relatively small overlap of the median 95% confidence intervals (Table 1). Hypothesis testing of the difference in medians using the Wilcoxon rank-sum test and bootstrapping yielded p-values < 0.05 for all comparisons (Figure 2, Table 1).

Figure 2: Box plots of stiffness distributions of L-EVs derived from Gli36 and MGG cell lines. Pairwise comparisons were conducted using the two-sided Wilcoxon rank sum test. *p < 0.05, **p < 0.01.

Table 1: Summary of bootstrap hypothesis testing and 95% confidence interval (CI) statistics for comparisons between L-EV stiffness distributions. 100,000 bootstrap iterations were used.

Cell Line	N	95% CI: G Median [Pa]	95% CI: difference in medians [Pa]	Bootstrap Hypothesis Test p-value
Gli36 WT	203	10.79 – 13.89	0.235 – 5.42	0.0145
IDH1 mut	172	13.56 – 17.37		
MGG WT	198	11.52 – 13.76	-0.150 – 4.36	0.03169

Lipidomics showed that the four L-EV populations had different lipid content. In the PCA analysis, the four analyzed samples were in

different quadrants, indicating that the lipid components of each sample showed distinct characteristics. The amounts of phospholipids, a major component of membranes, decreased in both Gli36 and MGG cells with the IDH1 mutation. Larger numbers of unsaturated lipids were decreased in L-EVs from IDH1-mutated cell lines compared to saturated lipids.

DISCUSSION

Our L-EV stiffness and lipidomics data suggest that the stiffening could be related to the changes in lipid compositions of L-EVs. A significant reduction of unsaturated lipids means relatively more saturated lipids in L-EVs from cell lines with IDH1 mutations compared to those from wild-type cell lines. Saturated lipids pack more tightly than unsaturated lipids that contain double carbon bonds, leading to larger attractive intermolecular forces and stiffer biomembranes [5]. Further study is needed to determine if this change in lipid composition is a driving cause of L-EV stiffening with the IDH1 mutation. One such study could be to measure L-EV stiffness variation with distinct levels of the IDH1 mutation such that multiple points along the lipid composition spectrum between wild types and mutant cases are measured. Our results are consistent with recent studies that reported that the IDH1 mutation caused changes in lipid content and lipid order rearrangements in the membranes of internal organelles [6].

The advantages of our microfluidic approach over AFM are higher throughput and non-contact EV deformation. Though further validation of our technique is needed, our L-EV measurements here and in our previous publication [3] match a physical intuition that vesicles are softer than cells. In contrast, several AFM studies reported EV stiffnesses that are several orders of magnitude larger than cell stiffnesses [1]. In our view, approaches both should be used in a complementary manner and further improved to gain a more complete understanding of EV mechanics. Currently, AFM is the only mechanical measurement technique for nanoscale EV mechanical properties, while microfluidics offers an alternative microscale technique.

We are limited to studying microscale L-EVs because our microfluidic technique requires visual measurements of single L-EV deformation from optical microscopy, which is limited by the diffraction of visible light. To improve the size resolution of microfluidics, other imaging modalities (e.g., digital holography) that have a smaller diffraction limit could be used.

Most EV research has focused on smaller exosomes and microvesicles. The L-EVs studied here could be easier to handle and separate due to their large size and the ability to see them easily with conventional optical microscopy. L-EVs likely hold more biomolecular cargo that could make assays more accurate and robust for (large) EV subpopulation characterization. This study may imply that the less-studied L-EVs could also rich multiplex biomarkers for bioanalysis.

PARTIAL MENISCECTOMY OF THE MENISCAL INNER PART INCREASES THE MENISCAL DEFORMATION AND EXTRUSION

INTRODUCTION

The hoop stress is generated in the meniscus under the femoral compression load [1]. At that time, in the mid-substance of the meniscus, the compression and tensile stresses might be generated in the inner part and the outer part respectively like a beam bending situation due to the compression force from bony contact and tensile force from anterior and posterior horns. Based on that prediction, we hypothesized the inner part loss of the meniscus due to the partial meniscectomy may break the mechanical balance of the meniscus and may lead to the deformation and extrusion of the meniscus. Therefore, the aim of the present study was to investigate the effect of the inner part loss of the meniscus on its deformation and extrusion based on the biomechanical test for the radial meniscal tear model using the porcine knee joint.

METHODS

Porcine knees (n=6) were used for the test. The tibia was cut at 5 cm distally from the joint line after removed femur, and the soft tissue around the tibia was dissected down while the medial meniscus (MM) and medial capsule were preserved. The specimen was set at the lower jig of the material testing apparatus (ElectroForce 5500, TA instruments), and a 3 mm diameter indenter was touched down to a 2 mm inner point on the mid-region at the rim of the anterior-posterior length of the MM (Figure 1). As a pre-load, 1 N of compression force was applied to the MM on the specimen, and this configuration was defined as a reference to calculate the meniscus displacement. After recording the reference configuration, the compression force was applied up to 10 N to the MM. During the test, the meniscus motion and deformation were measured by a 3-D motion capture system (V120 Trio, OptiTrack). The markers for the measurement were placed at the meniscus-ligament junction of the anterior and posterior horns, and the mid-point of the meniscus outer surfaces. After the measurement of the intact state, the radial tear with 80% length of the mid-substance width was created from the inner edge at the mid-point of the MM, and the

measurement was repeated. Finally, the MM had been removed a total of 10 mm anterior-posterior length based on the radial tear and it was defined as partial meniscectomy in the present study, and then the measurement was repeated. The meniscus deformation was calculated based on the anterior-posterior length change and it was standardized by reference configuration. The meniscus displacement was calculated based on the reference configuration and it was standardized by the meniscus width in each specimen.

To statistically compare the radial tear and partial meniscectomy groups, paired t-test was performed on the displacement and deformation data.

Figure 1 Experimental setup

RESULTS

In the anterior-posterior length change of the MM, the radial tear group showed $0.9 \pm 0.9\%$ and $0.8 \pm 1.3\%$ decrease compared to the intact in response to 1 N and 10 N of compression load, respectively in the radial tear group (Figure 2). The partial meniscectomy group

showed $4.5 \pm 2.0\%$ and $4.3 \pm 2.2\%$ in response to 1 N and 10 N of compression load, respectively, and those decreases were significantly greater than those of the radial tear group.

In the displacement of the meniscus, the radial tear group showed $3.5 \pm 1.7\%$ and $6.1 \pm 2.1\%$ displacement in response to 1 N and 10 N of compression load, respectively. The partial meniscectomy group showed $7.0 \pm 3.9\%$ and $10.7 \pm 2.7\%$ displacement in response to 1 N and 10 N of compression load, respectively, and those values were significantly larger than those of the radial tear group (Figure 3).

Figure 2 Anterior-posterior length decreasing ratio with respect to the reference configuration in the radial tear and partial meniscectomy groups

Figure 3 Mid-substance marker displacement ratio to meniscus width in intact, radial tear, and partial meniscectomy groups

DISCUSSION

In the present study, the change of the meniscal motion and deformation due to the radial tear and partial meniscectomy were clearly indicated based on the biomechanical test. As a main result of the present study, the partial meniscectomy generated great anterior-posterior deformation and mid-substance part displacement.

In the anterior-posterior length change, the partial meniscectomy group showed a significantly large decrease compared to applying the radial tear individually. In general, under outward direction loading at the mid-substance of the meniscus from the femur, the ligament of the anterior and posterior horns generate inward direction tensile force to prevent the meniscus extrusion. During that situation, the meniscus deforms like a U or V shape, and this deformation generates tensile and compression stresses at the outer and inner parts, respectively. At the inner part, the tissue is compressed under loading and sustained each

other to keep the structure shape and function. After the radial tear was created, although the same deformation was generated by the loading, the structure still remained and could support each tear side. Therefore, the anterior-posterior length change was small in the radial tear group while the partial meniscectomy group generated a significantly larger change due to the loss of the tissue at the inner part.

The amount of displacement of the mid-substance marker of the meniscus was significantly greater than that of the normal meniscus in both the radial tear and partial meniscectomy groups, although the partial meniscectomy group showed significantly greater displacement than the radial tear group, with approximately 130% and 45% greater than the intact and radial tear groups, respectively. Those results suggested that large V shape deformation due to the loss of the inner part resulted in the large displacement of the mid-substance. That result indicated that individually applying the radial tear affected the displacement compared to the intact state, while the partial meniscectomy more strongly affected the displacement compared to the radial tear individual applied state.

The V shape deformation was led by the bending torque at the mid-substance generated by the ligament tensile force and compression forces from the bone. To estimate the resistance capability to the bending torque at the mid-substance of the meniscus, calculated the cross-sectional secondary moment. In the intact meniscus, the shape of the cross-sectional area at the mid-substance is a triangle. On the other hand, the shape of the remained cross-sectional area after partial meniscectomy is a trapezium (Figure 4). From the ratio of each part between the intact and partial meniscectomized menisci based on the present experimental procedure, the cross-sectional secondary moment decreased by 98% in the partial meniscectomized meniscus compared to the intact meniscus. It is suggested that the weakness to resistance to the bending torque is one of the factors to lead the large V shape deformation in the partial meniscectomized meniscus.

Those results suggested that loss of the inner part of the meniscus led to the abnormal deformation of the meniscectomized part and resulted in its large displacement related to the extrusion. Those results supported our hypothesis based on the bending torque generated by the outward direction loading. Additionally, it is suggested that repairing the inner part for remaining the structure to resist the bending torque is the key to the prevention of meniscus extrusion.

INTRODUCTION

To better understand the mechanisms of concussion, head impact sensors such as instrumented mouthguards have been increasingly used in recent years. These devices measure the motion of the skull upon an impact, and researchers have primarily used the peak of the linear and angular acceleration signals to describe the exposure to potentially injurious events [1]. Concussion has been shown to occur in the absence of any high-magnitude singular event [2], but the effects of low-magnitude sub-concussive head impacts on mid- and long-term health remain unclear.

The lack of a strong relationship between head impact exposure and brain injury may be partially explained by the inadequacy of peak kinematics to describe trauma to the brain. In contrast, the amount of strain experienced by the brain, estimated using finite element modeling, has been shown to be a relevant descriptor of injury [3]. However, global measures of strain may not appropriately describe the damage sustained by the various regions of the brain. Therefore, the objective of this research is to describe the regional distribution of brain strains resulting from sub-concussive head impacts.

METHODS

Head acceleration events were collected from collegiate football players during practices and games from 2018 to 2021. The Stanford instrumented mouthguard (MiG2.0) [4], containing a triaxial accelerometer (sampling rate: 1000 Hz) and a triaxial angular rate sensor (8000 Hz), was used to record 200-ms events when the linear acceleration on any axis crossed a 10-g threshold. True head impacts were later classified using a three-step process. First, a deep learning algorithm eliminated events that were likely to result from spurious triggering. Second, the remaining events were reviewed on video and were kept only if they resulted from a direct impact to the head. Third, an author visually analyzed the raw kinematic signals and eliminated the events showing abnormal frequency content and high-magnitude

spikes, which would be indicative of the mouthguard decoupling from the skull or of an electronic issue [5].

For verified head impacts, the kinematics signals were processed with a Butterworth filter at a cutoff frequency of 160 Hz. Angular acceleration was derived, and linear acceleration was transformed to the estimated head's center of gravity. The peaks of the resultant linear acceleration, angular velocity, and angular acceleration signals were extracted as PLA, PAV, and PAA, respectively.

To compute brain strains, we used a deep learning algorithm [6] based on the KTH head and brain finite element model, composed of 4,124 elements divided into anatomical regions with specific material properties [3]. The algorithm used features extracted from the angular kinematic signals to estimate the maximum principal strain (MPS) experienced by each element. The 95th percentile of the MPS (MPS95) was calculated for each impact, as well as the cumulative strain damage measure (CSDM), which represents the percentage of brain volume experiencing strains above a defined threshold (here 15%).

A Shapiro-Wilk test determined that the distribution of the peak kinematics and brain strains was significantly skewed towards low magnitude values. Therefore, the differences in strain between brain regions were examined with a Kruskal-Wallis analysis of variance test with a Dunn-Šidák correction.

RESULTS

Over the duration of the study, acceleration events were obtained from 45 athletes over a total of 1369 player-sessions. Here, we present preliminary results on a subset of 209 verified head impacts, collected from 21 athletes over 77 player-sessions (see an example impact in Figure 1A). For the 209 impacts, the median and inter-quartile range for the PLA, PAV, and PAA were, respectively: 21.07 [14.74 - 26.85] g, 13.25 [10.59 - 16.49] rad.s⁻¹, and 1,135.94 [908.47 - 1,599.85] rad.s⁻².

The median MPS95 for the whole brain was 6.16 [5.06 - 7.75] %. The MPS95 varied across brain regions ($p < 0.001$), with the strains in

the midbrain, grey matter, white matter, and corpus callosum being significantly higher than in the thalamus, brainstem, and cerebellum (Table 1). Overall, the median CSDM was 0% with 18 impacts (8.6% of the dataset) showing element-wise strain over the 15% threshold. For those impacts, the whole brain CSDM ranged from 0.02 to 62.71%; CSDM values for each region are presented in Table 1.

Table 1: Median [interquartile range] of the MPS95 for the 209 verified head impacts and CSDM for the 18 impacts over 0%, for the whole brain and the various regions. The abbreviations in the MPS95 column indicate significant differences between regions.

Brain region	MPS95 (%) (N = 209)	Regional CSDM (%) (N = 18)
Whole Brain (WB)	6.16 [5.06 - 7.75] ^{CC, TH, BS, CL}	6.57 [1.58 - 24.56]
Midbrain (MB)	6.70 [5.87 - 8.40] ^{WM, CC, TH, BS, CL}	6.25 [0.00 - 38.28]
Grey Matter (GM)	6.51 [5.41 - 8.21] ^{WM, CC, TH, BS, CL}	9.88 [2.62 - 33.16]
White Matter (WM)	5.73 [4.64 - 7.02] ^{MB, GM, TH, BS, CL}	4.65 [0.60 - 21.94]
Corpus Callosum (CC)	5.33 [4.33 - 6.91] ^{WB, MB, GM, TH, BS, CL}	2.44 [0.00 - 62.80]
Thalamus (TH)	3.91 [3.19 - 4.99] ^{WB, MB, GM, WM, CC, CL}	0.00 [0.00 - 1.43]
Brainstem (BS)	3.83 [3.09 - 4.92] ^{WB, MB, GM, WM, CC, CL}	0.00 [0.00 - 0.00]
Cerebellum (CL)	2.02 [1.63 - 2.60] ^{All}	0.00 [0.00 - 0.00]

DISCUSSION

In this study, we calculated and described the global and regional brain strains experienced as a result of direct head impacts in collegiate football. The global strains (MPS95) from our sample of 209 impacts (median of 6.16%) were slightly lower than previously reported for collegiate women's soccer headers (8.84%) [7]. While differences may be due to the sport and/or the population, there are also multiple methodological distinctions between the two studies, such as the impact selection process. Here, we visually selected impacts based on the raw kinematics to keep only events that were most likely to represent true head motion. It has been shown previously that sensor decoupling from

the skull results in the overestimation of head kinematics [4], which would result in the overestimation of brain strains. Further analysis is required to determine the effect of signal quality on the magnitude of brain strains.

No other study has reported regional MPS95 values. However, the results from studies reporting regional peak MPS are similar to our findings, with the strain measured in the midbrain and corpus callosum being generally higher than in the thalamus and brainstem [8,9]. Studies involving neuroimaging can elucidate the consequences of these regional variations.

The limitations of the present study include the absence of strain rate. It has been suggested that strain rate is a valuable predictor of brain injury, and future versions of the deep learning model will allow the calculation of this important metric. Additionally, our analyses may benefit from the use of region-specific strain thresholds, as the properties of each brain region differ and they may not respond similarly to strain.

INTRODUCTION

Current research increasingly indicates the importance of structural proteins in the function of highly dynamic tissues in the body [1]. Specifically, elastin provides resilience and unique kinematic capabilities to many components within the respiratory and cardiovascular systems. Recently, our lab reported that the epicardial layer, rich in elastin, acts like a prestrained 'balloon' that wraps around the heart and functions as an extra confinement and protective interface for the ventricle [2]. This novel discovery alone indicates the necessity of elastin as an integral component of overall cardiac output. Moreover, these conclusions emphasize the importance of a full biomechanical characterization of the epicardial layer, which has vastly been ignored compared to the myocardial layer. For instance, how the elastin fibers arrange themselves into epicardium interface is still a missing component of our current understanding. Though we now know this intricate fiber network enables a significant dynamic deformation during the ventricular diastolic expansion and systolic contraction, we have limited knowledge on how this is so. To begin answering some of these questions, we designed a custom miniature uniaxial stretcher compatible for imaging under a laser scanning confocal microscope (LSCM) to reveal the epicardial elastin kinematics under mechanical loading. Using this technique will enable us to explore the microstructural arrangement and dynamic behavior of the elastin fibers responsible for maintaining cardiac output.

METHODS

Fresh adult epicardial layer samples were dissected from the porcine left ventricle and sutured to denote the heart longitudinal direction. The epicardial layers were cleaned of most excess muscular tissue (remaining sample ~1 mm thick). The samples were decellularized for 24 hours in 0.1% SDS and rinsed with distilled water overnight to remove any excess detergent. The decellularized samples were treated with glycerol to replace the water content in a gradient

fashion, i.e., 30 minutes in 25% glycerol, 30 minutes in 50% glycerol, 30 minutes in 75% glycerol, and 30 minutes in 100% glycerol. The glycerol has an optical index very close to collagen fibers and thus make the collagenous tissue transparent. Water, on the other hand, has an optical index different from collagen fibers. The mismatched optical index between the water and collagen interface is integral to the imaging process, as the interface dissipates light. This optical behavior causes the hydrated collagenous tissue to appear as an opaque whitish color. The transparency of the tissue sample enables a deeper laser penetration, allowing for LSCM imaging of the 3D elastin fiber matrix.

Glycerol-treated samples were mounted onto a custom-made uniaxial stretcher, which was designed to fit onto a LSCM sample stage for imaging. Markers were used to indicate the position of the sample stretching so deformation could be tracked. One end of the tissue was attached to stationary hooks within the uniaxial stretcher. The other end of the tissue was attached to a movable stand via hooks so that the tissue could be stretched to different strains for LSCM imaging. The following step strains were applied: 0%, 10%, and 20%. These strains were chosen to capture the elastin fiber morphology at the reference state (0%), in the toe region (10%), and in the linear region (20%) of the stress-strain curve. Note that the loading direction for this experiment is along the heart longitudinal direction.

A Nikon LSCM (Nikon A1R HD25) was used for 3D elastin fiber imaging. The tissue was imaged using the CY3 channel, Ex 543 nm to obtain 2D images and z-stacks of the elastin at different tissue strain levels. A small weight was placed on the tissue to ensure a close tissue contact with the glass imaging window that allows confocal laser passing through. Images were further processed in ImageJ to determine waviness ratios among groups, as well as fiber alignment distribution. Mean \pm standard deviation was used to present the experimental data and determine if the parameters were statistically different using one-way analysis of variances (ANOVA). Data was considered significant when $p < 0.05$.

RESULTS

The 3D elastin fiber structure at different step strain levels were captured by LSCM imaging. The real time elastin fiber structure tracking showed unique engagement of fiber kinematics at different stages of the tissue's loading conditions (**Figure 1**). Under 0% strain (**Figure 1A**), fibers appeared closely bundled and wavy, with a significant degree of alignment. Note that the uniaxial loading was conducted along the horizontal direction of the image plane, which was also the longitudinal direction of the epicardium sample. Hence, the elastin fibers in **Figure 1A** indicated an alignment slightly deviating from the circumferential direction of the left ventricle. At 10% tissue strain (**Figure 1B**), the deformation reached to the toe region of the stress-strain curve, i.e., where fiber uncrimping took place. The rotations and realignment of fibers occurred as the tissue was stretched, and a defined, mesh-like structure appeared as each fibers uncrimped and clearly separated from each other. At this stage, the elastin fibers were spread wider in the horizontal loading direction, which was perpendicular to the original overall fiber orientation. While most fibers appeared largely parallel, this strain level initiated the load bearing capabilities of a number of fibers that spanned in the direction normal to the preferred-fiber direction (**Figure 1B**).

Under 20% global tissue strain, fibers showed further mesh-pulling kinematics, in which the alignment shifted from a unimodal to a flattened distribution (**Figure 1C**). The high longitudinal strain appeared to engage even more fibers rotating towards the longitudinal direction. Mesh-like fiber network at 20% global tissue strain showed a taut and stretched morphology, consistent with the fact of tissue stretching was in the linear region of the stress-strain curve. Waviness ratio of elastin fibers under 10% and 20% global strains were smaller when compared to the elastin fibers under no strain.

DISCUSSION

We were able to image elastin fibers under different step strains to reveal the engagement of epicardial elastin fibers in global tissue deformations. At 0% global tissue strain, elastin fibers exhibited a high degree of waviness and fibers bound closely. Elastin fibers appeared relaxed and entangled, resulting in a less distinguished 3D fiber image due to autofluorescence signal disbursement. Under 10% global tissue strain, the elastin fibers were pulled apart and the mesh-like elastin architecture were shown with the 3D reconstructed LSCM image. This uncrimping, fiber rotation and mesh pulling kinematics corresponded well with the mechanical behavior in soft tissue toe region. Additionally, under 20% global tissue strain, elastin fibers indicted more fiber rotation towards the external loading direction with a taught, web-like mesh morphology. The distribution of fiber alignment reflected this fiber dynamic, with the alignment distribution shifting from a unimodal to a flattened distribution. Though there are still many gaps in our understanding elastin kinematics, our approach opens a new avenue to understand the structural mechanism of epicardium under dynamic, complex large deformations that associated with vigorous cyclic pumping of the heart.

INTRODUCTION

Cardiomyocytes derived from human induced pluripotent stem cells (hiPSC) are promising tools to predict drug-induced arrhythmias and study inherited diseases, but physiologic immaturity remains a challenge. Compared to hiPSC-derived cardiomyocytes (hiPSC-CM) grown in monolayers, hiPSC-CM within engineered tissues typically show hallmarks of better maturity, as evidenced by more “*in vivo*-like” cell shape, sarcomere architecture and pharmacology. However, mechanisms through which “*in-vivo*-like” cellular organization translates into more mature physiology remain uncertain, making it challenging to devise strategies to accelerate maturation further.

We hypothesized that prestress transmitted across cell-cell contacts is higher in aligned 3D tissues and enhances hiPSC-CM maturation. To test this hypothesis, we developed a double molding approach to replicate high resolution 3D prints into elastomers and leveraged this tool to study how geometrically-determined tissue prestress, together with the presence of desmosome plaques that link cell-cell junctions to intermediate filaments [1], regulates electrophysiology of hiPSC-derived micro-heart muscles (μHM) [2].

METHODS

Devices: μHM are formed by seeding hiPSC-CM into dogbone-shaped molds atop culture substrates. Dogbones consist of square “knobs” (1mm x 1mm) connected by a rectangular shaft (200μm wide, and either 0, 1 or 2mm long). We developed a double molding technique to replicate high-resolution 3D printed features into poly (dimethyl siloxane) (PDMS). Briefly, dogbones were printed in FormLabs ClearResinTM on a Form3 printer. Either agar or alginate hydrogels were formed as negative replicas of the 3D print. Sylgard 184 PDMS was then crosslinked within the gel negatives [2]. Replication fidelity was gauged based on a user-defined “fidelity score” from 1-5 (5 being best).

Cardiomyocyte Differentiation: Wild-type iPSC (WT) were genome edited using CRISPR to induce a homozygous knockout of

plakophilin-2 (PKP2). PKP2^{-/-} and control iPSC were differentiated into hiPSC-CM by manipulating Wnt signaling [3]. hiPSC-CM together with stromal cells were seeded together at a density of 7.5x10⁷ cells/mL (3μL) into PDMS stencils to form μHM with 0, 1 or 2mm shafts.

μHM Phenotyping: Electrophysiology was assessed optically in spontaneously contracting day 15 μHM stained with the voltage sensitive dye BeRST-1 [4]. Ca²⁺ was tracked using GCaMP6f, a genetic Ca²⁺ indicator [5]. Action potential and Ca²⁺ transient waveform morphology were analyzed using open source Matlab pipelines [6].

Saxitoxin (STX) was used as a probe for sodium current (*I_{Na}*), and E4031 was used as a probe for the rapidly rectifying potassium current (*I_{Kr}*). Cellular structure and protein localization were assessed in confocal micrographs of 12μm longitudinal μHM cryosections stained for cell shape (Wheat Germ Agglutinin; WGA), nuclei (Hoescht) and with antibodies against Sarcomeric α-Actinin, sodium channels (Nav1.5) and gap junctions (Connexin 43).

Statistical Analysis: Comparisons amongst groups were made first by ANOVA followed by post-hoc Holm-Sidak test. Comparison between only two groups was performed with two-tailed student *t*-test.

RESULTS

Hydrogel assisted molding replicated 3D printed features into PDMS with high fidelity (**Fig. 1A,B**). Gel ultimate modulus was critical for predicting feature transfer success (**Fig. 1C**). Increased μHM shaft length was hypothesized to increase tissue prestress based on a Comsol model of μHM uniform compaction (**Fig. 2A,B**). Within predicted regions of prestress in μHM shafts, we observed cellular alignment and sarcomere organization (**Fig. 2C,D**). We verified robust nuclear alignment in both control and PKP2^{-/-} μHM (**Fig. 2E**). However, tissue-geometry induced nuclear elongation was reduced in PKP2^{-/-} compared to controls, suggesting that the nascent desmosomes are required for complete transmission of cell-cell junctional stress throughout the cell (**Fig. 2F**).

Figure 1: Scanning electron micrographs of (A) stereolithographic 3D prints and (B) PDMS replicas. (C) Hydrogel crosslink concentration regulates replication fidelity.

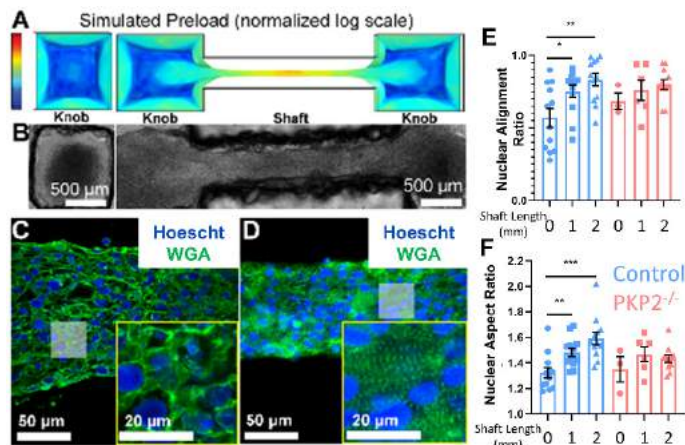

Figure 2: (A) Simulated prestress (Comsol) developed during compaction of μ HM with different shapes. (B) Micrographs of μ HM with either 0mm (left) or 2mm (right) shaft length. (C-D) iPSC-CM in μ HM stained with (C) WGA and (D) antibodies against Sarcomeric α -Actinin (ACTN2). (E-F) analysis of (E) nuclear alignment with respect to shaft, and (F) nuclear aspect ratio, a measure of nuclear deformation in.

Tissue prestress had global effects on electrophysiology (Fig. 3A). Strikingly, studies in day 15 μ HM with the sodium current (I_{Na}) specific probe saxitoxin (STX) suggest that I_{Na} was absent in 3D tissues without geometrically-induced prestress (Fig. 3B). In contrast, E4031-dependent hERG block was not dependent on μ HM geometry. qRT-PCR, immunostaining, and western analysis suggest that changes in sodium channel function triggered by tissue prestress are not directly related to expression of SCN5A, the pore forming subunit of the channel (data not shown). However, there may be changes in trafficking. PKP2^{-/-} μ HM showed much lower electrophysiologic change in response to tissue geometry compared to wild type controls. Although cardiomyocytes in PKP2^{-/-} μ HM exhibited nuclear alignment, these tissues had no response to STX (Fig. 3C).

Figure 3: (A) Changes in action potentials in μ HM with different shaft length. (B) Action potential upstroke duration in response to dose of Saxitoxin (STX), a specific sodium channel blocker. (C) Fold response (normalized increase in upstroke duration) to 2 μ M STX in either wild type control (WT) or PKP2^{-/-} μ HM.

DISCUSSION

Our data show that hydrogels can be used to effectively replica mold high resolution 3D prints to create PDMS devices for tissue engineering. Using this technique to modulate tissue geometry/prestress, we observed global effects of tissue prestress on cellular electrophysiology. Pharmacologic studies indicated that a threshold level of prestress is necessary to generate STX-response sodium currents, while other channels such as hERG are less sensitive. This suggests a role for prestress in sodium channel function.

Prior studies performed in 2D micro-patterned cells have suggested that the channel protein $K_{ir2.1}$, encoding rectifying potassium current (I_{K1}), is directly regulated by integrin-ECM adhesion plaques, whereas the sodium channel is less sensitive to the presence of adhesions [7]. Here, we observed direct control over STX-responsive sodium currents by overall tissue geometry. Our finding that PKP2 knockout tissues allowed cardiomyocyte alignment but did not lead to STX-response currents suggest that alignment alone is insufficient to induce functional sodium channels, and instead that mechanical transmission of prestress across cell-cell junctions is critical to this response. While important to cardiomyocyte maturation, other currents, including hERG, appear less sensitive to prestress.

Because the overall levels of transcript and protein encoding SCN5A, the pore forming subunit of the sodium channel, were unchanged across conditions, our findings point to post-translational regulation mechanisms, potentially related to sodium channel trafficking [8] and/or activation, in response to prestress.

Our studies have limitations that will be addressed in future work. First, all-optical analysis of cellular electrophysiology precludes direct measurements of resting membrane potential and the absolute magnitude of the action potential upstroke. Second, our system thus far only allows geometrically-induced changes in prestress. In the future, we plan to address this limitation by dynamically stretching the μ HM. Finally, the resolution of the 3D prints we used in this study was insufficient to reveal whether there are fundamental limits to the resolution that can ultimately be achieved in transferring 3D prints into elastomers using gel intermediates. We are currently studying these resolution limits using 3D prints created by 2-photon photopolymerization on a NanoscribeTM system.

INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is often caused by genetic disorders, resulting in abnormal sarcomere, thickening of the heart muscle, and overgrowth of the left ventricular septum. This overgrowth can block the outflow of blood, disrupt the mitral valve coaptation, and increase the mechanical stress experience by the heart. Besides the hypertrophied and disarrayed cardiomyocytes, overexpressed fibrotic collagen alters the septum constitutions and microstructures [1]. As a result, cellular hypertrophy and the fibrotic environment change the mechanical properties of the hypertrophied septum, contributing to the abnormal biomechanical behavior of the septal tissues. For example, previous research showed that the circumferential myocardial shortening of ventricular muscle during contraction often takes place and contributes to the preservation of left ventricular systolic performance in HCM [2]. Due to the thickening of the wall, reduced left ventricular strain is also associated with poor cardiac performance, consequently resulting in heart failure [3]. However, the mechanical properties of human hypertrophied septum are not well investigated. In this study, we performed viscoelastic mechanical tests such as stress relaxation testing and creep testing, as well as shear mechanical testing on human hypertrophied septum obtained from myectomy surgeries and compared with the healthy septum.

METHODS

Hypertrophic septal samples were obtained from the surgical waste of clinical myectomy of the HCM patients (UTSW: IRB STU 082017-072). Patients include both male and female and range in age from 19 years to 71 years. Healthy human septal tissues were obtained from a tissue bank under the same IRB protocol. Septal tissues were then dissected for viscoelastic and shear mechanical tests. Samples prepared for viscoelastic and shear tests were aligned with the longitudinal direction of the septum. For viscoelastic tests, tissue samples were mounted onto the TestResources Universal Testing Machine

(Shakopee, MN) and tested in 1X Phosphate Buffered Saline (PBS). After preconditioning, the following testing protocols were completed: (1) Stress Relaxation: hypertrophied and healthy samples were loaded to 100g and the achieved strain was kept constant while recording the stress decay up to 15 minutes. (2) Creep: hypertrophied and healthy samples were loaded to 100g and kept at this constant load while deformation was continuously monitored up to 15 minutes. (3) Failure test: hypertrophied and healthy samples were loaded until failure (tissue breakage). Each sample was pulled at a rate of 0.5 mm/s. Simple shear testing was performed to assess shearing property of the septal tissues. 3 mm x 3 mm x 3 mm cubed septum samples were mounted onto custom-built steel shear plates with minimal cyanoacrylate. The shear direction is along the longitudinal direction of the septum tissue. The shear plates were then mounted on the TestResources Universal Testing Machine. The samples were subjected to positive and negative shear up to 50% strain with a loading rate of 0.02 mm/s.

RESULTS

We found that the healthy septum exhibited a stress decay similar to most soft tissues, $57 \pm 6.3\%$. On the other hand, hypertrophied septum exhibited a much larger stress decay, $68 \pm 11\%$. Both healthy septum and hypertrophied septum showed a small amount of creep over time. The final creep amount at 15 minutes reached $9.1 \pm 1.0\%$ for healthy septal tissues and $9.8 \pm 4.2\%$ for hypertrophied septum. We also observed that the healthy septum showed a very typical nonlinear concave upward stress-strain relation. However, the hypertrophied septum showed a stress-strain trend that was much less nonlinear. The hypertrophied septum had an initial modulus that was higher than healthy septal tissues, most likely due to the abundant fibrotic collagen associated with HCM. An important observation was that the healthy septum had much higher mechanical strength than the hypertrophied septum (failure stress -

healthy: $2,561 \pm 919$ kPa vs HCM: 494 ± 206 kPa). In the high strain region, the healthy septum was also stiffer than the hypertrophied septum. Both healthy and hypertrophied septum demonstrating a nonlinear shear behavior. The hypertrophied septum appears much stiffer with greater energy dissipation than the healthy septum. The maximum shear modulus of the healthy septal tissues and hypertrophied septum were 100 ± 12 kPa and 250 ± 73 kPa, respectively.

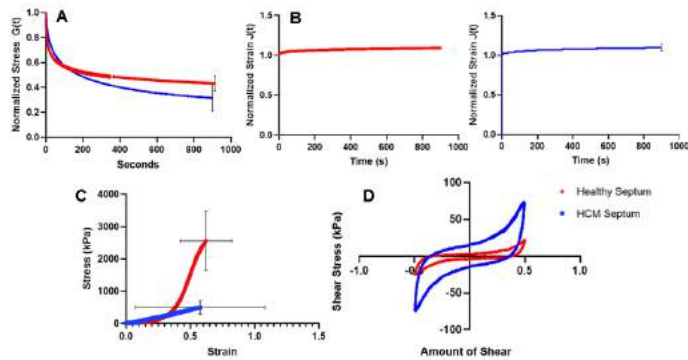

Figure 1: (A) Average stress relaxation curves, (B) Average creep curve, (C) Average stress-strain curves up to tissue failure, and (D) Shear stress-strain curves for human healthy septum (red) and hypertrophied septum (blue).

DISCUSSION

Overall, hypertrophied septum had larger stress relaxation, larger creep, and was stiffer at the initial phase of tissue loading, less nonlinear, less stiff in the linear region, and much weaker in mechanical strength. We also found a stiffer shear behavior and a greater energy dissipation during simple shear test. The stress relation and creep behavior, the failure behavior, and the shear property all reflected the fact that hypertrophied septum had more disorganized fibrotic collagen fibers when compared with the healthy septum. The poorly organized, pathological compositions in hypertrophied septum seemed to lose the benefit of native tissue design and hence exhibited an inferior viscoelastic and shear mechanical behavior as described above. Our viscoelastic and shear mechanical data build a strong foundation to understand tissue behavior of hypertrophied septum and the degree of its deviation from the healthy septum.

INTRODUCTION

Articular cartilage found in synovial joints primarily functions to provide a smooth, lubricated surface to facilitate joint movement and load transmission [1]. Chondrocytes, the resident cells of cartilage, maintain and interact with the surrounding extracellular matrix (ECM) to maintain this function. Numerous studies have been conducted with the goal of developing tissue constructs that mimic native articular cartilage by culturing chondrocytes in three-dimensional hydrogels under compression, shear, or articular motion [2-4]. However, the role of specific ECM molecules, like hyaluronan (HA), in mechanical response remains unclear. The ECM is mechanosensitive to loading, therefore affecting tissue mechanical and biochemical properties [5]. By simulating the microenvironment of cartilage, cellular proliferation and ECM composition within hydrogel constructs can be enhanced. The goal of our study is to outline the mechanism of action of HA in chondrocyte-embedded hydrogels in response to compression over 21 days. The primary objective of the first time point (day 1 of loading) is to evaluate the performance of a custom bioreactor system and will be followed by a full three-week study, with more specific outputs.

METHODS

A custom bioreactor (Figure 1) was fabricated using machined aluminum for the base and 3D printed materials for the compression posts. An actuation waveform was created using a programmable logic controller to control the pneumatic cylinder, enabling a set frequency without causing extraneous vibrations or unwanted disturbances to unloaded samples. The system was verified using a displacement gage to compare the heights of individual compression posts and image analysis to compare strains applied to hydrogel constructs.

Human chondrocytes (SW1353, ATCC, passage 4) were seeded at a density of 2×10^5 cells/mL in neutralized type I collagen solution

(4mg/mL RatCol, Advanced Biomatrix) to form cylindrical hydrogel constructs (3.08 ± 0.32 mm \times 6.64 ± 1.35 mm ϕ , mean \pm SD). Following overnight polymerization, hydrogels were moved to a 24-well plate within a custom bioreactor. After 72 hours, hydrogels were subjected to a bout of unconfined, dynamic, uniaxial compression at 10% peak-to-peak strain superimposed on a 1% static offset strain, respectively to the initial dimensions, at a 1 Hz for three hours, based on a duty cycle of one hour of loading followed by one hour of unloaded rest. Separate, unloaded samples were used as free-swelling controls. Two hours after the end of loading, loaded and free-swelling hydrogels were evaluated for change in volume and viscoelastic behavior ($n = 3$), total sulfated glycosaminoglycan (sGAG) content ($n = 3$), or gene expression ($n = 3$).

Figure 1: Custom compressive bioreactor. A: Compressive loading device. Loading platen situated over wells and to apply desired load.

B: Illustrative description of hydrogels loaded by the platen versus free swelling (not to scale). C: Schematic showing input parameters.

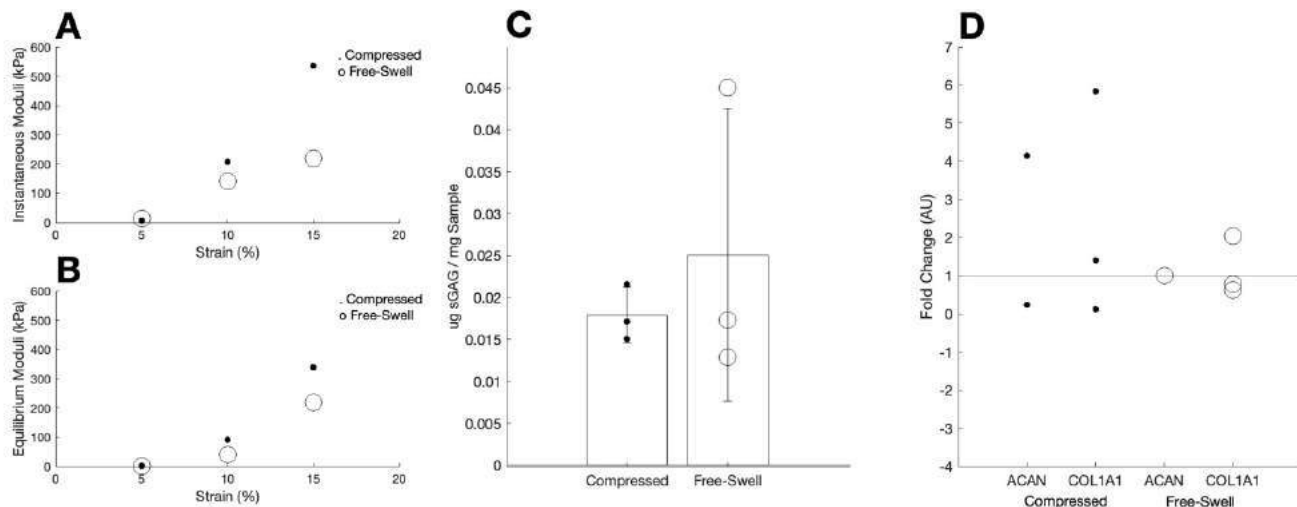

Figure 2: Cyclic compression does not significantly alter mechanical behavior, ECM composition, and gene expression after 1 day in culture.

A: Representative Instantaneous hydrogel moduli (kPa) response, $p > 0.05$ **B:** Representative Equilibrium hydrogel moduli (kPa) response, $p > 0.05$

C: sGAG expression quantified per mg of sample, $p > 0.05$ **D:** Fold changes in gene expression corrected for 18S rRNA, $p > 0.05$

Hydrogels were measured with a caliper to determine volume change. Samples then underwent stress relaxation experiments using an Electroforce 5500 test instrument while remaining hydrated in 1x phosphate buffered saline. Separate hydrogels were weighed and digested in 1mL of 50 μ g/mL Proteinase K solution overnight before sGAG content was measured using a 1,9-dimethylmethylene blue (DMMB) colorimetric assay. RNA was extracted and purified from remaining hydrogels using Qiazol reagent and rapid homogenization. TaqMan®-based qRT-PCR was used to measure expression of aggrecan (*ACAN*), type I collagen (*COL1A1*), and 18S rRNA.

RESULTS

The custom bioreactor was calibrated to ensure consistent loading could be applied, across the well plate and experiments. Post heights were measured using a displacement gauge and found to be statistically similar. To ensure 10% compression could be accurately applied, constructs were created from various materials (PDMS, agarose, and collagen), and compressed by the loading system. Images were taken prior to and during loading to verify the set strain amplitude. Target strain levels could be achieved with less than 1.5% deviation.

Following intermittent loading, hydrogels decreased in volume by $22.7 \pm 6.1\%$ and free-swelling hydrogels decreased in volume by $22.2 \pm 12.9\%$, showing no significance between groups. Stress relaxation tests were used to derive the instantaneous and equilibrium moduli (Figure 2A, 2B). While only one sample was usable from this output group, one can see a general trend where loaded samples have higher response moduli compared to free swelling samples. No significance was observed between the expression of sGAG concentration (Figure 2C) in compressed hydrogels (0.018 ± 0.003 ug sGAG / mg sample) versus free-swelling (0.025 ± 0.017 ug sGAG / mg sample). *ACAN* and *COL1A1* expression was evaluated with respect to the housekeeping gene 18S rRNA. The $2^{-\Delta\Delta C_t}$ method was used for analysis, showing no significant changes in *ACAN* or *COL1A1* relative gene expression levels, though a general trend can be seen in which compressed samples have higher expression (Figure 2D).

DISCUSSION

We observed that a single bout of compressive loading did not produce significant alterations in mechanical behavior, ECM content, or gene expression of chondrocyte-embedded collagen hydrogels. This

is supported by previous dynamic loading studies, which typically do not report significant changes between free-swelling and loaded culture groups until the third week of culture. Significant changes in contraction and moduli levels are not significant between free swelling and dynamic groups until week two of culture [6]. Biochemical metrics also tend to take two weeks in culture prior to demonstrating significances between culture parameters. For example, DNA content begins to differ after 7 days in culture and GAG synthesis begins to show significant differences after 14 days in culture [6]. Additionally, significant changes in *ACAN* and *COL1A1* are not generally observed until 14 days of culture [6-7].

We evaluated the biomechanical and biochemical response of chondrocyte-embedded type I collagen hydrogels after one bout of dynamic compressive loading. As expected, no significant effects are observed yet. Additional time points (3, 7, 14, and 21 days) are expected to yield significant differences of the aforementioned metrics. Future outputs will consist of metabolism-based assays to demonstrate cell viability over a longer period, immunofluorescent staining to highlight the location of ECM molecules, and additional probes specific to hyaluronan (i.e., *HAS*, *CEMIP*, *MMP*, and *HYAL* genes) to provide a fuller understanding of the effects of dynamic loading on HA and associated molecules in articular cartilage growth. Outlining the influence of dynamic loading on HA will be incredibly useful, as little is known about HA's mechanism of action in cartilage, despite gaining acceptance in treatment of cartilage-degenerating diseases [8].

INTRODUCTION

Cardiovascular diseases are a group of disorders of the heart and blood vessels and are a leading cause of morbidity and mortality¹. Abdominal Aortic Aneurysm (AAA) is the permanent dilation of the abdominal aorta that is caused by the local weakening of the arterial wall resulting from reoccurring inflammation processes caused by atherosclerosis² and the influence of hemodynamic forces. AAA is typically in fusiform shape and occurs mainly in the infrarenal aorta³ and when exceed 5.5 cm may lead to its rupture and a life-threatening internal bleeding with mortality of approximately 80%. If detected unruptured, patients are treated with either open surgery or endovascular aortic repairs, both comes with major post-operative complications. To date, there are no drug treatments that can inhibit AAA progression⁴.

Here, we study the deposition under physiological flow of particulate carriers coated with a collagen high affinity receptor, glycoprotein VI (GPVI), in *in vitro* models replicating mouse and human AAAs (see Figure 1 and Table 1).

Figure 1 - AAA models - human vs. mouse

	Human	Mouse
Parent Vessel Diameter [mm]	24	1.2
Flow Rate [ml/min]	1000	15
Reynolds number	100	300

Table 1 - Human vs. mouse AAA models properties

METHODS

We fabricated 2 μ m GPVI-coated polystyrene particle carriers and then tested their deposition in an *in vitro* real-size reconstructed mouse and human AAA models. STL files of the mouse and human models were acquired and converted from US or CT angiogram scans (see Figure 1), respectively. The STL files were altered to our needs in SOLIDWORKS and printed out in a 3D printer. The 3D printed models acted as a negative template and then silicone was poured and was allowed to solidify, see Figure 2 for mice AAA model and Figure 3 for the human AAA model. We then coated the models with a type I collagen and cultured endothelial cells (ECs) on their walls. The GPVI particles were then perfused in a closed-circuit perfusion system which mimicked physiological flow conditions (see Table 1). GPVI particle accumulation at the models was observed using fluorescent microscopy. In addition, we used computational fluid dynamics (CFD) simulations to obtain local flow characteristics such as streamlines and wall shear stress (WSS) maps to allow better understanding of the local flow patterns and their correlation with the particle adhesion in the experimental section.

Figure 2 - Fabrication of the *in vitro* real size mouse AAA model. (A) The STL mouse AAA model. (B) The CAD mouse AAA model. (C) The 3D printed mouse AAA model and (D) The ready to use transparent 3D mouse AAA model.

Figure 4 - 2 μ m GPVI-PS Particle deposition inside the collagen and EC coated mouse model. Particles are in red (B) and Blue is DAPI staining for ECs nuclei (C).

Figure 3 - *In vitro* human AAA fabrication process. (A) CAD model. (B) The 3D printed model and (C) The ready to use transparent 3D human AAA model.

RESULTS

In the mouse AAA model, the results show the enhanced accumulation of the 2 μ m GPVI particles at the collagen coated aneurysm (see Figure 4A&B), and almost no accumulation in the EC coated model (see Figure 4C). We further showed that the 2 μ m GPVI particles adhered at the collagen coated aneurysm region significantly more than the pre- and post-aneurysm regions as can be seen in Figure 4A. This is influenced by the low WSS and the recirculation zone at the aneurysm. However, preliminary results in the human AAA model show no significant difference in the accumulation of the 2 μ m GPVI particles at the aneurysm, pre- and post-aneurysm regions (see Figure 5). This is maybe influenced by the lower WSS levels in human circulation compared to mice throughout the human AAA model.

DISCUSSION

Our results suggest that GPVI particles can serve as drug carriers to target injured/inflamed collagen exposed AAA sites, however it is required to properly engineer the particle size and GPVI density on the surface of the particles in order to accommodate the WSS and the flow patterns in AAA as relevant to human AAAs and circulation.

COMPUTATIONAL STUDY OF ROLE OF ULTRA LARGE VON WILLEBRAND FACTOR IN COVID-19 RELATED THROMBOSIS

INTRODUCTION

The Coronavirus 2019 (COVID-19) pandemic has had a significant impact on global health, causing widespread illness and death. The effects of COVID-19 on the respiratory and vascular systems, specifically the occurrence of thromboembolism in patients, particularly those in the intensive care unit, are particularly concerning. The causes of thromboembolism are suggested to be related to hypoxia, severe inflammation, and immobilization [1]. The underlying mechanisms of thromboembolism in COVID-19 patients are by examining the role of released von Willebrand factor (VWF) multimers, from endothelial cell, which is activated by COVID-19 and facilitates to platelets and leukocyte adhesion to the vessel wall. Additionally, the moderate deficiency of the zinc-containing metalloprotease ADAMTS13, which is responsible for cleaving VWF multimers, in COVID-19 patients has been observed and it leads to the newly released ultra-large VWF (UL-VWF) multimers [2]. A computational model is used to investigate the underlying mechanism of the adhesion process between platelets and VWF multimers that leads to the onset and progression of thrombosis, and also examines the effects of this adhesion process on hemodynamics.

METHODS

In this study, the Lattice Boltzmann Method (LBM) was used to model the blood plasma flow as an alternative to directly solving the Navier-Stokes equations. The open-source LBM code Palabos (Ver 2.0r0) [3] was used to calculate the fluid velocity and density at each Eulerian node of the flow domain.

The goal of the study was to use LBM to provide a better understanding of the flow behavior in the cardiovascular system. Additionally, the coarse-grained spectrin link membrane method was used to model the deformable bodies (red blood cells, platelets, and von Willebrand factor strings) floating in the plasma flow. The method was implemented using the Hemocell open-source code (Ver 2.1) and discretized using triangular elements. The deformation of cells is governed by a set of reaction forces on the nodes of the discretized cell membrane, including stretching and compression, bending, local surface conservation, and volume conservation. The spring stiffness coefficients in these equations were already found and validated for red blood cells and platelets using optical tweezers experiments.

The LBM model of blood and spring-network models of deformable bodies were coupled using the immersed boundary method (IBM) implemented and validated in the Hemocell open-source framework (V2.1) [4]. It is used to model the interaction between the Lagrangian grid of cells and the Eulerian fluid grid, assuming no-slip condition at the solid-fluid interface.

Finally, an adhesive dynamics model, proposed by Hammer and Apte [5], was used to simulate the platelet-von Willebrand factor and von Willebrand factor-von Willebrand factor interactions. This model uses a spring-based model integrated with a probability distribution function that employs a stochastic Monte Carlo method. The adhesion force of the receptor-ligand bond is calculated using the spring model as well as the effective force. The study investigated the adhesion among von Willebrand factor strings, platelets, and endothelial cells.

RESULTS

In this study, we observed that platelets initially stick to stretched and uncleaved UL-VWF multimers that are anchored to the walls of small blood vessels (Figure 1-a). By the end of this initial adhesion phase, the UL-VWF multimers and platelets form a mesh-like structure that captures red blood cells, leading to the gradual formation of a microthrombosis (Figure 1-b). The blood flow near the inlet slows significantly during the initial adhesion phase (Figure 2-a), and since the fluid flow velocity within the microthrombosis drastically decreased, it increased around the microthrombosis due to mass conservation. In addition, RBCs are increasingly caught as the thrombus forms and grows. This leads to the development and thinning of a cell free layer (CFL; the plasma-rich near-wall region without RBC cells). The increased velocity variation within the CFL caused increased velocity variation within the CFL and enhanced the wall shear stress around the microthrombosis (Figure 2-b). This results in a pressure drop of up to 6 times that of normal conditions.

Figure 1: Process of UL-VWF-induced thrombus formation in COVID-19 patients. (a-b)

Figure 2: (a) The velocity profile near the microvessel inlet, (b) The total wall shear force (obtained by integration of the WSS magnitude over the entire microvessel surface).

DISCUSSION

Thrombotic complications are estimated to occur in over 30% of critically ill COVID-19 patients in the intensive care unit and 70 to 100% of patients who died from COVID-19 experienced deep venous thrombosis [6].

Our findings demonstrate that the presence of uncleaved UL-VWF tethered to the endothelium contributes to thrombus formation and coagulopathy in COVID-19. The underlying mechanisms responsible for this phenomenon have been quantitatively investigated.

Our results represent that platelets first adhere to unfolded and stretched uncleaved UL-VWF multimers tethered to the microvessel wall. By the end of this initial adhesion phase, the UL-VWF multimers and platelets make a mesh-like trap in which the red blood cells increasingly accumulate to initiate a gradually growing microthrombosis. During the initial adhesion phase, the blood velocity drastically drops, and the wall shear stress is elevated near UL-VWF roots on the wall, and the pressure drops from 1.5 to 6 times compared to no clot situation and healthy condition and at wall locations closest to the thrombosis. As time passes, these trends progressively continue until the microthrombosis is fully developed and the effective size of the microthrombosis as well as flow quantities remain almost constant. While, in a vessel with a constant diameter, the pressure drop in the Poiseuille flow is directly proportional to the average velocity at the vessel inlet, in presence of thrombosis, the situation becomes more complicated because the flow velocity, thrombosis size, and pressure drop all depend on one another.

INTRODUCTION

Type A aortic dissection (TAAD) is a lethal disease that, if untreated, has a mortality rate of approximately 1% per hour once aortic dissection has occurred [1]. Increased age, hypertension, smoking, and atherosclerosis could serve as independent predictors of acute TAAD. However, such demographic parameters lack precision and cannot predict when and where the dissection would occur in individual patients. Patients with thoracic aortic aneurysm can undergo elective surgical repair prior to a dissection or rupture. The current risk assessment involves evaluating the aortic diameter, using medical imaging techniques such as computed tomography (CT) or echocardiogram scans, where surgical repair is recommended if the ascending aortic diameter is greater than 5.5 cm. However, studies have shown that aortic size alone does not completely predict type A aortic dissections [2, 3]. As such, indices other than diameter are needed as criteria to predict where an aortic dissection or rupture is likely to occur. In this study, we hypothesize that stress concentration in the aortic wall may lead to TAAD, and stress analysis may be used to predict where TAAD occurs on the aortic wall.

METHODS

We performed engineering analysis on a rare dataset of retrospectively obtained pre-dissection (PreD) with corresponding post-dissection (PostD) and post-repair (PostR) computed tomography (CT) scans from the same 8 patients from the Yale New Haven Hospital database. Each PreD CT scan was performed as part of their care, as dictated by their treating physician, and not for reasons associated with this study.

To obtain the aorta geometry of each patient, the entire aortic root, ascending aorta, aortic arch, and descending aorta, including true lumen, false lumen, and dissection flaps for the PostD state, were manually segmented from the CT scans using 3D slicer. A geometric quad-mesh

was then generated from the segmentations using Hypermesh and offset to mimic the aortic wall.

To obtain the aortic wall stress distribution of each patient, finite element analysis (FEA) was applied using Abaqus. The thickness of the normal wall was assumed to be 2mm, and the thickness of the dissection wall was assumed to be half the normal thickness. Three different values for systolic pressures (16 kPa, 18 kPa, and 20 kPa) were used to simulate normal systolic blood pressure, hypertension stage 1, and hypertension stage 2, as defined by the American Heart Association. Based on the principle of static determinacy [4], given the blood pressure and geometry, the stress distribution of the aortic wall is insensitive to material properties. Thus, the wall stress distribution was obtained by assuming very stiff material properties. The wall stresses at preD, postD, and postR states were collected and analyzed.

RESULTS

To investigate the correlations between the aortic wall stresses and the location of dissection, finite element analysis was performed using the static determinacy principle. Patient-specific geometries in pre-dissection state were used, with systolic pressure of 16 kPa. The mean aortic wall stress in different regions were calculated and compared. It is found that the mean stresses in the ascending aorta (208.25 ± 36.25 kPa), including the aortic root (215.10 ± 44.92 kPa) and the aortic arch (198.43 ± 44.16 kPa), were significantly higher than that of the descending aorta (139.62 ± 17.69 kPa, $P < 0.001$). Moreover, stress concentration regions were defined as greater than 75th percentile peak stress in the aortic wall and identified. As shown in Figure 1, the identified high stress regions based on FEA calculations showed strong correlations with the actual dissection border of the patients at post-dissection stage.

In addition, a more comprehensive patient-specific FEA were performed for different states (PreD, PostD, and PostR), at different systolic pressures (16kPa, 18kPa, and 20kPa). The mean stress and peak

stress at different regions of the aorta were obtained and compared. Five different regions of aorta were identified, which are the root, the ascending aorta (AsA), the aortic arch, the proximal descending aorta (pDsA), and the distal descending aorta (dDsA). As shown in Figure 2 (a), mean stresses increased from PreD to PostD, and decreased after the surgical repair (PostR). The mean stresses at the root, ascending aorta and arch are typically larger than those at the descending aorta. The mean stress increased significantly in the root region from PreD to PostD states under all pressure conditions, which correlates well to the location of dissection. At pressure conditions of 16kPa and 20kPa, the mean stresses in the root decreased significantly after surgical repair. As shown in Figure 2 (b), the peak stresses showed similar trend. The peak stresses in the root, ascending aorta and arch were consistently higher than those in the descending aorta. At the root and ascending aorta regions, the peak stresses increased from PreD to PostD state, which was not significant. On the other hand, the peak stresses decreased significantly from PostD to PostR state.

DISCUSSION

With this dataset of retrospectively obtained PreD and corresponding PostD and PostR CT scans from the same patients, we were able to perform aortic wall stress finite element analysis and compare them between different regions and different states. Our results showed that the high stress region of the aorta in PreD state correlates well with the actual *in vivo* dissection location, which indicates that stress concentration in the aortic wall may serve as a good predictor of TAAD. The mean stresses at the root and ascending aorta increase significantly after dissection occurred and decreased significantly after the surgical repair. This suggests that the mean stress can be useful for the prediction of dissection events, and current treatment plan can effectively reduce the rupture risk of TAAD patients.

This preliminary study has several limitations, such as the uniform wall thickness assumption. These limitations will be resolved in our future work. For example, the wall thickness can be obtained by using both the contrast and non-contrast CT images: the inner wall will be revealed by the contrast CT image, and the outer wall will be revealed by the non-contrast CT image. Our future work also includes machine learning-based FEA [5,6] to facilitate a fast and accurate estimate of aortic wall stress and allow for patient-specific diagnosis and prediction of TAAD.

Figure 2: Maximum principal stresses at the root, the ascending aorta (AsA), the aortic arch (arch), the proximal descending aorta (pDsA), and the distal descending aorta (dDsA) at the pre-dissection (PreD), post-dissection (PostD), and post-repair (PostR) states. (a) Mean stress within each region, averaged among all patients; (b). Peak stress within each region, averaged among all patients. Three different values of systolic pressures were applied, which are 16 kPa (P16), 18 kPa (P18), and 20 kPa (P20). The * sign suggests significant differences.

SCAFFOLDED AND ITERATIVE COURSE DESIGN IN A BIOMECHANICS LABORATORY COURSE

S Bansal (1), J Benson (1), S Sullivan (1), and E Corbin (1)

(1) Department of Biomedical Engineering, University of Delaware, Newark, DE, USA

INTRODUCTION

Engineering mechanics, statics, dynamics, and biomechanics courses are prevalent in Biomedical Engineering curricula, and a course to this effect is a core/required class in many BME programs. One method to supplement and enhance student learning is to include a studio or laboratory class in conjunction with a traditional lecture course. The incorporation of team-based learning has shown positive impacts on student comprehension and belongingness [1]. The inclusion of a lab course also allows the teaching team to uniquely address ABET Student Outcomes 5 (an ability to function effectively on a team whose members together provide leadership, create a collaborative and inclusive environment, establish goals, plan tasks, and meet objectives) and 6 (an ability to develop and conduct appropriate experimentation, analyze and interpret data, and use engineering judgment to draw conclusions). These two outcomes are in addition to outcomes 1 (an ability to identify, formulate, and solve complex engineering problems by applying principles of engineering, science, and mathematics) and 7 (an ability to acquire and apply new knowledge as needed, using appropriate learning strategies), which can be assessed during a lecture-based Biomechanics course. Due to the positive impacts of lab-based courses on student learning, we at the University of Delaware have developed a Biomechanics Laboratory Course in parallel with the Biomechanics: Statics class taken by all 3rd year students in our department.

Students self-select into one of three sections (Monday, Wednesday, or Friday) to attend the Laboratory course, which comprises of three modules. Each module focuses on a core mechanics concept and includes hands-on experimentation and data collection, a MATLAB assignment, and a final Lab Report written in a one-page abstract format. Given the importance of computer science in engineering and the importance of strengthening and integrating skills between classes [2], the MATLAB assignments were modified to require students to write a script to analyze their data in addition to figure generation. These last two deliverables (MATLAB and Lab Report) are scaffolded such

that Lab 1 templates are ~85% filled out for students, Lab 2 is ~50% guided, and Lab 3 requires students to develop MATLAB code, figures, and an abstract with minimal instructor input. Grading rubrics are adjusted to reflect the amount of guidance given to students in each Lab Module. In this way, the course is highly scaffolded to allow for skill growth, confidence, and independence.

This course is iterated upon from year-to-year as driven by student feedback. For example, Fall 2022 saw a reorganization of the course schedule as requested by students from the Fall 2021 semester, and we plan adjustment for Fall 2023 given Fall 2022 feedback. In addition to yearly iteration, this course benefits from constant adjustment throughout the week. Indeed, after Monday's class, the teaching team adjusts materials and in-class assignments for implementation on Wednesday, and similarly tweaks material in advance of Friday's section as needed. It is yet to be determined if these sorts of micro-adjustments impact student comprehension and learning outcomes.

Therefore, the purpose of this study is to determine how semester-long scaffolding and weekly iteration impacts student outcomes, both through qualitative and quantitative assessments. Our hypothesis is that scaffolding increases student confidence with writing and coding, and that iteration within weeks (i.e. the difference between sections) has a positive effect on student learning.

METHODS

Student outcomes were measured at the end of the semester via assignment grades and collation of student course evaluations. To explore the impacts of scaffolding, student grades on specific assessments (MATLAB and reports) were compared across modules. To understand the impacts of iteration, course evaluations were analyzed. Evaluation questions of interest to this study included "*The lectures were well organized*", "*This course positively impacted my learning in Biomechanics – Statics*", and questions regarding knowledge of topics covered in this course at the start and end of the

semester. Through these questions, knowledge “growth” was calculated by subtracting the self-assessment at the start of the course from the self-assessment at the end of the course. Lastly, students were asked if they were aware of year-to-year iteration and if that iteration was deemed helpful to the course. One-way ANOVA and Tukey Post-Hoc tests were used to compare student evaluation and final score data across sections and assignment scores across Modules. In addition to these quantitative data, qualitative comments about the course were reviewed.

RESULTS

We saw no differences in final course grades between sections (M: 94.7 ± 3.3 , W: 95.7 ± 2.5 , F: 94.2 ± 2.8 , $p = 0.29$). Assignment grades were similar between Labs 1 and 2 (MATLAB, Lab 1: $49.2/50.0 \pm 1.4$, MATLAB, Lab 2: $48.6/50.0 \pm 2.5$, $p = 0.37$; Report, Lab 1: $90.8/100.0 \pm 5.3$, Report, Lab 2: $89.6/100.0 \pm 5.6$, $p = 0.50$). However, both assignments saw lower scores in Lab 3 (MATLAB, Lab 3: $45.6/50.0 \pm 1.4$, $p < 0.0002$; Report, Lab 3: $86.9/100.0 \pm 6.0$, $p < 0.03$), **Figure 1**.

Figure 1: MATLAB grades for all students during each Lab Module.

Student assessment of course organization (scale: 1 – 5, “hardly ever” – “almost always”) increased across sections (M: 4.0 ± 0.9 , W: 4.4 ± 0.6 , F: 4.8 ± 0.4 , $p = 0.003$) although post-hoc testing indicated differences between Monday and Friday sections ($p = 0.002$), only, **Figure 2**.

Figure 2: Student assessment of lecture organization by section.

Self-reported impacts of the laboratory course on lecture comprehension (scale: 1 – 5, “strongly disagree” – “strongly agree”) was similarly lowest in Monday’s section and highest in Friday’s section (M: 4.5 ± 0.8 , W: 4.9 ± 0.3 , F: 5.0 ± 0 , $p = 0.006$). Here, post-hoc tests indicate significant differences between Monday and the other two sections ($p < 0.04$), **Figure 3**.

Figure 3: Self-reported student assessment of how lab impacted understanding in lecture by section.

Knowledge growth was consistent across sections (M: 1.6 ± 1.1 , W: 1.5 ± 1.2 , F: 1.4 ± 0.9 , $p = 0.93$). Through all sections, 63.6% of students were aware of the year-to-year iteration of the course and 97.9% of students believe the course benefits from iteration.

DISCUSSION

The lack of differences in final grades between sections indicates that sections were comparable in student achievement. Interestingly, assignment grades across modules suggests that course scaffolding should be adjusted, perhaps by reducing Lab 2’s level of instructor involvement to better prepare students for Lab 3. Even so, students recognized scaffolding and appreciated it, stating, “*I like that [the instructors] eased us into writing an abstract*”, and they appreciated that the course emphasizes “*a few topics very thoroughly*.” In particular, we plan to scaffold the modified MATLAB assignments more deliberately for the Fall 2023 semester. This is in direct response to student feedback, which suggested that while these assignments helped students “*gain a lot of MATLAB skills through this course*”, more explanation and guidance would be helpful in the future.

Regarding iteration, students recognized the adjustments made from year-to-year and believed them to be positive. Impacts of mid-week adjustments were unclear, however. There was a modest increase in perceived lecture organization and impacts on lecture understanding across the week but no change in self-assessment of knowledge gain at the end of the course. These results are inconclusive, but do not indicate any negative repercussions to adjustment. These results also suggest that perhaps macro-scale, semester to semester adjustment is more impactful than mid-week adjustment.

Overall, this course was successful in supporting student learning goals. It helped students gain confidence and skills in MATLAB, writing, teamwork, power tool usage, and dissection. In addition, multiple students reported that the laboratory class “*helped my understanding of [Statics]*” and “*demanding students to be problem-solvers*”, giving students an opportunity to “*feel like a biomedical engineer*”. Going forward, this course will continue to involve assignment scaffolding, which will be adjusted in response to student feedback.

ACKNOWLEDGEMENTS

The authors acknowledge the course TAs for their help with the course.

TRIBOLOGICAL ASSESSMENT OF PVA HYDROGELS AS INTERPOSITIONAL IMPLANT MATERIALS IN THE TEMPOROMANDIBULAR JOINT

Kevin M. Labus (1), Jason P. Kuiper (1), Christian M. Puttlitz (1,2,3)

- (1) Department of Mechanical Engineering, Colorado State University, Fort Collins, CO, USA
(2) School of Biomedical Engineering, Colorado State University, CO, U.S.A

INTRODUCTION

The temporomandibular joint (TMJ) provides articulation between the mandible and cranium during chewing, communication, and clenching. The TMJ contains of an interpositional articular disc between the mandibular condyle and the fossa of the temporal bone. For advanced TMJ disorders that consist of displacement and degeneration of the articular disc, disc resection is the most common treatment. However, disc resection fails to reduce pain in approximately 25% of patients [1]. The disc plays a critical role in distributing stresses and preventing wear on the joint surfaces. Thus, removing the disc can further disrupt the joint and advance degeneration. Therefore, there is a need for interpositional implants to replace the function of the disc when disc resection is required. Towards this goal, we have characterized the mechanical behavior of the TMJ disc to guide the development of biomimetic materials [2] and identified poly-vinyl alcohol (PVA) hydrogel as an excellent material due its biocompatibility, low friction, and mechanical properties that can be tuned to match the properties of the native disc [3].

The purpose of this study was to assess the wear performance of PVA hydrogels under cyclic loading. We compared three PVA hydrogel variants. PVA hydrogels are traditionally synthesized by mixing PVA with water and applying freeze-thaw cycles. PVA hydrogels have also been synthesized using a dry-cast method without freeze-thaw cycles, and the resulting hydrogels have shown more regular microstructure and lower wear [4]. Additionally, PVA hydrogels may require reinforcement in order to achieve adequate tensile properties. Therefore, wear tests were used to compare freeze-thaw (FT) PVA hydrogels with dry-cast (DC) hydrogels and FT hydrogels with an embedded melt-extruded polypropylene scaffold (FT + scaffold).

METHODS

Three variants PVA hydrogels were synthesized, all with 25% polymer weight content. (1) Freeze-thaw (FT) gels were produced by

dissolving PVA powder in deionized water, pouring the solution in a mold between two glass slides, and applying 6 freeze-thaw cycles, creating an opaque gel. (2) freeze-thaw gels with embedded scaffolds (FT + scaffold) were produced by printing angle-ply polypropylene scaffolds via melt extrusion, embedding them in the PVA solution, and applying the identical freeze-thaw protocol. (3) Dry-cast (DC) gels were produced by dissolving PVA powder in DMSO solvent, pouring the solution in a mold between two glass slides, allowing the solution to dry for 5 days, then rehydrating and rinsing the gels in deionized water, creating a transparent gel.

TMJ fossa cartilage specimens were extracted from sheep euthanized for unrelated studies, potted in a two-part epoxy resin for clamping during wear tests, and frozen until used for testing. Wear tests were conducted by translating the cartilage in a reciprocal sliding motion relative to a stationary hydrogel sheet clamped to the base of a lubricating bath of artificial synovial fluid [5] (Figure 1). Contact area was measured via ink transfer from hydrogel to cartilage under 1 kg mass, and weights were used to apply a constant 100 kPa mean pressure, an estimate for average TMJ pressure during use [6]. Friction forces were measured via an offset torque cell. Three tests of each hydrogel variant were conducted to 100,000 cycles at 1.5 Hz and 8 mm sliding distance, and one DC hydrogel was tested to 1 million cycles. Following the tests, a stylus profilometer was used to measure wear area and surface roughness of the tested hydrogels, tested cartilage, and untested (naïve) hydrogel and cartilage surfaces. Three scans were measured per specimen in the direction across the wear tracks.

RESULTS

The FT hydrogels exhibited a rapid increase in coefficient of friction after about 10,000 cycles (Figure 2). The coefficient of friction also increased over time for the FT + scaffold, but was significantly less than the FT group at 100,000 cycles ($p = 0.04$). The coefficient of friction in the DC group remained steady throughout the tests, including

for the sample tested to 1 million cycles and was significantly less than the FT group at 100,000 cycles ($p = 0.01$).

Figure 1: Wear testing setup of ovine TMJ fossa cartilage (articular surface shown in inset) sliding against a hydrogel sheet in an artificial synovial fluid bath.

Profilometry results showed a 5-fold and 15-fold decrease in mean wear area for the FT + scaffold and DC hydrogels, respectively, compared to the FT hydrogels (Figure 3). Differences in post-test hydrogel surface roughness were not significant between hydrogel variants. Mean surface roughness of the naïve hydrogels was four times greater in the FT gels compared to the DC gels. No significant differences in surface roughness were observed on cartilage surfaces between hydrogel groups or untested control cartilage surfaces. Qualitatively, surface damage was not visually observed on the tested cartilage specimens, except for the specimen tested to 1 million cycles, which exhibited minor burnishing.

Figure 2: Coefficient of friction results for all specimens.

DISCUSSION

The friction and wear area results demonstrate that the DC PVA hydrogels exhibit greater wear resistance compared to FT PVA hydrogels of the same polymer concentration. This comparative result has been demonstrated previously [4], but the current study was novel in the assessment of PVA hydrogel wear in an environment targeted to the TMJ, including a TMJ-specific load magnitude, and sliding against TMJ cartilage, which consists of fibrocartilage that is structurally

distinct from the hyaline cartilage found in most articular joints. The lower surface roughness measured on the naïve DC gels compared to FT gels may partially explain the improved friction and wear properties.

Compared to the FT hydrogels alone, the embedded scaffold hydrogels resulted in decreased wear and lower friction over time. The scaffolds were not exposed to the tested surface, so the improved friction and wear were likely due to stiffening of the bulk construct properties which would decrease plowing effects. Combining the scaffold-hydrogel composite construct with a DC hydrogel may further improve tribological performance.

Study limitations included a relatively low sample size; however, some statistically significant results were still found. Also, tests were conducted to a fairly small number of cycles. The use of 100,000 cycles was chosen to provide a relatively rapid screening test for hydrogels while still obtaining measurable wear results. Future tests will use a greater number of cycles in order to better estimate the expected lifetime of materials for implantation in the TMJ joint. These results will guide the development of TMJ disc replacements to provide a new treatment option for TMJ disorders.

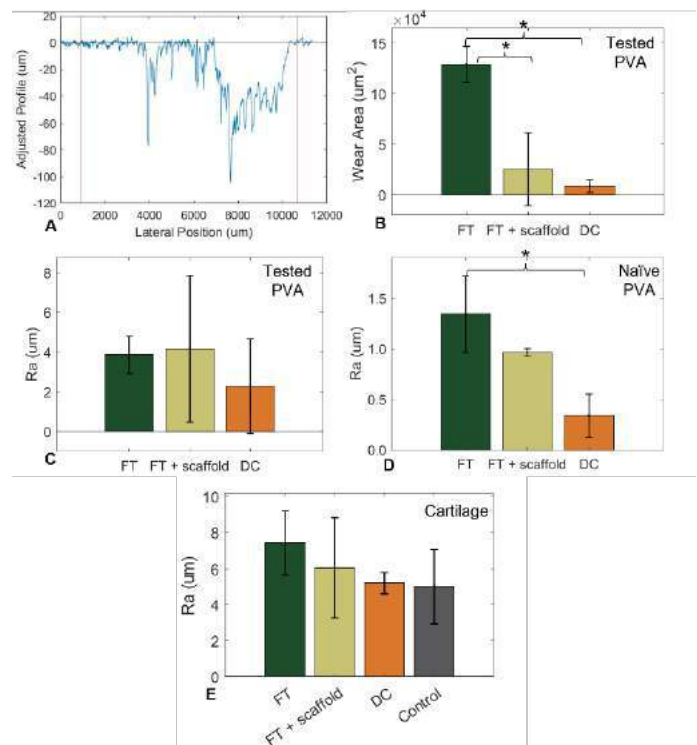

Figure 3: Profilometry results, including (A) example profile curve from a FT specimen, (B) hydrogel wear area, measured as the area above the profile curve, (C) average roughness of the tested hydrogels, and (D) average roughness of the naïve (untested) hydrogels, and (E) average roughness of the cartilage surfaces. Plots show mean \pm standard deviation. * represents $p < 0.05$ from one-way ANOVAs with Tukey post-hoc tests.

CORRELATING BALL DELIVERY PARAMETERS WITH HEAD IMPACT KINEMATICS FOR A COMMON SOCCER HEADING PROTOCOL IN BRAIN INJURY RESEARCH

Keili R. Shepherd (1), David Luke (1), Rebecca Kenny (2), Lyndia C. Wu (1,2)

- (1) Biomedical Engineering, University of British Columbia, Vancouver, BC, Canada
(2) Mechanical Engineering, University of British Columbia, Vancouver, BC, Canada

INTRODUCTION

There is growing concern that repetitive subconcussive soccer headers may cause long-term neurological deficit¹. Given this concern, many studies have investigated brain response (e.g. cognitive function, postural control and blood biomarkers)²⁻⁴ following a bout of controlled soccer headers. These studies often employ a heading protocol using standard sports ball launchers that enable a range of ball delivery speeds and angles. However, study protocols have been highly inconsistent, with ball speeds varying between 6 and 24 m/s⁷. This inconsistency may explain the largely conflicting results from literature, i.e., some studies found neurological changes after heading while others did not^{3,4,8-10}. Additionally, while sports head impact studies typically report head kinematics, as the motion of the head during an impact is deemed one of the most important indicators of brain injury risk¹¹, most controlled soccer heading studies only report ball delivery settings. Our objective is to investigate the influence of ball launch speed, angle, and participant height on ball impact speed and head impact kinematics through analytical modeling and human participant experiments. This information will not only help to standardize future study protocols, but also provide context to past soccer header study results and potentially explain the discrepancies in reported neurological effects of heading.

METHODS

ANALYTICAL MODEL: A 2D analytical model of the soccer ball trajectory in the sagittal plane was used to predict the speed and angle at which the soccer ball impacts the head (horizontal = 0°). Ball velocity was calculated using equation (1)

$$\vec{v}_i = \vec{v}_{i-1} + (\vec{a}_{di} + \vec{a}_g) \times \Delta t \quad (1)$$

where \vec{v}_{i-1} is the velocity of the previous time step, \vec{a}_{di} and \vec{a}_g are the components of acceleration from air drag and gravity, and Δt is the time step (0.001s). The acceleration component from drag was calculated using (2)

$$\vec{a}_{di} = -0.5\rho\vec{v}_i^2 C_D A / m \quad (2)$$

Where ρ is the density of air of 1.2 kgm^{-3} , C_D is the drag coefficient (0.3), A and m are the frontal area (0.0314 m^2) and mass of the soccer ball (0.4 kg), respectively. The inputs to the model were the initial ball speed, the initial launch angle, and the height at which the ball contacted the participant. We simulated three common initial angles of 40°, 45° and 50° and ball speeds between 6-24 m/s, and heights corresponding to those of a 5th and 50th percentile female, as well as a 50th and 95th percentile male¹². The analytical model predictions were verified through ball launching experiments, where ball speeds were determined through video analysis.

HUMAN PARTICIPANT SOCCER HEADING EXPERIMENT:

A ball delivery system (Pro Trainer Ball Machine) was used to deliver balls at initial angles of 45 and 50° and initial speeds between 7 and 13 m/s. Participant testing was done in an indoor, covered space to reduce the effects of wind and weather. Soccer balls were inflated to 0.7 atm. The participant was instructed to perform a standard frontal header (non-jumping) where the ball contacts the forehead. Headers were excluded if the head was rotating in the transvers plane, or if the ball hit the top or side of the head. GoPro cameras (2.7K Resolution, 60 FPS) were used to record each ball launch and verify head impacts. We calculated ball speeds from the experiments through video analysis. The human participant protocol was approved by the UBC Research Ethics Board (H21-00958).

HEAD KINEMATICS MEASUREMENT AND ANALYSIS:

One male participant, with a height of 188cm, was fitted with an athletic boil and bite mouthguard, to which a PCB 356A32 tri-axis accelerometer (2500Hz) and a DTS ARS3 tri-axis gyroscope (2500Hz) were secured via a custom acrylic bite bar. Accelerometer and gyroscope data were filtered using a 4th order lowpass Butterworth filter at 300 Hz and 256 Hz respectively¹³. Linear kinematics were transformed from the mouthguard to the head center of gravity.¹⁴ We

calculated peak linear acceleration (PLA), peak rotational velocity (PRV) and peak rotational acceleration (PRA) from each heading impact.

RESULTS

Figure 1A and 1B show the ball impact speed and angle predicted by the analytical model given varying launch speed, angle, and participant height. We show a reference line at 11.2 m/s, the ball launch speed most commonly used in past studies^{4,8}. In experimental testing, the initial speed of the ball was found to be correlated with dial setting ($r = 0.9612$) (Fig 1C). The average standard deviations of the initial and impact ball speeds for each dial setting were 0.43 m/s and 1.1 m/s. The predicted and measured impact speeds were linearly correlated with Pearson's correlation coefficient $r = 0.8963$ (Fig 1D) and Mean Absolute Error (MAE) of 0.4 m/s.

In the human participant experiment, soccer balls were launched at initial speeds between 7.25 and 12.6 m/s. Entering these velocities into the analytical model generated velocities at impact between 4.5 and 10.2 m/s. Kinematic parameters in the sagittal plane for all trials were plotted as a function of predicted impact speed and angle. A generalized linear model determined that PLA in the superior-inferior direction was linearly correlated with ball speed at time of head impact ($p < 0.05$). No other correlations were statistically significant (Fig 2).

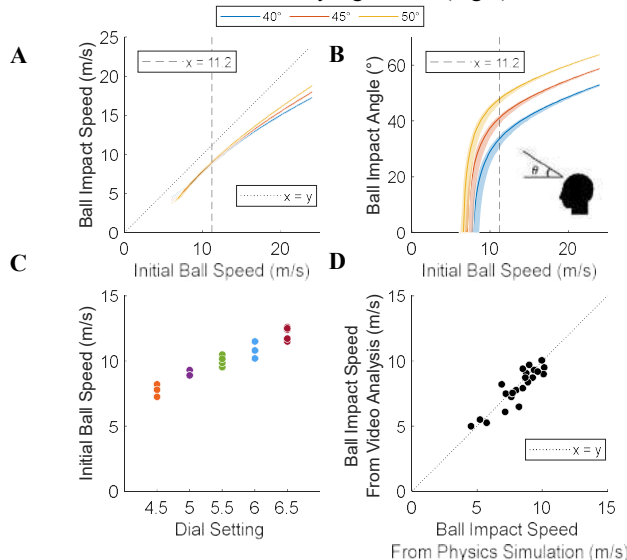

Figure 1: Predicted speed (A) and angle (B) of the soccer ball at the time of head impact for initial launch angles of 40°, 45°, and 50°. Upper and lower limits of shaded regions correspond to heights of a 95th percentile male and a 5th percentile female participant. Correlation between analytical and experimental impact speeds (C). Initial speed of balls launched at each dial setting on the ball delivery system (D).

DISCUSSION

Based on a simple analytical model of the soccer ball's projectile motion, the relationship between initial ball speed and impact speed is close to linear, especially in the range of 6–15 m/s initial speed. Further, the ball impact angle also increases with increasing launch speed. We found that the analytical model was fairly good at predicting impact speeds when compared to speeds determined experimentally ($r = 0.8963$). However, even in a highly controlled environment the initial launch speeds of the ball are variable. The variability is higher for ball speeds at impact, suggesting additional variance likely occurs due to factors such as spin and drag during flight. Also, while ball impact speed

is correlated with inferior-superior linear head acceleration, other components of kinematics are not significantly correlated with ball speed. We found high variability in head kinematics for the same ball launch setting, which may be attributed to subtle changes in the participant's stance and head/neck position. Based on our findings, both ball and head kinematics are variable, which may explain discrepancies in the reported neurological effects of heading. We recommend that future soccer heading protocols measure head kinematics, rather than rely on controlled launching parameters. In addition, future investigations of brain injury risk will also benefit from the design of more repeatable head impact experimental methodology.

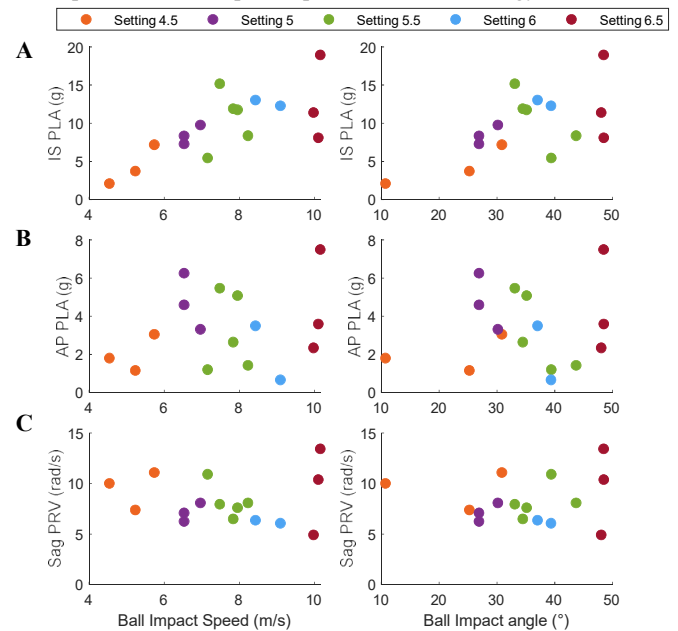

Figure 2: Kinematic parameters obtained from frontal headers as a function of soccer ball speed and angle at the time of head impact. A) PLA in the superior-inferior (Z) direction, B) PLA in the anterior-posterior (X) direction, and C) PRV in the sagittal (Y) plane.

CLUSTERED LOW SEVERITY IMPACTS MAY LEAD TO CONCUSSIONS

INTRODUCTION

While concussions were once thought to be caused by single severe impacts, there is growing evidence of repetitive head impact exposure being a predisposing factor. Athletes with a delayed onset of symptoms often have difficulty identifying a single impact that caused their concussion. Indeed, a higher frequency of sports impacts with higher kinematics in a single day have been more likely to lead to a concussion than a lower frequency of impacts with lower kinematics [1]. Furthermore, impacts closer together have resulted in prolonged recovery and higher brain physiology alterations in animal models [2]. A shorter time window between impacts has also been correlated with a higher risk of concussion in athletes [3, 4]. All the evidence suggests that we may have to consider the impact history, and not just a single impact, when identifying the input mechanism for a concussion. However, limited concussion data with impact exposure information are available to investigate the potential interaction between impact severity and timing in concussion risk, especially in female athletes. In the current study, we deployed instrumented mouthguard sensors to varsity women's rugby and men's hockey athletes. Our objective is to characterize head impact exposure on days of diagnosed concussions and examine the relationship between impact magnitude, timing, and injury occurrence.

METHODS

34 UBC Women's Rugby Team (Research Ethics Protocol H21-03824) and 35 UBC Men's Hockey Team (H21-00400) athletes were recruited to wear Prevent Biometrics mouthguard sensors [5] during one and two competitive seasons, respectively (Figure 1). Concussion diagnoses were made by team physicians following the Berlin consensus guidelines [6]. Only impacts captured by the mouthguards that passed a 5g head center-of-gravity (CG) linear acceleration threshold and verified with video review on the day of concussion were included for analysis. Head impacts that led to symptoms were

identified on video by the athletes who sustained the concussion. Impact kinematics were transformed to head CG and low-pass filtered using a 4th-order Butterworth filter at 200Hz. Peak linear acceleration (PLA) and peak angular acceleration (PAA) were computed for each head impact to characterize the impact severity.

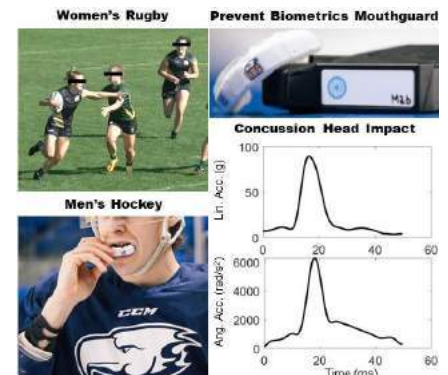

Figure 1: UBC women's rugby and men's hockey. Prevent Biometrics mouthguards capture head impact kinematics.

RESULTS

We collected data from seven women's rugby concussions over one season and four men's hockey concussions over two seasons. One women's rugby player (Athlete 6) and one men's hockey player (Athlete 3) each sustained two concussions within the same season. The number of impacts observed on the day of concussion ranged from 2-35 for women's rugby and from 2-7 for men's hockey. Women's rugby players identified between 1-7 impacts that occurred during play as symptom-inducing, while men's hockey players identified between 1-2. The time between the first and last head impact ranged from less than 1 second-67 minutes for women's rugby and from less than 1 second-114 minutes for men's hockey. The timing and peak linear/angular kinematics of impacts sustained by athletes on the day of their concussion are shown in Figure 2. The peak kinematics of impacts that led to symptoms ranged from 7-31 g and 569-6213 rad/sec² for women's rugby, and from 10-90 g and 459-6288 rad/sec² men's hockey athletes.

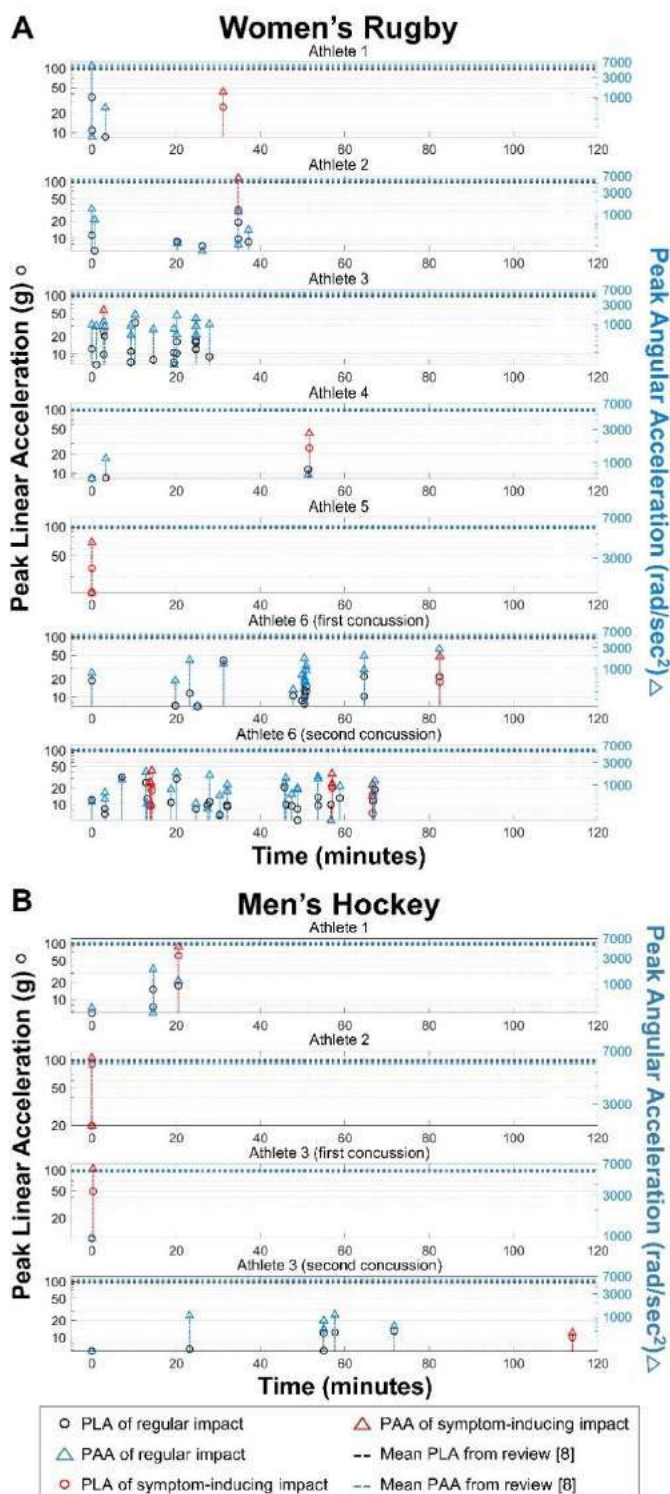

Figure 2: A) Women's rugby and B) men's hockey athletes' head impact exposure on the day of concussion. Black circles and blue triangles represent the peak linear acceleration (PLA) and peak angular accelerations (PAA) of impacts, respectively. Symptom-inducing impacts (red) are highlighted. Mean PLA and PAA for concussion impacts from literature [7] are shown for reference (dashed lines). Time zero is set at the time of the first impact.

DISCUSSION

Most impacts sustained by athletes on days of diagnosed concussions in the current study are mild (<30 g, <3000 rad/s²), including those identified by athletes to be symptom inducing, especially for women's rugby athletes and repeat concussions. In comparison, a 2017 systematic review on wearable head sensor-based concussion kinematics in male athletes reports a pooled mean (95% confidence interval) of 98.7 g (82.4-115.0 g) and 5576 rad/sec² (4584-6970 rad/sec²) [7], and a 2021 systematic review reports mean peak kinematics from concussive sports impacts ranging from 71-145 g and 3379-7951 rad/sec² [8]. Since prior studies mostly applied helmet-based sensors, which may overestimate impact kinematics, additional concussion data collected using mouthguard sensors [9] may help understand the discrepancies in impact kinematics levels.

The impact history, which includes both the number and timing of impacts, has been largely omitted when attempting to determine a kinematic threshold for concussion, but may explain the occurrence of concussion after low severity impacts in the current study. Impacts that were identified as symptom-inducing appear within 20 seconds of another impact in nine of the eleven exposure sets, with six sets having symptom-inducing impacts within 1 second of another impact. This suggests that the timing of these repetitive head impacts may be an integral part of concussion predisposition, and clusters of relatively mild impacts may also be symptom-inducing. Most injury criteria only consider impact severity, and not timing, of the impacts. One previously proposed criterion, Impact Density, considers the severity, timing between, and frequency of impacts [3]. However, Impact Density still relies on the assumption that a single impact can be identified as the concussive event, and only 19 impacts prior to this impact are included in the risk function. With these assumptions, Impact Density could not be calculated for all concussions from the current dataset. In several of our same-day exposure datasets, athletes experienced over 20 head impacts, continued to play after experiencing symptoms and were not able to identify a single event as the cause of the concussion.

In summary, our results demonstrate the possibility that clusters of mild sports head impacts may also be symptom-inducing and lead to concussion diagnoses. This mechanism seems to be at play for the women's rugby concussions and repeat concussions in our study, highlighting potential sex-based differences and increased vulnerability of athletes with recent prior concussions. As such, further development of injury criteria may need to account for this potential mechanism.

ACKNOWLEDGEMENTS

We would like to thank the Canadian Institutes of Health Research, Canada Foundation for Innovation and the Natural Sciences and Engineering Research Council of Canada for funding these ongoing studies. We would also like to thank the UBC Women's Rugby Team and UBC Men's Hockey Team coaches, staff, and players, Prevent Biometrics, and Susan Schmitz of UBC Dentistry for their support.

INTRODUCTION

The Abdominal Aortic Aneurysm (AAA) is an unphysiological localized enlargement of the abdominal aortic lumen. The pathogenesis of the AAA is modulated by a complex interplay between systemic, biological, and hemodynamic risk factors. Concerning hemodynamics, local blood flow disturbances have been linked to AAA evolution [1], because they might alter the transport of biochemicals and fluid-wall interactions which are involved in the progression of the disease. In this context, a plethora of hemodynamic quantities has been proposed over the years to provide potential indicators of flow disturbances in relation with aggravating biological events. However, the proposed hemodynamic quantities (1) often fail in describing/extracting fluid structures hidden in the arterial hemodynamic richness and (2) resulted only moderately associated with aneurysmal progression/rupture risk. These still unsatisfactory (both in terms of mechanistic comprehension and clinical translation) results suggest that the richness of fluid structures characterizing AAAs hemodynamics should be explored differently to identify more effective hemodynamic markers/predictor of disease. Starting from the observation that the presence of large-scale vortices with rich dynamics dominates the AAA hemodynamics, here we propose a quantitative analysis of the vorticity in AAAs based on the terms of vorticity transport equation. The final aims are (1) deciphering more clearly the intricate hemodynamics in AAAs, and (2) identifying vorticity-based quantities to be tested as biomechanical markers of the disease. The vortex structures analysis is carried out on patient-specific computational hemodynamics models of AAA characterized by a large anatomical inter-variability.

METHODS

Computational hemodynamics. The 3D geometry of eight AAAs was reconstructed from CT-scan data using the software PRAEVAorta (<https://www.nurea-soft.com>) [2]. The unsteady-state discretized Navier-Stokes equations were numerically solved using the

finite element-based open-source code SimVascular [3], prescribing a flow rate waveform available from literature [4] as inflow boundary condition.

Vorticity transport equation. The AAA velocity data from computational fluid dynamic simulations were used to compute the terms of the vorticity transport equation:

$$\frac{D \boldsymbol{\omega}}{Dt} = (\boldsymbol{\omega} \cdot \nabla) \mathbf{u} + \nu \Delta \boldsymbol{\omega} \quad (1)$$

where \mathbf{u} is the velocity, $\boldsymbol{\omega}$ is the vorticity and ν is the kinematic viscosity. The physical interpretation of eq. (1) is that the material derivative of the vorticity, describing the rate of change of vorticity of the moving fluid particles (left side term), is given by the contribution of a stretching term, quantifying the vortex deformation due to velocity gradients, and of a term quantifying vorticity diffusion due to viscosity (first and second term on the right side, respectively). We consider eq. (1) because vorticity typically develops in terms of vortex tubes which, transported by the local flow, are stretched, tilted, and disrupted in consequence of the local velocity gradients.

Vortex detection. The local vortex *swirling strength* and vortex core line (i.e., the vortex centerline) were adopted to visualize and reconstruct the vortex dynamics within AAAs. More in detail, the swirling strength of a vortex was quantified by computing the absolute value of the imaginary part of the complex eigenvalue of the velocity gradient tensor, while vortex core lines were identified applying the parallel vectors method proposed elsewhere [5].

Interaction of a vortex with the vascular wall. The analysis of the Wall Shear Stress (WSS) topological skeleton, which is composed by WSS critical points (where WSS vanishes) and critical lines (identifying WSS contraction/expansion action [6]), was carried out aiming at exploring how the near-wall vortex structures affect WSS topology on the AAA luminal surface. The WSS topological skeleton features were identified by applying a recently proposed Eulerian-based approach based on the divergence of the normalized WSS [6]:

$$DIV_{WSS} = \nabla \cdot \left(\frac{\tau}{\|\tau\|_2} \right) = \nabla \cdot (\tau_u) \quad (2)$$

where τ_u is the WSS unit vector. Technically, DIV_{WSS} negative values identify WSS contraction regions, while positive values identify WSS expansion regions.

RESULTS

Examples of volumetric maps of vortex stretching and diffusion terms (eq. (1)) are presented in Figure 1 for two explanatory models. The dynamics of the AAA volume-average values of vortex stretching and vortex diffusion (normalized in terms of min-max scaling) along the cardiac cycle are also presented (Figure 1). The two presented explanatory AAA models were selected because model AAAI is characterized by a marked expansion, while model AAAII presents a quasi-physiological blood flow canalization due to intraluminal thrombus formation. The inflow jet in AAAI rolls up into a well-defined vortex ring entering the expansion region due to the presence of the pressure-gradient mechanism. This large vortex ring undergoes stretching and tilting during the systolic deceleration phase (as confirmed by the second peak of vortex stretching time-history in Figure 1B) and dissipates in the AAA sac causing a stirring/mixing effect during diastole. Contrarily, in model AAAII vorticity transport is dictated mainly by the viscous diffusion mechanism.

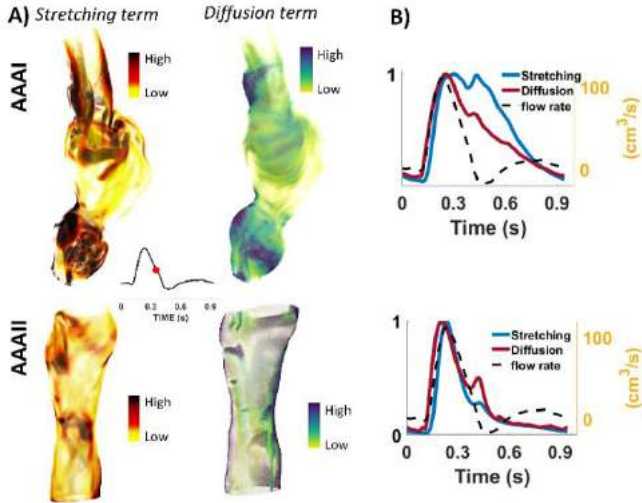

Figure 1: A) Instantaneous volumetric maps at mid-deceleration point and B) time-histories of volume-average values of the vorticity equation terms in two representative AAA models.

The evolution along the systolic deceleration phase of the vortex ring generated as a consequence of model AAAI expansion is analyzed in Figure 2A through the visualization of (1) instantaneous volumetric maps and (2) isosurfaces of the local swirling strength superimposed to the vortex core lines. Contrarily to model AAAI, due to the quasi-physiological geometry, the inflow jet does not roll up into a vortex ring in model AAAII (data not shown).

Finally, the WSS topological skeleton distribution on the luminal surface of AAAI and the sagittal section of velocity field at systolic peak are presented in Figure 2B (vortex core lines are plotted in black to highlight the presence of the vortex ring). It emerges that WSS topological skeleton features are the footprint of the interaction of vortex structures with the AAA wall, with WSS contraction and expansion regions (identified by negative and positive DIV_{WSS} values, respectively) identifying the boundary of the vortex ring on the luminal surface, highlighting flow separation and recirculation regions.

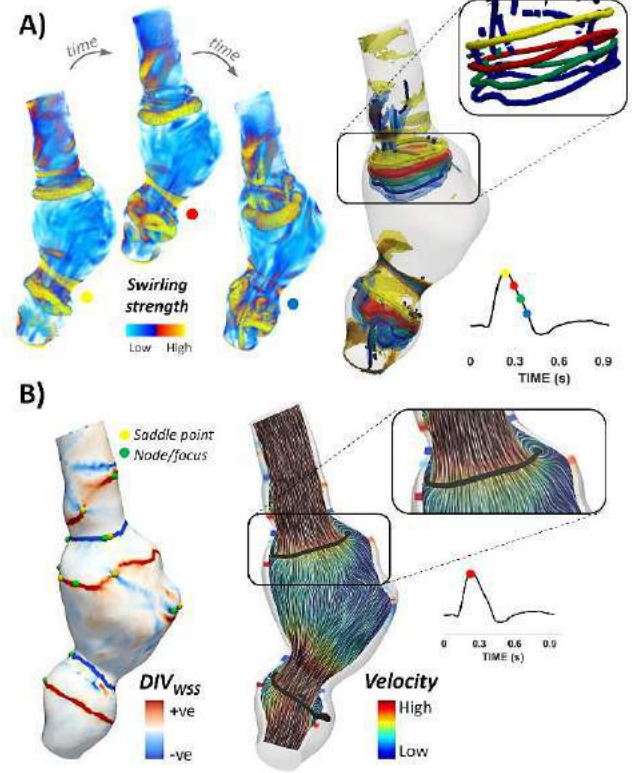

Figure 2: A) Volumetric maps and isosurfaces of the swirling strength and vortex core lines at different times along the cardiac cycle in AAAI. B) WSS topological skeleton and sagittal surface of velocity vector at the systolic peak in AAAI.

DISCUSSION

In this study a quantitative analysis of vorticity transport in computational hemodynamics models of AAA is performed, with the aim to decipher the AAA hemodynamic richness in AAA and the existing link between large-scale vorticity and WSS. A thorough characterization of vortex stretching/tilting and diffusion as well as vortex dynamics within AAAs may represent a useful approach for better elucidating the mechanistic link between organization of intravascular blood flow patterns, shape of the aneurysm, and clinical observations. This is particularly relevant because the transport of vortex structures is expected to be markedly involved in intraluminal thrombus formation, inflammatory mechanisms, as well as platelets dynamics, as it was suggested that platelets are ‘trapped’ inside vortices and when vortices break-up they release the activated platelets that aggregate and/or adhere to the wall [7]. In conclusion, the here vorticity transport-based quantitative analysis may contribute to a deeper understanding of the hemodynamics-driven processes underlying AAA progression, potentially improving risk assessment and the clinical management of AAA patients.

SENSITIVITY OF PLATELET ACTIVATION IN AN ECMO PUMP DUE TO DIFFERENT MODELLING APPROACHES

Francesco Fiusco (1), Lars Mikael Broman (2,3), Lisa Prahli Wittberg (1)

(1) FLOW, Dept. Engineering Mechanics, KTH Royal Institute of Technology, Stockholm, Sweden

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a life-saving therapy used in the critically ill to treat both heart and lung failure. The circuit comprises a membrane oxygenator with heat exchanger, a blood pump to drive the circuit, cannulae to drain and reinfuse the blood to/from the patient and tubing with connectors. Its use is associated with a number of complications, with thromboembolism and hemolytic damage being primary causes of morbidity and mortality by the treatment[1].

It is widely recognized that mechanical stresses play a role in platelet activation, which can be characterized by means of a platelet activation state (PAS)[2]. In this perspective, Computational Fluid Dynamics (CFD) can be a valuable tool to assess the effect of the flow structures on the thrombogenic properties of the various components in different scenarios. Besides assigning appropriate boundary conditions, modeling of these flows requires different assumptions regarding liquid properties or the way the different blood components respond to flow unsteadiness. This work focuses on how the forces considered in Newton's second law influence the particle (platelet) trajectory in a centrifugal blood pump flow. The purpose is to assess the sensitivity and potential effect on the simulation results.

METHODS

In this work, Lagrangian Particle Tracking (LPT) was used to inject 100'000 spherical particles (representing platelets) in an ECMO blood pump (geometry shown in Figure 1) and record their stress history. Thereafter, platelet activation was computed by considering the mechanical dose accumulated along each platelet pathline. The activation state was assessed according to the model by Nobili *et al.*[2]:

$$\frac{dPAS}{dt} = ca \|\tau(\mathbf{x}_i(t), t)\|^{b/a} \mathcal{D}(t)^{a-1} \quad (1)$$

where a, b, c are model constants. \mathcal{D} is the mechanical dose, function of shear stress history:

$$\mathcal{D}(t) = \mathcal{D}(t_0) + \int_{t_0}^t \|\tau(\mathbf{x}_i(t), t)\|^{b/a} dt \quad (2)$$

Figure 1: Geometry of the blood pump. Adapted from [3]

The LPT was carried out as a post-processing step on time-resolved 3D volume data produced using the commercial CFD package Star-CCM+, generated by solving the incompressible Navier-Stokes equations with a sliding-mesh approach. Blood was treated as a Newtonian fluid. According to Fuchs *et al.*[4] and Fiusco *et al.*[3], the particle inertia can as a first approximation be neglected, given the small size ($r = 1 \mu m$) and density of the platelets (similar to blood), i.e. Stokes number $< 2E-8$. Thus, the platelets can be considered as passive tracers following the flow, neglecting the forces acting on the platelets.

However, if considering particle inertia, Newton's second law needs to be used to computing the particle velocity:

$$m_p \frac{d\mathbf{v}_p}{dt} = \sum \mathbf{F}_i \quad (3)$$

where m_p represents the mass of the particle, v_p particle velocity and F_i are all the forces acting on the particles. In this work, the following two forces were considered:

- Drag force:

$$D = 6\pi r\mu(\mathbf{u} - \mathbf{v}_p) \quad (4)$$

where μ is the carrier phase viscosity and u is the fluid phase velocity at the particle center.

- Saffmann lift force:

$$L = 1.61d_p^2\sqrt{\rho_f\mu}\frac{(\mathbf{u} - \mathbf{v}_p) \times \boldsymbol{\omega}}{\sqrt{\omega}} \quad (5)$$

where ω is the vorticity of the carrier phase at the particle location.

The impact of these forces on particle trajectories and platelet activation will be studied.

RESULTS & DISCUSSION

In the case neglecting the forces acting on the particle, i.e. the tracer particle case, some typical pathlines are shown in Figure 2.

Figure 2: Typical platelet pathlines for the tracer case. Adapted from [3]

As depicted in Figure 2, a backflow phenomenon was observed at the inlet pipe[3]. The distribution of PAS values of the platelets, as illustrated in Figure 3, showed a peak of platelets with moderate PAS levels.

Figure 3: Distribution of platelet activation state (PAS) values for the injected platelets. Adapted from [3]

Given the characteristics of the flow, the question on which parameters play a role on blood damage arises. Thus, the aim of this work is to assess the influence of modelling techniques on the observed behavior of platelets and their activation. For that purpose, a similar analysis as for the tracer particles will be conducted on the case in which particles are subject to lift and drag force. Platelet activation models are usually power laws that are calibrated experimentally. In ECMO pumps the flow situation is such that the stress values fall outside the activation models' calibrated range. However, the models can be used comparatively providing valuable insights regarding the effects on different flow conditions and modelling approaches. In particular, the scope of this work is to assess the sensitivity of both quantities of clinical interest (such as overall levels of platelet activation and their distributions) as well as gain an improved fluid-dynamical understanding of the forces influencing the motion of blood components in a flow field characterized by highly unsteady turbulent behavior. Such knowledge will prove useful to improve the predictive modelling of particle tracking, e.g. to predict areas of high thrombogenic potential, as well as to characterize which phenomena need to be accounted for to correctly compute platelet (and other particles) trajectories.

INTRODUCTION

Computational fluid dynamics (CFD) is a widely used tool in research to improve the understanding of various cardiovascular diseases. Patient-specific blood flow simulations enable high-resolution visualization of key hemodynamic indicators, such as the wall shear stress. Fluid Structure Interaction (FSI) simulations consider the motion of the vessels, providing a more accurate solution for the blood velocity and pressure fields [1]. However, the computational cost of the standard ALE-FSI method is significantly higher than that of a rigid wall CFD simulation, making it infeasible for the clinical practice. To address this issue, the coupled momentum method for fluid-solid interaction problems (CMM-FSI) has been proposed [2]. In the CMM-FSI approach, the flow domain is kept fixed and the wall is treated as a linear elastic membrane, reducing computational cost while providing similar results when deformations are less than 10%. The aim of this work is to do a rigorous in-vitro validation of the coupled momentum using a flexible thoracic aortic phantom. A novel Hybrid Mock Circulatory Loop (HMCL) was used to replicate different physiological conditions in the flexible phantoms and the gathered experimental data were compared with the results of numerical simulations.

METHODS

A thoracic aortic model was manufactured with a photopolymerization 3D printer (J735 PolyJet, Stratasys) and the printing material was characterized via uniaxial tensile testing using four dumbbell shape samples. Each sample was loaded up to a strain of 0.4, repeating the cycle varying the strain rate from 0.01 to 0.3 s^{-1} . The aortic model was connected to a HMCL system, described in [3, 4] and shown schematically in Figure 1. A physiological flow rate was imposed at the inlet of model with a piston pump, and the outlets were connected to Hybrid-Units that regulate the pressure with a PID controller according to a 3-Element Windkessel model. The Windkessel parameters (proximal resistance R_p , distal resistance R_d , compliance C and ground pressure P_0) were tuned for each outlet to achieve a desired flow split and pressure range. A pressure range of 0-40 mmHg was reproduced. A camera system was synchronized with the piston pump to take images at 100 fps with a resolution of 24 px/mm. The obtained images were segmented, and the contours were extracted to track diameter variation during the cardiac cycle. The CMM-FSI simulation was set up with the CRIMSON software environment [5]. The measured experimental data were used to set boundary conditions; more specifically the same inlet flow rate and outlet pressures were prescribed. The Young's modulus assigned to the aortic phantom was obtained via a linearization of the stress strain curve. A rigid material was assigned to the adapters, whereas the piping to the Hybrid Units were modelled as additional resistors and inductors. Three cardiac cycles were simulated to achieve convergence.

Figure 3: Outlets flow rates. Comparison between the experimental data (HMCL) and the results of the numerical simulation (FSI).

Figure 4: Diameter variation at the aortic root. Comparison between the experimental data (HMCL) and the results of the numerical simulation (FSI).

RESULTS

The stress strain curve of the printing material for the different strain rates is shown in Figure 2. It is evident that the material exhibits a strain rate dependent behaviour. Consequently, evaluating the maximum loading rate of the phantom (Figure 4), we estimated the Young's modulus of 1 MPa, from the stress strain curve corresponding to a strain rate of 0.2 s^{-1} . This Young's modulus was then used for the numerical simulation. Figure 3 shows that there is a good agreement between the measured flow rates at the outlets and the results of the numerical simulation. Moreover, the difference between the sum of the outlets flow rates, and the inlet flow rate (labelled as sum Figure 3) indicates that the total volume variation of the phantom was well predicted. Analogously, the simulation successfully replicated the diameter variation at the middle section of the aortic root (Figure 4).

DISCUSSION

The presented experimental setup can be used to rigorously validate fluid-structure interaction simulation strategies. The obtained data were used to validate the coupled momentum method, as it is attractive due to its low computational cost, when compared to the standard ALE approach. Moreover, the coupled momentum method was previously validated in-vitro only using straight phantoms with only one outlet [6]. In our study we found that the experimental and numerical results were in good agreement, both in terms of flow rates and deformations. Nonetheless, a closer examination revealed some minor discrepancies. Specifically, the flow rate at the first epiaortic branch (Br_1) was overestimated between the systolic peak and the beginning of the diastolic phase. The diameter variation at the aortic root was instead underestimated. These discrepancies could be attributed to the fact that the wall is modelled as a linear elastic membrane, whereas the results of the uniaxial test indicate a strain rate dependent behaviour. In order to better investigate the effects of this approximation, as a future development it would be interesting to repeat the numerical simulation adopting an ALE approach using more realistic material properties.

INTRODUCTION

Directed migration of cancer cells in the tumor microenvironment is a critical step in tumorigenesis, local invasion, and metastasis [1, 2]. The tumor microenvironment imposes multiple, heterogeneous environmental cues on cancer cells [2, 3]. These cues include various chemokines or growth factors such as transforming growth factor- β (TGF- β) and epidermal growth factor (EGF) [4, 5], stiffness and microstructure of the extracellular matrix, and interstitial fluid flow [6-10]. Understanding the underlying mechanisms of directed migration has a profound impact on cancer biology as well as drug discovery to prevent and suppress cancer metastasis.

Because of its importance, the directed migration of cancer cells has been extensively studied [6, 7]. Many of these studies have focused on the relationship between a single environmental cue and corresponding signaling molecules and pathways of migration. Among the environmental cues, chemical cues are the most actively studied. These studies have led to the discovery of several key molecules of the cell. However, these reductionist approaches are not easily translatable to predict migration behavior within the complex tumor microenvironment.

In this study, we will provide our perspective of using a minimal systems approach to understand directed cell migration under complex environmental cues. We have been investigating cancer cell's migratory behaviors by approximating a cancer cell as a system of sub-cellular systems of sensing, signal processing, and actuator, as illustrated in **Figure 1**. We reverse-engineered cancer cell's migratory behavior to construct these sub-cellular systems. The underlying rationale is that directed migration may require sensing, polarization, and motility. A cell's ability to execute these interrelated aspects of directed migration determines its migration performance, including the accuracy, persistence, and speed of migration. Our systems approach enables understanding and prediction of how cells decode complex environmental cues during directed migration.

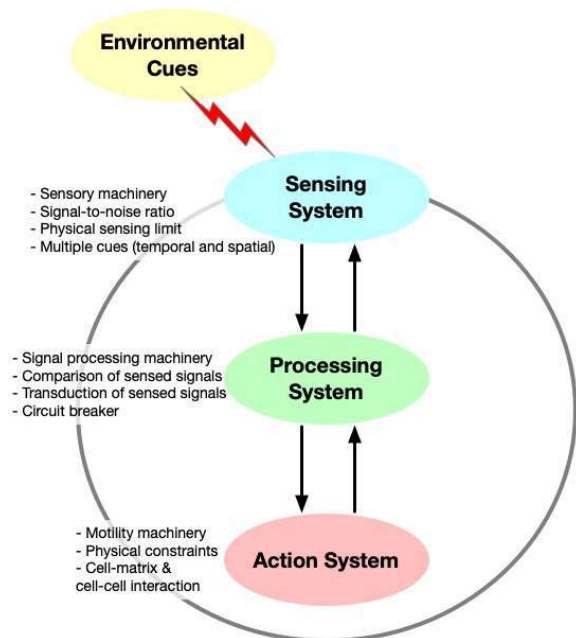

Figure 1: Systems approach to directed migration of cancer cells.

METHODS

We use a combination of experiment and theory to build a systems approach to directed cell migration, as illustrated in **Figure 2**. Experimentally, we employ microfluidic devices designed to subject cancer cells to multiple heterogeneous and simultaneous cues, including chemical gradients and fluid flow. Theoretically, we employ mathematical modeling and computational simulation to validate experimental results and make new predictions.

Figure 2: Joint experiment-theory approach employing microfluidics and microscopy, combined with mathematical modeling and simulation.

RESULTS

Several interesting results emerge from our approach when we consider the directed migration of cancer cells subjected to multiple cues. In one example [4], we present cells with two growth factor gradients, TGF- β and EGF. When each cue is presented individually, cells migrate up the gradient, resulting in a positive chemotactic index, CI (red and blue in Figure 3, left). When both cues are presented together, aligned in the same direction, cells no longer migrate up the gradients as strongly, resulting in a lower CI (purple in Figure 3, left). This counterintuitive behavior, known as antagonism, was successfully explained by a model in which the intracellular response pathway to each cue converges at a common point which then leads to migration. The convergence causes saturation of the signaling response when both cues are present. A mathematical model based on this concept successfully reproduced the experimental results (Figure 3, right).

Figure 3: Both experiments and theory exhibit antagonism: the migratory response of a cell to each chemical gradient individually (red, blue) is weaker than its response to both together (purple).

In a second example [8], we also present cells with two cues, but now the cues are of heterogeneous natures: a TGF- β gradient and fluid flow. The first result we find is that these two cues are intrinsically coupled, as the flow necessarily affects the shape of the TGF- β profile. The second result we find is that cells preferentially respond to the gradient over the flow. This is illustrated in Figure 4 (top left), where we see that in the cases where the two cues compete (upper right and lower left corners), the cells migrate in the direction of the TGF- β gradient, not the flow. In fact, as illustrated in Figure 4 (top right), these experimental results can be described by a ternary logic gate, where the three input states are the presence of a cue pointing right (+), pointing left (-), or absent. This logic implies a systems-level circuit that

describes the migratory behavior of the cell and can be used to make future predictions (Figure 4, bottom).

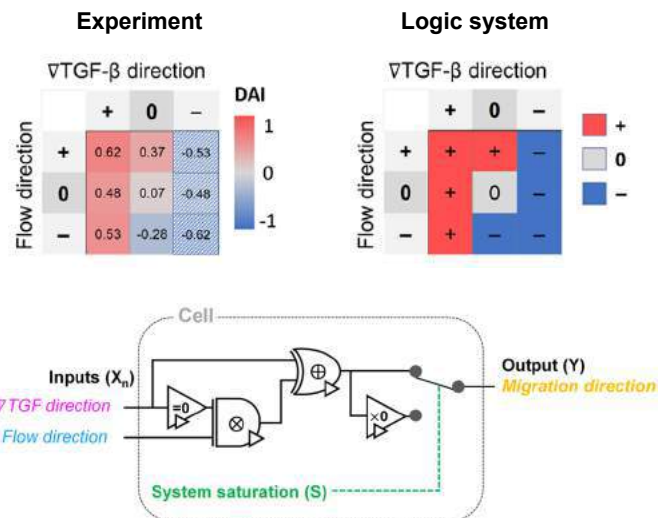

Figure 4: Cells migrate preferentially up a chemical gradient rather than up a fluid flow, and this can be described by a ternary logic gate.

DISCUSSION

Through this framework, we proposed the physical sensing limits, individual and collective sensing, a system capacity of the signal processing, and physical constraints of precision and persistence of cancer cell migrations. All these concepts not only supplement the existing molecular signaling pathways of cell migration but also provide new insights into how cancer cells sense, decode and determine migration direction. This approach and the resulting understanding may lay the groundwork for a unified framework to explain the migration of other cell types in the tumor microenvironment, including endothelial cells during angiogenesis and immune cells during anti-tumor immunity.

INTRODUCTION

Abdominal aortic aneurysms (AAA) affect 4-6% of the general population and are characterized by a rupture-prone inflated abdominal aorta. Despite decades of biomechanics research aimed at understanding the underlying disease pathophysiology and at identifying the most accurate predictor of rupture, current methods of clinical management of AAAs continue to focus on the maximum diameter threshold (5.5 or 5 cm for male or female patients respectively). Thus, it is crucial to replace clinically impractical techniques with routinely available ones in the AAA biomechanics evaluation protocol. In this study, we utilize the availability of functional ultrasound (US) images from AAA patients, and use it in combination with a modified virtual fields method (mVFM) [1] to estimate patient-specific material parameters. This is only possible due to the ability of 4D US to non-invasively assess AAA wall motion, which inherently contains information about its material behavior.

METHODS

US acquisition

AAA patients were imaged using a clinical US probe in a supine position to acquire 4D-US images at a frequency of 4-8Hz over multiple heartbeats. The image volumes were segmented at diastole and an in-house speckle-tracking algorithm [2] was used to track the inner wall and outer wall over the cardiac cycle. Point clouds generated from this process were fitted with B-spline grids at systolic and diastolic configurations. The two geometries were co-registered by minimizing the distance between neighboring knots in the two grids, and subsequently, the displacement fields of the inner wall and outer wall were generated. Displacement fields of the nodes in the bulk of the AAA wall were evaluated by interpolating between the displacement vectors of their neighbors located in the inner wall and outer wall. An unsupervised, discretized, spline smoother was used to smooth the 3D

deformation field and was post-processed before using it as a replacement for 3D full field deformation data. The overall schematic of the material estimation process is presented in Figure 2.

Figure 1a: Automatic segmentation of US images. b: illustration of 3D speckle tracking of the inner wall of AAA.

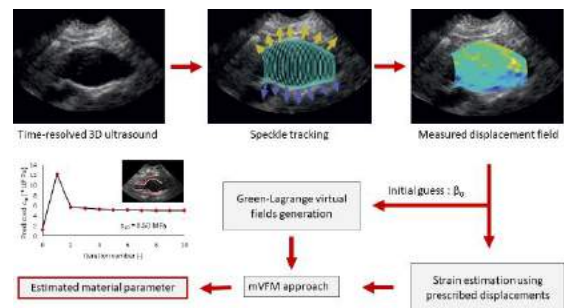

Figure 2: Overall schematic of the material parameter estimation method.

Modified virtual fields method

mVFM combines the strengths of two robust inverse methods – the finite-element model updating (FEMU) technique and the traditional virtual fields method (VFM). While FEMU's iterative nature and VFM's principle of virtual work-based cost function are integrated within mVFM, FEMU's high computational costs and VFM's difficulty in choosing an appropriate test function are both eliminated. Thus, mVFM is able to achieve quick convergence of a problem that is setup automatically.

Two different models of FEA were simulated to implement VFM:

- (1) Strains were evaluated in the current configuration, where the displacement vectors derived from US-based 3D tracking were prescribed to each node.
- (2) Virtual fields were derived automatically using a stressed intermediate configuration where an initial guess for the material parameter was provided. An intraluminal pressure load corresponding to the displacement field was applied, and displacements were prescribed in every boundary where traction was not known.

RESULTS

Using an uncoupled, Neo-Hookean material model with an initial guess of $c_{10}=1.2 \cdot 10^6$ Pa, the predicted material parameter values converged within three iterations when global patient-specific values of c_{10} were sought. Later, the mesh was divided into three regions based on location and presence of AAA as shown in Figure 3a. This led to ten iterations before convergence was achieved while predicting the material model parameters in all three regions.

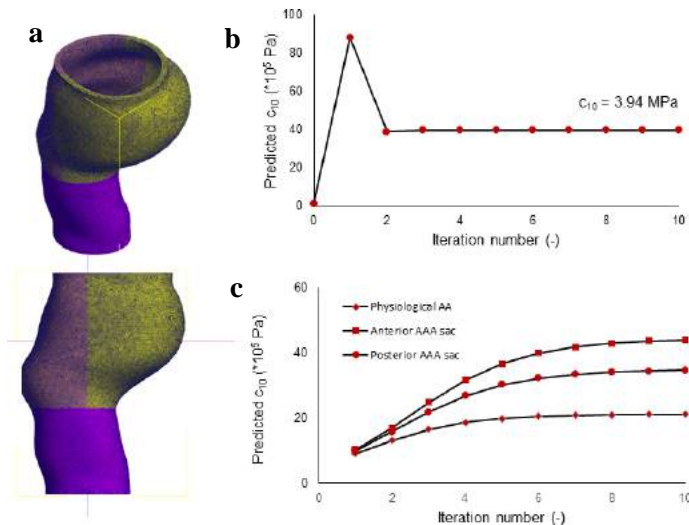

Figure 3a: AAA mesh showing physiological (purple), anterior AAA (yellow) and posterior AAA (orange) wall. Prediction of b: global and c: local values of material model parameters

DISCUSSION

We were able to demonstrate, for the first time, the feasibility of using an innovative combination of 4D US and mVFM to determine unknown constitutive material model parameters in different regions of the AAA. The deformation fields obtained from routine US images were

input into the modified VFM algorithm. FEMU has been previously used to evaluate Neo-Hookean material parameters using US images. However, about two weeks were needed to achieve convergence for one dataset while using a quad core CPU with 32GB RAM [3]. Using mVFM, we were able to achieve convergence within 3 hours while using a 6-core CPU with 16GB RAM. This drastic reduction in computational time suggests the immense potential of our new technique in in-vivo, patient-specific, material characterization, and demonstrates a high translational value.

While performing regional mechanical characterization, it was observed that the anterior AAA sac had a higher shear modulus when compared to that of the posterior AAA sac tissue. It was also seen that non-aneurysmatic abdominal aortic tissue had the least shear modulus when compared to its pathological counterparts. This observation is in line with other studies which investigated the effect of location on AAA tissue properties where anterior wall was found to be the stiffest, compared to the lateral and posterior wall tissue specimens [4].

One of the limitations of our method is the use of simple Neo-Hookean material model to characterize AAA tissue, while it has been proven to be anisotropic. As a next step, the use of more sophisticated material models and local material characterization within the mVFM framework will be evaluated. The latter requires more precise input data [5].

INTRODUCTION

Stroke is the second leading cause of death globally and resulted in over 6 million deaths in 2019 [1]. Acute ischemic strokes (AIS) are most commonly caused by embolic occlusions of a cerebral artery. Mechanical thrombectomy, whereby stent retriever devices are used to remove occluding clots, has revolutionized treatment of AIS [2,3]. However, while complete recanalization of the vessel is achieved in 85% of cases, 80% of AIS patients still suffer long-term disabilities [1]. Clot composition, specifically the red blood cell (RBC) and fibrin fiber content, has been shown to be a key determinant of the success of thrombectomy procedures [2,4,5]. Clot fracture and distal embolization during thrombectomy has been shown to be a significant risk for RBC-rich clots [1,5]. Clinically, fragmentation during thrombectomy leads to multiple clot-removal attempts (passes) and increases the risk of poor long-term patient outcomes [4].

Direct aspiration (DA) is emerging as a promising alternative to stent-retriever devices. In DA, an aspiration catheter is used to apply a negative suction pressure on the proximal end of the clot, with the aim to ingest the clot into the catheter [1,3,4]. Large-bore catheters have recently been developed with the aim of increasing DA efficacy [3,4,6]. However, the influence of catheter design on clinical outcomes, including clot fracture and distal embolization, has not fully been established [6].

In the current study we present the first analysis of the effect of DA catheter design on clot deformation and fracture. We develop a finite element (FE) framework to simulate the aspiration of red blood cell (RBC) -rich clots and fibrin-rich clots. We develop a novel anisotropic material model based on experimental mechanical testing of a range of clot compositions [5]. Our results demonstrate that the success of DA treatment of AIS is highly dependent on catheter diameter and clot composition.

METHODS

In order to develop the first customized FE model of DA, we consider the case of a cylindrical clot which is in direct contact with the catheter at its distal surface, as shown in Figure 1A. Based on a range of devices currently under development, we consider three catheter diameters, 1.2 mm, 1.62 mm and 2.5 mm, while assuming a clot diameter of 3 mm and length 10 mm, based on an M1 occlusion [7]. A negative suction pressure is applied to the clot surface inside the catheter. As the pressure is increased, the model simulates the deformation of the clot into the catheter which is characterized by the length of the aspirated section (u). The critical pressure is defined as the computed pressure required to fully ingest the clot into the catheter.

In order to simulate the clot material, we develop and implement a customized composition-dependent constitutive law [5,8,9] as a user defined material subroutine (UMAT) in the FE software Abaqus. In summary, this anisotropic hyperelastic material law considers non-linear volumetric and isochoric deformation of the RBC components of the clot, in addition to an anisotropic representation of the fibrin network. The volumetric stress is given as

$$\sigma_{vol} = \begin{cases} \kappa_1(J - 1), & |J - 1| \leq |D_{1v}| \\ p_v(J - 1)^2 + q_v(J - 1) + r_v, & |D_{1v}| < |J - 1| < |D_{2v}| \\ \kappa_2(J - 1 - D_{2v}) + (p_v D_{2v}^2 + q_v D_{2v} + r_v), & |J - 1| \geq |D_{2v}| \end{cases} \quad (1)$$

where κ_1 and κ_2 are the bulk moduli at low and high strains, respectively. The parameters p , q and r govern a strain stiffening transition region.

The principal isochoric stress components are given as

$$\bar{S}_i(\bar{\lambda}_i) = \quad (2)$$

$$\begin{cases} \frac{9\kappa_1 G_1}{3\kappa_1 + G_1} (\bar{\lambda}_i - 1), & |\bar{\lambda}_i - 1| \leq |D_{1m}| \\ p_m (\bar{\lambda}_i - 1)^2 + q_m (\bar{\lambda}_i - 1) + r_m, & |D_{1m}| < |\bar{\lambda}_i - 1| < |D_{2m}| \\ \frac{9\kappa_2 G_2}{3\kappa_2 + G_2} (\bar{\lambda}_i - 1 - D_{2m}) + (p_m D_{2m}^2 + q_m D_{2m} + r_m), & |\bar{\lambda}_i - 1| \geq |D_{2m}| \end{cases}$$

where G_1 and G_2 are the shear moduli at low and high strains, respectively. $\bar{\lambda}_i$ are the isochoric principal stretches.

The anisotropic stress tensor in the fibrin network is calculated as $\sigma_{\text{aniso}} = \sum_{i=4,6} \sigma_{fi} \mathbf{a}_i \otimes \mathbf{a}_i$, where the vector \mathbf{a}_i describes the deformed orientation of fiber i . The axial fibre stress is given as

$$\sigma_{fi} =$$

$$\begin{cases} E_{1f}(\lambda_{fi} - 1), & \lambda_{fi} - 1 \leq D_{1f} \\ p_f(\lambda_{fi} - 1)^2 + q_f(\lambda_{fi} - 1) + r_f, & D_{1f} < \lambda_{fi} - 1 < D_{2f} \\ E_{2f}(\lambda_{fi} - 1 - D_{2f}) + (p_f D_{2f}^2 + q_f D_{2f} + r_f), & \lambda_{fi} - 1 \geq D_{2f} \end{cases} \quad (3)$$

where E_{1f} and E_{2f} are the axial tangent moduli of a fibrin fiber at low and high strain, respectively. λ_{fi} is the stretch of fibre i . The total stress tensor is obtained assuming additive decomposition of the strain energy density function.

We first simulate fibrin-rich clots (5% hematocrit (H)) and RBC-rich clots (40% H), with parameter calibration based on experimental testing performed by our group [5]. We then perform a parametric study to investigate the influence of bulk moduli, shear moduli, and fibrin tangent moduli on DA outcomes.

RESULTS

Maximum principal stress distributions for a 1.2 mm catheter diameter are shown in Figure 1B. Computed values for the RBC-rich clot exceed the reported fracture strength for this composition (0.01 MPa [4]). In contrast, computed values for the fibrin-rich clot do not exceed the reported fracture strength (0.045 MPa [4]). This suggests a higher probability of fragmentation of RBC-rich clots during DA.

Our model predicts that RBC-rich clots are aspirated further into the catheter than the fibrin-rich clot at any given sub-critical pressure (Figure 1C). Furthermore, for a 1.2 mm catheter diameter, the critical pressure required to fully ingest RBC-rich clots (165 mmHg) is significantly lower than that for fibrin-rich clots (198 mmHg).

With regards to catheter design, our simulations reveal that the critical pressure required to fully ingest a clot increases as the catheter diameter decreases (Figure 1D). Fibrin-rich clots are fully ingested into the catheter at 198 mmHg, 60 mmHg, and 15 mmHg for catheter diameters of 1.2 mm, 1.62 mm, and 2.5 mm, respectively.

As shown in Figure 1E, a ten-fold increase in the bulk moduli (κ_1 and κ_2) prevents full ingestion of fibrin-rich clots into a 1.2 mm catheter, even when the maximum clinical pressure of 660 mmHg is applied. In contrast, ten-fold increases in shear moduli or in fibrin moduli do not prevent full ingestion of the clot. This suggests that clot compressibility is a key determinant of the success of a DA treatment.

DISCUSSION

Our study presents the first FE analysis of DA thrombectomy. Results reveal that higher aspiration pressures are required to fully ingest a fibrin-rich clot in comparison to a RBC-rich clot. This provides insight into the clinical observation that fibrin-rich clots have a higher probability of failing to be fully ingested during DA [10]. However, our models predict that RBC-rich clots are predicted to have a higher risk of fragmentation and distal embolization due a low fracture strength that is exceeded by the principal stresses in the clot. Clinical studies report that distal embolization presents a higher risk for RBC-rich clots during

stent retriever thrombectomy [5]. Our results suggest a high fragmentation risk will also be encountered during DA. Our investigation of the effect of DA catheter diameter supports suggestions that the use of a large bore catheters will increase the probability of full ingestion while reducing fracture risk [3]. Our finding that clot compressibility significantly influences the probability of full clot ingestion during DA has significant clinical implications. Clot compressibility is highly dependent on the level of contractility that is actively generated in platelets [8]. The use of agents to reduce platelet contractility could be considered as part of an optimized DA protocol. Future model developments will incorporate inelastic clot deformation in order to analyze the influence of dynamic applied pressure as a means of increasing the probability of full ingestion of fibrin-rich clots.

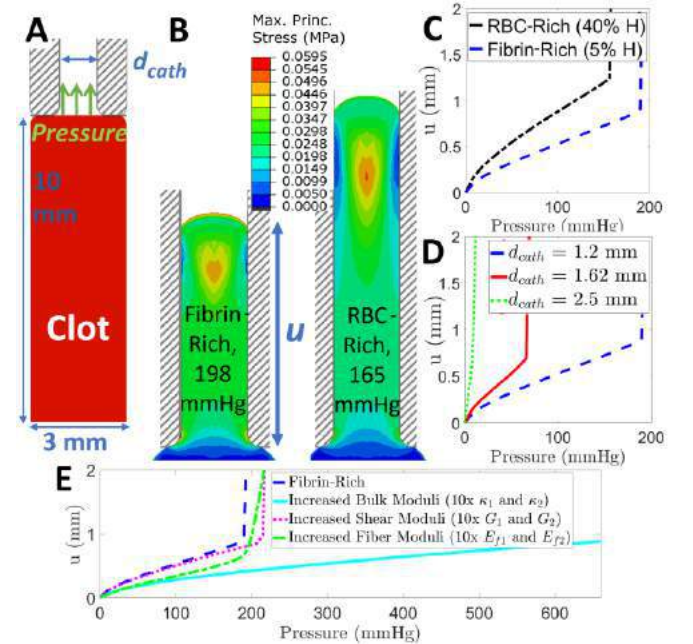

Figure 1: A) FE model of the clot and catheter with diameter d_{cath} . B) Deformation and distribution of maximum principal stress during DA for fibrin- and RBC-rich clots ($d_{\text{cath}} = 1.2$ mm). C) Aspiration length (u) as a function of applied pressure for fibrin-rich and RBC-rich clots. Initiation of full ingestion is characterized by a dramatic increase in slope at a critical applied pressure. D) Influence of catheter diameter on DA of a fibrin-rich clot. E) Parametric investigation on the effect of bulk, shear, and fibrin tangent moduli.

EFFECT OF GAGS ON TENSILE PROPERTIES OF PORCINE CORNEA

H. Hatami-Marbini (1)

(1) Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, IL USA
Email: hatami@uic.edu

INTRODUCTION

The cornea is the transparent protective layer of the eye protecting its delicate internal components while refracting incoming light such that it focuses on the retina in the back of the eye. The cornea is responsible for the majority of the eye's total focusing power; thus, distorted or blurred vision could occur when the corneal highly organized microstructure and composition get damaged. The corneal extracellular matrix, i.e., stroma, constitutes about 90% of its thickness and is responsible for its mechanical strength. The stroma primarily consists of collagen fibrils and proteoglycans (PGs). The collagen fibrils dominate biomechanical properties of the cornea in tension and PGs are responsible for corneal compressive properties. PGs are composed of a core protein covalently attached to glycosaminoglycan (GAG) side chains. PGs fill the space between collagen fibers and play an important role in the creation and maintenance of the precise organization and composition of collagen fibrils in the corneal stroma. The primary objective of the present study was to determine the effects of GAGs on the mechanical properties of the cornea.

There are different types of GAGs in the corneal stroma such as chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS). KS constitute the majority of the corneal GAGs [1] and its density is altered in different eye diseases. For example, KS GAG density decreases significantly in keratoconus. Furthermore, the cornea loses its mechanical strength in keratoconus [2]. Thus, it is important to determine the possible role that KS GAGs may have in resisting external forces that are applied to the corneal tissue. In the present research, we used keratanase II enzyme to remove KS GAGs enzymatically from porcine corneal samples. We then used uniaxial tensile experiments to determine the mechanical properties of GAG depleted corneal samples and quantified the effect of GAGs on the tensile response of the corneal tissue.

METHODS

Samples preparation. Fresh porcine eye globes were collected from a local abattoir and transported to the laboratory. After removing excess muscles and fat, we excised corneal rings with 2 mm sclera from eyeballs. The thickness of corneal rings was measured by an ultrasonic pachymeter (DGH Technology Inc., PA) and a custom-made double bladed device was used to cut corneal strips in the nasal temporal direction. For the mechanical experiments, the samples were divided into three groups, i.e., control (n=10), buffer (n=10), and enzyme (n=10). Eight additional samples were prepared in each group for GAG content quantification studies.

Enzyme and buffer treatment. 0.1 M sodium acetate buffer solution at pH = 6.0 was prepared. In order to remove KS GAGs (enzyme group), we placed corneal strips in the buffer solution with 0.1 U/ml keratanase II enzyme for 18 hours at 37 °C with gentle agitation. The samples in the buffer group were kept in the buffer solution without the enzyme for 18 hours. Furthermore, control samples were used after dissection.

GAG quantifications: The Blyscan assay (Biocolor Ltd., UK) was used to determine the GAG content of control, buffer treated, and enzyme treated samples. To this end, they were first dried in a desiccator and their dry weight was determined. Then, they were incubated in the buffer solution or enzyme solution for 18 hours and the Blyscan assay was used to determine their GAG content.

Mechanical tests: An RSA-G2 (TA Instruments, DE) tensile testing machine was used to determine the mechanical properties of corneal strips. For this purpose, corneal strips were mounted to the RSA-G2 machine and sandpaper was used at the grips to avoid any sliding. The thickness of corneal strips before the test was brought to 700 μ m to minimize possible hydration effects on tensile measurements [3,4]. A prestress $\sigma_{initial}$ was applied to the samples in order to straighten them and determine their initial length. The length of samples after applying the prestress was used to calculate the engineering strain. The

tensile strain of $\varepsilon = 20\%$ with a displacement rate of 2 mm/min was used to measure the tensile response of corneal strips.

Numerical Analysis: The experimental tensile stress-strain curves were represented using the following relation,

$$\sigma = A\varepsilon^B + \sigma_{initial}, \quad (1)$$

where σ is the tensile stress, A, and B are the unknown constants that were determined by fitting the above equation to the experimental stress-strain data.

Statistical Analysis: The experimental data were reported as mean \pm standard deviation and the analysis of variance (ANOVA) with $P = 0.05$ was done to determine any statistically significant difference between the measurements.

RESULTS

The GAG content studies showed that the GAG content of enzyme treated samples was significantly lower than that of the control and buffer treated specimens ($P < 0.05$). Furthermore, the numerical equation (1) represented the experimental strain-stress curves successfully. The dotted lines in Figure 1 show the numerical fits. The tensile response of control and buffer treated specimens was almost similar without any significant difference. However, GAG depletion caused a significant tensile property softening ($P < 0.05$).

Figure 1: Stress-strain curves obtained from the experimental measurements. The dotted lines represent the numerical fits and the symbols denote the experimental data. The enzyme treated had a significantly softer tensile mechanical response; however, no difference was observed in the tensile response of buffer treated and control samples.

DISCUSSION

The stroma is made up of collagen fibrils that are arranged in an approximate hexagonal packing arrangement. PGs fill the space between the collagen fibrils such that their GAG side chains interact with each other. GAGs are known to have significant role in collagen fibril assembly and their maintenance in a hexagonal lattice arrangement, which is required for corneal transparency [5]. However, there has not been any previous research in characterizing the role of GAGs in tensile properties of cornea. The present work removed KS GAGs from corneal strips and measured the effect of GAG depletion on mechanical properties of porcine cornea.

The tensile modulus of control samples from this study was in agreement with previous studies [6,7]. Figure 1 shows that GAG-depleted corneal strips became soft and their tensile stiffness decreased significantly. In particular, we found that the average maximum tensile stress of enzyme treated samples was 0.55 MPa, which was significantly less than that of the average maximum tensile stress of control samples. This significant reduction in tensile properties could be explained in

terms of a popular hypothesis that GAGs form bridges between collagen fibrils and behave as many tiny yardsticks holding them together, Figure 2. In particular, PGs attach to collagen fibrils by their core proteins while their GAG side chains form interfibrillar duplexes between neighboring collagen fibrils. The GAG quantification studies showed that enzyme treated samples had significantly less GAGs, which implies that the number of GAG bridges between collagen fibrils was significantly less in the enzyme treated samples. If we assume that corneal extracellular matrix behaves as a composite material composed of collagen fibrils that are placed in a PG matrix domain, the removal GAG weakened the matrix domain, which in turn caused the composite domain to show a softer mechanical response, Figure 2.

In conclusion, the present research determined for the first time the structural role of KS GAGs in tensile properties of porcine cornea. The findings are important as they could be used to relate the mechanical changes in disease such as keratoconus to the microstructural changes of the corneal tissue.

Figure 2: (a) A schematic showing the GAG duplexes exist between the collagen fibrils and b) some of them are removed because of enzymatic digestion of GAGs in GAG-depleted samples. This is hypothesized to be the reason why enzyme treated showed a softer tensile response compared to the control samples.

INTRODUCTION

The cornea is a collagen-rich connective tissue that transmits light and protects the inner parts of the eye. The cornea is composed of five distinct layers (from top to bottom), epithelium cells, Bowman's layer, stroma, Descemet's membrane, and endothelium. The stroma forms about 90% of the corneal thickness and is responsible for its mechanical properties. The composition and microstructure of stroma are necessary for the corneal function; any change to the highly ordered structure of the stroma could affect corneal shape and curvature, which are necessary for its transparency and refractive function. The corneal stroma is composed of many collagen fibrils with almost uniform diameter that are embedded in a matrix domain composed of small leucine-rich proteoglycans (PGs). Decorin and biglycan are the primary PGs in the corneal stroma. PGs consist of glycosaminoglycans (GAGs) that are attached to a core protein. Chondroitin sulfate, dermatan sulfate, and keratan sulfate are found in the stroma. PG core proteins are important for fibrillogenesis and its regulation. GAGs are negatively charged and attract water molecules inside the corneal ECM; thus, they play an important role in defining the hydration of the cornea [1]. Furthermore, GAG chains could form bridges between neighboring collagen fibrils and influence the mechanical properties of the cornea [2]. In a recent work, we have characterized the effect of GAGs on mechanical properties of the cornea by conducting uniaxial tensile tests [3]. The collagen fibrils are known to be the primary structural elements resisting tensile forces. However, because of the unique microstructure of collagen fibrils in the posterior regions of the cornea, it is expected that the PG matrix defines the shear properties. The primary objective of the present work was to characterize the effect of GAGs on shear properties of the cornea.

The microstructure and composition of the cornea is different through thickness, i.e. the collagen lamellae interweave in the anterior regions while they are parallel to each other in posterior part [4]. Thus,

although shear properties of the anterior region are a function of both collagen fibrils and PGs, GAGs are expected to have a significant role in defining the shear response of posterior layers. In this study, we prepared posterior flaps from porcine cornea and measured their shear response. Then, we used keratanase enzyme to remove GAGs from the posterior layers in order to determine the role of GAGs in defining the shear properties of cornea.

METHODS

Porcine eye globes were collected from a local slaughterhouse and were divided into two groups, control and enzyme. The eyeballs were used to prepare corneal rings from which we obtained posterior flaps. In particular, a DSAEK system was used to excise the anterior part of the cornea from the corneal rings. Then, a circular biopsy puncher was used to obtain 8 mm corneal disks from the remaining posterior region. A pachymeter (DGH Technology Inc., PA) was used to measure the thickness of all posterior disks.

Figure 1. The corneal samples were mounted in a rheometer. Then, an axial force was used to ensure full contact between corneal samples and upper geometry. The shear properties of control and enzyme treated corneal discs were measured as a function of applied compressive stress.

The GAGs were removed from the samples using the procedure that we used before [3]. For this purpose, corneal disks were allowed to complete dry in a desiccator and their dry weight was measured using a digital scale (Mettler Toledo, OH). The dried corneal disks were then immersed in a 0.1 M sodium acetate buffer solution containing 0.1 U/ml keratanase enzyme. The pH of the solution was 6.0 and the samples were kept inside the solution at 37 °C.

The shear response of control and enzyme depleted samples was determined using a rheometer (Discovery HR-2, DE), Figure 1. For this purpose, corneal disks were placed between two parallel surfaces of the machine. We used sandpaper in order to prevent slippage during the oscillatory shear tests. After mounting the samples, we brought down the upper geometry of the rheometer and ensured a full contact between its surface and corneal disks following the procedure that was described in our previous work [5-6]. Then, we used frequency sweep and shear sweep experiments to characterize their shear response. It is noted that in order to determine the shear response of the samples as a function of compressive force, we brought down the upper geometry incrementally and measured the shear response of the samples. The compressive stress was allowed to reach equilibrium between consecutive shear measurements.

RESULTS

The complex shear modulus was computed and plotted as a function of compressive stress in Figure 2. In agreement with previous studies [5], it is seen that the complex shear modulus of posterior flaps increased with increasing the compressive stress. The enzyme treatment significantly decreased the shear modulus of flaps ($P < 0.05$). The difference between the shear modulus of GAG depleted and control samples was dependent on the compressive stress and was reduced with increasing the compressive stress.

Figure 2. Complex shear modulus of porcine corneal flaps as a function of applied compressive stress. The vertical error bars indicate one standard deviation. A significant reduction of shear modulus was observed because of GAG depletion ($P < 0.05$).

DISCUSSION

The main objective of this study was to investigate the shear properties of enzyme-treated porcine corneal flaps. The shear moduli of both control and enzyme group samples changed nonlinearly with increasing compressive stress. The shear modulus of control samples was similar to porcine corneal shear modulus that was previously found [5-6]. The enzyme-treated flaps showed significantly less strength under shear deformation in comparison with the control flaps, Figure 2. The enzyme treatment reduced the GAG density in the enzyme treated samples; this was confirmed by performing histochemical analysis and immunochemistry (results not shown here). Thus, the number of GAG bridges between adjacent collagen fibril is expected to be less than the ones in the control samples, Figure 3.

Figure 3. Schematic plots describing the proposed explanation for the softening of shear properties of porcine cornea because of GAG removal. In corneal stroma, the PGs are attached to the collagen fibrils such that their side chains extends out. The GAG sides interact with each other and form structures that behave as tiny ropes attaching neighboring collagen fibrils together. The number of GAG bridges significantly reduces in (b) GAG depleted samples, which is why they showed a softer shear response in comparison to (a) control samples.

With increasing the compressive stress, the shear modulus of samples increased. This is because with increasing the compressive force, collagen fibrils became closer with each other and stronger GAG bridges form between the collagen fibrils. Although we successfully quantified the importance of GAGs in the corneal shear modulus, this study had a number of limitations. First, we did not consider the effect of the breed and age of the pigs. These factors may affect the density of GAGs in the porcine corneal samples and subsequently the mechanical measurements. However, the significant difference between the shear modulus of different sample groups suggest that these effects were not statistically important. Furthermore, because of the scarcity of human donor cornea, we used pig corneas to investigate the effects of GAGs on corneal shear response. In future studies, the human cornea can be used to make a comparison and quantify the similarities and differences between pig and human cornea after GAG removal. Despite these limitations, the present work characterized the effect of GAGs on the shear properties of the cornea as a function of compressive stress.

KINEMATIC DECOMPOSITION OF A LIVING OCTOPUS: APPLICATION TO SOFT ROBOTIC ASSISTIVE DEVICES

Garrett S. Weidig (1), Brittany Bush (1), Fermin Jimenez (1), Galit Pelled, Ph.D. (1),
Tamara Reid Bush, Ph.D. (1)

INTRODUCTION

Octopuses are capable of some of the most unique movements, including complex bending and twisting throughout the arm. Because of this, they have been great inspirers in the field of soft robotics [1]. Robotics applications range from grasping tools on assembly lines to being used as a wearable device. However, most existing devices are not able to mimic the full function that can be obtained with an octopus arm. Additionally, methods to quantify three-dimensional (3D) octopus movements (or similar robotic devices) do not exist.

Researchers have largely studied octopus arms and their ability to bend and twist, as those movements had the most influence on the overall posture of the arm [2, 3]. However, the technology and the methods used to capture and analyze these movements were not sophisticated enough to comprehensively define the posture of the arm in 3D. Instead, they focused on measuring movements that were simpler and had fewer degrees of freedom.

One of the simplified movements was bend propagation, where researchers observed bending to be approximately on one plane. Thus, all motion was attributed to either curvature (magnitude of bending toward the suckers) or twist (magnitude of the torsion of the arm). However, this neglected one of the most interesting capabilities of octopus arms: the ability to bend the arm in multiple directions, not just towards the suckers.

In scenarios of sufficiently complex octopus arm movements and in soft robotic applications, the current definitions for octopus movements are not comprehensive enough. There is a need for a new set of complex, kinematic octopus data along with new movement definitions that can better be applied to the octopus and the soft robotics for humans they may inspire. Thus, the goal of this work was to develop a set of methods to fully quantify the complex octopus arm movements, and compare them to results using previous mathematical definitions. In order to do this, 3D movements were collected on a living, swimming octopus.

METHODS

A four-camera underwater motion capture system was used to collect 3D movement data on one arm of a live octopus, species *Octopus bimaculoides*. Five retroreflective markers were adhered along the arm while the octopus was anesthetized in a small tank (Fig. 1a). Once the octopus woke up, it was placed in the larger tank with the motion capture cameras (Fig. 1b). Data were collected at a frame rate of 150 Hz and for as long as all five markers remained on the octopus' arm.

Figure 1. Reflective markers (a) attached to octopus arm while anesthetized and (b) on a free-swimming octopus.

For analysis, the arm was divided into a proximal segment consisting of the first three markers and a distal segment consisting of the last three markers (the segments shared the middle marker). Computations were then made on each segment to describe the overall 3D posture of the arm, which included both curvature and relative rotation between the two segments.

The magnitude of bending (curvature) on a segment was defined as the angle deviation from collinearity of the three markers. Thus, as the arm bent more, the greater the reported curvature for that segment.

The arm was also capable of twisting and ‘out of plane’ bending (bending of one segment on a different plane than another segment). Thus, it was necessary to define the plane on which each segment moved. This was called planar orientation and was done by creating separate, orthogonal local coordinate systems on the proximal and distal segments. Next, rigid body rotation angles (α , β , and γ) were used to measure differences in orientation between the two planes (Fig. 2a). Conceptually, α represented the amount of orientation change of the distal segment in the same plane as the proximal segment. β and γ represented the amount of orientation change of the distal segment in planes perpendicular to the proximal segment (either due to twisting or out-of-plane bending).

In previous studies, only one angle (θ) was used to define this out of plane movement and was attributed to twist only. Twist was measured by the angle between the two normal vectors of the two segments. This previous method was also used in this study to compare to the novel planar orientation method (Fig. 2b).

Figure 2. View of markers on octopus arm. (a) Local coordinate systems were created for both segments to determine the three angles of rotation (α , β , and γ) between the two segments. (b) Depiction of prior method used for computing twist in the literature, which is done using the angle (θ) between the two normal vectors on the proximal and distal planes which cannot capture complete 3D motions.

Two key postures were analyzed: simple bending and complex bending. Simple bending occurred when the proximal and distal curvatures were observationally on the same plane (e.g., θ , γ , $\beta \approx 0$ degrees). Complex bending was defined when the proximal and distal curvatures clearly occurred on different planes (e.g., θ , γ , $\beta \neq 0$ degrees). Analysis included computing curvature for the two segments, the angle of twist between the two segments, and the three planar rotation angles between the two segments.

RESULTS

The curvature, twist, and planar rotation angles for the two postures are reported below (Table 1). In the simple bending condition, the proximal and distal segments were curved 27 and 20 degrees, respectively. It was expected that, as reported in the literature, these curvatures occurred on near exact planes (θ , γ , $\beta \approx 0$ degrees) or any out of plane motion would be caused by twist (θ , γ , $\beta \neq 0$ degrees). These data showed that most of the movement of the distal plane occurred on a similar plane as the proximal one, indicated by the largest orientation value having been α . However, the 22 degrees of twisting alone was not comprehensive enough to describe the out of plane motion, since there

were non-zero values for both β and γ , meaning that reported twist (θ) likely had components of both twisting and out-of-plane bending.

Table 1. Analysis of two key postures. Curvature, planar rotation and twist angle results: simple and complex bending cases for a live, swimming octopus. Prior approaches using only θ are missing key pieces of information.

Posture	Prox. Curve	Dist. Curve	α (°)	β (°)	γ (°)	Twist θ (°)
Simple Bending	27	20	28	19	13	22
Complex Bending	33	12	-25	-11	-145	142

*negative sign is rotation in opposite direction based on right hand rule

In the complex bending condition, the bending on the proximal and distal planes were 33 and 12 degrees, respectively. Visually, these curvatures were clearly on two different planes, unlike the simple bending scenario. Using the method of twist in the literature, these planes were separated by 142 degrees. Mathematically, this meant that the two normal vectors were pointing in near-opposite directions. This level of twist at one location was not feasible. Instead, this was a result of the arm bending in more than one direction. Thus, it was clear that θ alone was not comprehensive enough to visualize posture in 3D and that all three orientation angles (α , β , and γ) were required.

DISCUSSION

To the authors’ knowledge, this was the first 3D, marker motion capture study completed with a living, swimming octopus. Two positions were analyzed from its motion: the simple bending condition, which was assumed in previous octopus studies, and a complex bending condition, which was new.

These postures are important and require the appropriate definitions because they are frequented by octopuses and potentially by the devices they inspire. Whether it will be for an orthosis, prosthetic, or on an assembly line, it would not be possible to comprehensively understand the overall posture of an octopus arm in 3D without these kinematic data and new definitions.

The biggest limitation to this study was the number of markers used. Because of the arm’s near infinite degrees of freedom, there was no number of markers that could be used to obtain the true overall posture of the octopus arm. Too many markers would be too heavy for the arm and prohibit movement. Thus, it would be difficult to speculate how many markers would be sufficient for a given arm length. For segmented soft robots with uniform curvature (where curvature values at each point along a given segment remained uniform throughout movement), it would be appropriate to have three markers per segment.

Whether it be an octopus arm grasping for food, or a soft robotic prosthetic being used to open a door, it is crucial to understand the 3D kinematics required for completing a task. In the future, the impact of these novel, kinematic analyses span across better understanding complex movements of the octopus, visualizing soft robotics in 3D, as well as streamlining communication between biologists, roboticists, biomechanists, clinicians, and those who would operate an octopus arm-inspired device.

ACTIVE MICROTISSUE ARRAYS FOR PROBING TISSUE RESPONSE TO DYNAMIC CONDITIONING

William P. Cortes (1), Kalyn R. Younger (2), Thao D. Nguyen (2), and Daniel H. Reich (1)

INTRODUCTION

The structure of soft collagenous tissues is highly dynamic and mechanoresponsive. Identifying how an applied load induces changes in tissue-level mechanical and structural properties remains challenging. Various active cellular processes occur concurrently with collagen deformation and reorganization in the extracellular matrix (ECM), and these processes and their interactions can depend on loading conditions [1]. Such structural changes in the ECM are widely relevant in physiological, pathological, and bioengineering contexts [1,2]. Thus, a more complete understanding of how loading directs the underlying processes of collagen growth and remodeling is important.

Disentangling the micromechanisms implicated in collagen growth and remodeling and their interactions calls for a versatile, high-throughput experimental platform. Previously, Reich and coworkers developed a magnetic microtissue tester (MMT) to probe the mechanical behavior of sub-millimeter cell/ECM constructs [3,4]. In this device, arrays of cell/ECM microtissues are suspended between pairs of flexible pillars, whose deflection reports the microtissues' contractile force. A magnetic bead affixed to one pillar for each microtissue enables actuation with a magnetic tweezer (Fig. 1A-C) allowing measurement of individual tissues' mechanical properties under dynamic loads. However, due to the construction of the magnetic actuation apparatus, these experiments were constrained to minutes to hours, which limits the ability to study collagen growth and remodeling. Here, we describe the integration of the MMT arrays with a system that provides long-term mechanical stretch of the entire array (Fig. 1D, E), enabling loading conditions compatible with studying growth and remodeling processes (Fig. 1F).

METHODS

MMT. MMT arrays are fabricated in polydimethylsiloxane (PDMS) and consist of over 100 400 μm x 800 μm wells, each containing two flexible posts. An individual microtissue is formed between the posts of each well and contractile forces exerted on the

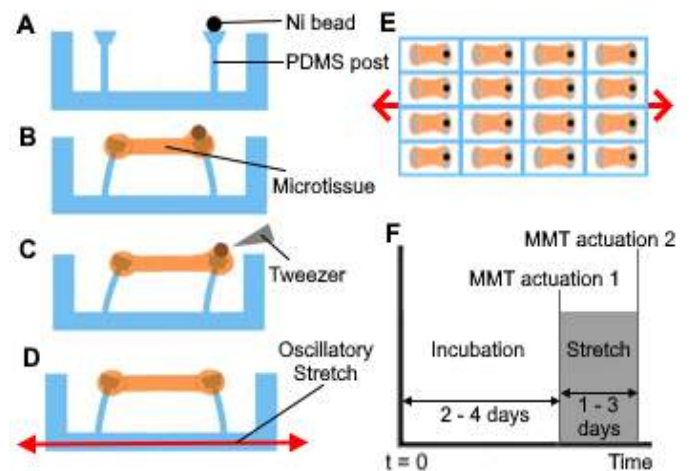

Figure 1. Scheme for long-term loading and mechanical characterization experiment. A) An empty MMT well is seeded with B) a cell-ECM microtissue and C) subjected to a magnetic field via tweezer. D&E) The entire membrane is then subjected to stretch over times much longer than the magnetic measurement. F) Time-course of experiment.

posts are determined from observations of the displacements of the pillar heads. Nickel beads (dia. $\sim 100 \mu\text{m}$) enable magnetic actuation.

Stretching apparatus. A commercial cell-stretcher (STREX 1400) was adapted for MMT arrays. The STREX stretching chambers are PDMS blocks with a 2 cm x 2 cm well with thin bottom membranes. Cells are cultured on this membrane, and the chamber is mounted between two plates, one of which is linearly actuated to produce stretch (Fig 2D). The unit is housed in a CO₂ incubator. Data are collected by unmounting the chamber and imaging the cells.

Figure 2. Fabrication of stretching chamber. A) Molds are 3D printed and B) combined with PDMS negatives (circled in red) to produce stretch chambers. C, D) Stretch chambers on the STREX at 0 and 0.16 strain. E, F) Portions of unstretched and stretched MMT array. Scale bar: 2 mm.

Fabrication. PDMS MMT negative molds were replica molded [5] and macroscopic chamber molds were produced via LCD resin 3D printing (Fig. 2A). Final chamber molds were constructed by mounting the negatives to the 3D print (Fig 2B). The final devices were cast in PDMS, yielding stretching chambers with comparable tolerances to the OEM devices, but with MMT elements patterned along the membrane. Fig. 2C, D shows an MMT chamber mounted on the STREX stretcher.

Microtissues. A mixture of Type I collagen ECM-analogue and adult human dermal fibroblasts (nHDFs) was centrifuged into the stretching chamber and incubated following previously described protocols [5]. The cells compacted the ECM, forming dog-boned shaped microtissues after 48 hours incubation.

Mechanical characterization. Microtissues were uniaxially strained by applying a triangular magnetic up-down ramp to the magnetic pillar. The tensile stress-strain relationship was determined by observing the pillar displacements and microtissue geometry via microscopy. Tissue elastic modulus was calculated over the initial 0 – 0.1 strain region of the stress-strain curve. Selected microtissues were probed for active recovery for 5 minutes after magnetic actuation.

Stretching protocol. Microtissue-seeded chambers were subjected to oscillatory stretch (0.1Hz 2-10%), for 24 hours after 48-hour microtissue formation. Tissue stiffness was measured by magnetic mechanical characterization before and after loading

RESULTS

The strain applied to the MMT arrays under stretch was characterized via videos of MMT chambers without microtissues subject to strains up to 0.16 (Fig. 2E, F). The well-to-well variation of the peak strain over the array was $< \pm 0.01$ as determined by measuring the displacement of embedded MMT well walls.

This work represents the first characterization of the active dynamics of nHDF microtissues under magnetic stretching in MMTs. The displacements of the pillars under magnetic stretching of such tissues are illustrated in Fig. 3A. An example of the stress and strain response to magnetic actuation is shown in Fig. 3B, along with the resulting stress-strain loop (Fig. 3C). The microtissue stiffness was comparable to other cell-ECM constructs studied on this platform [3,4]. The stress-strain curves displayed hysteresis during actuation arising from tissue viscoplasticity, followed by a longer-term recovery driven by active force generation of the cells in the tissue [3].

Initial stretching experiments up to 24 h duration have shown that the microtissues remain in good contact with the pillars, retain their characteristic morphology under low-frequency oscillatory strain (0.1Hz 2-10%), and are amenable to magnetically actuated mechanical characterization following loading (Fig. 4). Preliminary results are indicative of stiffness increases compared to unstretched controls.

Further studies of changes in ECM morphology will also be presented. We also note that results to date indicate strain-rate dependence in the dynamic response (Fig. 3C,4); these effects will also be discussed.

Figure 3. Magnetic actuation of microtissue is used to determine tissue mechanical properties. A) Pillar displacements used to extract mechanical properties. B) Current pulse applied to magnetic tweezer over 40 s. Shown below are the accompanying stress response and applied strain (Initial strain rate: 0.001/s). C) The resulting stress-strain curve (red) and linear fit (blue) over 0-0.01 strain yield an elastic modulus of 15 kPa. Scale bars: 200 μ m.

Figure 4. Stress-strain curves A) before and B) after 24 h stretch conditioning, with tissue images inset. The elastic modulus observed was 2.5 kPa and 3.2 kPa respectively (Initial strain rate: 4×10^{-4} /s). These measurements did not probe the active recovery phase. Scale bars in insets: 200 μ m.

DISCUSSION

Here, we describe the construction of an apparatus for applying long-term mechanical stimulation to a microtissue array model. At low oscillatory strain rates, MMTs were shown to be compatible with long-term conditioning via stretch. The fabrication process described can be used to integrate a variety of bio-MEMs architectures with long-term conditioning, and the compatibility of this platform with many standard cell culture assays allows for a wide range of experimental studies that can provide new input for the development of models that relate cellular function and ECM mechanics to the effects of applied loads.

EXPERIMENTAL STUDY OF FLOW-MEDIATED FIBRIN CLOT ACCUMULATION IN PROSTHETIC HEART VALVES

Yevgeniy Kreinin, Moran Levi, Yahel Talmon, Josué Sznitman, Netanel Korin

Department of Biomedical Engineering, Technion - IIT, Haifa, Israel

INTRODUCTION

Heart valve disease is a condition in which one or more of the heart's valves do not function properly. Heart valve replacement surgery has increased the survival rate and quality of life for patients with severe valvular disease. The most common valve to be replaced is the aortic valve, and there are two types of prosthetic heart valves (PHVs) used to replace it: mechanical heart valves (MHVs) and biological heart valves (BHVs) [1]. However, one of the known problems associated with aortic MHVs is valve thrombosis. This is linked to abnormal hemodynamics in MHVs, resulting in high shear stress around the device and low shear zones where clots accumulate [2].

In this study, an *in vitro* fibrin-clot model was developed to study thrombosis in MHVs under relevant hydrodynamic conditions while allowing real-time imaging. 3D-printed aortic valve models were inserted into a transparent glass aorta model and connected to a perfusion system. Fibrin clot formation was initiated via thrombin injection into a fibrinogen solution. Clot accumulation was quantified via image analysis and weight measurements. Results of valves positioned in a normal vs. a tilted configuration showed that clot accumulation correlated with areas of low shear, high residence time, and re-circulating flows, as observed by Computational Fluid Dynamic (CFD) simulations.

METHODS

In Vitro: We developed and built a closed-loop experimental system that enabled volumetric pulsatile flow at a physiological rate simulating an aortic artery flow profile as well as real-time monitoring of the pressures, controlled injection of thrombin, and timelapse imaging of the valves placed in a custom glass aorta model, see Figure 1. For the valve models, we 3D printed MHVs, using an SLA technology 3D printer (Elegoo Mars) and ABS-like resin. The 3D printed MHV and tilted MHV were positioned in the glass aorta model, see Figure 2. A fibrinogen solution was perfused in a

concentration of 0.3[mg/ml], and 1 ml of 31.6 [μ g/ml] thrombin was injected at 1 [ml/hour] rate into the system for clot formation. At the end of the experiments, the model was weighed in order to check the weight of the clots that accumulated on the valve. In addition, the images of the valve surface were analyzed by a custom Matlab® code to estimate the area covered with clots. A comparison was made between two types of implants, a normal implant, and an angled valve implant.

CFD: MHV and aortic root were modeled in SolidWorks®. The models were meshed in ANSYS GAMBIT 21 R1 and the simulations were conducted in ANSYS fluent 21 R1. The blood flow was simulated in a steady state using a Newtonian fluid and incompressible flow. The flow was assumed as laminar based on the clinical data reported by Yamaguchi and Parker [3]. We used a blood viscosity value of 3.5×10^{-3} and blood density of 1080 Kg/mm^3 . Flow path lines and Wall shear stresses were extracted from the simulations.

Figure 2: MHV models. (a) CAD illustration of regular orientated implantation of a MHV. (b) CAD illustration of angled-tilted implantation of a MHV. (c) Photo images of the 3D-printed valve in the transparent aorta model during an experiment.

RESULTS

First, as seen in Fig. 3A, under normal conditions clots accumulated in the sewing area around the valve as known to occur in patients [1]. A comparison of the results of clot accumulation between the two configurations revealed that a significantly lower number of clots settled on the angled-orientated valve as compared to the other configuration (Fig.3). Computational fluid dynamics (CFD) analysis, presented in Figure 4 has revealed that the sites of clot accumulation correspond to regions of low shear and stagnation within the flow field. The difference between the clot accumulation can be potentially explained by the CFD results, which indicate that the angled configuration is characterized by less recirculation and stagnation areas, as well as streamlines that suggest increased washing of the sewing areas (Fig.4c-f). Overall, these findings underscore the importance of considering the effects of implantation orientation on clot formation in the design and development of valvular prostheses.

DISCUSSION

The results of this study demonstrate the utility of an in-vitro experimental system for monitoring clot accumulation in prosthetic heart valves. The CFD results obtained in this study were found to match the coagulation zones observed in the *in vitro* experiments, providing validation for the use of this method. Notably, the CFD results also revealed that the valve implanted in a rotated manner had better washing around the valve, which was consistent with the results obtained in the *in vitro* experiments. This highlights the potential of this method to provide a better understanding of the clot accumulation processes in prosthetic heart valves as well as study new approaches to reduce thrombosis in MHVs.

EXCESSIVE SHEAR RATE, NOT SHEAR STRESS, IS RESPONSIBLE FOR CELL MECHANOLYSIS IN SMALL BORE NEEDLE INJECTIONS

INTRODUCTION

There are nearly 3000 ongoing cell therapy clinical trials for over 900 medical indications, and many involve cell injection through small-bore needles. A significant challenge for these therapies is that the passage from the syringe through the needle applies harsh mechanical conditions on the cells. Long term cell survival rates below 5% have been reported [1]. This means that to achieve clinical effectiveness, large volumes of cell suspensions must be injected, perhaps over the course of several extra treatments. Injections can be done very slowly to try to minimize mechanolysis, but this implies steady hands applying carefully controlled forces for perhaps tens of minutes.

There have been efforts to develop hydrogel-based suspension fluids in the hope that they increase survivability. These formulations have shown partial success [2, 3], but the experiments were not done under appropriately controlled conditions or with the requisite fluid mechanical analysis to determine the actual biomechanical conditions that cause cell deaths. Thus, the bioengineering challenge of designing injectors, suspension fluids and injection protocols has remained guesswork. Using a combination of fluid mechanical analysis of prior studies and targeted cell injection experiments, we demonstrate that the shear rate of a flow field is the most appropriate parameter that determines likelihood of cell survival in cylindrical tube flows.

METHODS

A simple, appropriate starting point for analysis of the flow of a cell suspension through a needle is a force balance of a fully developed flow (Figure 1). The force balance applies anywhere in the flow field up to the tube wall. Thus, shear stress is a linear function of radial position. Note that this applies regardless of the fluid properties.

Figure 1. Illustration of force balance for the fully developed flow of a fluid in a cylindrical tube. p = pressure, t = r - z component of shear stress tensor, r = radial coordinate, z = axial coordinate, L = axial length, i = inlet, o = outlet.

$$\tau = r \frac{p_i - p_o}{2L} \quad (1)$$

To obtain the velocity profile (and shear rate), one must specify fluid properties. For Newtonian fluids, the shear rate is proportional to shear stress, and thus also a linear function of radius. For shear-thinning fluids such as blood and most hydrogels, the velocity profile is blunted relative to the parabolic profile indicative of a Newtonian fluid. This gives a nonlinear shear rate profile that varies from a low value in the middle of the tube to a higher value at the wall.

This approach is sufficient for a proper interpretation of the results of Aguado et al. [2], who injected cells suspended in different fluids through small-bore needles. Key aspects of that study in this context include the fact that they used the same flow rate throughout, provided viscous properties of all fluids, and assessed variations in cell viability using a calcein-AM/ethidium homodimer-1 live/dead assay. Cell viability varied from 59% for PBS suspensions to 89% for a crosslinked alginate hydrogel. These data provide a basis for determining if cell viability is better correlated with shear stress or shear rate. A useful

concept for making this determination is the critical radius, r_c , defined as the radial position at which the shear stress or shear rate transitions from below a critical mechanolytic value to higher than the critical value. Cells located within $r < r_c$ are presumed to survive because both shear stress and shear rate increase monotonically with radial position.

We also performed a set of experiments in which Human Umbilical Vein Endothelial Cells (HUVECs) were suspended in Newtonian fluids of different viscosities and injected through small bore needles using a precision controlled syringe pump. Briefly, cells were suspended in room temperature PBS, 2.7% Dextran, 3.9% Dextran, 7.4% Dextran solutions (w/w) (Sigma-Aldrich), at concentrations of 5×10^6 cells/ml. 500 μ L samples of encapsulated cells were loaded into a 10ml glass syringe fitted 30G needles. The flow rate was adjusted to achieve the desired shear rate and shear stress profile combinations. Two sets of experiments were performed: one set in which wall shear stress varied but wall shear rate was held constant, and another in which shear rate varied but shear stress was held constant. Live/dead assays were performed as in Aguado et al. [2].

RESULTS

Analysis of the results of Aguado indicate that cell survival was actually higher when cells were subjected to higher shear stresses. A primary finding of theirs was that cells suspended in the alginate hydrogel showed a significantly higher survival rate than cells suspended in the much less viscous PBS. Because their experiments were done at a consistent flow rate, the pressure drop (and thus shear stress, see Equation 1) for the hydrogel experiments was some 2x the pressure drop in the PBS experiments, based on the rheological properties they reported.

Employing the critical radius concept, we backed out the critical values of both shear stress and shear rate from their various experiments, assuming that all cells within $r < r_c$ survived and all cells $r > r_c$ died. The results indicate that the critical shear stress amongst the experiments varied from 20 to 300 Pa, whereas the critical shear rate was consistently around 20,000 1/s (Figure 2).

Figure 2. Estimations of (a) critical shear rate, and (b) critical shear stress based on the experimental data of Aguado et al. [2], rheological properties of fluids used and the critical radius concept.

In our own experiments, we controlled for comparisons of the effects of shear rate and shear stress on cell viability. The results indicated a relationship between viability and wall shear rate in which the slope was negative (95% confidence interval). The slope of the relationship with shear stress could not be identified as positive or negative (Figure 3).

DISCUSSION

We sought to determine the most appropriate fluid mechanical criterion that determines mechanolysis of cells during injections through small-bore needles, as might occur during cell therapy administration or bioprinting. Previous studies have provided indications that viability rates do vary with injection rate and fluid composition, but their application to improving injection protocols has been impeded by the

Figure 3. Results from cell suspension needle injection experiments using Newtonian fluids of different viscosities. (a) Data from experiments in which shear stress was held constant and shear rate was varied, showing a relationship with a negative slope (95% CI). (b) Data from experiments in which shear rate was held constant and shear stress was varied, showing an indeterminate slope.

a priori assumption that shear stress is the relevant parameter. Based on previously reported experiments as well as our own, we conclude that excessive shear rate is the appropriate parameter. This information can be applied to designing syringes and injection protocols to minimize the number of cells subjected to these mechanolytic conditions. Note that it is likely that the critical shear rate depends on cell type.

The reason for shear rate being the appropriate criterion is that it represents the relative velocity at which adjacent fluid layers and suspended cells must slide past each other. Even if the cells do not contact each other, that process increases the cell membrane stress several fold, relative to the stress experienced by a single cell in the same shear field [4]. For shear thinning fluids such as alginate hydrogels, the shear rate near the middle of the tube is low due to the plug flow-like conditions and the cells do not have to slide past each other with such high relative velocities.

We have assumed that the fluid composition has no direct effect on cell viability, which is supported by our experimental data (not shown). In the analysis shown in Figure 1, we have assumed fully developed flow. Under most injection conditions, the entry length is a fraction of the needle length. Aguado et al. [2] did show that extensional normal viscous stresses can be high in this entry region, but that measure did not correlate with their viability results. We also note that the damage accumulated by cells during the injection process should not be considered a binary determination of live vs. dead. It is likely that some cells damaged during injection would still stain as “live” but fail to survive long term.

INTRODUCTION

It is well known that a prominent source of failure for small diameter vascular grafts is compliance mismatch between the native artery and the graft. Clinically used synthetic and autologous grafts tend to be overly stiff compared to the native vessel. This mismatch alters hemodynamic flow in the vessel and contributes to the development of intimal hyperplasia and eventual graft failure [1]. In 2021 there were an estimated 185,000 coronary artery bypass graft (CABG) procedures performed in the US alone [2]. These procedures still have up to a 40% failure rate depending on the graft used [1]. Therefore, this work aims to continue development of a tissue engineered vascular graft (TEVGs) that remains compliance matched throughout host integration.

The Soft Tissue Biomechanics Laboratory has previously developed a compliance matched vascular graft made from layers of electrospun polycaprolactone (PCL) and gelatin. These compliance matched grafts showed improved acute (<28 days) remodeling when compared to stiffer grafts [3]. However, insufficient vascular smooth muscle cell (VSMC) infiltration and degradation of the biopolymer causes the TEVG to become hypercompliant with long term remodeling.

Additionally, our lab has shown that TGFβ2 is a key regulator in VSMC fate. Low concentrations of TGFβ2 have been shown to increase VSMC infiltration into biopolymer grafts, whereas high concentrations of TGFβ2 have been shown to cause an increase in collagen deposition through cellular remodeling [4]. Ideally, TGFβ2 can be incorporated into a TEVG to both maximize initial VSMC infiltration and increase ECM synthesis as the biopolymer degrades to ultimately

minimize scaffold compliance loss. Therefore, the goal of this study is to fabricate Poly(lactic-co-glycolic) acid (PLGA) microparticles (MPs) that exhibit tunable delayed burst release of TGFβ2 and incorporate them into our compliance matched TEVGs.

METHODS

TGFβ2 MPs were fabricated using a water in oil in water (w/o/w) emulsion [5]. Briefly, lyophilized recombinant human TGFβ2 (Peprotech) was reconstituted and added to a PLGA and dichloromethane (DCM) solution. PLGA formulations used in this study can be seen in **Table 1** (Boehringer Ingelheim Chemical). Each formulation has a unique molecular weight and lactic acid to glycolic acid (LA:GA) ratio to alter release kinetics. The mixture was then sonicated to create the primary emulsion and homogenized in a polyvinyl alcohol (PVA) to create the secondary emulsion. Resulting MPs were washed, frozen in liquid nitrogen, and lyophilized.

Scanning electron microscopy (SEM) was used for surface characterization of MPs. To characterize release, MPs were submerged in phosphate buffer solution and bovine serum albumin and spun on a rotary mixer at 37°C for a total of 93 days. Releasate was collected and replenished every 24 hour for the first three days of release and then every three days for the remainder of the study. A TGFβ2 ELISA (R&D Systems) was used to assess protein loading and release.

Gelatin TEVGs were fabricated via electrospinning and MPs were included via electrospraying. The grafts were then genepin crosslinked and SEM was used to confirm successful inclusion of MPs.

RESULTS

The average loading of protein into the MPs can be seen in **Table 1**. All formulations were fabricated using 2.5ng of TGFβ2 and yielded approximately 100mg of MPs and had n = 3 samples.

Table 1: Microparticle formulations and loading.

Formulation	Molecular Weight	LA:GA Ratio	Loading (ng of TGFβ2/mg of MP)
RG503H	24 - 38 kDa	50:50	0.439±0.22
RG504H	38 - 54 kDa	50:50	0.059±0.01
RG653H	24 - 38 kDa	65:35	0.298±0.051
RG753H	24 - 38 kDa	75:25	0.113±0.011

All formulations displayed an initial burst release of TGFβ2 within the first 24 hours. The polymer with the most successful delayed burst release was RG753H which has the highest LA:GA ratio. Delayed release begins around day 60 and was maintained until day 87. These results can be seen in **Figure 1**.

Figure 1: Release profile of RG753H microparticles.

The other formulations displayed either complete burst release within the first 24 hours (RG504H) or constant sustained release over the 93 days (RG503H & RG653H). These release profiles can be seen in **Figure 2**.

Figure 2: Release profile of TGFβ2 containing microparticle

Electrospraying of MPs yielded a seemingly uniform distribution of particles throughout the scaffold. Successful inclusion of MPs into TEVG scaffolds can be seen in **Figure 3**.

Figure 3: SEM image of TEVG surface with MPs.

DISCUSSION

From our results we have shown that PLGA microparticles can successfully delay the burst release of TGFβ2 for over 50 days as well as create sustained protein release over 90 days depending on the polymer formulation chosen. This delay is sufficiently long to begin TGFβ2 release before scaffold degradation leads to a hypercompliant environment.

As expected, the formulation with the highest LA:GA ratio displayed delayed burst release. This has been demonstrated previously with MPs containing proteins such as BSA and melittin [6]. Surprisingly all other formulations had little to no delayed burst release. This could be due to electrostatic interactions between the polymer and the protein, degradation kinetics of the polymer, encapsulation efficiency, or a variety of other fabrication factors that need to be further studied.

Surprisingly the polymer with the highest molecular weight only demonstrated initial burst release. Usually, polymers made of larger molecules are expected to degrade at a slower rate. It is possible that release from these MPs was below the detection limit of the assay used due to the poor initial loading efficiency.

There were large variations in loading efficiency across the formulations. The encapsulation efficiency of a MP is highly dependent on the unique interaction of PLGA and the specific protein being loaded. Due to this, many studies showcase contradicting correlations between changes in LA:GA ratio and/or molecular weight with encapsulation efficiency [7].

As this work continues we hope to increase the efficiency of release to evaluate the release profiles of the MP containing grafts, evaluate VSMC migration and infiltration *in vitro*, and monitor graft remodeling within a small animal model.

ASSOCIATION OF HEMODYNAMIC FORCES WITH PATTERNS OF CORONARY ARTERY DISEASE AND ATHEROSCLEROTIC PLAQUE PHENOTYPES

INTRODUCTION

An elevated translesional pressure gradient is considered the main biomechanical hallmark of atherosclerotic coronary artery disease (CAD) [1], as it has been associated with plaque destabilization and adverse clinical events [1]. Measurement of the translesional pressure gradient is typically performed in the distal segment of the coronary artery and thus it reflects the cumulative pressure losses along the vessel length [2]. However, focal narrowing can be almost entirely responsible for the pressure loss. Nonetheless, diffuse pressure losses outside angiographic stenotic regions contribute to the total decrease in pressure. The assessment of pullback pressure measurements allows quantifying the distribution of pressure loss [2], promising standardization in the diagnosis of focal vs. diffuse CAD. Besides pressure gradients, wall shear stress (WSS) features are associated with plaque nucleation, progression and destabilization [3], potentially predicting adverse clinical events [4].

In this work, invasive pressure assessment, WSS profiles obtained from angiography-derived computational fluid dynamics (CFD) simulations, and atherosclerotic plaque phenotype characterization based on optical coherence tomography (OCT) were combined to uncover the links between focal vs. diffuse intracoronary pressure gradients, WSS and atherosclerotic plaque features.

METHODS

Study design. 105 vessels presenting with significant flow impairment by distal fractional flow reserve (FFR) ≤ 0.80 underwent assessment of intracoronary pressure gradient and angiography-based 3D reconstruction for WSS analysis. Of those vessels, 51 had OCT pullbacks. Study protocol was approved by local ethics committee.

Pressure pullback measurements. Motorized FFR pressure pullback tracings were acquired using a pullback device (Volcano R100, Volcano Corporation, USA) and used to obtain functional CAD descriptors. Technically, FFR was defined as the lowest ratio between

distal and proximal coronary pressures during hyperemia. An FFR value was extracted from the pressure tracing every 10 mm. The pullback pressure gradient (PPG) was calculated from the FFR pullback curves [2] according to the formula:

$$PPG = \frac{1}{2} \left[\frac{MaxPPG_{20mm}}{\Delta FFR_{vessel}} + \left(1 - \frac{L_{FD}}{L_{TOT}} \right) \right] \quad (1)$$

where $MaxPPG_{20mm}$ was defined as the maximum PPG over a 20 mm length; ΔFFR_{vessel} as the difference between FFR values obtained at the ostium of the vessel and at the most distal anatomical location; the length of functional disease L_{FD} as the length with FFR drop ≥ 0.0015 per mm; the total vessel length L_{TOT} was derived from the motorized pullback pressure tracing. PPG is a non-dimensional continuous quantity, ranging from 0 (diffuse CAD) to 1 (focal CAD) [2].

Quantitative coronary angiography (QCA). Vessel geometries were reconstructed based on 3D QCA from vessel ostium to pressure sensor position, using two end-diastolic frames at least 30° apart (CAAS Workstation WSS software, Pie Medical Imaging, the Netherlands). The lesion was characterized by the percentage area stenosis (%AS) and defined as the coronary segment including the minimum lumen area, delimited proximally and distally by the intersection of the QCA vessel diameter function line with the interpolated reference line (Fig. 1). Within the lesion, the mid lesion segment was delimited on the QCA diameter function line using the 60% relative severity of the minimum lumen diameter as threshold value (Fig. 1).

OCT. Plaque composition analysis [5] was performed acquiring OCT pullbacks of 75 mm length, using Dragonfly OPTIS Imaging Catheter (Abbott Vascular, USA).

Computational hemodynamics. CFD simulations were carried out on the reconstructed 3D vessel geometries using a finite element-based code (CAAS Workstation WSS software, Pie Medical Imaging). In addition to the time-average WSS (TAWSS), the variability of the WSS

contraction/expansion action along the cardiac cycle was quantified by the topological shear variation index (TSVI) [4,6]:

$$TSVI = \left\{ \frac{1}{T} \int_0^T [DIV_w - \overline{DIV_w}]^2 dt \right\}^{1/2} \tag{2}$$

where DIV_w is the divergence of the normalized WSS vector field [4] and T is the duration of the cardiac cycle. On each model, TAWSS and TSVI values were averaged over the mid segment of the lesion.

Statistical analysis. The median PPG value was used to define groups with focal or diffuse disease. The Chi-squared test was used for comparing categorical variables, the Student’s t test (or Mann-Whitney test as appropriate) for continuous ones. Generalized linear models were used to perform regression analyses on continuous OCT variables and PPG- or WSS-based quantities. Logistic generalized linear model was used in case of categorical OCT variables. Odd ratios (OR) per unit increase in the independent variable were obtained from the exponential of the standardized correlation coefficients. A p-value < 0.050 was considered significant.

Figure 1: Anatomical definition of the mid lesion segment.

RESULTS

Focal lesions (PPG above the median value of 0.67) had significantly lower FFR, higher %AS, and higher TAWSS and TSVI (Table 1). Both TAWSS and TSVI were associated with PPG (Fig. 2). The association between TSVI and PPG was retained after adjustment for the %AS. OCT-based plaque characteristics of 51 vessels are reported in Table 2. Thin cap fibroatheroma (TCFA) and plaque rupture were more prevalent among focal lesions. PPG was associated with the presence of TCFA (OR 2.85, p=0.029) and plaque rupture (OR 4.94, p=0.002). TAWSS was associated with the presence of macrophages (OR 1.15, p=0.018). TSVI was associated with plaque rupture (OR 1.01, p=0.024) and the presence of cholesterol crystals (OR 1.01, p=0.041).

DISCUSSION

The findings of this study, summarized in Fig. 3, support the hypotheses that: (i) the hemodynamic profile, identified by pressure gradients and WSS-based quantities, is different in patients presenting with focal and diffuse CAD; (ii) the different hemodynamic profile characterizing focal vs. diffuse CAD is associated with different atherosclerotic plaque phenotype; (iii) focal CAD and elevated TAWSS and TSVI are associated with high risk plaque phenotypes at the OCT evaluation; (iv) TAWSS and TSVI represent different hemodynamic cues, as they are associated with different plaque features. Taken together, these findings point towards a synergistic role of pressure gradients and adverse WSS features in the destabilization mechanisms of lesions presenting a focal pressure drop pattern. Thus, the analysis of pressure gradients and WSS profiles appears promising in augmenting diagnosis, risk assessment, stratification, and tailoring preventive therapeutic strategies for CAD patients.

INTRODUCTION

Hemolysis is the damage to red blood cells that causes the release of hemoglobin into the plasma. Mechanical hemolysis may occur in blood-contacting medical devices when the red blood cells are exposed to a high level of flow-induced stress for a prolonged time. Historically, the hemolytic potential of a medical device was assessed experimentally. Over the last decade, computational fluid dynamics (CFD) has become more and more used for predicting mechanical hemolysis. The most popular hemolysis model is the stress-based hemolysis model [1], which correlates empirically the release of hemoglobin from red blood cells (RBCs) to the exposure time (t_{exp}) and intensity of fluid-induced shear stress (σ_{shear}):

$$H = Ct_{exp}^a \sigma_{shear}^b \quad (1)$$

H is the relative fraction of plasma-free hemoglobin to the total blood hemoglobin; C , a , and b are coefficients traditionally obtained by statistical regression of data from simplified experiments in Couette-type blood shearing devices where the red blood cells are typically subjected to a uniform-shear laminar flow for a well-defined exposure time [2]. Even though these simplified experiments depart significantly from the working conditions in which real medical devices operate (i.e. turbulence, non-uniform shear stress, highly variable exposure time), such *idealized* coefficients are more than often used to perform numerical hemolysis predictions. As a result, absolute hemolysis predictions using idealized coefficients for the power law model are traditionally inaccurate.

Craven *et al.* [3] developed a novel approach for calibrating the coefficients of the power law model in a real medical device to potentially improve the accuracy of absolute hemolysis predictions. The approach consisted in combining a CFD-based Kriging surrogate model with experimental hemolysis measurements in a real device to determine a set of *calibrated* coefficients that can be used to obtain numerical simulations matching experiments. In theory, these calibrated hemolysis coefficients can be used to predict absolute plasma-free hemoglobin levels for the same device used for calibration but operating at different conditions or in a completely

different device sharing similar design features. The success of this strategy relies on the universality of the power law model and the extent of differences between the device used for calibration and the device of interest. It has yet to be investigated, however, whether calibrated coefficients from one device can be reliably used to predict hemolysis in a similar device.

The aim of the study is to assess the validity of the approach of using calibrated hemolysis coefficients to improve the power law model hemolysis predictions in real medical devices. Experimental hemolysis data in a 1-mm diameter capillary tube [4] were used by Craven *et al.* [3] to calibrate the power law model coefficients. In this study [5], we used the same calibrated coefficients to predict relative and absolute hemolysis levels in the 4-mm diameter FDA benchmark nozzle and compared the results with different experimental hemolysis data [2, 6].

METHODS

Large-eddy simulations (LES) and Reynolds-averaged Navier–Stokes (RANS) simulations of flow and hemolysis were performed for the FDA nozzle benchmark geometry [6] in both sudden contraction and gradual cone orientations (Fig. 1).

Figure 1: FDA benchmark nozzle in the sudden contraction orientation. The gradual cone orientation is symmetric with respect to the y-axis. Figure adapted from Mantegazza *et al.* [5]

The Eulerian power law model was used for hemolysis simulations [3]:

$$\frac{\partial H'}{\partial t} + (\mathbf{u} \cdot \nabla) H' = (C\sigma^b)^{1/a} \quad \text{SB}^3\text{C2023-371}$$

Copyright 2023 SB³C Foundation, Inc.

where $H' = H^{1/a}$ is the linearized plasma-free hemoglobin fraction and σ is the effective scalar stress defined as the resolved viscous stress. The power law model was tuned using the calibrated set of coefficients from Craven *et al.* [3]: $C = 2.875 \times 10^{-10}$, $a = 0.5$, and $b = 2.65$. Given the solution of Eq. 2, a modified index of hemolysis (MIH_{CFD}) was calculated to directly compare the CFD hemolysis predictions with the experimental data [6]:

$$MIH_{CFD} = 10^6 \frac{\int_A (H\mathbf{u}) \cdot d\mathbf{A}}{\int_A \mathbf{u} \cdot d\mathbf{A}} \quad (3)$$

where \mathbf{u} is the flow velocity and $d\mathbf{A}$ is the area normal vector of the cross-section A where hemolysis is evaluated. Fluid properties and boundary conditions were specified to reproduce the experimental conditions reported by Herbertson *et al.* [6], who measured hemolysis in separate experiments at conditions corresponding to 5 and 6 L/min through the FDA nozzle for both the sudden contraction and gradual cone orientation. The fluid was treated as Newtonian: $\rho = 1040 \text{ kg/m}^3$ and $\mu = 4.24 \text{ cP}$. For all simulations, a laminar fully developed inlet velocity boundary condition was used and a parabolic velocity profile was prescribed as an initial condition throughout the entire domain. A zero-gradient pressure boundary condition and a zero-pressure condition were applied at the inlet and outlet, respectively. For the plasma-free hemoglobin, we imposed $H = 0$ as initial condition and as inlet boundary condition, whereas a zero-gradient Neumann condition was prescribed at the outlet and on the walls. For the RANS simulations, we used the $k - \omega$ SST model with the SIMPLEC algorithm. Time-resolved LES simulations were performed with the PIMPLE algorithm. All computations were performed with OpenFOAM using second-order accurate discretization schemes. The convergence of the steady simulations was assessed by ensuring that the normalized residuals were less than 10^{-10} and by monitoring minimum and maximum values of variables of interest such as inlet pressure and flow rate. Given the flow solution, Eq. 2 for hemolysis prediction was solved using a custom solver previously developed and verified [3].

RESULTS

Absolute hemolysis predictions. Both LES and RANS predicted that the maximum plasma-free hemoglobin concentration (H) was found along the wall of the throat region just downstream of the sudden contraction. Using the calibrated coefficients from Craven *et al.* [3] and the sudden contraction configuration for the FDA nozzle at 5 L/min, we obtained MIH values of 421 and 210 for the LES and RANS, respectively (Fig. 2a).

Figure 2: (a) CFD absolute hemolysis predictions for the FDA nozzle in the sudden contraction orientation at $Q = 5 \text{ l/min}$ compared with the experimental data from Herbertson *et al.* [6] and Ding *et al.* [2]. (b) CFD relative hemolysis predictions for the FDA nozzle in the sudden contraction (SC) and gradual cone (GC) orientation at $Q = 5 \text{ l/min}$ and $Q = 6 \text{ l/min}$ compared with the experimental data from Herbertson *et al.* [6]. Figures adapted from Mantegazza *et al.* [5].

This difference is ascribed to the fact LES predicted that some hemolysis is generated by the resolved turbulent viscous stresses in the core of the nozzle throat, while RANS predicted hemolysis generation in the nozzle near-wall region only. However, this CFD absolute MIH difference is negligible as both CFD predictions differ by approximately 3 orders of

magnitude from the experimental data from Herbertson *et al.* ($MIH = 0.292 \pm 0.249$) [6]. To investigate whether using calibrated coefficients improves the accuracy of the hemolysis predictions, we performed an additional RANS simulation with the idealized power law coefficients from Ding *et al.* [2] ($C = 9.772 \times 10^{-7}$, $a = 0.2076$, and $b = 1.4445$) obtained in experiments using simplified Couette-type shearing devices. The CFD simulation using these traditional idealized coefficients yielded an MIH of 2974, which is more than 4 orders of magnitude larger than the experimental data (Fig. 2a) and in error compared to the calibrated RANS simulations by approximately one order of magnitude.

Relative hemolysis predictions. In addition to the sudden contraction (SC) at 5 L/min that we considered for the absolute hemolysis predictions, we performed two additional RANS simulations to test the power law model accuracy of relative hemolysis predictions: gradual cone (GC) orientation at both 5 L/min and 6 L/min. CFD results were compared to experimental data [6]. For both the experiments and CFD, relative MIH was calculated by normalizing the absolute MIH value for each case by the respective MIH value for the GC orientation at 6 L/min. Fig. 2b shows that relative hemolysis numerical predictions generally match experimental results. In fact, CFD correctly predicts the rank ordering of the relative hemolysis levels for all three conditions. For the SC orientation at 5 L/min, the relative MIH from CFD is 34.9 compared to an MIH of 13.9 from the experiments. For the SC orientation at 6 L/min, the CFD relative MIH prediction of 62 is in excellent agreement with the value of 59 from the experiments.

DISCUSSION

Our study showed that reasonably accurate relative hemolysis predictions in the FDA nozzle can be obtained using the power law model in combination with model coefficients (C, a, and b) calibrated for a similar device. This is a valuable result for medical product development because it allows the investigation of the hemolytic impact of small design modifications to an existing device without the need of performing additional *in vitro* experiments. However, highly inaccurate absolute hemolysis predictions were found despite the use of calibrated model coefficients. To be noted, the device-specific calibration approach used in this study improved the absolute hemolysis predictions by one order of magnitude compared to using the traditional empirical coefficients from simplified Couette-type shearing devices with idealized flow conditions. The main reason why the power law model failed to accurately predict absolute hemolysis levels lies in the subtle fluid dynamic differences between the FDA nozzle and the capillary tube used by Craven *et al.* [3] for the calibration of the model coefficients. This is due to the entirely empirical nature of the power law model which does not take into account RBC damaging mechanisms that lead to RBC damage. Thus, the power law model lacks universality and cannot be applied across all operating conditions. To obtain accurate absolute hemolysis predictions, the power law model has to be first calibrated under fluid dynamic conditions that closely match those in the hemolytic regions of the device of interest.

INTRODUCTION

Muscle volume and its cross-sectional area are essential parameters in estimating the force and strength of young athletes[1], the elderly[2], and patients[3]. Specifically, muscle volume accurately predicts torque [2], and strength[4]. Patients with Achilles tendon injuries suffer from long-term reduction in the gastrocnemius muscle volume (GMV) and soleus muscle volume (SOLV). Reduced muscle volume is related to lower-leg functional outcomes [5]. Therefore, a quick and accessible measurement tool for muscle volume is essential for assessing patient recovery after an Achilles tendon rupture (ATR). Muscle volume can be calculated using 3D imaging techniques such as MRI (Magnetic Resonance Imaging) and 3D ultrasonography (3D US)[6],[7]. However, MRI and 3D ultrasound are expensive and not readily available in many clinical settings. We have previously used parameters from panoramic ultrasound images to accurately estimate the volume of gastrocnemius muscles[8]. However, obtaining spatially-accurate panoramic images of the Soleus muscle is challenging due to its depth, size and shape. Therefore, this study aims to develop a method to estimate Soleus muscle volume from anthropometric parameters that can be easily measured with standard ultrasound equipment.

METHODS

This study was approved by the Pennsylvania State University IRB (STUDY00019121). The current study aims to propose a clinically applicable tool to measure SOLV. For this aim, five healthy participants (three females, two males, age=30.8±1.9, weight=67.6±15 kg, height=167±7 cm), without lower limb injuries or disease, take part in this study. 3T whole-body MRI system (Siemens Prima Fit) was used to gather the imaging data with the following parameters: T1-weighted, time to echo= 3.69 ms, time to repetition= 7.8 ms, and 6 mm slice thickness. Ultrasound panoramic ultrasound data were obtained within 15 days of the MRI test using a SIEMENS (ACUSON P300™) Ultrasound System. Free software 3D Slicer 4.13.0, and Sante DICOM viewer were used to create the volume from MRI images and measure the different parameters (Figure 1- a). The sagittal and cross-sectional area of the Soleus muscle in five participants are normalized and plotted, to examine the possibility of defining a shape factor (The ratio between muscle volume and predictor factors) for this muscle. Furthermore, the

possibility of estimating the soleus muscle volume by measuring the ratio of the Soleus muscle to the Gastrocnemius muscle was examined. Additionally, seven equations to estimate the SOLV involving anthropometric and ultrasound-measurable parameters were considered (Eqs 1-7). The parameters considered are Soleus length (Ls), Maximum axial cross-sectional area (Aa), Maximum sagittal cross-sectional area (As), the thickness of the Soleus muscle at the maximum Aa (t), the thickness of the soleus muscle at a bulging point of the leg (tm), the circumference of a leg (C), the thickness of the fat (tf), half of the circumference of the leg omitting the fat and the skin (Cs), Knee-ankle (Lateral femoral epicondyle, standing - Medial malleolus) distance (Ll). The accuracy of the prediction was evaluated using regression analysis.

$$MVS = a + b (t \times Ls) \quad (1)$$

$$MVS = c + d (Aa \times Ls) \quad (2)$$

$$MVS = e + f \left(Aa \times \frac{As}{t} \right) \quad (3)$$

$$MVS = g + h \left(Cs \times \frac{As}{tm} \right) \quad (4)$$

$$MVS = i + j (Cs \times Ls) \quad (5)$$

$$MVS = k + l (Cs \times Ll) \quad (6)$$

$$MVS = m + n (Cs \times Ll \times tm) \quad (7)$$

Where a, b, c, d, ... m, n are constant parameters obtained from regression analysis.

RESULTS

Figure 1-a shows the volume segmented for the participants in 3D Slicer. Figure 1- b shows the ratio between the soleus and gastrocnemius muscles in different participants. While the soleus muscle is always bigger than the gastrocnemius muscle volumetrically, the ratio between these muscles varies from person to person. The main axes of the soleus muscle with tibia bone in different participants do not have the same angle, therefore to analyze the normalized axial and sagittal cross-sectional area of the muscle, first, the soleus muscles are rotated in all three axes to become aligned. Figure 2 illustrates the normalized area of the soleus muscle in axial and sagittal directions over the normalized length and width.

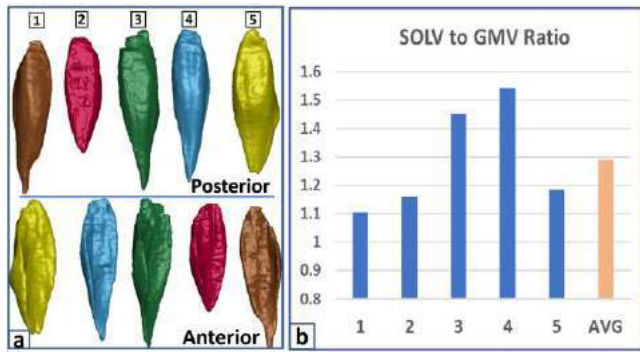

Figure 1: a) Posterior and anterior view of the segmented Soleus muscle, b) Soleus to Gastrocnemius muscle volume ratio

Figure 2: Change of normalized axial area of Soleus over Length percentile, b) Changes of the normalized sagittal area of Soleus over width percentile

The trends for both normalized curves in figure 2 are the same for all the muscles, and these similarities increase the possibility of defining the shape factor for analytical equations to estimate the soleus muscle volume. The maximum axial cross-sectional area of the soleus muscle is around % 50-70, and the maximum sagittal cross-sectional area of the soleus muscle is around % 75-85. After plotting normalized curves, the validity of the equations suggested in the methodology section is studied. Table 1 illustrates the anthropometrical, and parameters measured based on US and MRI-acquired images.

Table 1: Measured parameters

Sob No.	Anthro data		MRI data								US data		
	Ll	C	Vol	Aa	As	t	tm	tf	Cs	Ls	Cs	tf	tm
	(cm)	(cm)	(cm ³)	(cm ²)	(cm ²)	(cm)	(cm)	(cm)	(cm)	(cm)	(cm)	(cm)	(cm)
1	35	35	365.8	22.4	71	3	3.2	0.8	15	31.9	15.3	0.7	3.6
2	33	32	246	17.4	54	2.5	2.5	0.9	13.2	24	13.3	0.8	2.5
3	38.4	38	531.6	30.9	108.3	3.8	3.96	0.6	17.1	33.5	17.4	0.5	3.94
4	35.5	34	401	25.7	84.5	2.9	3.6	0.9	14.2	31	14.7	0.73	3.5
5	37.8	39	620	40.21	125	4.3	4.4	0.4	18.2	30.5	18.4	0.34	4.3

The soleus muscle is a deep muscle and considering the difficulty in following the curvature of the leg while moving the probe on the skin, acquiring the axial panoramic images for this muscle with the US is not convenient for general clinical examination. We did not consider the area of sagittal panoramic images in our analysis while capturing it is not as hard as axial panoramic images. In the first column of table 2, the regression result for suggested equations based on MRI data is demonstrated, and in the second column of table one, the regression results based on the measured parameters in the US are shown.

Table 2: Regression analysis to estimate SOLV

EQUATION	REGRESSION ANALYSIS (MRI DATA)	REGRESSION ANALYSIS (US DATA)
$a + b (t \times Ls)$	a= - 54.881 b= 4.8384 R= 0.9432	—
$c + d (Aa \times Ls)$	c= 38.855 d= 0.47 R= 0.9953	—
$e + f \left(Aa \times \frac{As}{t} \right)$	e= 90.145 f= 0.4625 R= 0.9559	—
$g + h \left(Cs \times \frac{As}{tm} \right)$	g= - 116.77 h= 1.4193 R= 0.9514	—
$i + j (Cs \times Ls)$	i= - 180.9 j= 1.2985 R= 0.8467	—
$k + l (Cs \times Ll)$	k= 57.596 l= 0.2177 R= 0.9746	k= - 330.14 l= 1.3322 R= 0.9642
$m + n (Cs \times Ll \times tm)$	m= 48.24 n= 0.1883 R= 0.9973	m= 24.12 n= 0.1949 R= 0.9785

DISCUSSION

Although in all cases the Soleus muscle, volumetrically, is bigger than the Gastrocnemius muscle, there is not a constant ratio between these two muscles. Since the functionality of these muscles is different, we are hypothesizing the ratio between these muscles is mostly a function of the daily activity and routine exercises, and by knowing the volume GMV, we cannot estimate the SOLV. The normalized axial and sagittal cross-sectional area over normalized length and width shows the same trend in the shape of the muscle, and this increase the possibility of defining the shape factor in analytical equations to estimate the muscle volume. Capturing accurate axial panoramic images for the soleus muscle might not be convenient. It is possible to capture sagittal panoramic images for the soleus muscle, but MRI analysis showed that using the sagittal cross-sectional area does not improve the estimation of the muscle. Also, since the angle of this muscle with the tibia bone varies in different subjects, defining the correct plane for acquiring the sagittal cross-sectional area is not easy. Therefore, this parameter is not included in the US regression analysis. But according to the regression analysis, measuring the circumference of the leg, the thickness of fat, and the thickness of the Soleus muscle on the bulging part of the leg can provide a good estimation for SOLV. A limitation of this study is the deformation of the skin while moving the probe, which can cause an error in measuring the thickness of the fat, also defining the accurate, boundaries for the soleus muscle with the current resolution of the MRI pictures are not easy. In conclusion, this study showed that considering US data and anthropometric parameters of the leg can provide a good estimation of the volume of the soleus muscle.

CLINICAL IMMERSION OF UNDERGRADUATE BIOMEDICAL ENGINEERING STUDENTS: BEST PRACTICES FOR SHORT-TERM PROGRAMS

Emily L. Lothamer (1,2), Katherine R. Moravec (1,2), Amy Hoene (1), P. Mike Wagoner (1), Daniel J. Beckman (1,3), Craig J. Goergen (2,3)

INTRODUCTION

Engineering curricula, although functional at delivering technical skills, often fail to impart many vital aspects of a successful engineer [1]. This includes exposure to experiences designed to create a deeper understanding of how these skills translate to real-world impacts [2-3]. While biomedical engineering students often benefit from immersive clinical experiences, especially at the undergraduate level, such opportunities can be difficult to provide due to challenges associated with implementation [4-5]. There is, thus, a need for strategically developed clinical immersion programming within biomedical engineering curricula that contribute to the training of well-rounded students using comprehensive clinical experiential learning.

METHODS

To address this challenge, we designed, implemented, and assessed a two-week cardiovascular clinical immersion program for biomedical engineering undergraduate students from Purdue University. This was accomplished through a partnership with Indiana University Health (IUH) Methodist Hospital and associated branches of IU Health and intentionally structured relationships established between IU Health administration, Purdue University faculty, and an engineering student intern. Since it began in 2014, this yearly program has expanded from five students for one two-week period in May to twelve students total over two separate two-week periods in May and August. To provide equitable program access to the greatest number of biomedical engineering students, we target students finishing their sophomore year and ask for a brief, open-ended application that includes their interest in the program and eventual career goals, with 15-20 students being selected for interviews. This two-phase application process was implemented to allow for multiple interactions with potential participants before deciding on a final group. In most years, thirty or more students apply to the program, demonstrating the demand and interest in clinical immersion programs. From 2014-2022, data was

collected from students via program application materials and open-ended reflections post-program. Repeating motifs in the data were operationalized and quantified to examine pre- and post-program career objectives and common takeaways from participants. This study received a Category IV exemption from Purdue University's IRB based on the use of these data (2022-844).

Student participants hear from clinical specialists employed by medical device companies of several relevant cardiovascular technologies and tour the facilities of IU Health's Simulation Center and 3D Innovations Lab for further exposure to the intersection of biomedical engineering and clinical medicine. Additionally, participants shadow and interact with medical professionals in several clinical departments involved in cardiovascular care throughout the duration of the program. These typically include Cardiology, Cardiothoracic Surgery, Radiology, and Interventional Radiology. Each program runs Monday-Friday for two weeks entirely on-site at the hospital, typically from 7am to 3pm each day. The focus of the first week is preparatory and includes lecture-based components, while the second week centers on active shadowing.

RESULTS

Response data from students who participated in this minicourse suggests that the experience is beneficial by exposing students to a wide variety of careers. While previous studies have shown that participation in a clinical shadowing program does not increase students' likelihood of intending to enter industry [5], our program does provide evidence that students unsure of their future career goals have a better idea of what they want to pursue post-graduation (Figure 1). Of the 55 program reflections we received, 30 indicated both pre- and post-program career objectives. Eleven started as unsure, and of those, five (42%) heavily preferred a specific path after the course. One student started with a pre-med objective and decided against this pursuit during the two-week program, becoming "unsure" as a result of their clinical experiences.

The seven students that ended the program undecided on a career path all stated feeling like they better understood the options available to them (100%). Of the 18 reflections with the same starting and ending career goal, six (33%) indicated in their reflection that they felt more confident in their path, while the remaining twelve (66%) did not discuss this aspect of their program experience. While the participant group composition included a higher-than-representative number of students interested in pursuing medicine, a greater number of undecided students indicated an increased interest in graduate school or industry compared to medicine. This demonstrates that clinical shadowing programs could have the ability to increase the biomedical engineering workforce. Previous data has shown that exposure to shadowing increases desire to attend medical school, so this may hold true for industry and graduate school as well since students see firsthand what careers each path may entail [6].

Figure 1: Self-reported career interests before and after program participation for participants between 2014-2021.

We found through our program that the successful organization and implementation of clinical immersion programs is dependent upon 1) close connections with and support from administrative personnel and 2) sustained relationships with clinicians and other medical professionals at the host facility. The support from administrative staff at the host facility is invaluable during the process of scheduling and obtaining clearance for the student participants. Maintaining connections with professionals who have previously participated in the program allow for continued support and the introduction of additional opportunities for future groups. For example, several cardiothoracic

surgeons have given guest lectures and hosted students during operations for multiple years in a row, leading to incredible learning experiences, continuity, and expansion to other clinicians in cardiology and radiology. Within the IU Health program, an engineering student intern is chosen each year from the pool of previous participants. This intern serves as a primary contact for participant selection and program coordination and, although funded through the hospital, focuses on communication with hospital administration and student and clinical program participants. Overall, the coordinated effort of these individuals is crucial to the execution of clinical immersion programs.

DISCUSSION

This experience provides biomedical engineering students at Purdue University with a rare, unique opportunity to gain hands-on access to the clinical environment of a top cardiovascular care center. Students interact with clinicians in cardiothoracic surgery, radiology, cardiology, interventional radiology, and other departments. The course has demonstrated potential to be life-changing for participants, as stated in multiple student reflections upon completion of their two-weeks. Key strategies for success include recruitment of student participants with diverse interests, provision for a funded intern position, developing staff and clinician contacts for year-to-year program constancy, and strategic program scheduling. Overall, both industry-focused and pre-med students alike can benefit from programs like this that give engineering students first-hand knowledge of current success and challenges associated with clinical care. While our program was targeted at undergraduate students, future endeavors could open opportunities to graduate students to benefit a wider group of students.

ACKNOWLEDGEMENTS

Funding for student interns came from Indiana University Health Methodist Hospital.

PRONLONGED SUBCULTURE AND PROGERIN EXPRESSION SENSITIZE VSMCS TO THREE DIMENSIONAL FIBER STRUCTURES

Yu-Yu Hsueh and Pen-hsiu Grace Chao

Department of Biomedical Engineering
National Taiwan University
Taipei, Taiwan

INTRODUCTION

Vascular smooth muscle cells (VSMCs) respond to various environmental signals, such as injury or inflammation, by changing their phenotype to maintain vascular structural and mechanical homeostasis [1, 2]. In vascular aging, VSMC dedifferentiation from the 'healthy' contractile phenotype is accompanied by elastin fiber fracture and excessive ECM deposition, resulting in arterial wall stiffening. The fragmented elastin fibers in the aged tissues also lose their wavy structure, a crucial component of vascular mechanics [3].

Hutchinson-Gilford progeria syndrome (HGPS) is an accelerated-ageing syndrome, caused by expression of the mutated lamin protein, progerin [4, 5]. HGPS patients suffer from atherosclerosis and heart failure, leading to death in their teens [6]. Progerin accumulation in VSMCs leads to altered mechanotransduction and phenotypic changes in mouse models [7]. We previously developed straight and wavy scaffolds to approximate the changes in ECM structure [8]. In this study, we investigate the effects of fiber structure on aging VSMCs, simulated with progerin-expressing VSMCs and prolonged passing [9].

METHODS

Electrospun Scaffold Poly-L-lactide (PLA, 6% in HFP) fibers were co-electrospun with 15% polyethylene oxide (PEO, in ethanol) on a rotating collector. The PEO fibers were removed with water to increase scaffold porosity. Fiber crimp was induced by heat treatment [8]. Materials were coated with polydopamine and type I collagen.

VSMC Culture Cre-LoxP-flanked PGK-neo-4XpA transgenic mice were provided by Dr. Chi Ya-Hui [10]. VSMCs were isolated from 10-week-old aortae via explant cultures. Cells were treated with 1 μ M 4-hydroxytamoxifen (4OHT) at passage 1 (P1) to induce progerin::FLAG production. VSMCs were subcultured to P6 and P9, and seeded on fiber scaffolds at 15,000 cells/cm².

Phenotypic Analysis Cell proliferation was quantified by either cell doubling time or normalized metabolic activity using AlamarBlue

assay according to the manufacturer's protocol. Immunofluorescence staining of phenotypic markers, including alpha smooth muscle actin (α SMA, Sigma), transgelin (SM22, Abcam), and calponin 1 (Abcam), were used to assess percentage of cells expressing these contractile markers.

Statistics Nonparametric Kruskal-Wallis test, Fisher's exact test, and 2-way ANOVA were performed using R.

RESULTS

To establish the effects of prolonged passing and progerin expression on VSMC phenotype, we monitored cell proliferation and phenotypic marker expression in 2D cultures. 4OHT induction resulted in more than 95% cell expressing progerin (data not shown). Population doubling time decreased with serial passing, indicating higher proliferation rate. At the same time, expression of most contractile markers tested reduced with subculture. Overall, prolonged cell passing increased cell proliferation and attenuated contractile marker expression, indicating a change in VSMC phenotype. Progerin induction had only minor effects.

Figure 1 (A) Cell doubling time (B) Proportion of VSMCs staining positive for contractile markers (* $p < 0.05$ vs P2, line: $p < 0.05$ vs indicated groups)

We cultured the dedifferentiated VSMCs on straight and wavy fiber scaffolds for 3 weeks (Fig 2A). P6 VSMCs followed fiber structure in the straight group and had more random orientation in the wavy scaffolds (Fig 2B). Interestingly, P9 VSMCs are more elongated in both fiber groups and exhibited better fidelity to fiber structure. Progerin expression reduced shape conformity to fibers. Immunofluorescence staining of contractile marks found similar reduction with serially passaged cells, and wavy fiber structure increased contractile marker expression. Contrary to the 2D finding, progerin induction reduced phenotypic marker expression (Fig 2A and C).

Figure 2 (A) Electrospun fiber structure, visualized by SEM, (B) immunofluorescence images of VSMC morphology and marker expression, and (C) proportion of cells positive for contractile markers.

We also monitored cell metabolic activities as a proxy for proliferation during scaffold culture. Both cell passaging and progerin expression increased VSMC proliferation rate (Fig 3). In P6 control cells, fiber structure did not change VSMC proliferation, while in P6 progerin-expressing cells, the increased proliferation was suppressed by wavy scaffold. For all groups, P9 VSMCs had increased proliferation rate. The effect of progerin expression was minimized but wavy fiber structure significantly reduced proliferation. In conjunction with results from Fig 2, our data indicate significant changes in VSMC phenotype with serial passaging and progerin induction. The wavy fiber structure partially rescues the phenotypic changes in these ‘aged’ VSMCs.

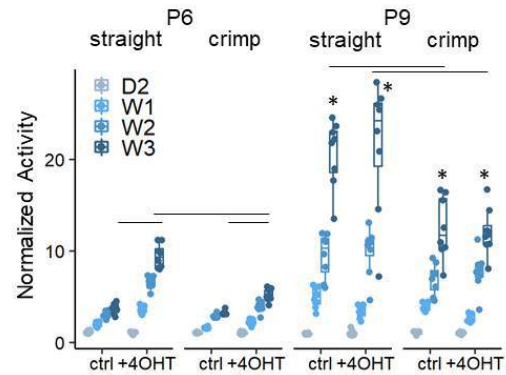

Figure 3 Cell activity, normalized by day 2, from Alamar Blue assay. Culture time had statistically significant effects on cell activity ($p < 0.05$, not shown on figure, Line: $p < 0.05$ in indicated groups at W3, * $p < 0.05$ vs P6 at W3).

DISCUSSION

Increased arterial stiffness is a significant risk factor for atherosclerosis and cardiovascular diseases. While inflammation and endothelial signaling play important roles in its regulation, VSMC manifest the arterial changes by altering its phenotype [2]. This is particularly evidenced by mice with VSMC-specific progerin expression [11]. In this study, we established ‘aged’ VSMCs by prolonged passaging and progerin expression (Fig 1) and investigated the effects of extrinsic structures on VSMC.

In the ‘healthy’ VSMCs (P6 without progerin expression), fiber structure did not change their contractile phenotype. With further passaging or progerin expression, however, VSMCs had decreased marker expression and increased proliferation, yet was able to respond to fiber structure (Fig 2, 3). In preliminary studies, P3 VSMCs was also not sensitive to fiber structure (data not shown). These findings suggest that the intrinsic VSMC contractile phenotype plays a dominant role, and the dedifferentiated cells are more mechanosensitive and plastic [12]. It is interesting to note that while progerin expression had only a minor effect in 2D cultures, its impact in 3D fibrous cultures was more robust. This result is in agreement with the different cell morphologies on the fibrous scaffolds and supports previous findings that progerin disrupts nuclear membrane structure and changes cell mechanotransduction [13]. Overall, we demonstrate that prolonged subculture and progerin expression sensitizes VSMCs to wavy fiber structure to promote a more contractile phenotype. As the crimp structure is lost with aging and disease, our findings suggest the intrinsic and extrinsic changes with aging interact to exacerbate vascular health.

INTRODUCTION

Reconstruction of 3D geometric models of pelvic organs based on 3D magnetic resonance imaging (MRI) is a very important and challenging task for computer-aided diagnosis, treatment and prognosis of female pelvic organ prolapse. The 3D geometric model can show the spatial structure of the organ, help the physician visualize the specific shape of the organ, analyze the etiology [1], and provide a good basis for subsequent finite element analysis [2] and surgical planning. Traditional methods usually first manually or automatically segment 2D MRI slices, and then perform post-processing such as 3D geometric model reconstruction and complex geometric repair based on the segmentation results. However, due to the complex shape of the pelvic organs, the traditional methods still have some problems, such as complex manual operations, high workload and long working time.

Deep learning has been widely used in computer vision tasks in the past decade, for automatic natural image classification, detection, and segmentation. There have also been some methods to automatically segment MRIs using deep learning. However, the segmentation results still require manual post-processing to make them conform to the real

3D geometry. In addition, the error tolerance rate of such automatic segmentation method is quite low. Once there is a segmentation error in one slice, the whole structure can be changed significantly, which affects the reconstruction of the 3D geometric model. End-to-end deep learning could directly learn the process "from MRI to the final 3D geometric model". This not only automates the reconstruction process, but also makes it possible to focus on the global structural information of the 3D geometric model, which in turn has a higher error tolerance rate and more realistic reconstruction results.

In this work, we aimed to develop an end-to-end deep learning-based reconstruction technique for 3D geometric model reconstruction of pelvic organs from 3D MRI.

METHODS

Figure 1 shows a proposed architecture for the end-to-end 3D geometric model reconstruction, along with exemplary inputs and outputs. For example, a set of 3D MRIs (where 480×480 is the size of one slice and 18 is the number of slices per set) and a spherical point cloud (uniformly sampled from a spherical 3D geometric model with diameter 1) were used as inputs to predict the 3D geometric model of

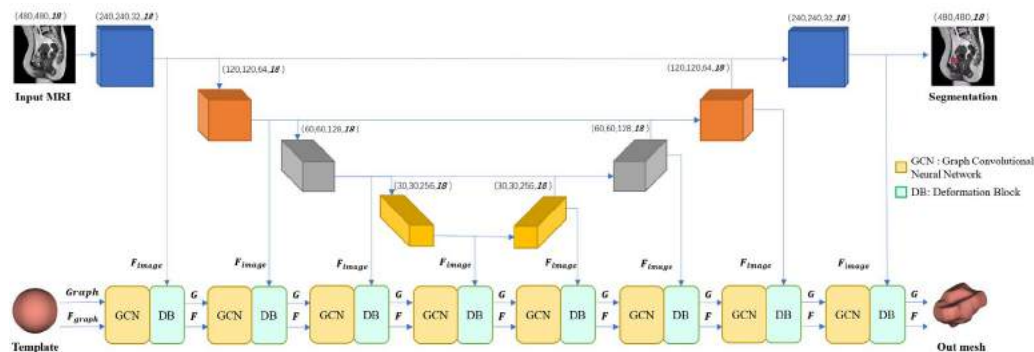

Figure 1: Network architecture.

the pelvic organs. First, a convolutional neural network (CNN) was used to extract layer-specific image features. Then, the spherical point cloud was constructed into a graph, and a graph convolutional neural network (GCN) was used to extract 3D structural features. GCN is a feature extractor for graph data structure, which has been widely used in 3D shape analysis in recent years. It can exchange features between neighboring nodes and eventually return to each node. In addition, a Deformation Block (DB) was designed to integrate image features with 3D structural features and transform spherical point cloud into a new point cloud. This completes a deformation of the point cloud. The above process was repeated eight times to extract deeper and more comprehensive feature information. Finally, the transformed point cloud was generated with the corresponding 3D geometric model of the organ. A manually reconstructed 3D geometric model was used as the ground-truth for the supervised training process.

The detailed structure of the Deformation Block (DB) is shown in Figure 2. A CNN was first used to encode the image information into a 1D vector. Next, each point of the sphere was concatenated with this 1D vector, and a multilayer perceptron (MLP) was used to learn the global features of the point cloud. We concatenate this feature with the 3D structural feature extracted by the GCN. Next, another MLP was used to learn the global changes, and EdgeConv [4] was used to learn the local changes to reconstruct the point cloud. Finally, the PointNet [5] was used to reconstruct the new point cloud.

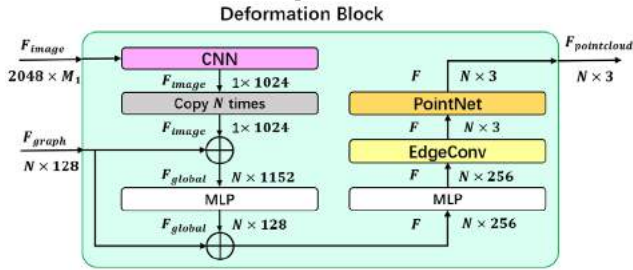

Figure 2: The detailed structure of the Deformation Block.

Several loss functions [6] were used to train our network, including Chamfer distance loss, Edge loss, and Laplacian loss, which were defined as follows.

$$L_{CD} = \sum_p \min_g \|p - g\|_2^2 + \sum_g \min_p \|p - g\|_2^2 \quad (1)$$

where p is the vertex coordinate of the predicted surface mesh, and g is the vertex coordinate of the ground-truth surface mesh.

$$L_{edge} = \sum_p \sum_{k \in N(p)} \|p - k\|_2^2 \quad (2)$$

where $N(p)$ are the neighbor vertices of p .

$$L_{Lap} = \sum_p \|\delta'_p - \delta_p\|_2^2, \delta_p = p - \sum_{k \in N(p)} \frac{k}{\|N(p)\|} \quad (3)$$

where δ_p and δ'_p are the Laplacian coordinates of vertex p before and after deformation.

The overall loss is a weighted sum of all four losses, defined as:

$$L = \lambda_1 L_{CD} + \lambda_2 L_{edge} + \lambda_3 L_{Lap} \quad (4)$$

where $\lambda_1 = 1.0$, $\lambda_2 = 0.01$, $\lambda_3 = 0.1$.

Chamfer distance (CD), Earth Mover's Distance (EMD), PC-to-PC L2 Distance (L2) and PC-to-PC L1 Distance (L1) were used as the evaluation metrics.

We used the Adam optimizer with a learning rate $1e^{-4}$ and a batch size of 2 for training in all experiments conducted. The network was implemented using Python 3.6.0, Pytorch 1.10.0, Dgl 0.7.2, and all experiments were streamlined and executed on an Nvidia Titan RTX graphic card with 24GB of computational memory.

We built a 3D MR dataset with 17 subjects from Peking University People's Hospital. Specifically, the T2 3D sagittal MR data of each subject at rest were used. The spacing of the MR images was 2 mm with a slice thickness of 2 mm. We randomly divided the annotated dataset

into a training set (13 series) and a testing set (4 series). Each training sample contains a source-target pair, where the former is the original 3D MR image and the latter is the corresponding bladder surface mesh. To make the deformation process more reasonable, we first normalized each coordinate value of the real bladder to a range of 0 to 1. Then we moved the geometric center of the original sphere and the geometric center of the normalized real bladder to the origin (0,0,0). To prove the effectiveness of our model, we compared it with two other advanced 3D reconstruction of natural objects, including Pixel2mesh and Pixel2mesh++.

RESULTS

The testing result of the 3D reconstruction with comparison is summarized in Figure 3.

Figure 3: 3D reconstruction performance on the testing set. Smaller metrics better 3D reconstruction results.

In addition, the visualization results of the 3D reconstruction of the bladders of three subjects in the testing set are shown in Figure 4. From the results, our 3D reconstruction results are close to the ground-truth.

Figure 4: A visual comparison of 3D reconstruction results. Results of different views were compared with the ground truth labeling.

DISCUSSION

This study presents a novel end-to-end deep learning method with the CNN and GCN for fast reconstruction of 3D geometric models of pelvic organs from 3D MRI. Unlike traditional manual methods that are time-consuming and laborious, our method takes only 3 seconds. The experimental results demonstrate that the proposed network has achieved good qualitative and quantitative results in 3D reconstruction of the bladder. In the future, a larger training dataset will be expected to improve the reconstruction process.

ENGINEERED COMPOSITE FIBROUS HYDROGELS THAT MIMIC DYNAMIC DEVELOPMENTAL SIGNALS DURING FIBROUS TISSUE DEVELOPMENT

INTRODUCTION

Fibrous tissue (tendon, annulus fibrosus, meniscus) growth and development is exemplified by dramatic transitions from cell rich-disorganized aggregates to ones that are cell-poor but rich in organized extracellular matrix [1]. As such, development of these tissues includes a transition from a state in which information is relayed through cell-to-cell contacts to one governed by cell-to-matrix contacts. Importantly, differential presentation of cell-cell adhesion vs. cell-matrix adhesion cues can regulate cell behavior [2]. Further, forming tissues often use boundaries as mechanical anchorage points against which cell-mediated contraction occurs [3]. Not only are these growth and remodeling events necessary to achieve the final functional form of these fibrous tissues, but these same physical cues can regulate resident cell differentiation and function to drive regional tissue specialization [4]. In a series of recent studies, we queried meniscus development from its point of origin (E15) to postnatal maturity [5,6]. Once the meniscus was identifiable, it consisted of a highly aligned cellular template that spanned from either end of the tibial plateau [6]. During this phase, active cell contraction, mediated by large, organized actin stress fibers, deformed the meniscus cell nuclei. Soon after, nascent extracellular matrix (collagen) was deposited and interwoven between cells. At this stage, the large actin stress fibers began to disappear, and the nuclear deformation relaxed, indicating a transition to force transfer through the ECM rather than through the cell template. As development further progressed, this original cell and ECM templating culminated in an organized ECM separating cells with a differentiated phenotype.

Clearly, there is a dynamic and time-evolving interplay during fibrous tissue development between the cells, their deposited ECM, and forces imposed by other knee structures. How, and to what extent, this crosstalk governs cell function is difficult to study given the complexity of the *in vivo* situation and inability to decouple these cues. To address this, we and others have developed increasingly sophisticated neo-tissue constructs. Most commonly, investigators utilize micropost-based

systems to introduce boundary constraints coupled with cells embedded in collagen or other natural polymers that cells can contract [7]. However, these natural polymers are poorly defined and limit independent exploration of how multiple extracellular inputs, such as mechanics, degradation, and adhesion moiety type, influence cell behavior [8]. To that end, we developed a tunable and dynamic composite fibrous hydrogel system that can undergo both cell-mediated contraction and dynamic phase transitions at defined time points in response to exogenous stimuli.

METHODS

Material Fabrication: Our composite material (**Fig 1**) consists of a continuous phase of acrylated hyaluronic acid (AHA) and a fragmented fiber phase consisting of short RGD-modified methacrylated HA fibers (produced by electrospinning followed by mechanical fragmentation [9]). In this composite material, crosslinking occurs via a Michael

Figure 1: Schematic of material fabrication.

addition reaction with the sequential addition of dithiothreitol (DTT) at a basic pH. **Cell-Mediated Contraction Assays:** Constructs were created by mixing juvenile bovine meniscal fibrochondrocytes with the prepolymer solution, pipetting into circular polydimethylsiloxane (PDMS) molds, and allowing constructs to partially crosslink for 1 hour at pH 8 and 37°C (during which time a specific proportion of the acrylates are consumed, leaving the remaining groups free for subsequent crosslinking steps). To fully crosslink constructs, additional DTT was added at defined time points and allowed to crosslink as above. **Imaging:** Fluorescent fibers and cells were visualized through staining for actin cytoskeleton or CellTracker Red. Viability was assessed via Live/Dead assay. Images were taken of constructs using a brightfield microscope and construct area was quantified using ImageJ. **Statistics:** Contraction studies were repeated 3-5 times for each group and timepoint. Outcomes were compared using one-way ANOVA with Bonferroni posthoc, with significance set at $p < 0.05$.

RESULTS

Initial studies focused on identifying the concentration of the continuous phase (CP) and degree of partial crosslinking required to form a stable gel that is conducive to cell contraction. Partial crosslinking was performed by introducing cells within the prepolymer solution as it began crosslinking. With a 20wt% fragmented fiber (FF) concentration and a 0.7 wt% CP concentration, we observed progressive contraction of 30% over the first day, which increased to 37% by day 3 (Fig 2). Notably, cells transitioned from a rounded to an elongated morphology over this time. Next, to determine the impact of FF concentration, we evaluated contraction over 3 days when FF levels were set at 5, 10, or 20% (with CP held at 0.7 wt%). Results showed that reducing the fiber concentration resulted in a greater extent of contraction (Fig 3A). To determine how cell concentration regulated the rate of contraction, we set the starting cell density at 5, 7, or 10e6 cells/mL. Reducing cell concentration decreased the rate of construct contraction (Fig 3B). Finally, to determine if we could arrest contraction by transitioning the construct from partial to full crosslinking, DTT was added in excess to consume remaining acrylate groups, 2.5 hours after gels were formed (Fig 4). With this full crosslinking, constructs no

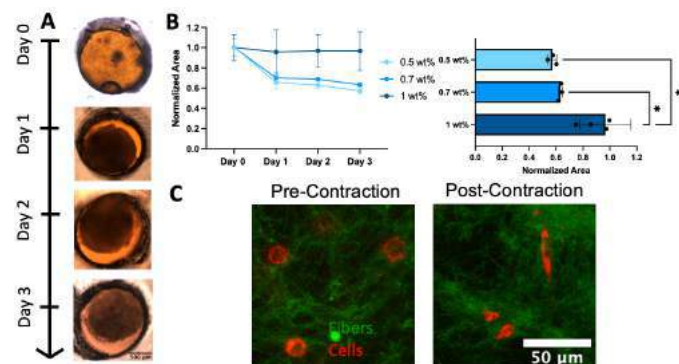

Figure 2: Representative images (A) and quantification of contraction over time (B, left panel) and on day 3 (B, right panel) of construct (0.5, 0.7, and 1wt% CP, 20wt% FF, 10e6 cells/mL). Representative images of cells prior to (C, left panel) and after (C, right panel) contraction. * $p < 0.05$.

longer contracted. Notably, cells within fully crosslinked constructs remained viable throughout all crosslinking steps (Fig 4B).

DISCUSSION

Herein, we describe an engineered composite fibrous hydrogel system in which cell-mediated contraction can be halted in a user-defined manner by dynamic stiffening of the extracellular environment. The partial crosslinking of the acrylate groups in the CP produced a

Figure 4: Quantification (A) of construct contraction (0.7 wt% CP, 20wt% FF, 10e6 cells/mL) over time with partial and full crosslinking. (B) Live/Dead imaging of fully crosslinked construct on day 3. ** $p < 0.01$ compared to partial crosslink at same time point.

mesh size that allowed cells to interact with their extracellular environments. Notably, the only adhesive ligands present in the composite were on the FF, which suggests that cells are interacting with and pulling on these fibers to mediate contraction. We also showed that consumption of free acrylate groups could arrest construct contraction, suggesting the opportunity to influence cell contractility by tuning the full crosslinking of the extracellular environment.

Future directions of this work include the introduction of boundary constraints to promote alignment in the forming of neo-meniscus tissues. We will also explore how cell-cell interactions (through introduction of N-cadherin-based moieties) in addition to cell-matrix interactions (RGD moieties) influence cell contraction. Ultimately, these tunable materials will be used to probe molecular signaling and how perturbations to contraction, adhesion, and external physical cues regulate meniscus progenitor cell differentiation. This novel material system will enable exploration of key developmental inputs that guide meniscus formation, providing new insight into regenerative strategies that may be leveraged towards meniscus repair.

LOCAL NONLINEAR ELASTIC RESPONSE OF EXTRACELLULAR MATRICES

Haiqian Yang (1), Ming Guo (1)

(1) Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA

INTRODUCTION

Nonlinear stiffening is ubiquitous in biopolymers [1, 2], including the extracellular matrix (ECM) polymers such as collagen, fibrin and basement membrane [3–5]. In these ECM materials, cells such as fibroblasts and certain types of cancer cells are known to deform and stiffen the matrix [4, 6]. However, the bulk response is the primary focus of existing studies on the nonlinear elasticity of biopolymers [3, 7, 8], while cells embedded in the ECM interact with the matrix locally. For example, a fibroblast in the collagen matrix extends filopodia and pulls on the fibers (Fig. 1A-C), such loading from a cell is localized, and it generates a nonuniform deformation field in the matrix, which is distinct from uniform bulk measurements [9]. How much resistance does a cell feel when pulling on its surroundings, and how does the resistance increase with the force applied?

Here we show experimental results by optical tweezers that the nonlinear response of collagen to a local force deviates from the expectation from the bulk response $k \sim F$, but instead is closer to $k \sim F^{1/2}$, where k is the differential stiffness and F is the force. We find that this weaker power-law relation can be explained by a minimal scaling argument of an effective probe: the observed local nonlinear response is similar to the case of using a larger effective probe (radius R^*) to linearly deform the far-field matrix whose shear modulus is G , and R^* grows as $(\frac{F}{G})^{1/2}$. Surprisingly, this argument suggests $k \sim F^{1/2}$ is a universal relation for local mechanical measurements independent of bulk stiffening behaviors provided that the stiffening is sufficiently strong. Our results highlight the significant differences between nonlinear responses upon local and bulk force applications, relevant to cell-ECM and cell-cell interactions in multicellular living systems.

METHODS

Optical Tweezers Measurements. Microparticles (2 μm , C37278, ThermoFisher, and 4.5 μm carboxylate microspheres, Polyscience) are embedded in the gel prior to polymerization. The laser beam is moved at a constant velocity of 1 $\mu\text{m s}^{-1}$. The relative distance between the laser and the bead is recorded.

Finite Element Simulations. An axial symmetric geometry is used, where a rigid spherical domain of radius R_0 is embedded in a cylindrical matrix of radius $R = 250R_0$ and height $H = 2R$. The lateral surface

of the matrix is fixed and the top and bottom surfaces are traction-free. A series of point forces are applied at the center of the rigid spherical domain and the displacement is recorded. The matrix is modeled as an incompressible material with a free energy function $W_{exp} = \frac{G}{2b} \exp(b(I_1 - 3))$, where G is the linear shear modulus, b is a stiffening parameter, and I_1 is the first invariant of the deviatoric Cauchy-Green deformation tensor. Calculations are also performed with variations of this free energy $W_2 = \frac{G}{2}(I_1 - 3) + \frac{Gb}{4}(I_1 - 3)^2$, and $W_4 = \frac{G}{2}(I_1 - 3) + \frac{Gb}{8}(I_1 - 3)^4$.

Figure 1: Local nonlinear elastic response. (A) A mouse embryonic fibroblast (green, cytoplasm) within collagen networks (grey). (B) The same cell with one filopodium released. The dashed circle marks the highly deformed region. (scale bar, 10 μm .) (C) The filopodium applies a point force to the matrix and creates a highly deformed zone. (D) A particle (2 μm in diameter) embedded in a 4 mg mL^{-1} collagen gel. A laser trap applies force F . (E) Force F is a nonlinear function of displacement u . (F) Differential stiffness k deviates from the bulk scaling law ($n=23$). The yellow line is the average. SB³C2023-377

RESULTS

Local stiffening in collagen deviates from bulk stiffening. A bead is displaced a distance u from its equilibrium position by an optical force F (Fig. 1D), and the differential stiffness k can be calculated by $k = \frac{dF}{du}$. When we perform this measurement in 4 mg mL⁻¹ collagen gels with 2 μ m-in-diameter beads, we find that the material indeed stiffens with increasing force (Fig. 1E); the differential stiffness k shows a linear regime followed by a nonlinear regime (Fig. 1F). Interestingly, the logarithmic slope in the nonlinear regime clearly deviates from the bulk slope of 1 since the initiation of nonlinear stiffening and ranging 2 orders of magnitude of the applied force ($10^{-2} \sim 1$ pN). A closer examination reveals that the logarithmic slope is about 1/2, suggesting $k \sim F^{1/2}$ (Fig. 1F). To further confirm this behavior, we perform this experiment in collagen gels of different concentrations (e.g. 1.6, 2.4 and 3.2 mg mL⁻¹) with a different particle size (4.5 μ m in diameter); these experiments all show logarithmic slopes close to 1/2 in the nonlinear regime (Fig. 2). Moreover, we perform measurements on fibrin gels. Remarkably, the local nonlinear response of fibrin gels is also close to $k \sim F^{1/2}$ (Fig. 2), regardless of the different bulk stiffening response of collagen and fibrin gels [3, 10]. These results demonstrate the generality of this weak power-law relation $k \sim F^{1/2}$ in local micromechanics measurements.

Figure 2: All the experimental and theoretical curves can be collapsed to a single master curve by nondimensionalizing stiffness and force. The master curve shows $k \sim F^{1/2}$ in the nonlinear regime. The characteristic force F^* is defined as the force at which the differential stiffness is twice the linear stiffness.

Increase of effective probe size. To understand this 1/2 power-law relation, we first follow a dimensional analysis of the nonlinear elastic boundary value problem defined in the method section. Considering the force balance, the point force to perturb the particle is balanced by the integral of traction fields on an arbitrary closed surface containing this point force, $F = - \int \sigma_{ij} n_j e_i^1 dA$, where σ_{ij} are the stress components, n_j are components of the surface normal vector and e_i^1 are components of the unit vector along the point force. In the matrix, strain and stress fields decay away from the probe. Although F can be comparably large that nonlinearly deforms the vicinity of the probe, because the strain and stress fields approach 0 at infinity, there must be a closed surface above which the material only undergoes moderate strain, and thus behaves almost linearly. A stress scale on this surface is the linear shear modulus G . Denoting the length scale of this closed surface as R^* , the force balance equation yields $F \sim GR^{*2}$, so R^* scales as $(\frac{F}{G})^{1/2}$. Because the material within this range R^* is more severely deformed and much stiffer than the outside as a result of nonlinear elastic stiffening, effectively we are using a larger rigid particle of length scale R^* to probe the linear matrix surrounding this rigid particle. This yields $k \sim GR^*$ similar to the Stokes-Einstein law. Consequently, the stiffness $k \sim R^* \sim F^{1/2}$ (Fig. 3D). As we examine the profile of displacement in the direction of the applied force in simulation, the direct adjacency of the particle moves with it almost rigidly; indeed, there is a critical length R^* above which the displacement field starts to rapidly decay (Fig. 3B). By perturbing the particle at different forces, we find $R^* \sim F^{1/2}$ (Fig. 3C).

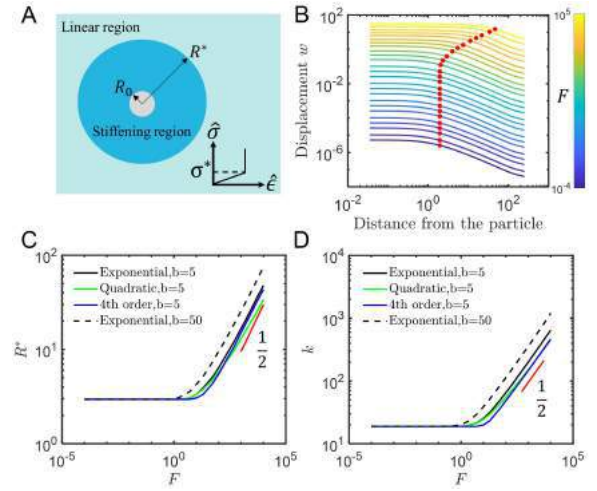

Figure 3: The local stiffening response can be attributed to the growth of an effective probe size R^* . (A) The adjacency of the particle is stiffened over the length scale R^* such that the point force probes the far-field linear matrix with an effective larger size R^* . (Inset) The extreme case is an 'elastic-rigid' simplification. (B) R^* is estimated as the distance when the axial displacement decays to half of that of the particle. (C) Effective probe size R^* grows as $F^{1/2}$. (D) Stiffness k grows as $F^{1/2}$.

DISCUSSION

We report the stiffening relation in bulk no longer holds for localized force applications. Instead, we find the relationship is closer to $k \sim F^{1/2}$ (Fig. 1F). We show that this local response ($k \sim F^{1/2}$) can be explained by introducing an effective probe (radius R^*) that grows with increasing forces (Fig. 3). We, therefore, propose a hypothesis that local forces such as those applied by cells feel the nonlinear elasticity through an effective probe that nonlinearly grows with the applied force. These results may provide insights into understanding cell-cell interactions through ECM, and mechanobiology of complex living systems such as tissues and organs.

BRINGING DISCUSSIONS OF ACCESSIBILITY TO ENGINEERING CLASSROOMS

N. Rich (1), S. Johnson (1), C. Bellini (2)

(1) Tatum Robotics, Hudson, MA, USA
(2) Department of Bioengineering, Northeastern University, Boston, MA, USA

INTRODUCTION

Discussing accessibility and assistive design in engineering classrooms, where students learn product design principles and implementation, keeps disabled groups at the forefront of the students' attention when they develop their ideas.

There exist misconceptions about designing for disabilities among the able-bodied population; namely, that inclusive design is something that able-bodied groups do not benefit from, and therefore an emphasis on inclusive design is unprofitable and only serves the needs of the few.

To alleviate this issue, we aimed to introduce students to inclusive design principles, explain the importance of including disabled groups themselves within research (rather than using disability simulations to envision product needs), and prompt students to design product ideas that consider the objectives of inclusive design.

METHODS

Targeting upper-level undergraduate and graduate bioengineering students, we created a lesson plan that highlighted the essentials of inclusive design, adaptive technology, and assistive technology.

Warm-up. Incorporating the fundamentals of inclusive design (such as text-to-speech tools, large print, easy navigation, the one-fits-one model, etc.) [1] showed students how web-based media often adds features that are meant for accessibility.

Disability models. We discussed the social model of disability (as opposed to the medical model of disability), which defines the limiting factor in a disabled person's life as the obstacles society presents rather than the disability itself. Where the medical model aims to "fix" a person's disability—a task that may not even be possible in most cases—the social model aims to eliminate the societal obstacles that limit the disabled community's access [2]. For example, a person in a wheelchair may struggle not because of the fact they are in a wheelchair at all, but because buildings are inaccessible. The social model focuses on what we can change about our shared environment, rather than what

an individual should go through to assimilate with the able-bodied world at their own personal cost.

Assistive technology (AT). After, we showed examples of positive AT, such as the white cane that blind people use for navigation, or eye-gaze tracking software that people who are nonverbal or have a physical disability that prevents them from accessing other technology. We discussed the qualities of poorly designed AT that did not consider the needs of real people with disabilities. We specifically cited companies that used disability simulations, wherein someone without the target disability simply fakes the disability to test the product (i.e. covering their eyes to simulate blindness) rather than asking a disabled person for their feedback. We emphasized that able-bodied people are unable to make informed guesses about the lived experiences of disabled people; instead, one must ask target users what kind of technology would suit them without making assumptions.

Guest lecturers. First, Tatum Robotics speakers explained their model of development in the disability space. Tatum Robotics is developing technology to make digital media accessible to the isolated DeafBlind community. Tatum Robotics engages with the DeafBlind community at social events and invites DeafBlind individuals to regularly offer their feedback on their devices. All features and designs are informed by the feedback, needs, and desires of the target user.

Secondly, a Deaf guest speaker named Spencer Montan shared his experience and fielded questions from curious students who had never considered the daily problems a Deaf person might encounter. Montan is the Associate Director of the Center on Access Technology at the Rochester Institute of Technology, where he works with students to create AT projects alongside his own innovations.

Debriefing. Once the lecture was over, we had students, in groups, compile lists of problems that they face on a regular basis that some type of innovation could potentially solve. After, groups traded problem statements with one another and picked a problem another group had written to design an innovation that could solve it. This activity was

followed by a class discussion on their proposed solutions, design strategy, and where the inclusive design strategies were utilized within their process.

Students completed a survey before and after the lecture. The survey evaluated how confidently students understood inclusive design, accessibility, and disabled communities. They answered questions on a scale of 1 – 5. Using the de-identified data, we calculated the percent increase in confidence levels for each question, as depicted in Table 1.

RESULTS

The student groups each gave brief presentations to share their final designs and ideation processes. Each idea began with the purpose of solving a fellow able-bodied classmate's frequent struggle, but was then expanded to encompass the needs of disabled communities as well. Discussion with the class about both tools recalled questions about the proposed user interface. All tools could be made further accessible by designing voice command capabilities or large buttons.

Group 1. The first group's idea was a wet pet food dispenser to solve the student problem statement that they struggle to remember to leave food out for their cat, who only eats wet food. The students drafted a product that can, on a timed basis, open packs of wet food automatically and dispense the contents into a dish for the pet. Students explained that while automating this process would be helpful for anyone, the product is especially helpful to people with certain disabilities. Anyone with limited mobility or finger dexterity would benefit from the device. Anyone struggling with memory would also benefit, since one would no longer need to remember exactly when to feed their pet to be a responsible pet owner.

Group 2. The second group addressed the common struggle with trying to open jars. The group's innovation was modeled after existing tools that make opening jars and bottles easier, except this tool had a more enclosed design, meant to keep the tool as safe as possible for those with limited vision as many of the existing tools have exposed parts. The design is meant to best accommodate anyone with arthritis, limited vision, missing limbs, or a lack of finger dexterity. Additionally, able-bodied people would benefit from a tool that could open tight jars independently.

Group 3. The third group aimed to solve the problem of forgetting to call people and return phone calls. Their solution was a service that would make the call for you—if one scheduled a call, they would receive a call at the scheduled time which would then connect them to the receiver upon your answering the call. This service intended to help forgetful students and employees was also thought about through the lens of helping those with cognitive disabilities. Additionally, not having to find the contact information of those called would help those who struggle with finding contacts in their phones due to visual impairments.

DISCUSSION

Both the results of the innovation activity and the increase in confident survey responses attest to the effectiveness of the lecture. Students learned about important standards and exceptional AT used to ensure accessibility for disabled communities. Additionally, by teaching students about how inclusive design improves products' overall usability as well as outcomes for target users and disabled users alike, students demonstrated their understanding through their projects and class discussions highlighting universal design.

In the survey, the question that resulted in the highest percentage increase was about the guidelines for accessible design and development. The 161.25% increase in confident answers for this question after the lecture series was over indicates that, while students

Table 1: Student surveys completed before and after the series, all questions were formatted as “On a scale from 1 to 5, how confidently can you:” with the subsequent question.

Survey Question	Student Evaluation Percent Increase
Define “accessibility” as the term relates to technology and media	28.78%
Give an example of inclusive/universal design	38.21%
Give an example of how accessible technology is used by people with disabilities	38.21%
Give an example of a technological barrier somebody with a disability might face	25.35%
Define the purpose of the Americans with Disabilities Act	98.00%
Explain guidelines for accessible design and development	161.25%
Consider accessibility and universal design during the design process	38.21%
How familiar are you with the accessibility features built into devices?	60.77%

before were unfamiliar with accessibility guidelines in design and development, the lecture made them far more aware. Similarly, the survey results showed a 98% increase in confident student responses to a question about the purpose of the Americans with Disabilities Act (ADA), a landmark moment in American history for disabled individuals. The ADA itself addresses many key points of accessibility design, making it a useful document for engineers to be familiar with.

One strength of this study was the inclusion of a guest speaker from a disability group who is also an expert in assistive design. Including Spencer Montan gave the students exposure to a disabled entrepreneur as well as an environment where spoken language interacts with signed language. Many students had never encountered a Deaf individual before or had never directly interacted with someone through an interpreter. When students asked questions, they were forced to be cognizant of the requirements that accessibility demanded of them, and each student responded positively to the experience.

A limiting factor of the study was time. Ideally, we would have had more time to lecture and would have given more time to students to research, draft, and design their ideas. Additionally, while many students had deafness on the mind when brainstorming ideas because of the guest lecturer's talk, involving experts from other disability groups could only have made the study stronger by exposing students to the experiences of other disability groups.

In conclusion, our study shows that, when given proper attention and nuance, education about disability groups and assistive design improves engineering classrooms by disambiguating community needs, providing steps towards achieving inclusion, and introducing students to ways of life they ordinarily would not be challenged with considering.

ACKNOWLEDGEMENTS

The team is grateful for the Teach Access grant program which provided the funding to Northeastern University for this series, and Spencer Montan and the NTID Center on Access Technology.

THE EFFECTS OF CEREBROSPINAL FLUID AND HYPERELASTIC MODEL ON ANEURYSM WALL VIBRATION USING HIGH-FIDELITY FLUID-STRUCTURE INTERACTION SIMULATIONS

INTRODUCTION

A cerebral aneurysm is a pathological dilation of an artery in the brain and its rupture is known to be a life-threatening condition. It is estimated that 3-5% of the population harbor aneurysms [1]. Throughout years of biomechanical research, computational fluid dynamics has been used to retrospectively correlate flows and shear stress with rupture status in search of a prospective clinical tool. However, the mechanisms of aneurysm growth and rupture are not fully understood.

Aneurysms produce sounds known as bruits that originate from either transitional blood flow or flow-induced vibration of the aneurysm wall [2]. To use these sounds as a non-invasive way of detecting aneurysms, clinicians have conducted acoustic measurements by placing a transducer on the eyelid [3]. These measurements have revealed a narrow-banded peak in the frequency spectrum, which is indicative of high-frequency vibrations [3]. From a mechanobiological perspective, vibrations have also been proposed as a potential cause of various disorders, such as poststenotic dilatation [4]. Despite this, the vibration of the aneurysm wall is not well studied and only a small number of recent studies have explored this phenomenon.

A recent study from Souche and Valen-Sendstad [5] showed that an aneurysm wall could vibrate at ~ 120 Hz in a high-fidelity fluid-structure interaction (FSI) simulation, which was previously reported *in-vitro* study [6]. This study was, to our best knowledge, the first one to numerically demonstrate the existence of wall vibration in a cerebral aneurysm, but the model included several limitations. In the present study, we focused on the two limitations of that previous study: the lack of response from the cerebrospinal fluid (CSF) surrounding aneurysms, and the lack of non-linearity in the material model. The results of simulations with different models are compared to examine the effects of these two model improvements on the frequency and amplitude of the wall vibration.

METHODS

We considered a single patient-specific geometry of a middle cerebral artery aneurysm, which was previously shown to exhibit weakly unstable flow with a prominent fluid frequency of 100-150 Hz [7] and vibrations in the range of 100-500 Hz [8]. FSI simulations were carried out using a high-

fidelity finite-element solver, turtleFSI [9]. The computational mesh was constructed by the Vascular Modelling Toolkit [10] with roughly 110,000 and 40,000 elements in the fluid and structure domains, respectively. Since the movement of an artery in the brain is restricted by its surroundings, we selected the deformable region to be in the vicinity of the aneurysm sac as shown in Figure 1(a). Prior to performing FSI simulations, a zero-pressure geometry was approximated by inversely applying the deformation obtained in a separate simulation. Inflow was prescribed as Womersley flow using a waveform shown in Figure 1(b) and the pulsatile cerebral perfusion pressure was applied at the fluid-structure interface in the range of 70-110 mmHg.

Figure 1: (a) is a computational domain where the part of the structure domain is removed to show the fluid mesh. Only the light red part is deformable. (b) represents waveform of the fluid velocity used at the inlet and the pressure used at the fluid-structure interface.

To account for the damping effects of the CSF on the deformation of the aneurysm wall, we specified the Robin boundary condition to the outer wall of the deformable region with the following formulation [11]:

$$\sigma_s \cdot n_s = -k_s d_s - c_s u_s, \text{ on } \Gamma^s. \quad (1)$$

where σ_s is the stress tensor of the solid, n_s is the outward normal vector at the solid surface, k_s and c_s are the elastic and viscoelastic response of the CSF, d_s and u_s are the deformation and the velocity of the solid, and

Γ^s represents the surface of the solid region. To determine the value for the coefficient k_s , c_s , we conducted a simple numerical experiment where a cylinder was submerged into the fluid with properties of CSF and forced to oscillate by inducing a body force in a very short time period. Based on the result of this numerical experiment and the assumption that the viscosity of CSF has dominant effect to the motion of aneurysm wall, we chose $k_s = 0$ and $c_s = 100 \text{ N} \cdot \text{s}/\text{m}^3$.

For the material model, we used the three-parameter Mooney-Rivlin (MR) model with the following strain energy density function [12]:

$$W = C_{10} (\bar{I}_1 - 3) + (\bar{I}_2 - 3) (C_{01} + C_{11}(\bar{I}_1 - 3)) + \frac{1}{D_1} (J - 1)^2. \quad (2)$$

where three parameters, C_{10} , C_{01} , C_{11} , are calibrated to match the experimental data from Robertson et al. [13]. Compared to the previously employed St. Venant-Kirchhoff (SVK) model, which behaves almost linearly, the MR model has higher non-linearity in its strain-stress relationship, which is more physiologically accurate.

RESULTS

To present a global overview of the deformation of the aneurysm wall, sac-averaged spectrograms shown in Figure 2 were generated following previously published methodology [14]. Here, the same threshold of -42 dB for the color (i.e., power) intensity was applied and the time frame was taken from the second cardiac cycle.

Focusing first on the effects of modelling CSF, a comparison of results with and without damping reveals a noticeable difference in amplitude of vibration. In the case of no damping, frequency bands near 300 Hz persisted throughout the cardiac cycle, but were quickly dampened after systole in the model that included CSF. It is worth noting that these narrow-bands were not completely eliminated with damping; they just have lower power and thus do not stand out as prominently on the spectrograms using these particular dB threshold.

Shifting focus to the effects of hyperelastic constitutive law, the SVK model had relatively higher frequencies than the MR model, notably in the narrow-banded spectrum $\sim 350 \text{ Hz}$ vs $\sim 300 \text{ Hz}$, respectively. Additionally, the amplitude of the vibration increased slightly from the SVK to MR model.

Figure 2: Spectrograms of wall displacements for all the models. The x-axis indicates the time while the y-axis shows the frequency, and the intensity of the color represents the amplitude of the frequency component.

DISCUSSION

To the best of our knowledge, this simulation is the first FSI study to investigate the impact of CSF on the vibration of a cerebral aneurysm. A

key finding was that the inclusion of damping from CSF in the model resulted in a reduction of the post-systolic narrow-band “ringing” that has been previously reported [8]. The narrow-bands were still present but with a decreased intensity, which is in line with clinical observations [2]. It has been observed that transitional flow is responsible for driving wall vibrations after peak systole and during early deceleration. However, the aneurysm sac continues to vibrate even after the flow has become laminar, likely as a result of the sac’s inertia. During the post-systolic phase, the flow instability has ended and the vibrations become free vibrations, not driven by any external forces. Therefore, it is likely that the effect of damping is more significant in the diastolic phase than the systolic phase. This stabilizing effect of CSF was previously shown against perturbations but with a simplified geometry [15]. Since the prominent bands remained in a similar regime with and without damping, it is suggested that the damping force affects the amplitude more than the frequency.

The utilization of a non-linear hyperelastic material model resulted in variations in the amplitude and frequency of the wall vibrations during the cardiac cycle. The amplitude increased and the frequency decreased, indicating that the MR model had a lower effective stiffness compared to the SVK model. Despite these differences, both models predicted similar patterns of prominent vibrations persisting into diastole, indicating that the overall biomechanical impact of the vibrations may be consistent.

In summary, we found that both damping and non-linear hyperelastic model can affect the vibration of the aneurysm wall. However, the locations of vibrations were consistent across different wall/damping models, which suggests that the biomechanical implications of the vibrations may be similar despite differences in their characteristics. The present study, however, only considered one specific geometry and value for the damping coefficient. Therefore, it is not clear how vibrations would be affected in other cases. As a next step, we will apply these improved models to a highly-unstable-flow aneurysm case and conduct a sensitivity analysis of the parameter. One limitation of the present study is that the Robin boundary condition may not fully represent the characteristics of the surrounding CSF, which also acts as an additional mass on the outside of the aneurysm. Another limitation is the uniform wall thickness, as the wall thickness is known to be heterogeneous. Nevertheless, the present work is an important step towards establishing a reliable and robust model of aneurysm vibrations.

INTRODUCTION

The innate immune response is facilitated by a range of different antigen-presenting cells, such as dendritic cells, that undergo surveillance of tissues for antigen. When a dendritic cell (DC) encounters antigen within peripheral tissues, its migration to the lymph node is mediated by gradients of chemokines, including CCL21, which is secreted by lymphatic endothelial cells. A fundamental understanding of how these gradients are formed and regulated has yet to be realized. They depend on complex physical and biological interactions, including diffusion, advection, scavenging, as well as extracellular matrix (ECM) and cell binding, among others.

To gain critical insight into chemokine gradient establishment, a microfluidic device was fabricated that allows for the recreation of specific sets of *in vivo* conditions with fine control in a reproducible manner. DC migration can then be analysed in response to known, controllable chemokine gradients, which cannot be achieved *in vivo*.

METHODS

Chip design and fabrication: A microfluidic chip was designed that facilitates the individual assessment of the effects of diffusion, advection, ECM binding and unbinding on chemokine gradients. The chip has a three-dimensional hydrogel region between two fluid channels (Figure 1), with four inlets and a common fluid outlet. Trapezoidal posts keep the hydrogels in place whilst allowing fluid, macromolecules, and cells into and out of the hydrogel. To generate controllable advection across the hydrogel, screw-actuated membrane valves have been placed between the hydrogel region and the fluid outlet [1]. Depending on the configuration of the screw deflections, a range of both positive and negative Peclet numbers can be generated.

The chip implements a “sandwich” hydrogel region, with two narrow outer hydrogels that envelop a central hydrogel. These outer hydrogel channels, made of 5 mg/ml Collagen I hydrogels, provide structure support to the central 1.4 mg/ml Collagen I hydrogel. This

facilitates collagen fiber spacing of 20-30 μm in the central hydrogel region, which we have previously determined to be critical to enable physiological DC migration.

Figure 1: Schematic of the microfluidic chip.

The microfluidic chips were cast with polydimethylsiloxane (PDMS) on a silicon wafer, and then subsequently cured at 80°C. Devices cut and bonded to glass slides using a plasma oxygen generator and baked overnight at 80°C to restore hydrophobicity.

Cell culture: The inguinal and mesenteric lymph nodes were dissected from wild type mice and digested using 0.2 mg/ml Collagenase P, 0.8 mg/ml Dispase and 0.1 mg/ml DNase I. DCs were then isolated from the digested fraction by magnetic cell sorting using the MojoSort Dendritic Cell Isolation Kit (BioLegend, San Diego, CA,

USA) and matured overnight in culture with 200 ng/ml of Escherichia coli LPS.

Live cell imaging: DCs were encapsulated in a 1.4 mg/ml Collagen I hydrogel and injected into the central hydrogel region, after injection and polymerization of the outer collagen hydrogel channels. The chip was transferred to a confocal microscope (Leica Microsystems Ltd, United Kingdom) with a custom environmental chamber for live cell imaging. Syringe pumps were used to deliver 100nM of AF647-conjugated CCL21 at 3 μ l/min. Z-stacks, 60 μ m in height, were acquired continuously every 4-5 s for 80 minutes. After experiment completion, cells were fixed *in situ* with 4% PFA and stained with MHCII, CD11c, and CD86 fluorescent antibodies. This allowed for post-hoc identification and tracking of immature and mature dendritic cells.

RESULTS

A gradient of CCL21 was established across the hydrogel region (Figure 2(a)). A rapid decay in CCL21 concentration was observed across the outer hydrogel region, decreasing from its source concentration of 100 nM to approximately 30 nM. This is owing to the reduced diffusivity of the 5 mg/ml Collagen I hydrogel. A refractive effect at the fluid-gel interface was observed and accounts for the increase in CCL21 concentration at the boundary. In the central hydrogel region, where DCs are encapsulated, a physiological concentration of CCL21 ranging from 30 nM to 5 nM was established [2].

DCs migrated in the direction the chemokine gradient (Figure 2(b)), from left to right. Analysis of the cell tracks indicate a preferential motion of the DCs along collagen fibers, referred to as contact guiding. This creates a persistence at a length scale equal to the size of the collagen fibers. The collagen fibers have a preferential vertical orientation due to the direction of the hydrogel injection, which results in DC migration in both x and y, rather than purely in the x-direction of the chemokine gradient. After experiment completion, cells were fixed and stained *in situ*, and a high-resolution z stack was taken to identify cells' phenotype (Figure 2(c)). Most cells positively stained for CD86, MHCII, and CD11c, indicative of a mature DC phenotype.

DISCUSSION

A novel microfluidic chip was developed that investigates the effects of transport phenomena on chemokine gradient formation, maintenance, and modification, including diffusion, advection, and binding. Work is currently ongoing to quantify chemokine binding to ECM substructures, including glycosaminoglycans, in the developed chip using a novel application of FLIM-FRET. This method can capture the transient binding and unbinding kinetics, which has not been previously realized.

The microfluidic platform described herein will enable an improved understanding of critical immunological processes that aid in protection from infection and drive pathology in a variety of diseases. The resulting quantitative knowledge base can facilitate the development of immunoengineered therapies involving chemokine gradient manipulation.

REGENERATIVE REHABILITATION OF MUSCLE DEFECT UNDER MECHANICAL STIMULATION: AN ORGAN CULTURE STUDY

D. Jacho (1), E. Yildirim-Ayan (1) *

(1) Department of Bioengineering, University of Toledo, Toledo, OH, USA

INTRODUCTION

Muscle damage and muscle strain caused by high-force lengthening contractions are among the most common muscle ailments associated with \$50 billion in health care costs annually in the US ^{1,2}. Recovery from a muscle injury or muscle strain includes a series of overlapping processes starting with inflammation and regeneration and subsequently remodeling¹. While physical therapy or mechanotherapy is the first line of non-invasive treatment method for muscle repair³, it is still relatively unclear how mechanical strain applied during mechanotherapy affects the muscle as an organ and cellular responses exposed to the loading. Our preliminary 3D in vitro data showed that mechanical loading exerted on cell-seeded scaffolds can initiate autocrine or paracrine tissue healing via mechanical strain amplitude-dependent manner³. In particular, 12% mechanical strain at 0.1Hz frequency on fibroblast residing within 3D tissue promoted the fibroblast-to-myofibroblast (FMT) differentiation with upregulation of α SMA and increased stress fiber formation³. Further investigation needs to be conducted to understand how supra-mechanical loading, such as 12% mechanical strain, affects the muscle tissue and cellular response using a physiologically relevant platform. Organ culturing can be a superior alternative to the 3D in vitro culturing platform because it maintains the original structural relationship between cells and their interactions. This setup also allows researchers to study the long-term effects of external stimuli.

The structural and molecular changes within the skeletal muscle tissue were analyzed to assess the inflammation and tissue regeneration range upon mechanical loading. To this end, a custom-built ex-vivo muscle organ culture system was used for 21 days to understand how 12% mechanical strain applied to the mouse leg (muscle tissue) affects the cellular response towards regeneration. The unloaded mice legs were used as a control group.

METHODS

Extraction of Mouse legs and Mechanical Stimulation under Organ Culturing Conditions.

Mouse back legs were extracted from 2-month-old mice. Legs were deskinning to expose the skeletal muscle tissue. Then, a longitudinal incision (~2mm) was made on the top lateral of the femur, followed by a blunt separation of the hip bone from the body. Extracted legs were kept in phosphate-buffered saline (PBS) with 3% penicillin-streptomycin on ice.

Following extraction, mice legs were vertically positioned on a computer-controlled custom-built muscle organ culture bioreactor. Legs were gripped-secure from the bottom and top bones to the plates of the bioreactor. A 12% mechanical tensile strain at 0.1 Hz stimulation was applied 4 hours a day for 21 days per our well-established protocols. 50% of new media was replaced every 4-5 days.

Gross Imaging and Scanning Electron Microscopy Analysis

After 21 days of organ culture, legs were extracted from the bioreactor and analyzed through optical imaging. Then, longitudinal incisions were made to remove sections of the tibialis anterior muscle tissue for scanning electron microscopy. Briefly, tissues were washed with PBS and fixed with 4% paraformaldehyde for 30 min. The samples were

dehydrated and in sequential ethanol solutions for 15 min each. Samples were then submerged into sequential ethanol/hexamethyldisilane (HDMS) solutions for 10 min each for image quality enhancement. Finally, samples were dry out overnight, gold-sputter coated and imaged.

Histological Analysis

To further evaluate the fibrotic area, myofiber bundle size, and the number of cells after mechanical stimulation, Masson's trichrome and hematoxylin and eosin staining (H&E) were carried out on the muscle tissues. Briefly, muscle tissues were incubated in 10% formalin after extraction, dehydrated using an ethanol gradient, and cleared with xylene before embedding in paraffin. The paraffin-embedded samples were sectioned at 5um thickness using a microtome and mounted on microscope slides.

Molecular Analysis

The gene expression analysis was performed using real-time PCR to understand the specific molecular changes in the skeletal muscle regeneration and fibrosis processes. Tissues were harvested and analyzed. RT-PCR was performed using TaqMan SYBR Green (Bio-Rad, USA) according to the manufacturer's protocol. The relative gene expression for fold difference between control and stimulated samples was obtained using $\Delta\Delta C_t$ method, and GAPDH as a housekeeping gene. Markers for inflammation, myogenesis, and fibrosis were checked.

Statistical Analysis

Statistical Analysis was conducted using RStudio. Data were analyzed for normalization, and proper statistical analysis was selected. Student's t-test was carried out where appropriate. Symbols on top of each bar profile summarize the student's t-test of at least two independent groups ($P < 0.05$). The data is reported as the mean \pm SE.

RESULTS

Figure 1 shows the gross observations from the control and stimulated legs. The data show significant morphological differences in the integrity of the tissue and a marked increase of H&E staining in the stimulated group. The H&E images showed increased cellularity and that the tissue regions of the stimulated samples were significantly occupied with bridging tissue. Masson's trichrome staining also demonstrated that fibrosis was increased upon mechanical stimulation. The number of cluster cells (area of fibrosis) increased in the stimulated group (Fig.1C). We further investigate myogenesis and fibrosis, figures 2 and 3 show the RT-PCR results for fibrosis markers (α SMA), myogenesis markers (Pax7, MyoD, and Myogenin) and pro and anti-inflammatory markers. The gene expression data demonstrated that 12% strain-stimulated legs significantly enhanced the expression of α SMA almost 3-fold.

Similarly, IL1 β and TNF α (pro-inflammatory) showed a significantly increased expression compared to the control group, while anti-inflammatory markers were downregulated. Additionally, myogenic markers were also upregulated. Pax7, MyoD, and Myogenin increased by 6-, 4-, and 2-fold, respectively, compared to the unstimulated control group.

Figure 3. Gene expression analysis of fibrosis, pro- and anti-inflammatory markers after 21 days of organ culture

DISCUSSION

The data presented in this study support our previous 3D in vitro investigations that mechanical stimulation plays a more significant role in understanding the regenerative process of tissues. Muscle tissues exposed to 12% mechanical strain demonstrated an increase in inflammation and regeneration, as seen by the bundle's tissue bridges formed upon stimulation. SEM imaging also reflects fiber diameter and alignment increase, correlating with the increased number of bundle bridges in histology images. PCR also confirmed this by the increased expression of myogenesis and fibrosis markers. Specifically, a decrease in fiber size but not fiber number is characteristic of the downregulation of Pax7, while an increase in myogenic markers enhanced fiber production and marked muscle. These findings suggest that acceleration of the muscle healing process can be achieved through mechanical stimulation.

Moreover, these findings presented here are the first demonstration of a thriving organ culture set up for 21 days while preserving cell viability and molecular changes. Additionally, our results indicate that skeletal muscle regeneration with external stimulation can overcome previous treatments and studies done with conventional setup (2D in vitro) treatments.

In conclusion, our study showed that mechanical stimulation in the form of tensile strain could accelerate the progression of skeletal muscle healing. This process of mechanical stimulation can be further applied with the addition of cell-based therapies for skeletal muscle injuries from laboratory to clinical applications.

INTRODUCTION

Military aircrew are exposed to elevated loads on their lumbar spine during flights associated with their seating posture, high amplitude accelerations, body-borne equipment, and low frequency vibration ([1-2]). Low back pain in airmen occurs at a higher rate than the general population due, in part, to this loading ([3-4]), in which the intervertebral disc (IVD) annulus fibrosus (AF) is particularly susceptible. Understanding how these loads can damage the AF is important to develop effective mitigation solutions and strategies to reduce injury risk and improve aircrew effectiveness. Finite element modeling can be used to understand injury mechanisms unique to this environment. Modeling enables comprehensive parametric studies to be performed, as occupant and environment related factors within the model can be incrementally changed to elucidate their influence on spine biomechanics. However, accurate mechanical properties of the AF are needed to produce realistic prediction of spine biomechanics. Previous studies used postmortem human subjects (PMHS) to investigate elastic and failure properties of the AF and some inconsistencies among studies regarding the role of different factors in AF biomechanics were noted. For example, some studies reported that AF properties varied between different regions of the disc ([5-8]), whereas others reported no significant regional differences ([9-10]). Elastic modulus (E) was also shown to be dependent on spinal level whereas ultimate tensile stress was independent of spinal level ([9]). One contributor to these inconsistencies across studies may be the quality and type of tissue. PMHS are limited in supply and often of advanced age. Because the AF degrades with age ([11]), previously reported mechanical properties may have been derived from degraded tissue. This can increase variability among specimens/studies in addition to the measured properties not being representative of younger military aircrews. In turn, these factors can all affect the accuracy of a finite element model. An alternative to PMHS are animal models. Hedlund et al ([12]) has shown that porcine cervical spines offer an

acceptable substitute to PMHS lumbar spines due to their anatomical and range-of-motion similarities. In addition to anatomical similarities, young porcine cervical spines are free of age-related degenerative changes making them more applicable to a younger military population. The goal of this study is to characterize elastic and failure properties of the AF across different anatomical regions and levels using a porcine model to determine its applicability for use in modeling efforts of AF damage experienced by aircrew.

METHODS

Fresh porcine cervical spines were acquired from a local abattoir (Johnsonville, LLC). Specimens were refrigerated until the day of testing. All specimens were tested within five days postmortem. On the day of testing, AF test specimens were dissected from C2/3 to C6/C7 IVDs. Each IVD was separated into four anatomical regions: anterior, posterior, and two lateral regions. Test specimens were cut with a scalpel from the outer third of each anatomical region and oriented in the circumferential direction relative to the vertical axis. The targeted width of each specimen was the height of the disc, the targeted length was at least 10 millimeters, and the targeted thickness was approximately one millimeter. Test specimens were then hydrated in a bath of physiologic saline for approximately one hour to ensure uniform hydration levels between specimens. Specimen length, width, and thickness were measured using ImageJ Software (Version 1.53) following hydration and prior to testing. A fine metal mesh was secured to each end of the specimens to prevent slippage during tensile testing and the specimen was mounted in the load frame (ElectroForce 3200, TA Instruments, New Castle, DE) using grips with knurled contact surfaces. Because individual collagen fibers are oriented ± 30 - 45° off the circumferential axis ([13]), and not continuous around the circumference of the AF, care was taken to ensure collagen fibers were clamped on both free ends.

The loading protocol consisted of preconditioning the specimens with five cycles of 20% strain at 0.5 Hz followed by a five-minute recovery. They were then pre-loaded to 0.1 N and held for ten minutes to allow for stress relaxation equilibrium. Finally, specimens were quasi-statically distracted to failure at a rate of 0.005 mm/s. As temperature variations during mechanical testing can affect mechanical properties of spinal tissue [14], specimens were submerged in a saline bath and heated to a constant temperature of 37°C. Force and displacement were measured via a 45-N loadcell (TA Instruments, New Castle, DE) and a linear variable differential transformer (LVDT) internally within the load frame, respectively, at a rate of 5 kHz. Force was converted into stress using the mid-length cross sectional area of the specimen as measured prior to the initiation of the loading protocol and displacement was converted into strain based on the length of the specimen at the 0.1-N pre-load step in the loading protocol. Stress versus strain was subsequently plotted for each specimen. E and ultimate tensile stress and strain for each specimen were then calculated. E was calculated as the slope of the linear region of the stress/strain curve. Ultimate tensile stress and strain were the point at which each specimen reached peak stress. To analyze level and regional based differences, two factor ANOVA tests ($p < 0.05$) were used with a Tukey post hoc test to determine if any significant differences existed.

RESULTS

A total of 79 specimens were tested across five porcine cervical spine IVDs with four anatomical regions per level. It was determined that no difference existed between the right and left lateral regions of the AF ($p > 0.05$), and consequently, lateral specimens were grouped together. All statistical tests analyzing regional based differences were subsequently conducted with three groups: Anterior, lateral, and posterior. Each specimen had an average clamped length of 4.6 ± 1.1 mm, a width of 5.8 ± 1.4 mm, and a thickness of 1.0 ± 0.3 mm.

Ultimate stress was significantly dependent on spinal level ($p = 0.001$), but not anatomical region ($p = 0.8$). C3/C4 had the highest ultimate stress, and the ultimate stress for each level decreased inferiorly and superiorly of this level (Figure 1). Tukey post hoc tests determined that ultimate stress of C3/C4 was significantly higher than C2/C3, C5/C6, and C6/C7.

Ultimate strain was not significantly dependent on spinal level or anatomical regions ($p > 0.05$). The average ultimate strain across all specimens was 0.51 ± 0.16 . While the strains were not dependent on spinal level, it was found that ultimate strain was lowest for C2/C3 (0.45 ± 0.14) and increased slightly each spinal level until peaking at C6/C7 (0.57 ± 0.16).

Figure 1: Mean E (black), ultimate stress (light grey), and ultimate strain (grey diamond). Both stress and elastic modulus were determined to be significantly dependent on the cervical spinal level. Error bars display + one standard deviation.

Elastic modulus was significantly different across each of the cervical spinal levels ($p = 0.004$), but not across the anatomical regions of the AF ($p = 0.7$). C3/C4 had the stiffest E, and E for each level decreased inferiorly and superiorly of this level, similar to the ultimate stress behavior (Figure 1). Tukey post hoc tests determined that E of C3/C4 was significantly stiffer than C2/C3, C5/C6, and C6/C7.

DISCUSSION

This study quantified elastic and ultimate tensile mechanical properties of isolated porcine AF specimens. These data are valuable in developing more refined finite element models to predict intervertebral disc mechanics in military environments. These results demonstrated that spinal level is an important factor in the biomechanics of the IVD, but mechanical properties did not vary throughout the different regions of the disc. Level dependent stiffness variation was expected as Stemper et al. had previously reported level-based differences for human lumbar AF ([9]). Compared to the present study, porcine E ranges varied from 9 MPa to 18.5 MPa, they found human AF to have a slightly stiffer response, ranging from 15 MPa to 22 MPa. Their slightly stiffer response may be explained by the difference in test specimen thickness (0.8 mm compared to our 1 mm), as Werbner et al. has shown that thinner specimens, have a stiffer response ([15]). The overall strength of the AF reported in the present analysis was also dependent on level, ranging from 2.86 to 4.97 MPa, which is similar in magnitude (2.25 - 10.30 MPa) to previous studies ([6], [8-9]). Ultimate strain was not dependent on the level or the region, in agreement with previous studies ([9]). With the data generated by these experiments, a more accurate model of the human AF can be created. The elastic and failure properties found can provide valuable information to characterize the dynamic response of the AF, and ultimately, how the forces experienced by aircrews may lead to degradation of the AF. This knowledge will result in a more accurate finite element model of the AF that can be used to better understand degradation of the AF and how to reduce the risk of it occurring to future generation of military aircrews.

INTRODUCTION

Patients with Type-B aortic dissection (TBAD) exhibit delamination of the descending thoracic aorta wall distal to the left subclavian artery. In the presence of one or more tears of the intima, a so-called false lumen (FL) is formed in parallel to the effective, true lumen (TL), both separated by a dissected membrane called the intimal flap. In the acute phase, this leads to altered hemodynamics with an in-out flow of blood from the FL. Endovascular treatment of TBAD with a stent graft aims to interrupt the exchange of blood between the TL and FL to enhance FL thrombosis. The long-term prognosis of patients with TBAD largely depends on the extent of thrombosis that can be achieved in the FL, with clinical studies indicating that partial FL thrombosis has a negative impact on the long-term mortality risk in patients [1].

Little is known about the (biomechanical) mechanisms underlying the association between partial FL thrombosis, patient outcome and progression of disease. Some hypothesized that pulsatile inflow through the intimal tears into a lumen with impaired outflow (when there are no re-entry tears) would increase blood pressure in the FL which leads to a higher risk of lumen expansion, dissection and rupture. However, we have previously estimated the direct effect of inflow on FL pressure (arising from dynamic pressure) to be limited to 5mmHg [1]. In addition, aortic side branches sprouting from the FL provide alternative outflow, and may thus prevent pressure build-up within the FL. We also stated that realistic computational fluid-structure interaction (FSI) models accounting for in- and outflow of the false lumen via intimal tears and side branches may help elucidate the pressure build-up within the false lumen and mechanical stresses within the aortic wall [1].

The aim of this study is therefore to setup FSI simulations in a model of an aortic dissection that allows the assessment of impact of the outflow via side branches emanating from the FL on the pressure build-up inside the FL, the transmembrane pressure and aortic wall stresses.

METHODS

An idealized dissection model with an axial length of 60 mm, a dissection length 40 mm and two tears were generated using the in-house geometry and mesh generation tool PyFormex [2]. We define two new parameters called extent of dissection ($s/S = 0.66$) where 's' is the circumference of the FL and 'S' is the total aortic circumference and flap thickness ratio ($t/T = 0.4454$) where 't' is the thickness of the dissected membrane and 'T' is the overall aortic thickness. To the resulting configuration, a side branch with a diameter (d) of 3 mm (~0.1 time the diameter of the aorta) and a length of 15mm was added in the FL resulting in a geometry as seen in Figure 1.

Figure 1: 3D model indicating the fluid model boundary conditions

The resultant structural model was meshed using 151128 linear tetrahedral (C3D4H) elements in Abaqus (Dassault Systems, USA) and the interior lumen was filled with 374592 tetrahedral elements using ICEMCFD (Ansys Inc, PA, USA). A flat velocity profile was prescribed at the inlet [3] and scaled to match a mean flow of 3.87 l/min [4] in the descending aorta. Downstream, 3-element windkessel models (WK)

were imposed and the WK parameters were tuned to achieve diastolic/systolic pressure of 80/120 mmHg. Two cases were considered: one with 5% and the other with 0.5% of the total flow through the side branch. For the soft tissue, a linear elastic model was considered to model the material properties chosen from Delpano [5]. Stiffness of the aortic tissue was 5.39MPa and that of the intimal flap was 0.51MPa. Nodes at the inlet and outlets were fully constrained except for movement along the radial direction. Initial stresses in the structural model without a side branch were determined using the pre-stretch algorithm previously implemented by Famaey [6]. The resulting stresses were mapped to the configuration with side branch using nearest neighbor interpolation using an in-house implemented python script.

The governing fluid equations were solved using the finite volume solver Fluent (Ansys Inc, PA, USA) and structural equations were solved using the finite element solver Abaqus (Dassault Systems, USA). Coupling between the flow and structural solver was performed using the in-house coupling code CoCoNuT [7]. A partitioned FSI simulation where 72 cores were used for the fluid solver and 48 for the structural solver took ~27 hours for four cardiac cycles where a time period of 0.6 seconds for each cardiac cycle was chosen.

RESULTS & DISCUSSION

Figure 2: Pressure in Pa at peak systole when (a) 0.5% and (b) 5% of the total flow is prescribed at the side branch with top panels indicating the longitudinal and bottom panels indicating transversal cuts

Since the intention of this study is to assess the impact of outflow via side branches, pressure variation across the TL and FL are studied. As observed from Figure 2, an increased side branch outflow resulted in an increased pressure in the TL at systole, leading to an increased transmembrane pressure difference (TL-FL) of 4.1 mmHg compared to 3.2 mmHg with reduced flow through the side branches. A localized pressure drop is observed in the side branch when there is an increased flow which can be attributed to the reduced resistance value at this outlet.

Maximal principal wall stresses are shown in Figure 3 for the case with increased flow through the side branches. Given the relatively small differences in residing pressure, stress differences between both cases studied are limited. Note that our approach to generate the model leads

to relief of the initial stresses of the intimal flap as the aortic wall delaminates. Stresses on the flap thus remain lower even at peak systole and regions of higher stresses are observed on the outer aortic wall. This is consistent with increased displacement observed in the outer walls compared to the intimal flap, even though flap motion was limited (0.9 mm displacement in the intimal flap at peak systole) and FL volume changes were mainly due to outer wall expansion rather than flap displacements. This can be attributed to increased s/S, high membrane thickness and material stiffness in the configuration. To indicate the influence of material stiffness, Baumler [8] showed that reducing the flap stiffness to 0.02 MPa (currently used stiffness is 0.51MPa) with simplified properties showed flap motion mimicking motion observed in-vivo.

Figure 3: Max principal stresses (Pa) at systole when there is 5% of total flow through the side branch (very similar results were obtained for the other case).

While a partitioned FSI study or even a numerical study that includes variable flow through side branch in the FL has never been studied, there are some limitations which need to be addressed. Even though realistic initial stresses are used, rather simplistic material properties are considered for the flap and the aortic tissue. Nonetheless, we present promising initial results of pressure variation in the TL and FL with variable flow through the side branch. Future work would also include a fully coupled simulation with lower values of (s/S), thinner and less stiff intimal flap in patient-inspired geometries. These additional parametric simulations would give us a broad(er) understanding of geometrical and material influence on pressure distribution for variable outflow through side branches in the FL in vivo.

INTRODUCTION

Fibroblasts are highly sensitive to the biomechanical and biochemical cues of their residing niche [1]. During wound healing, inflammatory stimuli leads to aberrant collagen remodeling [2], and pro-regenerative stimuli leads to myofibroblast activation, resulting in excessive deposition of collagen I [1, 3]. The fibrotic matrix, in turn, impacts the phenotypic shift of fibroblasts, contributing to a vicious cycle of scar formation [1, 3]. Type V collagen, a minor regulatory collagen, plays a key role in regulating collagen I fibril assembly in vivo [4], and thus, could be a central player in this process. Indeed, atrophic scar formation is a prevalent symptom observed in patients with classic Ehlers-Danlos syndrome (cEDS), a connective tissue disorder caused by the mutation of human *COL5A1* gene [3]. Understanding the role of collagen V in fibroblast mechanosensing can provide new insights into the cell-matrix crosstalk of fibrosis. This study aims to determine how the deficiency of collagen V alters fibroblast response to external inflammatory and mechanical stimuli.

METHODS

Fibroblast culture. Primary normal adult human dermal fibroblasts (ATCC: HDFa) and collagen V mutant cEDS fibroblasts (ATCC: JaySen) were maintained in complete DMEM. To provide inflammatory stimuli, cells were treated with the inflammatory cytokine, TNF- α (20 ng/ml) to simulate M1-macrophage-induced proinflammatory response, or DMEM as a control. CytoSoft gels (Advanced BioMatrix) with Elastic Modulus of 2 kPa (soft) and 64 kPa (stiff) were used to subject fibroblasts to mechanical stimuli. **Immunofluorescence imaging:** Fibroblasts were stained with F-actin/phalloidin (ThermoFisher), and anti-FAK antibodies (ThermoFisher) and imaged (Leica SP8). **Cell-derived matrix (CDM) generation:** Cells were grown on 35 mm glass dishes coated with 0.2% bovine skin gelatin. Upon reaching confluency, L-ascorbic acid was supplemented every 2 days for 14 days. Cells were

denuded and resulting CDMs were stained with Succinimidyl Ester (ThermoFisher) and imaged via a Zeiss LSM700 Confocal Microscope. **AFM-nanoindentation** was applied on the CDMs to measure indentation modulus (in kPa), using a microspherical colloidal tip ($R \approx 5 \mu\text{m}$, $k \approx 0.03 \text{ N/m}$, HQ: CSC38/tipless/Cr-Au, NanoAndMore) and a Dimension Icon AFM (BrukerNano). The loading portion of the resultant force-indentation depth curve was then fit to the finite-thickness corrected Hertz model [5] via least-squares linear regression to calculate the effective indentation modulus, E_{ind} , following our established procedures [6, 7]. **Statistical analysis:** An unpaired two-sample student's *t*-test was used to determine any significant differences in CDM indentation modulus. In all tests, the significance level was set at $\alpha = 0.05$.

RESULTS

The reduced collagen V expression in cEDS cells was confirmed by decreased collagen V staining relative to the normal control (Fig. 1a). Also, cEDS cells showed higher cell density and DAPI staining, indicating loss of collagen V may lead to accelerated cell proliferation. On the soft substrate, both groups expressed low amount of F-actin, and we did not notice substantial morphological differences between the normal and cEDS cells (Fig. 1b). However, when seeded on the stiff substrate, cEDS cells adapted a more elongated morphology. In alignment with this morphological change, the F-actin cytoskeleton also became more aligned along the long axis of cEDS cells. The contrast was further aggravated when cells were stimulated with the inflammatory cytokine, TNF- α (Fig. 1b).

When characterizing focal adhesion formation, we did not detect appreciable changes in FAK expression in the control group with or without TNF- α stimulation, with notable expression along the actin fibers, as shown by zoomed-in green rectangle (Fig. 2). For the cEDS

group, we did not observe any notable differences in FAK expression under normal culture conditions relative to the control. When stimulated with TNF- α , there was a marked decrease in FAK expression along the fibers (Fig. 2). Meanwhile, cell derived matrices (CDMs) from the cEDS fibroblasts developed a significantly higher indentation modulus (Fig. 3a), as well as a denser matrix in comparison to those produced by the normal cells (Fig. 3b).

DISCUSSION

This study highlights the important role of collagen V in the inflammatory phase of wound healing. Studies have shown that collagen V regulates the expression of integrins in human cell lines [8]. While we have not elucidated the role of collagen V in integrin expression patterns yet, this study provides direct evidence on the impact of collagen V loss on altered fibroblast mechanotransduction, as shown by changes in F-actin expression (Fig. 1) and FAK localization (Fig. 2). It is widely known that integrins often serve as direct mechanotransducers and are crucial in regulating downstream biomechanical signals [9]. Our data suggest that despite the low concentration of collagen V in vivo, changes in F-actin dynamics and FAK expression due to the collagen V deficiency may result in the change of types and expression of integrins. This, in turn, would disrupt mechanosensitive pathways that are crucial to tissue homeostasis or pathogenesis, such as YAP/TAZ, Rho/Rock, Notch and Wnt signaling [10, 11]. For example, stimulation with inflammatory cytokines such as TNF- α would further perturb these mechanosensitive pathways, and collagen V could play an important role in mediating the mechano-inflammatory response of fibroblasts, as supported by the altered FAK pattern in TNF- α -treated cEDS fibroblasts (Fig. 2).

When assessing the matrix mechanics of collagen V deficient CDMs, we noticed a marked increase in indentation modulus when compared to the normal group (Fig. 3a). This could be due to altered fibril assembly of the CDM in the deficiency of collagen V. For example, we noticed a porous matrix deposition in the healthy group, while cEDS matrices were denser (Fig. 3b). These observations corroborate the canonical role of collagen V in regulating collagen I fibrillogenesis and limiting aberrant fibril lateral fusion or alignment [4]. Building on our observed impact of collagen V on the CDM at normal conditions, our ongoing studies are further investigating the roles of collagen V in mediating the CDM formed under inflammatory stimuli. Integrating these results with the roles of collagen V in regulating integrin activities, our findings provide a basis to elucidate a new mechanobiological role of collagen V at the cell-fibrous matrix interface under inflammation. This would provide a basis for developing collagen V-based biomaterials to modulate fibroblast immunoresponses and injury-induced fibrosis.

INTRODUCTION

Thoracic aortic aneurysms affect 17,000 Americans annually, with a 90% mortality rate when the aneurysm ruptures [1]. When determining the risk of rupture, the ability to account for changes in aortic material property due to its remodeling is important. However, this requires a large amount of data. Various studies have used different imaging modalities in humans to try to estimate aneurysm or aortic wall mechanics *in vivo* [2]. However, there is a lack of data on (1) a set of *in vivo* images that could be used to estimate aortic wall mechanical properties, and (2) the corresponding data on the true mechanical properties of the wall of the same sample *ex vivo* [2].

Wild-type mice infused with angiotensin II (Ang-II) are often used to study the development of thoracic aortic aneurysms. Ang-II increases the pressure within the vessel [2], and the aorta, under abnormally high pressure, will stiffen, thicken, and dilate, increasing propensity to develop an aneurysm and rupture [3]. This model system presents an opportunity to generate the desired data set.

In addition, many studies use population-based, generalized growth parameters and geometry [4]. Yet, due to large variability in complications associated with thoracic aortic aneurysm [5], mouse-specific data would be more valuable. However, difficulty in obtaining non-invasive longitudinal mechanical data impedes efforts in the development of aneurysm growth model on an animal-specific level. Therefore, this study focuses on generating non-invasive mechanical data from ultrasound images in Ang-II infused mouse models, with results validated against biaxial extension-inflation tests [6].

METHODS

The non-invasive mechanical testing method used in the current study is based on inverse finite element (FE) and computational fluid dynamics (CFD) models, fitted to vessel deformation obtained from volumetric ultrasound images, as illustrated in Fig 1. It can be described thusly: first, ultrasound images were obtained from three, 16-week-old mice that had been infused with 1000ng/kg/min Ang-II for 4 weeks,

Figure 1: Inverse Finite Element Approach. (a) Aortic wall is segmented and tracked from 4D ultrasound image. (b) CFD is used to determine wall stresses. (c) FE model is used to calculate wall displacement from stresses. (d) Optimal FE stiffness is determined.

during which the aorta was expected to grow and remodel [2]. 4D ultrasound images of the thoracic aorta were obtained from a high frequency ultrasound system (25-55 MHz, Vevo3100, VisualSonics), resulting in approximately 0.03x0.03x0.1mm resolution at 40 frames per cardiac cycle. The ascending and proximal descending thoracic aorta were then segmented, and deformation was tracked over the cardiac cycle with B-spline Fourier-based image registration, as described and validated in [7].

Velocity at the ascending, descending, and the three branches of the aortic arch were obtained by pulsed wave Doppler imaging. Those velocities and the tail cuff pressure of the mice were used to calibrate a resistor-capacitor-resistor (RCR) model of the downstream circulation for CFD (Fig1b), via differential evolution [8]. CFD simulation was then performed with Ansys Fluent to obtain traction forces on the aortic wall.

The traction forces were then used as loads for an FE model of the aortic arch in FEBio. Branch ends had prescribed deformation based on the ultrasound images. Robin boundary conditions were assigned at the outer vessel wall to describe stiffness of the surrounding tissue and loads from CFD applied to the inner vessel wall of the unloaded aortic geometry (Fig1c). The unloaded geometry of the aorta was obtained by gradual reduction of its radius until the computed loaded geometry during systole matched the *in vivo* ultrasound image (Fig1d).

A quasi-incompressible neo-Hookean model was used:

$$W = \frac{\mu}{2}(I_1 - 3) - \mu \ln J + \frac{\lambda}{2}(\ln J)^2$$

$$\mu = \frac{E}{2(1 + \nu)}, B = \frac{\nu E}{(1 + \nu)(1 - 2\nu)}, \nu = 0.45 \quad (1)$$

where W is the strain energy density function, I_1 is the first invariant of right Cauchy-Green deformation tensor, J is the determinant of the deformation gradient tensor, μ is shear modulus, B is the bulk modulus, and ν is the Poisson ratio, taken to be close to incompressible. For the model, the Levenberg-Marquardt algorithm was used to find the optimized parameter value E_{opt} that minimized the disparity between aortic deformation from ultrasound images (\vec{X}_{US}) and FE model (\vec{X}_{FE}), given by the following equation:

$$E_{opt} = \operatorname{argmin}_E (|\vec{X}_{US} - \vec{X}_{FE}(E, \nu)|^2) \quad (2)$$

RESULTS

There exists a neo-Hookean parameter (E) that minimizes the tracked displacement error for the three mice studied (values in Fig 2). The displacement error curves for the three mice maintained the same shapes: the error increases drastically at low E and plateaus at high E as the vessel becomes effectively rigid. The geometrical fit can be observed qualitatively from the ultrasound and FE images in Fig 3a and 3b during diastole and systole, respectively.

Comparison between mechanical testing and FE model is done with the stress-strain curve shown in Fig 3c. The range of stretches displayed (circumferential and axial) were within diastolic to systolic ranges, accounting for additional axial and circumferential pre-stretch. Due to the material model, the FE result is nearly linear with overlapping lines for different λ_z values, in contrast to the four fiber family models, which can isolate the circumferential and axial stiffness.

DISCUSSION

In this study, a linear-based, hyper-elastic material model was used, which is common for inverse FE models [9]. Fiber-based material models, however, are favored in forward FE problems in arteries [10]. Fiber-based material models were also tested but converged to an isotropic matrix with neo-Hookean behavior. This effect likely arises from the small range of strains induced by diastolic to systolic pressure changes, and from the single loading condition (pressurization). The resulting stress-stretch curve could be fitted with linear relationship (Fig 3c).

Comparison between *in vivo* and *ex vivo* material property estimations from the same tissue have been performed previously, but such studies are uncommon [2]. Comparisons are often based on higher resolution CT scans on larger subjects, with errors in the material property estimation ranges of 10-25% [12]. The current study resulted in larger errors despite a similar methodology. However, direct comparisons between the results in this study against the others are difficult to make due to different material models, studied vessels, and image quality. With respect to the image quality, relative to the size of the aorta, the ultrasound image in the current study has ~40% lower resolution than CT scans. An increase in Gaussian noise on the image by 5% can result in increased error of material properties estimation by 1.5% [13], and this effect might not be additive, but multiplicative.

One of the largest uncertainties in the inverse FE approach is the determination of the unloaded geometry or the pre-strain of the *in vivo* geometry [14]. Indeed, the actual *in vivo* axial pre-stretch of the geometry is unknown and is often directly prescribed in modeling studies [11]. Similarly, in this study, the axial pre-stretch was assigned based on the excised unloaded geometry. Increases in the axial pre-stretch would reduce the approximated material stiffness, as the material

needs to be more compliant to ensure that pressure would still cause radial deformation against the pre-tensioned vessel.

INTRODUCTION

Achilles tendon ruptures (ATR) have increased 10-fold in the past few decades[1]. Lower-leg functional deficits include decreased heel-rise height, heel-rise work, reduced plantar flexion strength, and decreased ability of the ankle to generate power[2]. These deficits persist as far out as 14 years after injury[3]. The cause of long-term functional deficits remains unclear and is thought to be multifactorial. Structural changes in the tendon-muscle unit after ATR are strongly related to deficits in plantarflexion function. Specifically, ATR results in long-term tendon elongation, increased tendon area, altered mechanical properties, and reduced calf muscle volume. These structural changes rapidly develop over the first weeks of recovery, slowly progress for a few months after injury, and change very little thereafter. The rapid initial development of muscle and tendon abnormalities coincides with the period of no weight bearing or partial weight bearing of current rehabilitation protocols. Neuromuscular electrical stimulation (NMES) can potentially provide muscle activity and mechanical stimulus to the healing tendon during the first weeks of recovery to minimize the large initial decline. NMES can positively impact several of the factors affecting recovery from ATR and has been successfully applied as part of rehabilitation protocols for knee surgery to preserve muscle volume and strength[4]. Therefore, NMES can potentially attenuate muscle atrophy during the first weeks of recovery after ATR repair surgery. To safely apply NMES, the tensile forces need to be modulated based on the strength of the healing tendon. Unfortunately, there is limited information about the mechanical properties of the Achilles tendon during the early stages of healing (first 4 weeks). Shear wave elastography (SWE) is an imaging method that quantifies the healing tendon's mechanical properties without applying load. It has been shown that the shear modulus measured via SWE is correlated to Young's modulus[5] and the ultimate tensile strength of the tendon[6]. Therefore, the shear modulus can serve as a surrogate property to evaluate the tensile strength of the tendon during the first weeks of healing after an Achilles rupture. This study aims to determine the tendon mechanical properties in the first 12 weeks of healing for patients undergoing surgical repair and a standard rehabilitation protocol.

METHODS

This study was approved by the Penn State University IRB (STUDY00016462). The SWE tests on participants were performed at Penn State Biomechanics and Imaging Lab, and Hershey Medical center. Patients who participated in this research consented before any data collection. All the participants were treated surgically in the same procedure without adding grafts. After surgery, participants received almost the same rehabilitation program, including the use of CAM Walker Boot from week 1, and weight bearing from day 10. To avoid any stress on tendons at the time of performing SWE measurements, the participants laid down on the bed, in a prone position and their legs were on the bed.

Figure 1: B-mode images of the a) Contralateral healthy Tendon and b) Injured Tendon at week 12

The SWE measurements were obtained by applying light skin compression on desired points, using a handheld transducer. The colored SWE map was provided for each participant by utilizing B-mode imaging. The measurements on a defined ROI window were captured. The shear speed was measured on the surgically treated part of the ATR and the collateral leg on any weeks 2, 4, 6, and 12 after the injury. Figure 1 shows B-mode images of the healthy and injured tendons of one of the participants at week 12. The green arrows illustrate the boundaries of the tendon. The red rectangle shows the region where the speed map was calculated. An ROI of approximately 10x10 mm was used.

diameter was selected inside the tendon to calculate a representative value of the shear wave speed. Each measurement was repeated 5 times. Measurements were taken from both legs to calculate the stiffness ratio. The ankle angle was measured in both the injured and the contralateral legs. The difference in plantar flexion angle of both feet at rest in the prone position was measured as an indication of tendon elongation.

RESULTS

Eleven patients were recruited for this study (4 women and 7 men). The average age was 32.6 y/o. Figure 2 shows the ratio of the stiffness of the injured tendon to the contralateral one in different weeks and the curve fitted on the average of these results. ANOVA analysis resulted in $p = 0.012 < 0.05$, $F = 4.8713$, $F_{crit} = 3.1967$, and this means that time has a significant effect on the stiffness ratio. Figure 3 shows the absolute value of the angle differences in the healthy and injured legs. The ANOVA analysis on results illustrated in figure 3, resulted in $p = 0.418 > 0.05$, $F = 1.0128$, $F_{crit} = 3.41$. Meaning that there is not a significant difference between angles with time.

Figure 2: Change of ratio of the Stiffness between the injured leg and the healthy leg

Figure 3: Healthy and Injured leg angle differences

DISCUSSION

The stiffness (shear modulus) ratio illustrated in figure 2, shows the increasing trend as expected for healing tendons. Previous studies have shown that the shear modulus is proportional to the ultimate strength of the tendons[6]. Therefore, the ratio presented here can also be viewed as a percentage of tendon strength re-gained as a function of time after rupture. This information is crucial for the development of rehabilitation techniques.

Week 12 is particularly important in current rehabilitation protocols because it marks the time point when patients are allowed to walk with normal footwear and full weight bearing. Walking forces at the Achilles tendon have been well characterized[7]. Therefore, those values can be taken as a reference for allowable forces at that time point. Using the stiffness ratio, allowable forces can be estimated at earlier time points.

Current rehabilitation techniques prescribe a timeline for increasingly applying a fraction of weight bearing to the injured leg. However, there is no consensus on the timing and amount of load bearing for optimal healing. Inconsistencies in the rehabilitation protocols can potentially contribute to the variability of functional outcomes in this patient population. Information about the strength of the healing tendon can be used in the design of more consistent protocols that would prescribe activities and exercises that would progressively increase the tensile demands of the tendon.

NMES is a technique often used in the rehabilitation of knee injuries and surgeries to prevent quad muscle atrophy. NMES can offer several advantages in the rehabilitation of Achilles tendon ruptures. By controlling the stimulation intensity and position of the pads, the amount of force applied to the healing tendon can be reduced, while still applying a significant contraction to the muscle. The position of the pads can be changed to stimulate the entirety of the calf muscles. This combination of low force and significant muscle contraction cannot be achieved by voluntary contractions. NMES can potentially reduce the variability in current rehabilitation protocols since it doesn't rely on voluntary contraction or percentage of body weight which are very difficult to control.

Mechanical properties of tendons are also important for potential personalized treatment strategies or identification of delayed healing. Achilles tendon ruptures are common in athletes. In this patient population, the timing of the return to activities can play a big role in the athlete's career. Evaluation of the mechanical properties of the healing tendon can inform clinicians and trainers of the best time to return to activities. Similarly, mechanical properties can alert clinicians of delayed healing in patients with risk factors such as diabetes and smoking.

Limitations of this study include that the rehabilitation protocol was not controlled. As mentioned above, surgeons may use rehabilitation protocols that may have subtle differences. Another limitation is the relatively small number of patients recruited for the study.

In conclusion, the stiffness ratio is a mechanical parameter that can be used to estimate tendon strength at the early stages of tendon healing, to guide the design of rehabilitation protocols, and to personalized evaluation of tendon healing.

EVALUATING THE EFFECTS OF COORDINATE SYSTEM SELECTION ON THUMB CARPOMETACARPAL JOINT ANGLES

Adam J. Chrzan (1), Nicole D. Arnold (1), Kevin Chan, M.D. (2), Tamara Reid Bush, PhD (1)

(1) Mechanical Engineering, Michigan State University, East Lansing, MI, USA
(2) Orthopedic Hand and Upper Extremity Surgery, Spectrum Health, Grand Rapids, MI, USA

INTRODUCTION

The human thumb is essential for performing activities of daily living, and accounts for 40-50% of overall hand function [1]. The carpometacarpal (CMC) joint of the thumb, located at the interface of the thumb metacarpal and trapezium at the base of the thumb, is of particular importance because it is capable of complex, multi-planar movement and is responsible for the majority of thumb motions required for task completion [2]. Consequently, loss of CMC motion poses challenges for the completion of activities of daily living.

To determine the three joint angles (flexion, abduction, internal rotation) of the thumb CMC joint using motion capture, two coordinate systems (CSs) are needed: one on the thumb metacarpal, and one on the hand. The dorsum, or back, of the hand is often used because it is accessible and does not interfere with hand motions. By attaching reflective markers to key bony landmarks, cartesian CSs can be established in a variety of ways. Many different CSs on the dorsum of the hand have been used in previous works. The International Society of Biomechanics proposed a standard CS constructed using bony landmarks on the trapezium, but this location is difficult to confirm with surface markers. Some have suggested the use of a pod of rigidly connected markers on the 3rd metacarpal as a more accessible substitute for the trapezium, but the practice is not widely used. The effects of CS choice on thumb CMC motion has not been studied in detail. In particular, the placement of markers used to establish hand dorsum CSs were hypothesized to have a significant effect on motion data outcomes.

Therefore, the goals of this work were to 1) determine the effect of hand dorsum coordinate system choice on thumb CMC joint angle ranges, and 2) identify the most accurate CSs for each of the three joint angles.

METHODS

Motion data were both collected from a custom designed reference system that was used to establish the ground truth alignment of CSs as

well as human participants. All three-dimensional (3D) positional data were gathered using reflective markers and a six-camera motion capture system (Qualysis, Gothenburg, Sweden) at 100 Hz. Each system described below.

A custom axial rotation device (ARD) was used to identify three perpendicular planes of motion (Fig. 1). The ARD consisted of a rigid vertical wall with an aligned marker pod (Fig. 1a) and three additional marker pods, each mounted on a uniaxial bearing (Fig. 1b-d). Bearings were positioned to rotate only about the axes of a cartesian CS on the ARD (Fig. 1a).

Participants placed their hand and forearm flat against the rigid wall of the ARD, aligning it with the ARD. Participants then performed a circumduction motion to move the thumb through its maximum range of motion to examine the impact of hand dorsum CS choice on thumb CMC joint angle ranges. Each participant performed the motion three times and results were averaged. Recruited participants had no history of significant hand injury, hand surgery, or diagnosis of arthritis, were right-hand dominant, and not pregnant. This work was approved by the university (IRB #00006111) and all participants were consented.

A rigid marker pod containing four markers was placed on the thumb metacarpal and individual markers were placed on the ulnar styloid (denoted as U), distal radial tubercle (R), and the distal ends of the 2nd (2) and 5th (5) metacarpals (Fig. 2). A second order zero-phase low-pass Butterworth filter with a cutoff frequency of 6 Hz was applied to all marker data.

Five hand dorsum CSs (RU2, RU5, R25, U25, RU25) were constructed using different combinations of the single markers denoted as R, U, 2, and 5 (Fig. 2). Each was then compared to the three known planes from the ARD. Flexion, abduction, and internal rotation angles were calculated between pairs of CSs using the Grood and Suntay method with modifications by Dabirrahmani and Hogg [3]. Flexion was the rotation about an axis pointing out of the palm, abduction about an axis pointing in the 'thumbs-up' direction, and internal rotation about an

axis pointing from the wrist to the distal end of the fingers (Fig. 2). Thumb CMC angle ranges were calculated between CSs on the hand dorsum and thumb metacarpal. The error of each hand dorsum CS was evaluated as the average difference of the angles resulting from the ARD CSs and hand CSs. CSs with errors closest to zero (positive or negative) were considered more desirable because they had greater alignment with the hand dorsum.

Analysis was performed using MATLAB (MathWorks, Natick, MA). One-way ANOVA tests were used to determine the impact of CS on each of the three joint angle ranges, while pairwise multiple comparisons were done using the Tukey adjustment.

Figure 1: Axial rotation device (ARD). Coordinate systems were established on the ARD aligned marker pod (a), and each of the uniaxially rotating bearing pods (b-d).

Figure 2: A) RU2, B) RU5, C) R25, D) U25, and E) RU25 hand dorsum coordinate systems constructed using single markers placed on the ulnar styloid, distal radial tubercle, and the distal end of the 2nd and 5th metacarpals. A rigid marker pod was attached to the dorsal surface of the thumb metacarpal.

RESULTS

62 participants (30M, 32F, avg. age = 40.4 years \pm 17.8) performed the circumduction motion, and a subset of 10 participants (4M, 6F, avg. age = 25.6 years \pm 4.7) performed the axial rotation tests with the ARD.

The effect of CS on joint angle ranges (Fig. 3) was significant for all three angles ($p < .01$ for each) – flexion, abduction, internal rotation. Pairwise comparisons revealed three CS pairs that were significantly different for all three angle ranges, three pairs for two angle ranges, and three pairs for one angle range. Only the U25-RU25 pairing was insignificant for all three angle ranges, meaning that all other CS pairs should not be directly compared and that significant differences in motion between studies could be solely a result of CS choice.

The effect of CS on error (Fig. 4) was significant for each axial rotation ($p < .01$ for each), signifying that the most appropriate choice of CS differs depending on the thumb motion that is analyzed.

DISCUSSION

Five hand dorsum coordinate systems were evaluated to identify their effects on thumb CMC joint angle ranges. When performing a circumduction motion, the choice of CS significantly affected each of the angles - thumb CMC flexion, abduction, and internal rotation (Fig. 3). This highlights the need for careful consideration of CS selection, particularly with regard to thumb motion. This is critical as differences in motion could be a result of the CS selection, and not related to any

Figure 3: Thumb CMC joint angle ranges during the circumduction motion (N=62) were significantly different across coordinate systems.

Figure 4: Average coordinate system errors were significantly different across each of the three angles (N=10).

physiological or disease associated changes. This work also provides insight into interpreting past results when comparing studies that utilized different CSs and could be used to adjust angle range numbers for comparison purposes.

Ground truth testing using the ARD showed CS errors differed across all three angles. If only interested in thumb CMC flexion, or if a motion is performed that predominantly utilizes CMC flexion, the RU25 CS would be the most attractive choice because it had the flexion error that was closest to zero ($\sim 2.9^\circ$) (Fig. 4). All CS errors in abduction were $>11^\circ$, but if interested in only abduction, the RU2 CS had the error closest to zero. In internal rotation the RU2 and RU5 had errors of $\sim 1^\circ$ and would both be suitable. Overall, when considering all angles, the RU2 CS had the lowest average error across all three angles, which would make it an appropriate choice for the study of complex, multiplanar thumb motions.

Future work will apply this knowledge to clinically collected data to report accurate findings of results.

BIOMECHANICAL ANALYSIS OF A FETAL PULMONARY HEART VALVE REPLACEMENT

Sanchita S. Bhat (1), Katelynne Berland (1), Anna Farnan (1), Katherine Vietmeyer (1), Lakshmi Prasad Dasi (1)

(1) Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA, US

INTRODUCTION

Congenital heart diseases account for nearly one third of all congenital defects, and require surgical repair or medical management [1]. Pulmonary atresia with intact ventricular septum (PA/IVS) is one type of extremely rare congenital heart defect that occurs in 1% of total heart defects [2]. In this defect, the pulmonary valve is underdeveloped and atretic leading to hypoplasia of the right side of the heart and limiting flow through the right ventricle and main pulmonary artery. Many of these patients undergo palliation, but are subject to high risks of morbidity and mortality, eventually requiring heart transplantation or a pulmonary valve replacement [3]. Although these replacements are made from biocompatible materials, they can become dysfunctional, requiring further intervention and multiple surgeries. Attempts have been made to restore normal flow dynamics and allow for remodeling of the heart for biventricular circulation *in utero*, using minimally invasive techniques such as balloon valvuloplasty of the fetal pulmonary valve [4-5]. Performing fetal valvuloplasty can reverse the ventricular hypoplasia and allow a biventricular circulation, but most of these patients will go on to ultimately require postnatal valve replacements over their lifetimes. In an attempt to avoid the aforementioned circumstances, a completely bioresorbable tissue engineered heart valve was developed by our group for percutaneous implantation in the fetus [6]. The unique environment of the fetus and the fetal milieu may serve as an excellent host for tissue engineering concepts, because of the large number of progenitor cells. Our previous fetal tissue engineered heart valve (TEHV) could not be reliably reproduced, due to design challenges with the stent, as well as assembly challenges of mounting the leaflets on the stent frame. Therefore, this study aims to develop an alternative fetal transcatheter pulmonary valve replacement (FTPVR) with a novel sutureless technique to mount leaflets, thus eliminating premature catastrophic failure of valves, for use in endovascular repair *in utero*.

METHODS

Stent design and simulations. A balloon expandable stent frame was designed in-house using 3D CAD Software (Solidworks, Dassault Systems, Vélizy-Villacoublay, France) based on our adult transcatheter aortic valve replacement (TAVR) design, which exhibited improved hemodynamics (**Figure 1**). The stent structure comprised of a large commissural region, with cell regions comprising of the skirt and

leaflet. A commissure-to-commissure strut ensured the stent would not break during crimping and expansion. Computational simulations simulated our resolvable prototype stent made of nontoxic magnesium alloy (WE43) and a cobalt-chromium (Co-Cr, L605) stent for testing in the current study. We established a proof-of-concept design with Co-Cr, commonly used as medical grade stent material for the purposes of this study. The material properties were modeled as described in literature [7,8]. The 150 μm thick stent model was meshed using Altair Hypermesh (Altair Engineering, Troy, MI, USA) and boundary conditions were applied such that the stent was crimped and expanded.

Figure 1: Stent CAD showing different regions of prototype

Valve manufacturing and assembly. Stent prototypes were laser cut using a 5mm tube of Co-Cr in a rotational stage in the OPTEC Femtosecond laser on high setting. To establish the efficacy of manufacturing and testing, a Co-Cr prototype was used. Post manufacturing, the stent prototypes were mounted with polycaprolactone (PCL) leaflets made from 0.75% PCL in chloroform (wt/vol) using an in-house spray coated technique. This was adapted to eliminate point stresses on the sutures that previously held the leaflets, leading to catastrophic failure of the valve. N=3 prototypes were manufactured with Co-Cr and ones with WE43 stents are currently underway.

In vitro performance. We mounted the FTPVR in a custom acrylic test chamber connected in our fetal right heart simulator (FRHS) as shown in **Figure 2**. Two pressure transducers, PI, P2, were placed upstream and downstream of the test valve respectively. A clamp-on flow

transducer recorded forward flow through the system from the FRHS via a LabView (National Instruments Corp, Austin, TX, USA) system. Additional details on the simulator have been previously reported [24]. We employed the following test conditions: 0.5 L/min cardiac output, 70/45 mmHg pulmonary artery pressures, heart rate 140 beats per minute and a working fluid of 60/40 water/glycerin (99% pure glycerin), representative of the fetal pulmonic physiological conditions around the 22 to 24 week gestational period, where the implant typically would take place. The effective orifice area (EOA) was computed using the Gorlin's equation and regurgitant fractions (RF) were calculated as the ratio of the closing volume (CV) and leakage volumes (LV) to the forward flow volume (FV):

$$EOA = \frac{Q}{51.6 \sqrt{PG}} ; RF = \frac{LV + CV}{FV}$$

Q represents the root mean square aortic valve flow over the same averaging interval of the pressure gradient, ΔP.

Figure 2: A: Acrylic test chamber and B: FRHS

RESULTS

The maximum stresses were found to be 300 MPa for WE43 alloy and between 877 MPa and 895 MPa for Co-Cr, observed mostly at the struts near the skirt region. The values for high stresses were distributed along the cell shape and within the ultimate tensile strength for both materials, indicating low susceptibility of catastrophic failure.

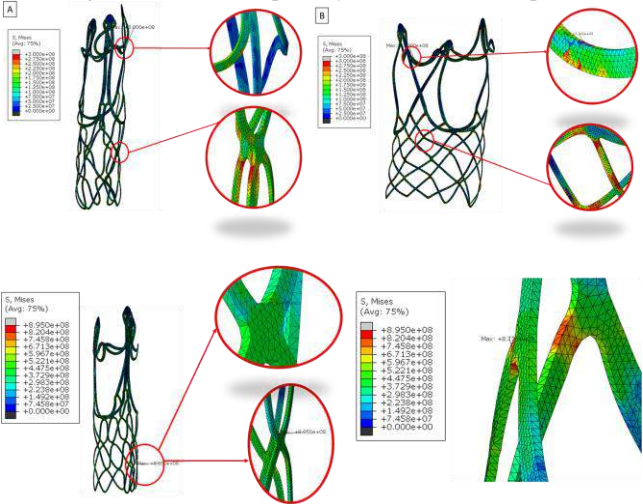

Figure 3: Results of WE43 (top) and Co-Cr (bottom) prototypes

Three trileaflet FTPVRs were successfully tested in the FRHS. On average, the valves had an EOA of 0.10 cm², a mean transvalvular pressure gradient of 5.79 mmHg and a regurgitant fraction of 8.9%. Between the prototypes, each of the measured metrics had a moderate standard deviation with the exception of regurgitation fraction, due to one prototype having higher than average regurgitation.

Prototype	Effective Orifice Area (EOA) (cm ²)	Mean Pressure Gradient (mmHg)	Regurgitation Fraction (%)
FTPVR – 1	0.07	8.07	2.8
FTPVR – 2	0.18	3.84	3.9
FTPVR - 3	0.07	5.48	20.06
Average	0.10	5.79	8.92

Table 1: Results from FRHS experiments

DISCUSSION

In patients who have PA/IVS, treatment may be beneficial, due to the regenerative capacity of the fetal milieu since most postnatal valve replacements that are limited by size and availability. In our preliminary computational simulations, we observed leaflet stresses to be very high at suture points. Since PCL is ductile when it is first manufactured, the high-stress regions will hold until PCL degrades to its brittle state, where suspected failure can happen. To avoid these circumstances, the sutureless method was adopted. This study, for the first time, incorporated a custom *in vitro* setup that mimicked the physiological conditions for a fetus at 22–24-weeks of gestational age. Imposing accurate conditions increases the efficacy of successful valve development. The standard deviations between prototypes were low, with the exception of one prototype having high regurgitation fractions, contributing to higher standard deviations in that metric.

Overall, this indicates the need to further fine tune and streamline the manufacturing protocol. To supplement the efficacy of this FTPVR, a full biomechanical analysis accounting for degradation rates and patterns within various designs is needed, and studies are underway. The hemodynamic characterization of a fetal valve prototype does not account for neotissue growth *in vivo*. The growth of the neotissue along with valve degradation will change its performance. For this, future animal studies are needed to supplement this data.

INTRODUCTION

We present a multi-scale finite element (FE) framework for modeling fluid saturated materials with a porous microstructures. Mixture theory and the theory of porous media both play an important role in many diverse areas of engineering, including the biomechanics of soft tissues (e.g. liver, brain, and cartilage), as well as coupled problems in material science and environmental sciences. The remarkable macro-mechanics of soft tissues derive from the complex micro-mechanics of their constituents, e.g. proteoglycans, collagens, and electrolytic fluid, and their interactions, thus multiscale models arise naturally. To facilitate mechanistic understanding and improved analyses (e.g. of experimental results) of the multi-scale mechanics of soft tissues we aimed to establish a computational framework specific to fluid-saturated, fibrous soft tissues and engineered materials.

We implemented a 3-D multiscale framework within FEBio (Version 3.5.1, University of Utah) combining mixture theory [1] and the FE²-method [2] (i.e. finite elements of multiscale mixtures or FE2M) to solve two-scale, non-linear, coupled, and time dependent boundary value problems (BVPs) for poro-hyperelastic, fluid-saturated porous media. We attached a representative volume element (RVE) of the microstructure at each material point of the macrostructure and performed discretizations of the BVPs on both macro- and micro-scales. After successful implementation of this algorithm in 3-D nonlinear FEs, we investigated the effect of the microstructural RVE size with respect to the macrostructural model.

METHODS

Theory. We write the pull back of the balance of linear momentum of the mixture (from the current to reference configuration \mathcal{B}_{0S}) as

$$\int_{\mathcal{B}_{0S}} \text{Div} (\mathbf{P}_E^S - p \mathbf{F}_S^{-T} J_S) dV_{0S} = \mathbf{0}, \quad (1)$$

where \mathbf{P}_E^S is the first Piola-Kirchhoff solid extra stress, p is the fluid pressure, \mathbf{F}_S and J_S are the deformation gradient and Jacobian of the solid. We

write the corresponding balance of mass of the mixture as

$$\int_{\mathcal{B}_0} \text{Div} [(n^F \mathbf{w}_{FS} + \mathbf{x}'_S) \mathbf{F}_S^{-T} J_S] dV_{0S} = 0, \quad (2)$$

where n^F is the current volume fraction of the fluid, \mathbf{w}_{FS} is the filtration velocity, and \mathbf{x}'_S denotes the velocity of a material point of the solid.

Numerical implementation. To solve the partial differential equations governing the macroscopic BVP, (1) and (2), we used the finite element method twice. We first provide macroscopic quantities, calculated from an intermediate solution of the macroscopic FE model, as boundary conditions (BCs) on the microscopic RVE, i.e. the deformation gradient $\bar{\mathbf{F}}_S$ and the gradient of pressure times the volume fraction of the fluid $\text{Grad}(n^F p)$. After solving the microscopic FE model with these BCs, we evaluate the macroscopic material tangent $\bar{\mathbf{A}}$ and measures $\bar{\mathbf{P}}, (\bar{\mathbf{E}}_S)_S^T \cdot \mathbf{C}_S \mathbf{J}_S, n^F \mathbf{w}_{FS}$ (first P-K stress, Green Lagrange strain rate, right Cauchy-Green tensor, respectively) at each Gauss integration point by a volume averaged solution of the underlying RVE. We perform computational homogenization of an arbitrary microscale quantity \bullet over a RVE or over a representative surface element in order to calculate its macroscopic counterpart $\bar{\bullet}$ following

$$\langle \bar{\bullet} \rangle \approx \frac{1}{V_{0S}} \int_{\mathcal{B}_{0S}} \bullet dV_{0S}, \quad [\bar{\bullet}] \approx \frac{1}{A_{0S}} \int_{\partial \mathcal{B}_{0S}} \bullet dA_{0S}, \quad (3)$$

where V_{0S} and A_{0S} are reference volumes and areas respectively.

Numerical analyses of size effects. We considered single-scale models as benchmark solutions for comparison to corresponding solutions from equivalent two-scale models, see Fig. 1. In Fig. 1 we illustrate the scale separation in the macrostructure, meaning that each cell in a single-scale model is equivalent to an RVE (considering we have periodically repetitive cells). The shaded region in the single-scale model is equivalent to the shaded element in the two-scale model, i.e we solve an RVE for each Gauss point within each element of the macrostructure. To study the size effect we use the same RVE in progressively larger macrostructures, thus increasing the difference in scales, and compare results obtained from single and two-scale models for displacement, stress, and fluid pressure.

Figure 1: Schematic comparison of single-scale vs. two-scale models.

Single-scale models as benchmark solutions. We considered 3-D square plates with circular holes of length $4L$, $12L$, and $18L$ with $L = 0.4$ mm; thickness $t = 0.04$ mm; and radius of holes $r = 0.04$ mm, see Figs. 2(a)-(c). We subjected the plates to traction $T_x = 10$ MPa and allowed that surface to freely drain. We used a biphasic, neo-Hookean model with properties $E = 100$ MPa, $\nu = 0.3$, $K_d = 1e - 6$ mm⁴/(Ns) and extracted the numerical results at time $t = 1$ s. We used eight-node hexahedral elements for all finite element models.

Figure 2: Single-scale finite element models: (a) Macro 1 ($4L \times 4L \times t$), (b) Macro 2 ($12L \times 12L \times t$), and (c) Macro 3 ($18L \times 18L \times t$).

Corresponding two-scale models. We considered 3-D square plates of lengths nL with $n = 4, 12, 18$ and $L = 0.4$ mm, and thickness $t = 0.04$ mm (for the macro-scale models), see Fig. 3(a). We subjected the macro-scale models to the same BCs as the single-scale models above. For the microstructural RVEs we considered a 3-D square plate of length $L = 0.4$ mm and thickness $t = 0.04$ mm with a circular hole $r = 0.04$ mm (using 1160 elements and 1968 nodes and the same material model as above), see Fig. 3(b). We detail the number of nodes, elements, and holes for both single-scale and two-scale (macro-scale) models in Table 1.

Figure 3: Two-scale finite element models: (a) macro-scale 3-D plate ($nL \times nL \times t$) and (b) micro-scale RVE ($L \times L \times t$).

Table 1: Number of nodes/elements in single- and two-scale models.

		Macro 1	Macro 2	Macro 3
Single-scale	Nr nodes	30,003	155,673	348,141
	Nr elements	18,560	101,376	227,412
	Nr holes	16	144	324
Two-scale	Nr nodes	27	147	300
	Nr elements	8	72	162

RESULTS

In Fig. 4 we show the comparison between single-scale and two-scale models based on volume integrals, considering the traction plus free-draining surface boundary conditions. In Fig. 5 we show the convergence plot in $\|e\|_2$ for fluid pressure ($n = 4, 12, 18$ and $L = 0.4$ mm). For Macro 1, 2, and 3 (Fig. 4(a), (c), and (e)), the results of the total Cauchy stress for our two-scale models showed excellent agreement with the single-scale (benchmark) solutions. As the difference in length scales increases between the macrostructure and the microstructural RVE, the error in the fluid

pressure decreases significantly to 2.8% and 1.6% for Macro 2 (Fig. 4(d)) and Macro 3 (Fig. 4(f)), respectively.

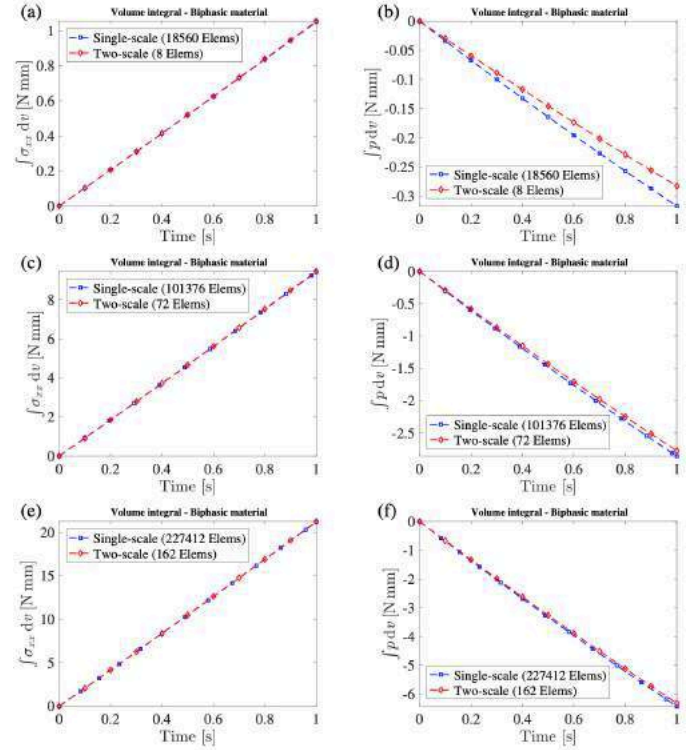

Figure 4: Single- vs. two-scale models based on volume integrals: total Cauchy stress (σ_{xx}) for (a) Macro 1, (c) Macro 2, (e) Macro 3; and fluid pressure for (b) Macro 1, (d) Macro 2, (f) Macro 3.

Figure 5: Convergence plot in $\|e\|_2$ for fluid pressure ($n = 4, 12, 18$ and $L = 0.4$ mm). The slope of the regression line is 1.26.

DISCUSSION

We established a 3-D multiscale homogenization scheme for fluid-saturated porous media. Our results demonstrate that size effects do influence results, e.g. distributions of stress and fluid pressure, within our multiscale solutions. However, the size effects are manageable as we can make them arbitrarily small by increasing the difference in length scales between macro- and micro-scale models. As this difference increases, e.g. increasing n in $1/nL$ ($n = 4, 12, 18$), the $\|e_p\|_2$ -norm error decreases with slope 1.26. Our FE2M framework (FE analyses augmented to derive the material behaviors from a distribution of finer scale FE analyses) facilitates studies of engineering materials for applications in biomedical engineering, material science, and environmental sciences. In particular, our FE2M framework is ideally suited to bridge the joint, tissue, and intra-tissue scales for problems in biomechanics, but has not yet been applied to multi-phase, fibrous soft tissues.

INTRODUCTION

Atrioventricular valves regulate the unidirectional blood flow between the atria and the ventricles. These one-way check valves are complex structures that consist of the *leaflets* that seal the atrioventricular orifice, the *annulus* that is the hinge between the leaflets and surrounding cardiac tissue, and the *chordae* that anchor the leaflets to *papillary muscles* in the ventricle wall. The synergistic function of these sub-valvular components is crucial to healthy valve function.

Recent studies have revealed that dynamic annular shape is an important contributor to healthy valve function and patient outcomes [1-2]. More recently, research groups have used *in vivo* data from animal models [3] and patients [4] to extend these findings to consider annulus mechanics. Specifically, these studies used embedded sonocrystals or annular curve fitting techniques to determine annular displacements and kinematic measures (e.g., stretch). However, no study has yet employed deformable image registration to automatically provide annulus deformations with point-to-point correspondence between phases.

Thus, the objective of this study is to explore the use of elastic registration in determining atrioventricular annulus mechanics (e.g., stretch). We leveraged open-source tools in SlicerHeart to define the annulus for one representative tricuspid valve (TV) and custom deformable image registration code to automatically propagate the user-defined annulus throughout the cardiac cycle. This allowed us to evaluate existing approaches for determining annular kinematics and explore the influence of inter-user variability on annulus stretches.

METHODS

This study was performed according to a protocol approved by the Institutional Review Board at the Children's Hospital of Philadelphia.

Image Acquisition: 3DE images of the TV were acquired using EKG gated, Full Volume or 3D Zoom mode. Transthoracic X7 or X5 probes were used with the Philips IE33 and EPIQ 7 ultrasound systems (Philips

Medical, Cambridge, MA).

Annulus Modeling: 3DE images of one patient with hypoplastic left heart syndrome and a Fontan circulation were imported into 3D Slicer using the SlicerHeart extension, and the TV annulus was manually defined using the Valve Annulus Analysis module in SlicerHeart [5]. We considered three phases: end diastole (ED), mid systole (MS), and end systole (ES) (**Figure 1**). Timing of the cardiac cycle was determined by valve position. Three independent observers repeated this process to understand how inter-user variability influenced annulus definition as well as subsequent elastic registration and mechanics-based analysis.

Figure 1. Representative TV annulus during the cardiac cycle.

Elastic Registration: The annulus curve was resampled to 200 uniformly distributed control points. These points were then automatically propagated to the ED and ES phases via custom code using Elastix image registration [6] with frame-to-frame propagation.

Annular Stretch Quantification: The manually generated and automatically propagated annuli for the three cardiac phases were then transformed to cylindrical coordinates (**Figure 2**) and the annulus stretches were computed using two methods. The first “*correspondence*” approach considered the 200 automatically propagated annulus control points as virtual fiducial markers. On the other hand, the second “*fitting*” approach used moving least squares to fit the manually generated annulus point cloud with a periodic curve and

generate 200 uniformly distributed material points [4]. The acquired points from both methods were used to compute the annulus stretch.

Figure 2. Transformed TV annulus to cylindrical coordinates. Colors indicate the cardiac phase (see also Figure 1).

RESULTS

Inter-User Variability in Annulus Definition: The three independent users produced manually generated annuli with minimal inter-user variability (<1 mm) (Figure 3). The variation was larger for the radius compared to the height.

Figure 3. Annulus radius and height for one representative TV repeated by three independent users (denoted by color).

Annulus Stretches Computed Using Correspondence vs. Fitting: Annulus stretches determined via the correspondence and fitting approaches are provided in Figure 4. We noted some similarities with regions of larger discrepancies likely due to limitations in the fitting approach outlined in the Discussion.

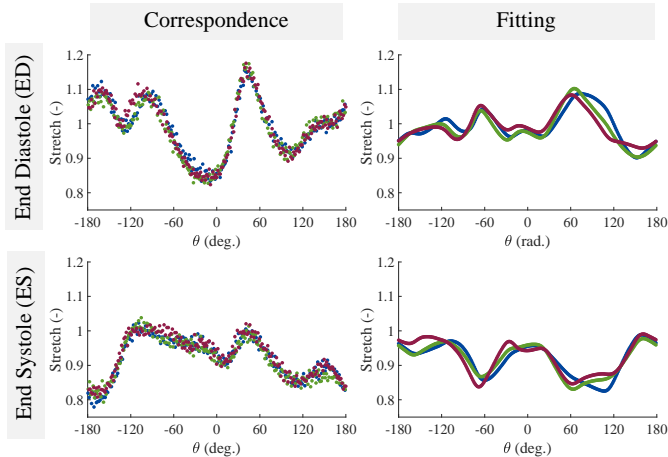

Figure 4. Annulus stretches computed using the correspondence and fitting approaches for three independent users.

Annulus Stretches Computed Using Registration vs. User Definition: The annulus stretches computed using automatically propagated and manually generated annuli are provided in Figure 5. Interestingly, we observed that the relatively small inter-user variability (Figure 3) resulted in substantial variations in the computed annulus stretches. On the other hand, elastic registration led to less variation in the computed annulus stretches for both ED and ES.

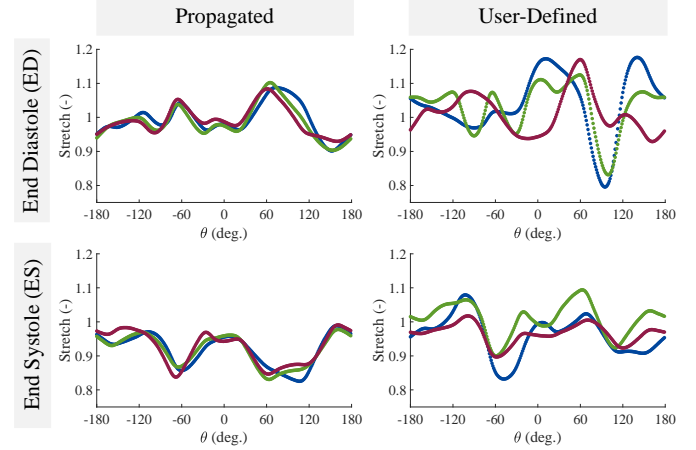

Figure 5. Annulus stretches computed via fitting with the propagated and user-defined annuli for three independent users.

DISCUSSION

In this investigation, we explored the use of elastic registration to support the analysis of atrioventricular valve annulus mechanics. We leveraged open-source tools in 3D Slicer and SlicerHeart to define the TV annulus in MS and custom Elastix image registration code to propagate it to ED and ES. The resulting manually generated annuli and automatically propagated annuli allowed us to compare two methods of computing annulus stretches. Our *primary finding* was that the existing curve-fitting approach resulted in incorrect annulus stretches when compared to our new method that ensures correspondence between cardiac phases. Specifically, lack of correspondence for the existing curve-fitting approach resulted in erroneous annulus stretches for large changes in annulus radius or height. Our *second finding* was that inter-user variability of the user-defined annulus did not strongly influence computed stretches for automatically propagated annuli but led to significantly different stretches for manually generated annuli.

There are several extensions of this work. First, the present analysis can be extended to consider other image registration methods (e.g., ANTs [7]) or emerging deep learning approaches [8]. Second, future animal studies can consider affixing sonocrystals to the atrioventricular valve annulus [3] to experimentally evaluate the accuracy of deformable image registration. Finally, application of these tools can be applied to more effectively understand differences in annular mechanics for normal and dysfunctional valves. We have demonstrated the value of using elastic registration for more accurate determination of annulus mechanics, and future studies should consider more patients for more powerful statistical comparisons.

PATIENT-SPECIFIC FLAP MOTION, FL FLOW, AND AORTIC STIFFNESS IN ACUTE UNCOMPLICATED TYPE B AORTIC DISSECTIONS USING 4D FLOW MRI AND 2D PC MRI: A PRELIMINARY STUDY

INTRODUCTION

Aortic dissection is a life-threatening condition that is defined by a tear within the aortic wall separating it into a true and false lumen (FL). Stanford type B aortic dissections (TBAD) occur in the descending aorta (DescAo) and can be classified into acute (< 7 days onset), subacute (< 30), and chronic phases (> 30). While some uncomplicated TBAD cases can be medically managed, others fail medical therapy and develop false lumen aneurysms. To prevent rupture, these cases can be treated with thoracic endovascular aortic repair (TEVAR) ideally within the acute and subacute phases to eliminate antegrade false lumen flow and achieve optimal aortic remodeling [1]. Determining which cases will lead to aortic growth remains a challenge due to inadequate methods of dissection characterization and lack of studies within the acute phase. Identifying independent predictors of aortic growth early on would allow early intervention, improving patient outcomes.

Studies aiming to identify unique morphological features of TBAD (e.g., entry tear size, aortic length, diameter, tortuosity) or flow- and thrombus-derived metrics lack consistent findings [2-5]. Some recent studies, however, are showing that FL flow assessments via 2D and 4D flow MRI data may be predictive of adverse complications for patients with TBAD [4,6]. One such study found that systolic antegrade flow greater than 30% and diastolic retrograde flow greater than 80% within the FL identified patients at higher risk for complications [6]. Burris *et al.*, similarly demonstrated that a large percentage of FL diastolic retrograde flow measured at the entry tear is associated with an increased aortic growth rate [4]. Both studies point toward false lumen pressure being the strongest identifier of high-risk cases, but only investigated TBAD cases in the chronic phase when the dissection flap is much stiffer (i.e., less suitable for TEVAR).

Therefore, there is currently an unmet need for a simple, yet thorough assessment of the false lumen particularly in acute TBAD to identify patients that would benefit from early TEVAR. While it is understood the flap distensibility is much larger in the acute phase, it is

poorly quantified and its role in overall FL stiffness and flow is also underexplored. Here, we present a novel, preliminary approach that assesses flap motion in the acute phase using 2D PC-MRI. We also aim to assess FL aortic stiffness and pressure of these acute cases using 4D flow and 2D PC-MRI techniques previously applied to chronic TBAD.

METHODS

Patient Demographics and Data Collection. 2D PC MRI and 4D flow MRI were acquired on five patients (P1-5; 3M/2F) with acute uncomplicated TBAD using a Siemens 3T scanner at Emory University Hospital. We acquired the 4D flow over the entire thoracic aorta region and acquired the 2D data at planes in both the proximal and distal regions of the descending thoracic aorta. Data were analyzed using Siemens 4Dflow (v2.4), Horos (v3.3.6), and Medviso Segment [7]. CTA images from routine clinical acquisition were used to identify and measure the dominant entry tear size (i.e., largest tear), branch locations, and growth. The CTAs were collected at the time of diagnosis and at a one month follow up. We segmented the CTAs using VMTK for visualization of the geometry.

Flap motion. To determine flap motion amplitude, we placed a line on the longest axis parallel to the dissection flap and a perpendicular line that reached from the long axis line to a point on the dissection flap furthest from that line (Fig. 1a) throughout the whole cardiac cycle on each 2D PC-MR image (proximal and distal DescAo). The flap movement was calculated by recording the length of the perpendicular, short axis line at all 20 timesteps. We took the difference between the highest and lowest values in the waveform to find max. flap amplitude.

False lumen flow. False lumen ejection fraction (FLEF), established by Burris, *et al.* [4], was calculated at the dominant entry tear as mean diastolic retrograde flow (mL/s) divided by mean systolic antegrade flow (mL/s) from 4D flow data (Eq. 1). FL_{DR} and FL_{SA} represent false lumen diastolic retrograde and systolic antegrade, respectively. We placed the planes perpendicular to the primary entry tear. 4D flow data

was omitted for P5 due to acquisition errors. Using 2D PC-MRI, FL systolic antegrade and diastolic retrograde flows were measured distal to the entry tear within the descending aorta.

$$\frac{FL_{DR}}{FL_{SA}} = FLEF \quad (1)$$

Pulse wave velocity. We calculated FL pulse wave velocity (PWV) by dividing the length (m) from the ascending aorta 2D PC-MRI acquisition plane to the descending plane by velocity wave propagation time (s) from the ascending aorta to descending within the false lumen (locations of planes in Fig. 1).

RESULTS

From the standard clinical CTA analysis, we found that entry tear sizes ranged from 40 - 132 mm². P1 and P5 exhibited growth at follow-up (no follow up for P4). Due to the substantial growth, P5 underwent TEVAR at 3 months. Analysis of the 4D flow MRI data, revealed that FLEF substantially varied among the four cases (26.125% ± 22.15, Fig. 1a, Table 1).

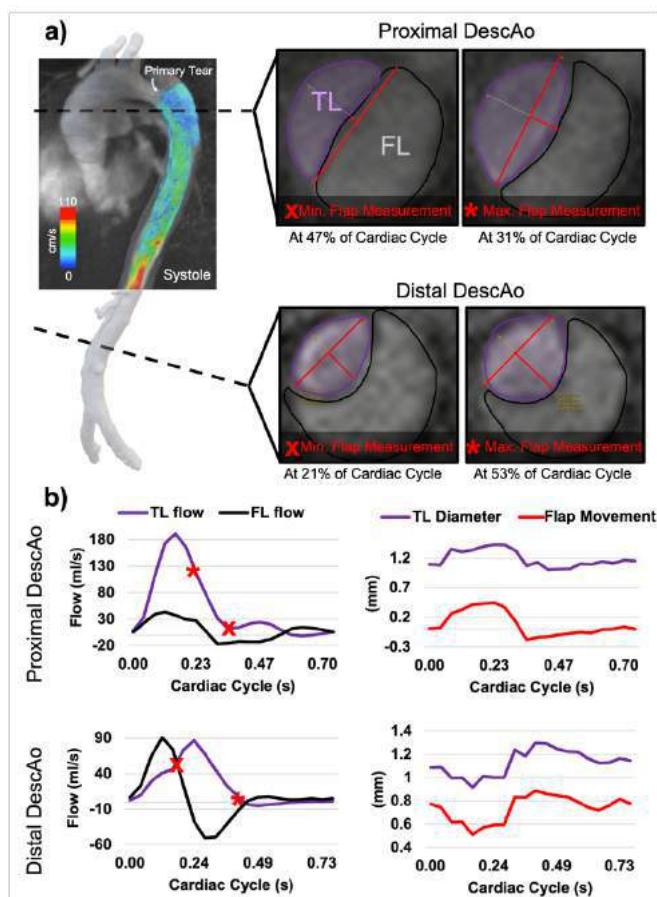

Figure 1: a) CTA segmentation overlaid on 4D Flow MRI of P3. Proximal and distal 2D PC-MRI planes with representative flap measurements (min. (x) and max. (*) locations shown on TL flow); b) 2D PC-MRI-derived flow and flap movement measurements over one cardiac cycle. TL = true lumen; FL = false lumen

From our 2D PC-MRI data, we recorded the peak flap amplitude in Table 1 and generally found that the distal plane yielded lower peak amplitudes. Figure 1 shows example cross-sections from P3 of flap movement over one cardiac cycle. Our FL_{DR} and FL_{SA} and PWV values are reported in Table 1. We observed that patients with higher PWV also had lower flap amplitude.

Table 1: Summary of measured parameters.

PID	CTA	4D Flow	2D PC-MRI		
	ΔD at 1 mo. (mm)	FLEF (%)	Flap Amplitude (mm)	FL _{DR} /FL _{SA} (%)	PWV (m/s)
P1	6	29.6	6.7	42 / 43	--
P2	0	8.3	6.2	63 / 77	3.79
P3	0	56.1	11.5	57 / 49	1.58
P4	--	10.5	8.0	67 / 77	18.14
P5	14	--	5.7	87 / 44	23.45

ΔD = diameter difference; FLEF = false lumen ejection fraction; FL_{DR} = false lumen diastolic retrograde flow; FL_{SA} = FL systolic antegrade flow; PWV = pulse wave velocity

DISCUSSION

This study demonstrates how 2D PC-MRI and 4D MRI flow can be used to investigate *in vivo* FL flow for patients with acute uncomplicated TBAD. Given the preliminary nature of this study and the limited number of patients currently enrolled, we were unable to identify significant trends between FLEF, flap motion, wall stiffness and aortic growth. More patients will be needed to confirm the suitability of these metrics in stratifying uncomplicated TBAD and predict the risk of growth. All our metrics showed a high degree of variability, requiring further investigation and comparison to follow-up measurements as a potential unique study of TBAD progression.

Patient 5 proved to be an interesting case: Based upon findings from Evangelista *et al.*, FL_{DR} and FL_{SA} values for P5 suggested that the patient was at high risk for complications, which was confirmed by the large follow up growth and subsequent TEVAR. We also noted the lowest flap amplitude and highest PWV in P5, suggesting a greater aortic stiffness. On the other end of the spectrum, P3 showed the highest flap amplitude and lowest PWV with no growth at follow-up.

Our long-term goal is to incorporate these into a larger predictive risk model to identify patients with acute TBAD that might benefit from early endovascular therapy. More sophisticated approaches to quantify flap motion will be considered to link the cyclic deformations to local flow features as measured with 2D and 4D Flow MRI.

One limitation of our study is the acquisition of 2D PC-MRI at fixed levels resulting in variable distances from entry tear. The other notable limitation is our small sample size due in part by the difficulty of collecting data from acute TBAD patients.

There are many 4D flow studies and approaches to investigate chronic TBAD. However, standardization and implementation of these methods remains limited. Our current findings demonstrate the potential for methodologies that combine the anatomical assessment provided by CTA analysis with PC-MRI measurements of FL flow and proxies for FL pressure in the acute phase of TBAD. We believe this approach has potential for identifying patients at risk for aortic growth thereby improving the timing of intervention which may result in improved survival for patients with this lethal disease.

ACKNOWLEDGEMENTS

We would like to acknowledge the effort of the healthcare team and the patients willing to participate in this study.

INTRODUCTION

The cornea is the outermost part of the eye considered the eye's window. Among five layers, the thickest layer of the cornea is the stroma which forms almost 90% of the corneal total thickness. The corneal stroma is composed of many collagen lamellae. These lamellae are interwoven in the anterior region; however, the amount of their interlacing decreases moving towards the posterior layers such they become almost parallel with respect to each other and form a plywood structure in the posterior region of the cornea [1].

The individual collagen lamellae are made up of thin collagen fibrils that are embedded in a hydrated proteoglycan matrix. The proteoglycans (PGs) are shown to be important for corneal transparency as they determine the hydration of the cornea in vivo conditions. PGs are composed of glycosaminoglycans (GAGs) that are attached to core proteins. The major PGs in the human cornea are decorin, lumican, keratocan, and mimecan that primarily contain keratan sulfate and chondroitin sulfate GAGs. PGs bind to collagen fibrils at specific location by their core proteins [2]. The negatively charged GAG chains of PGs attract charged ions and water molecules inside the corneal stroma by osmosis. The mechanical properties of the cornea depends on hydration [3]. Thus, GAGs are believed to be important in defining the mechanical response of the cornea. They also play a role in preventing neighboring collagen fibrils come together and maintain their hexagonal arrangement [4]. It has been proposed that the interaction between GAG chains creates molecular attractive forces between adjacent collagen fibrils. This model suggest that GAGs are important for the corneal mechanical strength. In a recent work, we showed that removing GAGs from the corneal samples results in a significant softening of corneal mechanical properties [5]. This work is a continuation of our recent research with the primary objective of determining the relation between structural functions of GAGs and the anisotropic corneal microstructure. Here, we prepared corneal strips from the posterior part

of the cornea and used keratanase enzyme to remove keratan sulfate GAGs from the corneal strips. We then performed uniaxial tensile experiments to assess the effect of GAGs on tensile response of posterior flaps.

METHODS

We collected fresh porcine eyes and used a sharp scissor to remove excess tissue and fat. The epithelial layer was removed using the blunt edge of a scalpel. Then corneal rings were excised using a sharp scissor. The thickness of the specimens was measured by a digital pachymeter (DGH Tech.). The corneal rings were dried in the air until the thickness reached about $800\mu m$. Then, the anterior 400 μm part of corneal samples was removed using a DSAEK system. The remaining portion of the cornea was referred to as posterior region and a custom-made double bladed device was used to cut strips. The specimens were divided into two control and enzyme groups.

For the enzyme treatment, the samples were completely dried and were then immersed in sodium acetate buffer solution (0.1M) with keratanase enzyme (KS II, 0.1 U/ml). The pH of the solution was 6.0 and samples were kept in the solution at $37^{\circ}C$ for about 20 hours. This was similar to the method that we used to remove GAGs from full thickness corneal samples in a previous study [5].

All the specimens were tested using ARES G2 uniaxial testing machine. Before testing, the thickness of the corneal specimens was measured. Then, the corneal strips were mounted into the machine using sandpaper at the grips. A tare load was applied to straighten the samples and confirm their firm grip [6]. The corneal strips were stretched to 20% strain at the displacement rate of $2mm/min$. The initial cross-sectional area of the strips was used to calculate the tensile stress from the measured force.

The experimental data were processed and analyzed in Microsoft Excel. Statistical analyses were performed in SAS analytical tool. Shapiro–Wilk test was performed for the normality check of the data while one-way ANOVA was used to determine the possible significance level of difference that existed in the behavior of different groups. P-value of 0.05 was used.

RESULTS

The stress of each group of corneal flaps was plotted as a function of tensile strain in Figure 1. The results suggested that the enzyme treatment reduced the tensile strength of posterior flaps but the effect of GAG removal was not significant at all levels of applied strain. In Figure 2, the tangent moduli were shown at 5%, 10%, 15%, and 20%. The tangent modulus followed a similar trend of tensile stress, i.e., the enzyme treatment did not have a significant effect on the tensile modulus of posterior flaps.

Figure 1: Stress-strain curve of porcine corneal posterior flaps.
The vertical error bar indicates the standard deviation.

Figure 2: Distribution of tangent modulus of porcine corneal flaps at 5%, 10%, 15%, and 20% strain. The vertical error bar indicates the standard deviation.

DISCUSSION

The main purpose of this study was to characterize the tensile response of enzyme-treated porcine corneal flaps that were prepared from the posterior parts of the cornea. All the stress-strain curves reported in this study (Figure 1) appeared to be nonlinear which was consistent with previous studies characterizing the tensile stress-strain response of the cornea. Although enzyme treated samples had a softer tensile stress-strain behavior compared with the response of control

samples; the difference between the behaviors of two groups was not significant. This was different than our previous finding for the role of GAGs on the tensile response of full thickness cornea [5]. This suggests the importance of the arrangement of collagen lamellae throughout the corneal microstructure. The collagen lamellae lie on top of each other in the posterior regions. In a previous study on characterizing the efficacy of corneal collagen crosslinking treatment, we found no significant tensile property improvement of posterior flaps because of this treatment procedure [6]. The previous imaging studies of the cornea showed that collagen lamellae in the anterior region appeared to be interwoven whereas the ones in the posterior part are parallel with respect to each other. PGs attach to collagen fibrils with their core proteins while their GAG side chains interact with each other and act as a glue connecting the neighboring collagen fibrils together [4]. In enzyme treated sample, the GAG density was significantly reduced because of their enzymatic digestion. Thus, the number of GAG bridges was reduced, which is why the tensile properties of enzyme treated samples were lower compared to those of the control samples. However, the difference was not significant because of the specific arrangement of collagen fibrils in the posterior regions of the cornea. Based on the present experimental study, we propose that collagen fibrils are primarily responsible for tensile properties of the cornea in the posterior regions. However, GAGs become important when collagen lamella interweaving is significant. We are currently conducting additional experimental studies in order to characterize the effect of GAGs on tensile properties of the corneal strips prepared from anterior region to test this hypothesis. The lack of these experiments can be seen as a limitation of the current work. Furthermore, future studies are required to characterize the response of human corneas. Although the tensile properties of human and porcine corneas did not show significant variation [7], human cornea exhibited higher amount of stiffening than the porcine cornea when they were undergone collagen crosslinking treatment.

INTRODUCTION

Despite its vital importance for establishing proper cardiovascular function, the process through which the vasculature develops and matures postnatally remains poorly understood. From a clinical perspective, the ability to mechanistically model the developmental time course in arteries and veins, as well as to predict how various pathologies and therapeutic interventions will alter the maturation process of affected vessels, is vital to improving treatment approaches and long-term clinical outcomes, particularly in pediatric patients suffering from congenital heart disease. Several investigations have uncovered remarkable changes in vessel wall composition, structure, and mechanical properties during postnatal development [1,2]. However, the relative role of mechanoregulation (along with genetic programming/predetermination and other mechanisms) in governing vascular maturation is not well quantified. As a first step toward predictive modeling of vascular development and maturation, there is thus a critical need to synthesize and extend previous insights within a mathematical modeling framework in order to elucidate how (and to what extent) developmental phenomena at the tissue and cellular scales are coupled to the evolving loading conditions on the vessel.

Toward this end, we seek to construct a predictive mechanobiological model that (1) links the tissue-level mechanical loading state to subcellular changes in biosynthetic activity and (2) uses the corresponding age-dependent gene/protein expression information to predict compositional/structural changes within the vessel wall. In the present study, we focused on the development of the murine thoracic aorta and examined the relationship between *in vivo* functional stresses, collagen I and III expression, and observed collagen content over the postnatal developmental time period as well as in maturity.

METHODS

All data for the present study were collected from wild-type C57BL/6J mice, in accordance with protocols approved by the Yale

University IACUC. Following euthanasia, the thoracic aorta was excised from the aortic root to the diaphragm. Biaxial mechanical data were collected at ages of $t = 1.5, 3, 6$, and 14 wk, using methods previously described in [3]. Briefly, vessels were preconditioned and then subjected to three cyclic pressure–distension protocols and four axial force–extension protocols, under age-specific loading conditions. An established four-fiber-family constitutive model [3] was then used to fit the mechanical data for each specimen, which enabled calculation of directional stresses and stretches, tangent stiffness tensor components, and stored elastic energy at configurations corresponding to the age-specific *in vivo* diastolic and systolic states.

Relative expressions of collagen I and III (*Col1a1* and *Col3a1*) were measured via quantitative reverse transcription PCR (qRT-PCR) for mice at $t = 0, 1.5, 3, 6, 9, 12$, and 24 wk of age. PCR data were normalized to 0 wk using GAPDH as a loading control and were interpolated using piecewise cubic Hermite interpolating polynomials (PCHIP) to ensure continuity over the entire time range considered.

Total collagen area within the medial layer was quantified from histological cross sections using custom image analysis software. Collagen area as a function of age was predicted assuming that the rate of production of functional collagen was directly proportional to a weighted sum of the *Col1a1* and *Col3a1* expressions. Specifically,

$$\frac{d}{dt}(A_{\text{col}}) = f_{\text{production}}(t) - f_{\text{removal}}(t) = \xi_I[\text{Col1a1}](t) + \xi_{III}[\text{Col3a1}](t) - f_{\text{removal}}(t), \quad (1)$$

where A_{col} is the medial collagen area, ξ_I and ξ_{III} are coefficients for the contributions of collagen I and III, respectively, to the production function, and $f_{\text{removal}}(t)$ is the removal rate function, which was defined empirically in the present study by treating the removal rates at $t = 0, 1.5, 3, 6, 9$, and 12 wk as free parameters. The removal rate function was constrained to be monotonically decreasing between 0 and 12 wk, and constant afterward. All parameters (8 total) were optimized via least-squares regression to the collagen area data.

RESULTS

Among all the mechanical metrics considered, the ratio between the circumferential stresses at systole and diastole ($\sigma_{\theta,sys}/\sigma_{\theta,dia}$) was found to correlate most strongly with collagen gene expression (Figure 1). The expression of collagen I was mostly closely associated with the age-dependent stress ratio, with both peaking at 2 wk and then dropping sharply by 6–8 wk. Collagen III followed the same trend qualitatively, but exhibited a more sustained expression until 6 wk, subsequently dropping to its mature steady-state value by 9 wk.

The gene expression-driven model of collagen accumulation within the media was able to capture the observed collagen area data well (Figure 2). Notably, model parameter optimization resulted in a ratio of production rate function coefficients $\xi_I:\xi_{III}$ close to 15:85, which is consistent with prior knowledge that the medial layer contains mostly type III collagen. The inferred removal rate function (Figure 2b) suggests that collagen removal is highest at birth, and drops sharply to its mature steady-state value by $t=6$ wk. Accordingly, collagen half-life is likely much shorter in early postnatal development (e.g., 4.5 days at $t=2$ wk vs. 70 days in maturity).

Figure 1: Correlation between the systolic-to-diastolic circumferential stress ratio and collagen gene expression.

DISCUSSION

The present study is a natural extension of previous efforts to describe how vessels alter their size, geometry, internal composition, and matrix architecture during the postnatal development and maturation period [1,2]. Unique to the present study, however, we have explicitly linked tissue-level cyclic mechanical loading patterns to cell-level transcriptional activity, which we used in turn to predict structural growth and remodeling of the collagen network back at the tissue level. This work thus represents an important step in the larger endeavor to construct a predictive multiscale model of vascular development and maturation, which must ultimately be robust to deviations from normal conditions (i.e., pathology, intervention) in order to ensure clinical applicability.

Our results suggest that the production of collagen in the developing aorta is tightly correlated with the *relative* magnitude of loading *over the cardiac cycle*, as quantified by the ratio of circumferential stresses between systole and diastole. While both systolic and diastolic circumferential stresses increase monotonically during development (result not shown), the ratio between them increases from birth to 2 wk and then decreases to its mature value by 6–8 wk, as does collagen expression (Figure 1). This result is consistent with previous studies showing biosynthetic sensitivity of

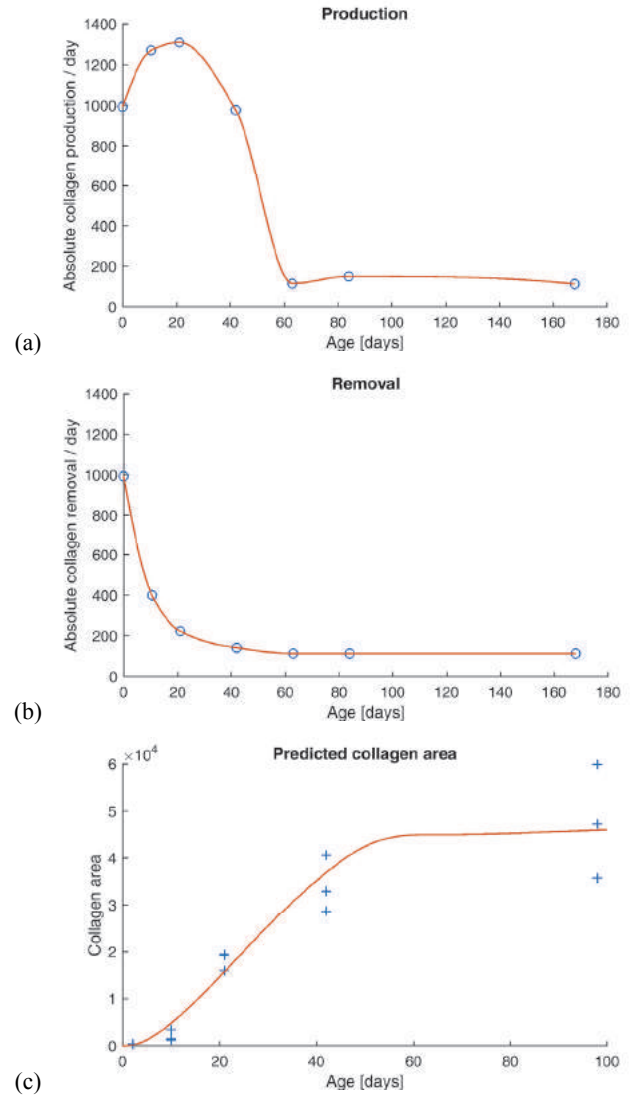

Figure 2: (a) Collagen (I + III) production rate function estimated from *Col1a1* and *Col3a1* expression. Open circles denote ages at which qRT-PCR data was collected. (b) Empirically determined collagen removal rate function. (c) Histological data (blue crosses) used to fit the model, and predicted collagen area (red curve).

vascular smooth muscle cells to the frequency and magnitude of cyclic loading [4]. Moreover, we have shown herein that collagen expression data can be used to predict extracellular collagen accumulation through the inference of associated production and removal rate functions (Figure 2), which themselves have broad implications for mechanobiological studies that include developmental time points.

INTRODUCTION

The rupture of an abdominal aortic aneurysm (AAA) is a nearly fatal event, carrying an overall mortality rate of 80%. The U.S. clinical standard to assess the need for AAA repair is 5.5 cm of maximum transverse diameter for male patients and between 5.0 cm and 5.4 cm for females [1]. However, wall stress measures have been postulated to be better predictors of rupture risk compared to size alone. To estimate accurately patient-specific wall stress, a subject's intra-aneurysmal blood pressure, wall and intraluminal thrombus (ILT) material properties, and the spatially distributed wall thickness would be needed at the time of clinical imaging. Along with wall stress, an estimate of wall strength can also be used concurrently to assess AAA rupture risk, in the form of a rupture potential index (RPI). Wall strength requires knowing the patient-specific familial history of AAA, sex, local diameter, and the ILT thickness. In addition, AAA geometric measures other than maximum diameter have also been implicated in rupture risk assessment [2].

The present work was performed to accomplish two primary objectives. The first objective was to interrogate the existence of an association between global AAA geometric measures and their growth rate with RPI, and biomechanical deterioration rate in a sample of surveillance AAA models generated from serial computed tomography angiography (CT) images. The second objective was to assess whether there is a relationship between spatially distributed AAA geometric measures with wall stress and RPI in the same aforementioned population sample. We hypothesized that RPI is positively correlated with ILT thickness and ILT volume, and is negatively correlated with wall thickness, AAA wall surface area, and AAA sac volume, in surveillance AAA.

METHODS

We retrospectively acquired images from 23 computed tomography angiography (CTA) exams obtained from seven AAA

patients with at least two CT exams performed at Allegheny General Hospital (Pittsburgh, PA) and Northwestern Memorial Hospital (Chicago, IL), following Institutional Review Board approval at both clinical centers (see Table 1). The CTA images were segmented from the renal arteries to the aorto-iliac bifurcation using a custom in-house MATLAB®-based (MathWorks Inc., Natick, MA) script [3] to generate the point cloud of three contours of interest (lumen, inner wall, and outer wall). Using another in-house code script [4], we generated volume meshes for each AAA model from which triangular surface meshes of the outer wall surface (in the range of 35,000-80,000 elements) were created with ICEM (ANSYS Inc., Canonsburg, PA).

Table 1. Surveillance AAA subject information (F and M refer to patient sex; the time in months is between each CT exam).

Patient	CT	Time (months)	Patient	CT	Time (months)
AAA1 (F)	CT1	-	AAA4 (F)	CT1	-
	CT2	5.3		CT2	13.9
	CT3	10.4	AAA5 (F)	CT1	-
	CT4	6.1		CT2	30.8
	CT5	4.4		CT3	3.9
	CT6	2.4		CT4	6.9
AAA2 (F)	CT1	-	AAA6 (M)	CT1	-
	CT2	15.2		CT2	12.8
	CT3	14.5		CT3	15.7
AAA3 (M)	CT1	-	AAA7 (F)	CT1	-
	CT2	8.4		CT2	12.1
	CT3	11			

Geometric indices were calculated using previously developed in house MATLAB® scripts [2]. The AAA wall thickness was calculated for each surface element based on the known CTA-measured thickness

prior to following a nonlinear elastic membrane analysis (NEMA) method to compute the first principal normal and shear stresses at the wall [5]. The proximal and distal ends of the models were fixed and an intraluminal pressure of 120 mmHg was applied. The wall strength was calculated using the following Eq. (1) proposed by Vande Geest et al [6].

$$\text{Wall Strength} = 72.9 - 33.5 * (\sqrt{ILT} - 0.79) - 12.3 * (NORD - 2.31) - 24 * HIST + 15 * SEX \quad (1)$$

where ILT is the ILT thickness(cm) and NORD is the normalized local diameter (dimensionless) at each node of the surface mesh, HIST is the familial history of AAA (+0.5 for positive familial history; -0.5 otherwise), and SEX is the sex of the patient (+0.5 for male; -0.5 for female).

The RPI for each element of the AAA surface mesh was calculated as the ratio of the first principal normal stress and the wall strength. Absolute and relative growth rates and biomechanical deterioration rate were calculated with the expression proposed by Lindquist et al [7].

RESULTS

Jarque-Bera and Shapiro-Wilks normality tests were calculated with a confidence interval of 95%. Both tests showed that most of the data is not normalized. RPI vs. time for patients with at least 3 CT exams revealed evidence of a positive nonlinear slope. Thus, a Spearman's correlation was used to obtain correlations for each pair of variables. Conversely, a Kolmogorov-Smirnov test was used to examine the normality of the data of each AAA and globally ($n > 1$ M) for the NEMA surface meshes, as it shows all variables are not normally distributed. Further, a Spearman's rank correlation coefficient ρ was calculated for the correlations of ILT thickness and wall thickness with wall stress and RPI for each surface element and globally for all AAA.

The following AAA global geometric measures were used: γ , ratio of ILT volume to AAA sac volume; V_{ILT} , ILT volume; V , AAA sac volume; S , surface area of the AAA wall; and D_{max} , maximum diameter of the AAA.

Figure 1. Spearman's rank correlation coefficients for geometric measures correlated with RPI.

The highest Spearman's rank correlation coefficients were 0.894 and 0.883 for γ and V_{ILT} , respectively (see Fig. 1). The maximum correlation between growth rate and RPI was 0.841 (for V_{ILT}) while the lowest was 0.776 (for D_{max}). All correlation coefficients between growth rate and deterioration were at least 10% lower than the correlations between growth rate and RPI.

In Table 2, PS indicates a patient-specific correlation, while Global refers to a correlation generated by the seven patients' data. The AAA spatially distributed geometric measures used were TH, aortic wall

thickness; TT, ILT thickness; NORD, normalized local diameter; GC, Gaussian curvature; and MC, mean curvature.

Table 2. Element based correlations for wall stress and RPI.

	Wall Stress				
	TH	TT	NORD	GC	MC
PS	[-0.7430 0.00087]	[-0.2851 0.47835]	[-0.2262 0.22853]	[-0.2113 0.05009]	[-0.3880 - 0.0845]
Global	-0.4633	0.39592	0.04980	-0.0857	-0.2600
	RPI				
	TH	TT	NORD	GC	MC
PS	[-0.7390 -0.0017]	[-0.1741 0.74486]	[-0.1420 0.29394]	[-0.1520 0.09192]	[-0.3489 - 0.0626]
Global	-0.3891	0.6334	0.19860	-0.0336	-0.2182

The strongest positive correlation for RPI was 0.633 for TT and the strongest negative correlation for wall stress was -0.4633 for TH. NORD and the Gaussian and mean curvatures do not exhibit strong correlations with wall stress or RPI.

DISCUSSION

Surveillance AAAs represent the most clinically relevant population group of this vascular disease, since the standard of care clinical guidelines for interventional repair do not apply due to their relatively small size. Thus, measures characteristic of the AAA size and shape, and biomechanics-based metrics can be used to interrogate which variables are associated with AAA growth.

The correlations presented herein indicate there is a strong association between RPI and growth rates of global size-based geometric measures, with the ratio of ILT volume to AAA sac volume, and the ILT volume being the most important measures. We infer that AAAs under surveillance that grow nonlinearly are associated with a high risk of rupture dependent on the ILT volume present in the AAA sac. Wall thickness and ILT thickness are the two most relevant spatially distributed variables strongly associated with wall stress and RPI. Collectively, this may indicate the need to develop automated image processing methods that can estimate the change in wall thickness and ILT volume and thickness over time.

Some limitations of this study are the relatively small population sample size, the peak systolic pressure, which was assumed the same for all patients due to the lack of patient-specific cuff or intraluminal aortic pressure. In addition, a more balanced number of male and female subjects may offer more insightful inferences on the sex-specific associations of geometric measures with RPI.

INTRODUCTION

Stroke is the 2nd leading cause of death worldwide. Endovascular thrombectomy is the current standard of care for patients with large vessel occlusions. However, these procedures are not effective in up to 40% of the cases [1]. Thrombi causing stroke are diverse in their composition. The main components are red blood cells (RBCs), fibrin, platelets, and white blood cells, and the thrombus composition is an important factor influencing successful recanalization [2]. The exact reason for this is unknown, but it is known that the composition and platelet-driven thrombus contraction affect the mechanical properties of thrombi, which has been postulated to influence the interaction with the thrombectomy device [3, 4, 5]. A pre-interventional estimation of the mechanical properties is hypothesized to aid in selecting the most suitable treatment on a case-by-case basis to improve success rates.

Computed Tomography (CT) imaging is the most commonly used imaging modality for diagnosis of stroke and could therefore potentially be useful to assess thrombus properties prior to the thrombectomy [3]. The purpose of this study is to examine the imaging and mechanical properties of clot analogues with different RBC compositions and degrees of contraction.

METHODS

Blood was drawn by venipuncture from six healthy human donors. Clots were made by reconstituting the platelet rich plasma and RBCs in five different volumetric RBC percentages of 0, 0.5, 2, 5, and 40% in order to span the range of compositions from ex vivo thrombi [2]. Also, clots were made with a low, medium, and high degree of contraction. The effect of platelet concentration on the degree of clot contraction was assessed by varying the platelet concentration in twelve 5% RBC volume clots (n=3 donors). From this, three platelet concentrations were selected to study three distinct degrees of contraction. To assess the extent of thrombus contraction, the weight of each clot was measured

and expressed as a percentage of the weight of the original clotting mixture [5].

To determine the mechanical properties, unconfined compression tests were performed using a custom made compression tester [4]. For this, the clots were cut into 2 mm slices. The samples were 80% compressed, with a compression and retraction speed of 0.2 mm/s (10% strain/s). As a measure for the stiffness, the high strain (approximately final 2%) secant moduli was measured from the slopes of fitted straight lines of the non-linear nominal stress-strain curves [4].

Clinical CT was used to determine the clot imaging characteristics. First, a non-contrast computed tomography (NCCT) was made to study the density. Subsequently, an iodinated contrast agent was added and a scan was made 20 minutes after administering the contrast in order to study the perviousness, which reflects the permeability of a clot. In each scan, three non-overlapping regions of interest with 1 mm diameter were defined in each clot, of which the mean density was measured in ImageJ [6].

The composition of the clot was analysed using histology. Hemotoxylin and Eosin (H&E) and Martius Scarlet Blue (MSB) stain was used to identify the percentage of RBCs using Orbit Image Analysis software.

One-way ANOVA tests were performed to assess whether the differences in clot properties between the clot types are significant. A p-value lower than 0.05 was considered statistically significant.

RESULTS

A non-linear relationship between the platelet concentration and the degree of contraction was observed (Fig.1). To produce clot analogues with distinct degrees of contraction, 30, 90 and 270 x 10³ platelets/ μ L concentrations were selected to create 'high', 'medium' and 'low' degrees of contraction.

Figure 1: Platelet concentration vs degree of clot contraction.

Figure 2A presents representative images of high, medium and low contraction groups for 2% RBC volume clots. RBC volumes of 0, 0.5, 2, 5, and 40% produced clots with 0.04, 25, 77, 94 and 99% RBC content, respectively ($P < 0.001$) (Fig.2B). There was no significant difference in RBC content of the three contraction groups (high, medium and low) within each clot RBC type (Fig.2B). The degree of contraction significantly increased with increasing platelet concentration within each RBC volume clot group ($P < 0.05$) (Fig.2C).

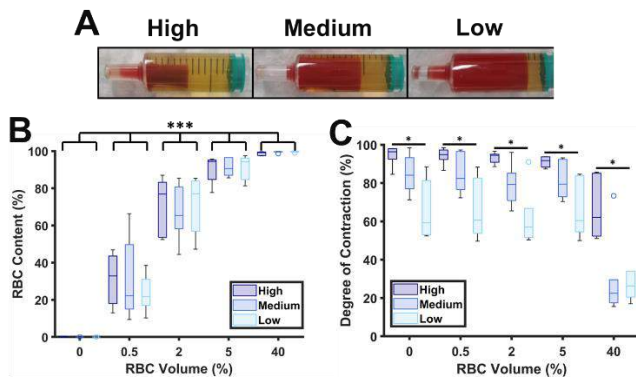

Figure 2: Confirmation of clot analogue composition and degree of contraction. (A) Representative images of a high, medium and low degree of contraction for 2% RBC volume clots. (B) RBC content for each RBC volume and contraction group. (C) Degree of clot contraction for each RBC volume and contraction group.

The compressive stiffness significantly increased with increasing contraction level, regardless of the RBC volume group (Fig.3A). In terms of RBC volume, for high degrees of contraction, the 0, 0.5 and 2% RBC clots had significantly higher stiffness values compared with the 40% RBC group (Fig.3B). In the medium contraction group, 0.05 and 5% RBC clots were significantly stiffer than the 40% RBC clots. There were no significant differences for the low contraction group.

The clot CT density significantly increased with increasing degree of contraction within each RBC volume group (Fig.4A). The clot CT density is also dependent on the RBC content (Fig. 4B). For each contraction group the density tends to increase with increasing RBC content, with significance occurring between the lower and higher RBC groups. Highly contracted clots tend to have higher perviousness values compared with medium and low groups, but not significantly (Fig.4C). There is only a significant difference between the perviousness values of RBC clot groups when they are highly contracted (Fig.4D), with significance occurring between the lower and higher RBC groups.

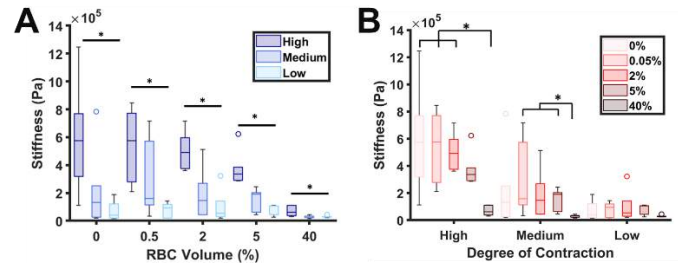

Figure 3: Clot mechanics. (A) Compressive stiffness per RBC volume group. (B) Compressive stiffness per contraction group.

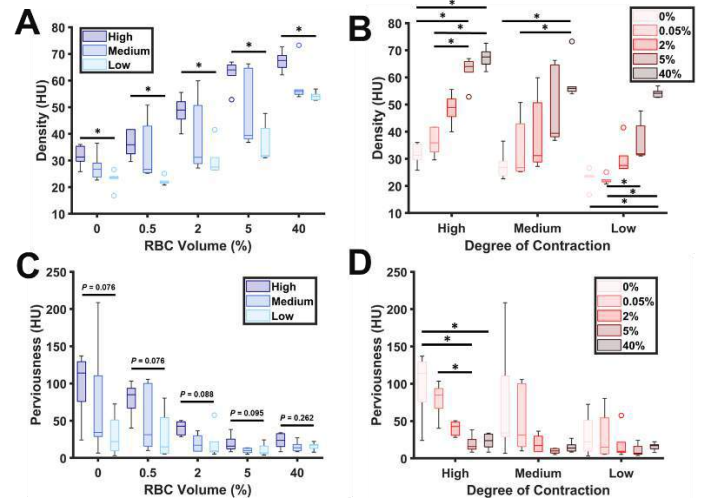

Figure 4: Clot imaging characteristics. (A) NCCT density per RBC group. (B) NCCT density per contraction group. (C) Perviousness per RBC group. (D) Perviousness per contraction group.

DISCUSSION

We successfully produced clots with 5 different RBC contents and 3 different degrees of contraction. Compressive stiffness increased with decreasing RBC content and increasing degree of contraction. This is as expected since clots with a lower RBC content contain a denser network of thicker fibers compared to RBC-rich clots [7], and contraction causes a higher clot compactness [5], both leading to a higher stiffness. We showed that the clot CT density increased with increasing RBC content, which confirms earlier findings [3]. For the first time, we showed that the density also increased with increasing degree of contraction (when the RBC content is unaffected), indicating that the RBC concentration is not the only factor affecting the CT density. It was hypothesized that highly contracted clots would contain denser structures and therefore a lower perviousness compared to less contracted clots; however, the opposite was observed in this study. Furthermore, perviousness values are only affected by RBC volume in the highly contracted group. The implication is that the assessed CT imaging characteristics alone cannot directly characterize a clot's RBC content and degree of contraction, and may therefore not be predictive of the mechanical behaviour.

INTRODUCTION

Magnetic resonance elastography (MRE) is an imaging technique used to estimate a tissue's mechanical properties remotely by measuring and analyzing the propagation of elastic body waves through the tissue. MRE of the liver provides a clinically approved assessment to support the staging of liver fibrosis [1]. In this setting, the mechanical waves are commonly produced at 20-200 Hz by an external actuator [1]. Preclinical MRE in animals is typically performed at a higher frequency range (200-1500 Hz) [1]. However, it is important to characterize the mechanical response of tissue at lower actuation frequencies because 1) mechanical properties tend to be frequency dependent, 2) new biomarkers owing to different mechanical phenomena may be available, and 3) body tissues undergo low-frequency displacements due to normal physiological processes which may be altered by disease.

In this study, various material models were employed to analyze and simulate the mechanical response of a cylindrical agarose gel sample to 10 Hz axial actuation. While pressure waves, as opposed to shear waves, are often ignored in MRE, a full viscoelastic inversion method was implemented to ascertain their potential contribution to the displacement field at low frequencies. Finite element method (FEM) models of the MRE experiment were developed to complement the inversion results by predicting the displacement field for a range of pressure and shear wave speeds.

METHODS

A cylindrical sample of 0.12% agarose gel measuring 60 mm in length and 19 mm in diameter contained in a glass vial was used as a tissue phantom for the MRE experiments. The free circular face of the gel was displaced axially by a piston 11 mm in diameter attached to a custom piezoelectric actuator operated at 10 Hz. A pulsed gradient spin echo (PGSE) sequence was used to acquire the 3D MRE data on a 7 T Bruker Biospin scanner. The displacement distribution data were acquired for 0.5 mm isotropic voxels in a 30 x 25 x 25 mm FOV using

a Hadamard encoding scheme with $b = 0$, 250 s/mm², $\delta/\Delta = 1.5/10$ ms, and $TR/TE = 200/16$ ms.

Viscoelastic properties of the sample were estimated using the full algebraic inversion of the differential equation (AIDE) method described in Oliphant et al. [2]. In this method, the displacement field is substituted into the frequency domain formulation of the linear viscoelastic momentum equations assuming an isotropic, locally homogeneous material (Eq. 1)

$$\mu \nabla^2 \mathbf{u} + (\lambda + \mu) \nabla(\nabla \cdot \mathbf{u}) = -\rho \omega^2 \mathbf{u} \quad (1)$$

Here λ and μ are Lamé's first and second parameters, ρ is density, ω is the angular actuation frequency, and \mathbf{u} is the complex-valued displacement at the actuation frequency. Complex-valued parameters λ and μ were estimated at each voxel by algebraic inversion and used to calculate the pressure and shear wave speeds by Eq. 2.

$$c_s = \sqrt{\frac{2|\mu|^2}{\rho(\mu' + |\mu|)}} \quad (2)$$

Above, μ' is the real part of μ . The pressure wave speed c_p can be found by substituting the pressure wave modulus $\lambda + 2\mu$ in place of μ . The full AIDE method was implemented in MATLAB R2022a.

FEM models were developed to predict the dynamic displacement field within the agarose gel phantom when subjected to the experimental loading conditions. The gel was modeled as either a compressible, isotropic linear elastic solid or a biphasic mixture. The biphasic mixture material consisted of a linear elastic solid matrix with pores through which an incompressible fluid phase may flow according to Darcy's law.

A half-cylinder geometry was subjected to sinusoidal axial displacement at 10 Hz on the piston-gel interface. No motion parallel or

perpendicular to the tube walls was permitted. A symmetry boundary condition was prescribed on the remaining flat surface of the half-cylinder. The mesh consisted of 9,216 trilinear hexahedral elements with a maximum side length of 1.87 mm. The model was solved with the dynamic quasi-newton solver available in FEBio.

RESULTS

Axial actuation of the cylindrical agarose sample by a circular piston at 10 Hz produced a nearly axisymmetric displacement field consisting of alternately rotating toroids propagating axially (Fig. 1).

Figure 1: Measured displacement field in a sagittal cross-section. A) Displacement streamlines. B) X-direction displacement. C) Z-direction displacement. Scale bar = 5 mm. The piston is represented by the gray bar at the bottom of each panel moving along the sample axis.

While the X-direction displacement is orthogonal to the propagation direction, indicative of a transverse shear wave, the Z-direction displacement is parallel to the propagation direction, suggesting a longitudinal wave is present. An axially alternating pattern of positive and negative dilatation is apparent near the centerline of the sample (Fig. 2).

Figure 2: Viscoelastic wave properties derived from the displacement field. A) Divergence of the displacement field. B) Pressure wave speed. C) Shear wave speed.

Algebraic inversion of the viscoelastic momentum equation resulted in a shear wave speed estimate of ~ 0.1 m/s and a pressure wave speed approximately 3 to 6 times greater for many voxels in the sample, although the latter estimate is considerably noisier.

A linear elastic solid FEM model of the MRE experiment showed that in a material with lower compressibility (pressure wave speed = 2.4 m/s) the axial wavelength of the displacement waves is longer than in the experiment. A more compressible material (pressure wave speed = 0.6 m/s) resulted in a displacement field with a shorter axial wavelength, which is more like that observed in the experiment (Fig. 3).

Figure 3: Varying pressure wave speed in solid FEM models. A) X-direction displacement and (B) Z-direction displacement for $c_p = 2.4$ m/s and $c_s = 0.1$ m/s. C) X-direction displacement and (D) Z-direction displacement for $c_p = 0.6$ m/s and $c_s = 0.1$ m/s.

An FEM model of a biphasic material consisting of a solid matrix with fluid-filled pores produced better agreement with the experiment than the linear elastic solid model (Figure 4). The solid and fluid velocities are nearly the same for this material, meaning they tend to move in-phase at this actuation frequency. However, dynamic changes in volume fraction of each phase appear to enable the development of axially shorter displacement waves.

Figure 4: Modeled displacement and velocity fields for a biphasic material. A) X-direction displacement. B) Z-direction displacement. C) Solid and fluid phase velocity (same appearance).

DISCUSSION

This study demonstrates that low-frequency actuation of agarose gel can produce complex displacement fields exhibiting both transverse and longitudinal waves. While the longitudinal wave evident along the centerline of the sample in Fig. 1C may be an example of a “longitudinal shear wave” [3], our viscoelastic inversion (Fig. 2B) and FEM analyses (Fig. 3) suggest that slower pressure wave speeds (0.3 - 0.6 m/s) than typically assumed for tissue (~ 1540 m/s) [1] are present in the sample. The corresponding “compressibility” of the gel is not likely an intrinsic property of the gel constituents since the gel is mostly water but may instead be a consequence of changes in the local volume fraction of fluid. Such poroelastic effects may be relevant at lower actuation frequencies [1], and our biphasic model (Fig. 4) matches the measured displacement field better than the solid model (Fig. 3). The unexpected behavior of the gel at 10 Hz suggests the need to characterize mechanical properties of tissues at low frequencies to better understand their mechanical response to normal physiological loading.

INTRODUCTION

Cell migration is a fundamental process in normal physiology, development and pathology [1]. Cells migrate inside the tissue to maintain the tissue homeostasis and to close the wounds. During development, cells migrate to neo-tissues and for subsequent deposition of the extracellular matrix. Cancer cells migrate through tissues to metastasize. Significant effort has been reported to understand the dynamics of single and collective cell migration in two dimensional and three-dimensional settings using *in vitro* and animal model.

The cell nucleus is emerging as a key mediator of the cell migration and has become a topic of recent interest to both the basic science and clinical research communities [2, 3]. The nucleus is the stiffest organelle in the cell and therefore appears as a limiting factor in cell migration through small pores. Recent discoveries show that cancer cells evolved to squeeze through small pores in tissues by adapting a specific mechanism in the cell nuclear envelope [4]. However, limited understanding exists regarding the role of intranuclear chromatin mechanics and architecture on cell migration, which are often compromised with aging and associated genomic instabilities [5]. The objective of this work is to elucidate how the chromatin mechanics and architecture affect two-dimensional (2D) cell migration using a model of the scratch wound assay with murine embryonic fibroblasts (NIH 3T3 cell line).

Scratch wound assay is a simple technique to understand the mechanism of cell migration. It is easy to control the biochemical and biophysical environment of the cells by changing the substrate chemistry and by adding pharmacological agent to the cell culture medium. We hypothesize that maintaining the nuclear stiffness (chromatin mechanics) and the chromatin remodeling (chromatin architecture) are critical factors for the efficient cell migration. To test this hypothesis, we decreased the nuclear stiffness by the application of a pharmacological agent trichostatin A (TSA) and inhibited the chromatin remodeling using GSK126.

METHODS

Cell culture: NIH 3T3 cells were cultured according to the ATCC protocol. Passage 4 cells were used for all the experiments. Cells were cultured in an ibidi 8 well slides to confluency. These slides have a thin transparent polymer bottom for imaging using an inverted microscope. **Scratch wound assay:** After cells reached confluency, a scratch was made using a 200 μ M pipette tip. DPBS was used to wash the debris. Subsequently, fresh medium was added to the wells. **Cell migration imaging:** Time lapse imaging of the wound closure and cell migration was performed using a live DNA stain – Nucblue to visualize the nucleus and also in the bright field to visualize the cells. The cells were maintained in an incubation chamber during the migration period. The incubation chamber has the environmental control to maintain a physiological condition of temperature, carbon di-oxide concentration and humidity. **Modulation of chromatin mechanics and architecture:** TSA (100 ng/ml) softens the nucleus by HDAC inhibition thus compromising chromatin mechanics. GSK126 (20 μ M) hinders chromatin remodeling by inhibiting EZH2 methyltransferase thus compromising chromatin architecture. Both drugs were added 12 hours before the scratch was made so that drugs are already in effect. Drugs were also added after the wash while adding the fresh medium. **Analysis:** ImageJ was used to track the individual cell nuclei in order to quantify several cell migration parameters such as speed, distance travelled and persistence of migration. The bright field images were used to quantify the wound closure by calculating the area covered by the cells. **Statistics:** ANOVA and post hoc tests was used for all statistical analysis.

RESULTS

The wound closure efficiency of cells was affected by the chromatin softening and by hindering the chromatin remodeling. Figure 1A shows that softened nucleus (TSA treated) and condensed chromatin (GK126 treated) decreases the wound closure efficiency by more than

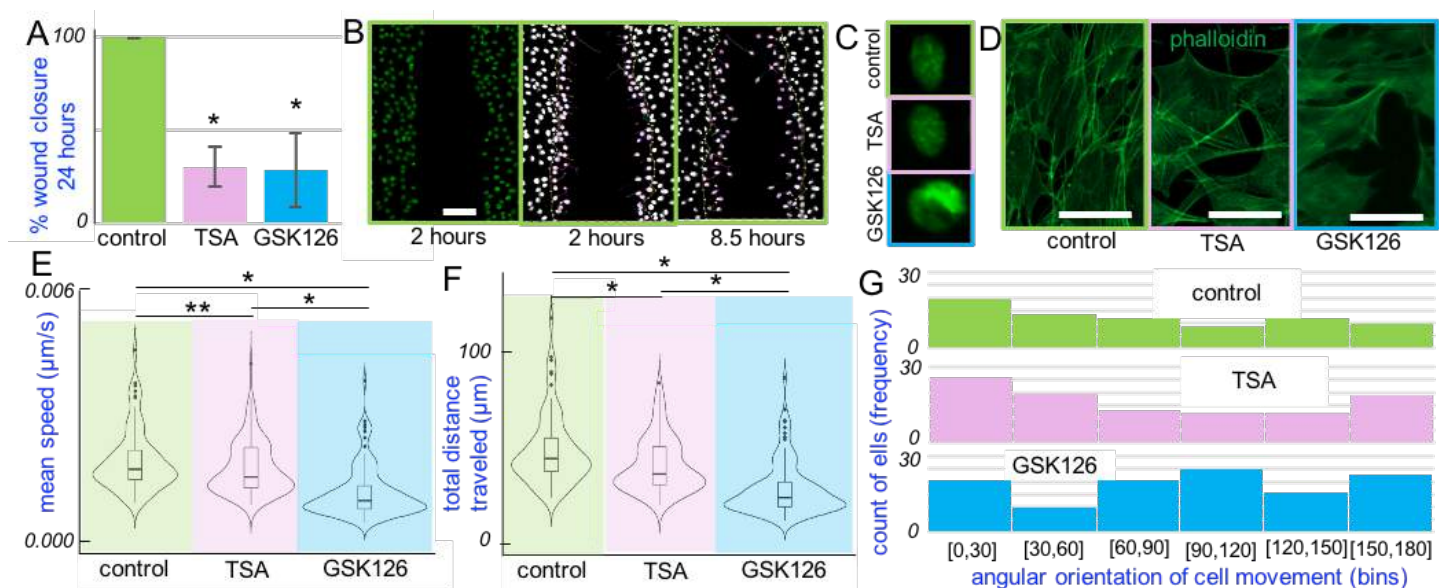

Figure 1. (A) Altering the chromatin mechanics (TSA) and chromatin architecture (GSK126) decreases wound closure efficiency. (B) Live cell imaging and automated tracking shown for a sample control group. Scale: 100 μ m. (C) TSA does not visibly affect chromatin architecture but GSK126 causes chromatin condensation. (D) F-actin structure is not affected by TSA and GSK126. Scale: 50 μ m. (E) Cell speed is drastically decreased by GSK126 but slightly decreased by TSA. (F) Track distance is drastically decreased by GSK126 and significantly decreased by TSA. (G) TSA does not change the migration persistence, but the GSK126 drastically hinders the migration persistence. For all cases, * $p < 0.01$ and ** $p < 0.05$. Data reported based on 3 technical replicates and at least 500 cells.

50% at 24 hours post scratch. In the control group, cells completely repopulate the wound at 24 hours. Figure 1B shows a representative image of cells migrating after the wound is created. Nuclear softening does not visibly affect the chromatin architecture but hindering the chromatin remodeler leads to a condensed chromatin (Figure 1C). The cytoskeletal architecture is not significantly affected by either drug treatment as shown by the F-actin staining Figure 1D. The cell shape is intact and stress fibers are visible in all groups.

Next, we wanted to investigate how softening of the nucleus and the inhibition of chromatin remodeling affects the specific cell migration parameters. Softening of cell slightly decreases the cell speed compared to control but blocking the chromatin remodeling significantly reduces the cell speed (Figure 1E). Similarly, the distance moved by cells significantly decreased by the chromatin softening and drastically decreased by the inhibition of chromatin remodeling (Figure 1G). The persistence of cell migration was calculated by computing the angle between the direction of cell movement and the direction perpendicular to the wound edge, at a given time point (Figure 1G). The distribution of the angular orientation shows that softening of nucleus does not significantly affect the persistence, but inhibition of chromatin remodeling drastically affects the persistence. Note that for a persistent migration, most cells will be oriented at 0° and 180° whereas for non-persistent migration, the cells are least oriented in 0° and 180° angular directions resembling the cells are undergoing mostly a random movement.

DISCUSSION

In this work we show that maintaining an optimal nuclear stiffness and the chromatin remodeling is required for efficient cell migration and wound healing in a two-dimensional plane. Stiff nucleus is known to be a barrier in 3D migration but in 2D context, certain amount of nuclear rigidity is required. This rigidity might be required for maintaining the

mechanical dynamics and force balance inside the cell during the leading edge protrusion and trailing edge contraction. The chromatin remodeling is turning out to be a critical component in several physiological process and our work identifies that plasticity of the chromatin remodeling is required for cells to migrate. It should be noted that none of the pharmacological inhibition affects the cytoskeletal structure. Therefore, the cell migration is primarily affected by an exclusive nuclear mechanical role. Our future work includes the profiling of other cytoskeletal proteins known to be responsible for cell migration so that we can understand if the pharmacological inhibition affects only the nuclear mechanics or also affects the cytoskeletal proteins. Other future works will include experiments with aged cells and cells with compromised nuclei (cancer and laminopathy). Finally, we are currently working to understand how the substrate stiffness plays an additional role in coordination with the nuclear mechanics during the cell migration.

AGING INFLUENCES STATIC AND DYNAMIC PROPERTIES OF PRIMARY MOUSE PULMONARY FIBROBLASTS THROUGH CELLULAR SENESCENCE

L. Lee (1), K. Penumatsa (2), M. Guo (1)

(1) Department of Mechanical Engineering, MIT, Cambridge, MA, USA
(2) Division of Pulmonary and Critical Care Medicine, Tufts Medical Center, Boston, MA, USA

INTRODUCTION

Half of all heart failure cases are found within the 6% of the US who is older than 75, and the prevalence of heart failure rises to almost 10% of the population older than 80. With an increasingly aging population estimated to reach 70 million or 25% over the age of 65 by the year 2030, the connection between cardiopulmonary aging and cardiopulmonary diseases becomes increasingly important to investigate [1]. In particular, the strong association between aging and structural and pressure-volume alterations from cardiopulmonary diseases suggests a mechanical difference at the cellular level. A central hallmark of aging lies in the increased presence of senescent cells, which express the phenotype of permanent cell-cycle arrest as proliferation and apoptosis comes to a halt [2]. These issues lead to an impaired ability to repair damaged tissues and an accumulation of unhealthy cells, which can cause a myriad of aging-related diseases.

Cell mechanics of aging and senescence have been investigated for geometric, static, and dynamic differences. Early sampling of cardiomyocytes from deceased human donors aged 17-90 years showed a progressive increase in cell volume but a decrease in cell count [3]. Multiple research groups measured aging cells to be stiffer than younger cells, including monkey vascular smooth muscle cells (VSMCs) [4] and rat cardiomyocytes [5], both measured using Atomic Force Microscopy (AFM). There are studies on cell spread and migration such as the comparison of human dermal fibroblasts in aging [6]. While previous studies focus on specific mechanical measurements, less work has been done to understand how these differences relate to one other. In addition, many cellular-level studies for cardiopulmonary systems focus on structural alterations from VSMCs and cardiomyocytes – knowledge is lacking on the functional differences of fibroblasts in those organs, which lead to the impaired wound healing abilities and other issues.

Because previous works observe mechanical differences in different cellular systems, this study aims to address the comprehensive understanding of how geometric, static, and dynamic properties are

influencing one another in the aging process. In addition, these aims seek to complement current knowledge of cellular mechanics in cardiopulmonary organs by investigating fibroblasts involved in the structural framework of tissues instead of VSMCs or cardiomyocytes. In order to investigate the differences in aging in cardiopulmonary fibroblasts, this study measures cell stiffness, migration, and cell spread area *in vitro* with primary lung fibroblasts isolated from senescence-resistant mice (SAMR1) and senescence-prone mice (SAMP8).

METHODS

Cell Culture and Substrate Preparation. Cells extracted from SAMR1 and SAMP8 mice (Envigo) were cultured at 37°C and 5% CO₂ in Fibroblast Medium (ScienCell) supplemented with 10% fetal bovine serum, 1% penicillin/streptomycin and 1% Fibroblast Growth Supplement. In all experiments, both groups were seeded on glass substrate coated overnight at 2°C with rat tail collagen I (4.06 mg ml⁻¹) diluted to 0.1 mg ml⁻¹ in phosphate buffered saline (PBS).

Optical Tweezers for Cytoplasmic Stiffness. Cell stiffness measurements were conducted by optical tweezers from a well-established method [7]. After cells had adhered to the surface of the substrate, polystyrene particles of diameter 870 nm were introduced into the media and endocytosed overnight. To measure the stiffness, the particles were dragged to the right by optical tweezers for 1 μm at a speed of 1 μm s⁻¹. The displacement of the bead and the resultant force were recorded and the stiffness, defined as the slope of the force-displacement curve, was calculated via linear curve fitting in MATLAB.

Fluorescent Imaging for Cell Spread Area. Cell spread area was calculated from cytoplasm stained using CellTracker CMFDA Green (ThermoFisher) with recommended protocols (1:1000 for 30 minutes at 37°C). The fluorescent images were taken using LEICA 8 confocal microscope on 63x water objective of z-stacks at pinhole 1.00 AU. Using ImageJ, z-stacks were projected onto a 2D image with maximum intensity, and thresholding was applied to obtain the area measurements.

Cell Migration Tracking for Long Time Scales. 2D migration studies were conducted with LEICA 8 confocal microscope on 10x dry objective. Cells were seeded at low density and allowed to spread for two days on the glass substrate, stained with CellTracker CMFDA Green and then placed on the stage at 37°C and 5% CO₂. Same locations were imaged every 5 minutes for a total of 10 hours. The positions of the cells were traced the TrackMate plugin in ImageJ [8], and the analysis of the positions, such as mean squared displacement, moving velocities, and trajectory plotting, were conducted using MATLAB.

RESULTS

Cell Stiffness. Taking samples from SAMR1 (n=5) mice and SAMP8 (n=4) mice, the optical tweezers measurements conclude differences ($p = 0.0025$) in the subject-level means tested against the null hypothesis with the student's t-test (Figure 1). SAMR1 stiffness measured 1.39 ± 0.0931 (SE) Pa while SAMP8 stiffness measured 2.79 ± 0.323 (SE) Pa, showing that the SAMP8 cytoplasm is 2.00 times stiffer than the SAMR1 cytoplasm on average.

Figure 1: Schematic of optical tweezers (left) and a comparison of elastic moduli of SAMR1 vs SAMP8 cells (right)

Cell Spread Area. The subject-level means tested against the null hypothesis using the student's t-test shows $p = 0.0386$ (Figure 2). SAMR1 spread on $7,296 \pm 737$ (SE) μm^2 while SAMP8 spread on $19,316 \pm 2,320$ (SE) μm^2 . The comparison of the sample means shows that SAMP8 spreads 2.65 times larger on average than SAMR1.

Figure 2: Representative fluorescent images of SAMR1 (left) and SAMP8 (middle) and spread area of SAMR1 vs SAMP8 (right)

Cell Migration in 2D. Preliminary results from cell migration tracking show shorter trajectories in SAMP8 cells compared to SAMR1 cells (Figure 3), and correspondingly, characteristics of its movement such as the mean-squared displacement and the moving velocities of the two are displaying some differences.

Figure 3: Cell tracking method on ImageJ TrackMate plugin (left) and 10-hour trajectory maps of SAMR1 and SAMP8 (right)

DISCUSSION

Cell Cytoplasm Stiffens. SAMP8 cells showed a twofold increase in stiffness from SAMR1 cells. This is consistent with previous literature that aging stiffens cells and complements other results due to the location the optical tweezers probe. These measurements take place inside of the cell and delineates the overall stiffness of the cells to measure specifically the internal cytoplasmic network of cells. While other studies utilize AFM, Deformable Cytometry, and the like to measure stiffness of the whole cell, this study was able to confirm the stiffening of one area of the cell during the aging process, adding more detail into the understanding of cell stiffening in the aging process.

Cells Seem to Spread More on Glass Substrate. Cell spread area measurements conducted in this study suggests that aging causes more than 2.5x larger spread area, and this observation aligns with the previous results conducted by Park et al. on human dermal fibroblasts [9]. This study contextualizes these numbers against the stiffness measurements to draw correlations between them. With the framework that stiffness and cell spread may be related [10], more work can provide hints toward other physical properties of these cells, such as cell adhesion or growth. In particular, the fundamental size difference of aged versus young cells is especially of interest since both cell groups in this study tend to spread more thinly on the glass substrate than other types of fibroblasts used in cell studies.

Cell Migration Seems Slower and Shorter. Tracking the 2D migration on glass substrate, SAMP8 cells traveled less and more slowly than SAMR1 cells. These results seem to suggest a lower motility in the aging phenotype, which is also observed in other studies. One interesting observation from the preliminary results show anomalous diffusion [11] in the motion of these cells with mean squared displacement slope close to 1.5 (not shown), which are not fully explained in previous works on aging studies.

A Comprehensive Mechanical Study of Aging. This study encompasses a wide variety of mechanical changes in cells due to aging, from the static to the dynamic properties *in vitro*. The different parameters may assess the cellular-level causes into both the structural and functional deterioration of aging in cardiopulmonary organs. While this study contextualizes different mechanical properties of the aging phenotype by measuring cytoplasmic stiffness, cell spread area, and 2D migration, the results are unable to conclude the underlying mechanism behind these changes. Given the three trends observed, the density of cytoplasmic proteins within the cell becomes a question of interest and a possible explanation behind the mechanism of mechanical change.

INTRODUCTION

Osteoarthritis (OA) is the most prevalent musculoskeletal disease classified by irreversible degradation of articular cartilage extracellular matrix (ECM), a hydrated composite of collagen II/IX/XI fibrils entrapping the aggrecan aggregate networks [1]. Current reparative and regenerative strategies are challenged by the incomplete understanding of molecular activities of ECM molecules that regulate the matrix assembly and degradation [2]. Our recent study identified decorin, a small-leucine rich proteoglycan (SLRP), in mediating the biomechanical functions of cartilage during post-natal growth [3] and attenuating cartilage breakdown in OA [4]. Specifically, in decorin-null murine model, loss of decorin leads to reduced aggrecan content in both the PCM and bulk territorial/interterritorial matrix (T/IT-ECM), and in turn, chondrocyte in situ mechanotransduction [5]. This impact on aggrecan integrity cannot be directly interpreted by its canonical role in regulating the structure of collagen fibrils [6]. This study thus aims to further delineate the molecular activities of decorin in regulating the aggrecan integrity versus mediating collagen fibril assembly. We investigated the role of decorin in mediating distribution and retention of newly synthesized proteins and glycosaminoglycans (GAGs) using the click-labeling method [7], and at the same time, assessed its impact on the mechanical properties of collagen network via AFM nanoindentation.

METHODS

Explant culture model with metabolic click labeling. Femoral head cartilage explants were harvested from age-matched, 21-day-old (P21) decorin-null (*Dcn*^{-/-}) and wild-type (WT) C57BL/6J mice, and cultured for studying. Explants were first pre-cultured for two days with an additional 1% penicillin-streptomycin, followed by 3 days of metabolic labeling with either 30 mM N-azidoacetyl-galactosamine-tetraacylated (GAL) (1086, ClickChemistryTools) in phenol red deficient high

glucose DMEM or 30 mM L-azidohomoalanine (AHA) (1066, ClickChemistryTools) in DMEM-LM to label for newly synthesized GAGs and proteins, respectively. *Nascent proteoglycans released* into the supernatant were collected daily over a period of 6 days after an overnight wash post-click labeling with 30 mM AZDye 488 DBCO (1278, ClickChemistryTools). Tissues were digested with 2% papain, and the relative release percentage was calculated. *Confocal images* of neo-proteoglycan and proteins were obtained 24 hours following click labeling at the time point of interest to assess the spatial distribution of nascent proteoglycans and proteins (Fig. 1). *AFM-nanoindentation* was applied to quantify the indentation modulus, E_{ind} , of fresh medial femoral condyles of *Dcn*^{-/-} and WT mice in PBS using a microspherical tip ($R \approx 5 \mu\text{m}$, $k \approx 5.4 \text{ N/m}$), following established procedure [3]. To pinpoint the role of decorin in the integrity of collagen network, we quantified the modulus of 1) untreated tissue with native proteoglycans intact, 2) sGAG-depleted via treatment of 0.5 U/ml chondroitinase ABC (chABC) and 500 U/ml hyaluronidase, 3) exogenous decorin-infiltrated (20 $\mu\text{g/mL}$ for 24 hours) for both genotypes. A repeated measure two-way analysis of variance (ANOVA) was applied to compare release at each day and regular two-way ANOVA was applied to compare E_{ind} for each genotype and treatment condition, followed by the Tukey-Kramer multiple comparison to correct for family-wise errors. The significance level was set at $\alpha = 0.05$.

RESULTS

Fluorescence imaging showed clear differences in the distributions of nascent GAGs (Fig. 1a) and proteins (Fig. 1b). From AHA-labeling, at both day 2 and day 6, the nascent proteins were distributed nearly homogeneously throughout the intercellular spacing. In contrast, from GAL-labeling, there was a high concentration of nascent GAGs surrounding individual cells, illustrating preferred localization of newly synthesized proteoglycans in the pericellular spacing. At both time points, we did not observe any salient differences between the WT and

Dcn^{-/-} groups, except for a mildly increase in the GAL-fluorescent signal in the T/IT-ECM at day 6 (black arrowheads). On the other hand, when stimulated by inflammatory cytokine IL-1 β , an increasing percentage of nascent GAGs were released from the explant (Fig. 2). Given that cartilage GAGs are mainly contributed by aggrecan, this evidenced the reduced retention of neo-aggrecan in degenerative cartilage upon inflammatory attacks with the loss of decorin.

Under AFM nanoindentation, *Dcn*^{-/-} cartilage showed significantly lower modulus in comparison to the WT (Fig. 3). Furthermore, removal of sGAGs significantly decreased the cartilage modulus for both WT and *Dcn*^{-/-} groups, albeit the degree of reduction was much greater for the WT group. Meanwhile, infiltration of exogenous decorin significantly elevated the modulus of WT, but not *Dcn*^{-/-} group.

DISCUSSION

This study highlights a crucial role of decorin in regulating the assembly and integrity of articular cartilage matrix. Previously, we have shown that loss of decorin reduces the retention of aggrecan network in cartilage without altering the architecture of collagen II fibrils [3]. It begs the question how does decorin mediate the individual assembly of collagen fibrils and aggrecan network, and in turn, integration of the two. As collagen II is the major protein content of cartilage matrix, the AHA-click labeling shows loss of decorin does not directly impact the assembly of nascent collagen molecules, consistent with our previous observation that the collagen content was not reduced in adult decorin-null cartilage [3]. Meanwhile, we show that the nascent aggrecan is mainly concentrated in the PCM following its biosynthesis, and then, diffuses to the T/IT-ECM (e.g., day 6). Although loss of decorin does not show a clear effect within the 6-day culture duration (Fig. 1), increasing aggrecan fragmentation via IL-1 β leads to accelerated loss of nascent aggrecan (Fig. 2). Thus, the impact of decorin on cartilage matrix integrity is mainly on the retention of aggrecan, and this effect is mainly manifested through the retention of aggrecan within the collagen network.

Comparing the impact of sGAG removal on the moduli of WT and *Dcn*^{-/-} cartilage (Fig. 3), the major impact of decorin was to regulate the contribution of aggrecan to E_{ind} . On the other hand, the differential effects of exogenous decorin indicated a role of decorin in mediating the collagen fibril networks. For WT sGAG-depleted cartilage, decorin was able to elevate E_{ind} , suggesting that decorin could strengthen the collagen network by providing additional physical linkages between collagen fibrils. In contrast, for the *Dcn*^{-/-} group, such effect was minimal. Here, loss of decorin during collagen fibrillogenesis results in disrupted assembly of collagen II fibrils, including altered fibril diameter in the PCM and increased fibril heterogeneity in both PCM and T/IT-ECM [5]. It is thus possible that exogenous decorin is unable to strengthen the altered collagen fibril network. As a result, although the integrity of aggrecan may not be affected in the short duration, this disrupted fibril network is unable to sustain the retention of aggrecan under external instigations. For example, in vivo, the effect of decorin loss is minimal in newborn mice, but increases progressively with age [8]. Here, upon accelerated aggrecan degradation IL-1 β , the effect of decorin loss becomes more apparent. Taken together, our results suggest a crucial role of decorin in mediating the interplay between collagen fibril network and aggrecan network, which is necessary for the maintenance of cartilage integrity, especially upon the fragmentation of aggrecan under inflammation or in disease initiation.

EVALUATING THE EFFECT OF SOFT TISSUE FORCES ON THE FIXATION MECHANICS OF REVERSE SHOULDER ARTHROPLASTY: A FINITE ELEMENT ANALYSIS DRIVEN BY MUSCULOSKELETAL SIMULATIONS

INTRODUCTION

Reverse shoulder arthroplasty (RSA) is used to alleviate pain and restore shoulder function to patients with rotator cuff arthropathies [1]. Despite promising clinical results, multiple complications still exist, such as reduced post-operative function, impingement, and glenoid loosening [2]. Numerous cadaveric and computational studies have investigated the fixation of the glenoid, including finite element (FE) analyses conducted to understand the bone-implant fixation [3-5]. Unfortunately, the current FE models in the literature use simplistic loading profiles which are applied to the glenohumeral (GH) joint and do not consider the effect of the multiaxial loads that are typically observed during activities of daily living. Moreover, these models have not considered the loads applied by the soft tissues during these complex movements. Therefore, we sought to use a musculoskeletal model of the shoulder to determine physiological loading conditions and then transfer these loads to a corresponding FE model to holistically evaluate the fixation mechanics at the bone-implant interface. With this approach, we sought to test the hypothesis that including soft tissue forces during FE simulations of an activity of daily living would increase the bone-implant micromotion of RSA.

METHODS

Our computational approach used the outputs of a multibody musculoskeletal model (the Newcastle Shoulder Model – NSM [6]) as the inputs to a corresponding FE model. The NSM, which consists of 6 segments (thorax, clavicle, scapula, humerus, ulnar, and radius), 31 muscles, and 3 ligaments (soft tissues), determined the soft tissue forces and the glenohumeral (GH) joint contact forces of the RSA joint using inverse dynamics and optimization techniques. The FE model then used all the soft tissue and GH joint contact forces as inputs to determine the micromotion at the interface of the implant and resected glenoid on the scapula (Fig. 1). Both the musculoskeletal and FE models were adapted with the glenohumeral anatomy of five patients with rotator cuff arthropathies. The scapula and humerus were reconstructed from pre-operative CT scans and soft tissue attachments were customized to the patient-specific attachment sites. A commercially available RSA system (Comprehensive Reverse Shoulder System. Biomet, Inc., Warsaw, IN) was then virtually implanted into each model. The component placement was verified by a board-certified shoulder orthopaedic surgeon (LG). The musculoskeletal model simulated a single activity of daily living (reaching for an object at head height) and determined the soft tissue and GH joint contact forces throughout the activity, which were then transferred to the matching patient-specific FE models. The GH joint contact forces were applied to the center of rotation (center of the glenoid sphere) and the soft tissue forces on the scapula were applied at their attachment sites (i.e., the same locations as used in the musculoskeletal models). The bone was modeled as a non-homogenous material, with an elastic modulus (E) determined from the pre-operative CT scans using a pooled density-modulus relationship [7]. The glenosphere was modeled as a rigid body and the superior, inferior, and central locking screws and metaglene were modeled as a solid titanium alloy ($E=113.8$ GPa, Poisson's ratio, $\nu=0.3$). The bone-implant interface

was modeled as frictional, with a coefficient of 0.6. The bone was fixed at the medial border of the scapula and at the acromioclavicular joint [4]. For each FE model, we simulated two loading configurations: 1) application of only the GH contact forces (Fig. 1a) and 2) application of both the GH contact forces and the soft tissue forces (Fig. 1b). For each configuration, our primary outcome measure was the bone-implant micromotion (measured in micrometers, μm), which was computed as the difference in displacement between each pair of closest nodes at the bone-implant interface.

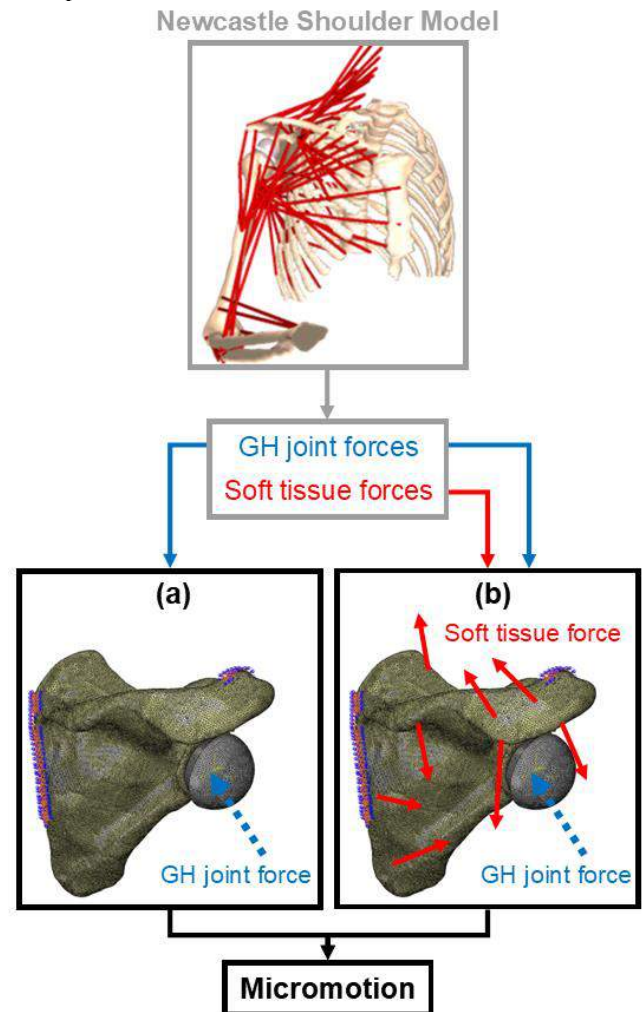

Figure 1: Overview of our computational approach to determine bone-implant micromotion. It used the NSM to predict soft tissue and GH joint contact forces and then transferred these forces to corresponding FE models which used (a) only the GH joint contact force and (b) both the soft tissue and GH joint contact forces.

RESULTS

The net GH joint contact force (reported in bodyweight, BW) exhibited a first, larger, peak of $0.52 \text{ BW} \pm 0.03 \text{ BW}$ at 31% of the cycle and a second, smaller, peak of $0.47 \text{ BW} \pm 0.05 \text{ BW}$ at 65% of the cycle (Fig. 2; top). Within these two peaks, the arm was elevated as it reached for the object at head height. At the first loading peak, the compression and shear forces were $0.49 \text{ BW} \pm 0.04 \text{ BW}$ and $0.17 \text{ BW} \pm 0.06 \text{ BW}$, respectively. In addition, the compression force represented 50% - 92% of the net GH joint contact force throughout the activity.

When only the GH joint contact force was considered, the average peak micromotion varied from $3 \mu\text{m} \pm 1 \mu\text{m}$ (at 33% of the cycle) to $6 \mu\text{m} \pm 2 \mu\text{m}$ (at 73% of the cycle). Conversely, when both the soft tissue and GH joint forces were considered, the peak micromotion ranged from $13 \mu\text{m} \pm 9 \mu\text{m}$ (53% of the cycle) to $18 \mu\text{m} \pm 11 \mu\text{m}$ (79% of the cycle, Fig. 2; bottom). At the instant of the overall peak micromotion, the compression force represented 72% of the net GH joint contact force. This was a 16% reduction compared to the instant of peak GH loading (31% of the cycle).

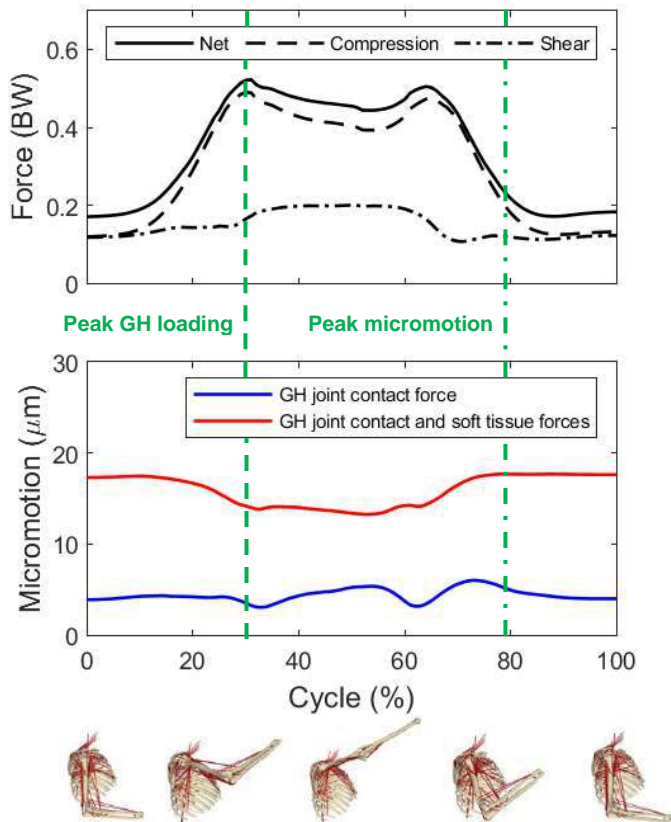

Figure 2: Top: Average GH joint contact forces (in BW) during the activity cycle. Solid line: net GH joint force; dashed line: compression force; and dot-dashed line: shear force. Bottom: Peak micromotion (in μm) at the bone-implant interface during the activity cycle. Blue line: configuration where only GH joint contact forces were considered; red line: configuration where both soft tissue and GH joint contact forces were considered. The dashed green vertical line represents the instant of peak net GH loading, and the green dot-dashed line represents the instant of overall peak micromotion.

DISCUSSION

By simulating an activity of daily living, we found that the instant of peak micromotion did not correspond with the instant of peak GH joint contact force, which has been a commonly used loading scenario for prior FE models of shoulder replacements. From our observations, we postulate that this may be attributed to the changing distribution of the compression and shear forces in the GH joint throughout the activity. For example, the compression force accounted for 88% of the net GH joint contact force at the instant of peak GH loading and 72% at the instant of peak micromotion. Moreover, these changes may also have an interaction with the inherently complex geometry of the scapula.

For both loading configurations, the peak micromotion throughout the cycle was small and within the acceptable limits for bone ingrowth to occur for cementless implants [8]. However, by including the soft tissue forces in the FE models, we observed an average increase in micromotion by 370% across the activity cycle. Thus, our results suggest that the omission of soft tissue forces can lead to an underestimation of the burden placed on the bone-implant interface.

Our study considered a fixed acromioclavicular joint, and this may be a limitation. In our future studies we intend to investigate the impact of the acromioclavicular joint as a non-fixed boundary condition as the muscle forces attached to the acromion may also contribute to the bone-implant micromotion.

In conclusion, by connecting musculoskeletal and finite element models, we found that the peak micromotion during an activity of daily living did not correspond with the instant of peak GH joint loading and that the inclusion of soft tissue forces led to the prediction of increased micromotion. These methodological updates to the FE modelling of shoulder arthroplasty are important as future FE studies should investigate more representative activities cycles, with soft tissue forces, to holistically assess the impact of shoulder biomechanics on the fixation mechanics at the bone-implant interface.

Going forward, we aim to use to our workflow to evaluate the impact of the design and placement of total and reverse shoulder arthroplasty components on both the joint mechanics and implant fixation mechanics of the post-operative glenohumeral joint.

AN EULER-LARGANGE APPROACH FOR MODELING PARTICLE-LADEN FLOWS IN BIOLOGICAL APPLICATIONS

INTRODUCTION

Fluid mechanics plays a crucial role in numerous physiological processes related to health and disease. Advances in medical imaging, computational power, and mathematical algorithms have made it possible to perform real-time, patient-specific computational fluid dynamics analyses. However, many problems involve complex interactions between fluids and particles of varying mass and size,

Figure 1: Snapshot from a simulation of a concentrated particle-laden flow through unstructured grid geometry.

which presents challenges in understanding and modeling their dynamics. The goal of this work is to develop a computationally efficient, scalable, physics-based framework for particle-laden biological flows in complex subject-specific geometries (e.g., Figure 1) to enable the next generation of methods for computer-aided diagnostics and disease research. The proposed scheme is based on a volume-filtered Euler-Lagrange formulation of the incompressible Navier-Stokes equations in which particles and fluid are fully coupled, and the finite volume fraction effect of the particles is accounted for explicitly.

METHODS

In the Euler-Lagrange method, the fluid flow governing equations are solved on an Eulerian grid. Particles within the fluid are treated as discrete points, which can interact with the fluid and other particles through the exertion and experience of forces. For cases where the particle mass and volume fraction are small, feedback of the particles on the fluid can be reasonably neglected, leading to "one-way" coupled models. However, to ensure applicability to a wide range of particle-laden flows, we have implemented a fully coupled model, also referred to as a "4-way" coupling in literature. The level of coupling can be easily adjusted depending on the specific problem and desired level of accuracy. These methods and models are implemented within the CRIMSON framework [1], providing a flexible and user-friendly platform for simulating particle-laden flows in patient-specific geometries. The equations are solved using the finite element method. The fluid governing equations shown below are derived from the incompressible viscous flow equations after application of a filtering (averaging) operator. See [2] for a detailed derivation. The volume filtered fluid phase equations take the form

$$\frac{\partial u_i}{\partial x_i} + \frac{1}{\phi_f} \frac{D\phi_f}{Dt} = 0 \quad (1)$$

$$\rho \left(\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} \right) = - \frac{\partial p}{\partial x_i} + \frac{\partial \tau_{ij}}{\partial x_j} + \frac{1}{\phi_f} f_i^p \quad (2)$$

where the velocity and pressure should be understood to be volume filtered quantities. ρ is the density of the fluid phase, ϕ_f is the volume fraction of the fluid phase, and f_i^p is the momentum source that couples the particles to the fluid phase, which can be understood as the reaction force felt by the fluid due to the drag experienced by the particles. The fluid equations are solved using a stabilized finite element method

which incorporates streamline-upwind/Petrov-Galerkin (SUPG), pressure-stabilizing/Petrov-Galerkin (PSPG) and grad-div stabilizations. This allows for solving advective incompressible flows with equal order elements for velocity and pressure. The equations are solved implicitly and marched in time using a generalized- α method.

The particle dynamics are calculated individually in accordance with the Newton's laws of motion where each particle's position is obtained by integrating the following

$$\frac{d\mathbf{X}_p}{dt} = \mathbf{V}_p, \quad m_p \frac{d\mathbf{V}_p}{dt} = \mathbf{F}_d + \mathbf{F}_c, \quad I_p \frac{d\boldsymbol{\Omega}_p}{dt} = \mathbf{T}_d + \mathbf{T}_c \quad (3)$$

where \mathbf{X}_p is the position of the particle, \mathbf{V}_p is the translational velocity, m_p is the mass, $\boldsymbol{\Omega}_p$ is the angular velocity and I_p is the rotational moment of inertia of the particle. \mathbf{F}_d is the drag force experienced by the particle and \mathbf{F}_c is the force due to collisions with other particles. \mathbf{T}_d is the hydrodynamic torque on the particle and finally \mathbf{T}_c is the collisional torque arising from friction between the interacting particles. Numerous drag models have been developed and used for Euler-Lagrange simulations in the literature. Here we use the drag model put forth by Tenneti [3], which is well suited for the parameter space of problems relevant for biofluid applications:

$$F(\phi, Re_m) = \frac{F_{\text{isol}}(Re_m)}{(1-\phi)^3} + F_\phi(\phi) + F_{\phi, Re_m}(\phi, Re_m) \quad (4)$$

here, F_{isol} is the drag force acting on an isolated sphere moving in an unbounded medium. The remaining two terms are given by

$$F_\phi(\phi) = \frac{5.81\phi}{(1-\phi)^3} + 0.48 \frac{\phi^{1/3}}{(1-\phi)^4} \quad (5)$$

$$F_{\phi, Re_m}(\phi, Re_m) = \phi^3 Re_m \left(0.95 + \frac{0.61\phi^3}{(1-\phi)^2} \right)$$

where ϕ is the particle volume fraction and Re_m the Reynolds number based on particle diameter and mean slip velocity. Particle collisions are modeled using the soft-sphere discrete element method (DEM).

RESULTS

A critical component of the volume filtered Euler-Lagrange scheme is the transfer of physical quantities between the Lagrangian and Eulerian representations. For instance, the particle distribution must be projected onto the finite-element mesh before the governing equations

Figure 2: Left: Projected volume fraction due to a single particle at the origin, with increasing grid resolution. Right: Plot showing convergence of the projection procedure employed.

can be solved. For consistency, this process needs to be conservative and convergent. This is achieved via a two-step procedure that decouples particle size from the element size which allows flexibility and gives convergent solutions. Figure 2 shows the convergence plot for the projection process as implemented in the current FEM setting.

Results from preliminary simulations are shown in Figure 3 for a T shaped geometry where the left and right sides of the T are inlets, and the stem is an outlet boundary. Initially, XX particles of RR radius and rho density are uniformly distributed over the volume of the geometry. As the simulation goes on, fluid enters the domain from the inlet faces and particles are carried out of the domain through the outlet.

Figure 3: Results from a particle-laden simulation showing distribution of particles in a T-shaped geometry. Top frames show the initial condition and bottom frames shows the state at $t = 0.9s$. Particles are shown explicitly on the left, while the projected particle volume fraction field is shown on the right.

DISCUSSION

We have developed a scalable volume-filtered Euler-Lagrange scheme for the simulation of particle-laden flows on unstructured grids. This method is applicable to a range of biological fluid dynamics phenomena. It involves a Lagrangian to Eulerian projection of conserved quantities for unstructured finite element grids, which is consistent, conservative and convergent. These improvements contrast with existing methods that lacked this combination of qualities. We have presented preliminary results which demonstrate the capabilities of our proposed multiphase flow solver. Further development and validation of the solver is currently ongoing. Our CFD-DEM solver will enable efficient large-scale simulations of particle-laden flows, while retaining important microscale physics. This will provide a versatile tool for computer-aided diagnostic applications. While the CRIMSON framework is specialized for cardiovascular flows, it is easily generalizable to other biofluid applications, and we plan to apply these developments to study particulate flow in the inner ear to aid in the analysis and treatment of benign paroxysmal positional vertigo caused by suspended particles settling in the semi-circular canals.

A DEEP LEARNING APPROACH FOR CARDIAC MODEL CONSTRUCTION FOR CONGENITAL HEART DISEASE PATIENTS

Fanwei Kong (1), Alison L. Marsden (1, 2, 3)

- (1) Department of Pediatrics, Stanford University, Stanford, CA, USA

INTRODUCTION

Congenital heart defects (CHDs) are the most common birth defects and are characterized by abnormal cardiac anatomies that can dramatically impact cardiac functional outcomes. CHD patients often have unique but complex cardiac malformations and anatomical arrangements that warrant patient-specific treatment planning and surgical interventions. Personalized computer models of the heart derived from patient image data can simulate various aspects of cardiac function and can thus model complex clinical scenarios in CHD patients and have demonstrated potential to facilitate personalized treatment planning and decision-making¹⁻². However, prior studies often require prohibitively laborious human effort to generate models that accurately capture CHDs from patient image data, thus limiting large-scale validation studies and clinical translation of this novel paradigm. Therefore, there is a strong need for automated image-based modeling of the heart for CHD patients to support virtual surgery planning in real clinical settings.

Although deep learning (DL) methods have demonstrated immense potential in automatic medical image analysis in the area of whole heart reconstruction and segmentation³, prior approaches were mostly developed to model normal cardiac structures and cannot be generalized to model cardiac malformations seen in CHD patients. For example, our prior work proposed a DL method to deform a *template mesh* of a healthy heart to automate the model generation process for various cardiac simulations⁴. This method thus cannot capture the CHD anatomies that have peculiar cardiac arrangements and topologies that differ significantly from those in the mesh template.

Therefore, we aim to develop an DL algorithm to automatically and efficiently generate cardiac models from image data of CHD patients. Rather than deforming an explicit mesh template, we propose to implicitly represent the shapes of the heart using *signed distance fields* (SDF) learned by neural networks to conveniently capture the unique arrangements and topologies of the cardiac shapes in several

types of CHDs. We then deform the SDFs based on patient image data to reconstruct personalized cardiac models that successfully capture the structural abnormalities.

METHODS

Figure 1: Example segmentations for different CHD types.

Dataset: We considered a few types of CHDs that cause abnormal arrangement and anatomy of heart chambers and great vessels in our study. Namely, we included a total of 51 CT images that covered 29, 14, 12, 5, and 5 instances of ventricular septal defects (VSD), atrial ventricular septal defects (AVSD), Tetralogy of Fallot (ToF), transposition of great arteries (TGA), and pulmonary atresia (PuA), respectively, as well as 5 CT images that do not have the above CHDs. Among those, we used 35 images for training, 4 for hyperparameter tuning, and 12 test images for final evaluation. The 12 test images contain at least 2 images for each CHD type. The CT images were selected from the public imageCHD dataset⁵ which includes ground truth segmentations of 7 cardiac structures including the myocardium (Myo), blood pools of right atrium (RA), left atrium (LA), right ventricle (RV) left ventricle (LV), aorta (Ao), and pulmonary arteries (PA). Fig. 1 shows example segmentations for different CHD types.

Figure 2: Diagram of the proposed approach

Network Design: Fig. 2 illustrates the proposed algorithm to automatically construct meshes of cardiac structures from CT images of patients with CHDs. We used neural networks as a field function to model SDFs that can represent the shapes of the cardiac structures. Namely, an SDF assigns any point $\mathbf{p} \in \mathbb{R}^3$ a scalar value $s \in \mathbb{R}$, such that $\text{SDF}(\mathbf{p}) = s$, where the magnitude of s represents the distance from \mathbf{p} to surfaces of cardiac structures and the sign represents whether \mathbf{p} is inside or outside. Given the types of CHD that a patient could have, we represented this diagnostic information as a vector containing true or false values, corresponding to whether the patient modeled had those allowable CHD types we chose to include in this study. We then trained multilayer perceptrons (MLP) to model the SDFs of cardiac structures corresponding to the input CHD type. To deform the type-specific SDFs to match the predicted cardiac shapes with patient images, we used convolutional neural networks to extract image features. We then sampled these features at the point locations in the type-specific SDF and then used MLP to predict the corresponding locations on the image data. We further predicted a correction field from the image features to add to the deformed SDFs to more accurately match patient-specific anatomical features that cannot be modeled by simply deforming type-specific cardiac shapes. The final meshes were generated at the 0 level set of the SDFs by the marching cube algorithm.

Network Optimization: Ground truth SDFs of the whole heart constructed from manual segmentations were used to supervise the training of the neural network model. We supervised the accuracy of deformed type-specific SDF both before and after adding the correction field by computing the mean squared error (MSE) between the predicted SDFs the ground truth SDFs. We also minimized the L2 norm of the predicted gradient field to encourage smoother deformation from the type-specific SDFs.

RESULTS

Figure 3: Surface meshes (top row: whole heart; bottom row: myocardium) extracted from the learned type-specific SDFs.

Fig. 3 visualizes the cardiac structures extracted from the automatically learned SDFs corresponding to various CHD types. Our networks were successfully trained to predict SDFs that captured the typical abnormalities given the CHD type as the input, namely, the ventricular septal defects in AVSD, the shifted aortic opening and the

narrowed PA trunk in ToF, the transposed aorta and PA in TGA and the missing PA outlet in PuA.

Table 1 displays the average Dice scores (a similarity index) of the reconstruction results of both the whole heart (WH) and individual cardiac structures for all samples in the testing datasets and for each CHD type, respectively. Our method generally performed better for heart chambers than for great vessels. Fig. 4 visualizes example reconstruction results of our methods for both training and testing samples. The deformation network was able to morph the learned type-specific cardiac shapes shown in fig. 3 to better match the patient image data and the ground truth segmentations. The predicted correction field was able to capture some additional patient-specific anatomical details, such as the vessel branches. Our method produced worse reconstruction for testing samples than for training samples, indicating overfitting and a lack of diversity of the training dataset.

Table 1: Dice scores for different CHD types in the test dataset

	WH	LV	RV	LA	RA	Myo	Ao	PA
Total (n=12)	0.66	0.68	0.60	0.71	0.74	0.66	0.52	0.48
VSD (n=6)	0.73	0.77	0.66	0.80	0.73	0.73	0.62	0.61
AVSD (n=5)	0.59	0.58	0.51	0.62	0.73	0.58	0.41	0.37
ToF (n=2)	0.79	0.82	0.70	0.82	0.82	0.79	0.73	0.75
TGA (n=2)	0.61	0.56	0.47	0.58	0.80	0.62	0.38	0.17
PuA (n=2)	0.68	0.63	0.75	0.59	0.79	0.72	0.68	0.38

DISCUSSION

Automatic construction of cardiac structures from image data of CHD patients can greatly facilitate patient-specific virtual treatment planning. We have demonstrated preliminary results from a novel DL approach to automatically construct cardiac shapes represented by SDFs from CT images. Compared with prior approaches that were designed for normal cardiac anatomies, our method was trained to capture the different abnormal cardiac anatomies corresponding to various types of CHDs. Our method produced an average WH Dice score of 0.66 on the test dataset, whereas prior methods that model healthy can achieve a WH Dice score of around 0.8-0.9³⁻⁴. This is partly due to the limited number of training images available and the greater diversity of cardiac anatomies both within a single CHD type and across different CHD types. In the future, we will train and evaluate the proposed method using larger datasets and continue to improve the method to produce more accurate reconstructions.

DESIGN AND EVALUATION OF A FLOATING PLATFORM SYSTEM FOR MECHANICAL TESTING OF MESOSCALE GELS AND TISSUES

Tyler G. Tuttle (1), Sarah Calve (1)

(1) Mechanical Engineering, University of Colorado Boulder, Boulder, CO, United States

INTRODUCTION

Measuring the mechanical properties of biological tissue is crucial for understanding healthy physiological and pathological function in many organs. Accurately describing and modeling systems in the fields of biomechanics and mechanobiology hinges on the ability to properly execute mechanical tests. Mechanical tests come in all shapes and sizes, including tensile, compressive, or shear deformations, can be performed uniaxially, biaxially, or even triaxially [1], and apply deformations in temporally linear or sinusoidal patterns, or set deformations followed by constant stresses or strains. All of these mechanical tests come with challenges. The challenges outlined below focus on tensile testing but are applicable to many other types of tests.

When designing a mechanical testing setup, it is necessary to consider the method of force measurement, mounting system, and imaging techniques. Additionally, protocol considerations for testing and post-processing (*i.e.* preload, maximum applied stress/strain, temperature, sampling frequency, choice of reference configuration) must cater to the material/tissue being used and the hypotheses being tested. For force measurement, proper load cell capacity with adequate signal to noise ratio for the intended force range is important, and this can be greatly affected by not only the force measurement system, but the mounting system as well. Mounting systems may include some amount of friction or other off-target forces that need to be corrected in post processing. Other mounting issues may be sample slipping, damage, or imperfect application of the intended deformation. Imaging systems must have the resolving power to measure sample geometry, including cross-sectional area, initial sample dimensions, and amount of applied deformation. Finally, when combining these systems the testing protocol, post processing, and data analysis choices must be thought out thoroughly, as something as simple as choice of reference configuration for the measurement of stretch can drastically impact results [2]. The compounding effects of these challenges contribute to

the variability seen between data of the same tissue, using similar tests, but by separate research groups with different testing setups.

This work aims to address some of these challenges, namely, friction and off-target forces. This is accomplished through the design and validation of a multi-buoy floating platform mechanical testing setup.

METHODS

The design of the mechanical testing system consists of a fibrin gel mounting system, a multi-buoy floating platform, and a bath. Equipment used for testing consisted of a micromanipulator system (FemtoTools FT-RS1002) that allows for application of microscale uniaxial tensile displacements and force measurement. Imaging of the fibrin gels was performed with a confocal microscope (Leica, STELLARIS 5) and a dissecting microscope (Leica, M80).

Mechanical testing was performed on fibrin gels (2 and 4 mg/mL fibrinogen). Fibrinogen-soaked porous polyethylene blocks were glued to laser-cut frames with cyanoacrylate adhesive. The frames were designed with mounting through-holes for M2 threads. Fibrin was polymerized to the blocks in a custom 3D printed mold (Figure 1a) to create mounted fibrin gels for mechanical testing (Figure 1a-b). Gels were approximately 0.7 x 1.4 x 6.6 mm in size.

The multi-buoy floating platform (Figure 1c) was designed with three buoys for stable floating. The front buoy has a raised section with holes, where a stainless-steel wire is glued to allow the micromanipulator to hook to the floating platform. An angled cylindrical extrusion was offset from between the back buoys to hook onto the fibrin gel frame through-holes. The floating platform was designed in SolidWorks, and 3D printed (Stratasys J750) with a photopolymer (VeroClear, Stratasys) that is similar to acrylic.

The bath was designed to contain the floating platform with enough room to apply more than 4 mm displacement to the fibrin gel. Circular arc barriers were designed into the bath floor to hold the

Figure 1. (a) Fibrin gel mold and the resulting frame-block-gel assembly for mechanical testing, (b) representative fibrin gel, (c) model of the multi-buoy floating platform mechanical testing setup showing the force sensor, floating platform, bath, and gel, and (d) an image of the setup in use with the confocal microscope.

floating platform in place while applying no deformation to the fibrin gel. These barriers prevented rotation and translation of the platform without obstructing the application of tensile deformation. A raised M2 threaded hole was used mount the frame to the bath.

The following mechanical testing protocol was used to test the system. The bath was filled with 20 mL of PBS and the fibrin gel frame was mounted to the bath with a M2 screw. The floating platform was hooked into the other end of the frame, and the platform was lowered into the bath. The sides of the frame were then cut and removed to allow application of deformation. The micromanipulator force sensor arm was hooked onto the wire loop on the front buoy of the floating platform. A 100 μ N preload was added to the fibrin gel to ensure engagement of the hook. Stress-relaxation tests were performed in 1 mm increments at 66 μ m/s, with 60 minute relaxation times, to a final displacement of 3 mm. Water (50 μ L) was pipetted into the bath every 5 minutes to minimize evaporation related changes in platform height and PBS osmolarity. Additionally, a test was performed with no fibrin gel attached to evaluate the presence of off-target forces due to inertia or drag from the solution during movement.

RESULTS

The buoy system enabled the combination of mechanical testing with imaging on both a confocal microscope (Figure 1d) and dissecting microscope (not shown). The mechanical testing system captures the stress-relaxation behavior of fibrin gels, and resolves differences in force between gels with different concentrations of fibrinogen (Figure 2a). Mechanical data collected with no sample attached shows a flat signal with noise centered at zero load with a mean \pm standard deviation of 0.01 \pm 0.09 mN. During the movement phase the noise is slightly greater than in the stationary phase, but still centered at zero load (movement: 0.02 \pm 0.13 mN, stationary: 0.01 \pm 0.07 mN).

DISCUSSION

This multi-buoy floating platform mechanical testing setup allowed us to resolve differences in forces measured from same-sized fibrin gels containing different concentrations of fibrin. The zero-centered forces in the no-sample test suggest that there are negligible off-target forces acting from inertia or drag from the PBS. Beyond the investigation of fibrin gel mechanics [3], modified versions of this setup are currently

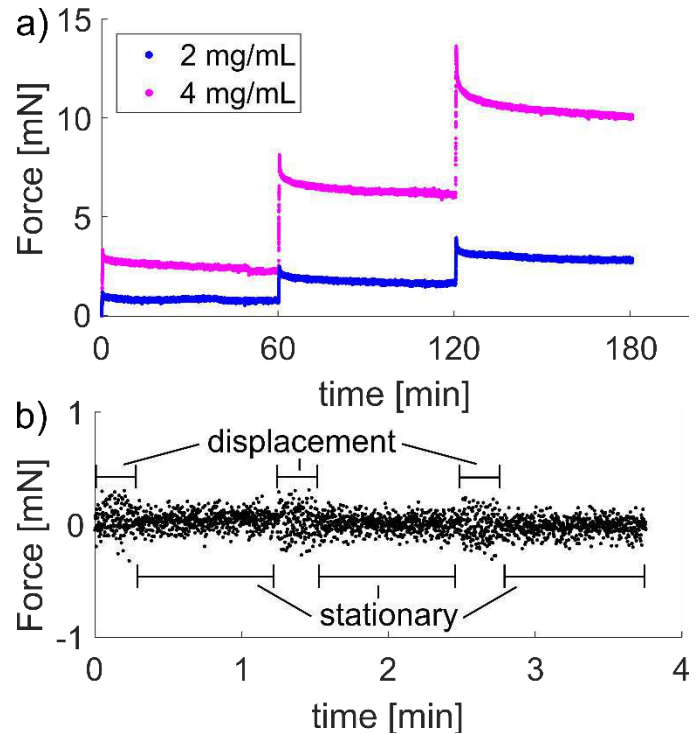

Figure 2. (a) Representative fibrin gel stress-relaxation test force-time data for 2 and 4 mg/mL samples, and (b) shortened stress-relaxation mechanical test with no sample attached demonstrating minimal off-target forces during movement and stationary phases.

being used to study mechanics of uterosacral ligaments, forelimb tendons, and other tissues in our lab. This design has the potential to push forward the field of biomechanics by allowing improved collection of mechanical data for a wide array of tissues and materials.

There are some limitations with the design that are in the process of being addressed. First, evaporation is an irrefutable problem. Proper measurement of force with this system requires a constant height of the floating platform, and some tissues may be susceptible to changes in mechanics or geometry based on changes in solution osmolarity [4]. Both of these issues could be present with excessive evaporation of solution. A second issue is the off-axis application of deformation and force reading. Due to the force sensor attachment being out of the bath and the sample being in the bath, deformation application and force measurement are not colinear with the sample. The amount of error from this problem may be negligible but requires evaluation or a creative redesign of the sensor attachment.

The advancement of the field of biomechanics hinges partially on the ability to improve mechanical testing methodologies. The design presented in this abstract minimizes friction and off-target forces, which is particularly beneficial for studying small organs and tissues.

INTRODUCTION

Stent thrombosis is a serious complication that is defined as a thrombotic occlusion of a coronary stent. It has been associated with high rates of morbidity and mortality. Stent thrombosis can be caused by a number of factors, such as injury or endothelial disruption caused by the stent struts, and hypercoagulability of the patient (an increased tendency for the blood to clot) [1]. The efficacy of metallic stents and bioresorbable scaffolds to treat coronary artery stenosis is related to the hemodynamic environment. The struts of these devices disturb the local flow field and induce flow recirculation zones and endothelial damage [2]. Computational work has been utilized to analyze the relation of coronary stents to hemodynamics and platelet aggregation [3]. However, despite the central role of fibrin network formation in thrombosis, limited research has been done on the effect of stent design on coagulation dynamics.

The aim of this study is to improve understanding of the impact of injury induced blood coagulation on stent thrombosis and to identify risk factors that contribute to it, with the ultimate goal of improving stent designs. This will be studied analyzing local hemodynamics together with patient-specific clot formation using computational fluid dynamics (CFD).

METHODS

A biophysical model of a fibrin-rich clot is developed based on the framework presented earlier in Bouchnita et al. [4]. A system of coupled convection-diffusion-reaction (CDR) equations is used to solve the concentration of factor IX and X, prothrombin, thrombin, fibrinogen, fibrin, and fibrin polymer. The production or consumption of each of these agonists is incorporated into the source terms in the CDR equations.

The computational domain consists of a 2D channel (8x1mm) including a stent strut representing a large bioresorbable scaffold (180x157 μm) (Fig.1) [2]. A section of 200 μm of the bottom wall

(indicated in red in Fig.1) serves as a surface flux boundary condition representing a tissue factor (TF) coated surface. The Navier-Stokes equations are used to describe blood flow, in which the blood is considered as a Newtonian fluid. The clot is modeled as a porous medium with the porosity depending on the concentration of fibrin polymer [5]. A velocity inlet was prescribed with an initial wall shear rate of 250s^{-1} . The model is implemented into the computational fluid dynamics software FLUENT 2021 R1.

In order to compare the simulation results with the model of Bouchnita et al. and in vitro experiments of Shen et al. [4, 6], the time for blood clotting initiation near the TF patch while increasing the initial wall shear rate was computed (with a maximum physical time of 1200 seconds). This experiment was mimicked by using the 2D geometry of Figure 1 with a single TF patch, excluding the stent strut. Finally, in the geometry with stent strut a set of cases are studied with 3 different TF patch locations (indicated in Fig.1), with both average healthy and hypercoagulant coagulation parameters for a physical time of 30 minutes. The parameters are taken from the work of Ratto et al., in which an approach to patient-specific modelling was proposed based on conventional thrombin generation tests, allowing for the determination of parameters of a reduced kinetic model [4].

Figure 1: Part of the 2D geometry visualized with a contour plot of the shear rate and streamlines around the stent strut. The 3 tissue factor (TF) patch locations are indicated in red.

RESULTS

The relationship between clotting initiation time as a function of wall shear rate under undisturbed flow conditions is illustrated in Figure 2. We found that the value of the clotting initiation time increases with increasing wall shear rate until a shear rate of 40s^{-1} . Our results are in good agreement with the model results of Bouchnita et al. and the experiments of Shen et al. in which they observed a threshold response at a shear rate of 35s^{-1} and 30s^{-1} , respectively. Above this threshold no clot was formed near the TF patch within the measured time frame.

Figure 2: The moment of clotting initiation as a function of the initial wall shear rate for normal pooled plasma. Results of the current model, the model of Bouchnita et al. [4] and experimental results of Shen et al. [6] are shown for comparison.

For the disturbed flow conditions in the presence of a stent strut, the results for the healthy and hypercoagulant plasma are shown in Figure 3. When comparing the impact of the location of the TF patch, we observed that in the healthy case the initiation of clot formation occurred earlier proximal to the stent strut where a denser clot was formed, but a larger clot was observed to form distal to the strut after 30 minutes (Fig. 3A-D). When the TF patch was located after the recirculation zone no fibrin polymer was formed (Fig. 3E-F). In the case of hypercoagulant plasma, it was found that clot formation occurred at a significantly faster rate and resulted in a larger clot compared to the case of healthy plasma (Fig. 3G-J). Also in this case the clot proximal to the strut was denser compared to the clot distal to the strut in which the fibrin was completely spread downstream of the recirculation zone after 30 minutes (Fig. 3H). Even for the hypercoagulant case no clot was observed when the TF patch was located after the recirculation zone (Fig. 3K-L).

DISCUSSION

We successfully implemented a computational model of fibrin-rich clot formation in order to study blood coagulation in stent thrombosis. The largest clots were formed when the wall was damaged right after the stent strut. This phenomenon can be attributed to the presence of the recirculation zone, characterized by a low shear rate of about 5s^{-1} , which allows for prolonged interactions between coagulation factors. When the wall damage occurred proximal to the stent strut a smaller clot was observed, but it exhibited a relatively high concentration of fibrin polymer. This is likely due to the confinement of coagulant factors by the stent strut, leading to the formation of a more concentrated clot. The presence of a high shear rate (250s^{-1}) at the TF patch after the recirculation zone was observed to prevent clot formation in both the healthy and hypercoagulant cases. This outcome was expected from previous understanding of healthy blood flow dynamics.[6] but was previously unknown in the context of hypercoagulability. Results furthermore demonstrated that the clot growth rate and size were increased in a hypercoagulant case compared to a healthy case. This highlights the importance of incorporating patient-specific parameters,

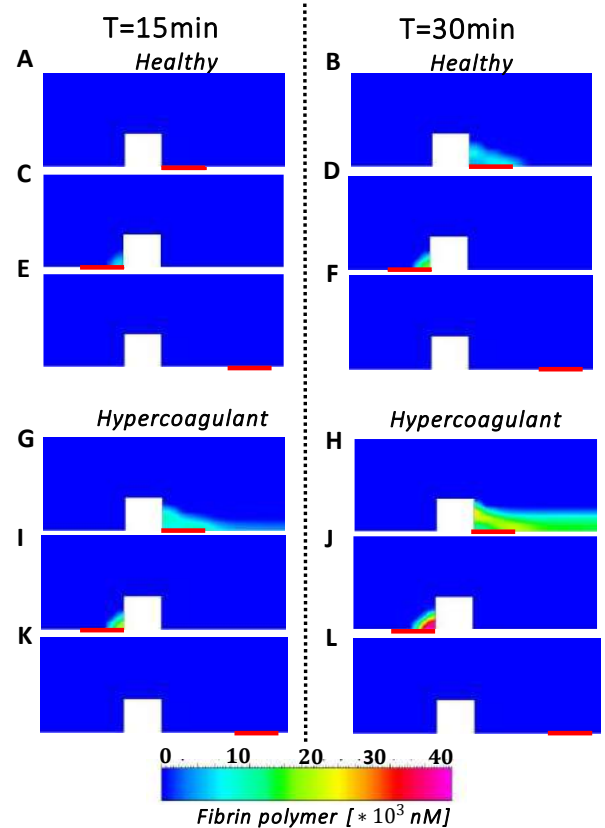

Figure 3: Results of the 2D simulation including a stent strut after 15min. (left) and 30min. (right) for different TF patch locations indicated in red, with (A-F) healthy plasma and (G-H) hypercoagulant plasma.

which is most often not taken into account into computational thrombus formation modeling.

It is important to acknowledge that the current study did not include all coagulation pathways, for instance the protein C pathway, which has been demonstrated to inhibit coagulation at undamaged vessel walls. The absence of this pathway may contribute to the observed formation of a fibrin network along the entire distal side of the strut in the hypercoagulant case (Fig. 3H). We are currently investigating the effects of various stent designs and flow conditions on coagulation dynamics, and future studies will aim to incorporate additional coagulation pathways and examine the formation of platelet plugs.

INTRODUCTION

Mechanical stiffness has been shown to play a determining role in tissue fate and function, particularly in cancer, where increases in tissue stiffness are correlated with progression and metastasis [1]–[4]. However, clinical measurements of tissue stiffness in metastatic patient samples do not consistently demonstrate increased zonal stiffness, suggesting that transient stiffening mechanisms may be at play [5]. However, the precise nature of these mechanisms remains unclear.

The extracellular matrix (ECM), primarily composed of type I collagen, is the non-cellular component of tissues and is a significant contributor in determining local mechanical properties. Changes in collagen organization and protein content mediated by fibroblast remodelling have been shown to permanently alter stiffness and scaffold function [1], [2], [6], [7]. Soft tissues require large strains to observe significant strain-stiffening, beyond the typical fibroblast span, suggesting that other transient stiffening mechanisms may be at play *in vivo*.

As part of the innate immune response, neutrophils have the capability of spraying out sticky protein-DNA webs to trap pathogens, termed neutrophil extracellular traps (NETs) [8]. NETosis is significantly affected by the state of the neutrophil population, and in the context of breast cancer, neutrophil populations skew from being primarily mature, high-density neutrophils (HDNs) towards immature, low-density neutrophils (LDNs). NETs formed from LDNs correlate with more aggressive disease progression and poorer prognoses [9], [10].

In this work, we hypothesize that NETosis acts as a transient mechanism for heterogeneously stiffening surrounding tumour matrix. Considering the physical limitation imposed by pore size in 3D biomaterials (Fig. 1 images), NETs are proposed to locally cross-linking and create stiff “hot spots” within the tissue (Fig. 1 schematic). Furthermore, we hypothesize that NETs from disease-associated neutrophil populations (LDNs) increase heterogeneous stiffening and promote breast cancer progression by destabilizing the tumor structure and encouraging metastatic dissemination.

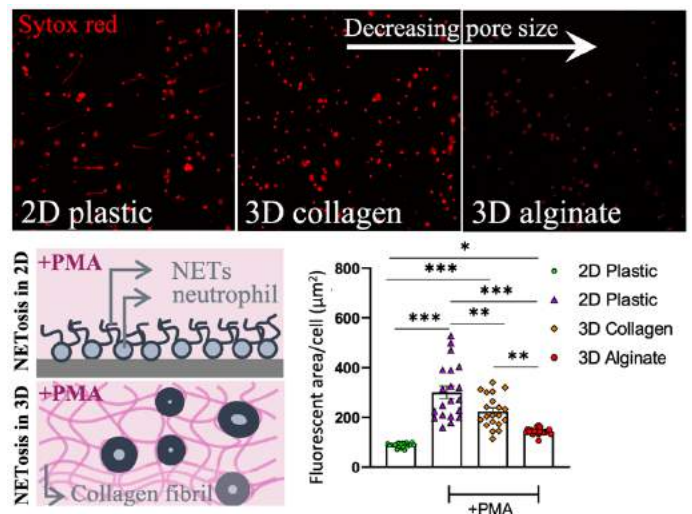

Figure 1: Constriction of NET dispersal with decreasing pore size in 3D matrices as proposed mechanism for heterogeneous stiffening.

METHODS

Either murine or human neutrophils were isolated and induced with phorbol 12-myristate 13-acetate (PMA) to produce NETs *ex vivo* within 3D collagen matrices. Local mechanical properties were assessed by optical magnetic twisting cytometry while bulk properties were quantified by shear rheology.

An inducible 3D breast cancer invasion assay was used to observe effects of NETosis on dissemination and invasion. Spheroids were formed from non-invasive MCF7 breast cancer cells with an inducible Src oncogene, embedded in collagen-NET gels and monitored for varying degrees of invasion. As controls, homogeneously stiffened collagen gels were prepared by glycation to increase cross-linking while maintaining a constant collagen concentration.

RESULTS

In situ NETosis was found to significantly stiffen collagen matrices both locally (Fig. 2A) and in bulk (Fig. 2B). Upon degradation by DNase, gels regain the same stiffness as those not subject to NETosis (Fig. 2A), demonstrating that NETs content are responsible for the observed stiffening. In contrast, the addition of either harvested or purified DNA-containing NETs with or without cell bodies does not result in significant stiffness changes (data not shown). This suggests that NETosis must be triggered *in situ*, and the NET dispersal must be constrained within collagen pores to cause a stiffening effect, likely due to intertwining and crosslinking of the NETs with collagen.

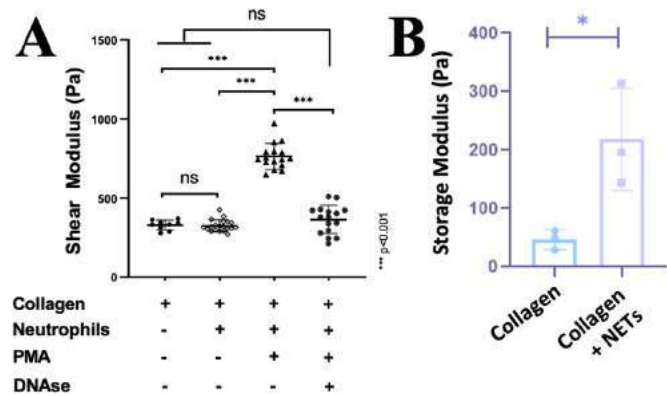

Figure 2: *In situ* NETosis from human neutrophils stiffens 3D collagen matrices (A) locally and (B) in bulk.

Breast cancer spheroids embedded within heterogeneously stiffened collagen matrices by murine NETs exhibited more invasive behaviours with observed dissemination into the surrounding matrix (Fig. 3). Interestingly, LDN NET-stiffened collagen prompted more extensive invasive spheroid behaviour in comparison to HDN NET-stiffened collagen, suggesting a compositional and functional difference between their responses *in vivo*. Invasion was not observed in collagen matrices that homogeneously stiffened through chemical glycation, suggesting that heterogeneous mechanical properties are required for disruption of architecture and inducing invasion.

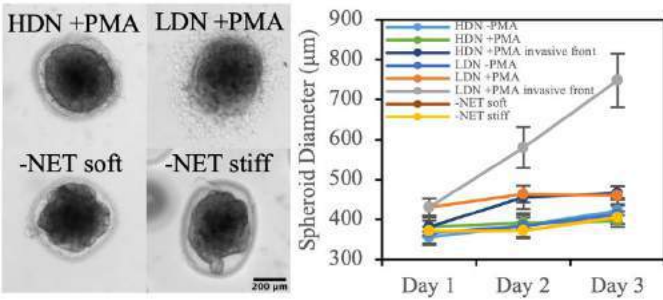

Figure 3: Heterogeneously stiffened collagen by murine NETs promote breast cancer invasion.

DISCUSSION

Together, this *in vitro* study suggests that NETs, particularly those associated with the presence and progression of cancer, may play a previously unsuspected role in transient biophysical regulation of cancer metastasis. Additionally, varying neutrophil populations may produce compositionally and functionally different NETs as part of their contribution in the immune response, affecting breast cancer progression. Future proteomic analyses of purified NET populations may provide significant insight on potentially fundamental differences.

Other studies in cancer have found similar trends of heterogeneity supporting these findings, particularly in the context of stiffness [5], [11], where more aggressive breast cancer spheroids were shown to have stiff hot spots throughout the tissue architecture [5]. This work provides a potential mechanism for transient heterogeneous stiffening in tumors, contributing to better understanding the role of the immune response in breast cancer progression, as well as potentially providing new therapeutic targets to limit progression.

THE IMPACT OF REGULATING THE PLANTARFLEXION AND DORSIFLEXION RESISTANCE OF AN ARTICULATED ANKLE FOOT- ORTHOSIS ON LOWER LIMB KINEMATICS AND KINETICS OF STROKE SURVIVORS DURING AMBULATION.

INTRODUCTION

During ambulation, stroke survivors often experience a decreased ability to push off with their ankles due to plantar-flexor muscle weakness [1], and some show a typical dragging of the foot in a foot-drop presentation due to weakness of their dorsiflexors. This ankle muscle weakness results in functional limitations that could cause long-term disability, so assistive devices in the form of orthotics like the Ankle Foot Orthosis (AFO) are recommended for rehabilitative or assistive purposes [2] in affected persons.

AFOs are prescribed to stroke survivors to ensure stability, improve gait, prevent foot drop through the swing phase of gait, and improve their overall functional capacity [3]. Specifically, these devices improve the function of the weak ankle muscles through a sagittal plane resistance to plantarflexion (PF) and dorsiflexion (DF) characteristic also referred to as bending stiffness [2]. This AFO characteristic augments the weak ankle muscle functions, such that AFO PF resistance functions to augment weak dorsiflexors at the initial contact (by ensuring proper loading response) and the swing phase (prevent toe dragging) of the gait cycle, while the DF resistance augments plantarflexor muscles function primarily at the midstance phase of the gait cycle [4]. This DF resistance prevents excess DF at mid-stance ensuring stability as the shank translates anteriorly over the foot at this 3rd rocker [4]. This resistance characteristic is tuned distinctly in 2 AFO categories of the articulated and non-articulated types; the articulated AFO types have the merit of possessing joints through which AFO resistances can be tuned post-fabrication [2].

There exists a constraint in clinically prescribing AFO stiffnesses because of the difficulties in converting laboratory research setup to the clinic [2]. Clinicians are riddled with the challenge of balancing the concerns of ankle and knee instability while deciding on the right stiffness for individual patients. This study looked to further inform clinical AFO prescription by investigating how the independent tuning

of the plantarflexion and dorsiflexion resistance of a 3D-printed articulated AFO coupled with triple action joints impacted the gait of stroke survivors walking over the ground. We hypothesized that increasing the PF resistance will increase the peak ankle DF moment, the knee flexion angle at initial contact, and the ankle angle at initial contact. We also hypothesized that increasing the DF resistance will decrease peak DF angle at stance, peak knee extension moment, and peak positive ankle power at stance, while there will be increased peak ankle PF moment.

METHODS

This study was done in two sessions with a minimum of 1-week interval. We recruited five Subjects (3M and 2F; age: 64.6 ± 5.7 yrs; stroke onset: 6.0 ± 5.2 yrs) who have had a stroke for more than 6 months and could walk independently with or without a walking aid (current AFO users: 2). We customized the articulated AFO's footplate and calf section for each of the subjects by using a 3D scanner in scanning the shank -to- foot of the participants before fitting the image in a predetermined design, which we 3D printed using Polylactic Acid printing material. The printed parts were assembled into the final product with a commercially available mechanical joint for each of the participants (*figure 1, images a-i*). These fabrication processes were done from the first visit till before the second session. At the second session, participants were fitted with their customized AFO and had a 2-minute minimum walking trial to adapt to the new device for each of the analyzed resistance settings. Afterward, they were instructed to walk over inground force plates at their comfortable walking speed in the same direction for 3 trials for each resistance setting. We tested 3PF (PF1-low; PF2-medium; PF3-High) and 3DF (DF1-low; DF2-medium; DF3-High) resistance settings for all participants. We utilized a double randomized set-up between the two-resistance settings group of PF and DF, and within each of the groups for the 3 conditions of low, medium,

and high resistance settings. Data was collected using a 20-camera motion capture system (at 100Hz) and the joint kinematics and kinetic variables were derived in visual 3D software (C-Motion, Inc., Germantown, MD, USA).

Simulation modeling analysis (SMA v11.10.16) for single-case time-series data was used in analyzing the data on a case-by-case basis for each participant for the investigated variables of the peak DF moment, knee flexion angle at initial contact, and the ankle angle at initial contact for the PF resistance settings while it was the peak DF angle at stance, peak knee extension moment, peak ankle positive power at stance, and the peak PF moment for the DF resistance settings.

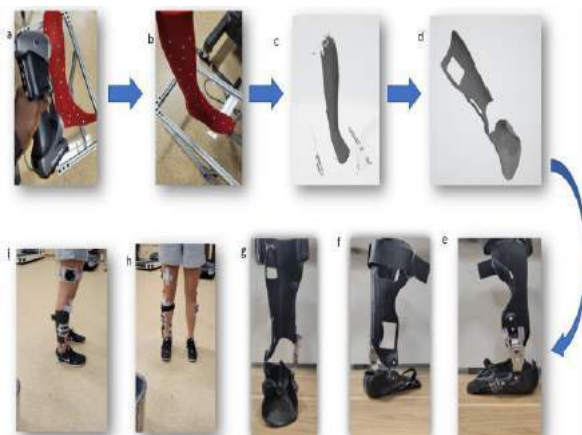

Figure 1: Images (a – i) show the stepwise process for AFO fabrication

RESULTS

There were significant phase changes in some participants when the DF resistances were tuned through DF1, DF2, and DF3. All the participants had significant phase changes ($p < 0.05$) for the peak DF angle at the stance phase of gait when the DF resistance was tuned, while only participants S01, S02, and S05 had significant phase changes for their peak positive ankle power ($p < 0.05$) at the stance phase of gait when the DF resistance was increased from DF1 through DF2 to DF3. The peak knee extension moment and the peak PF moment were not impacted by the DF resistance settings of the AFO ($p > 0.05$).

Tuning the PF resistance through PF1, PF2, and PF3 resulted in significant phase changes in the peak ankle DF moment for participants S01, S04, and S05 ($p < 0.05$) while there were significant phase changes for only participants S01 and S02 for their knee angle (flexion) at initial contact ($p < 0.05$), and the ankle angle at initial contact was significantly impacted by the PF resistance settings in participants S01, S03, and S04 ($p < 0.05$) with a noted increase from PF1 through PF2 to PF3.

DISCUSSION

The findings from this study showed the ability of the articulated AFO with mechanical joints to impact the gait characteristics of stroke survivors by causing significant phase changes when the PF resistance was increased so that participants S01, S04, and S05 experienced an increase in their DF moment. Also, the time series data showed that this DF moment was increased at the loading response phase of their gait, a

finding consistent to that of a pilot study by Kobayashi et al. (2017) [2] where they tested the mechanical properties of a similar triple action joint in an AFO and reported a more normalized DF moment in the heel rocker phase of their participant's gait cycle. This result implies that increasing the PF resistance may optimize the heel rocker phase of the gait cycle, but we cannot be exceedingly certain because the participants responded differently to changing the PF resistance of the AFO device. With increased DF resistance, the SMA showed significant phase shifts with lower mean DF angles in the stance phase of the gait cycle for all the subjects. When stroke survivors have weak plantarflexor muscles, it is imperative to prevent excessive DF during the stance phase of the gait cycle. Our findings showed that the AFO DF resistance settings can prevent this possible excessive DF and complement the weakness in the plantarflexors which could cause increased DF leading to instability.

Importantly, 3 participants had significant phase changes in peak ankle power at the terminal stance with noted decreases when DF resistance was increased. A previous study has indicated that decreased ankle power generation may imply limited propulsion at the 3rd rocker of the gait cycle [3]. Although, our study did not evaluate the propulsion characteristics of the participants we understand that a wrong AFO prescription could impede the optimal gait function of users. Future studies will look to explore the impact of changing AFO resistance characteristics on the propulsive forces of the affected lower limb.

This study is limited in the small sample size recruited, although we looked to complement this in the statistical analysis method and the technique used in AFO fabrication. The technique of fabricating the AFO using the 3D scanning and printing devices enabled ease in centralizing the joint support forces to each participant's sagittal plane in order to minimize frontal and transverse plane movements, while the SMA method revealed phase changes in the compared resistance levels for the individual participants. This method brings visibility to the distinct response of each participant to changing the AFO resistance characteristics especially considering the heterogeneous nature of the stroke population; stroke patients present in clinics as individuals and this study shows how the articulated AFO device with triple action joints systematically changes the kinematic and kinetic properties of stroke survivors. We believe this study structure gives an advantage over studies that utilize statistical methods emphasizing group means.

Overall, this study reinforces the potential of the articulated AFO with triple action joint as a viable assistive device for 'onsite resistance tuning' to aid the clinical prescription of AFOs for stroke survivors. Further investigation with a larger sample size will ensure the development of a standardized prescription mechanism by incorporating the objective and subjective clinical measures of patients.

INTRODUCTION

Blood clots, or thrombi, are critical to our well-being by playing a vital role in the healing process following vascular injury. However, blood clots – as the source of thromboembolic disease – also lead to significant morbidity and mortality. In fact, thromboembolic disease accounts for 1 in 4 deaths worldwide [1]. Thromboembolic disease follows from blood clots forming and detaching from distant vessels in the circulatory system. Once broken off, these embolized thrombi, i.e., emboli, travel downstream, potentially occluding vital arteries or veins such as those in the heart, lungs, or brain [2]. Because it is the blood clots' ability – or lack thereof – to resist mechanical forces, understanding its mechanics (especially its fracture mechanics) is crucial to our understanding of thromboembolic diseases. Therefore, the mechanical properties of thrombi have been extensively studied. To this end, a large body of literature has used fibrin gels as blood clot mimics [3]. However, blood clots are more complex than fibrin gels, as they are also comprised of platelets and red blood cells.

In our own previous work, we have therefore focused on characterizing blood clots made from whole blood [4,5]. Our current project now aims to bridge the gap between others' past work on fibrin gels and our work on whole blood clot. To this end, we are comparing four critical markers of these materials' mechanics: the tangent modulus as a measure of these materials' elastic properties and strength, work-to-fracture, and fracture toughness to understand their fracture behaviors which contribute to their critical role in thromboembolic disease.

METHODS

We generated blood clots from bovine blood obtained from a commercial service (Lampire Biological Laboratories, PA, USA)

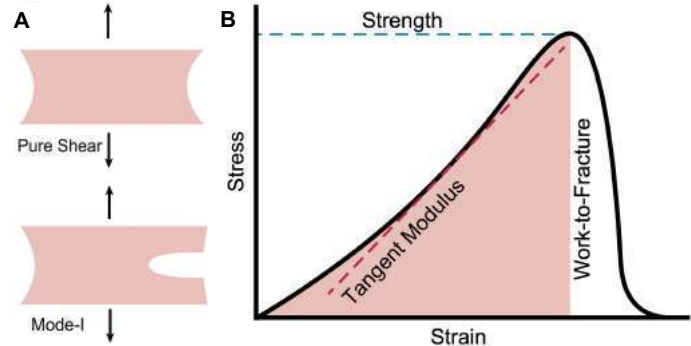

Figure 1: A) Sample geometries for pure shear and mode-I fracture experiments. B) Model stress-strain curve from which a sample's tangent modulus, strength, work-to-fracture, and fracture toughness (not pictured) are computed.

where blood is collected directly into CPDA-1 anticoagulant. We added calcium chloride to a concentration of 20 mM to reverse the anticoagulant and cast samples into a pure shear geometry following prior protocols [6]. We cast fibrin gels into the same pure shear geometry following standard protocols using fibrinogen concentrations of 20, 30, and 40 mg/ml (please note, lower concentrations did not yield testable gels). After 60-minute coagulation or incubation periods, respectively, samples were mounted to our tensile testing machine (Instron, Norwood, MA, USA). We conducted two tests: extension-to-failure in a simple pure shear geometry and extension-to-failure in a mode-I fracture geometry, as shown in Figure 1A. We conducted all tests until failure at a displacement rate of 0.1 mm s^{-1} , corresponding to

a strain rate of 1% s⁻¹. Figure 1B illustrates the definitions of three of our mechanical metrics, while we computed fracture toughness as

$$\Gamma_c = W(\lambda_c)H, \quad (1)$$

where H is the reference sample height and $W(\lambda_c)$ is the strain energy density of the pure shear sample at the fracture stretch λ_c .

Finally, to compare these mechanical metrics between the fibrin and whole blood samples, we conducted two-tailed independent Student's t-tests. We defined differences to be statistically significant for p-values less than 0.05.

Figure 2: Stress-stretch curves of fibrin gels and blood clots during pure shear and mode-I fracture experiments.

RESULTS

Figures 2 and 3 summarize the mechanical data from our study. Specifically, Figure 2 shows the average (± 1 standard deviation) stress-stretch curves for each sample type studied for both pure shear and mode-I fracture experiments ($n=3$ per group). While variability between samples increased as they neared failure, the fibrin gels consistently had a higher tangent modulus than blood clot, as can be observed qualitatively based on the steeper loading slopes of the fibrin gels in Figure 2.

Figure 3A shows this data quantitatively, as it compares the samples' tangent modulus in the pure shear samples at a stretch of 1.35. From these data, we can see that the fibrin gels are significantly stiffer than blood clot. This holds true for all fibrin concentrations, i.e., 20 mg/ml, 30 mg/ml, and 40 mg/ml. Similarly, Figure 3B summarizes the samples' peak stress before failure, i.e. their strength. Fibrin gels of all concentrations have consistently higher strength than blood clot. On average, fibrin gels can withstand anywhere from two to six times the amount of stress before failing in comparison to blood clot. Furthermore, Figures 3C and 3D show that work-to-fracture and fracture toughness of fibrin gels, regardless of the fibrinogen concentration, are also higher than those of blood clot. Even at a fibrinogen concentration as low as 20 mg/ml, fibrin gels show a work-to-fracture and fracture toughness double that of blood clot. At 40 mg/ml, these values are closer to ten times the magnitude of blood clot.

DISCUSSION

There is extensive literature studying the mechanical behaviors of fibrin gels in an effort to understand blood clots. However, because of significant compositional differences between fibrin gels and blood clots, our work aimed at comparing the mechanical properties between the two. Thereby, we are hoping to bridge the gap between prior work on fibrin and others' – and our work – on blood clot. We chose four mechanical metrics that describe both materials' elastic (tangent modulus) and fracture properties (strength, toughness, and fracture

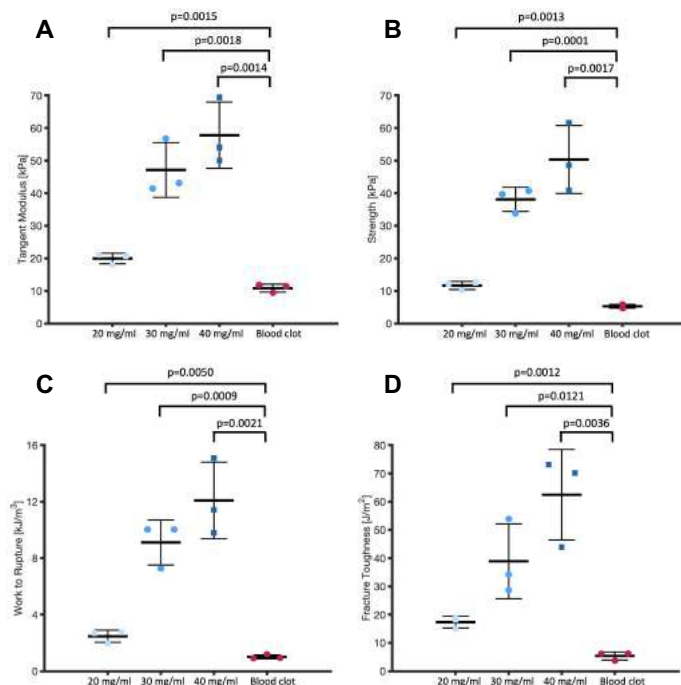

Figure 3: Quantitative comparison of the A) tangent modulus, B) strength, C) work-to-fracture, and D) fracture toughness between fibrin gels and blood clots.

toughness), all of which are critical in understanding clots role in thromboembolic disease. In summary, fibrin gels have a higher stiffness, strength, and show an increased resistance to fracture. These data suggest that using fibrin gels to study the mechanical behavior of blood clots may have to be done with care. That is, the role of platelets and red blood cells in blood clots' mechanics should not be overlooked. For example, recent studies demonstrated that platelets and red blood cells significantly alter a material's behavior [7], which supports the results of our study. Therefore, future work using fibrin gels as blood clot mimics should be careful when interpreting their work. Naturally, our study is subject to limitations. For example, our study used bovine blood, which may differ from human blood. Additionally, for experimental reasons our lowest fibrin concentration exceeds that of human blood. In future work, we aim at overcoming this experimental limitation to include lower fibrin concentrations in our study.

DEVELOPMENT OF A NOVEL POLYMERIC TAVR VALVE – DESIGN OPTIMIZATION AND ADDRESSING TAVR CLINICAL COMPLICATIONS

B. Kovarovic (1), R. Helbock (1), O.M. Rotman (1), K. Baylous (1), M. Slepian (2), D. Bluestein (1)

INTRODUCTION

Transcatheter aortic valve replacement (TAVR) is a minimally invasive alternative to the high-risk surgical approach, in which a stented bioprosthetic valve is deployed inside the failing aortic valve. TAVR is rapidly becoming the standard treatment for aortic stenosis (AS) with favorable hospital stay times, in 2019 the number of TAVR procedures exceeded the surgical standard [1]. TAVR was originally designed to treat severe aortic stenosis (AS) patients who were deemed too high-risk for the invasive surgical approach, but with the widespread adoption of TAVR, recently trails for lower-risk and younger patients were approved in US.

Despite the expansion, TAVR is subject to persistent clinical complications which are primarily a result of the chemically-fixed tissue bioprosthetic valve material. The most precarious complication of TAVR is the unknown *in vivo* durability of the leaflet structures. Bioprosthetic valves have historically been subject to structural valve degeneration (SVD) or intrinsic and extrinsic factors that lead to wear and tear or recalcification of the prosthesis and eventual valve failure [2]. TAVR is hypothesized to be subject to increased rates or faster progression due to damage of the leaflet tissues during the crimping and deployment phases [2]. The tissue material is also subject to promoting thrombosis, which may lead to subclinical leaflet thickening or thromboembolic events.

To address these shortcomings of tissue valve, polymeric valve alternatives currently being investigated. Polymeric technology allows the design of an optimal valve configuration that would exploit the ease, cost-effectiveness, and control of polymer manufacturing. Polymeric valve devices have been attempted since the 1950's but were all subject to limitations of the available material due to the extreme demands on the material. The polymer must be hemocompatible, flexible, and extremely durable (expected to remain functional for 25 years *in vivo*). For polymeric TAVR devices, the main shortcoming is that polymer material is generally not compressible compared to tissue materials, and

therefore the design must reduce the total volume of polymer to allow crimping into reasonable delivery catheter sizes.

The presented study demonstrates the progress and development of our polymeric TAVR device. We began with developing a surgical valve (Figure 1) and with further refinement of the material properties and development of an *in silico* optimization strategy, we are presenting the latest generation polymeric TAVR device, PolyV2 27 mm (PolyNova Cardiovascular Inc, Stony Brook, NY).

Figure 1: Timeline of polymeric TAVR development to the PolyV-2 design.

METHODS

The PolyV-2 device is based on the progress and success of the cross-linked SIBS based thermoset “Flexamer” material, which recently demonstrated both anti-thrombotic material characteristics [3] and extreme durability while achieving 25 *in vivo* year equivalent 1 billion accelerated wear cycles [4]. The goal of the development and optimization of the PolyV-2 was to generate larger valve sizes, achieve suitable radial anchoring forces, target a 18F delivery catheter, increase the valve performance, and design for “sutureless” molding, allowing the cast of the leaflets and sleeve on the stent frame in a single operation. This sutureless molding helps eliminate the most significant source of manufacturing error, the multi-day hand suturing of the tissue to the

stent frame. The design process was achieved with the use of *in silico* trials, utilizing finite element analysis (FEA, Abaqus 2022, Dassault Systemes, Vélizy-Villacoublay, France), to optimize first the stent frame design, second the leaflet profile, and finally the leaflet thickness.

The self-expandable nitinol stent was designed from an initial cut profile and the heat-treatment/shape-setting steps were simulated to obtain the final profile, which was confirmed with manufacturing of the design. Radial force and crimping study on the open profile (implicit FEA, rigid crimping surface with radial movement, stent with superelastic material and C3D8R elements post convergence study) was used to determine the radial force in the deployment region, both along the axial length of the device and within the deployment diameter range, optimized against the volume of the stent for a lower crimping profile and confirming no plastic deformation at 16F crimp. The leaflet stresses were also simulated (polymer Arruda-Boyce material, C3D8R elements post convergence study) with a typical normotensive aortic pressure waveform over the cardiac cycle.

Figure 2: (Left) Radial force normalized to material volume vs the crimping diameter. (Right) Stress distribution of original and optimized strut design.

RESULTS

Optimization of the stent frame is seen in Figure 2 with larger radial force in the deployment range targeted for the device. The final strut design features more curvilinear struts and wider attachment angles to distribute the stresses away from joints. The final stent design does not achieve the radial force of current popular commercial TAVR stents but were confirmed to have comparable anchorage forces while reducing the total stent volume due to the restriction of polymer TAVR valves.

Figure 3: Comparison of maximum principal stresses over the cardiac cycle versus the initial “free-stress” opening profile.

Optimization of the leaflet structures began with first selecting an opening profile of the device allowing the design and selection of the “free-stress” state of the polymer, which is not easily achievable with tissue-based valves. Figure 3 demonstrates the tradeoff of the selection of an open profile for reduced systolic stresses and increased diastolic

stresses, or visa versa for a closed profile. The final profile was influenced by the valve sized and was selected also based on the ability to cast the final design. Lastly, the polymeric design allows the optimization of the leaflet by varying the thickness across the entire leaflet structure to reduce cycle stresses. The cyclic leaflet stresses of the uniform thickness leaflets were extracted and processed in an in-house code that varied the thickness across the leaflets based on the absolute stress magnitude. The new varying thickness profile was simulated again and processed repeatedly to determine the final optimal thickness profile seen in Figure 4 which was able to dramatically reduce the stress magnitude below the fatigue limit of the polymer and reduce material thickness/volume.

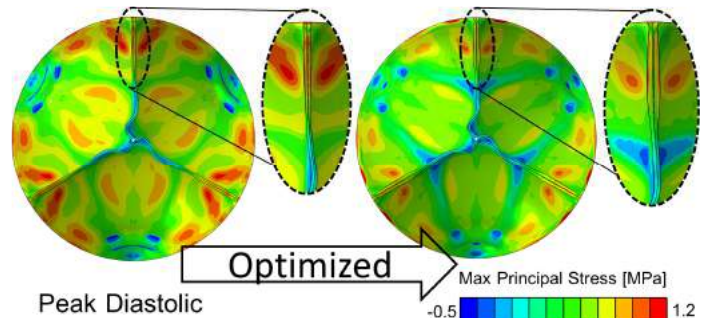

Figure 4: Maximum principal stress distributions of the uniform thickness leaflet (left) versus the non-uniform optimized leaflet (right). Inset highlighting uniformity of the leaflet free edge.

DISCUSSION

Upon casting the initial articles, the hydrodynamic performance of the PolyV-2 design will be measured according to the ISO-5840 standard and benchmarked against other commercial TAVR devices. Accelerated wear testing will begin again to confirm the durability of the new larger size device. With confirmation of performance, acute ovine animal trials will be conducted to begin study of the *in vivo* performance.

Polymeric TAVR technology offers the immense benefits over the intrinsically flawed tissue based TAVR devices currently on the market. Since polymeric valves can be cast in virtually any shape, compared to the uniform stamp-cut and hand-sutured shapes of tissue valves, the design of the leaflets can be optimized and tailored to the anatomy. The PolyV-2 leaflet profile has a unique variable thickness- optimized to reduce the leaflet stresses over the cycle for enhanced durability and improved hemodynamic performance. After finding a suitable material and manufacturing process for polymeric TAVR, proper design is critical to the success of the device. Many devices have failed at this stage and prior to large investments of resources, optimization and simulated trials can be easily conducted so that the subsequent *in vivo* trials are predictable. The PolyV-2 valve was optimized with *in silico* trials and the material was fully tested *in vitro* to develop a design construct with superior hemodynamics and performance mitigating persistent, common complications of current TAV devices.

MODELING THE FRACTURE MECHANICAL PROPERTIES OF LOAD-BEARING SOFT BIOLOGICAL TISSUES

Christopher Miller (1) and T. Christian Gasser (1,2)

(1) Solid Mechanics, Department of Engineering Mechanics, KTH Royal Institute of Technology,
Stockholm, Sweden

(2) Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark

INTRODUCTION

Collagenous soft biological tissues are composed of numerous extracellular matrix (ECM) proteins. Their complex structural arrangement and interaction define their macroscopic material properties. Fibrous collagen is known to be the principal load-bearing ECM constituent. Its hierarchical architecture and deformation mechanisms that act over several length scales, greatly determine observed physical phenomena such as its nonlinearity and time-dependency.

However, our current understanding of soft tissue damage and failure is somewhat restricted, specifically, those multiscale structure-function relationships that give rise to macroscopic fracture behavior are not well known. An improved general comprehension of soft tissue failure could have potentially beneficial implications for the treatment and management of certain pathologies, such as abdominal aortic aneurysms (AAA) in vascular tissue.

The difficulty in discerning such information experimentally has prompted the development of constitutive models. A versatile material description for load-carrying soft biological tissue should therefore incorporate salient microstructural deformation mechanisms and be able to reliably predict complex load-case scenarios. Yet, the computational modelling of damage and failure in materials undergoing finite deformations is a particularly challenging feat, and various approaches have been considered for the tackling of such problems, which can be generally divided into either a continuous or a discontinuous representation of the fracture process.

METHODS

We present an extension of our previous microstructural continuum model that includes proteoglycan-mediated collagen fibril sliding towards capturing the non-linear time-dependent properties of collagenous tissue [1]. It incorporates an interfibrillar failure (fibril pull-out) mechanism and gives rise to physiologically reasonable damage-induced mechanical behaviour across several length scales [2].

A bottom-up approach is followed, whereby the microstructural model is employed in a single-element representation of the modes of fracture. A qualitative description of soft tissue rupture is accordingly attained, to which a transversally isotropic cohesive zone model for the equivalent fracture surface is then calibrated. In doing so, a phenomenological surface-based discontinuous characterization of failure is derived directly from the upscaling of irreversible and dissipative damage mechanisms from the microscale. The constitutive description has been implemented in FEAP (Univ. of California at Berkley, US) using an in-house PUFEM description [3].

Furthermore, a novel crack initialisation criterion has been introduced, whereby the positive definiteness of the intermediate stiffness tensor is evaluated. Specifically, a negative eigenvalue and its associated eigenvector, inform the initialisation of the localisation and its orientation, respectively. Importantly, once a discontinuity is inserted within a particular element, the further accrue of damage within the continuum (bulk) material is switched off. Accordingly, all failure-related (strain-softening) behaviour is encapsulated by the cohesive model.

RESULTS

A number of representative examples were investigated in order to highlight the efficacy of the outlined computational framework. The standard uniaxial tensile test, in which a monotonically increasing load was applied until eventual failure, was evaluated. Additionally, the symmetry-constrained compact tension (symconCT) test was replicated, see Figure 1a. The setup consists of a square excised aorta specimen, clamped between two grips, to which a force/displacement may be applied. A polymer beam inserted above the sample, ensures the rotation of the grips and therefore the propagation of fracture, whilst also ensuring that the crack remains centralized. Such a configuration permits the stable propagation of fracture relative to other tests in the literature, and the consequent investigation of underlying microstructural damage/failure mechanisms.

Figure 1: (a) Experimental setup for the symconCT testing of the abdominal aorta, displaying the propagation of a crack through the specimen from an initial notch. (b) Preliminary results relating to the application of the discussed PUFEM constitutive description to the problem, showcasing comparative fracture behavior.

In both cases, qualitatively similar failure behavior was arrived at; both in terms of the resulting force-displacement profile and the path of the discontinuity through the material, see Figure 1b.

DISCUSSION

There is a paucity in the academic and clinical communities' fundamental understanding of soft tissue damage/failure processes at small-length scales. Computational modelling strategies present as a viable tool towards the exploration of hypothesized experimentally informed microstructural mechanisms. Such approaches may advance our view of disease and injury, and could prove a potential pathway towards enhancing patient outcomes.

This work has introduced a constitutive formulation for the study of fracture in collagenous soft biological tissues. A microstructurally informed continuum (bulk) material has been used, and a discontinuous surface-based description of fracture has been qualitatively derived from said model. Both models are implemented within the previously introduced PUFEM formulation, in which the discontinuity is embedded within the bulk material.

Finally, the application of the computational framework to a series of applicable examples demonstrated its suitability for the computational modelling of real-world soft tissue fracture mechanical problems.

ACKNOWLEDGEMENTS

The authors would like to thank Marta Alloisio and Marína Chatziefrimídou for providing experimental data and images in relation to the symconCT test.

A VASCULARIZED TISSUE MODEL TO INVESTIGATE HUMAN SYNOVIOCYTE – ENDOTHELIAL CELL CROSSTALK IN JOINT HEALTH AND DISEASE

Hannah M. Zlotnick (1), Abhishek P. Dhand (1, 2), Matthew D. Davidson (1), Gabriel J. Rodriguez-Rivera (1), Christopher J. Calo (1, 3), Hannah K. Weppner (1, 3), Laurel E. Hind (1, 3), Jason A. Burdick (1, 3)

INTRODUCTION

The synovium is a connective tissue that is present throughout the knee joint (and all articulating synovial joints). When injured or diseased, the synovium becomes hypervascularized through angiogenic processes (**Fig 1A**). Synovial angiogenesis has been studied most frequently in cases of rheumatoid arthritis (RA), a chronic autoimmune inflammatory disease; however, there is recent evidence to implicate the vascular system in the progression or pathogenesis of osteoarthritis (OA) [1,2], which can occur after joint injury or with age. Within patients with OA, it has been suggested that fibroblast-like synoviocytes (FLS) release the potent angiogenic factor vascular endothelial growth factor (VEGF), which contributes to the increased endothelial cell proliferation and vessel sprouting observed in the synovium [3]. In addition, immune cell populations within the synovium and neighboring tissues may contribute to the angiogenic response. To probe such complex behaviors, *in vitro* models are needed where specific cell populations can be introduced and monitored. In this work, we establish both spheroid and vascularized microfluidic models of the synovium to probe the coordinated signaling of FLS cells and endothelial cells in homeostasis and with OA.

METHODS

Validation of human FLS. FLS (P4 adult human synoviocytes) spheroids (50,000 cells/spheroid) were formed using 96-well U-bottom plates and synoviocyte growth medium. Seven days after spheroid formation, samples (n = 3 / stain) were fixed for whole mount immunofluorescence (lubricin), and fixed, processed, and sectioned for paraffin histology (haematoxylin & eosin). **HUVEC sprouting potential.** Multicellular spheroids consisting of human umbilical vein endothelial cells (HUVECs) and human mesenchymal stromal cells (MSCs) in a 2:1 ratio (1,000 cells/spheroid) were formed as previously described [4]. After 1 day of pre-culture, spheroids were mixed into a norbornene-modified hyaluronic acid hydrogel with adhesive (RGD)

moieties and a matrix metalloproteinase (MMP)-degradable crosslinker. The spheroid-laden gels were cultured in media with VEGF, Sphingosine 1-phosphate (S1P), and phorbol 12-myristate 13-acetate

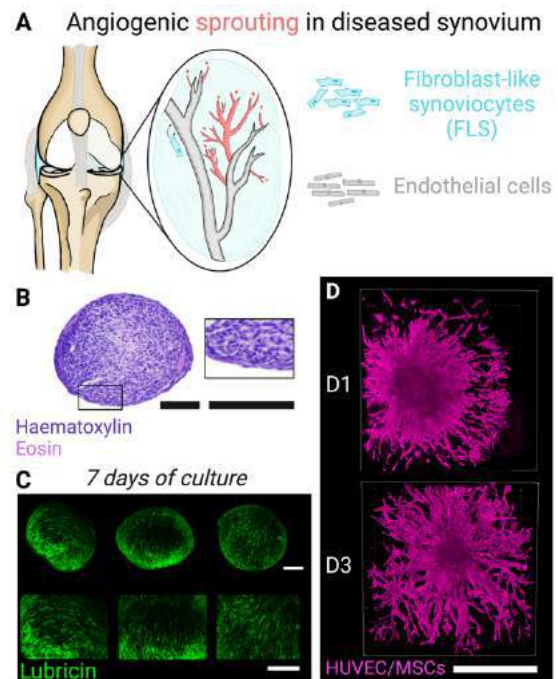

Figure 1: Cellular crosstalk within the synovium. (A) Angiogenic sprouting in the synovium. (B, C) Validation of adult human synoviocytes in spheroid culture. Scale bars = 100 μ m. (D) Sprouting of HUVEC/MSC (labeled actin) spheroids. Scale bar = 400 μ m.

(PMA) for 3 days. **Microfluidic device fabrication.** Microfluidic devices were fabricated as previously described [5]. Briefly, polydimethylsiloxane (PDMS) was poured on silicon masters, and baked for 4 h at 60 °C to create the top and bottom layers of the devices. PDMS rods were formed via extrusion through 23-gauge blunt needles, resulting in lumens ~340 µm in inner diameter. The top and bottom PDMS layers were aligned, and a PDMS rod was inserted through the inner channel of each device. **Endothelialized synovium formation.** FLS (3 million mL⁻¹) were encapsulated in 2 mg mL⁻¹ bovine collagen hydrogels and injected into the hexagonal chamber of the devices. To expedite collagen polymerization, the devices were incubated at 37 °C for 1 h. Post-gelation, the PDMS rods were removed from the devices, permitting the influx of media with HUVECs (20,000 cells/µL). The devices were rotated for 2 h to permit endothelial cell adhesion. **Nascent synovium viability and spreading.** After 4 and 10 days, the nascent synovium tissues (n = 3 / time point) were stained with calcein-AM, and ethidium homodimer-1 to assess live and dead cells, respectively. The calcein-AM images were also used to assess cell spreading using Cell Profiler. **HUVEC retention.** After 4 days, devices were fixed (n = 3), stained with DAPI, and imaged to assess the retention of the HUVECs in the vessel and positioning of synoviocytes. **Statistical analysis.** The mean cell spread areas were compared using a t-test in GraphPad. n = 96-256 cells / device, N = 3 devices / time point. * p < 0.05.

RESULTS

Healthy human FLS self-assembled into a synovium-like tissue when cultured in U-bottom wells. The spheroid tissues developed a thin outer lining a few cell layers thick, as evident by H&E staining (Fig 1B), reminiscent of the synovial intima. Interestingly, the synovial spheroids also developed a shell-like distribution of lubricin along the surface of the tissues (Fig 1C), similar to native synovium that has heightened lubricin expression in the intimal layer.

To verify the sprouting potential of the HUVECs in the presence of a mesenchymal cell population (alike the synovium), spheroids were fabricated that contained both HUVECs and MSCs. After encapsulation in a hyaluronic acid-based hydrogel with adhesive moieties and MMP-degradable crosslinkers, the spheroids began emitting cellular protrusions into the surrounding hydrogel (Fig 1D). Sprouting was observed as soon as 1 day after encapsulation in the hydrogel in the presence of angiogenic factors VEGF, S1P, and PMA.

To enhance the physiologic relevance of the spheroid tissue model, we next fabricated PDMS microfluidic devices containing inner hollow lumens (Fig 2A, B). The lumens were created by injecting a synoviocyte-seeded collagen solution into the device, allowing this solution to gel, and then removing the PDMS rod through the media inlet. The gelation period and subsequent culture did not disrupt synoviocyte viability, as the cells appeared nearly 100% viable after 10 days of culture (Fig 2C). In fact, the synoviocytes significantly spread over time in the collagen gel (Fig 2D). When the lumens were seeded with HUVECs, the HUVECs coated the central channel of the devices, and remained in the channels, as evident 4 days post-seeding (Fig 2E).

DISCUSSION

Our work establishes both self-assembled spheroid and 3D vascularized models of the synovium to investigate joint health and disease. It is currently unknown why and how the synovium becomes hypervascularized during RA and to a lesser extent during OA. To piece apart the complex signaling between the cell types in the synovium, *in vitro* models of varying complexity are needed. We show that human FLS self-assemble into tissues reminiscent of the synovium, with cells on the surface of the tissue preferentially expressing lubricin. Next, mesenchymal cells can be interspersed with HUVECs and surrounded

by a hydrogel matrix to permit sprouting—indicative of disease in the case of RA/OA.

To enhance the physiologic relevance of our model, we utilized a microfluidic device that contained a vascularized channel in the center of an engineered synovium-like tissue. This device is unique to any multicellular synovium model previously created as it enables the investigation of angiogenic sprouting, and FLS – endothelial cell interactions. Ongoing work is exploring the inclusion of diseased synoviocytes, and the impact of disease severity on HUVEC sprouting in this multicellular vascularized tissue model. We are also exploring the addition of exogenous inflammatory factors to the tissues to better understand the interplay between inflammation, angiogenesis, and OA.

INTRODUCTION

An aortic aneurysm forms when the thoracic or abdominal aortic wall weakens and irreversibly expands. The ballooning and expansion are attributed to a gradual loss/breakdown of extracellular matrix (ECM), primarily elastin [1]. Aneurysm rupture caused 9,923 deaths in the US in 2018 [2] and occurs when localized wall stress exceeds wall strength [3]. For this reason, it would be clinically impactful to better understand and predict wall tissue strength for aortic aneurysms.

Protease treatments have been used to alter vascular ECM and to explore its impact on mechanical properties of tissue [4,5]. In general, reduced ECM leads to a less robust tissue. It has also been shown that the density of concrete can be used to predict failure [6]. We conjecture that polymer and aortic tissue behave similarly (i.e., material strength relates directly to density) and hypothesize that a decrease in wall tissue density will result in a decreased strength.

The purpose of this study was to investigate the relationship between experimentally altered density and mechanical properties of polydimethylsiloxane (PDMS) and porcine thoracic aortic tissue.

METHODS

PDMS Specimen Curation: 27 PDMS samples (100mm x 5mm) were curated either at a 10-1 curing ratio (n=11) or at a half-density, 20-1 curing ratio (n=10). Since the 20-1 dilution specimens contain half the amount of curing agent, they are considered half-density of the 10-1 dilution PDMS samples. The samples had their density measured as described below. All samples were uniaxially tensile tested to failure on an Instron (model 5543A, Norwood, MA).

Porcine Specimen Treatment: Freshly excised, intact porcine thoracic aortas were obtained from a local abattoir and cut into longitudinally-oriented rectangular (80mm x 4mm) specimens and submerged in phosphate buffered saline (PBS) overnight. The initial (untreated) saturated mass and volume were measured for each specimen and initial density calculated as described below. The samples

were then submerged in a collagenase (50 mg/mL, n=7) or elastase (0.01 mg/mL, n=7) solution to selectively degrade collagen or elastin, respectively. Sham/control specimens were submerged in pure PBS (n=7). Submerged specimens were then incubated with end-over-end rotation at 37 °C for 24 hours. Post-treatment mass and volume were measured, and density calculated for each specimen following incubation and then uniaxially tensile tested to failure. The stress-stretch curve was used to calculate nominal ultimate tensile strength (UTS) and tangent modulus, and all statistical analysis was performed using an ANOVA with Tukey's post-hoc.

Specimen Density Measurements: Mass (m) of all porcine specimens was measured using a precision balance (PR503, Mettler Toledo, Columbus, OH). The width-length surface area and average thickness were determined from images captured of the specimens prior to testing. Solid volume (V) was calculated from the measured surface area (SA) and average thickness (t) across the specimen (**Equation 1**).

$$V = SA * t \quad (1)$$

Density (ρ) was determined for each specimen before and after enzymatic degradation (**Equation 2**).

$$\rho = \frac{m}{V} \quad (2)$$

Percent density change (before vs. after treatment) for each specimen was calculated.

Material Modeling: Stress/stretch curves were imported for each specimen and analyzed independently (either 10:1 vs 20:1 for PDMS, or sham vs collagenase vs elastase for porcine tissue). These stress stretch curves were fit with a Vorp-Raghavan 2 parameter hyperelastic isotropic material model [7] (**Equation 3**)

$$W = \alpha(I_B - 3) + \beta(I_B - 3)^2 \quad (3)$$

Here I_B is the first invariant of left Cauchy-Green deformation tensor B . The mechanical properties α and β were determined by nonlinear regression analysis.

RESULTS

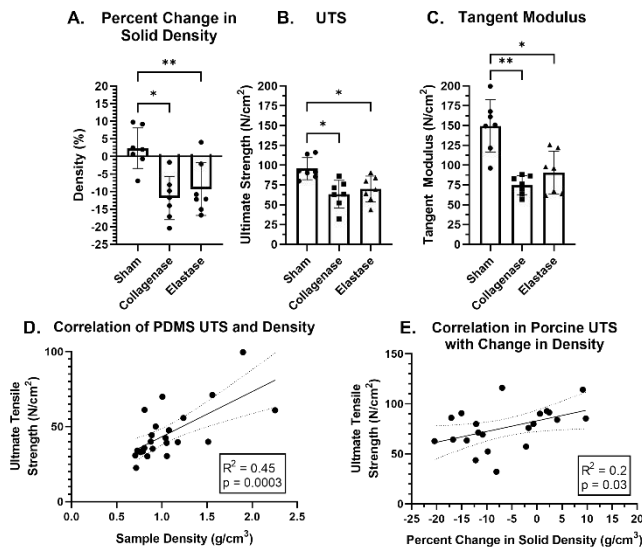

Figure 1: A) Percent change in density of material after proteolytic treatment, B) UTS of protease treated porcine aortas, C) Tangent modulus of protease treated porcine aortas, D) Correlation of PDMS samples comparing UTS and sample density, and E) Correlation of porcine samples comparing UTS and sample density. *p-value < 0.05 and **p-value < 0.01.

The results for the PDMS show a significant difference in solid density between the 10-1 and the 20-1 (1.16 ± 0.44 g/cm³ vs 0.88 ± 0.13 g/cm³, respectively; $p=0.03$). The UTS (55.0 ± 19.5 vs 37.1 ± 8.26 N/cm², respectively; $p=0.002$) and tangent modulus (38.9 ± 14.7 vs 10.5 ± 1.91 N/cm², respectively; $p<0.001$) were both also higher for the 10-1 compared to the 20-1.

The results for the porcine aortic tissue show a significant difference in % change in solid density between sham ($2.3 \pm 5.3\%$) and both collagenase-treated ($-11.8 \pm 5.7\%$, $p=0.005$) and elastase-treated ($-9.2 \pm 6.9\%$, $p=0.011$) tissue (Figure 1A). Parallel differences were also seen for the UTS for the sham (95.70 ± 12.8 N/cm²) and the collagenase (63.5 ± 16.2 N/cm², $p=0.024$) and the elastase groups (69.9 ± 15.2 N/cm², $p=0.03$) as shown in Figure 1B. The tangent modulus also showed similar differences between the sham (149.5 ± 30.7 N/cm²), collagenase (74.8 ± 11.1 N/cm², $p=0.007$) and the elastase groups (90.8 ± 25.0 N/cm², $p=0.025$), as shown in Figure 1C.

Linear regression reveal that density is a significant predictor of UTS in PDMS ($R^2=0.45$, $p=0.0003$) (Figure 1D). Similarly, % change in density is a significant predictor of UTS for porcine thoracic aorta ($R^2=0.2$, $p=0.03$) (Figure 1E).

PDMS material parameters, when fit to the Vorp-Raghavan Model [7] (showed a significant difference from each other Figure 2A). For the α values, the 10-1 dilution (7.6 ± 0.5 N/cm²) was significantly higher than in the 20-1 (3.7 ± 0.1 N/cm², $p<0.0001$). This trend remained for the β values, for the 10-1 (0.5 ± 0.2 N/cm²) were significantly higher than in the 20-1 (0.04 ± 0.02 N/cm², $p<0.0001$).

For the porcine tissue material parameters (Figure 2B) The α values were not different in sham control (9.8 ± 2.7 N/cm²) compared to collagenase-treated (10.8 ± 3.4 N/cm², $p=0.20$) or elastase-treated (6.5 ± 1.2 N/cm², $p=0.68$) specimens. However, there was a difference when comparing the α values of collagenase- (10.8 ± 3.4 N/cm²) and elastase-treated samples (6.5 ± 1.2 N/cm², $p=0.0071$). The β values were different when comparing the sham control (4.8 ± 1.3 N/cm²) with collagenase-treated samples (1.2 ± 0.7 N/cm², $p=0.01$), but no difference compared to elastase-treated samples (2.0 ± 0.3 N/cm², $p=0.10$).

Similarly, there was no difference when comparing collagenase- (1.2 ± 0.7 N/cm²) versus elastase-treated samples (2.0 ± 0.3 N/cm², $p>0.99$).

Figure 2: A) Model fit of PDMS samples in a Vorp-Raghavan model, and B) Model fit of protease treated porcine treatments in a Vorp-Raghavan material model.

DISCUSSION

We demonstrated that altering the material density gives insight into the material strength. By using different curing agent concentrations, we were able to successfully perturb PDMS to tune its material density. The 10-1 samples had significantly higher bulk specimen densities, UTS, and tangent moduli. These experimental results are also shown in the model fit of the PDMS specimen. From the model, α is representative of the low-stretch region of the tissue's response and β represents the high-stretch region [8]. The α and β parameters were both significantly larger in high-density (10-1) samples compared to the half-density (20-1) samples. Thus, the high-density samples have stiffer responses in low and high stretch regions than the half-density samples. This observation supports our hypothesis that higher density provides mechanical strength to the sample.

Additionally, we found that altering material density in porcine tissue shows a similar relationship between density and biomechanical failure properties. The experimental tests on the porcine tissue revealed that through proteolytic treatments we can manually manipulate the density to decrease the bulk tissue density, UTS, and tangent modulus, as shown in Figure 1A, 1B, and 1C. Correlation between PDMS strength and density was exhibited here (Figure 1D). Additionally, porcine tissue also exhibits density as a significant predictor of UTS (Figure 1E). The porcine tissue model fit has no difference in α between sham or treatment groups, however, β is significantly higher in sham compared to collagenase. This is corroborated with prior literature[5] as we are reducing the strength of the tissue by removing some collagen from the ECM. Schriebl et al noted the same experimental results in regards to low and high stretch stiffness[9].

This study is limited by assuming that when using collagenase, there is only a reduction in the collagen content. Similarly, we assume when using elastase there is only a reduction in elastin content. Future work will include a ninhydrin and hydroxyproline assay of the treated tissue to quantify the collagen and elastin content in the treated and sham specimen. Future studies will work to measure local densities rather than assign a bulk density value to an entire section of tissue.

INTRODUCTION

Modern computational modeling & simulation (CM&S) tools have become ubiquitous within the field of biomechanics. CM&S has provided engineers, scientists, and clinicians with new strategies to advance biomedical research, medical device design, and interventional/surgical planning. Moreover, CM&S is recognized by the FDA as central to evaluating device safety and effectiveness [1]. Hence, CM&S has become increasingly important for biomedical engineering trainees. However, medical device consortiums have highlighted barriers to broadly using CM&S, including user expertise, scientific maturity, and cost [2]. To address these limitations, efforts to integrate CM&S as an instructional tool into biomedical engineering curriculums, particularly at the undergraduate level, have been undertaken to promote understanding and application [3].

Initiatives contend that biomedical engineering students should learn computing concepts to improve the educational environment [4]. The introduction and use of computational software that utilizes, for example, finite element (FE) modeling is traditionally taught in graduate-level biomechanics courses due to the advanced nature of the topics. However, CM&S tools have many attractive features that complement standard pedagogical approaches for undergraduate courses in biomechanics and augment student learning and comprehension. Herein, we aimed to develop and implement interactive learning modules developed in the open-source FE software *FEBio* and *FEBio Studio* within our undergraduate biomechanics course and evaluate the effectiveness of this integration in providing a foundation for CM&S to undergraduate biomedical engineering students.

METHODS

Course Overview and Student Participants: *Biomechanics I* is a core (required) course in the undergraduate curriculum in biomedical engineering at the University of Utah. Across 15 weeks, with two 80-minute didactic lectures per week, the course covers topics in continuum

mechanics (e.g., finite deformation kinematics, stress), linearized elasticity, and the mechanical behavior of biological materials. Additionally, this course includes a laboratory component where students perform hands-on experiments to reinforce topics covered in the lecture. In Fall 2022, there were 83 students at the junior or senior level enrolled in the course.

FEBio Learning Modules and Instructional Efforts: We developed and implemented four learning modules that supplemented the course lectures, in-class discussions, assignments, and laboratory exercises. Each module contained self-enclosed lessons that were completed in 90-120 minutes. Across 8 lab sections, with 9-11 students in each section, students were divided into 2-3 person groups. Each group had access to a desktop PC with an Intel® Core™ i7-6700 (3.40 GHz) processor and 16 GB of memory. Modules began with a brief 10-minute lecture by a teaching assistant (TA) to provide clinical/biomedical rationale and describe relevant background information. Next, student groups completed tutorial(s) to construct FE models, including geometry creation, discretization, assignment of boundary conditions, and material selection. In addition, students were provided with pre-built models where they analyzed and interpreted simulation results that reflected concepts from the didactic lectures. At least one TA was always present to provide supplementary instructions, answer questions, and assist with FEBio.

The title and topic of each module are listed in Table 1. Module 1 introduced the basic principles and applications of FE and FEBio, and students simulated simple deformations of a unit cube (e.g., extension, simple shear). For Module 2, students simulated a tensile

Table 1. FEBio Learning Modules

Title
1. <i>Introduction to FEBio:</i> finite deformation kinematics
2. <i>Tensile Testing Simulation:</i> analysis of strain and stress
3. <i>Linearized Elasticity:</i> elastic constants and anisotropy
4. <i>Beam Bending Simulation:</i> verification and validation

Figure 1. (A) Longitudinal PK1 stress in a dog-bone sample under uniaxial tension, (B) Comparison of Cauchy and PK1 stresses, (C) Von-mises stress in a hip implant, (D) Representative student plot of V&V results via beam-bending experiment.

testing experiment and analyzed the strain and stress predictions (Fig. 1A-B). In Module 3, students investigated material symmetry and elasticity constants (e.g., Young's modulus, Poisson's ratio). Lastly, Module 4 introduced verification and validation (V&V) for a simple beam bending experiment and included a case study on material yielding in the setting of a prosthetic hip implant (<https://grabcad.com/library/hip-prosthesis-1>, Fig. 1C-D).

Student Assessment and Surveys: Following the completion of the tutorial(s) for each module, students completed an assessment to evaluate tutorial effectiveness. In groups, students were given a problem statement and tasked to construct and analyze more advanced FE model(s) that extended concepts and principles from the tutorial(s). The number of attempts each group needed to complete each exercise correctly was recorded. In addition, students were asked to complete questionnaires offered before Module 1 (pre-evaluation), after Module 2 (mid-evaluation), and after Module 4 (post-evaluation; Table 2). Students answered survey questions (Q) 1 and 3 as Yes/No. Q2 and Q4 responses were on a scale of 1 (*strongly disagree, not interested*) to 5 (*strongly agree, extremely interested*). Q5 and Q6 allowed open-ended responses to evaluate module effectiveness and how to improve the educational material. Responses were anonymized. Data are reported as mean \pm standard deviation where appropriate.

Table 2. Student Survey Prompts

	Question
Pre	Q1. Before this course, have you heard of "finite elements/FEA"?
Pre, Mid, Post	Q2. How interested are you in <i>continuing</i> to learn CM&S?
Post	Q3. During this course, have you explored FEBio on your own?
Post	Q4. How effective were the FEBio modules in providing a computational foundation and understanding of theoretical concepts introduced during lectures?
Post	Q5. What was the most beneficial aspect of these modules for you?
Post	Q6. What biomedical applications or diseases would you find most interesting to <i>apply</i> FE to study?

RESULTS

Most students had not heard of FE or FE analysis before the modules, as <35% of students had previously heard those terms. However, as the modules progressed, students became more interested in CM&S (Fig. 2D). The heightened interest coincided with students demonstrating an increased understanding and comprehension of FE model development and use of FEBio (Fig. 2A-C). Not only was there a reduction in the number of attempts across exercises within a module, but fewer attempts were needed as students progressed through the modules. In Module 1, for example, the number of attempts across two exercises decreased from 4.56 ± 2.20 to 2.94 ± 1.64 , while in Module 3,

the number of attempts across three exercises ranged from 1.56 ± 1.33 to 1.80 ± 1.04 . It was encouraging to learn that >60% of students explored FEBio outside of the educational environment and included students exploring user projects in the FEBio Studio model repository. Furthermore, students indicated that the modules integrated well with the didactic lectures and aided understanding of theoretical concepts introduced during lectures (Q4 score: 4.25 ± 0.67 , Fig. 2E). Responses to the open-ended questions (Q5,6) were largely positive, including a few noteworthy statements:

Q5: "... visualizing what we learned in class. Just observing what different deformations looked like helped give context to everything learned in class. Also, getting familiar with real-world tools for solving biomechanics problems was good exposure for third-year BME students."

Q6: "... medical implants in patients. Before this class, I mostly thought of medical device compatibility in the setting of device rejection by the body. However, I should also think about it in the sense of biomechanics. Making sure a medical device does not physically break has to be one of the most important considerations in this field."

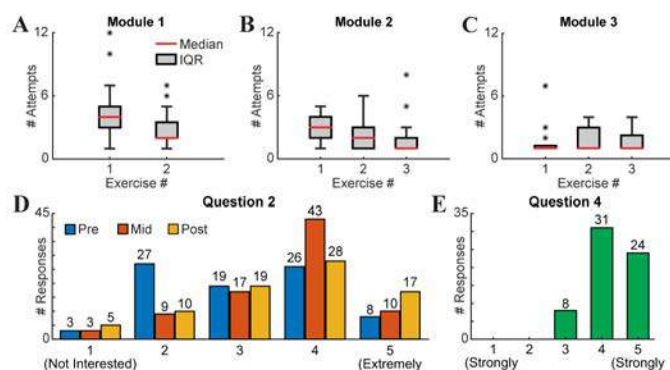

Figure 2. (A-C) Student assessment scores for Modules 1-3. (D-E) Student survey responses for questions Q2 and Q4.

DISCUSSION

Our efforts demonstrate that CM&S can be successfully integrated into an undergraduate biomechanics course and serve as an effective and interactive educational tool. Assessment data indicated that the FE modules increased learning for both course content (i.e., fundamental biomechanics principles) and the application of FE analysis. Importantly, students recognized the advantages of CM&S in evaluating the mechanical behavior of complex systems. The continued integration of CM&S into undergraduate biomedical engineering curriculum holds much promise in training students in modern techniques and tools broadly used in their professional work.

INTRODUCTION

Advances in medical imaging, computational mechanics, biomechanics, and computing power now provide the ability to perform computational simulations and predict arterial tissue deformations at the patient-specific level [1]. In addition to the model geometry, boundary conditions, and numerical approaches to solve the governing equations, the constitutive relation(s) describing the behavior of the material(s) are required to compute the transmural wall stresses under conditions of interest, which influence the homeostatic and maladaptive mechanobiological processes. While experimental approaches have been developed to characterize the nonlinear, pseudo-elastic, and anisotropic material response of vascular tissue under loading, there is much variability in the employed techniques, ranging from experimental testing protocols to fitting approaches [2]. Furthermore, variability within and across tissue samples leads to uncertainties in the material parameter(s) describing the mechanical properties of vascular tissue. These uncertainties may ultimately propagate to variability in the simulation-predicted mechanical environment.

As simulation results have the potential to influence clinical outcomes (e.g., predict major adverse event), there is a pressing need to provide confidence in simulation predictions and demonstrate that results are reliable and safe prior to clinical adoption. Such confidence in simulation pipelines is marred by uncertainties, which manifest through unaccounted for subject and clinical variabilities that cloud the predictive and prognostic lenses of computer-based modeling. Therefore, the goal of this study was to leverage uncertainty quantification (UQ) techniques to examine the impact of tissue material property uncertainty on the variability in model outputs, namely the predicted stress and strain.

METHODS

Material Parameter Probability Distribution Sampling: Material parameters derived from previous layer-specific mechanical

testing of thirteen human non-atherosclerotic left anterior descending (LAD) coronary artery tissue were employed [3]. Best-fit material parameters for the media and adventitia layers were determined using the microstructurally motivated strain energy function (SEF),

$$W = \mu(I_1 - 3) + \frac{k_1}{k_2} e^{k_2[(1-\rho)(I_1-3)^2 + \rho(I_4-1)^2]} - 1, \quad (1)$$

where μ represents the ground matrix stiffness, k_1 is a fiber “stress-like” parameter, k_2 is a dimensionless parameter, ϕ specifies the angle of circumferential fiber orientation in the circumferential-axial plane, ρ is a measure of fiber dispersion, and I_1 and I_4 are the first and fourth invariants, respectively, of the right Cauchy-Green deformation tensor.

Probability distributions were created for each constitutive parameter in the medial and adventitial layers (10 in total). Material parameters μ , k_1 , k_2 , and ϕ employed gamma distributions to avoid non-physiologic parameters, whereas ρ used a beta distribution. Probability density functions (PDFs) were fit to experimental data via MATLAB (MathWorks, Natick, MA), and defined within *UncertainSCI*, a novel open-source, Python-based UQ software tool [4]. A tensorial distribution (i.e., parameter ensemble), which sampled the entire parameter space and accounted for the interplay between distributions, was created from the 10 PDFs (Fig. 1A).

Idealized Artery Computational Model: A generalized computational model of a human LAD coronary artery was constructed and modeled as a multi-layered, axisymmetric quarter-cylinder ($R_i = 1.59$ mm, $R_o = 2.25$ mm), with a medial and adventitial layer thickness of 0.32 and 0.34 mm, respectively. The SEF defined by Eq. 1 described both layers. Based on a mesh convergence study, the artery was discretized with 8-node hexahedral “brick” elements with 6 elements in the radial direction for each layer. Boundary conditions included: a lumen pressure up to 80 (diastolic) and 120 (systolic) mmHg, fixing the vessel ends, and symmetry boundary conditions to restrict rigid body

Figure 1: Schematic of UQ integrated into modeling framework. (A) Probability distributions fit to n -material parameters, with m -parameter combinations generated via UncertainSCI sampling. (B) Automated batch-processing scheme created m -number of FE models to predict tissue deformation, strains, and stresses.

motions. The open-source, nonlinear finite element (FE) software *FEBio* (<https://febio.org/>) was used to perform the quasi-static analysis [5]. A batch-processing scheme was implemented via MATLAB to iterate through material parameter combinations derived from the tensorial distribution, creating m -unique input files for FEBio (Fig. 1B). Simulation results were post-processed to evaluate the deformed inner and outer radii, transmural distributions of 1st and 3rd principal stresses (σ_1 , σ_3), and distensibility.

UQ and Sensitivity Analysis: Utilizing UncertainSCI, a parameter-to-model-output emulator was constructed via polynomial chaos expansion (PCE) to approximate the mapping between the SEF parameters (inputs) and FE-predicted principal strains and stresses (outputs). Importantly, the emulator allowed direct extraction of statistics, uncertainty characteristics, and model sensitivity. PCE quality was assessed by quantifying the relative error between PCE approximations and FE-predicted model outputs for orders (p) 1 to 5, over 5 independent PCE runs for each order.

Statistical measures (e.g., mean, standard deviation, coefficient of variance) were calculated directly from PCE output. Sensitivity indices, via first and second-order Sobol indices, were calculated across the SEF parameters to measure the direct contribution of individual parameters (unary interaction) and two-parameter combinations (i.e., binary interaction) to the overall variability in the model output for 1st principal stress. Binary interactions were only evaluated between SEF parameters within each arterial layer.

RESULTS

The number of parameter combinations generated across PCE orders ranged from 21 for order 1 to >3000 for order 5. Evaluation of the relative error and error variability for the 1st and 3rd principal stresses demonstrated that PCE order 2 resulted in error values of <1%, with an error variability of <0.03% across 5 runs. Furthermore, first-order Sobol indices maintained stability at PCE order 2 and higher orders. The FE results from PCE order 2 simulations demonstrated a range of deformed arterial geometries. For instance, vessel diameter, thickness, and distensibility values range from 3.76–4.39 mm, 0.52–0.38 mm, and 5.75–13.88 MPa⁻¹, respectively.

The propagation of material parameter uncertainties to the transmural distribution of 1st principal stress at 120 mmHg yielded standard deviations >40 kPa within the medial and adventitial layers (Fig. 2A). While average stress values and standard deviations decreased radially through each layer, there was an abrupt increase in the standard deviation at the innermost region of the adventitia. Notably, the coefficient of variation in the adventitia was >2× the value in the media, indicating adventitial σ_1 stress values had larger dispersion around the mean (Fig. 2B).

Sensitivity analysis highlighted that the anisotropic material parameters of the adventitia, k_1 , k_2 , ϕ , and ρ accounted for nearly

64.7% of the variance in predicted σ_1 stress (Fig. 2C). Moreover, uncertainty in the stiffness of the adventitial fibers (k_1) alone accounted for >40% of first-order interactions. The stiffness of the ground matrix (μ) for both the media and adventitia had a negligible effect. While unary interactions were dominant (80.8%), binary interactions accounted for 19.2% of predicted σ_1 variance (Fig. 2D). Specifically, binary interactions in the media and adventitia accounted for 5.8% and 13.4%, respectively. In particular, the interaction between the adventitia parameters, fiber angle (ϕ), and dispersion (ρ), accounted for 7.6% of the variance in predicting σ_1 stress.

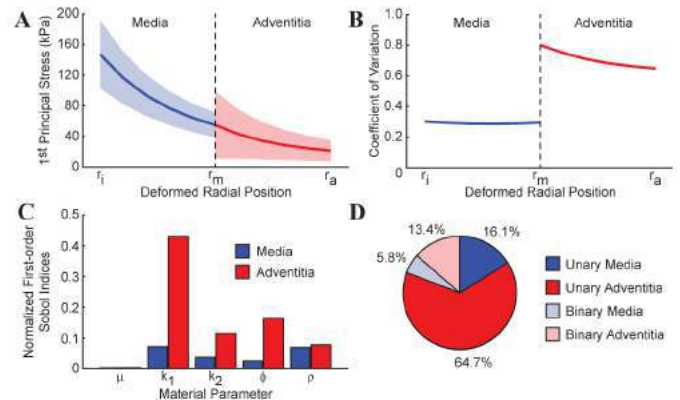

Figure 2: (A) Transmural distributions of 1st principal stress (solid line: Mean, shaded region: ± 1 SD). (B) Coefficient of variation. (C) Normalized first-order Sobol indices (unary interactions) for material parameters in the media and adventitia. (D) Percent variance due to unary versus binary interactions. All data were derived from order 2 PCE analysis.

DISCUSSION

In the present study, we demonstrated the utility of an integrated FE-UQ framework to evaluate the intrinsic uncertainty in material parameters on the variability of the arterial mechanical environment. Our results indicate that the uncertainty in the stiffness of the adventitial fibers, k_1 , drives the variance in FE-predicted stresses. In addition, the pairwise interaction between adventitia fiber angle (ϕ) and dispersion (ρ) had a greater effect on variance in stress than any single parameter in the media. These results highlight not only the importance of accurate measurements of these material parameters to provide confidence in FE-predictions but also the need to acquire considerably more data across tissue samples, including donor/patient age and sex, to obtain improved parameter distributions. Ultimately, these efforts must be integrated into patient-specific modeling frameworks within the clinical setting to promote the safety and reliability of model predictions prior to clinical adoption.

INTRODUCTION

Central venous catheterization (CVC) is a common, albeit invasive, approach to access the central venous system. CVC is often used to deliver sclerotic medications and provides a reliable means by which clinicians deliver large volumes of fluid to critically ill patients. Despite these benefits, its presence as a foreign body within the central venous system can result in thrombosis which may obstruct the fluid flow within the lumen or blood flow within the vessel in which the catheter resides. In addition to the local thrombosis, thromboembolic events arising from the catheter can occur. This feared event can lead to the obstruction of the pulmonary arteries which can be fatal [1]. It is well documented that there are a number of complex biochemical reactions involving soluble factors within the blood that lead to thrombosis however, the hemodynamic parameters also play an important, and often underappreciated, role in the development of thrombosis [2], [3].

Direct measurements of hemodynamic parameters are not conducted routinely in clinical practice. Therefore, computational fluid dynamics (CFD) is widely used to simulate blood flow around the CVC, and the derived hemodynamic parameters are used for analyses. However, CVC numerical studies are very limited in the literature. In the CFD study performed by Peng *et al.*, CVC elevated the wall shear stress (WSS) level and disrupted the blood flow's spiral rotation [2]. Park *et al.* suspected that the increments of time-averaged WSS and normalized transient WSS on the venous lumen should be related to the thrombosis incidence [3]. The tip placement of the catheter may vary in the proximity of the cavo-atrial junction, and De Oliveira *et al.* revealed its effects on the surrounding blood flow in terms of shear stress, recirculation region, and percentage of tip volume with high shear stress level in an idealized right atrium (RA) [4].

The first two studies mentioned above had no RA in the numerical models, and the last one included an idealized RA and the catheter's tip portion only. This study reconstructed an anatomical model based on

patient-specific images, and a double-lumen CVC was inserted along the centerline.

METHODS

The geometry of the anatomical model, including RA, SVC, and IVC, was based on the CT images of a pediatric patient from Penn State College of Medicine (IRB approved), as shown in Fig. 1a. The reconstructed model represents the characteristics of the venous structure. The geometry of the 5 French catheter was segmented from a microCT scan, and the surface was represented by millions of facets in stereolithography (STL) formation in Fig. 1b.

Figure 1: (a): CT image segmentations (orange) and reconstructed model including right internal jugular vein (RIJV), right subclavian vein (RSV), left internal jugular vein (LIJV), left subclavian vein (LSV), SVC, IVC and RA. (b): Double lumen 5 French catheter reconstructed from microCT scan.

The catheter was inserted virtually into the anatomical model along the centerline, as demonstrated in Fig. 2a. Note that the CT scan only

captured images at one-time point, so the numerical model was assumed to be rigid. In this study, the blood was assumed to be an incompressible Newtonian fluid with a density of 1035 kg/m^3 and a dynamic viscosity of $0.0035 \text{ Pa}\cdot\text{s}$, respectively. The numerical models were meshed using cfMesh implemented in the OpenFOAM framework. The numbers of grids in the model with and without the CVC were approximately 4.5 million and 2.6 million, respectively (Fig 2b). Based on the averaged flow rate and the effective SVC diameter, the Reynolds number was about 750, and thus the flow inside the model was laminar. The governing equations were solved using the pimpleFoam solver in OpenFOAM. The flow rates in SVC and IVC were derived from 4D MRI measurements [6], and the cardiac output of the model was assumed to be 5 L/min at a heart rate of 72 beats/min (Fig. 2c).

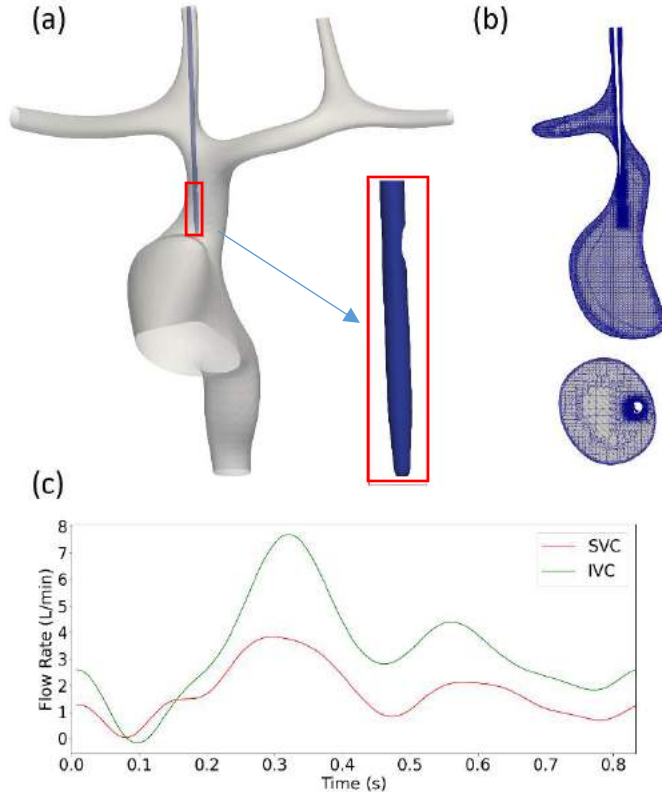

Figure 2: (a): Numerical model with a catheter inserted along the centerline from RIJ to RA. (b): Cross sections of mesh generated using cfMesh. (c): Flow rate profiles in SVC (red) and IVC (green).

RESULTS

Figure 3 shows the time-averaged flow patterns on the cross-sectional plane in the models with and without catheter. The presence of a catheter mainly alters the flow in SVC, and the flow in IVC is not affected. Due to the flow resistance induced by the catheter, the RA region influenced by the IVC flow is slightly larger in the model with the catheter. At the tip and side-hole, the blood in the lumen has zero velocity, as indicated by the contours in Figure 3c.

Figure 4 shows the WSS magnitude elevates at RIJ, owing to the insertion of the CVC. However, the changes in WSS magnitude in other regions are insignificant. The cavities at the tip and side-hole induce low WSS regions ($< 1 \text{ Pa}$), where flow stagnation occurs.

DISCUSSION

In this study, the CVC effects on the flow in the RA and surrounding veins have been simulated. As the catheter tip was placed

near the junction of SVC and RA and its diameter was relatively thin, its influence on RA flow was insignificant in terms of flow patterns and WSS. Instead, the IVC flow dominated the flow in RA and directed the flow in a clockwise direction. This characteristic flow pattern was also observed in the 4D MRI study [7] and thus validated that the simulation results were reasonable. WSS is an important hemodynamic parameter related to thrombosis, its value increased slightly after the insertion of CVC at RIJ, and the potential of thrombosis was altered marginally. However, the flow stagnation and low WSS magnitude at the tip and side-hole could promote the development of a thrombus, which will be thoroughly investigated in future studies. The main significance of this work is establishing the framework for CFD simulations, including CVCs using image segmentation, reconstruction, virtual catheterization, and CFD modeling.

INTRODUCTION

An abdominal aortic aneurysm (AAA) is a common cardiovascular disease which causes the irreversible enlargement of the terminal aorta by more than 50%. AAA can become fatal if ruptured, which makes it the 13th leading cause of death in the US [1]. Surgical intervention can be performed to stabilize the aneurysm and prevent further growth/rupture. There are two methods of intervention: a high-risk open surgical repair or low-risk minimally invasive endovascular aneurysm repair (EVAR) where an endograft is deployed via a catheter inserted through the femoral artery [2]. Nearly 70% of AAA repair cases now use EVAR due to its lower mortality rate; however, roughly 30-50% of patients with AAA are not eligible for EVAR due to geometric constraints [3].

Short aortic neck lengths (< 10 mm) pose compatibility issues for the typical EVAR procedure as it hinders proper stent-graft anchoring and sealing. For aneurysms without an appropriate neck length, fenestrated EVAR (FEVAR) was introduced to extend the anchoring point past the visceral arteries (renal, superior mesenteric, and celiac) with openings for bridging stent-grafts. The EVAR grafts are either surgeon modified or prefabricated according to the patient's anatomy. In either case, fenestrations or holes are created in the graft to allow for bridging stents to be placed and restore blood flow through the visceral arteries. However, extensive planning is required to fabricate fenestrated EVAR (FEVAR) grafts including computed tomographic (CT) imaging and reconstruction, and manufacturing to guarantee precise placement of fenestrations [4].

The Cook Zenith graft (Cook Medical LLC, Bloomington, Indiana) is currently the only FDA approved custom graft on the market. The preparation and manufacturing of this custom graft necessitates a 4-8 week wait period for patients until implantation can occur [5]. The lead time for delivery poses a rupture and death risk for patients that need immediate repair. Katsarygyris et al. reported that ~4% of patients died and ~2% experienced aneurysm rupture before a FEVAR operation

could take place [6]. Alleviating wait times and extensive costs for the FEVAR procedure can improve AAA repair.

The goal of this work is to develop a device to create *in situ* fenestrations (ISF) for off-the-shelf endografts. To perform ISF, it is necessary to detect and visualize the openings of visceral arteries from inside the graft. The purpose of the current study was to develop and validate a prototype to achieve this using fiber optics in an *in vitro* test bench.

METHODS

Summary: Several feasibility studies were performed to assess the ability of evolving prototypes to detect an orifice of an artery. This was achieved by developing a test-bench, stent-graft patch (metal struts with woven polyester fabric), and various media (air and blood) to test whether infrared light in a visceral artery model could be detected with the fiber-optic probe. Additionally, the loss of light intensity was measured and statistically compared between air and water. The device consists of a bundle of fiber optic cables for transmitting light and a camera for real-time visualization of the light. Fiber optic cables consist of thin strands of glass and are used for their ability to transmit light waves long distances. For this experiment, they were used to transmit light from a point source for real time visualization. An infrared light-emitting diode (LED) was used as the light source and connected to an Arduino (Arduino LLC, Boston, MA) for a light intensity of 300 mW at 500 mA. An external computer webcam (Logitech International, Lausanne, Switzerland) was used for visualization because it has a complementary metal oxide semiconductor (CMOS) sensor for detecting infrared light. A separate MATLAB (Mathworks, Inc. Natick, Massachusetts) script was used for visualization.

Fiber Optic Probe Development: A silicone molding technique was utilized to manufacture the fiber optic probe. The advantage of the molding technique enabled the fiber optics to be embedded without the need for additional adhesive. Two halves of the casting mold were

designed on Inventor (Autodesk, San Rafael, CA) and 3D printed using a Form 3 printer (Formlabs Inc. Somerville, MA). Each half cast contained half of the probe longitudinally. The probe was made 7 mm in diameter with six 700 μm fibers (Thorlabs, Newton, NJ) embedded in a 6 mm diameter circular pattern (**Figure 1A**). This number of fibers was chosen to be adequate for an initial feasibility study, size constraints, and minimizing equipment costs. One half of the cast included holes for silicone to be poured into the cast. A 10:1 XPS silicone (Silicones Inc., Woodbine High Point, NC) was poured into the cast chamber and allowed to dry for 24 hours. After sitting, the halves of the cast were separated, and the mold was released.

Experimental Setup: A test bench was designed using Inventor and 3D printed using a Form 3 printer. The test bench was 115 mm long, 60 mm wide, and 80 mm in depth (**Figure 1B**). In the center of the test bench is a half-cylinder mimicking 'inside the lumen' to outer wall to act as half of an aorta. The half cylinder had guiderails to allow for precise movement and tracking of the probe head relative to a 6 mm diameter orifice acting as the opening of an artery. A 5 mm LED emitter at a wavelength of 830 nm infrared (Vishay Optoelectronics, Malvern, PA) was placed into the 6 mm hole. A 10x10 mm piece of Zenith endograft material was cut and attached over the artery orifice using adhesive.

Visualization of the Orifice with Fiber Optics: The free end of each fiber was placed into a 38 mm diameter 3D printed disk in the same pattern as embedded in the probe. The disk is created to allow us to visualize what the probe is detecting (**Figure 1C**). The disk was attached to a tube which connected to the external computer webcam for live capture. The tube created a dark environment to reduce ambient light for better measurement of the light. A MATLAB script was written to capture live images in 3 second intervals. The images were converted to 8-bit grayscale ranging from 0 to 255; 0 being no light detected and 255 being the most intense light. The snapshots were later converted to a graphics interchange format (gif) and the gif would act as a live stream of the probe visualization. The greyscale values of a fixed area from each fiber (**Figure 1D**) were analyzed for average and maximum pixel intensity on ImageJ (National Institutes of Health, Bethesda, MD).

Figure 1. (A) Silicone probe in half of the 3D printed cast with 6 fiber optic wires embedded. The dark blue cables are the fibers, and the gray material is half of the mold cast. (B) Test chamber with endograft material glued over hole opening. (C) Visualization of the infrared light with the probe tip over the center of the opening from the MATLAB code. (D) Fixed area created over an individual fiber for intensity measurement using ImageJ.

RESULTS

The initial prototype successfully detected the orifice within air and blood. When testing in air, the light was transmitted through the fibers and all six fibers detected a maximum pixel brightness value of 255 meaning the artery was successfully detected (**Figure 2B**). The probe was also able to detect light in blood; however, the testing in blood resulted in a statistically significant drop in mean of average intensity from each fiber when compared to air (99.1 ± 10.5 vs. 37.6 ± 12.0 , $p < 0.0001$) (**Figure 2A**). The mean maximum intensity also experienced a significant drop from air to blood (255 ± 0.0 vs. 163.3 ± 71.2 , $p < 0.0346$) (**Figure 2B**). The sweep over the orifice indicated that

the probe could detect edges of the opening. In both air and blood, the feedback was void of an infrared signal when the probe was not over the orifice.

Figure 2. (A) Comparison of the average intensity emitted in the fixed area by each of the six fibers in air and in blood (**** indicates a $p < 0.0001$). (B) Comparison of the maximum intensity visualized from each fiber in air and in blood (* indicates a $p \leq 0.05$).

DISCUSSION

This study revealed that using fiber optics to find a point light source is a viable method of detecting a visceral arterial orifice in both air and blood through the endograft material. This approach highlights the potential for visceral artery detection that could be applied to the development of an ISF device. However, several steps still need to be taken until a clinically viable product can be developed. Future studies will include implementing more fiber optics, determining the feasibility of mechanical fenestration by puncturing the endograft material with a needle once the opening is seen with the fiber optics and creating an *in vitro* AAA phantom model with a pulsatile flow loop and deploying our prototype in the phantom model.

Current methods of ISF are limited; however, several cases have been reported using a mechanical needle, laser, or radiofrequency for fenestration [7]. Shu et al. reported midterm results of an adjustable puncture device used for ISF in thoracic endovascular aortic repair (TEVAR). In this study, several cases using a steerable sheath with an adjustable puncture needle were analyzed. The report found that the adjustable puncture needle demonstrated high technical success with low complications. This study highlighted the successful preservation of aortic arch branches in TEVAR cases and similar methods can be applied to visceral arteries of AAA cases [8].

There are several limitations to this work that need to be acknowledged. The test bench includes a 6 mm hole to act as the artery opening, which is on the larger end of a typical human visceral artery. The test bench also utilizes guide rails that were useful in locating the opening when submerged in blood.

A REVIEW OF THE STATE OF SOFT TISSUE MATERIAL PROPERTY DATA FOR HUMAN BODY MODELING

Justin Scott (1), Nicole Arnold (1), Tamara Reid Bush (1)

(1) Department of Mechanical Engineering, Michigan State University, East Lansing, MI, USA

INTRODUCTION

Finite element (FE) models evaluating internal stresses and strains in the human body's soft tissues are dependent upon realistic soft tissue property inputs. Studies showed that disparities in material properties by less than an order of magnitude can change tissue stresses and strains by up to 70% [1]. Because all soft tissues have a range of reported properties, researchers have described guidelines for using tissue properties in biomechanical models, including sensitivity, verification, and validation studies, allowing for streamlined communication of models' results and their uncertainties [2], [3]. Ideally, personalized data would be used for all human body models, but there are numerous challenges associated with doing so. Recently, two researchers conducted studies in clinical settings to determine personalized tissue properties [4], [5]. Yet, the application of these methods were limited to case studies or small numbers of participants and few body regions.

Several factors have been shown to affect the values of reported material properties. Among the sample or participant characteristics that affect properties are the tissue being *in vivo* or *ex vivo*, from humans or animals, the body region tested, body position, and whether or not participants had disabilities [6]–[8]. Consideration for the experimental setup also has to be given because several types of experimental methods were used to collect load and deformation data from tissue samples, and multiple definitions have been used for load and deformation. Lastly, material model choice has an effect. Early experiments used linear elastic material models, while recent studies characterized tissue using non-linear or viscoelastic materials [9], [10]. Without a method to convert between sets of material property values, there is no standard material characterization for each tissue.

Thus, this work aimed to aggregate material properties reported for muscle, fat, skin, and lumped tissue to categorize them by the source of the sample or participant population, the methods used to measure load and deformation, and material models used to characterize the tissues in an effort to compare and contrast reported results.

METHODS

The authors searched PubMed, Google Scholar, Science Direct, Elsevier, Taylor and Francis Group, Scientific Research, Springer Link, and the Wiley Online Library for studies that described the soft tissue property of both humans and animals. Keywords included in the search were “mechanical properties of human tissue”, “tissue parameters”, “material parameters”, “*in vivo* tissue properties of humans”, “*in vivo* tissue properties of animals”, “*ex vivo* tissue properties of humans”, and “*ex vivo* tissue properties of animals”. The authors found 77 papers to include in this review.

RESULTS

There were 15 studies that included tissue properties from *ex vivo* human tissue. 6 studies included data on muscle, 4 included data on fat, and 7 included data from skin samples. The muscle samples came from the leg, arm, shoulder, and back, while the fat samples were from the abdomen, heel pad, and leg, and skin data were collected from the forehead, arm, neck, back, and abdomen. Each study included a Young's modulus, shear modulus, ultimate stress or strength of the tissue, and/or isotropic material constants.

34 studies were found with data on *in vivo* soft tissue properties from humans. 15 studies included data from muscle, 1 study included data from fat, 12 studies included data from skin, and 8 studies included data from lumped tissues (defined as a homogeneous material of muscle, fat, and skin by lumping the parameters). Differences between the studies included the body region tested, number of participants, position of the body during testing, and whether or not the study included persons with disabilities. Muscle data were collected from the gastrocnemius, gracilis, sartorius, quadriceps, posterior thigh, heel pad of the foot, tibialis anterior, rectus femoris, buttocks, triceps surae, biceps brachii, flexor digitorum profundus, and brachialis. The body region from which the fat data were collected was unspecified. Skin data were collected from the arm, palm, back, shoulder, thigh, and calf.

Lumped tissue parameter data were collected from the buttocks, thighs, and legs. Body positions during these studies included the prone position, supine position, quadruped position, and seated position, while some studies did not report the position in which testing occurred. One study included data from the muscles of persons with disabilities, and one study included lumped soft tissue parameter data from persons with disabilities.

29 studies were found that included data from animals, 20 of which included *ex vivo* animal samples, while 9 included animals *in vivo*. 17 studies included data from the muscles of pigs, frogs, cows, rats, and rabbits. 4 studies included data from the fat of pigs, rats, and sheep. 8 studies included data from the skin of mice, pigs, cows, and rats. Muscle data were collected from the extensor digitorum longus, peroneus tertius, gluteus, semitendinosus, abdomen, tibialis anterior, gracilis, and pelvic and thoracic muscles. The fat samples were collected from the gluteal region, thighs, and legs. Skin samples were collected from the abdomen, posterior hindlimb, back, gluteus, legs, and shoulders.

Several deformation definitions were used in determining material properties with various measurement approaches. Definitions included deflection, strain, stretch, and tensors like the right Cauchy-Green deformation tensor. Measurement methods could be generally described as either measuring internal tissue deformation or external deformation. For internal tissue deformation, techniques such as magnetic resonance imaging and ultrasound were used, while electronic sensors like linear potentiometers and digital calipers measured external deformation.

Material parameters reported from the studies investigating human tissues were determined by the material models used to describe them. 47 distinct relationships were used to determine material properties. Of them, linear viscoelastic models were used in 11 of the studies to describe muscle, fat, skin and bulk tissue. Hyperelastic and viscoelastic terms were used to create models for 6 studies. Purely hyperelastic models were used in 16 studies. 4 studies focused on investigating the differences between multiple material models describing human tissues.

Figure 1. Semilog plot of the parameters reported for human muscle, fat, and skin *in vivo*. All C_{10} parameters are from Neo-Hookean models. The reported properties of muscle span over one order of magnitude, while the properties of skin span over two orders of magnitude.

DISCUSSION

The goal of this review was to collect material properties reported from experiments that studied the soft tissues and categorize them by their inclusion of human or animal data in *in vivo* or *ex vivo* settings, the

method of deformation measurements used, and the material model used, to compare and contrast the properties reported.

The studies showed that factors such as the body position, body region, inclusion or exclusion of persons with disabilities, and method of deformation measurement affect reported properties. As a result, the properties used in models should reflect the conditions of the model itself. For example, material properties from the buttocks in the seated position should be used for a model of the buttocks in the seated position. Inaccuracies in stress or strain predictions due to using inappropriate material properties may not be predictable because the values of material properties varied by up to two orders of magnitude. Examples of this phenomenon included the shear modulus of human muscle ranging from 8 kPa to 100 kPa and the *in vivo* Young's moduli of skin varying from 4.5 kPa to 850 kPa (Figure 1). Because differences within one order of magnitude affected strains by up to 70%, differences of two orders would likely affect strains even more [1]. Model choice is of further importance because there is no readily available method to convert parameters between material models, making comparisons between characterizations with different experimental factors difficult.

In addition to the other factors, whether data were collected *in vivo* or *ex vivo* also affected results. In the human forearm, Young's moduli of skin were at least 10 times larger than in *in vivo* studies (330-99,000 kPa versus 4.5-850 kPa). Because of the gaps between *in vivo* and *ex vivo* material properties, models using properties from the former would likely differ significantly from those using the latter. Whether the data came from *in vivo* or *ex vivo* sources is another factor that must be considered when deciding which material properties models use.

Characterizations of the material properties of soft tissue have grown in both sophistication and scope to describe more tissues from different sources in multiple loading conditions. Before human soft tissue material properties were reported, animal tissue properties were exclusively used in human body models. However, the prevalence of animal studies has decreased as human tissue data have become more widespread. The most recent tests have collected compressive tissue response data on *in vivo* humans, providing more appropriate data for modelers to use in models with compression loads as compared to tensile tests. The progress made in this field over the past several decades has assisted and will continue to assist in the creation of human body models with more realistic stress and strain predictions.

Yet, there are still areas that still need to be explored further. One of these areas is the characterization of soft tissues from persons with disabilities. Though some studies investigated the soft tissue properties of the lower limbs of persons with disabilities, the material properties of other body regions have yet to be explored at all. Until they are, models of persons with disabilities will likely lead to unrealistic predictions of tissue stress and strain.

INTRODUCTION

Glaucoma is the leading global cause of irreversible blindness [1]. Although glaucoma can occur at any level of intraocular pressure (IOP), elevated IOP is a primary risk factor, and is the only treatable risk factor [2]. IOP is largely determined by the resistance to aqueous humor flow generated by the tissues of the conventional outflow pathway, specifically the trabecular meshwork and the inner wall of Schlemm's canal (SC) [3]. In particular, inner wall SC cells play a key role in homeostatic control mechanisms that maintain IOP within a target range [4].

All conventional outflow of aqueous humor crosses inner wall SC cells through micron-sized pores [5]. There are two pore types: trans-cellular "I" pores and paracellular "B" pores [6]. These pores have different sizes and dependencies on IOP, but both may facilitate aqueous humor drainage. Mechanical stretch triggers pore formation [7], and SC endothelium is exposed to significant stretch due to the pressure drop across the inner wall [8], most obviously during giant vacuole formation. It is important to note that pores are not tears or ruptures in the cell, but membrane-delineated structures that are actively formed by SC cells.

The discovery of SC-active agents that exploit and enhance native processes controlling SC hydraulic conductivity could offer novel strategies for IOP control, yet such discovery is impeded by poor assays. Here, we aim to develop a high content *in vitro* mechanobiological assay to assess I-pore formation in subconfluent SC cells exposed to focal stretch delivered by ferromagnetic microspheres. We focus on I-pores since SC cells do not form tight intercellular junctions *in vitro*; thus, methods for high-content screening of B-pores are more challenging.

METHODS

Glass substrates (NuncTM Lab-TekTM chamber slide system) were coated with 0.5 mg/mL biotinylated gelatin cross-linked with 1 unit/mL microbial transglutaminase. Carboxyl ferromagnetic particles (dia. ~5 μ m, Spherotech CFM-40-10) were seeded onto the substrate, followed

by seeding with primary human SC cells (two normal SC cell strains: nSC89 and nSC82 and one glaucomatous cell strain: gSC57; all passage 5 or 6). Pores were detected using fluorescently labeled tracers [9]. Specifically, after 5-7 h of incubation, a first tracer (streptavidin, Alexa FluorTM 488 conjugate) was added to the media for 5 min. The first tracer was then washed away, and a second tracer (streptavidin, Alexa FluorTM 647 conjugate) was added for 20 min, during which time particles were exposed to a magnetic force created by neodymium N52 magnets (D38-N52, K&J Magnetics, Inc.) placed ~0.20 mm (high force; estimated ~1138 pN on each particle), ~0.55 mm (medium force; ~785 pN), or ~0.91 mm (low force; ~435 pN) above cells. The magnets attracted particles to create a local cellular stretch in the basal-to-apical direction in seeded SC cells. In some wells, magnets were not placed above cells as a negative (no force) control.

Cells were fixed, labeled with DAPI and Alexa FluorTM 555 phalloidin, imaged, and analyzed by counting punctate tracer signals that colocalized with particles under cells. The number and area of labelled substrate under I-pores were quantified using custom MATLAB code. I-pores were categorized as Type I (first tracer, i.e., present without magnetic force/stretching) or Type II (second tracer, i.e., present with magnetic force/stretching). We then computed the number and area of Type II pores minus Type I pores (normalized by the number of particles under cells) as an indirect measure of porosity. The number of cells and particles analyzed for each cell strain were: nSC89: 4 wells per force condition; 404 ± 78 cells/well, 106 ± 51 particle/well; nSC82: 4 wells; 71 ± 19 cells/well, 115 ± 39 particle/well; and gSC57: 8 wells; 203 ± 51 cells/well, 130 ± 39 particle/well. Two-way ANOVAs were performed with factors: (i) force level (control, low, medium, high); and (ii) disease state of the cell strains (normal, glaucomatous). Outcome measures were the number and the area of detected pores. When ANOVA indicated a significant factor effect, outcomes were compared pairwise using Tukey's honest significant difference (HSD) test for multiple comparisons. The statistical significance threshold was taken as 0.05.

RESULTS

The fluorescent tracers reached and bound to the substrate at locations not covered by the cells, i.e., surrounding subconfluent cells but also at I-pore sites (Figure 1). Actin microstructure (Figure 1B) was intact at the location of pores detected only by the first tracer (Figure 1C) but was disrupted at some pore locations detected by the second tracer (Figure 1D).

Even in the control wells, where no magnetic force was applied, some pores formed over the microbeads, indicating that the mere presence of the magnetic microbeads under the SC cells was sufficient to induce some I-pore formation (Figure 2). Two-way ANOVA indicated that force significantly affected the number of pores ($F(3,55) = 3.62$, $p = 0.019$); however, the number of pores was not affected by the disease state of the cell strains ($F(1,55) = 0.61$, $p = 0.439$). There was no interaction effect between force and disease ($F(3,55) = 0.92$, $p = 0.439$). Similarly, when considering pore area, force was a significant factor ($F(3,55) = 3.95$, $p = 0.013$), whereas disease state was not ($F(1,55) = 0.01$, $p = 0.906$), and again, no interaction effect was observed ($F(3,55) = 0.43$, $p = 0.733$).

DISCUSSION

Our mechanobiological assay allows assessment of I-pores in SC cells using automated (masked) image processing. In this preliminary study, we showed a correlation between focal magnetically-delivered force and pore formation, with more pores and greater pore area in normal SC cell strains in the high force condition vs. the no force condition. Some pores formed spontaneously (without magnets, i.e., Type I)

Figure 1: Representative fluorescent micrographs showing I-pores detected by the fluorescent assay colocalizing with magnetic particles under SC cells. (A) Cell nuclei (blue) overlain by brightfield image showing particles (dark spots). Particles are outlined by white circles in panels B-D. (B) F-actin labeling (phalloidin; red). (C) The first tracer (green). White arrow: Type I pore. (D) The second tracer (magenta). Yellow arrows: Type II pores. Note the disruption of the actin network in panel B at the position of Type II pores. Scale bars = 20 μm .

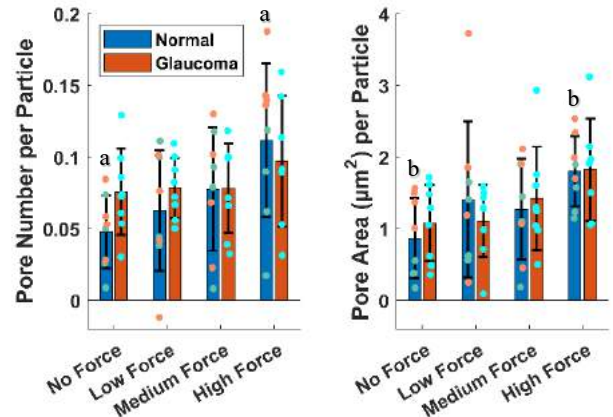

Figure 2: The number (left) and the area (right) of Type II pores minus Type I pores, normalized by the number of particles under subconfluent SC cells. Blue bars indicate normal SC cell strains (nSC89 and nSC82 shown with green and orange points, respectively), while red bars indicate glaucomatous SC cells (gSC57). Data shown as mean \pm standard deviations between wells. ^a and ^b signify differences at $p < 0.05$ by post hoc Tukey's HSD test.

through unclear mechanisms; we hypothesize that intracellular tension within SC cells adhered to the underlying gelatin substrate may cause local stretch over microspheres sufficient to trigger pore formation in some cases.

In glaucomatous cells, I-pores were also detected, and pore number and area showed an increasing trend with applied force by ANOVA; however, pairwise differences between force levels did not reach statistical significance (post hoc Tukey's HSD test, $p > 0.05$). Although based on only a single cell strain, this is consistent with the hypothesis that glaucomatous SC cells are less responsive to local force, perhaps due to their increased cell stiffness [10].

Disruption of actin microstructure only at some Type II pore locations suggests that I-pores form dynamically in our assay. All pores detected only with the first tracer and some pores detected by the second tracer were "closed" at the time of cell fixation, i.e. disruption of actin microstructure was not evident. More complete morphological studies of I-pores formed in this assay are needed and are ongoing.

Significant intra-assay variability was problematic, reduced statistical power, and must be addressed to improve the assay. There was also appreciable inter-well variability in outcomes, perhaps related to the fact that pores were relatively rare, with typically less than 0.1 pore/particle forming (Figure 2). Nonetheless, this assay shows significant potential for screening of agents that may eventually help control IOP in glaucoma patients.

INTRODUCTION

Understanding how extracellular matrix (ECM) properties change over time during the growth and remodeling phase of wound healing has been a goal of biomechanics and engineering research for decades. In particular, understanding the mechanics of heterogeneous materials, such as those found at the interface of healing dermal wounds and healthy tissue, is essential for designing materials that can modulate cell behavior in these environments.[1] In skin, post-wounding, a protein known as fibrinogen is polymerized into a fibrin clot via thrombin cleavage.[2] This fibrin clot provides a temporary matrix that cells use to infiltrate the wound and deposit more permanent ECM.[2] Additionally, fibroblasts and other cell types can differentiate into myofibroblasts and exert contractile forces on the wound to further alter the surrounding matrix.[3] Both behaviors are essential for wound closure, as well as growth and remodeling; therefore, understanding how changes in material properties and mechanical forces interact with these processes is essential for accurately modeling wounds.

Previous work by our lab established parameters for a multiscale model of fibrin gel mechanics with different concentration inclusions (Figure 1).[4] However, multiscale models that capture changes in tissue mechanics during wound healing due to cellular behaviors are lacking. To address this gap, we are developing a model to quantify cellular ECM production cultured in protein gels *in vitro* using a form of metabolic labeling known as bio-orthogonal non-canonical amino acid tagging (BONCAT).[5] Using this technique, newly synthesized proteins (NSPs) can be labeled with an azide moiety that can be reacted with alkynes via a click chemistry reaction, including affinity tags for enrichment of NSPs or fluorescent tags for imaging (FUNCAT).[6] Combining proteomics with BONCAT will facilitate computational modeling of cellular contributions to wound material properties.

METHODS

Fibrin concentrations of 2 or 4 mg/mL were prepared via combining a 1:10 ratio of human fibrinogen to Alexa Fluor (AF) 488 or

AF546 conjugated human fibrinogen with CaCl₂ to a final concentration of 6 mM and 0.002 U thrombin per mg fibrinogen in either Dulbecco's Modified Eagles Medium (DMEM) with cells or PBS. Gels used to measure fibrin material properties were formed between two porous polyethylene blocks that were glued to laser cut polyethylene terephthalate frames using Loctite Super Glue. To ensure consistent geometry, these gels were polymerized in 3D printed 2.5 × 6.6 × 0.75 mm ($w \times l \times h$) molds.

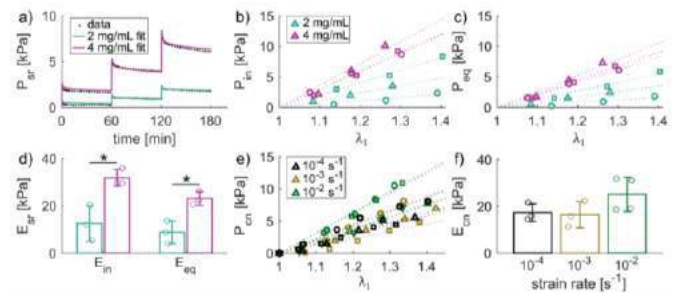

Figure 1: (A) Stress-time response of 2 and 4 mg/mL fibrin gels. (B) Initial stress versus strain. (C) Equilibrium stress versus strain. (D) Tangent modulus from (B) and (C). (E) Stress-strain response of 2 mg/mL fibrin gels with different strain rates. (F) Tangent modulus from (E). Figure from [4].

Two 50 × 50 × 200 μm ($w \times l \times h$) fiducial markers were photobleached on the surface of the fibrin gels 200 μm apart using a Leica STELLARIS 5 confocal microscope and a 10× water-immersible objective. A FemtoTools micromanipulator system was used to apply unidirectional tensile deformations to the fibrin gels with either a custom slider assembly (without a microforce sensor) to observe strain-dependent changes in fibrin network organization via fluorescent

confocal microscopy or a custom floating-platform mounting system with a microforce sensor to measure stress relaxation of the fibrin gels. Collected images were analyzed using a custom tracking script in MATLAB combined with thresholding functions and the OrientationJ plug-in in FIJI. Further experimental details for how parameters were collected and analyzed can be found in [4].

For shotgun proteomics, NIH 3T3 cells were cultured in 2 mg/mL fibrin gels created in 15 μ L Ibidi angiogenesis well plates for 4 days. Samples were then removed from wells with forceps and reduced, alkylated, and digested following a previously published protocol from our lab.[6] Peptides were detected using a Q-Exactive HF-X mass spectrometer (Thermo Scientific). RAW files were searched against the UniProt Mus musculus database supplemented with human sequences for fibrinogen α , β , and γ chains using MaxQuant v.1.6.14.0. Two missed cleavages were allowed per peptide and peptide and protein identifications were filtered at a 1% false discovery rate, determined by comparison to a reverse decoy database generated from the Mus musculus database. Results were further filtered to exclude proteins that were identified by only one unique or razor peptide across all samples, labeled as a potential contaminant by MaxQuant, or identified in only one replicate. Raw intensities were used to determine the percentage of total raw intensity to facilitate intrasample relative quantification. Data analysis was performed in Excel and Prism.

Figure 2: 30 most abundant proteins synthesized by NIH 3T3 cells within fibrin gels relative to fibrin.

For fluorescent imaging of NSPs, NIH 3T3 cells were cultured in 2 mg/mL fibrin gels for 2 days with methionine-free DMEM containing 10% fetal bovine serum, 1% antibiotic/antimycotic, and supplemented with either 20 mM methionine or azidohomoalanine (Aha). Gels were fixed using 4% paraformaldehyde and stained with DAPI (cell nuclei), wheat germ agglutinin-AF555 (glycosylated proteins), and dibenzocyclooctyne (DBCO)-AF647 (azides). Gels were imaged using a STELLARIS 5 confocal microscope and a 10 \times water-immersible objective. Images were processed in FIJI to increase contrast.

RESULTS

Using shotgun proteomics, we identified ECM proteins deposited by NIH 3T3 cells cultured in fibrin gels, including type I collagen α 1 chain (COL1A1), type I collagen α 2 chain (COL1A2), and fibronectin (FN1) (Figure 2). However, because fibrinogen peptides contributed >70% of the total raw intensity signal collected in each sample, lower abundance ECM proteins could not be identified using this technique. Therefore, BONCAT was investigated as a technique to allow separation of NSPs including ECM from the surrounding material as has been previously described and performed in our lab.[6]

The incorporation of the non-canonical amino acid Aha into NSPs by NIH 3T3 cells in fibrin gels was visualized using fluorescent confocal microscopy (Figure 3). Fluorescent signal was found exclusively in cultures containing Aha. There did not appear to be significant reaction between the DBCO fluorophore and the fibrin gel.

Figure 3: FUNCAT-based visualization of NSPs from NIH 3T3 cells embedded within fibrin gels.

DISCUSSION

While ECM proteins were identified through processing of whole fibrin gels containing cells, the high amount of fibrin peptides from the gel prevented the identification of ECM that 3T3 cells made in lower quantities. To better identify and quantify the ECM directly synthesized by the 3T3 cells, we investigated the utility of BONCAT in protein gels. This has previously been utilized as a means of studying ECM deposition dynamics of cells cultured in non-protein hydrogels but has not yet been used for proteomics of cells cultured in protein-based gel constructs. [6,7]

Fluorescently-labeled ECM was not readily apparent in the collected images but we expect that culturing longer than 2 days will be sufficient to label and visualize ECM NSPs, based on previous hydrogel studies.[6,7] Overall, our findings indicate that more comprehensive proteomics of ECM produced by cells cultured in protein cells will require enrichment techniques such as BONCAT. This technique is effective at labeling proteins in protein gels and will be used to collect more complete proteomics data quantifying ECM production by cells in an *in vitro* wound model. This data will be essential for informing multiscale computational models of wounds that account for cellular behaviors including ECM deposition. This technique can likely be extended beyond fibrin gels to analyze how changing composition due to cellular behaviors alters the mechanical properties of other protein-based constructs that better mimic biological environments.

INTRODUCTION

One of the main challenges across life sciences is the lack of pre-clinical models that mimic the complexity of the tissue microenvironment, which consequently limits the translatability to medical applications. Some of the most promising tools to capture tissue heterogeneity *ex vivo* are explant-based models, because these maintain the 3D architecture and cell diversity found within the native tissue microenvironment. However, larger explants that capture a significant portion of the microenvironment rapidly die in static culture due to insufficient oxygen and nutrient delivery by diffusion to the explant core [1]. To overcome the limitations of diffusion-dominated transport, we developed a fluidic platform having a microchannel that holds the explant within a specially designed constriction (Figure 1). The shape of the constriction is designed to achieve “self-sealing” between the explant and channel walls [2]. It is hypothesised that this self-sealing eliminates flow around the explant (known as peri-fusion) and thereby drives advective flow and nutrient delivery through the explant (perfusion), which preserves the viability and function of large (>1 mm) explants, ideally over several days for *ex vivo* drug screening and analysis.

METHODS

To investigate the effectiveness of tissue self-sealing, we examined the flow-pressure relationship of 2 mm mouse liver explants within the microchannel using an actuated reservoir, a pressure sensor and flow sensor. To improve self-sealing, we added a poly-lysine (PLL) adhesive coating to the microchannel wall. We measured tissue viability based on ATP levels and efficacy of perfusion based on the fluorescent

intensity of particles in sample lysates following perfusion in platforms, with and without the adhesive coating. In order to fully validate the platform and its use in *ex vivo* specimen perfusion, a peri-fusion platform with a cylindrical chamber that allows flow around the explant was used as a control case (Figure 1). Tissue viability via measurement of ATP levels was compared between fresh, perfused explants, perfused and statically cultured mouse liver tissue samples after 3 and 6 days. To assess the quality of intra-vasculature perfusion, we perfused mouse liver tissue explants with a fluorescently labelled breast cancer cell line (MDA-MB-231). To explore the potential of this platform in cancer-related drug assays, mouse and human omental tumour specimens from disseminated ovarian cancer were also perfused for 2 days and stained with haematoxylin and eosin (H&E). Immunohistochemistry stainings for WT1 (ovarian tumour marker), cleaved caspase-3 (CC3 – apoptosis marker) and Ki67 (proliferation marker) were also performed.

Figure 1: Schematic visualization of the fluidic platform with constriction for perfusion of explants and the control platform used for peri-fusion of explants.

RESULTS

The hydraulic resistance of mouse liver explants when they were properly loaded within the walls of the constriction was on the order of 2 mmHg/nl/min consistent with predictions from Darcy’s law based on reported values of liver permeability [3]. In contrast, resistance measures lower than 0.0005 mmHg/nl/min were expected when liver explants were not properly sealed within the constriction or when there was a functional peri-fusion route. Viability markers were elevated in liver explants perfused in PLL-coated microchannels, having an average ATP level of 167 ± 72 pM/mg protein compared to 92 ± 57 pM/mg protein in uncoated microchannels ($p<0.05$, $n=3$ samples each). The average quantity of fluorescent tracer microparticles recovered from perfused explants was higher with the PLL coating versus without, but this difference did not achieve statistical significance ($p>0.05$, $n=3$). ATP levels were higher in perfused relative to peri-fused and static cultured samples with 137 ± 77 , 52 ± 26 and 42 ± 22 pM, respectively after 3 days and 72 ± 24 , 43 ± 21 and 22 ± 16 pM, respectively after 6 days, but were significantly less than fresh samples with 835 ± 124 pM ($p<0.0001$, $n=3$). Infused red fluorescently labelled MDA-MB-231 breast cancer cells localised with the vascular network within the explant, identified based on GFP expression in endothelial cells (Figure 2). The H&E staining depicted tissue structure and WT1 enabled the identification of tumour regions for ovarian cancer. Perfused mouse omental tumour specimens exhibited lower levels of CC3 and higher levels of Ki67 compared to the peri-fused and statically cultured explants (Figure 3.A). Similarly, human omentum tumour explants showed reduced CC3 and preserved histology after 2 days of perfusion versus peri-fusion (Figure 3.B).

Figure 2: Confocal imaging on cryosections of red fluorescently tagged MDA-MB-231 breast cancer cells perfused in the green vasculature of liver tissue from Tie2-GFP mouse.

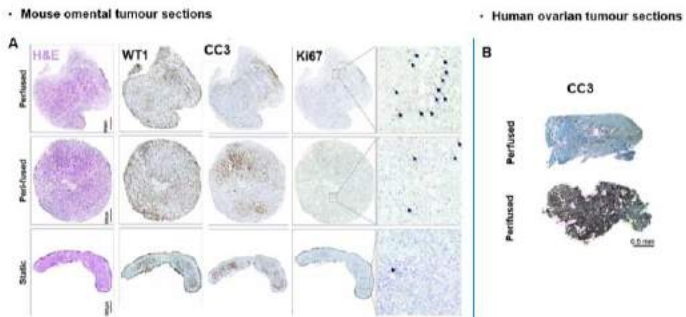

Figure 3: A. H&E, WT1, CC3, and Ki67 stainings on mouse omental tumour sections for three different culture conditions (perfusion, peri-fusion and static culture) after 2 days. B. CC3 staining on human omentum tumour sections for two different culture conditions (perfusion, peri-fusion) after 2 days.

DISCUSSION

The quality of self-sealing of the tissue explant within the constriction plays a critical role by limiting peri-fusion (i.e., flow around the explant) and driving per-fusion (i.e., flow through the explant). The significantly higher values of hydraulic resistance when explants were properly seated within the constriction demonstrate effective self-sealing and minimisation of peri-fusion. The improved viability and greater tracer retention with perfusion, which may be enhanced further by coating the microchannel with PLL, reveals that perfusion achieves effective nutrient delivery to the explant core necessary to support viability. The developed platform facilitates the preservation of viability of ex vivo explants over several days. Future work to extend this platform to human tumour specimens will be performed for *ex vivo* drug screening and analysis.

INTRODUCTION

Arteries are known to grow and remodel in response to mechanical stimuli to maintain mechanical homeostasis [1]. This process has been captured in various computational models [2,3]. Notwithstanding the valuable insights gained by these models, their approach has been predominantly phenomenological, ignoring the complex cellular mechanisms underlying growth and remodeling. As such, these models do not allow for the investigation of pathological mutations or targeted interventions involving these cellular mechanisms. To overcome this, cell signaling models can be coupled to growth and remodeling models to obtain a more mechanistic understanding of arterial growth and remodeling [4,5] and optimize and inspire medical therapies.

One of the key signaling pathways in vascular development and homeostasis is the Notch signaling pathway in vascular smooth muscle cells [6]. This pathway involves the interactions between membrane-bound Jagged or Delta-like ligands and Notch receptors of neighboring cells. Numerous studies have indicated a strong influence of Notch signaling on smooth muscle cells behavior, including growth and remodeling [7]. Moreover, Notch has been identified as mechanosensitive, as it is affected by the strains experienced by smooth muscle cells [8,9]. Together, this makes Notch a strong candidate to be an important player in mechano-regulated arterial growth and remodeling.

Here, we developed a multiscale computational framework (Fig. 1) to gain a deeper understanding of the role of Notch and Notch interventions in mechano-regulated growth and remodeling of arteries in response to hypertension.

METHODS

Our multiscale framework combines the widely adopted constrained mixture model for growth and remodeling [2,3] and a previously developed mechanosensitive Notch signaling model [9,10]. Briefly, the constrained mixture model captures the mechanics and

turnover of three structurally significant arterial constituents: collagen, smooth muscle, and elastin. The Notch model simulates interactions between receptors and ligands of the Notch pathway with a system of ordinary differential equations and accounted for the influence of smooth muscle strain on Notch signaling.

The coupling between these models is achieved as follows. The strains calculated in the constrained mixture model serve as input for the Notch model where they regulate the production of Notch receptors and Jagged ligands. In turn, the Notch activity predicted by the Notch model is assumed to regulate collagen synthesis and smooth muscle cell proliferation in the constrained mixture model as informed by in vitro data. In addition to this Notch contribution, a phenomenological contribution, capturing mechanisms other than Notch, is considered, controlling the production and removal of tissue constituents based on deviations in intramural stress and wall shear stress (Fig. 1).

Figure 1: schematic overview of the multiscale model

RESULTS

We first showed that our multiscale framework combining Notch-regulated and phenomenologically driven growth and remodeling can capture in vivo arterial adaptation in hypertension (Fig. 2). We imposed a pressure profile similar to the one observed in a previous in vivo study

[11] (Fig. 2A). This increase in pressure caused an increase in both circumferential strain and intramural stress. The former resulted in a decrease in Notch activity, while the latter affected the phenomenological contribution to growth and remodeling. Combined, these mechanisms resulted in an increase in collagen and smooth muscle densities (Fig. 2B,C) and, consequently, a thickening of the arterial wall (Fig. 2D) aimed at restoring the stress and strain toward their homeostatic values. The model was able to capture changes in density and thickness similar to previous *in vivo* findings [11]. This was achieved by fitting the parameters of the phenomenological contribution, while the Notch parameters were based on our *in vitro* experiments. Thereby, we demonstrated that a combination of specific mechanistic and phenomenological stimuli can describe *in vivo* arterial adaptation. Our results further suggest that Notch may contribute to arterial thickening in hypertension primarily by inducing smooth muscle cell proliferation (Fig. 2C). Other mechanisms, here captured in the phenomenological contribution, are required to capture the full remodeling response (Fig. 2B,C), emphasizing the need to account for multiple mechanisms and pathways.

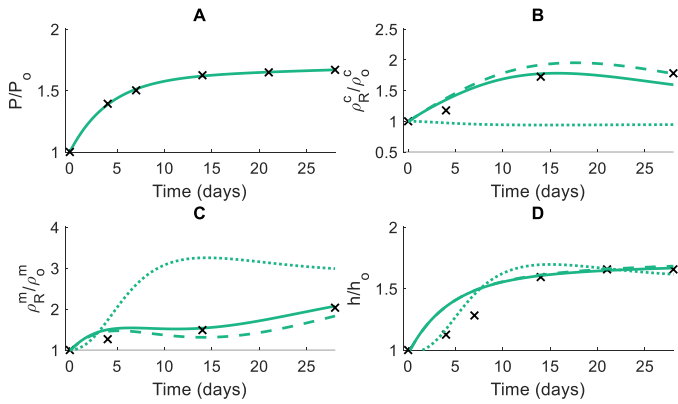

Figure 2: time courses of pressure (A), normalized mass densities of collagen (B) and smooth muscle (C) and wall thickness (D) under hypertension for the phenomenological, Notch, and combined models. Crosses represent *in vivo* data [11].

The inclusion of Notch as a mechanistic regulator of growth and remodeling enabled us to investigate the effects of interventions to Notch on the geometry and composition of hypertensive arteries. We simulated the introduction of either soluble or immobilized Jagged ligands to smooth muscle cells, common methods of Notch manipulation [12]. Our model predicted that soluble Jagged, assumed to inhibit Notch signaling, can decrease collagen density (Fig. 3B) and increase SMC proliferation (Fig. 3C) especially in the short term. Thickness was affected only marginally (Fig. 3D). In contrast, immobilized Jagged, assumed to enhance Notch activity, was predicted to increase collagen production (Fig. 3B) and lower SMC proliferation (Fig. 3C), again predominantly in the short term. A small increase in thickness was also observed (Fig. 3D). Together, these results suggest that Notch interventions can alter both arterial geometry and composition in hypertension.

DISCUSSION

Our multiscale computational framework provides a step forward in the development of more mechanistic descriptions of growth and remodeling by considering Notch signaling, a key mediator of vascular homeostasis. The adopted approach, combining a phenomenological and a mechanistic Notch contribution to regulate growth and

remodeling, enabled us to isolate and investigate the role of Notch. Our results indicate that a more detailed understanding of growth and remodeling may be gained by integrating individual pathways within phenomenological growth and remodeling models.

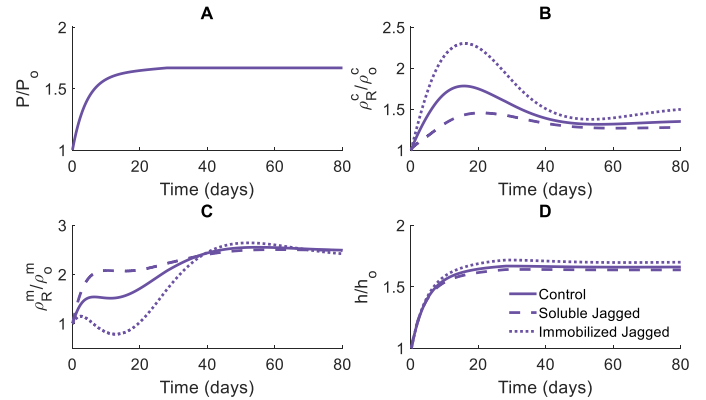

Figure 3: time courses of pressure (A), normalized collagen (B) and smooth muscle (C) mass densities and wall thickness (D) in hypertension with soluble and immobilized Jagged ligands.

By including a mechanistic Notch contribution, the model enabled the investigation of the consequences of Notch interventions for arterial growth and remodeling. Simulations predicted that soluble or immobilized Jagged ligands can be used to change arterial geometry and composition, especially in the short term. This may have promising applications in situations where it would be beneficial to (temporarily) control arterial growth and remodeling such as in vascular tissue engineering.

To further refine the model, future studies should focus on collecting more detailed, context-specific (*in vivo*) data on the effects of Notch signaling on arterial growth and remodeling. The inclusion of other relevant signaling pathways and their crosstalk with Notch should also be considered.

In conclusion, our model points at Notch mechanosensitivity as a key mechanism in arterial growth and remodeling, and it may provide a platform to efficiently optimize current methods in vascular tissue engineering and thereby accelerate clinical translation.

INTRODUCTION

Approximately 800,000 people in the America have a stroke every year. Towards better classification and outcome prediction, researchers have investigated if pre-treatment (mechanical thrombectomy) computed tomography (CT) imaging can indicate the biological properties of the problem clot. Specifically, several studies have aimed to find robust predictors of whether the clot can be easily retrieved during thrombectomy, using CT angiography and non-contrast CT images. However, the limited physical and biological interpretability of radiomics has hindered clinical application, which is an ongoing challenge across many domains. Understanding the relationship between clot presentation on CT imaging, the biological composition of the clot, and the mechanical properties of that that tissue, will help us better understand CT-based radiomic biomarkers.

To this end, we performed a multi-modal analysis on fabricated clot analogues. In order to determine how biological clot composition is related to the clot's mechanical properties (which effect how well it can be retrieved) and the clots presentation on CT imaging (for radiomic-based biomarkers), we varied fibrin-platelet (FP) and red blood cell (RBC) compositions and subjected each sample to microCT imaging, uniaxial stretch and compression testing. Numerical simulations of the clot tissue using the identified Elastic modulus will then performed to model the clots interaction with thrombectomy devices.

METHODS

Develop Thrombus Analogs: To make clots, we followed [1], but used human blood, enriched the clots for white blood cells (WBCs – to mimic clinical samples), and incubated of clots in a rotator during formation. Citrated, human whole blood was centrifuged (1500g, 15 min) to isolate RBCs, plasma, and buffy coat. WBCs were isolated and concentration was computed using the Countess 3 Automatic Cell Counter (Thermo Fisher). Analogs were prepared by combining RBC and FP isolates in fixed proportions of RBC (0%, 20%, 40%, 60%, 80%,

and 95%), and a fixed volume of WBCs was added (concentration=10⁶/mL). To induce coagulation, CaCl₂ was added, and clots were incubated (1 h, 37°C). Clots were stored overnight at 4°C, transferred to neutral formalin for 24 h, and later stored in 70% ethanol.

Tissue Processing and Imaging: Clots were stained with Lugol's iodine solution (50%, 24 hours) and imaged using the ScanCo μ CT 100 at 4.9 μ m resolution, 90 kV, 155 μ A. Following microCT imaging, clots were de-stained (3X 70% ethanol washes, 24 hours) and prepared for histology. Samples were embedded in paraffin, cut 4 μ m thick, mounted on clear glass slides, and H&E stained. Brightfield whole-slide images were collected at 40X magnification.

Image Analysis: MicroCT images of clots were segmented and quantified using 3D slicer (www.slicer.org). Image processing included application of a bottom-hat transform to remove background signal, global mean-based thresholding to segment the clot region, and use of the Segment Statistics module to compute first order statistics (e.g., mean Hounsfield units, HU). Clot component percent composition (%RBC, %FP, and %WBC) on H&E stained slides was calculated as previously described using Orbit Image Analysis (www.orbit.bio).

Mechanical Testing: Approximately 10 mL of clot of each composition was trimmed to a cylinder measuring 1x6 mm (for stretching) or 1x1 mm (for compression). Uniaxial compression and stretching was done over 10s on a Mark-10 ESM 1500 while load and distance were recorded. A Load-%Elongation graph was created.

RESULTS

% RBC of Clots is Related to Higher Intensity in CT: For analogs of increasing %RBC input as per our protocol, observable increases in clot HUs and RBC composition on histology were apparent (Figure 4A). To define the relationships between protocol %RBC, microCT mean and standard deviation HUs, and %RBC on histology, we completed regression analysis. We found that for every additional 10% RBC input to an analog, the analog's mean CT intensity increased

by ~146 units ($R^2=0.795$, $p=0.017$ [significance defined as $p<0.05$], Figure 4B). Histological %RBC was also found to trend positively with protocol %RBC ($R^2=0.915$, $p=0.003$, Figure 4C). Interestingly, the standard deviation in HUs was greatest for analog of ~60% RBC ($R^2=0.850$, $p=0.038$, Figure 4D). This finding makes sense given that a 50% RBC clot must also be 50% FP, and thus has the greatest composition and textural heterogeneity. The relationship between microCT mean HU and histological %RBC was similar to that of microCT HU and protocol %RBC. For every 10% increase in histological %RBC, microCT mean HUs increased by ~146 units ($R^2=0.877$, $p=0.006$, Figure 4E).

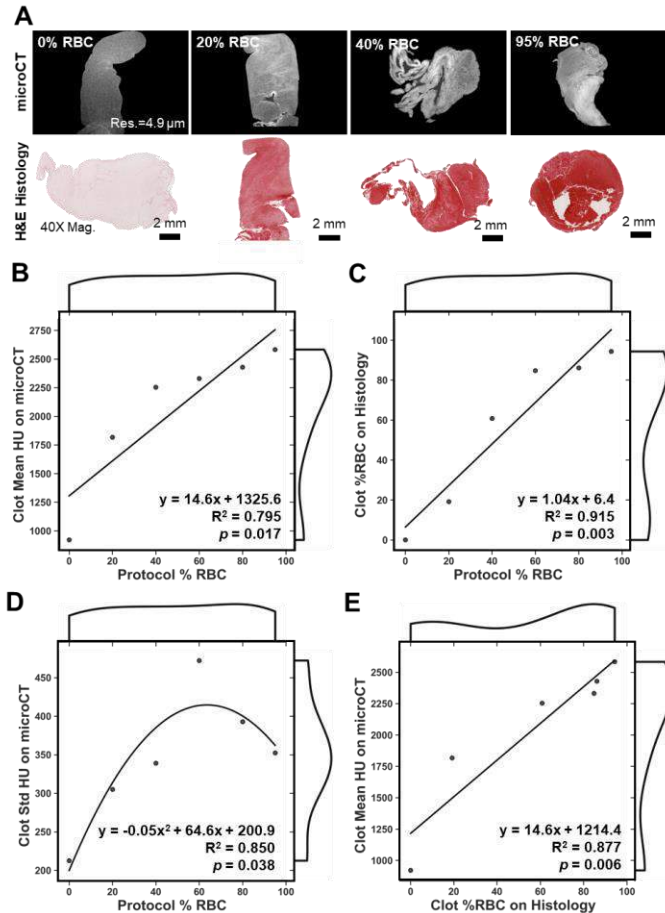

Figure 1: Association of Clot microCT imaging, H&E histology, and % composition calculation. A). Paired CT and histology show RBC portions are associated with higher intensity. B-E). Linear and polynomial correlation plots showing the relationship between clot % RBC and HU from microCT.

% RBC Related to Elastic Modulus (E): Uniaxial compression and stretch testing of clots of varying % composition demonstrated how biology effects the tissues material properties. Here, 0% RBC clots (Figure 2A) withstood the highest stress ($E=0.74$ MPa, Figure 2B), 20% RBC clots (Figure 2C) withstood the second highest stress ($E=0.19$ MPa, Figure 2D), and 40% RBC clots (Figure 2E) withstood the least stress ($E=0.16$ MPa, Figure 2F). A polynomial relationship between the protocol % RBC and the E of each clot was demonstrated ($R^2=1.00$, Figure 2 G).

DISCUSSION

In summary, we were able to build statistical models to define the relationships between analog protocols, and CT and histological modalities, that can be validated in future work predicting on resected stroke clots. Our CT and histology results demonstrate that RBCs contribute to higher HU regions in clot tissue, which is consistent with prior studies [3]. Furthermore, the elastic modulus of these clots (range of 0.16 MPa to 0.74 MPa), is also in line with previous reports of thrombotic (stroke and carotid endarterectomy) material in humans [4]. In the future, numerical simulation and benchtop testing will be used to determine if the makeup of a clot, and thus its stiffness, effect its ability to be retrieved via mechanical thrombectomy.

INTRODUCTION

The urinary bladder is a highly distensible organ capable of accommodating large volumes of urine at low pressures. An idealized spherical pressure vessel is the often-used model for mechanical analysis of the bladder. Studies have shown that bladder mechanical behavior can be affected by aging or disease such as diabetes [1, 2]. There are substantial differences in lower urinary tract anatomy and physiology between the sexes, which can affect bladder function. However, the effect of biological sex on the mechanical properties of the bladder has surprisingly received little attention. Thus, investigating sex as a variable in bladder function is crucial to understand its possible effects on disease progression [3].

In this study, a novel method has been used for analyzing bladder filling in 3D to assess the differences between male and female mouse bladder mechanical behavior. Researching how sex influences filling mechanics is part of understanding the basic functioning of the organ. Furthermore, it will allow improved bladder health care for patients on an individual basis.

METHODS

EXPERIMENTAL SETUP 23 C57BL/6 animals were included in the study, 14 males and 9 females, for comparison. Mouse bladders were extracted, cleaned, and mounted on a cannula connected to a pump and pressure transducer. A custom testing device was built to allow multiple views (i.e. top, left, right, front, & back views) of the organ to be imaged throughout filling (**Figure 1**). The bladder was empty when mounted, submerged in 37°C saline, and then filled at a rate of 30 $\mu\text{L}/\text{min}$ until a measured inner pressure of 25mmHg was reached.

A camera captured the bladder throughout the pressurization. Camera and pressure recordings were synchronized, so that images and pressure measures were collected at the same instant. The output was a video of the experiment at 10 frames/sec, and a spreadsheet of bladder pressure where each measure corresponds to a frame in the video.

Figure 1: Experiment setup. Bladder is mounted in the center (viewed from the top), and is surrounded by 4 mirrors which show front, back, left, & right views of the tissue.

IMAGE PROCESSING The data was processed with python. Custom code locates tissue boundaries and segments bladder silhouettes from the top, left, and front views (**Figure 1**) in each frame. First, a region of interest was selected in the final frame with the Paint.NET software. Within the region of interest, a Canny algorithm [4] is used to locate the tissue boundaries of each view (**Figure 2A**). In short, the brighter soft tissue in contrast to the dark background creates a sharp gradient along its edge—the result is a line denoting the bladder edge.

The edge line is not guaranteed to be a closed curve (**Figure 2A**), so an Open Curve Filling algorithm was developed [5]. This algorithm seeds a pixel at the center of the bladder view, and then pixels “grow” outwards in all directions until an edge is hit. In directions which are open (i.e., no edge will be found) the algorithm draws a connection

between the two nearest edges. The result is a solid silhouette of the bladder view (**Figure 2B**). These silhouettes are used to generate a 3D reconstruction of the bladder at each time point in the experiment (4D).

Figure 2: Segmentation of bladder front view. A) Output of Canny edge detection. B) Output of Open Curve Fill algorithm.

MESHING A 3D solid shape is created by the space carving method [6]. The method begins with a primitive rectangular prism, and then the two side views (**Figure 1**) are used to cut away from the primitive in the direction normal to their plane. The top view is then used to form the final shape by carving in the Z direction. However, in this case, the top view is mapped along the entire height of the bladder.

Finally, the voxel (3D pixel) representations of the tissue were transformed into surface meshes (**Figure 3 left**). The marching cubes algorithm [7] was employed for this step. The final result gave a set of bladder meshes at every time point imaged, which have a corresponding internal pressure measure that may be used for mechanical analysis.

Figure 3: 3D bladder reconstruction. Left) Surface mesh of bladder used for least squares fitting. Right) Least squares fitted sphere (black) superimposed on 3D voxel bladder shape (blue).

SPHERICAL MODEL

The bladder volume was approximated as a sphere via least squares fitting. (**Figure 3 right**) Spherical fitting allows the bladder be modeled as a thin walled spherical pressure vessel with an assumption of isochoric deformation. It follows that we can calculate spherical Cauchy stress (σ) and spherical stretch λ as

$$\sigma = \frac{P * r}{2 * t} \quad (1)$$

$$\lambda = r/r_0 \quad (2)$$

where, the internal pressure P , was obtained via pressure transducer, sphere radius r was obtained from the least squares fitting, r_0 represents the radius for a reference configuration at null internal pressure, wall

thickness t was measured by a researcher when the bladder was at max capacity, and estimated throughout the experiment using the isochoric assumption.

The stress and stretch state was calculated throughout filling from empty to max capacity for each bladder. Bladders were grouped based on sex and stretch was averaged within groups at 1mmHg pressure intervals between zero and maximum pressure. Statistical t-test was used to compare group averages of stress and stretch at max pressure. Results were graphed and significant differences were highlighted where $P < 0.05$ (**Figure 4**).

RESULTS

Figure 4: Pressure averaged stress-stretch curves for male and female bladder filling modeled as an idealized spherical pressure vessel. Standard errors shown.

Mechanical behavior between male and female groups was compared (**Figure 4**). At equal pressures, female bladders showed significantly lower wall stress. Smaller stretch was also observed in the female group, but the difference was not significant.

DISCUSSION

The methods described here were used to model bladder filling as a spherical pressure vessel. The differences in mechanical behavior of the mouse bladder shown here due to sex have not been reported before. This information is important for providing context for biomechanical studies. Specifically, considering sex as a variable is important in characterizing bladder function since it does play a role as shown here.
